The detailed mechanism of radical halogenation cannot yet be regarded as finally established. Complexes of halogen atoms with alkenes can be assumed to take part in the reaction: without this hypothesis the stereochemistry of the products of radical halogenation becomes incomprehensible.

---o0o---

Published information on the addition of halogens at a multiple bond shows the attention hitherto devoted to this reaction by research workers. Addition processes occur mainly in organic chemistry. They have formed the basis, in particular, for developing the concepts of carbonium ions, electrophilic and nucleophilic reagents, and π-complexes. The hydrohalogenation of alkenes has played an important part in establishing and developing the chemistry of free radicals.

The Review has considered the halogenation of multiple bonds mainly from the point of view of the possible role of halogen–alkene molecular complexes in this process. The existence of such complexes has been demonstrated experimentally, but their part in halogenation has been inadequately studied. Involvement of molecular complexes in the chemical change enables a unified view to be taken of the mechanism of halogenation. Available information can be summarised by Scheme 3.

Scheme 3.

The concept of complexes will explain the acceleration of the reactions with fall in temperature, the rapidity of the process in non-polar media and at low temperatures, the effect of specific solvation, and several other features of the reaction in systems where donor–acceptor interaction exists between the initial substances, but takes no direct part in the reaction.

The halogenation of multiple bonds shows that, depending on the properties of the medium and the reactants, subsequent changes in the complex can take place by ionic, radical, or molecular mechanisms. The investigation of such processes provides an approach to solving one of the problems of present-day chemical kinetics—elucidating the kinetic role of various types of complexes in chemical reactions. Examination of problems connected with this concept shows the absence of sharp distinctions between ionic and radical reaction mechanisms. Direct conversion of the complexes into the final products is also a possibility. The occurrence of such processes is of fundamental interest.

The halogenations of unsaturated compounds and in particular of alkenes have low activation energies. The reaction can take place in an inert phase over the temperature range 77–400°K, which enables individual stages in the process to be isolated and studied. The fact that the activation energy is comparable with the enthalpy of complex formation makes the halogenation of alkenes a convenient model for studying several general aspects of the effect of complex formation on a chemical process. New opportunities for controlling the rate and enhancing the selectivity of the most diverse processes are opened up by studying complex formation between reactants and paths for the further transformation of the complexes.

The Radical-anions and Dianions of Aromatic Hydrocarbons in Metallation Reactions

E.S.Petrov, M.I.Terekhova, and A.I.Shatenshtein

The review gives a general account of the literature data on the behaviour of the radical-anions and dianions of aromatic hydrocarbons in reactions involving the metallation of aliphatic-aromatic compounds and discusses the mechanisms of these reactions, the role of the counterion, the degree of its solvation, and the type of ionic association complexes in solutions of the reactants being emphasised. Since the carbanions of dihydro-derivatives of aromatic hydrocarbons are formed in the course of the reactions, data are presented also on their involvement in the metallation processes. The relative propotophilic properties of the three types of metallating agents, established experimentally and determined from the localisation energies of their protonation reactions calculated by the Pariser-Parr-Pople method, are compared.
The bibliography includes 120 references.

I. REACTIONS OF RADICAL-ANIONS AND DIANIONS AS REDUCING AGENTS AND BASES

Radical-anions (r.a.) of aromatic hydrocarbons are usually obtained in solution by electrochemical reduction at the cathode or by chemical reaction with an alkali metal [1,2]. Under favourable conditions, there is a possibility of the transfer of two electrons to the hydrocarbon molecule and the formation of a dianion (d.a.); trianions are generated much more rarely. The role of radical-anions and dianions in organic chemistry is very great and much attention has been devoted to the study of their formation, structure, properties, and reactivities (see the relevant reviews[1-13]).

As a result of intense study in recent years, it has been established that the transfer of one electron with formation of a radical-anion is the first step in many reactions (see the relevant reviews [9,11,14]). Such are, in particular, the reactions involving the metallation of aliphatic-aromatic compounds by alkali metals. The capacity of radical-anions to give up readily the unpaired electron in the non-bonding orbital of the aromatic hydrocarbon to compounds with a higher electron affinity permits numerous reduction reactions, including the sensitisation of anionic polymerisation leading to the formation of "live" polymers [7]. The protophilic properties of radical-anions are a consequence of the enhanced electron density at their carbon atoms. Dianions are more vigorous reducing agents and proton acceptors than radical-anions [15]. Adducts of aromatic hydrocarbons with alkali metals, which include radical-anions or dianions in their composition, have been used successfully for the metallation of a wide variety of organic compounds [16-20], behaving as proton acceptors, i.e. bases.

A mechanism of the protonation of aromatic radical-anions and dianions has been proposed by Laitinen and Wawzonek [21] and Hoijtink et al. [15], in relation to the electrochemical reduction of aromatic hydrocarbons (Ar) in aqueous dioxan. Initially the interaction of the primary reduction product, the radical-anion Ar^-, with the donor BH entails the formation of the radical ArH$^\cdot$:

$$Ar^- + BH \rightarrow ArH^\cdot + B^- . \quad (1)$$

Since it has a higher electron affinity [15], ArH$^\cdot$ combines with an electron and is converted into the carbanion of the dihydro-derivative of the aromatic hydrocarbon ArH^-:

$$ArH^\cdot + Ar^- \rightarrow ArH^- + Ar . \quad (2)$$

Apart from the radical-anion, the metal, cathode, etc. can behave as the electron donor. In the final stage, a proton adds to the carbanion and the dihydro-derivative is obtained:

$$ArH^- + BH \rightleftarrows ArH_2 + B^- . \quad (3)$$

Usually the rate of electron transfer [reaction (2)] is higher by several powers of ten than the rate of protonation [22] [reactions (1) and (3)].

The protonation of the dianion includes the stage involving the formation of ArH^-:

$$Ar^{=} + BH \rightleftarrows ArH^- + B^- \quad (4)$$

and then ArH_2:

$$ArH^- + BH \rightleftarrows ArH_2 + B^- . \quad (5)$$

The protonation of radical-anions and dianions of different structures by water, alcohols, and acids has been considered by a number of workers [23-35]. Weissman and coworkers [23] adopted the mechanism (1)–(3) for the reaction of sodionaphthalene with water. Its validity was demonstrated by Bank and Closson [25] using an isotopic method. Regardless of the rate of addition of tritiated water to the solution of sodionaphthalene in tetrahydrofuran (THF), a mixture of naphthalene, dihydronaphthalene, and a small amount of tetralin was obtained and only the last two products were radioactive.

In the discussion of this result, Bank and Closson noted that, if reaction (1) were followed by the disproportionation of the radicals ArH$^\cdot$,

$$ArH^\cdot + ArH^\cdot \rightarrow ArH_2 + Ar , \quad (6)$$

naphthalene would have been radioactive too.

Presumably the radical-anion could disproportionate initially:

$$Ar^{\cdot-} + Ar^{\cdot-} \rightleftarrows Ar^{=} + Ar, \quad (7)$$

and then the dianion would be protonated via reactions (4) and (5). Then, when the required amount of water is added slowly, one should expect the involvement of $Ar^{=}$, ArH^{-}, and Ar in the equilibrium. However, naphthalene would contain tritium under these conditions. Since there is no tritium in naphthalene, the mechanism (1)–(3) is correct.

The formation of the carbanions ArH^{-} in the reaction with the proton-donating dianions of a number of aromatic hydrocarbons was demonstrated spectroscopically by Velthorst and Hoijtink [26]. Krapcho and Bothner-By [36] applied the mechanism of the protonation of a radical-anion to the hydrogenation of organic compounds by an alkali metal in liquid ammonia with added alcohol (the Birch reaction). In liquid ammonia, the alkali metal M is ionised [37]:

$$M \xrightarrow{NH_3} M^{+} + e^{-}, \quad (8)$$

the cation and the electron (e^{-}) being solvated by ammonia. The addition of one or two electrons to the molecule of the organic substance converts it into a radical-ion or dianion, which then reacts with the alcohol [reactions (1)–(5)]. In addition to the dihydro-derivative, more highly hydrated compounds are frequently formed (see the relevant reviews [37-41]).

Eisch and Kaska [18] suggested that the metallation of aliphatic-aromatic hydrocarbons (in particular tri- and di-phenylmethane) by an adduct of an aromatic hydrocarbon and an alkali metal (lithiobiphenyl) takes place similarly, i.e. via stages (1)–(3). This mechanism of metallation, involving radical-anions, is now generally accepted.

When the acidity of the proton donor BH is low (for example, when BH is a CH acid), the protonation may not go to completion owing to the reversibility of reactions (3)–(5). When Ar is a polycyclic hydrocarbon, an equilibrium is frequently established in the disproportionation reaction of two carbanions of the dihydro-derivative [25,42]:

$$ArH^{-} + ArH^{-} \rightleftarrows ArH_2 + Ar^{=}. \quad (9)$$

The protonation (metallation) process can also be complicated by electron transfer from the radical-anion or the dianion to the proton donor [19,43,44]:

$$Ar^{\cdot-} + BH \rightleftarrows Ar + BH^{\cdot-}. \quad (10)$$

The mode of reaction depends on factors such as the ionisation potential and the protophilic properties of the radical-anion or dianion, and the acidity and electron affinity of the proton donor. Cations, which are not indicated in the above reactions, and solvents in which the reactions are carried out play an important role. The position of equilibrium in the formation of the radical-anions and their conversion into dianions by reduction or disproportionation depend to a considerable degree on the counterion and the solvent [5,7]. Nevertheless, in certain cases the last reaction may actually cause the protonation of the dianion and not the radical-anion, as shown by Szwarc and coworkers [35] for the perylene radical-anion.

Like other anionic organic reactions, the metallation processes involving radical-anions and dianions are frequently carried out in ethereal solvents, since the latter are very weak proton donors and effectively solvate the cations. Since the dielectric constants (DC) of ethers are low, (3–7 at 25 °C), ionic association effects are often of primary importance. In a general form, the equilibrium between the individual states of the organic derivative of the alkali metal (AM) in solution is described by mechanism (11), [45,46] which does not, however, take into account the solvation of the species:

$$(A^{-\delta}M^{+\delta})_n \rightleftarrows n\,A^{-\delta}M^{+\delta} \rightleftarrows A^{-}M^{+} \rightleftarrows A^{-} \| M^{+} \quad (11)$$
$$A^{-} + M^{+}$$

In glycol ethers and many cyclic ethers, the existence of the polar molecules $A^{-\delta}M^{+\delta}$ and their aggregates $(A^{-\delta}M^{+\delta})_n$ is atypical and two main types of ion pairs predominate, contact ion pairs ($A^{-}M^{+}$, c.i.p.) and separated ion pairs ($A^{-}\|M^{+}$, s.i.p.); on the other hand, the concentration of free ions (A^{-}, M^{+}) is low. The main difference between the separated and contact ion pairs is the presence of a layer of solvent molecules (usually the solvation shell of the cation) separating the ions, as a result of which the interionic interaction in a separated ion pair is of a Coulombic type and hardly depends on the radius of the cation.

In contact ion pairs, a decrease of the radius of the cation entails an appreciable enhancement of the interionic interaction and the exchange energy begins to play a decisive role in this process. The formation of separated ion pairs is favoured by an increase of the degree of solvation of the cation which may be a consequence of its reduced radius, the enhancement of the solvating capacity of the solvent, or a decrease of temperature. For large cations (K^{+}, Rb^{+}, and Cs^{+}), the existence of separated ion pairs in an ethereal medium is unlikely.

The different types of ion pairs are distinguished with the aid of many physicochemical methods—by the shift of the absorption band maximum in the spectrum of the carbanion; by the splitting of the components of the ESR spectrum as a result of the interaction of the unpaired electron with the magnetic moment of the nucleus of the cation; by the heat of dissociation of ion pairs, into free ions established by measuring the conductance of the solution as a function of temperature. Much information can be obtained also with the aid of the NMR method [47-50]. Contact ion pairs with unequal degrees of solvation of the cation may be distinguished spectroscopically [51] and by ESR [52] and it is also possible to detect the so called peripherally solvated [7,53] contact ion pairs which are isomeric with separated ion pairs. More detailed information about the state of organic compounds of alkali metals in solution is given in other reviews [5,7,13,49,53-56].

The extensive literature on the structure and properties of radical-anions and dianions and on the state of the adducts in solution has been summarised in other reviews [3-9,12,13]. The problem of the reactivities of radical-anions and dianions has been less thoroughly considered and general accounts of the information about their behaviour in metallation reactions, particularly as a function of the counterion, the properties of the solvent, and the type of ionic association complexes, are altogether lacking. The aim of the present review is to fill this gap. Since in the course of metallation reactions involving radical-anions and dianions the carbanions of dihydro-derivatives of aromatic hydrocarbons are formed, one of the sections of the review is devoted to the metallation of aliphatic-aromatic compounds by such species.

II. RADICAL-ANIONS AS METALLATING AGENTS

Normant and Angelo [16] were the first to note the possibility of using radical-anions for metallation. They showed that in THF sodionaphthalene, sodiobiphenyl, and

other adducts metallate in the CH bond aliphatic-aromatic hydrocarbons (fluorene, triphenylmethane, etc.), various derivatives of acetylene, nitriles, carboxylic acids, and certain heterocyclic compounds, both rapidly and in high yields. It has been established for the metallation of diphenylmethane that the naphthalene radical-anions are more effective than the phenanthrene radical-anions and that the rate of reaction increases when the sodium cation is replaced by potassium.

Table 1. Rate constants ($10^3 k$, litre mole^{-1} s^{-1}) for the reaction of radical-anions (K^+ cation) with triphenylmethane at 20°C.[57,58]

Radical-anion	DG	DME	DEE	DMP
Biphenyl	55	25	10	12
Napthalene	1.6	1.3	2	5
Anthracene	—	0.6	~0.1	—

Eisch and Kaska[18] observed that metallation with the aid of lithiobiphenyl in THF at 30°C is quantitative for triphenylmethane, takes place to the extent of 50% for diphenylmethane, and not more than 1% for toluene. The metallation reaction was accelerated by the addition of metallic lithium to lithiobiphenyl, which was explained by the formation of the biphenyl dianion more reactive than the radical-anion.

Table 2. Rate constants ($10^3 k$, litre mole^{-1} s^{-1}) for the reaction of radical-anions (Na^+ cation) with 9-phenylxanthene at 20°C.[58]

Radical-anion	DG	DEE
Biphenyl	16	200
Naphthalene	7	11

Later studies were made[57-60] on the dependence of the rate of metallation of certain aliphatic-aromatic compounds on the structure of the radical-anion, the substrate, and the cation on the solvating properties of the ether.

Usually the protophilic properties (or in the more general case the nucleophilic properties) of the carbanion become more pronounced as the interaction with the counterion weakens. This has been demonstrated in numerous instances of anionic polymerisation reactions[7,61], metallation by organolithium compounds[54], hydrogen isotope exchange between the CH bonds of two hydrocarbons in catalysis by bases[62], etc. The same cause is responsible for the acceleration of the majority of anionic organic reactions in solvents which effectively solvate cations and thereby activate the anions[5,63-65].

However, Tables 1 and 2 show that the effect of interionic interaction in metallation reactions involving radical-anions does not always obey the above rule and is related in a specific manner to the structure of the reactants.

Thus, in the reaction with triphenylmethane, the protophilic properties of the biphenyl radical-anion become more pronounced on passing from 1,3-dimethoxypropane (DMP) and 1,2-diethoxyethane (DEE) to solvents with a higher solvating capacity[5]—[1,2-dimethoxyethane?(Ed. of Translation)] (DME) and diglyme (DG) (Table 1). At the same time the opposite variation of the effect of the medium on the rate of reaction has been observed for the naphthalene radical-anion under the same conditions, i.e. an unusual behaviour has been observed, the protophilic properties of the radical-anion proving to be more marked the more intense its interaction with the cation. In the metallation of 9-phenylxanthene by sodium adducts the same behaviour is shown also by the biphenyl radical-anion (Table 2). It has been demonstrated[58] that the biphenyl and naphthalene radical-anions form with the Na^+ cation separated ion pairs in DG and contact ion pairs in DEE, i.e. contrary to the usual belief, the reactivity of the separated ion pairs is inferior to that of the contact ion pairs.

Table 3. Rate constants ($10^4 k$, s^{-1}) for the reaction of naphthalene radical-anions with triphenylmethane at 22°C.[57]

Solvent	Na^+	Li^+	K^+	Cs^+
DME	0.5	1	1	>10
DEE	0.8	1.2	2.5	>10

Essentially the same conclusion can be reached also on the basis of data for the effect of the cation on the rate of metallation of triphenylmethane by the naphthalene radical-anion in DME and DEE (Table 3). In DME, sodionaphthalene is present predominantly in the form of separated ion pairs and potassionaphthalene and caesionaphthalene are mainly in the form of contact ion pairs[5], but the rate of metallation is in fact higher for the contact ion pairs.

The above findings suggest that the cation enters into the composition of the activated complex for the reactions involving the metallation of aliphatic-aromatic compounds with participation of radical-anions.

An unusual dependence of the protophilic properties of the radical-anion on the intensity of interionic interaction has been observed also in certain other reactions with an acid-base mechanism. Thus weaker protophilic properties of the radical-anions entering into the composition of the separated ion pairs compared with the contact ion pairs were noted by Bank, who measured the rate of reaction of sodionaphthalene[38] and sodioanthracene[34] with water (Table 4).

For example, when tetraglyme (0.01% in relation to sodionaphthalene) is added to THF, the sodionaphthalene contact ion pairs are converted into separated ion pairs[7,53] and the rate of reaction with water then decreases by two powers of ten. The addition of tetraglyme (13 mole %) to THF causes a similar decrease (by a factor of 110) of the rate of protonation of the anthracene radical-anion. The type of dependence of k_1 and k_2 on the solvent is not altogether the same (cf. k_1 and k_2 for THF + DME and DME in Table 4). Bank and Bockrath attribute this to differences in the structure of the transition states[34].

Smid[49,55] showed that, when 1,4-dioxan (DO) is replaced by THF, the interionic interaction in the fluorenylsodium contact ion pairs is weakened. The protophilic

properties of the fluorene carbanion should then become more marked; however, measurements of the rate of reaction of fluorenylsodium with 1,2-benzofluorene [66] (Table 5) have shown that the protophilic properties of this anion become weaker. The addition of tetraglyme to THF causes the formation of separated ion pairs as for sodionaphthalene, but the rate of transfer of the proton to fluorenylsodium decreases by a factor of six, whereas in DME the formation of separated ion pairs is accompanied, as usual, by an enhancement of the protophilic properties of the carbanion.

Table 4. Rate constants (k, litre mole^{-1} s^{-1}) for the reactions of sodionaphthalene [33] (k_1) and sodioanthracene [34] (k_2) with water at 20°C.

Solvent	$10^{-4}k_1$	$10^{-4}k_2$
THF	1.06	0.66
THF + DME (50 vol.%)	0.79	0.013
DME	0.31	0.017
THF + tetraglyme	0.023	0.006

In a study of the kinetics of the isotope exchange of molecular deuterium with the adduct of an alkali metal and benzonitrile, Japanese workers [67] established that the rate of reaction increases with the radius of the cation in the adduct and on weakening of the solvating capacity of the solvent (Table 6).

Table 5. Rate constants (k, litre mole^{-1} s^{-1}) for the reactions of fluorenylsodium with 1,2-benzofluorene at 25°C. [66]

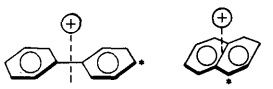
Solvent	Type of ion pair	$10^{-3}k$
DO	c.i.p.	4.2
THF	c.i.p.	3.5
THF + tetraglyme	s.i.p.	0.6
DME	s.i.p.	50

Consequently in this case the enhancement of the interionic interaction of the radical-anion with the counterion tends to increase the reactivity of the adduct (see Refs. 68–70 for other studies on these lines).

All that has been said concerning the anomalous dependence of the protophilic properties of the radical-anions and carbanions on the intensity of the interaction with the cations suggests that the cation can play a significant role in the transition state of the rate-limiting step of the proton transfer process. In particular, the observed effects can be accounted for if it is assumed [33,34,58,66] that the cation activates the bond which functions as the proton donor. An increase of the cation radius and a decrease of the solvating capacity of the solvent are accompanied by a decrease of the degree of solvation of the cation, which should entail an increase of the electrophilic properties of the latter. This leads to an acceleration of the reaction, in agreement with experimental results. The idea of an electrophilic attack by the cation on the CH bond of the substrate is not new—it was put forward and defended long ago by Morton [71]. Experimental data failed to confirm this hypothesis for reactions involving the substitution of hydrogen by a metal under the action of strong bases and it was justly criticised [72]. However, in relation to protonation reactions of radical-anions, the idea is supported by data for the kinetic isotope effect (KIE).

Table 6. Rate constants (k, ml h^{-1}) for isotope exchange between D_2 and the benzonitrile radical-anion [68].

Cation	Solvent	k	Cation	Solvent	k
Li$^+$	THF	0.1	K$^+$	DME	2.0
Na$^+$	THF	4.8	K$^+$	DG	0.58
K$^+$	THF	10.0	K$^+$	triglyme	0.32



Usually, in metallation reactions involving a protophilic hydrogen substitution mechanism, the rate-limiting stage is the dissociation of CH bonds [72]. In this case a high KIE is observed [73]. For example, a KIE close to the maximum possible value $k_H/k_D = 10$ has been observed [74] for the metallation of triphenylmethane by n-butyl-lithium in ethyl ether and THF. However, in reactions of potassiobiphenyl and potassionaphthalene with triphenylmethane in DEE [58] at 25°C, the ratio $k_H/k_D \simeq 1$. A low value of KIE was also established by Bank in the reaction of sodionaphthalene ($k_H/k_D = 1.37 \pm 0.44$) [33] and sodioanthracene ($k_H/k_D = 2.02 \pm 0.68$) [34] with water in THF at 20°C. The author adopted the concept of the involvement of the counterion in the transition state of the protonation reaction and emphasised that it remains important in the interaction of the radical-anion with acids such as triphenylmethane, and water which differ greatly in acid strength.

According to Melander [73], a low KIE should be observed in reactions where the electrophilic attack by the cation precedes or takes place simultaneously with the dissociation of the CH bond. This has in fact been established [33,34,58].

The reason why the cation must be involved in the proton transfer process may be the considerable degree of delocalisation of the charge in the radical-anions of aromatic hydrocarbons [3,13]. Therefore the electron density at the reaction centre of the radical-anion is low and its protophilic properties are comparatively weak. The available literature data for KIE in metallation reactions suggest that the degree of involvement of the cation in the transition state increases with decrease of the protophilic properties of the carbanion. For example, in the metallation of triphenylmethane by organolithium compounds in THF, [75] a tendency was observed towards a decrease of the k_H/k_D ratio on decrease of the basicity of the anion (alkyl > phenyl > benzyl) of the metallating agent. According to West et al. [75], the lithium cation is involved in the transition state, the degree of its involvement increasing on passing to less basic carbanions. However, under these conditions the dissociation of the CH bond remains the rate-limiting stage of the reaction ($k_H/k_D \simeq 9-4$).

On the other hand, one cannot restrict the role of the cation to electrophilic attack alone. In our view, one cannot rule out the possibility that the change of electron

density distribution, caused by the cation, in the radical-anion in the transition state, giving an increased electron density at the reaction centre, is also important. Then, if the cation is near the reaction centre, a decrease of the degree of its solvation and the increase of electrophilicity will promote such redistribution (the dissociation of the CH bond will probably not be [will probably be?] the rate-limiting stage, as before). On the other hand, if the cation and the reaction centre are far from one another, the decrease of the degree of solvation of the cation may retard the reaction. When the location of the cation in relation to the radical-anion is symmetrical, the reaction centre (designated by an asterisk) in the biphenyl radical-anion is further away from the cation than in the naphthalene radical-anion. This difference may be the reason for the opposite influence of solvents on the reactivity of potassiobiphenyl and potassionaphthalene:

On the other hand, if one remembers that the cation can fulfill a dual function—that of an electrophilic agent in relation to the CH bond and of a polarising agent in relation to the radical-anion—it becomes evident that the dependence of the rate of reaction with the given substrate on the structure of the radical-anion, the size of the cation, and the solvating capacity of the solvent may become complicated and difficult to predict.

Thus the study of the reactions of various proton donors with radical-anions led to the formulation of many new hypotheses concerning the relation between the state in solution and the reactivity of adducts of alkali metals and aromatic hydrocarbons. Similar phenomena have been observed also for the radical-anions of aliphatic-aromatic hydrocarbons formed in the reactions of the latter with alkali metals.

III. RADICAL-ANIONS IN REACTIONS OF ALIPHATIC-AROMATIC COMPOUNDS WITH ALKALI METALS

The interaction of alkali metals with various compounds containing a CH bond in which the hydrogen atom is mobile entails [1,72] the substitution of the latter by the metal. Liquid ammonia [37,76,77], in which alkali metals readily dissolve, and other electron-donating solvents, for example THF, [78] are convenient media for reactions of this kind. The effectiveness of these solvents is due to the solvation of the alkali metal cation, which facilitates the conversion of the metal atom into an ionised form. This conclusion follows, in particular, from the studies of Scherf and Brown [79,80], who showed that the reaction of fluorene with lithium, sodium, and potassium becomes easier in a sequence corresponding to the solvating capacity of the ethers [5,62]: DME > THF ≥ DEE > DO.

It was suggested initially that the reaction has an acid–base mechanism [72] with dissociation of the CH bond and ionisation of the metal atom in a single elementary step (here and henceforth the aliphatic-aromatic compound will be denoted by AH in contrast to the purely aromatic compound Ar):

$$AH + M \rightarrow A^{-\delta}M^{+\delta} + H^{\bullet}\,. \qquad (12)$$

The evolution of hydrogen, quoted by a number of workers [77-79], in the reactions of hydrocarbons with alkali metals is at first sight consistent with this view. However, later investigations [18,81,82] suggested that the reaction may be more complicated—it may proceed via a one-electron transfer stage with formation of a radical-anion $AH^{\bullet-}$:

$$AH + M \rightleftharpoons AH^{\bullet-} + M^{+}\,. \qquad (13)$$

The first ESR studies [83,84] already confirmed the formation of the radical-anions of aliphatic-aromatic hydrocarbons in their interaction with alkali metals in an ethereal medium. Comparatively stable (as a rule at low temperatures) radical-anions of indene [83], fluorene [83-86] and its derivatives [87-89], isomeric benzofluorenes [84,90], and 4,5-methylenephenanthrene [84,90-92] were obtained.

The mode of further reactions of the radical-anions in many ways depends on the structure of the hydrocarbon. Thus the radical-anions of arylmethanes mainly undergo the dissociation of the C–C bond with elimination of the benzene ring [81, 93-95]. The conversion of the radical-anion into a metallation product (the carbanion A^{-}) with dissociation of the CH bond and elimination of a hydrogen atom is possible [93-96]:

$$AH^{\bullet-} \rightarrow A^{-} + H^{\bullet}\,. \qquad (14)$$

Reaction (14) is more typical for the radical-anions of indene, fluorene, and similar compounds [82-84,97-98]. Hydrogen is evolved in a gaseous form and is consumed in the hydrogenation of the radical-anion,

$$AH^{\bullet-} + H^{\bullet} \rightarrow AH_2^{-} \qquad (15)$$

or of the initial hydrocarbon AH, or it remains in solution [83,84]:

$$AH + H^{\bullet} \rightarrow AH_2^{\bullet} \qquad (16)$$

and

$$AH_2^{\bullet} + AH^{\bullet-} \rightarrow AH_2^{-} + AH\,. \qquad (17)$$

When the reaction mixture contains sufficient of the initial compound AH, the latter may react with the radical-anions in accordance with Eqns. (18) and (19): [18,82-84]

$$AH^{\bullet-} + AH \rightarrow AH_2^{\bullet} + A^{-}\,, \qquad (18)$$

$$AH_2^{\bullet} + AH^{\bullet-} \rightarrow AH_2^{-} + AH\,. \qquad (19)$$

Eqns. (18) and (19) are analogous to Eqns. (1) and (2), AH playing the role of the proton donor BH in relation to its own radical-anions. The AH_2^{-} carbanions are usually more basic than A^{-} and are protonated by the initial hydrocarbon with formation of the dihydro-derivative AH_3:

$$AH_2^{-} + AH \rightarrow AH_3 + A^{-}\,. \qquad (20)$$

Thus the mechanism of the reaction in a system containing an aliphatic-aromatic hydrocarbon and an alkali metal is very complicated. One should note that the metal cation, the role of which in the process may be very considerable, as already demonstrated above, has been omitted from the equations.

It is usually almost impossible to obtain an unambiguous idea about the mechanism on the basis of kinetic data determined by any one method (for example from measurements of the electronic and ESR spectra and from the amount of hydrogen evolved). It is also difficult because all three modes of reaction of AH^{-} [reactions (14) and (15), (14)–(17), and (18)–(19)] are equivalent from the standpoint of the final result (the formation of the carbanions AH_2^{-} and A^{-}) and can be formally represented by the same overall equation for the disproportionation of two radical-anions:

$$AH^{\bullet-} + AH^{\bullet-} \rightarrow AH_2^{-} + A^{-}\,. \qquad (21)$$

The detection of AH_3 among the reaction products indicates the involvement of the initial AH in the reactions of the radical-anion but it is not clear in what capacity—as a hydrogen atom acceptor [Eqn.(16)] or as a proton donor [Eqn.(18)]. Nevertheless, it is important to know this also from the point of view of the characteristics of the reactivity of the radical-anion, which in the first case behaves only as an electron donor [Eqn.(17)] and in the second as a proton acceptor [Eqn.(18)]. In the determination of the activation parameters for the decomposition of $AH^{\cdot-}$, it is difficult to rule out the presence of AH, since equilibrium (13) shifts to the left with increase of temperature. However, even when the hydrocarbon AH is not present in solution, the possibility of the consumption of the radical-anion via two pathways [reactions (14) and (15)] remains. Taking this into account, we shall examine the available literature data for the effect of the metal and solvent on the course of the reaction involving the metallation of aliphatic-aromatic hydrocarbons by alkali metals.

Scherf and Brown [79] showed that the effectiveness of alkali metals in the reaction with fluorene decreases in the sequence K > Li > Na. The rate of conversion of fluorene radical-anions into carbanions, measured [83] by the ESR method in DME, decreases in the same sequence.

Since the kinetic data [79,83] characterise the overall reaction of the radical-anion [Eqns.(14)–(19)], it is difficult to derive from them a clear idea about the effect of the cation on the behaviour and reactivity of the radical-anion.

The results obtained by Tabner, who made a detailed investigation of the kinetics of the conversion of the radical-anions of fluorene [86] and its derivatives [88–90] into the corresponding carbanions, suffer from the same deficiency. The kinetic parameters were determined in a system containing the radical-anions prepared at a low temperature (−80°C) in the presence of an excess of the alkali metal. Therefore it was postulated that the free hydrocarbon is absent from the solution and reactions (16)–(19) were excluded from consideration *a priori*. Nevertheless, a certain amount of AH might have formed in the system on raising the temperature in consequence of a shift of equilibrium (13). Moreover, the rate of evolution of hydrogen was not determined and the conclusions concerning the mechanism and the role of the cation in it were reached on the basis of kinetic data obtained spectrophotometrically or by the ESR method. In view of this, a detailed analysis of Tabner's data is pointless, and we shall consider only the most important results.

Table 7 presents the free energies of activation ($\Delta G^{\neq}$, kcal mole^{-1}) for the conversion of the fluorene radical-anions into carbanions, the temperature ranges (t_1 and t_2, °C) in which the rate constants k were measured, the values of k corresponding to the extreme temperatures (k_1 and k_2), and the order of the reaction n with respect to the radical-anions.

It is difficult to infer the effect of the cation from the rate constants, since the measurements were made in different temperature ranges. Sometimes the k cannot be compared as they have different dimensions. Since the rate decreases as the temperature is reduced, it follows, judging from the value of k with the same dimensions, that the dependence of the rate of reaction in THF on the cation is represented by the following sequence: $Li^+ < Na^+ < K^+ < Cs^+$. In the case of Cs^+, the rate of reaction was so high that it could not be measured. The activation energy for the first-order reaction in THF also decreases with the radius of the cation. Tabner's results differ from the data of Scherf and Brown [79] and Bilevich et al. [83] by the position of lithium in the series of cations. Possibly this is due to the difference between the solvents and temperatures. The effect of the cation depends also on the structure of the hydrocarbon. Thus the rate of decomposition of the 1,2- and 2,3-benzofluorene radical-anions [90], obtained by the reaction with sodium, is higher than that of the radical-anions obtained by the reaction with lithium, while for 4,5-methylenephenanthrene the most stable radical-anions were in fact obtained in THF by the reaction with sodium.

Table 7. Effect of the cation and the solvent on the kinetics of the conversion of the fluorene radical-anions into carbanions [8].

Cation	Solvent	t_1,°C	t_2,°C	$k_1\cdot10^3$	$k_2\cdot10^3$	n	$\Delta G^{\neq}_{25}$
Li^+	THF	+9.4	−6.1	1.2	0.415	1	20.8
Li^+	THF	−20.2	−37.5	60.2*	21.3*	2	17.9
Na^+	THF	−30.7	−41.2	1.6	0.46	1	18.1
K^+	THF	−38.7	−53.2	25	1.8	1	14.8
Li^+	DME	−18	−43.3	25.8*	0.24*	2	16.9

Li^+	MTHF**	−23.2	−43.4	10.1	0.66	1	13.8

*The dimensions of the constants are litre mole^{-1} s^{-1}; in the remaining cases the dimensions are s^{-1}.
**THP = tetrahydropyran; MTHF = 2-methyltetrahydrofuran.

Tabner observed that the reaction may be of first or second order with respect to the radical-anion [86] (Table 7). Analysis of the conditions under which the reaction was carried out led him to the conclusion that a first-order reaction is observed for contact ion pairs and a second-order reaction for separated ion pairs. Admittedly the type of ion pairs was not identified, but Tabner's conclusion appears likely, since a second-order reaction was observed either at low temperatures (in THF) or in solvents with a relatively high solvating capacity (DME). In addition, a second-order reaction with respect to the radical-anion was observed also for isomeric benzofluorenes [90], where an appreciable delocalisation of the charge also favours the formation of separated ion pairs.

The second-order reaction may be a consequence of the fact that the transition state of the rate-limiting stage [it is believed that this is reaction (14)] has the structure of a contact ion pair, i.e. the cation is actively involved in its formation. In relation to the free radical-anion or the radical-anion forming part of the separated ion pair, the cation behaves in this case like a kinetically independent species, which leads to a second-order reaction.

The authors believe that the role of the cation consists in the localisation of the negative charge near the carbon atom of the CH aliphatic bond [86], which is favoured by the intense interionic interaction in contact ion pairs. The necessity to localise the charge near the reaction centre is believed to be due to the fact that the structure of the transition state is closer to that of the reaction product (the anion A^-) then to the initial radical-anion [90]. In particular, this is indicated by the correlation between the acidity of the hydrocarbons and the rate of decomposition of their radical-anions (Table 8).

The decrease of the solvation energy of the cation, tending to increase its electrophilicity, should probably enhance the localisation of the charge by the cation.

Possibly this is one of the reasons for the acceleration of the decomposition of the radical-anion with increase of the radius of the cation, since the greater its radius the lower the degree of its solvation. We may note that, on passing from diglyme to dioxan, the degree of solvation of the cation falls and the rate of evolution of hydrogen in the reaction of cyclopentadiene with potassium rises [97].

Table 8. The acidity of the hydrocarbons (pK) [99] and the relative rate constants (lg k_{rel}) for the decomposition of their radical-anions (Li^+ cation) in THF at 25 °C. [90]

Hydrocarbon	pK	lg k_{rel}
1,2-Benzofluorene	20.0	0.91
4,5-Methylenephenanthrene	22.6	0.51
Fluorene	22.9	0.00
2,3-Benzofluorene	23.2	—1.67

Nevertheless, it would be premature to assume that there is a fully unambiguous relation between the type of ion pairs and the effect of the cation in the conversion of the radical-anions of aliphatic-aromatic hydrocarbons into carbanions. There are facts which are difficult to account for within the framework of the above hypothesis concerning the structure of the transition states; these include, in particular, data [86,89,90] indicating a dependence of the activation parameters for the reaction on the cation and on the solvent. Possibly this difficulty will be overcome after more detailed studies of the decomposition of the radical-anion.

The increased probability of decomposition of the radical-anion involving dissociation of the CH bond via reaction (14) with increase of the acidity of the hydrocarbon was noted not only by Tabner [86] but also by other workers. Bosch and Brown [82] established that, when indene is metallated by potassium and lithium in DME at 85 °C, a much greater amount of hydrogen is evolved than in the metallation of a less acid hydrocarbon—fluorene (50–60% and 2–14% of theoretical respectively). It has also been noted [83] that the fluorene radical-anion is more stable than the indene radical-anion. On the other hand, it is evident that an increase of acidity tends to accelerate the protonation of the radical-anion [reaction (18)], which competes with reaction (14). Since the kinetics of both processes depend in a complex manner on the cation, the solvent, and the structure of the radical-anion, it follows that the relative contributions of reactions (18) and (14) can vary in different ways depending on the specific experimental conditions. This is confirmed by measurements [98] of the rate of metallation of the same hydrocarbons by potassium in THF at 25 °C (Table 9).

Probably not only the acidity of the hydrocarbon but also its structure as a whole has a significant influence. It has been suggested [84] that, for a fairly high degree of delocalisation of the unpaired electron (for example in the ring fragment of the naphthyl or phenanthryl ion), the radical-anions of fairly acid hydrocarbons can also be stable. For example, the radical-anion of 4,5-methylenephenanthrene [92] (pK = 22.6) is stable at room temperature.

In conclusion of this section, we shall mention yet another reaction which may occur in a system containing an aliphatic-aromatic hydrocarbon and an alkali metal. In the presence of an excess of the latter, the anions A^- may, like those of aromatic hydrocarbons, combine with a further electron and give rise to radical-dianions (r.d.a.):

$$A^- + M \rightarrow A^{=} + M^+ . \qquad (22)$$

One of the first radical-dianions of this kind was detected in the reaction of cycloheptatriene with potassium in RHF. [100,101] However, radical-dianions were in fact obtained even earlier. Thus it has been noted [80] that the reaction of a second equivalent of potassium with fluorenylpotassium proceeds without the evolution of hydrogen. The authors could not account for this phenomenon, since they assumed that the second hydrogen atom in the 9-position must be substituted by the metal. It was not until later that Janzen and Gerlock [84] showed with the aid of ESR that the addition of a second potassium atom with formation of a radical-dianion takes place under these conditions and not substitution. Syrkin and coworkers [102] observed the formation of radical dianions in the polarographic reduction of aromatic compounds in DMF. So far, the radical-dianions of fluorene [84,103], 9-phenylfluorene [87,103,104], benzofluorenes [87,103], and diphenylmethane [95] have been identified by ESR; the ESR spectra of 4,5-methylenephenanthrene have been investigated in greatest detail [84,92,103–105].

Table 9. The acidity of the hydrocarbons (pK) [66] and the rate constants (k, s^{-1}) for the evolution of hydrogen in the course of their metallation by potassium in THF at 25 °C. [98]

Hydrocarbon	pK	$k \cdot 10^8$
Cyclopentadiene	15—17	1.0
Indene	21	1.5
Fluorene	25	1.9

Usually radical-dianions are formed readily when hydrocarbons are metallated by potassium and the reaction can proceed even in the melt in the absence of a solvent [95]. With sodium, it is not always possible to obtain radical-dianions even for hydrocarbons with an extensive π-conjugation system, such as benzofluorenes. From the standpoint of reactivity, the radical-dianions have been hardly investigated; it has only been stated that they may be protonated by the solvent (DME). [92] There is no doubt that the study of the chemical behaviour of these species, which combine properties of a radical-anion and a dianion, can yield very interesting and useful results.

IV. DIANIONS AS METALLATING AGENTS

The dianions of aromatic hydrocarbons are stronger bases than the radical-anions. For example, the metallation of triphenylmethane by the dianions of naphthalene [106], biphenyl [107], and anthracene [57] is faster by several powers of ten than the metallation by radical-anions under the same conditions. The high reactivity of the dianions is to some extent an obstacle to its quantitative investigation. The protophilic properties of the dianions are so marked that they are protonated by the solvent and not only by fairly acid solvents such as ammonia [108] but also by much

weaker proton donors—ethers. Thus dilithionaphthalene cannot be obtained in an ethereal medium without admixture with an organic derivative of the alkali metal the absorption spectrum of which resembles that of the dihydronaphthalene carbanion [5,109,110]. It has been shown [106,111] that the diphenyl and anthracene dianions, obtained by the reduction of the corresponding radical-anions with potassium or lithium in DME and DEE, are converted after a time, in a solution free from acid impurities, into carbanions the spectroscopic properties of which resemble the carbanions of dihydro-derivatives.

It has recently been shown [112] that the protonation of the dianions by the solvent is the reason for the earlier observation [57] of the conversion of the naphthalene radical-anions into the carbanions of the above type in the presence of an excess of the alkali metal. This process is faster the lower the ionisation potential of the metal and the higher the solvation capacity of the solvent. In other words, this reaction is promoted by the same factors as those favouring the formation of the dianions [5]. Szwarc and coworkers showed that the protonation of the diphenylacetylene [113] and methylphenylacetylene [31] dianions in THF causes in the course of time a shift of the equilibrium in the reaction of these hydrocarbons with sodionaphthalene or sodiobiphenyl. A slow protonation of the naphthalene dianions by ethers (DO and THF) has been reported [28].

The low stability of solutions of the dianions hinders the study of the effect of the cation and the solvent on the reactivity of the dianions. One-electron transitions, which are more likely than in the case of radical-anions, give rise to an additional complication. For example, the interaction of the anthracene dianion with 2-methylnaphthalene leads to the formation of the carbanion of the latter. However, the naphthalene and biphenyl dianions convert 2-methylnaphthalene into radical-anions, while metallation does not take place [106].

Table 10. Rate constants (k, s^{-1}) for the reaction of diphenylmethane with anthracene dianions and the positions of the maxima (λ_{max}, nm) in the spectra of the dianions [106].

Cation	Solvent	k	λ_{max}
Li^+	DEE	$\gg 10^{-7}$	565
Na^+	DEE	$\sim 10^{-7}$	590
K^+	DEE	$2 \cdot 10^{-3}$	615
Na^+	DME	$1 \cdot 10^{-4}$	600
K^+	DME	$>10^{-3}$	615

The effects of the cation and the solvent on the reactivity of the dianion obey the usual relations governing the protophilic substitution of hydrogen, i.e. the reaction rate increases as the interaction between the dianions and the counterions is weakened. For example, the rate of reaction of the naphthalene dianion with diphenylmethane in THF ($k \simeq 10^{-2}$ s^{-1}) is much higher than in DEE ($k = 6 \times 10^{-4}$ s^{-1}), [106] where the lithium cation is less solvated. The interaction of the anthracene dianion with the cation becomes weaker with increase of the radius of the latter in the series $K^+ > Na^+ > Li^+$ or when the solvating capacity of the solvent is impaired (DME > DEE), as shown by the bathochromic shift of the absorption band in the spectrum of the anthracene dianion [111]. The rate of reaction of the anthracene dianion with diphenylmethane also increases in the same direction [106] (Table 10).

Apparently the protophilic properties of the dianion are fairly marked and there is no need for the activation of the metallated linkage by the cation or for the increase of the electron density at the dianion reaction centre in the transition state, as suggested for radical-anions. In this connection, it is interesting to note that a high KIE ($k_H/k_D \simeq 10$) [35] has been found for the reaction of the perylene dianion with alcohol in THF, as for metallation by lithium alkyls [74,75].

On the other hand, the problem of the effect of the cation on the reactivity of the dianion cannot be regarded as finely elucidated. According to the date of Ichikawa and Tamaru [114], the rate of isotope exchange of D_2 with anthracene dianions (it is assumed that the exchange involves an acid–base mechanism) increases when Li^+ and Na^+ cations are replaced by cations with a larger radius, in agreement with results [106] obtained in a study of metallation reactions. On the other hand, the adsorption of hydrogen in solutions of the dianions, leading to the formation of the carbanions of dihydroanthracene and the alkali metal hydride [70], is faster for cations with small radii [114].

V. CARBANIONS OF DIHYDRO-DERIVATIVES OF AROMATIC HYDROCARBONS AS METALLATING AGENTS

On reaction with proton donors, the radical-anions and dianions of aromatic hydrocarbons are converted into the carbanions of the dihydro-derivatives [mechanisms (1), (2), and (4)]. Until recently, special attention was not paid to the behaviour of these carbanions in the metallation or Birch reduction reactions and yet the final result of the process depends on them in many ways. For example, it has been shown [108] that, in the reductive alkylation of biphenyl in liquid ammonia, the species involved in the reaction with methyl bromide is not the biphenyl dianion formed in the first stage but its protonation product—the carbanion of dihydrobiphenyl.

In DME and DEE, the carbanions of dihydrobiphenyl are less protophilic than the biphenyl radical-anions, whereas in diglyme as a solvent, which has a higher solvating capacity, the opposite relation between their reactivities is obtained [106]. Therefore the metallation of triphenylmethane and 9-phenylxanthene in DME or DEE is complicated by the accumulation of dihydrobiphenyl carbanions in solution. In particular, the metallation of 9-phenylxanthene by sodiobiphenyl in DEE is on the whole slower for this reason than in diglyme, despite the fact that the rate of reaction of the biphenyl radical-anion with this substance in DEE is much higher than in diglyme (Table 11).

In general, in solvents with a comparatively low solvating capacity the rate of metallation directly by the radical-anion or dianion of biphenyl is ultimately determined by the reactivity of the dihydrobiphenyl carbanions [58,106,107]. At the same time, in all the instances where the reactions of aliphatic-aromatic compounds with the carbanions of dihydronaphthalene and dihydroanthracene were investigated, the reactions are faster than those with the corresponding radical-anions but slower than with the dianions [57,106]. Thus smaller rate constants have been obtained for the metallation of diphenylmethane by dihydronaphthalene carbanions [106] (with Li^+ cations), $k = 2.3 \times 10^{-5}$ s^{-1} in THF and 2.5×10^{-4} s^{-1} in DEE, than for the

naphthalene dianions (9.5×10^{-3} and 6×10^{-4} s^{-1} respectively). The higher reactivity of the dihydroanthracene carbanion compared with the anthracene radical-anion in protonation by water has also been noted [34]. It was explained by the fact that the electron density in the 9-position of the radical-anion is smaller by a factor of two than in the carbanions. Deuterium exchange with dihydroanthracene carbanions [114] is slower than with anthracene dianions, which also indicates more marked protophilic properties of the latter. As far as one can judge from the data in Table 11, an increase of the degree of solvation of the cation tends to increase the protophilic properties of the carbanions of the dihydro-derivatives.

Table 11. Rate constants for the metallation (litre $mole^{-1}$ s^{-1}) of triphenylmethane and 9-phenylxanthene by biphenyl radical-anions (k_1) and dihydrobiphenyl carbanions (k_2). [106]

Hydrocarbon	Cation	Solvent	$k_1 \cdot 10^3$	$k_2 \cdot 10^3$
Triphenylmethane	K^+	DG	55	>1000
"	K^+	DME	25	11
"	K^+	DEE	10	5
9-Phenylxanthene	Na^+	DG	16	>1000
"	Na^+	DEE	200	11

As already stated (Section I), the position of equilibrium in the reactions of such carbanions with aliphatic-aromatic compounds is determined primarily by the strength of the CH acids involved in them. Dihydrobiphenyl and dihydronaphthalene are apparently very weak CH acids ($pK > 33$), while the equilibrium acidity of dihydroanthracene, determined in cyclohexylamine [115] by the transmetallation method, is somewhat higher than that of triphenylmethane [116] (the respective pK values are 30.4 and 31.5).

Table 12. Equilibrium constants for the reactions of dihydroanthracene carbanions with triphenylmethane at 25°C. [115]

Cation	Solvent				
	DG	DME	DEE	DE*	CHA*
Li^+	2.3	2.8	44	125	—
Na^+	—	3.0	17	—	—
K^+	3.0	4.8	17	30	12
Cs^+	5.1	11	11	—	12

*DE = diethyl ether; CHA = cyclohexylamine.

Therefore the reactions of the anthracene radical-anions or dianions with triphenylmethane [57,106] do not go to completion and equilibrium is established in the last stage. Its position depends significantly on the cation and solvent [115] (Table 12). The observed effects have been explained by the unequal changes in the energy of the interaction of dihydroanthracene and triphenylmethane carbanions when the reaction conditions are varied, in particular by a difference in the type of ion pairs in many instances.

It is noteworthy that the elucidation of the factors governing the influence of the structure of the ion pairs of organic derivatives of alkali metals on the position of the acid–base equilibrium of the transmetallation reaction is important for the problem of estimating the strength of CH acids by the above procedure [115,117-120].

VI. COMPARISON OF THE PROTOPHILIC PROPERTIES OF METALLATING AGENTS

The combined data for the reactivities of the above three types of metallating agents lead to the conclusion that the dianions are the most protophilic among them. The carbanions of the dihydro-derivatives are less reactive. The naphthalene and anthracene radical-anions are less protophilic than the carbanions, while the biphenyl radical-anions can be more protophilic than the carbanions of dihydrobiphenyl under conditions where the degree of solvation of the cation is comparatively low. The relative reactivities of the dianions, radical-anions, and the carbanions of dihydro-derivatives established in the metallation reactions are consistent with quantum-chemical predictions, in particular with calculations by the Pariser–Parr–Pople (PPP) method of the proton localisation energies [106] (Table 13).

Table 13. Protonation localisation energies for the dianions (L_1) and radical-anions (L_2) of aromatic hydrocarbons and the carbanions of their dihydro-derivatives (L_3) (in eV). [106]

Hydrocarbon	L_1	L_2	L_3
Biphenyl	0.34	—4.6	—5.1
Naphthalene	1.4	—5.2	—4.2
Anthracene	0.3	—5.4	—4.5

The protonation of the dianions entails an energy gain by the π-electron system, while the protonation of the radical-anions and the carbanions of the dihydro-derivatives is accompanied by a decrease of the π-conjugation energy. This implies that the dianions must be more protophilic than the other two types of agents, as in fact has been observed experimentally. Also in agreement with experiment, theory predicts a higher reactivity of the dihydronaphthalene and dihydroanthracene carbanions than that of the corresponding radical-anions ($L_3 > L_2$). On the other hand, according to theory, the protophilic properties of the biphenyl radical-anions should be more marked than those of the dihydro-biphenyl carbanions ($L_3 < L_2$). The opposite relation between the protophilic properties of the above two species observed in many cases is due to the effects of the medium and the counterions, which are so far difficult to take into account quantitatively in quantum-chemical calculations.

The absence of a correlation between the rate constant k for the protonation by water of the radical-anions of aromatic hydrocarbons and the localisation energies ($L_{r.a.}$) calculated for the protonation of the radical-anions by the simple Hückel method (Table 14) has been noted [30]. It is assumed that $L_{r.a.} = L + m_{m+1}$, where L is the localisation energy for the hydrocarbon and m_{m+1} the energy of

the lowest non-bonding hydrocarbon orbital in β units. For example, the rate of reaction falls on passing from the biphenyl to the anthracene radical-anion, despite the decrease of $L_{r.a.}$. At the same time, the authors noted a satisfactory agreement between the values of k and $L + 2m_{m+1}$ (or, what amounts to the same thing, between k and the sum $L_{r.a.} + m_{m+1}$). In their view, this is evidence that charge transfer from the radical-anion to the proton-donor molecule plays an important role in the mechanism of the protonation of the radical-anions (m_{m+1} characterises the electron affinity of the hydrocarbon and hence also the ionisation potential of the radical-anion).

Table 14. Rate constants for the protonation by water (k, litre mole^{-1} s^{-1}) of the radical-anions of aromatic-hydrocarbons and the localisation energies L calculated by the simple LCAO-MO method [30].

Hydrocarbon	$k \cdot 10^3$	L	$-m_{m+1}$	$L_{r.a}$	$L+2m_{m+1}$
Biphenyl	18	2.447	0.705	1.742	1.037
Naphthalene	4.6	2.299	0.618	1.681	1.063
Phenanthrene	1.0	2.299	0.605	1.694	1.089
Anthracene	0.2	2.015	0.414	1.599	1.185
1,2-Benzanthracene	0.055	2.049	0.452	1.597	1.145
Pyrene	0.012	2.190	0.445	1.745	1.300

Moreover, calculation by the more sophisticated PPP method yields values of $L_{r.a.}$ (Terekhova et al.[106]), the variation of which in the series of hydrocarbons (L_2 in Table 13) is consistent with the variation of the rates of the metallation (Tables 1 and 2) and protonation (Tables 4 and 14) [30,57,58] reactions. We may also note that the sum $L + 2m_{m+1}$ essentially defines the localisation energy for the protonation of the dianions (in terms of Hückel's approximation), the protophilic properties of which decrease in the same direction as in the radical-anions judging from the available qualitative data [106].

---o0o---

The data presented in this review reveal certain characteristics of the metallation reactions involving the radical-anions and dianions of aromatic hydrocarbons. Metallation by radical-anions includes, together with their protonation, an electron transfer stage. The dianions react with proton donors as diacidic bases. However, in consequence of the high reduction potential of the dianions, there is a possibility of a side reaction involving electron transfer to the proton donor. The products of the protonation of the radical-anions and dianions (the carbanions of the dihydro-derivatives) are also highly reactive metallating agents. In the course of studies on metallation by radical-anions, an unusual feature was observed—an increase of their reactivity (protophilic properties) in the case of a strong interaction with the counterion. The details of the structure of the reactants, which determine the structure or the activated complex incorporating the cation, play an important role under these conditions.

Methods for the Cleavage of N-N Bonds in Organic Compounds

M.F.Marshalkin and L.N.Yakhontov

In the review an attempt is made for the first time to give a systematic account of the available extensive literature data on the methods for the dissociation of N-N single bonds in organic compounds. Reductive and acid cleavage, various rearrangements, interaction with oxidants, and thermal and photochemical processes have been examined. In order to account for the characteristics of the dissociation of N-N bonds, data for the energy characteristics of the N-N and N≡N groups are adduced. The bibliography includes 274 references.

I. INTRODUCTION

Processes involving the dissociation of N–N bonds in both cyclic and acyclic compounds occupy an important place in organic chemistry. They include the classical Fischer, Curtius, and Schmidt reactions, the benzidine rearrangement, and others, each of which has been the subject of serious and thorough reviews. However, there are no reviews giving a general account of different methods for the dissociation of N–N bonds. Even the familiar monograph of Weygand and Hilgetag[1], which constitutes a fairly complete encyclopedia of synthetic methods arranged systematically in accordance with the bond differences in the compounds, contains no section whatsoever dealing with the dissociation of N–N bonds. Other monographs[2-9], in which the general problems of the chemistry of organic compounds with N–N bonds are considered but the reactions involving the dissociation of such bonds are not specified, also fail to fill this gap.

A characteristic feature of a single bond between two nitrogen atoms is the low dissociation energy (37 kcal mole^{-1}) compared with other single bonds commonly encountered in organic compounds (for example the dissociation energy is 80 kcal mole^{-1} for C–C, 66 kcal mole^{-1} for C–N, and 64 kcal mole^{-1} for S–S).[10] On the other hand, the linkage with the highest bond multiplicity between nitrogen atoms (N≡N), which is characteristic of molecular nitrogen, has the maximum dissociation energy (225 kcal mole^{-1}) compared with the analogous C≡C (198 kcal mole^{-1}) and C≡N (209 kcal mole^{-1}) bonds[7]. In a saturated system, there is repulsion between the nitrogen *p* orbitals, which makes the N–N bond longer (1.40 Å)[11-13] than the sum of the radii of two nitrogen atoms (2 × 0.53 = 1.06 Å), while a characteristic feature of N≡N is the overlapping of the *p* orbitals, which causes additional bond stabilisation. In particular, the above characteristics are responsible for the behaviour of the relevant substances in chemical reactions. The dissociation of the saturated nitrogen–nitrogen bond takes place very rapidly, much more so than that of the C–C or C–N bonds, and, when competing reactions are possible, the dissociation of the N–N bond takes place preferentially and usually results in the formation of either the corresponding amino-derivative or of unstable products of the nitrene type with an electron sextet at the nitrogen atom. The latter can be stabilised in different ways via addition reactions, rearrangements, etc. The stability of molecular nitrogen noted above, the energy gain in its formation, and its capacity to be removed from the reaction sphere in the form of a gas also have a significant influence. In azides, azines, and other compounds, where the dissociation of N–N bonds with evolution of a nitrogen molecule is possible, this type of process usually takes place preferentially.

The above general features of the cleavage of N–N bonds can be readily traced in different types of reactions discussed in the present review. Naturally, within the framework of a journal article it is impossible to describe all cases of organic reactions involving the dissociation of N–N bonds. Therefore we thought it useful to describe in the review as fully as possible different types of processes at the expense of reducing the number of examples of each.

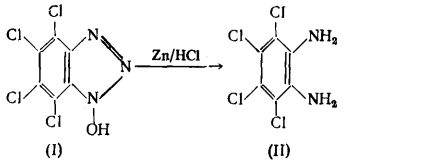
Together with a description of pioneer investigations, attention was concentrated on a selection of original papers reflecting most fully the scope of the method, the mechanism of the reactions, and their unusual course. The generally known classical reactions are not considered in the review. Whenever possible, references are given in all cases to review articles in which all the remaining literature is quoted.

II. REDUCTIVE CLEAVAGE OF N–N BONDS

The hydrogenolysis of N–N bonds is one of the most familiar methods of converting the various azines, azides, hydrazines, and their derivatives into the corresponding amines. The capacity of zinc in an acid medium to dissociate the N–N bond, observed by Curtius in the

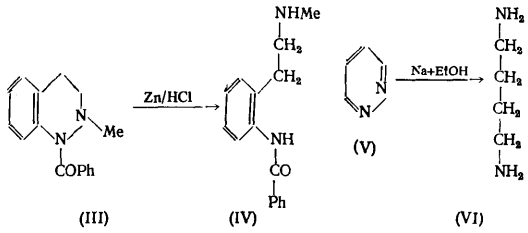
reduction of benzylideneazine and its homologues to mono- and di-benzylamines[14], was subsequently used successfully for the synthesis of aromatic perfluorodiamines from hydrazones[15] in the course of the complete synthesis of sphingosine[16]. Various reducing agents are employed to convert arylhydrazones and hydrazines into amines in the synthesis of aminosugars[17-22] and aminoacids[23,24].

The reduction of arylhydrazones of α-ketoacids constitutes the basis of the synthesis of aminoacids via the mechanism



$$RCH(OAc)COOEt \rightarrow R{-}C(=N{-}NHPh)COOH \rightarrow R{-}CH(NH_2)COOH .$$

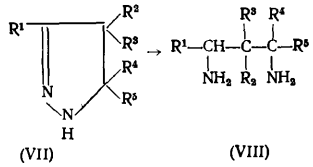
developed by Feofilaktov and coworkers[25-31].



Catalytic methods have found extensive applications in the dissociation of N–N bonds in azines, hydrazines, hydrazides, and hydrazones[32-46]. Catalytic reduction has been used also for the conversion of sulphonyl hydrazides into sulphonamides[47].

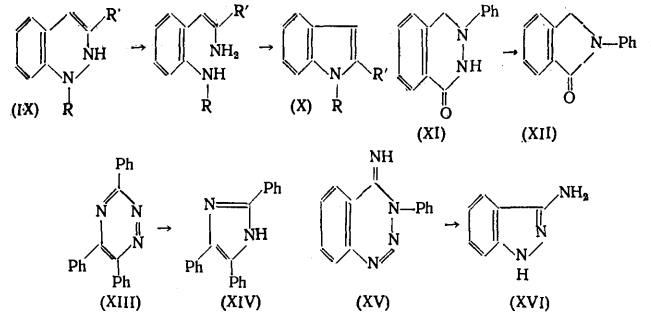
Earlier studies on the reductive cleavage of N–N bonds in hydrazines and their derivatives by chemical and catalytic methods have been discussed[48-50] and other reports have dealt with the polarographic reduction of arylhydrazones[51,52].

The N–N bonds in heterocyclic N–N systems have also been successfully cleaved by reductive methods[34,38,53-55] and the conversion of, for example, the benzotriazole derivative (I) into *o*-phenylenediamine (II),[56] of tetrahydrocinnoline (III) into the *o*-aminoethylphenylamine derivative (IV),[57] of pyridazine (V) into 1,4-diaminobutane (VI,[58] etc. has been achieved.

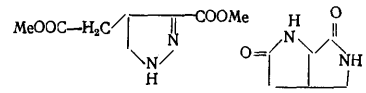


(I) (II)

(III) (IV) (VI)



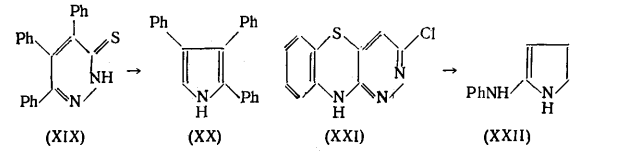
The hydrogenolysis of pyrazolines (VII) over a nickel catalyst constitutes the basis of the preparative synthesis of 1,3-diamines (VIII) developed by Kost and coworkers[59,60]:



(VII) (VIII)

The hydrogenolysis of cyclic hydrazines derived from 3,5-dioxopyrazolidines over a nickel catalyst was investigated in detail by Moldaver and coworkers[61-63]. The electrochemical reduction of heterocyclic N–N compounds has been described in a review[64].

In many cases the diamines formed on reduction of cyclic hydrazine derivatives can recyclise, becoming converted during the reaction into other heterocycles. Indoles (X) from cinnolines (IX),[65-69] phthalimidine (XII) from dihydrophthalozolone (XI),[70] imidazole (XIV) from triazine (XIII),[71] and indazole (XVI) from benzotriazine (XVI)[72] have been obtained in this way:

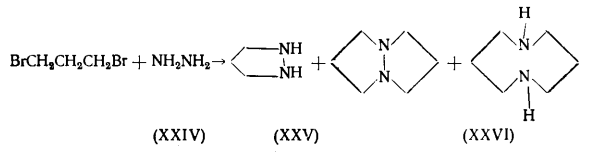


An interesting reaction was observed in the catalytic reduction of methyl 3-methoxycarbonylpyrazoline-4-acetate (XVII) where the diamine formed in the hydrogenation reaction is cyclised into a dilactam (XVIII):[73]

(XVII) (XVIII)

Unexpected results were obtained on heating 3-mercapto-4,5,6-triphenylpyridazine (XIX) with Raney nickel, when 2,3,4-triphenylpyrrole (XX) was isolated as the desulphurised product[74] and in the reduction of 5-chloro-3,4-diazaphenothiazine (XXI) in the presence of the same catalyst where the elimination of sulphur and the halogen was accompanied by the dissociation of the N–N bond, the elimination of ammonia, and the closure of the pyrroline ring with formation of compound (XXII):[75]

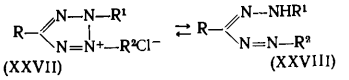
(XIX) (XX) (XXI) (XXII)



The cleavage of the N–N bond in 1-(2′-diethylaminoethyl)-2-phenylisopropylhydrazine (XXIII) on refluxing with hydrochloric acid without the addition of reducing agents was described by Elslager et al.[76]:

$$PhCH_2CH(Me)\underset{(XXIII)}{NHNH(CH_2)_2NEt_2} \longrightarrow$$
$$\rightarrow PhCH_2CH(Me)NH_2 + H_2N(CH_2)_2NEt_2 .$$

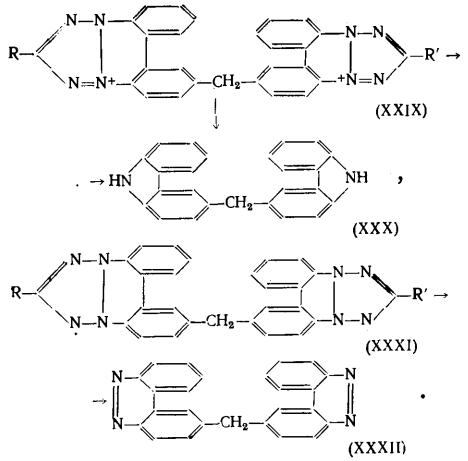
Probably a molecule of the initial compound (XXIII) behaves in this case as a reducing species; this mechanism is supported by the detection of phenylacetone in the reaction products.



A mechanism involving a diarylnitrenium ion has been proposed for the cleavage of tetra-arylhydrazines under the influence of acids to diarylamines and a stable radical-cation[77] and the homolytic cleavage of N–N bonds in tetra-arylhydrazines has been discussed in two reports[79,80]. The oxidation–reduction reaction involving the initial compound evidently takes place when hydrazine interacts with 1,3-dibromopropane, which results in the formation,

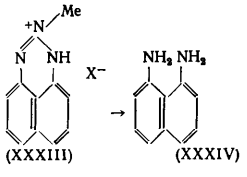
together with pyrazolidine (XXIV) and a bicyclic hydrazine (XXV), also of bistrimethylenedi-imine (XXVI):[81]

(XXIV) (XXV) (XXVI)



The reduction of quaternary tetrazolium salts (XXVII) with dissociation of the N–N bond and the formation of the formazan (XXVIII) takes place under the influence of bacteria, yeasts, germinating seeds[82], and also on treatment with ammonium sulphide[83] or on a cation-exchange resin treated with sodium dithionite[84]:

(XXVII) (XXVIII)



In the oxidation of formazan, quaternary tetrazolium salts are readily reformed[83]. The ease of the interconversion by a similar mechanism of substituted triazolium salts and 2-phenylamino-1-phenylazonaphthalenes made it possible to employ compounds of this kind as oxidation–reduction indicators of cobalt ions[85].

The conversion of quaternary bis-(2,3-*o*-diphenylenetetrazolium) salts (XXIX) into the corresponding carbazole (XXX) under the influence of zinc dust has been described; in the presence of sodium dithionite or hydrazine in an alkaline medium, free N-radicals (XXXI) are formed and reduced by nickel to phenazone (XXXII):[86]

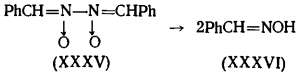
(XXIX) (XXX) (XXXI) (XXXII)

The tendency of quaternary tetrazinium salts to undergo hydrogenolysis at N–N bonds has served as a basis for the preparation of 1,8-diaminonaphthalene (XXXIV) from 2-methyl-1*H*-naphtho[1,8-*de*]triazinium halides (XXXIII):[87]

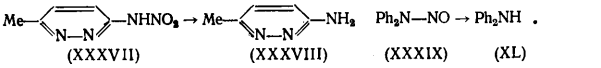
(XXXIII) (XXXIV)

The reduction of azides to the corresponding amines with cleavage of N–N bonds by both chemical and catalytic methods has been used to synthesise aminosugars[88–91] and aminosteroids[92]; methyl *p*-azidosulphonylcarbanilate is reduced by zinc in acetic acid to the corresponding sulphonamide[93].

When aryl azides are treated with hydrogen bromide, the N–N bonds are cleaved with simultaneous ring bromination; the following mechanism has been proposed to account for this process[94]:



The reductive elimination of nitrogen with dissociation of the N–N bond in acid azides under the influence of isopropyl alcohol in the presence of the diethyl peroxydicarbonate has been regarded by Horner et al. as a radical reaction proceeding via the formation of radicals, and isopropyl alcohol followed by their interaction with azides via the following mechanism[95]:

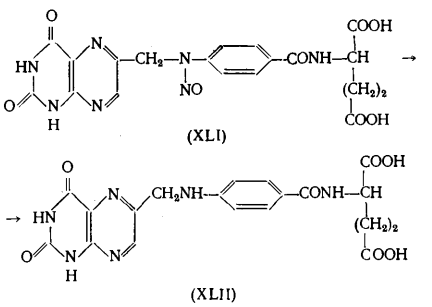


The reduction of acid azides by tributyltin hydride in the presence of azobisisobutyronitrile probably also proceeds via a radical mechanism[96].

There is an interesting case of the dissociation of the N–N bond in the reduction of benzaldehyde azine *NN'*-dioxide (XXXV) by ammonium sulphide in alcohol which gives a 78% yield of benzaldehyde oxime (XXXVI):[97]

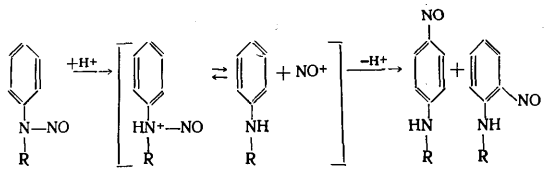
(XXXV) (XXXVI)

Reductive cleavage of the N–N bond is also known for *N*-nitro- and *N*-nitroso-compounds: 6-methyl-3-nitraminopyridazine (XXXVII) is reduced in the presence of palladium to 3-amino-6-methylpyridazine (XXXVIII)[98] and *N*-nitrosodiphenylamine (XXXIX) is reduced by lithium aluminium hydride to diphenylamine (XL):[99,100]



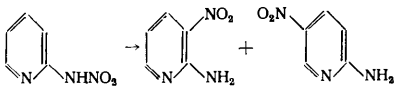
(XXXVII) (XXXVIII) (XXXIX) (XL)

III. ACID CLEAVAGE OF *N*-NITROSO- AND *N*-NITRO-DERIVATIVES

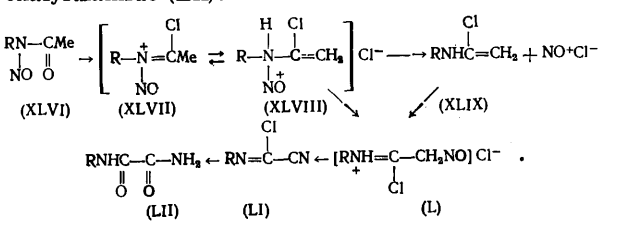


Together with the reductive cleavage of N–N bonds in *N*-nitro- and *N*-nitroso-compounds, the cleavage of compounds of this type by inorganic and organic acids, frequently in the presence of additives binding the nitro-groups and also binding or oxidising the nitroso-groups, has been described[101–105].

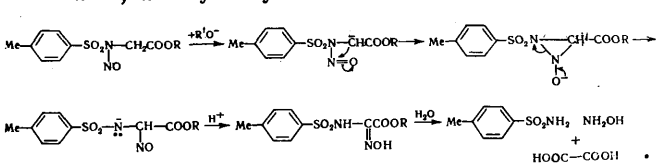
As an example, one may quote the denitrosation of *N*-[4-{[(2,4-dihydroxy-6-pteridyl)methyl]-*N*-nitrosoamino}benzoyl]glutamic acid (XLI) by hydrochloric acid in the presence of phenol in the course of the synthesis of the desaminohydroxy-analogue of folic acid (XLII)[105] and the cleavage of the N–N bond in *N*-nitro-compounds by hydrofluoric acid in the presence of anisole[106] or sulphuric acid with acetanilide[107]:



(XLI) (XLII)

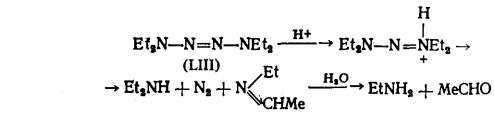


In certain cases the dissociation of the N–N bonds is accompanied by nitration or nitrosation of the denitrosated (or denitrated) compound itself and not of specially added substances with enhanced nucleophilic properties such as phenol, anisole, etc. Such rearrangements have been observed for the first time by Fischer and Hepp in the conversion of *N*-alkyl(aryl)-*N*-nitrosoanilines into the corresponding *p*-nitroso-derivatives [108]. Subsequently it was established that the nitroso-group can migrate not only to the *para*- but also to the *ortho*-position; it has been suggested that such rearrangement has a cationotropic mechanism [109–111]:

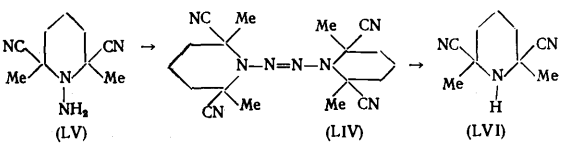


The isomerisation of 2-nitroaminopyridine (XLIII) into 2-amino-3-nitropyridine (XLIV) and 2-amino-5-nitropyridine (XLV): [112]

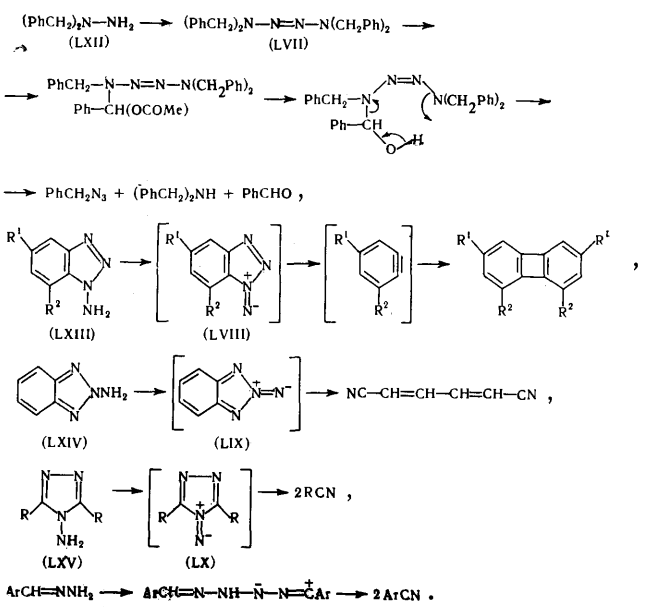
as well as rearrangements of the Fischer–Hepp type in many other aromatic nitramines [113–117] probably take place similarly. A different type of cleavage of the N–N bond was observed in the rearrangement of *N*-alkyl-*N*-nitrosamides (XLVI) to substituted oxalyldiamides under the influence of phosphorus pentachloride [118]. The mechanism of the rearrangement was associated with the formation of an intermediate iminochloride (XLVII) which isomerises to α-chlorovinylamine (XLVIII) with subsequent migration of the *N*-nitroso-group to the β-carbon atom of the vinyl residue either as a result of the elimination of nitrosyl chloride and its electrophilic addition to the double bond in compound (XLIX) or via an intramolecular shift with subsequent dehydration of compound (L) to the nitrile (LI). The final stage is the hydrolysis of (LI) to the *N*-substituted oxalyldiamide (LII):



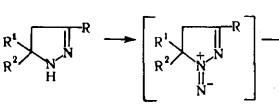
Under the influence of bases, the esters of *N*-nitroso-*N*-tosylglycine are cleaved into toluene-*p*-sulphonamide, oxalic acid, and hydroxylamine [119,120]:



IV. THE CLEAVAGE OF AZINES

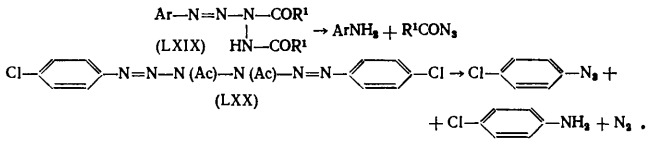


A common reaction involving the dissociation of N–N bonds is the cleavage of azines. For example, in acid tetraethyltetrazine (LIII) is converted into ethyl- and diethyl-amines, nitrogen, and acetaldehyde, the formation of which can be represented as follows [121]:



A similar acid cleavage of azines can be used in the synthesis of many carbohydrates [122] and some phenhomazine derivatives [103]. The oxidative deamination of *N*-aminopiperidine (LV) by potassium permanganate with subsequent treatment by hydrobromic acid probably also proceeds via the tetrazine (LIV); the final product of this reaction is 2,6-dicyano-2,6-dimethylpiperidine (LVI): [123]

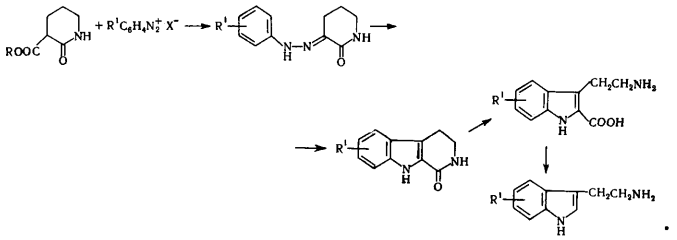
Another reagent frequently used to deaminate heterocyclic *N*-amino-compounds is nitrous acid [123,124]. The oxidation of 1,1-disubstituted hydrazines of type (LVII), [125,126] 1-aminobenzotriazole (LXIII) and 2-aminobenzotriazole (LXIV), [127] 1-amino-1,3,4-triazoles (LXV), [128] and also arylhydrazones (LXVI) [129] by lead tetra-acetate proceeds via the corresponding tetrazines (LVII)–LXI):



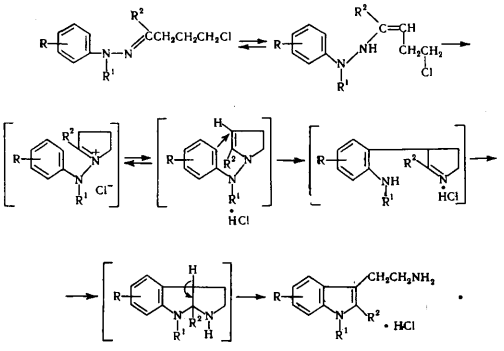
The triazine (LXVII) has been postulated as an intermediate in the nitrile cleavage of pyrazolines (LXVIII) under the influence of difluoroamine [130]:

Azines can be decomposed not only in acid [121–124] but also in alkaline media, as can be observed in the formation of acyl azides and aromatic amines [131] from the products of the reaction of 1,2-diacylhydrazines and arenediazonium

salts (LXIX) or in the alkaline cleavage of the hexaazadiene (LXX):[132]



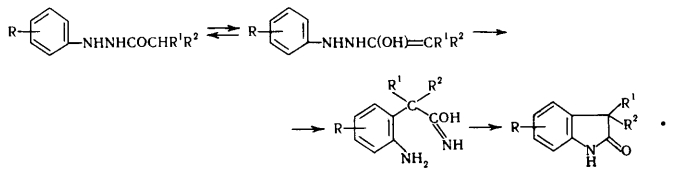
The thermal decomposition of azines with dissociation of N–N bonds has also been described[133–135].



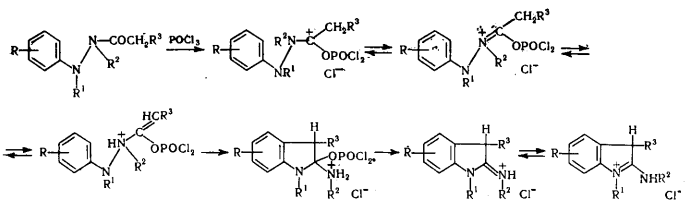
V. REACTIONS OF ARYLHYDRAZONES ANALOGOUS TO THE FISCHER REACTION

The very familiar Fischer reaction involving the synthesis of indole derivatives with dissociation of N–N bonds has been discussed in fine detail in many recent reviews[136–139], which obviates the necessity to analyse in the present report the extensive literature on this question. At the same time, one should mention that the great interest in the Fischer reaction and the detailed study of this method in various systems have led to the development of many other reactions analogous to the Fischer cyclisation and also involving the dissociation of N–N bonds.

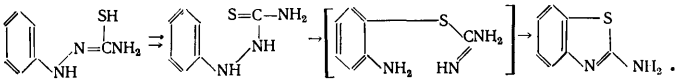
Here mention must be made in the first place of the reaction of Abramovitch and Shapiro which has found extensive application in the synthesis of tryptamines and which consists in the interaction of diazonium salts and 3-alkoxycarbonylpiperidine-2-ones with subsequent cyclisation, opening of the piperidinone ring, and decarboxylation[140]:



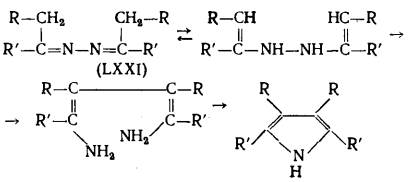
A novel method of synthesising tryptamines and homotryptamines in one step from arylhydrazones of γ- and δ-halogenocarbonyl compounds has been described by Grandberg and coworkers[141–145]:



Cyclic enamines have been introduced into the reaction with hydrazines instead of halogenocarbonyl compounds[146]; the use of α-substituted γ-halogenoketones leads to eseroline derivatives[147,148].

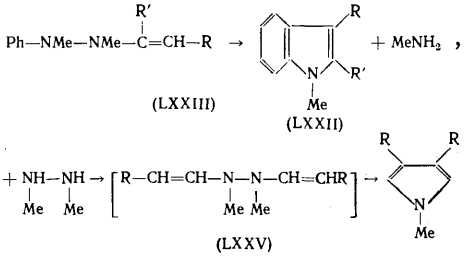


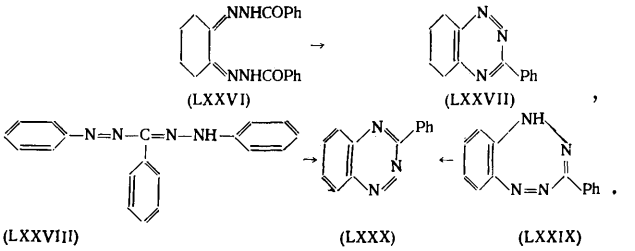
The synthesis of oxindoles from carboxylic acid arylhydrazides has been developed by Bruner[149–153]:



Kost and coworkers suggested a method for the synthesis of 2-aminoindoles based on the interaction with phosphoryl chloride of the arylhydrazides of carboxylic acids containing a methylene group in the α-position in the acid residue[154]:

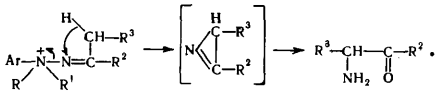
Even earlier, Fischer and Besthorn[155] and then other workers[156] showed that phenylthiosemicarbazide formed from phenylhydrazine and thiocyanate readily cyclises to 2-aminobenzothiazole when acted upon by acids:



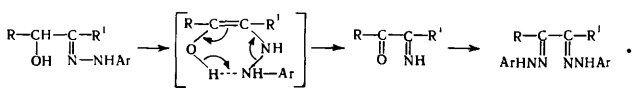


The synthesis of pyrrole derivatives by treating tetrasubstituted azines (LXXI) with acid catalysts has been developed by Piloty[157]:

A similar reaction has been used also to prepare octahydrocarbazole from cyclohexanone azine[158,159].



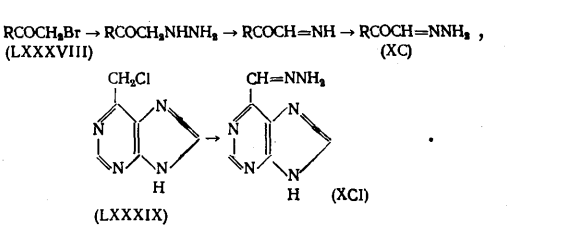
Other processes involving the dissociation of N–N bonds in *N*-substituted hydrazines, hydrazones, and their cyclic analogues are also closely related to the Fischer cyclisation: the synthesis of indoles (LXXII) from *NN'*-dimethylene-*N*-phenylhydrazines (LXXIII),[160] of symmetrical *N*-methylpyrroles (LXXIV) from 1,2-dimethylhydrazines (LXXV),[161] the rearrangement of the bisbenzoylhydrazone of cyclohexane-1,2-dione (LXXVI) to 3-phenyl-5,6-cyclohexeno-1,2,4-triazine (LXXVII),[162] and the rearrangement of 1,3,5-triphenylformazan (LXXVIII) and *C*-phenyl-*NN'*-*o*-phenyleneformazan (LXXIX) to 3-phenyl-5,6-benzo-1,2,4-triazine (LXXX):[163,164]



(LXXVI) (LXXVII) (LXXVIII) (LXXX) (LXXIX)

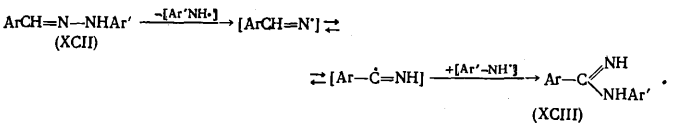
The dissociation of the N—N bond with the Neber rearrangement has been described for quaternary derivatives of arylhydrazones of ketones with an α-hydrogen atom [compounds (LXXXI)] [165-167] which, in contrast to the analogous aldehyde derivatives, are incapable of the nitrile rearrangement. It has been shown that the process is stereospecific, probably proceeds via a three-membered cyclic transition state (LXXXII), [168-170] and leads to the formation of α-aminoketones (LXXXIII):

(LXXXI) (LXXXII) (LXXXIII)



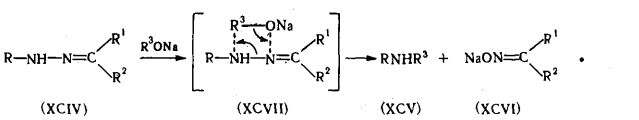
Many studies have been made on the dissociation of the N—N bond in the arylhydrazone of α-hydroxycarbonyl compounds (LXXXIV) with their conversion into osazones (LXXXV). [171-175] The mechanism of this reaction, which is important in sugar chemistry, has been investigated by Shemyakin and coworkers using labelled nitrogen [174]. It was shown that the arylamine is split off initially via a six-membered transition state, for which the authors postulate the structure (LXXXVI), and the monoimine of the α-diketone (LXXXVII) is formed and then converted into compound (LXXXV) under the influence of the arylhydrazine:

(LXXXIV) (LXXXVI) (LXXXVII) (LXXXV)



The monoimines of α-diketones (LXXXVII) can be isolated in the form of *N*-acetyl derivatives when compounds (LXXXIV) are cleaved in acetic acid; the addition of *o*-phenylenediamine leads to the formation of substituted quinoxalines [176,177].

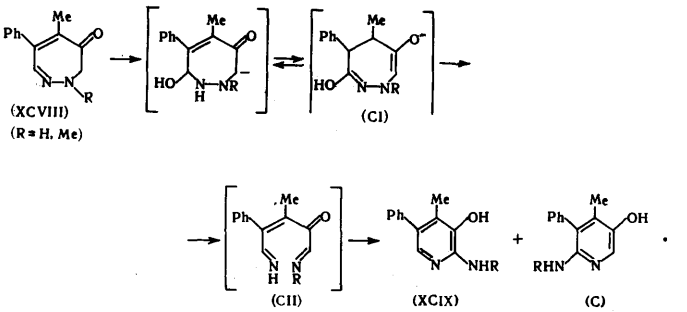
Reactions of hydrazine with phenylacyl halides (LXXXVIII) [178] and 6-chloromethylpurine (LXXXIX) [179] apparently also proceed via intermediate amino-derivatives and lead to the formation of the corresponding hydrazones (XC) and (XCI):



(LXXXVIII) (XC) (LXXXIX) (XCI)

Together with the well known benzidine rearrangement [180-186], it is appropriate to mention in this section the amidine rearrangement discovered by Robev [187-190], which is observed when the arylhydrazones of aldehydes (XCII) are heated with strong bases; it is initiated by atmospheric oxygen, probably has a radical mechanism [191,192], and leads to the formation of *N*-substituted amidines (XCIII):

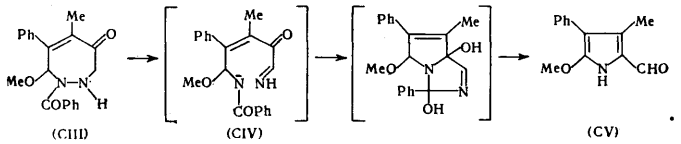
(XCII) (XCIII)



A new type of cleavage of the N—N bond in pyridyl-(aryl)hydrazones (XCIV) under the influence of alkali metal alkoxides has been described by Yakhontov and Marshalkin [193-195]. The reaction products are *N*-monoalkylpyridyl-(or aryl)amines (XCV) and the sodium derivatives of the *syn*-oximes of the carbonyl component (XCVI). The reaction takes place particularly smoothly with (4-pyridyl)- and (3-pyridyl)-hydrazones of aromatic aldehydes. Under these conditions, the corresponding pyridylhydrazines are cleaved only to the aminopyridines and *N*-alkylation products are not formed. It has been suggested that the reaction of alkoxides with compounds (XCIV) proceeds via a four-membered cyclic transition state (XCVII) with simultaneous dissociation of the N—N bond in the hydrazone and the C—O bond in the attacking alkoxide:

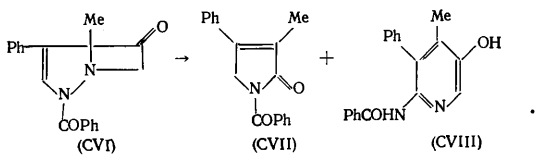
(XCIV) (XCVII) (XCV) (XCVI)

VI. REARRANGEMENT OF HETEROCYCLIC 1,2-DIAZA-SYSTEMS



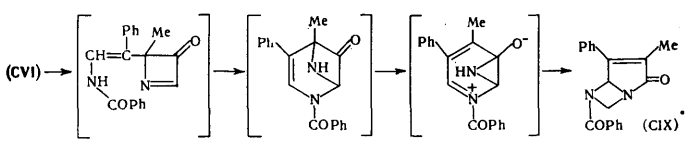
The rearrangements of heterocyclic 1,2-diaza-systems investigated in recent years are related to the methods of synthesising α-imino- and α-hydrazino-ketones described in the preceding section. An example of this type of rearrangement is the conversion of 2,3-dihydro-5-methyl-6-phenyl-1,2-diazepin-4-one (XCVIII) under the influence of alkali to substituted α-aminopyridines (XCIX) and (C), which probably takes place as a result of the nucleophilic attack on compound (XCVIII) by the hydroxide ion in the 3- and 7-positions with formation of the enolate (CI); the β-elimination processes involving the last product lead to the di-imineketone (CII), which can cyclise in two ways with conversion into the isomers (XCIX) and (C): [176,196]

(XCVIII) (R = H, Me) (CI) (CII) (XCIX) (C)



β-Elimination does not occur in the case of 1-benzoyl-7-methoxy-5-methyl-6-phenyltetrahydrodiazepin-4-one (CIII), since the anion (CIV) formed after the dissociation of the N—N bond is stabilised by the amide carbonyl and

a retro-Michael condensation takes place with formation of the pyrrole (CV):[197]

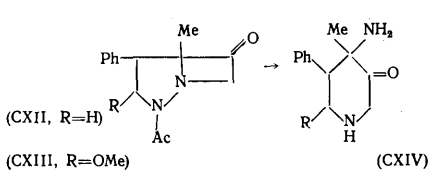


(CIII) (CIV) (CV)

It is suggested that the rearrangement of the substituted 2-benzoyl-1,2-diazabicyclo[3,2,0]hept-3-en-6-one (CVI) on refluxing in methanol to derivatives of pyrrole (CVII) and α-aminopyridine (CVIII) also proceeds via a derivative of 2,3-dihydro-1,2-diazepin-4-one[198,199]:

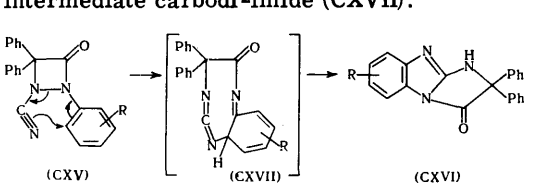
(CVI) (CVII) (CVIII)

Compound (CVI) undergoes a more complex rearrangement in boiling benzene, where 6-benzoyl-3-methyl-4-phenyl-1,6-diazabicyclo[3,2,0]hept-3-en-3-one (CIX) is formed by a mechanism analogous to the cleavage of α-hydrazinocarbonyl compounds[198]:



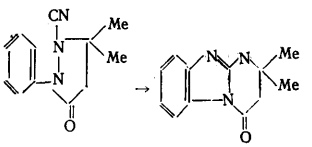
(CIX)

In an alkaline medium compound (CVI) is cleaved with formation of an acyclic enaminoketone (CX) and a saturated benzoylaminoketone (CXI):[198,199]



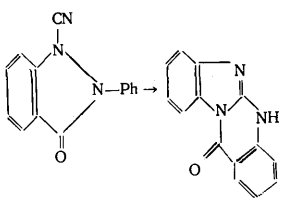
$$\text{CVI} \rightarrow \underset{\text{(CX)}}{H_2NCH{=}C(Ph)Ac} + \underset{\text{(CXI)}}{PhCONHCH_2CH(Ph)Ac}\ .$$

When bases act on 2-acetyl-5-methyl-4-phenyl-1,2-diazabicyclo[3,2,0]heptan-6-one (CXII) and its 3-methoxy-derivative (CXIII), a rearrangement takes place with dissociation of the N—N bond and the formation of substituted 4-aminopiperidin-3-ones (CXIV):[176,198]



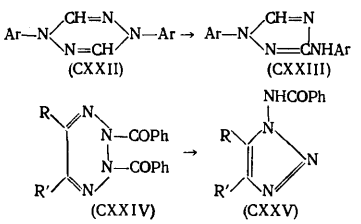
(CXII, R=H) (CXIII, R=OMe) (CXIV)

An interesting thermal rearrangement takes place in 1-aryl-2-cyano-3,3-diphenyldiazetidin-4-ones (CXV), which are converted in high yields into imidazo[1,2-*a*]-benzimidazole derivatives (CXVI), probably via the cleavage of the N—N bond and subsequent transannular cyclisation of the intermediate carbodi-imide (CXVII):[200]



(CXV) (CXVII) (CXVI)

Probably 2-cyano-3,3-dimethyl-1-phenylpyrazolidin-5-one (CXVIII) is converted via a similar mechanism into 1,2,3,4-tetrahydro-2,2-dimethyl-4-oxopyrimido[1,2-*a*]-benzimidazole (CXXI)[201] and 1-cyano-2-phenyl-3-indazolone (CXX) is likewise converted into benzimidazo-[2,1-*b*]-12-quinazolone (CXXI):[201]



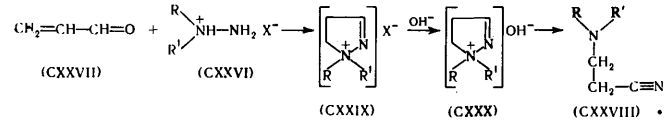
(CXVIII) (CXIX)

(CXX) (CXXI)

Tetrazine-triazole rearrangements, which also involve the dissociation of N—N bonds, constitute another type of rearrangement of heterocyclic 1,2-diaza-systems. They include the conversion of 1,4-diaryl-1,4-dihydro-1,2,4,5-tetrazines (CXXII) by sodium ethoxide into 3-arylamino-1,2,4-triazoles (CXXIII)[202] and of *C*-substituted 2,3-dibenzoyl-2,3-dihydro-1,2,3,4-tetrazines (CXXIV) in acid or neutral media into benzamido-1,2,3-triazoles (CXXV):[203-205]

(CXXII) (CXXIII) (CXXIV) (CXXV)

The conversion of 1-arylalkylindazoles on treatment with sodamide into 2-aryl-4-quinazolones discovered by Simonov et al.[206] can also be formally regarded as a rearrangement of heterocyclic 1,2-diazasystems.[206] However, this reaction has the mechanism of the nitrile rearrangement and can be more usefully considered in the next section of the review.



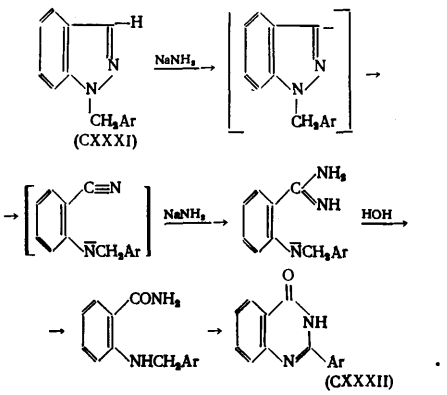
VII. THE NITRILE REARRANGEMENTS

In 1910 Arbuzov observed that, on heating with Lewis acids, the phenylhydrazones of aliphatic aldehydes undergo a rearrangement with dissociation of the N—N bond, the elimination of aniline, and the formation of a nitrile[207]:

$$R{-}CH{=}N{-}NHPh \rightarrow R{-}C{\equiv}N + PhNH_2\ .$$

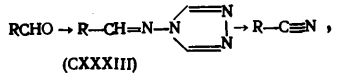
Subsequently Kost, Grandberg and coworkers showed that this reaction is common to compounds of the type $RCH{=}N{-}N(R^1)R^2$ and suggested that it proceeds via the formation of a complex of the hydrazone with the Lewis acid, a far shift of the electron pair of the N—N bond, the formation of a δ^+ charge on the neighbouring carbon atom, and subsequent deprotonation with dissociation of the N—N bond[208-211]. A similar rearrangement takes place also when the hydrochlorides of pyrazoline derivatives are heated[212,213].

Ioffe and Zelenin observed that the condensation of asymmetric dialkylhydrazines (CXXVI) with acrolein (CXXVII) involves a rearrangement with formation of β-dialkylaminopropionitriles (CXXVIII) for which it has been established that the process proceeds via the quaternary pyrazolinium derivatives (CXXIX) and (CXXX) according to the mechanism [214-216]:



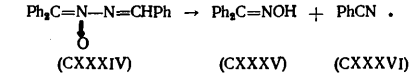
(CXXVII) (CXXVI) (CXXIX) (CXXX) (CXXVIII)

A similar nitrile cleavage of quaternary hydrazinium derivatives was observed in other instances also [217-221] and Grandberg and Naumov showed that the N–N bonds in compounds of this type are more labile than the C–N bond in quaternary ammonium bases [217].



The nitrile rearrangement of hydrazones can be achieved not only under the influence of Lewis acid but also in reactions in the presence of various nucleophilic agents (sodamide, alkalies, etc.) [208,209,222-226] and apparently proceeds via a β-elimination mechanism: the nucleophilic agent attacks the hydrogen atom at the C=N double bond and the highly polarised N–N bond in the anion formed after deprotonation is readily dissociated under the influence of heat [209].

In many reactions this process does not stop at the nitrile stage, the nitrile being converted further into an amidine and an amide capable of cyclising into 4-quinazolone derivatives, as happens in the conversion, mentioned above, of 1-arylalkylindazoles (CXXXI) in the presence of sodamide into 2-aryl-4-quinazolones (CXXXII): [206,225]

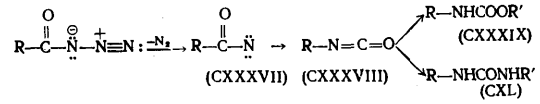


(CXXXI) (CXXXII)

The nitrile rearrangement is probably the final stage of the cleavage reactions of the azines (LXIV), (LXV), (LXVI), (LXVII), etc., described above (Section IV) and constitutes the basis of the method for the conversion of aldehydes into nitriles via 1-amino-1,2,4-triazoles derivatives (CXXXIII) proposed by Becker and Timpe [227]:

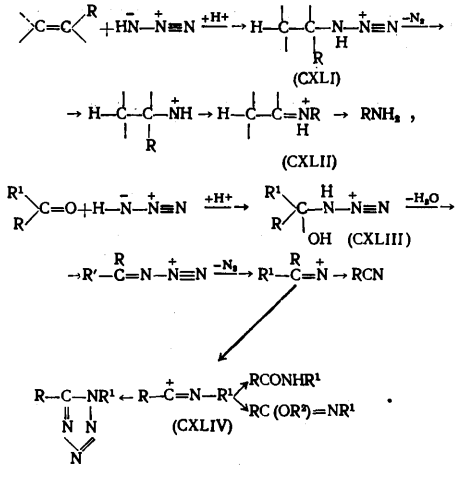
(CXXXIII)

as well as the conversion of aldehydes into nitriles via hydrazonium salts [220,228,229]. The polarisation of N–N bonds in the conversion from azines and hydrazones into their *N*-monoxides also promotes the cleavage of these compounds via a mechanism of the nitrile rearrangement type [230,231], as happens, for example, in the thermal decomposition of the azine *N*-monoxide (CXXXIV) to the corresponding oxime (CXXXV) and nitrile (CXXXVI): [230]



(CXXXIV) (CXXXV) (CXXXVI)

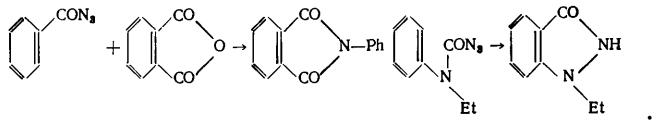
The thermal cleavage of non-oxidised azines and hydrazones, in which the polarisation of the N–N bond is less marked, proceeds with greater difficulty and the products of the nitrile rearrangement are obtained in lower yields [233-234]. It has been suggested that in such cases the reactions have a radical mechanism.



VIII. SEXTET REARRANGEMENTS OF THE TYPE OF THE CURTIUS AND SCHMIDT REACTIONS

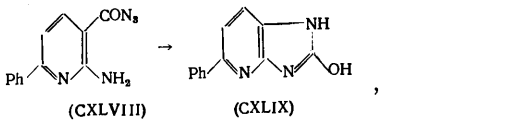
The conversion of acid azides into isocyanates with cleavage of the N–N bond and the evolution of a nitrogen molecule, called the Curtius reaction, proceeds via the intermediate formation of a product (CXXXVII) with an electron sextet, the rearrangement of which takes place owing to the tendency of nitrogen to acquire the missing electrons from the adjacent carbon atom. As a result of the migration of the alkyl or aryl residue from compound (CXXXVII), the isocyanate (CXXXVIII) is formed and can be isolated from non-polar solvents; in the presence of alcohols it is converted into carbamic acid esters (CXXXIX) and on treatment with ammonia or amines it gives rise to substituted ureas (CXL):

(CXXXVII) (CXXXVIII) (CXXXIX) (CXL)



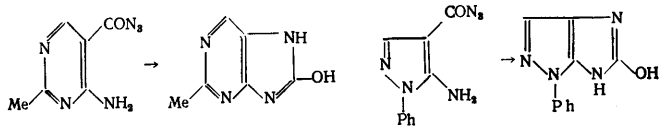
The Schmidt reaction, which consists in the interaction of equivalent amounts of hydrazoic acid and a carbonyl compound or an olefin in the presence of strong inorganic acids, has a similar mechanism. After the scission of nitrogen and the rearrangement, protonated *N*-substituted ketimines (CXLI) are formed from the adducts with olefins (CXLII) and can be readily hydrolysed to the corresponding amines. In the adducts with aldehydes (CXLIII, R′ = H), the sextet is usually stabilised via deprotonation with formation of a nitrile and the interaction of HN_3 with ketones entails a rearrangement with migration of the alkyl or aryl group, the resulting carbonium ion (CXLIV) being converted into amides on reaction with water, into iminoethers on reaction with alcohols, and into tetrazoles on reaction with an excess of HN_3:

(CXLI) (CXLII) (CXLIII) (CXLIV)



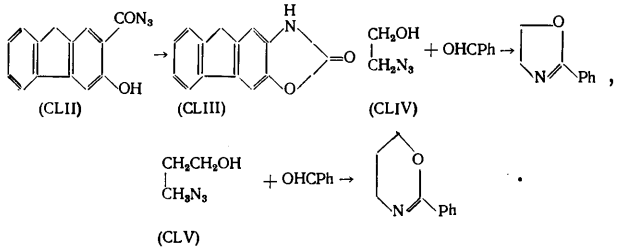
The Curtius and Schmidt reactions constitute important preparative methods for the synthesis of different classes of compounds: amines, amides, urethanes, substituted ureas, etc., which have been thoroughly investigated in a large number of instances and have been discussed in detail in many reviews [235-237]. This makes it unnecessary to consider them in detail here. Probably attention should be concentrated on sextet rearrangements of the type of the Curtius and Schmidt reactions, not included in the above reviews, which takes place with dissociation of N–N bonds and lead to the formation of more complex products.

As examples of reactions of this type, one may quote the formation of *N*-phenylphthalimide (CXLV) on heating benzoyl azide with phthalic anhydride [238] or the rearrangement of *N*-ethyl-*N*-phenylcarbamoyl azide (CXLVI) in boiling xylene to 1-ethyl-3-indazolone (CXLVII): [239]



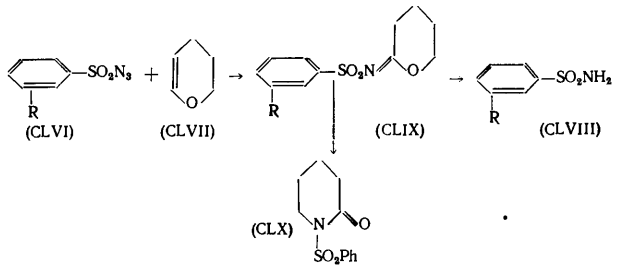
(CXLV) (CXLVI) (CXLVII)

When 2-amino-6-phenylnicotinoyl azide (CXLVIII) is heated in xylene, a quantitative yield of 2-hydroxy-6-phenylimidazo[4,5-*b*]pyridine (CXLIX) is obtained [240]. The thermal cleavage of the azides of 4-amino-2-methylpyrimidine-5-carboxylic (CL) and 5-amino-1-phenylpyrazole-4-carboxylic (CLI) acids takes place similarly [241]:



(CXLVIII) (CXLIX)

(CL) (CLI)



The rearrangement of the azides of 3-hydroxyfluorene-2-carboxylic acid (CLII) also leads to the closure of a new ring: the formation of 5*H*-fluoreno[2,3-*d*]oxazolidin-2-one (CLIII). [242] The closure of the oxazolidine or dihydrooxazine ring takes place also on heating of β- and γ-hydroxyalkyl azides, (CLIV) and (CLV), with benzaldehyde in the presence of sulphuric acid [243]. Probably this process proceeds via the mechanism of the Schmidt reaction with dehydration at the imino-derivative stage. Aliphatic and alicyclic carbonyl compounds do not enter into this reaction, in contrast to aromatic aldehydes:

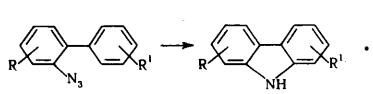
(CLII) (CLIII) (CLIV)

(CLV)

Sulphonylazides usually do not undergo the Curtius rearrangement. However, high yield of *m*-nitrobenzenesulphonamide (CLVIII, R = NO_2) was obtained on heating in alcohol *m*-nitrobenzenesulphonylazide (CLVI, R = NO_2) and dihydropyran (CLVII). [244] Evidently the sextet formed after the dissociation of the N–N bond and evolution of nitrogen is in this case stabilised by the addition of a molecule of (CLVII) and the formation of 2-(*m*-nitrobenzenesulphonylimino)tetrahydropyran (CLIX, R = NO_2), which is cleaved in alcohol to compound (CLVIII, R = NO_2). [245] Similar reactions with dissociation of the N–N bond have been observed also for unsubstituted benzenesulphonyl azide (CLVI, R = H), where the hydrolysis of compound (CLIX, R = H) results in the formation of benzenesulphonamide (CLVIII, R = H) and the thermal rearrangement of (CLIX, R = H) yields *N*-phenylsulphonylpiperidin-2-one (CLX): [245]

(CLVI) (CLVII) (CLIX) (CLVIII)

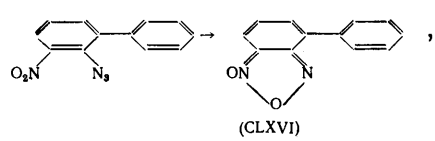
(CLX)



One should probably also include among sextet rearrangements the conversion of hydrazones into amides under the influence of sodium nitrite and concentrated sulphuric acid [246,247]:

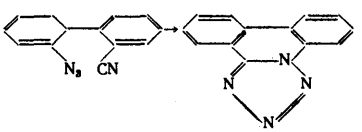
$$R_2C{=}NNH_2 \rightarrow RCONHR + N_2 ,$$

and also the rearrangement of 1-acetylimino-1-methyl-2-phenylpyrrolidine (CLXI), discovered by Wawzonek, which results in the formation of methyl isocyanate (CLXII) and 1-methyl-2-phenylpyrrolidine (CLXIII). [248]



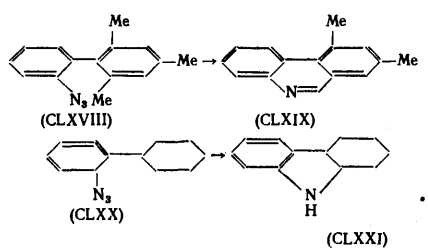
IX. THERMAL CYCLISATION OF AZIDES

The thermal cyclisation of azides discovered by Smith and Brown, which takes place with dissociation of the N–N bond [249], constitutes an important method for the synthesis of heterocyclic systems and merits special discussion. Initially this reaction was developed for the synthesis of carbazoles (CLXIV) from 2-azidobiphenyls (CLXV) and it was found that with 5-nitro- or 4′-5-dinitro-derivatives (CLXV) the yields of the tricyclic derivatives were appreciably higher than in the cyclisation of the 5-bromo- and 3,5-dibromo-derivatives or the unsubstituted compound (CLXV): [249]



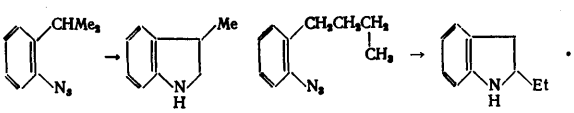
(CLXV) (CLXIV)

The 3-nitro-derivative of compound (CLXV) is converted into 4-phenylbenzofuroxan (CLXVI), i.e. the cyclisation involves the nitro-group, while with 2-azido-2′-cyanobiphenyl the process takes place without the evolution of nitrogen with formation of tetrazolophenanthridine (CLXVII): [250]



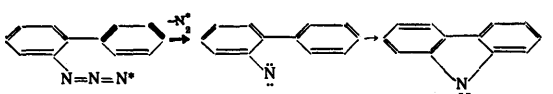
(CLXVI)

(CLXVII)



Subsequently the thermal cyclisation of azides were extended to aza- and thia-analogues of compound (CLXV) [251] and it was also shown that an analogous reaction with dissociation of the N–N bond can occur with participation of aliphatic residues. Thus the cyclisation of 2-azido-2′,4′,6′-trimethylbiphenyl (CLXVIII) yielded phenanthridine (CLXIX) [252] and hexahydrocarbazole (CLXXI) was obtained from *o*-azidophenylcyclohexane (CLXX): [252]

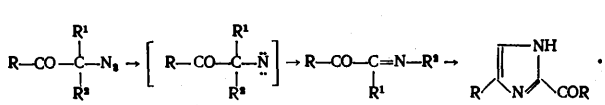
(CLXVIII) (CLXIX)



(CLXX) (CLXXI)

The application of the same reaction to *o*-azidoisopropylbenzene (CLXXII) and *o*-azidobutylbenzene (CLXXIII) permitted a new synthesis of indolines (CLXXIV) and (CLXXV), [252,253] in which tetrahydroquinolines and products of the reductive cleavage of the N–N bonds in the azides (CLXXII) and (CLXXIII) (*o*-alkylanilines) were obtained as side products:

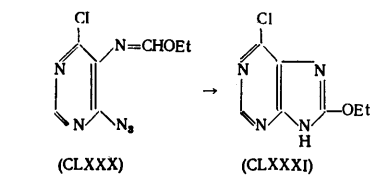
(CLXXII) (CLXXIV) (CLXXIII) (CLXXV)



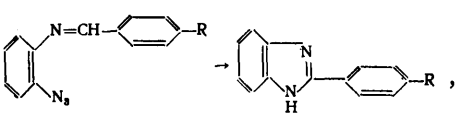
It was established with the aid of labelled nitrogen that the cyclisation of azides proceeds via a nitrene (CLXXVI) stage [250,254] with evolution of molecular nitrogen containing the label:

(CLXXVI)

This mechanism is supported also by the formation of phenyl isocyanate on thermal decomposition of phenyl azide in carbon monoxide and of carbazole and 2-biphenylyl isocyanate from 2-azidobiphenyl [255]. A similar mechanism for the decomposition of azides was proposed for the process catalysed by iridium salts [258].

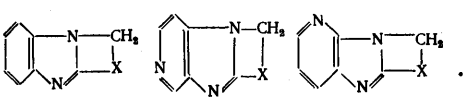


A radical process with formation of intermediate nitrenes has also been postulated for the thermal cleavage of α-azidocarbonyl compounds (CLXXVII), where the substituent R^2 was found to migrate after the elimination of the nitrogen molecule (the ease of migration increases in the sequence $CH_3 < C_6H_5 < H$) and a monoimino-derivative (CLXXVIII) of the α-dicarbonyl compound was formed:



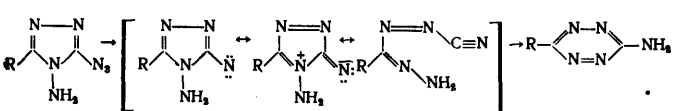
CLXXVII) (CLXXVIII) (CLXXIX)

This reaction has been used for the synthesis of substituted imidazoles (CLXXIX) from α-azidocarbonyl compounds (CLXXVII, $R^1 = R^2 = H$) via (CLXXVIII, $R^1 = R^2 = H$) by dimerisation of the latter with elimination of water [257].



Another method for the synthesis of the imidazole ring via the thermal cyclisation of azides has been described in connection with a new synthesis of purines, whereby 6-chloro-8-ethoxypurine (CLXXXI) was obtained on heating 4-azido-6-chloro-5-ethoxymethyleneiminopyrimidine (CLXXX). [258] 2-Arylbenzimidazoles (CLXXXIII) were obtained similarly in almost quantitative yields from 2-azidobenzylideneanilines (CLXXXII) [259] and tricyclic derivatives of benzimidazole (CLXXXIV) and pyridoimidazole, (CLXXXV) and (CLXXXVI), were obtained from *N*-(*o*-azidophenyl)- or *N*-(3-azido-4-pyridyl)-derivatives of pyrrolidines, piperidines, and morpholines [260]:

(CLXXX) (CLXXXI)



(CLXXXII) (CLXXXIII)

(CLXXXIV) (CLXXXV) (CLXXXVI)

(X=(CH$_2$)$_2$; (CH$_2$)$_3$; —CH$_2$OCH$_2$—)

On heating with chlorobenzene, the corresponding 4-amino-3-azido-s-triazoles (CLXXXVII) are converted in almost quantitative yields into 3-amino-1,2,4,5-tetrazines (CLXXXVIII), [261] which constituted a convenient method for the synthesis of symmetrical tetrazines. The process probably proceeds via a stage in which a nitrene is formed and exists in one of the canonical forms—the acylic nitrile (CLXXXIX) – which cyclises to (CLXXXVIII):

(CLXXXVII) (CLXXXIX) (CLXXXVIII)

Various reactions of nitrenes are considered in greater detail in special reviews [254,262–265].

X. PHOTOCHEMICAL DISSOCIATION OF N–N BONDS

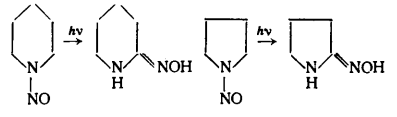
In the last decade publications on the photochemical dissociation of N–N bonds in organic compounds have appeared with increasing frequency. One of the first reports in this field concerned the photochemical cleavage of acetaldehyde azine and benzaldehyde azine to the corresponding nitriles [266,267]. The photolysis was achieved in the presence of benzophenone and proceeded via the mechanism

$$Ph_2C{=}O \xrightarrow{h\nu} Ph_2\dot{C}{-}O^{\bullet},$$

$$Ph_2\dot{C}{-}O^{\bullet} + PhCH{=}N \cdot N{=}CHPh \rightleftarrows Ph\dot{C}{=}N \cdot N{=}CHPh + Ph_2\dot{C}{-}OH,$$

$$Ph\dot{C}{=}N \cdot N{=}CHPh + Ph_2C{=}O \rightarrow 2PhCN + Ph_2\dot{C}{-}OH.$$

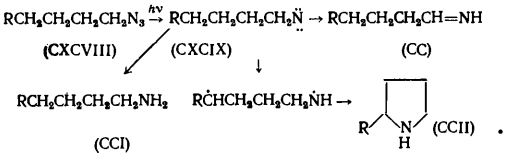
The photochemical decomposition of aliphatic and aromatic *N*-nitrosoamines (CXC) leads to the corresponding amines (CXCI) and amidoximes (CXCII):[268]



$$\underset{\text{(CXC)}}{PhCH_2N(NO)CH_2Ph} \xrightarrow[-NO^{\cdot}]{h\nu} \underset{\text{(CXCIII)}}{PhCH_2\dot{N}CH_2Ph},$$

$$\text{(CXCIII)} + \text{(CXC)} \rightarrow PhCH_2NHCH_2Ph + \underset{\text{(CXCI)}}{PhCH_2N(NO)\dot{C}HPh},$$

$$PhCH_2N(NO)\dot{C}HPh \rightarrow PhCH_2N{=}CHPh + NO^{\cdot},$$

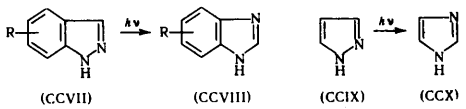


$$\text{(CXCIII)} \xrightarrow{+\dot{N}OH} PhCH_2NH{-}CH(\overset{+}{N}OH)Ph \xrightarrow{-H^+} \underset{\text{(CXCII)}}{PhCH_2NHC(=NOH)Ph}.$$

When *N*-nitrosopiperidine (CXCIV) or *N*-nitrosopyrrolidine (CXCV) is irradiated with ultraviolet light in aqueous methanol containing hydrochloric acid, the amidoximes (CXCVI) and (CXCVII) are formed in high yields[269]:

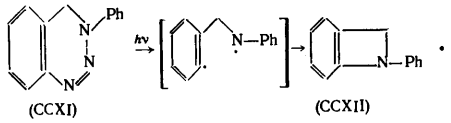
(CXCIV) (CXCVI) (CXCV) (CXCVII)

The photolysis of the non-aromatic azides (CXCVIII) results in the formation of the nitrenes (CXCIX) which can then react in three different ways: (a) they can isomerise to the imines (CC); (b) they can split off hydrogen from solvent molecules and be converted into amines (CCI); (c) they can undergo 1,5-deprotonation with cyclisation to pyrrolidines (CCII):[264,270]



On direct irradiation in isopropyl alcohol, particularly in the presence of added benzophenone, sulphonyl azides (CCIII) are converted via a radical chain mechanism into the sulphonamides (CCIV). The process is catalysed by iron(III) chloride and is accelerated by heat[271].

On irradiation in cyclohexane, the azides of aliphatic carboxylic acids (CCV) are converted into the amides (CCVI). The reaction is sensitised by acetophenone[272]:



$$\underset{\text{(CCV)}}{C_nH_{2n+1}CON_3} \xrightarrow{h\nu} \underset{\text{(CCVI)}}{C_nH_{2n+1}CONH_2}.$$

Unexpected reactions are observed when certain heterocyclic 1,2-diaza-compounds are irradiated with ultraviolet light. For example, unsubstituted and monosubstituted indazoles (CCVII) undergo photoisomerisation under these conditions into the corresponding benzimidazoles (CCVIII).[273] The introduction of 3-phenyl-, 5-methoxy-, and 5- or 6-chloro-substituents into compounds (CCVII) inhibits the process, while an increase of temperature favours the rearrangement. A similar photoisomerisation has been observed with the unsubstituted pyrazole (CCIX), which is converted into imidazole (CCX) in 12% yield on irradiation with ultraviolet light[273]:

(CCVII) (CCVIII) (CCIX) (CCX)

The irradiation of 3-phenyl-1,2,3-benzotriazine (CCXI) sensitises the radical process, which is accompanied by the dissociation of the N–N bond and evolution of molecular hydrogen, resulting in the formation of *N*-phenylbenzazetine (CCXII):[274]

(CCXI) (CCXII)

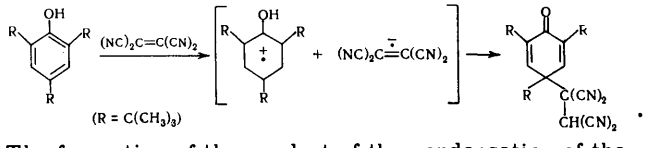
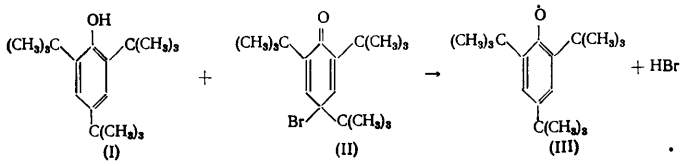
organic reactions and of the search for ways of synthesising compounds which have not as yet been described. In connection with the high specificity of the behaviour of these compounds in reactions with one-electron transfer, it is most convenient to examine separately the properties of phenols (phenoxides), phenoxy-radicals, and cyclohexadienones in these processes.



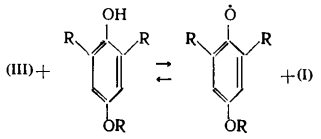
2. STERICALLY HINDERED PHENOLS (PHENOXIDES)

The hypothesis of the decisive role of the stability of the phenolic O—H bonds in reactions of sterically hindered phenols is nowadays generally accepted. It is assumed that, depending on the nature of the other reactant, the bond can be broken either homolytically[3-5] (for example in inhibited oxidation processes) or heterolytically, as in the interaction of sterically hindered phenols with electrophilic agents[6-8] (bromination, nitration and other reactions):



However, despite the important role of the O—H bond energy in the treatment of the mechanism of reactions of sterically hindered phenols, its value has been determined only for certain of the simplest alkylphenols[9,10].

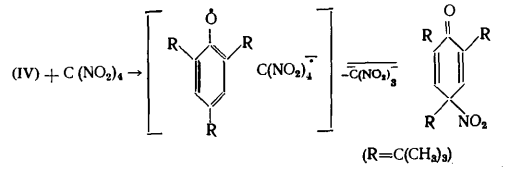
The involvement of the hydrogen atom of the phenolic hydroxyl in the initial step in chemical reactions of sterically hindered phenols was unquestioned until recently, although there existed an alternative mechanism of this process, namely one involving reactions with transfer of one-electron. The formation of a complex, within which there is a formal possibility of the transfer of one electron has been begun to be postulated recently even for classical radical reactions such as the interaction of peroxy-radicals with sterically hindered phenols[11]. The transfer of one electron as one of the elementary steps of the chemical interaction can be postulated for reactions of sterically hindered phenols with reactants exhibiting a high electron affinity. Thus, when alkylphenols react with quinones[12] and quinolide compounds[13-15], phenoxy-radicals are formed. An analytical method for the determination of phenols is based on the reaction of sterically hindered phenols with tetracyanoethylene[16]:



The formation of the product of the condensation of the phenol with tetracyanoethylene agrees fairly well with the possibility of the transfer of one electron in the first reaction stage. It has been shown for the reaction of 2,4,6-tri-t-butylphenol (I) with 4-bromo-2,4,6-tri-t-butylcyclohexa-2,5-dienone (II), which leads to only one product—the stable phenoxy-radical (III), that its rate is independent of the nature of the solvent and that there is no isotope effect when compound (II) is allowed to react with the phenol(I) deuterated in the phenolic hydroxyl[13]:

It follows from the kinetic data obtained for the interaction of 2,4,6-tri-t-butyl-4-nitrocyclohexa-2,5-dienone with various phenols that its activation energy depends significantly on the nature of the *para*-substituent in the phenol molecule and that it increases as the electron-accepting properties of the *para*-substituent are enhanced[15].

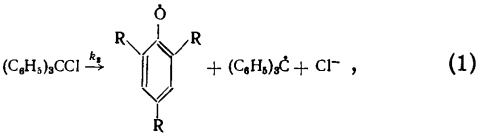
A typical homolytic reaction of sterically hindered phenols with phenoxy-radicals may be treated formally as a reaction in which there is an electron transfer from the phenol to the radical. If two stable radicals with approximately identical oxidation-reduction potentials are involved in this reaction, the latter is reversible[17]:



(R = C(CH$_3$)$_3$)

Studies on the transfer of a hydrogen atom between a phenol molecule and the corresponding phenoxy-radical by ^{1}H NMR have shown the possibility of the existence of an intermediate complex[18,19]. According to the views of Müller et al., this complex is an ion pair (see Section III) in which there is a transfer of one electron[20].

In contrast to sterically hindered phenols, their phenoxides have more marked electron-donating properties. For example, while the half-wave potential for the anodic oxidation of compound (I) is 1.0 V, the half-wave potential for the anodic oxidation of 2,4,6-tri-t-butylphenoxide (IV) is already in the region of zero potential[21-23]. The salts of sterically hindered phenols have been frequently used as nucleophilic components in order to confirm the hypothesis of the possibility of one-electron transfer in the interaction of two non-radical species[24-27]. Moreover, in the light of the mechanism involving one-electron transfer, the results of reactions investigated earlier, such as the oxidation of sterically hindered phenols by molecular oxygen in an alkaline medium[28-30] and the interaction of phenoxides with various reactants involving the formation of compounds characteristic of radical reactions[31,32] (the dimerisation and disproportionation products from phenoxy-radicals) become understandable.



The one-electron transfer stage in the reaction between the anion and a neutral molecule has been demonstrated by the formation of a radical and the corresponding radical-anion. In the reactions of (IV) with tetracyanoethylene[33], chloranil[33], and difluorodinitromethane[24], radicals were detected by ESR:

The nitration of (IV) by tetranitromethane probably proceeds by a similar mechanism[26]:

(R=C(CH$_3$)$_3$)

The study of the kinetics of the reaction of potassium 2,4,6-tri-t-butylphenoxide with chlorotriphenylmethane (trityl chloride) showed[25] that the formation of compound (III) in this case is possible via electron transfer from the phenoxide ion both to trityl chloride [reaction (1)] and to the trityl cation [reaction (2)]:

(1)

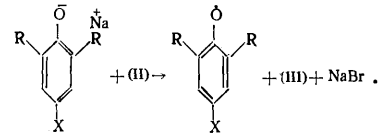
(2)

(R=C(CH$_3$)$_3$).

According to this mechanism the initial rate of accumulation of the phenoxy-radical (III) is described by the equation‡

$$W_0 = k_1'(\mathrm{TCl}) + k_2(\mathrm{TCl}) \cdot (\mathrm{ArOK})^2 .$$

The relative contribution of a particular mechanism depends significantly on the nature of the solvent. For example, an increase of the solvating capacity of the solvent leads to an increase of the contribution of reaction (2), while the reaction between the phenoxide (IV) and trityl chloride in heptane proceeds only as a trimolecular process [reaction (1)].[34] On passing from trityl chloride to trityl bromide, the rate of reaction with the phenoxide (IV) increases appreciably both via the monomolecular [reaction (2)] and the ter-molecular [reaction (1)] mechanisms. In the trityl chloride–phenoxide (IV) system, the transfer of one electron is much slower than in the reaction of trityl bromide with the phenoxide (IV), reaction (1) involving trityl bromide being 100 times faster and reaction (2) 50 times faster than the reaction of the radical (IV) with trityl chloride[35]. Tri-(*p*-nitrophenyl)methyl bromide reacts almost instantaneously with salts of sterically hindered phenols[35].



The reaction of salts of sterically hindered phenols with quinolide compounds may be regarded as a model of substitution reactions of the S_N2 type proceeding via a one-electron transfer stage[36], the activation energy of which increases in the sequence Br < Cl < NO_2 as a function of the geminal substituent in the quinolide compound. The rate of reaction depends significantly on the solvent owing to the different degrees of solvation of the metal cation by solvent molecules[36]:

$$(\mathrm{IV}) + (\mathrm{II}) \rightarrow 2(\mathrm{III}) + \mathrm{EX}$$
$$(\mathrm{X}=\mathrm{Br}, \mathrm{Cl}, \mathrm{NO_2})$$

Studies of the kinetics of the reactions of cyclohexadienone (II) (X = Br) with the sodium salts of 2,6-di-t-butylphenols containing various substituents in the *para*-position showed that, as the electron-accepting properties of the substituent become more marked, the activation energy increases and the reaction rate constant falls. This behaviour is probably related to the decrease of the effective negative charge on the oxygen atom in the phenoxide ion. The reaction does not occur with sodium 2,6-di-t-butyl-4-nitrophenoxide. The activation energy for this reaction is satisfactorily correlated with the σ_p constants of the substituents (r = 0.983; ρ = 10.2). On the other hand, this type of relation holds much less satisfactorily for the reaction rate constants[37]. The absence of a dependence of the reaction rate constants on the substituent constants may be a consequence of a compensation effect, since the pre-exponential factor for this reaction increases with activation energy (Table 1).

Table 1. Kinetic parameters of the reaction of (II) with substituted sodium 2,6-di-t-butylphenoxide in THF.

X	k (30°), litre mole^{-1} s^{-1}	k_0, litre mole^{-1} s^{-1}	E_{act} ± 0.5, kcal mole^{-1}	X	k (30°), litre mole^{-1} s^{-1}	k_0, litre mole^{-1} s^{-1}	E_{act} ± 0.5, kcal mole^{-1}

(R=C(CH$_3$)$_3$)

Comparative data for the kinetics of the reaction of (II) with 2,6-di-t-butyl-4(*p*-X-phenyl)phenols and their sodium salts have shown that the rate constants for reactions of phenols with (II) are smaller by 3–4 powers of ten than the rate constants for the analogous reactions of the corresponding phenoxide ions and the activation energies for the reactions with the phenols are almost twice as great as the energies for the reactions with their phenoxides[38] (Table 2).

Table 2. Kinetic parameters of the reaction of (II) with 2,6-di-t-butyl-4-(*p*-X-phenyl)phenols and their sodium salts in THF.

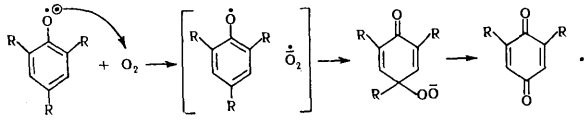
(R=C(CH$_3$)$_3$)

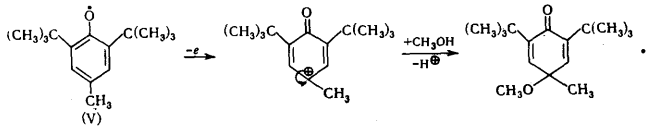


The pre-exponential factor for the reaction of (II) with sodium 2,6-di-t-butyl-4-(*p*-X-phenyl)phenoxides varies

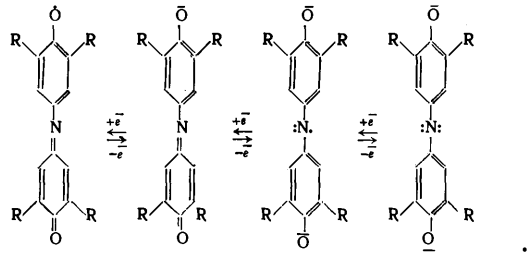
‡ It is assumed in this equation that $k_1 > k_1'$, where k_1' is the monomolecular dissociation constant of trityl chloride.

insignificantly and for this reaction series there is satisfactory correlation between the rate constants and the σ_p constants of the substituents in the phenyl group (r = 0.994; ρ = 1.45).

Data for the reaction of sterically hindered phenols with molecular oxygen in an alkaline medium are interesting from the standpoint of one-electron transfer. The extensive factual experimental data on this question have been reviewed[39], but the mechanism of this reaction has not been discussed in detail. That it is of a radical type appears evident. During the reaction, semiquinone radicals are detected and various quinolide compounds, hydroperoxides, quinones, hydroxyquinones, and products of their further reactions are formed[39-41]. It has also been suggested[42] that the first stage in the interaction of oxygen with phenols in an alkaline medium is the formation of the phenoxy-radical.



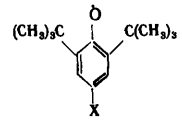
Analysis of the experimental data for the interaction of sterically hindered phenols with oxygen in an alkaline medium suggests that it does not involve a neutral molecule but the corresponding phenoxide and proceeds via a one-electron transfer mechanism. Since the phenoxy-radical and the oxygen radical-anion are formed in the "cage", the probability of their recombination increases greatly. Therefore, in the oxidation of sterically hindered phenols by atmospheric oxygen in an alkaline medium, the corresponding hydroperoxides and their decomposition products (quinones) are obtained preferentially[43,44]:

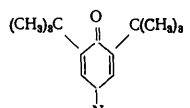


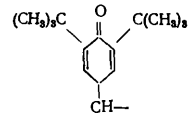
The formation of phenoxy-radicals or typical reactions products from phenoxy-radicals during the interaction of the lithium salt of 2,4,6-tri-t-butylphenol with benzenesulphenyl chloride[31] and in the interaction of potassium 2,6-di-t-butyl-4-nitrophenoxide with toluenesulphonyl chloride or chloroformate esters[32] can probably also be accounted for by one-electron transfers. It has been suggested in the literature that the reaction of salts of sterically hindered phenols with benzenediazonium chloride proceeds via a one-electron transfer stage[45].

3. STERICALLY HINDERED PHENOXY-RADICALS

In contrast to phenols, which are as a rule incapable of accepting electrons the corresponding phenoxy-radicals have distinct electron-accepting properties. Extremely unstable cations, which react in the carbonium form with the solvent, are formed as intermediates only in the anodic oxidation of certain phenoxy-radicals[21-23]. For example, the anodic oxidation of the 2,6-di-t-butyl-4-methylphenoxy-radical (V) in methanol results in the formation of 2,6-di-t-butyl-4-methoxy-4-methylcyclohexa-2,5-dienone:





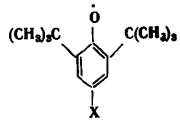


Studies on the polarographic reduction of many stable phenoxy-radicals have shown that the half-wave potentials $E'_{1/2}$ for the reduction of these radicals to the corresponding phenoxides depends on their structure and on the nature of the substituents in the phenoxy-radical (Table 3). Thus Coppinger's radical and the 2,2',6,6'-tetra-t-butylindophenoxy-radical (VI) are reduced at potentials close to zero, probably owing to the more extensive conjugation system in these radicals[46]. As a result of its structural features, the electrochemical reduction of radical (VI) entails the initial formation of a phenoxide, which is capable of accepting a further two electrons with formation of a radical-dianion and a trianion:

(VI) (R=C(CH$_3$)$_3$)

Table 3. Half-wave potentials in the polarographic reduction of the stable phenoxy-radicals[47].

X	$E'_{1/2}$, V	X	$E'_{1/2}$, V
	0.07	p-CH$_3$COC$_6$H$_4$	−0.29
		p-CH$_3$OCOC$_6$H$_4$	−0.31
		p-ClC$_6$H$_4$	−0.36
		C$_6$H$_5$	−0.37
		(CH$_3$)$_3$C	−0.38
	0.09	p-CH$_3$C$_6$H$_4$	−0.41
		p-C$_2$H$_5$C$_6$H$_4$	−0.41
p-OHCC$_6$H$_4$	−0.23	p-CH$_3$OC$_6$H$_4$	−0.45
(C$_6$H$_5$)$_3$CH	−0.28	p-(CH$_3$)$_2$NC$_6$H$_4$	−0.57



A two-electron wave ($E''_{1/2}$ = −1.4 V), which corresponds to the formation of a trianion, has been detected in the polarogram of radical (VI) in addition to the one-electron reduction wave. A similar wave has been observed in the polarographic reduction of the corresponding phenoxide. The existence of the trianion and its reversible conversion into the phenoxide ion have been demonstrated by ultraviolet spectroscopy and the intermediate formation of the radical dianion has been demonstrated by ESR.[46]

The values of $E'_{1/2}$ for 2,6-di-t-butyl-4-(p-X-phenyl)-phenoxy-radicals (Table 3) shift towards more negative potentials as the electron-donating properties of the substituent X become more pronounced and are satisfactorily correlated with the electrophilic constants σ^+ (r = 0.983). Thus, polarographic analysis shows that phenoxy-radicals are active electron acceptors and in reactions with nucleophilic agents are converted into phenoxides by

accepting one electron in a vacant orbital. Such reactions include primarily the thoroughly investigated reactions of stable phenoxy-radicals with alkali metals[48,49], phosphites[50,51], amines[2,52,53], organometallic compounds[54-57], and certain iodides[58-61]. A series of studies involving kinetic methods for the investigation of reactions of phenoxy-radicals have been made by Pokhodenko[2,49-51]. For example, he showed that the rate of reaction of triethylamine with phenoxy-radicals depends on the electron-accepting properties of the latter and that the reaction of the same phenoxy-radicals (III) with triethyl phosphite as a nucleophilic agent is much slower than that with triethylamine[50].

Comparison of the kinetic parameters for the reaction of triethylamine or diethylamine with a number of 2,6-di-t-butyl-4-(*p*-X-phenyl)phenoxy-radicals with the polarographic reduction potentials have shown that the reaction of phenoxy-radicals with tertiary amines proceeds only via the one-electron transfer mechanism (correlation of the reduction potentials of the radicals with kinetic parameters; Table 4), while in the reaction of phenoxy-radicals with secondary amines the transfer of one electron and the elimination of a hydrogen atom play a significant role simultaneously[62].

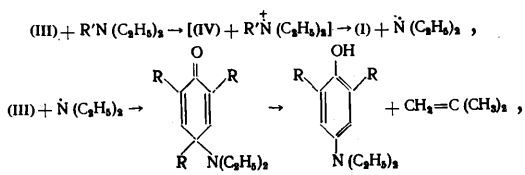


Table 4. Kinetic parameters of the re. on of the phenoxy-radicals

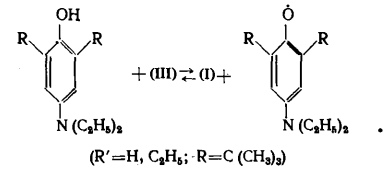

with amines.

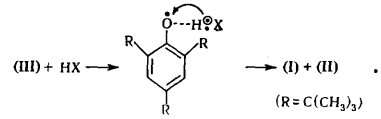
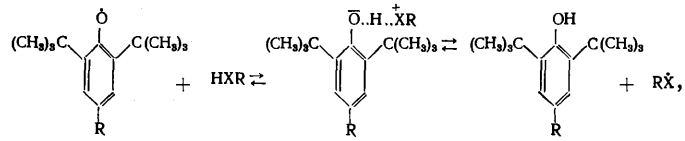
The main product of the reaction of phenoxy-radicals with amines is the corresponding phenol[62-64]. The formation of insignificant amounts of 4-*NN*-dialkylamino-2,6-di-t-butylphenoxy-radicals, detected by ESR, in the reaction of (III) with amines, shows that the interaction of the phenoxy-radical with the radical obtained from the amine takes place in the main reaction and that according to these data the overall reaction mechanism can be represented as follows:



The reaction of phenoxy-radicals with organomagnesium compounds takes place almost instantaneously even at −70°C. The reaction with alkylmagnesium halides yields, apart from magnesium phenoxide, *gem*-dialkylcyclohexadienones (VII) and (VIII) owing to the interaction of the phenoxy-radicals present in excess with the alkyl radicals[57].



The formation of biphenyl was observed in a study of the reaction of (III) with phenyl-lithium[54] and phenylmagnesium bromide[56].

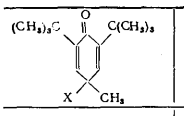
In recent years, reports have appeared in the literature in which dehydrogenation by phenoxy-radicals is regarded as involving the transfer of one electron in a complex[65-67]. This mechanism explains satisfactorily the dehydrogenation of inorganic acids by stable phenoxy-radicals[65,66,68,69], since the energy of the HX bonds in inorganic acids is as a rule higher than 100 kcal mole^{-1} [70] and therefore it is difficult to postulate the possibility of a direct elimination of a hydrogen atom from such a substrate by a phenoxy-radical:

Müller et al., who investigated a large number of reactions involving dehydrogenation by phenoxy-radicals, postulate the formation in the first stage of an ion pair complex in which one-electron transfer can take place[20]:

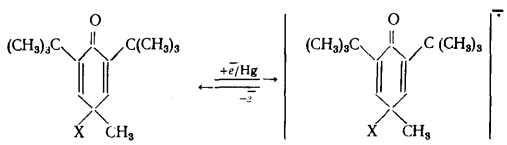
where X = heteroatom.

Among reactions of a similar type, the dehydrogenation of various phenolic compounds and amines by phenoxy-radicals has been most completely studied[71-76]. Although the investigators of these reactions in most cases supported the mechanism where atomic hydrogen is eliminated in the elementary step, nonetheless their experimental data fits satisfactorily the hypothesis of the one-electron transfer mechanism for the process.

4. STERICALLY HINDERED CYCLOHEXADIENONES



The factor which determines the reactivity of various cyclohexadienones (quinolide compounds) is the nature of the geminal substituents, which in many ways determines



the specificity of the chemical behaviour of the molecule and in the first place its tendency to undergo reactions with a one-electron transfer (reactions with nucleophilic agents and metals and electrochemical reduction). The effect of the nature of the geminal substituents on similar process has been shown most distinctly in the polarographic reduction of quinolide compounds[77].

Electron affinity (the energy of the lowest vacant molecular orbital[78]) is usually satisfactorily correlated with the half-wave potential for the polarographic reduction of the quinolide compound in aprotic media. Therefore polarographic reduction data for quinolide compounds can be used as indices of the reactivity of these compounds in their interaction with the electron, which is the simplest nucleophilic agent.

The polarographic reduction of 4-alkyl-2,6-di-t-butyl-4-methyl-cyclohexa-2,5-dienones (VIII) and (IX) at a dropping mercury electrode in dimethylformamide solution (DMF) gives rise to a one-electron wave, the analysis of which indicates the reversibility of the process occurring in the reduction of compounds (VIII) and (IX) (Table 5).[77]

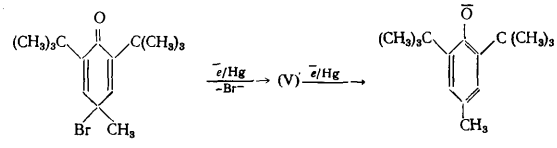


Table 5. Polarographic characteristics of quinolide compounds.

	$E'_{1/2}$, V	i_d, μA	α	$E''_{1/2}$, V	i_d, μA	α

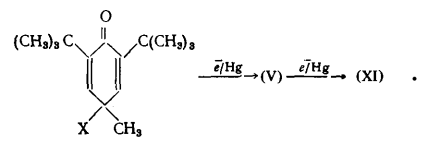
X=C(CH₃)₃ (VIII) X=C(CH₃)₃ (VIIIa)
X=CH₃ (IX) X=CH₃ (IXa)

The formation of the radical-anions (VIIIa) and (IXa) has been confirmed by ESR (the spectrum of the radical-anion consists of a 1:2:1 triplet, $a_{H(meta)}$ = 6.6 G).[79] The polarographic reduction of the quinobromide (X) gives rise to two polarographic waves:

(X) (XI)

At the first half-wave potential ($E'_{\frac{1}{2}}$ = −0.31 V), the phenoxy-radical is formed instead of the corresponding radical-anion which indicates the dissociation of the C—Br bond in the electrochemical reduction process with formation of the phenoxy-radical and a bromide ion[77,79]. The second one-electron wave is due to the reduction of (V) and is irreversible. The limiting current of the second half-wave for the polarographic reduction of the quinobromide (X) was found to be lower than would be expected for a one-electron process and is probably related to the simultaneous disproportionation of the phenoxy-radical via the mechanism[80]:

(XII)

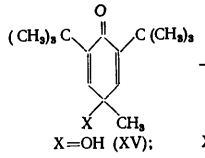


It is noteworthy that quinobromides react slowly with neutral mercury[48], forming phenoxy-radicals and this is why the limiting current for the polarographic reduction of the quinobromide (X) seems to be low, (i_d = 1 μA instead of i_d = 1.5 ± 0.2 μA for the one-electron process):

These two simultaneous processes involve the same mechanism but proceed at different rates. The initial stage is electron transfer in both cases.

The polarographic reduction of quinobromides, where the bromine atom is linked to a tertiary carbon atom, constitutes a specific example of the polarographic reduction of alkyl halides. Usually the electrochemical reduction of tertiary alkyl halides has a low transfer coefficient, since the reduction of these compounds has a S_N1-like mechanism[81]. In the polarographic reduction of compound (X), the transfer coefficient α = 1, which may indicate electron transfer from the cathode directly to the vacant orbital of the bromine atom in the molecule of (X).

The quinochloride (XIII) and the 4-nitrocyclohexadienone (XIV) interact with an electron at more negative potentials than (X) and (V). In these cases, one two-electron wave due to the stage-by-stage one-electron reduction is observed in the polarographic reduction process[77]:



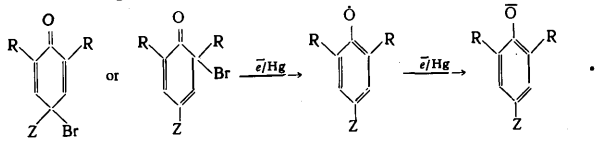
X=Cl (XIII); X=NO₂ (XIV)

The intermediate formation of a phenoxy-radical in a similar electrochemical reaction has been confirmed by ESR.[82]

Analysis of the results of the polarographic reduction of hydroquinone (XV) and its methyl ether (XVI) showed that the mechanism of their reduction differs from that described above. The difference consists primarily in the fact that the main (first) polarographic wave corresponds to a one-electron process. This rules out the intermediate formation of a phenoxy-radical as the main reaction product, since the reduction potentials of (XV) and (XVI) are more negative than the reduction potentials of (V) and other phenoxy-radicals[46]. In addition, the transfer coefficient in the polarographic reduction of (XV) and (XVI) differs markedly from the transfer coefficient for the first polarographic wave of (X), probably because of the decrease of the transfer of a fractional electronic charge in the transition state in the reduction of (XV) and (XVI). It is most likely that electron capture by hydroquinone (XV) or its ether (XVI) leads to the formation of

the corresponding phenoxide (with simultaneous elimination of the radicals $\dot{O}H$ or $\dot{O}CH_3$) and not of a phenoxy-radical and an anion:

$\xrightarrow{\bar{e}/Hg}$ (XI) + $\dot{X}$.



X=OH (XV); X=OCH_3 (XVI)

According to this mechanism of the polarographic reduction of (XV) and (XVI), the formation of a second wave ($E''_{1/2} \simeq -2.19$ V), the limiting current of which is smaller almost by a factor of three than that of the first wave, may be attributed to the reduction of substances produced from the solvent when it interacts with the radicals $\dot{O}H$ and $\dot{O}CH_3$ (Table 5).

Table 6. Polarographic characteristics of quinobromides.

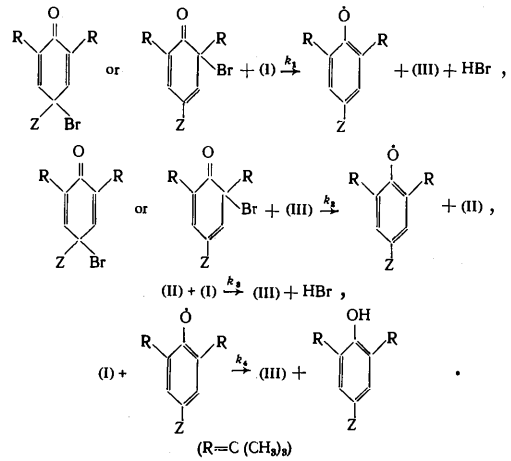
Position of bromine atom	Z	$E'_{1/2}$, V	i_d, μA	α	$E''_{1/2}$, V	i_d, μA	α
4	CH_2Br	—0.24	1.0	1.0	—0.39	1.0	0.9
2	CHO	—0.13	1.7	0.4	—0.42	1.4	0.4
2	$COCH_3$	—0.11	1.4	0.7	—0.47	1.5	0.4
2	CN	—0.01	1.0	0.6	—0.[illegible]	1.1	0.4
2	Br	0.05	0.9	0.8	—0.[illegible]	1.5	0.8
2	NO_2	0.13	1.0	0.3	—0.29	1.0	0.7

The introduction of a second functional group into quinolide compounds has a significant influence on the results of their polarographic reduction. Interesting data were obtained in the reduction of quinobromides with various substituents in the 4-position[77] (Table 6). In such cases, two one-electron waves are produced, corresponding to the individual stages of the reduction process occurring at different potentials. The first stage proceeds with transfer of one electron from the cathode to the quinobromide molecule, the reaction being accompanied by the formation of a phenoxy-radical and a bromide ion. The second stage is the reduction of the phenoxy-radical:

(Z=CH_3, CH_2Br; Br; CHO; $COCH_3$; CN; NO_2 R=C $(CH_3)_3$)

The electron affinity (the first half-wave potential) of substituted quinobromide compounds increases with increase of the negative inductive effect of the substituent.

The limiting current depends significantly on the nature of the substituent in the quinobromides and on the properties of the intermediate phenoxy-radicals. The dependence of the transfer coefficient on the solvent for quinobromide compounds indicate a significant contribution of the electronic effects of these substituents to the transition state. However, despite the fact that in the polarographic reduction of many quinobromides compounds the transfer coefficient changes and in addition the electrochemical reaction is accompanied by a chemical reaction, the calculated first half-wave potential for the polarographic reduction of quinobromides compounds are satisfactorily correlated with Taft's σ constants ($r = 0.952$). The presence of such correlation may serve as confirmation of the generality of the mechanism of the electrochemical reduction of quinobromide compounds. Probably the electron cloud of the bromine atom shifts under the influence of electronegative substituents, the atom requiring as a result a positive charge. In the electrochemical reduction, an electron is transferred to a vacant bromine orbital and more readily the higher the partial positive charge on the bromine atom. The elimination of a bromide ion with a formal homolytic dissociation of the C—Br bond in the quinolide compound molecule is a consequence of the electron transfer. The mechanism proposed for the interaction of quinolide compounds with an electron is satisfactorily consistent with experimental polarographic data and is fully consistent with the reactions of the various quinolide compounds involving one-electron transfer.



It has been found from kinetic data[83] for the reaction of (III) with hydrogen halides and the phenolic OH and halogen bond energies that $E_{C-Br} = 16.6 \pm 3$ kcal mole^{-1} and $E_{C-Cl} = 32.9 \pm 3$ kcal mole^{-1} for quinohalides:

2(III) + HX $\rightleftarrows$ (I) + (II) .

The unusually low bond energies between the halogen atom and a carbon atom of the six-membered ring of cyclohexadienones make quinobromides and quinochlorides compounds (as well as 4-nitrocyclohexadienones) thermally unstable, the compounds decomposing even at temperatures below 100°C with formation of phenoxy-radicals[58,84,85]. For this reason, certain quinobromides rearrange spontaneously on standing at room temperature to 3,5-di-alkyl-4-hydroxybenzyl bromides[85,86]. The reaction involves the intermediate formation of a phenoxy-radical.

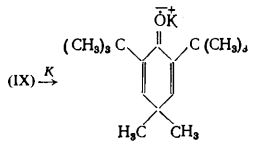
A kinetic study of the interaction of various quinobromides with (III) has shown that the activation energy increases with the electronegativity of the substituent in the quinobromide[87]. This relation indicates an increase of the resistance of the C—Br bond to homolytic dissociation in the series of bromocyclohexadienones with increase of the electronegativity of the substituent (Table 7).

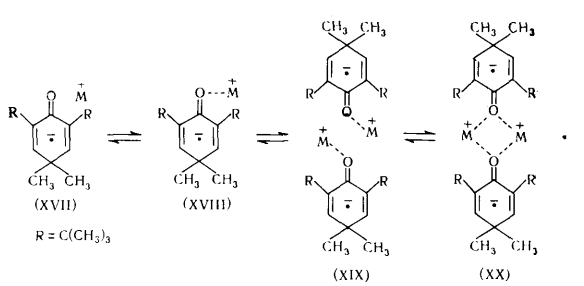
An analogous relation has been obtained in a kinetic study of the reaction of the same quinobromides with (I),[14] although the reaction does not stop in the first stage. In the presence of an excess of the quinobromide, the four reactions represented in the scheme below can occur:

(R=C $(CH_3)_3$)

In the reaction with a quinobromide containing the nitro-group (Z = NO_2), $k_1 = 7 \times 10^{-6}$, $k_2 = 8 \times 10^{-2}$, $k_3 = 5 \times 10^{-7}$, $k_4 = 10^3$ litre mole^{-1} s^{-1}.

gem-Dialkylcyclohexadienones, hydroquinones, and their ethers are as a rule more thermostable and therefore the bond energy between the geminal substituent and a carbon atom in the six-membered ring presumably differs little from the C—C or COR bond energy in the usual organic compounds. Consequently the properties of quinolide compounds change sharply on passing from quinobromide, quinochloride, and 4-nitrocyclohexadienones to other cyclohexadienones. Their behaviour in reactions with one-electron transfer is determined by the lower electron affinity of the geminal substituent and the higher stability of the bond linking it. Thus the reaction of *gem*-dialkylcyclohexadienones with metallic potassium in tetrahydrofuran yields a stable radical-anion[79]:





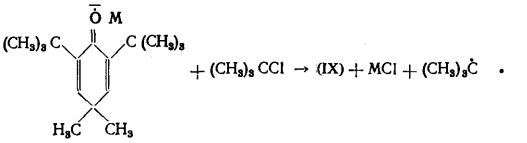


Table 7. Activation energies for the reaction of (III) with bromocyclohexadienones.

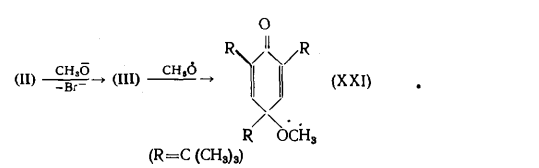
Z	Position of bromine atom	$E_{act} \pm 1$, kcal mole^{-1}	Z	Position of bromine atom	$E_{act} \pm 1$, kcal mole^{-1}
CH_3	4	4.2	CHO	2	13.1
CH_2Br	4	7.0	Br	2	13.7
CN	2	12.4	NO_2	2	13.2

The structure of the paramagnetic species obtained in the interaction of *gem*-dialkylcyclohexadienones with alkali metals depends significantly on the nature of the metal, the solvent, and temperature. A detailed analysis of the ESR spectra of the radical-anions from the cyclohexadienone (VIII), obtained in different media, made it possible to deduce the chain of reactions involving these radical-anions when the solvating capacity of the solvent is reduced[88]:

The ion pair (XVII) separated by solvent molecules is converted into a contact ion pair (XVIII) which is subsequently converted into the paramagnetic dimer (XIX) separated by solvent molecules. In turn, the dimer (XIX) is converted into a contact dimer (XX). It has been shown[88-91] that the cations are desolvated in the course of these transformations. It has been established for the reaction of the above radical-anions with t-butyl chloride[92], the rate-limiting stage of which is apparently the transfer of one electron from the radical-anion to the alkyl halide, that the reactivity of the radical-anion increases with decrease of the degree of desolvation of the cation:



The activation energy for this reaction is higher in solvating media and increases in the series of cations TBA§ < Na < Li (Table 8). The formation of metal chlorides is accompanied by the disruption of the solvation shell of the cation and presumably the differences between the activation energies are related to the difference between the heats of solvation of the corresponding cations. Indeed, the difference between the activation energies in THF and in ethyl ether for the reaction of t-butyl chloride with the radical-anion of 2,6-di-t-butyl-4,4-dimethylcyclohexa-2,5-dienone, with Na^+ and Li^+ as the cations, is the same as the difference between the heats of solvation of these cations by the solvent molecules, calculated by analysing the ESR spectra of the radical-anions[88-92].

Table 8. Kinetic parameters of the reaction of t-butyl chloride with the radical anion of the metal derivative of 2,6-di-t-butyl-4,4-dimethylcyclohexa-2,5-dienone.

Cation	Solvent	$10^3 k$ (0°), litre mole^{-1} s^{-1}	$10^{-10} k_0$, kcal mole^{-1} s^{-1}	$E_{act} \pm 0.5$, kcal mole^{-1}

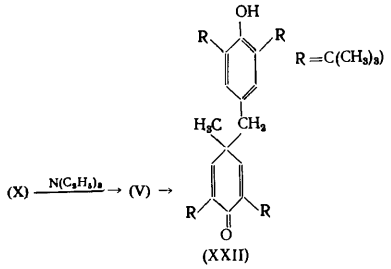
Lithium	Ethyl ether	0.40	0.04	14.7
TBA	THF	$5 \cdot 10^2$	0.1	11.3

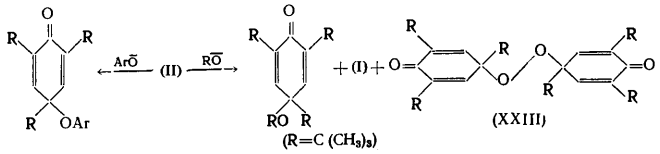
All the data quoted above show that, among quinolides of different types, the quinobromides should enter most readily into chemical reactions involving the transfer of one electron. Indeed, reactions of this type proved to be extremely characteristic of such compounds. The majority of known reactions of quinobromides, for which an ionic mechanism has been postulated earlier, probably proceed via the scheme under consideration. For example, 2,4,6-tri-t-butyl-4-methoxyhexa-2,5-dienone (XXI) was obtained in the reaction between compound (II) and alkaline solutions of methanol and the appearance of a blue colour in the course of the reaction was noted[48]. Only later was it shown that the blue colour is due to the appearance of the phenoxy-radical (III):[93]



The phenoxy-radical (X) is also formed when compound (II) interacts with amines[93-96], organomagnesium compounds[97], alkyl phosphites[50,51], triphenylphosphine[98], phenoxides[36-38,48,99], and various metals[48,49,54,58].

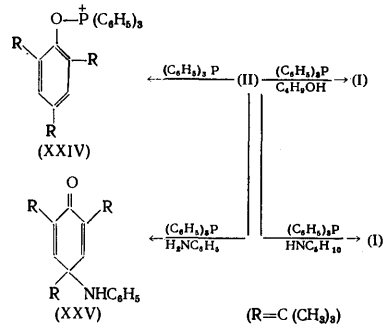
§ TBA = tetrabutylammonium.

Certain metals, such as mercury, silver, copper and zinc, are readily oxidised on reacting with quinobromides and only the phenoxy-radical is obtained from compound (II).[48] The radical (III) is also formed initially by the reaction of compound (II) with alkali metal and is capable of further reaction with these electron donors, so that the final product is the corresponding phenoxide[48,49]:



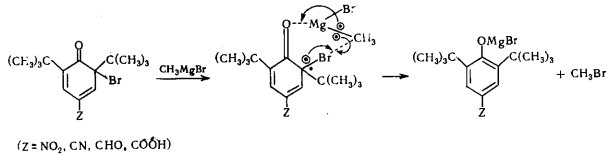
$$(III) \xleftarrow[95\%]{Ag} (II) \xrightarrow{K} (III) \xrightarrow{K} (IV).$$

The nature of the products of the reaction of quinobromides with nucleophilic agents depends significantly on the nature of the substituents in the quinobromide molecule and on the stability of the phenoxy-radicals formed. If unstable phenoxy-radicals are obtained in the reaction of quinobromides with nucleophilic agents, then a considerable amount of products of the recombination and disproportionation of the phenoxy-radicals are present in the reaction mixture[100-103]. Therefore reaction conditions have a significant influence on the results of the interaction of the same reactants. For example, at room temperature the quinobromide (X) reacts very slowly with triethylamine and therefore it has been stated[104] that it is stable in relation to triethylamine. However, at an elevated temperature the reaction of (X) with triethylamine and certain other amines is fairly vigorous and involves the formation of the quinolide compound (XXII) as the main product[95]:



(XXII)

The reaction of compound (II) with phenoxides leads to the formation of hydroquinone ethers in almost quantitative yields[105,106], but in the reaction with alkoxides (particularly at a reduced temperature) compound (I) and the quinolide peroxide (XXIII) are also formed in considerable amounts owing to the interaction of the radical (III) with oxygen[93]:



(R=C(CH3)3) (XXIII)

It is interesting that the hydroquinone ether (XVI) is also produced as a result of the interaction of the quinobromide (X) with methanol[107]. The effect of the solvent and other factors have been investigated in the reaction of compound (II) with triphenylphosphine[98]. The radical (III) is also formed initially in this reaction and then reacts further with formation of the substances indicated below:

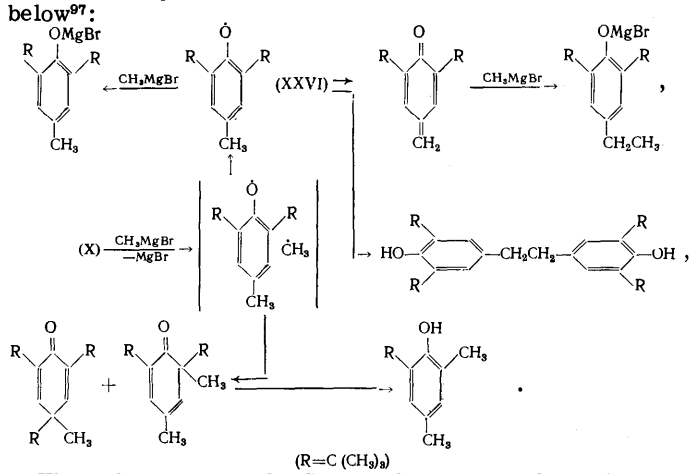
When the reaction is carried out in the absence of a solvent, the triphenylphosphine derivatives of 2,4,6-tri-t-butylphenol (XXIV) is formed, in solution in s-butyl alcohol or piperidine the product is compound (I), and in the presence of aniline the quinamine (XXV) is isolated. There is now no doubt about the radical mechanism of the reaction of quinobromides with alkyl phosphites[50,51], although initially an ionic mechanism was proposed for this reaction[108,109].

Interesting data were obtained also in a study of the reaction of quinobromides with organomagnesium compounds. Firstly, it was shown in this reaction that organomagnesium compounds can take part in reactions involving the transfer of one electron and, secondly, it was possible to elucidate the effect of the nature of the substituents in the quinobromide molecule on the properties of the bromine atom in chemical reactions involving the transfer of one electron. It was found that, depending on the nature of the substituents in the quinobromides, their reaction with a Grignard reagent results in the formation of either a magnesium halide and a phenoxy-radical or of an alkyl bromide and the corresponding phenoxide ion[110]. The second reaction pathway is possible for quinobromides containing electronegative substituents. Such quinobromides usually have an *ortho*-quinolide bond system[111]. It is noteworthy that in this case electronegative substituents enhance the electron affinity of the quinobromides to an even greater extent (see, for example, the data for their polarographic reduction in Table 6). To account for this reaction pathway, it has been suggested that the C—Br bond in quinobromides becomes more heteropolar under the influence of electronegative substituents than the corresponding bond in analogous compounds with alkyl substituents only[112]. Therefore, the transfer of one electron in the reaction of the above quinobromides with a Grignard reagent make more favourable the formation of a phenoxide ion (stabilised by internal conjugation) with the formal elimination of bromine in the form of a radical rather than the formation of a phenoxy-radical:

(Z = NO2, CN, CHO, COOH)

The same mechanism has been proposed also for the reaction of certain α-bromoketones with metal carbonyls and the formation of the bromine radical was confirmed experimentally[113]. It is interesting that an analogous reaction mechanism holds also in the interaction of organomagnesium compounds with cyclohexadienones in which one of the geminal substituents is the OH or OCH_3 group. These reactions yield only phenoxides[114]. Thus butyl methyl ether was isolated in addition to compound (XII) in the reaction of (XVI) with butylmagnesium bromide:

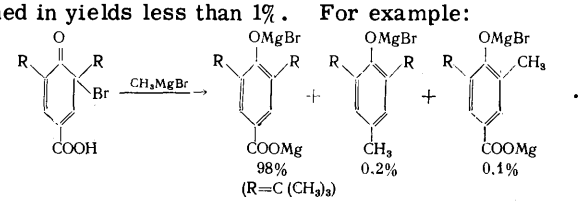
$$(XVI) + C_4H_9MgBr \rightarrow (XII) + C_4H_9OCH_3 .$$



gem-Dialkylcyclohexadienones are stable also in the presence of an excess of the Grignard reagent and form radical-anions, which are reconverted into quinolide compounds in the presence of acid.

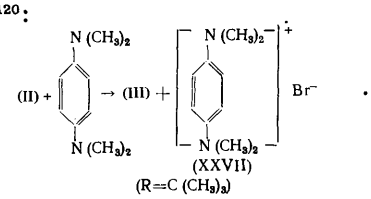
In a study of the above reactions of quinobromides with electron-donating agents accompanied by the formation of two radicals and the elimination of a bromide ion, account must undoubtedly be taken of the formation of a biradical "cage" and of the effects of its properties on the further reaction pathway. Hypotheses concerning the "cage" effect in radical reactions, in particular in reactions with one-electron transfer, are now being developed and have been generally accepted[115-117]. Depending on the properties of the "cage", determined by various factors, two processes are possible under these conditions. Firstly, radicals forming the "cage" may recombine within the "cage", yielding the expected reaction product. Secondly, on overcoming the solvation shell the radicals become kinetically independent species and as a rule give rise to a large number of side products in addition to the main reaction product. Usually these two processes are competitive. In the vast majority of cases, they take place simultaneously in reactions of quinolide compounds with one electron transfer, but their probabilities are different (depending on the nature of the nucleophilic agent, the solvent, temperature, and even the order in which the reactants are added). For example, the order of addition of the reactants in the reaction of quinobromides of types (II) or (X) with a Grignard reagent has a very significant influence on the results of the reaction.

Table 9. Rate constants for the reaction of (X) with amines at 40°C.[118]



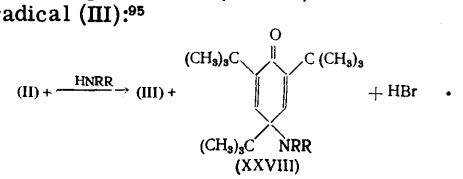
Amine	Solvent	10^3k, litre mole^{-1} min^{-1}	Amine	Solvent	10^3k, litre mole^{-1} min^{-1}
Morpholine	CCl_4	6.1	Di-isopropyl amine	Benzene	2.3
ditto	Heptane	5.5	t-butylamine	ditto	0.4
»	Benzene	6.1	Diethylamine	»	19.0
»	THF	15.0	Triethylamine	»	45.0
»	Dioxan	18.0	Piperidine	»	43.0

When an ethereal solution of (X) is added to a Grignard reagent, the phenoxy-radical (XXVI) is mainly formed and is consumed both in the disproportionation reaction and in the interaction with an excess of the organomagnesium compound. When the reactants are added in the opposite order, up to 20–30% of *ortho*- and *para-gem*-dialkylcyclohexadienones is formed in addition to compound (XXVI) and the products of its further reactions, part of the cyclohexadienones being formed as a result of the recombination of radicals within the "cage". The overall result of the secondary reactions of (X) with methylmagnesium bromide is the formation of seven different compounds via the mechanisms illustrated below[97]:



(R=C(CH$_3$)$_3$)

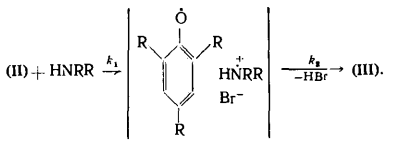
When the reaction of a Grignard reagent with a quinobromide containing electronegative substituents is carried out, the order of addition of the reactants no longer has a significant influence on the nature of the reaction products, since the transfer of one electron results in the preferential formation of the corresponding phenoxide and only a slight amount of phenoxy-radicals, which have been detected by ESR.[110] Therefore the products of the recombination of these phenoxy-radicals with alkyl radicals are formed in yields less than 1%. For example:



(R=C(CH$_3$)$_3$)

The effect of the "cage" on the nature of the products has been investigated also in the reaction of quinobromides with amines[118-120]. In a study of the reaction of (II) with tetramethyl-*p*-phenylenediamine by ESR, it was shown that the formation of (III) and the amine radical-cation (XXVII) is quantitative[120]:

(R=C(CH$_3$)$_3$)



On the other hand, in the reaction of (II) with morpholine and piperidine products of the substitution of bromine by an amine—the quinamines (XXVIII)—are formed in addition to the radical (III):[95]

It follows from the kinetic data obtained for the consumption of the initial quinobromide and the accumulation of the phenoxy-radicals that the reaction is bimolecular and is of first order with respect to the quinobromide and the amine. The rate constant for the reaction of (X) with morpholine increases only slightly with the solvating capacity of the solvent, but the rate of the reaction of the same quinobromide depends significantly on the nature of the amine (Table 9). It has been shown for the reaction of (X) with

diethylamine and its *N*-deuteriated analogue that there is no isotopic effect in this process.[118]

On the hypothesis of one-electron transfer, the mechanism of the initial reaction step can be represented as follows:

The amine radical-cation formed in this step readily split off a proton and is converted into an amine radical. The latter either recombines in the "cage" with a phenoxy-radical, which leads to the main reaction product (quinamine), or emerges from the "cage" to give other reaction products. Its liberation from the "cage" is accompanied by the accumulation of phenoxy-radicals. Bearing in mind that only phenoxy-radicals emerging from the "cage" with a probability φ are detected, according to the proposed mechanism the rate of accumulation of the amine hydrobromide and phenoxy-radicals can be formulated as follows: $d[\dot{PhO}]/dt = k_2[PhOBr]$, $d[HBr]/dt = k_1[PhOBr]$, and $k_2 = \varphi k_1$, where [PhOBr] is the concentration of the quinobromide, [PhO˙] the concentration of phenoxy-radicals, [HBr] the concentration of hydrogen bromide, and φ the fraction of radicals released from the "cage".

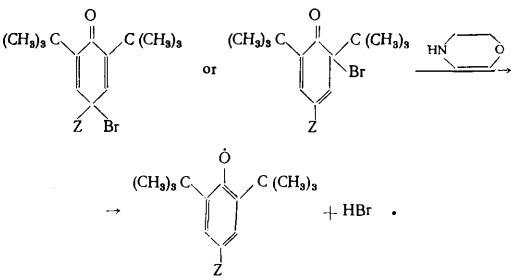


Table 10. Kinetic parameters of the reaction of (II) with amines and yields of quinamines.

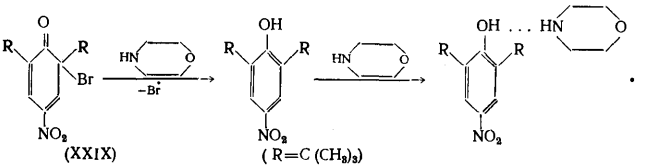
Method	Amine	k_1 (40°), litre mole^{-1} min^{-1}	$10^4 k_2$ (40°) litre mole^{-1} min^{-1}	$10^{-8}k_0$, litre mole^{-1} min^{-1}	$1-\varphi$*	Yield of quinamine, %
Accumulation of HBr	Morpholine	28	—	0.8	0.93	85
Accumulation of (III)	Morpholine	—	1.9	0.72		
Accumulation of HBr	Piperidine	18	—	7.0	0.33	12
Accumulation of (III)	Piperidine	—	12	12.0		

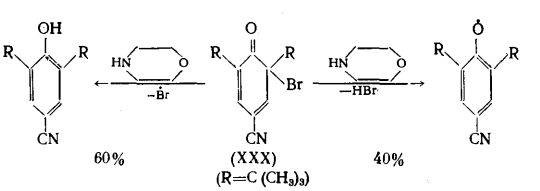
* $1 - \varphi$ is the fraction of radicals (III) recombining within the "cage".

The kinetics of the accumulation of both hydrogen bromide (amine hydrobromide) and of radicals (III) have been investigated for the reaction of compound (II) with morpholine and piperidine[118]. The fraction of radicals released from the "cage" was calculated from the constants obtained for the formation of the "cage" and the liberation of radicals from the "cage" (Table 10). The kinetic data for this reaction were found to be in good agreement with the corresponding experimental results. Thus the reaction of (II) with morpholine yields 85% of the quinamine [2,4,6-tri-t-butyl-4-(*N*-morpholinyl)hexa-2,5-dienone]. Analysis of the kinetics of this reaction showed that the yield of the quinamine is 93%. On the other hand in the reaction of (II) with piperidine, the main pathway involves the liberation of radicals from the "cage" and therefore the rate constants found by the two methods agreed to within 30%. These results may be regarded as one of the pieces of evidence in support of the proposed mechanism involving the transfer of one electron in the elementary step of the interaction between two neutral substances.



Additional data confirming the hypothesis of the one-electron stage were obtained in a study of the kinetics of the reaction of a number of quinobromides with an amine; depending on the nature of the substituents in the quinobromide molecule, the number of phenoxy-radicals liberated from the "cage" varied within wide limits[119]. Nevertheless the logarithms of the rate constants in this reaction series fit with a satisfactory correlation (r = 0.984) the relation with the first half-wave potential in the polarographic reduction of quinobromides. A similar relation, with a correlation coefficient r = 0.993 was established between the logarithms of the rate constants for the reaction of morpholine with quinobromides and Taft's constants σ for the substituents in the quinobromide molecule. It follows from these results that the effect of substituents in the reaction series investigated mainly involves an inductive mechanism:

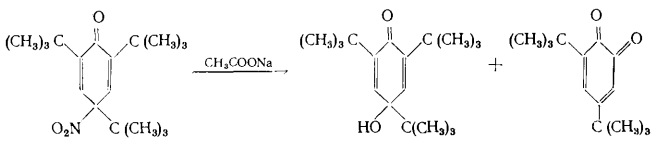
(Z=CH$_3$; C$_2$H$_5$; C(CH$_3$)$_3$; CH$_2$Br; COCH$_3$; Br)



When the reaction of morpholine with quinobromides containing functional substituents was carried out, the corresponding quinamines could not be isolated, which is evidence of the preferential liberation of radicals from the "cage" under these conditions[119]. The phenoxy-radicals formed in this instance are consumed mainly via two pathways; in the reaction with the amine with formation of the phenoxide anion and in the disproportionation reaction[100].

It is noteworthy that the reaction of morpholine with the quinobromides (XXIX) and (XXX), where the substituents are nitro- and cyano-group, takes place somewhat differently. For example, in the reaction of morpholine with (XXIX) (Z = NO$_2$), the formation of hydrogen bromide and of the phenoxy-radical is not observed and the reaction yields only 2,6-di-t-butyl-4-nitrophenol which forms a complex in the presence of an excess of the amine[119]:

(XXIX) (R=C(CH$_3$)$_3$)



About 60% of hydrogen bromide is formed in the reaction of morpholine with (XXX) (Z = CN), which is evidence of the occurrence of approximately equivalent pathways in the decomposition of the hypothetical radical-anion with formation of both the bromide ion and atomic bromine:

60% (XXX) (R=C(CH$_3$)$_3$) 40%

These results are satisfactorily consistent with the behaviour of the above cyclohexadienones in their reactions with organomagnesium compounds[112].

The general characteristics of the reactions of quinochloride compounds and 4-nitrocyclohexadienones with nucleophilic agents remain the same as those of the reactions with quinobromide compounds, but these types of quinolides have been much less thoroughly investigated. Thus, it is known that the reaction of quinochlorides and 4-nitrocyclohexadienones with metals[48,49,54], phosphites[50,51], amines[2], and organometallic compounds[114] results in the formation of phenoxy-radicals. When potassium iodide acts on quinochlorides, free iodine is liberated[121] while in the reaction of 4-nitrocyclohexadienones and quinochlorides in aqueous alcoholic solutions of alkali, phenoxy-radicals are also formed initially[49]. The final product of the reaction of 2,4,6-tri-t-butyl-4-nitrocyclohexa-2,5-dienone with alkali (in aqueous acetone solution) is the corresponding hydroquinone[60]. It is interesting that the analogous reaction involving the replacement of the nitro-group by a hydroxyl takes place also under the influence of sodium acetate in acetic acid solution[60,122,123]:

We believe that the mechanism proposed for this reaction and involving nucleophilic substitution[122] is doubtful, since the hydrolysis of 4-nitrocyclohexadienones results in the formation, apart from the hydroquinones indicated above, of products characteristic of reactions in an alkaline medium of the corresponding phenoxy-radicals; quinones, 3,5-di-t-butyl-4-hydroxybenzaldehyde, and others[122,123] (see also Refs. 33–42).

Hydroquinones, their ethers, and *gem*-dialkylcyclohexadienones are as a rule resistant to the reaction of the majority of nucleophilic agents and only active electron donors such as alkali metals (or others in electrochemical reduction) can react with these quinolides to form radical-anions[79]. Examples of reactions of hydroquinones involving the carbonyl group are also known. Thus the reaction of 2,6-di-t-butyl-4-hydroxy-4-methylcyclohexa-2,5-dienone with organolithium compounds results in the formation of the corresponding cyclohexadienediols[124].

---o0o---

The reactions of sterically hindered phenols and their derivatives discussed above are in many cases typical for substances of this type and probably involve one-electron transfer in the elementary step. Quinobromide compounds, which form either phenoxy-radicals or the corresponding phenoxides after the addition of the electron depending on the structure, are of greatest interest for the investigation of various aspects of the problem under consideration. This makes it possible to separate the various stages in processes involving one-electron transfer.

Thermal Stability of Anion-exchange Resins

P.E.Tulupov and N.G.Polyanskii

This paper is a logical continuation of the previous review by the authors[1] and reflects the present state of studies on the thermal stability of anion-exchange materials. It deals with the principal methods for the investigation of the thermal stability of anion-exchange resins and presents rational formulae for the recalculation of exchange capacities which facilitate comparison of the experimental data of different investigators. Attention has been concentrated on a general description of data on the thermal stability of different anion-exchange resins in air, in water and aqueous solutions, and in organic and mixed media. A new mechanism is proposed for processes involving changes in ion-exchange resins in the above media. Rigorous kinetic equations describing the decrease of the exchange capacity with respect to highly basic groups, deamination, and degradation of the amino-groups in anion-exchange resins have been obtained on its basis and agree satisfactorily with the experimental data. Further aims of studies on the thermal stability of ion-exchange resins have been outlined.
The bibliography includes 112 references.

I. INTRODUCTION

Anion-exchange resins, like cation-exchange resins, are in practice frequently subjected to heat treatment. In many cases heating accompanies even the preliminary preparation of the anion exchangers for experiments in order to remove as far as possible trapped water or another solvent. Some investigators dry anion-exchange resins in air[2], others *in vacuo* at 64°C, and yet another group use a thermostat at 100°C.[3,4] Regardless of the drying conditions, strongly basic anion-exchange resins undergo far-reaching chemical changes[5].

Anion-exchange resins are frequently employed at an elevated temperature for the analytical separation of multicomponent mixtures[6] but for the usual single employment of the sorbent the problems of durability have of course not been considered.

On the other hand, in catalysis by ion-exchange resins[7] durability is of prime importance, determining the possibility of reusing the catalyst and frequently deciding whether its employment is economical.

Water treatment undertakings are the largest consumers of anion-exchange resins (together with cation-exchange resins) and for these purposes the thermal stability of these high-polymer electrolytes determines not only whether or not the technological processes are economical but also the quality of the deionised water[8,9].

Despite the enormous theoretical and practical importance of this problem,the number of studies on the thermal stability of anion-exchange resins is not very great, and with few exceptions their standard is lower than in the corresponding field of research on cation-exchange resins[1].

The lag in studies on the thermal stability of anion-exchange resins is due to the inadequate systematic approach to the problem, the competitive reactions which frequently occur simultaneously, and to a certain extent the smaller availability of the specimens for study than in the case of cation-exchange resins.

Systematic studies on the thermal stability of anion-exchange resins began only after the development of reliable methods for the separate determination of their exchange capacities with respect to active groups of different basicity. Further development of studies in this field depends largely on the validity of the methods employed by investigators.

As in the original reports, attention is concentrated on AV-17 anion-exchange resin and its analogues which have been most widely used under industrial conditions.

II. METHODS FOR INVESTIGATING THE THERMAL STABILITY OF ANION-EXCHANGE RESINS

This section deals with methods which are of specific importance for anion-exchange resins. Technical anion-exchange resins are first freed from impurities by prolonged treatment in a column or on a filter with 3 N hydrochloric acid and then washed with water and converted into the hydroxide-form by passage of 1 N aqueous KOH solution. To condition the resins, the above operations are repeated twice and the last washing with water is terminated as soon as the consumption of 0.01 N hydrochloric acid in the titration of 100 ml of wash liquid falls to 0.3 ml.

When necessary, the anion exchanger is converted into a salt-form by passing through the column a 0.5 N solution of the corresponding acid until its concentration in the filtrate remains constant. To avoid hydrolytic scission of counterions, weakly basic anion exchangers are washed free of the electrolyte with 96% ethanol until the filtrate gives a neutral response.

Anion-exchange resins are heat-treated in air in weighing bottles or in other vessels suitable for weighing[5] and, when an aqueous or organic medium is employed, the heat treatment is in an open or sealed tube[10]. The devices recommended by the authors of this review[11] are very convenient for the investigation of gaseous nitrogen-containing compounds formed on heat treatment of anion-exchange resins.

After the specified duration of heat treatment has elapsed, the anion exchanger is repeatedly washed with deionised water until a neutral response is obtained with respect to phenolphthalein and the phases are investigated separately.

In the simplest case, the total content of basic substances is determined in the liquid phase (called the aqueous extract) by titration with hydrochloric acid [5]. In more complex cases, the substances passing to the aqueous extract and representing the resin degradation products are identified by general chemical [3,12,13], potentiometric [12], and spectrophotometric [12] methods. Finally, many investigators [14-17] disregard the aqueous extract, confining themselves to a more or less detailed study of the anion exchangers themselves before and after their thermochemical [14-16] or radiation [17] treatment. In the study of the mechanism of the changes occurring in anion-exchange resins, as in the determination of small losses of exchange capacity which are not revealed by the direct investigation of the solid phase, such limitation of the research technique used is completely unjustified.

An example of the most complete investigation of an ion-exchange resin after thermochemical treatment is that of Vinogradov and Kazantsev [14]. The authors determined the exchange capacity of the anion-exchange resin with respect to strongly and weakly basic groups, the total nitrogen content, and the physicochemical characteristics of the resin, such as absorption in the infrared spectrum, density, and the coefficieint of the moisture absorption capacity. Among the above properties, all the investigators attribute the greatest importance to the exchange capacity, for the determination of which a wide variety of methods have been developed, but these require a rigorous and critical approach.

A compilation of methods for the determination of the exchange capacity of anion-exchange resins and the relevant recipes may be found in monographs [18-20] and in an All-Union Standard [21]. All the methods for the determination of the static exchange capacity (SEC) taking into account without discrimination a proportion of the active groups which depends on the specific conditions of the analysis should be ignored. We believe that best results in the study of the thermal stability of anion-exchange resins can be obtained by the following method for the determination of the exchange capacity.

A differential determination of the strongly and weakly basic groups is provided for in Kunin's method [22], which was perfected in studies by English [23,24] and Czech [25] investigators. According to the evidence of Polak and Wyroba [26], Kunin's original method gives somewhat high values for the content of weakly basic groups. More reliable results were obtained using Stamberg's version [25]. With certain additional modifications, the method has been used to determine the exchange capacities of anion-exchange resins mixed with cation-exchange resins [27].

A direct determination of groups with different basicities without a preliminary conversion of the anion-exchange resins into a salt-form is achieved in the method of Polyanskii and Shaburov [28].

Studies of Kopylova and coworkers [29,30] on the use of non-aqueous media for the separate determination of primary, secondary, and tertiary amino-groups in anion-exchange resins are of great practical importance.

The methods of Fischer and Kunin [22] and Polyanskii et al. [31] yield the best results in the determination of the exchange capacities of anion-exchange resins in the Cl-form. In the method of Fischer and Kunin [22], it is recommended that the resin be washed in a column with 4% aqueous K_2SO_4 solution with subsequent titration of chloride ions in the filtrate by Mohr's method. Polyanskii and Shaburov [31] proposed a simpler static version of the method based on the titration of the Cl^- ions evolved on interaction of the anion-exchange resin with 10% aqueous K_2SO_4 solution without the separation of the phases.

Since strongly and weakly basic groups present in polyfunctional anion-exchange resins exhibit different thermal stabilities, the state of the anion-exchange resin can be fully characterised only by the separate determination of these groups; the method of expressing their concentrations is then important.

The majority of investigators assess the thermal stabilities of anion-exchange resins on the basis of the time variation of the exchange capacity or from the relative loss of exchange capacity R:

$$R = \frac{E_0 - E_t}{E_0} \cdot 100\% \ , \qquad (1)$$

where E_t and E_0 are the exchange capacities after and before this treatment. It is noteworthy that these criteria, in particular for polyfunctional anion-exchange resins, are only of relative value, since for a first-order reaction R is independent of the initial exchange capacity [32]. In studies on thermal stability, the exchange capacity of anion-exchange resins is referred to 1 g of dry (E^d) or swollen (E^h) resin and sometimes is expressed in fractions of the conversion of the functional groups [33,34]. One should note that all these quantities depend on many variables (the amount of bound water, the weight of functional groups, the type of counterions) and therefore they are unsuitable for the kinetic treatment of the experimental data when the ion-exchange resins are heated or irradiated.

As a rule, the most stable component of the resin is the matrix. Therefore in kinetic studies the exchange capacity is referred to 1 g of the matrix (E^M) without functional groups, counterions, and sorbed water.

The wide variety of existing methods for expressing the exchange capacities of ion-exchange resins hinder the comparison of the experimental data obtained by different investigators and require the derivation of conversion formulae in each case. Such recalculations are facilitated by the relations presented in Table 1 and in Eqns. (2)–(6), which are valid for all types of ion-exchange materials.

Table 1 may be supplemented by formulae for the calculation of exchange capacity when the ionic form changes from B to A, which can be written as follows for the dry and swollen resins [32]:

$$E_A^d = \frac{E_B^d}{1 + E_B^d(\epsilon_A - \epsilon_B)} \ , \qquad (2)$$

$$E_A^h = \frac{(1 + K_B)E_B^h}{(1 + K_A)[1 + E_B^h(1 + K_B)(\epsilon_A - \epsilon_B)]} \ . \qquad (3)$$

In the corresponding change of the ionic form of only one type (i) of functional groups in a polyfunctional resin [32], we have

$$E_{i,A}^d = \frac{E_{i,B}^d}{1 + E_{i,B}^d(\epsilon_{i,A} - \epsilon_{i,B})} \ , \qquad (4)$$

$$E_{i,A}^h = \frac{(1 + K_B)E_{i,B}^h}{(1 + K_{i,A})[(1 + K_B)E_{i,B}^h(\epsilon_{i,A} - \epsilon_{i,B}) + 1]} \ , \qquad (5)$$

where K is the coefficient of moisture absorption capacity in g H_2O/g dry resin, E the exchange capacity in mequiv. g^{-1}, ϵ the equivalent weight of the functional groups with counterions A or B, $K_{i,A}$ the coefficient of

Table 1. Formulae for the recalculation of the exchange capacities of ion-exchange resins.

moisture absorption capacity of the resin in which the groups i are in the A-form and the rest are in the B-form, and d is the density of the resin in g ml^{-1}.

When the ionic forms of all the functional groups change the exchange capacity with respect to one of them designated as the first is given by the following formula for the simplest case of the coexistence of two different functional groups [32]:

$$E_{1,A}^d = \frac{E_{1,B}^d(1+E_2^M \cdot \epsilon_{2,B})}{1+E_2^M \cdot \epsilon_{2,A}+E_{1,B}^d(\epsilon_{1,A}-\epsilon_{1,B})+E_{1,B}^d \cdot E_2^M(\epsilon_{1,A} \cdot \epsilon_{2,B}-\epsilon_{1,B} \cdot \epsilon_{2A})} \cdot \quad (6)$$

where the subscripts $1,A$ and $2,B$ imply that the capacity or the equivalent weight refers to the first type of functional groups in the ionic form A or to the second type of groups in the ionic form B.

In order to be able to employ the above formulae, it is necessary to know the densities d of the dry and swollen resins, the coefficient of moisture absorption capacity, and the degree of filling of the columns ϵ. The derivation of these quantities was considered in the preceding review [1]. However, in the measurement of the coefficient of moisture absorption capacity for strongly basic anion-exchange resins in the OH-form, one cannot employ the trivial method, since in the dehydration stage not only water but also nitrogen-containing compounds volatilise [5].

A compromise solution was proposed by Greben' [32], who employed the relatively high thermal stability of the salt-forms of ion-exchange resins. He derived a formula for the calculation of the coefficient of moisture absorption capacity K_A of the ionic forms A which decompose on drying, in terms of the weight of the swollen resin p in forms A and B, the corresponding equivalent weights of the functional groups, the exchange capacity, and the coefficient of moisture absorption capacity K_B of the thermostable form B:

$$K_A = \frac{(1+K_B)\,p_{A/p_B}^h}{1-(1+K_B)E_B^h(\epsilon_B-\epsilon_A)} - 1 \cdot \quad (7)$$

A decrease in the content of the functional groups is accompanied by a decrease in the weight of the resin, which is given by the following formula in the absence of degradation of the matrix to soluble oligomers:

$$W_{exp} = \frac{p_0^d - p_t^d}{p_0^d} \cdot 100\,\% = \left[1 - \frac{p_t^h(1+K_0)}{p_0^h(1+K_t)}\right] \cdot 100\,\% \cdot \quad (8)$$

The experimental weight losses can be usefully compared with the calculated values W_{calc}, which are given by the following expression when the condition mentioned above is fulfilled:

$$W_{calc} = (1+K_0)\sum_{i=1}^{n}\left(E_{0,i}^h - E_{t,i}^h \frac{p_t^h}{p_0^h}\right)\epsilon_i \cdot 100\,\% =$$

$$= \sum_{i=1}^{n}\left(E_{0,i}^d - E_{t,i}^d \frac{p_t^d}{p_0^d}\right)\epsilon_i \cdot 100\,\% = \frac{\sum_{i=1}^{n}(E_{0,i}^M - E_{t,i}^M)\,\epsilon_i}{1+\sum_{i=1}^{n} E_{0,i}^M \epsilon_i} \cdot 100\,\% \cdot \quad (9)$$

The satisfactory agreement between W_{exp} and W_{calc}, established in a study of the thermal stability of AV-17 anion-exchange resin [35] demonstrates the absence of degradation of the matrix to soluble oligomers under the experimental conditions.

To characterise the processes involved in the loosening or contraction of the three-dimensional network but not the breakdown of the matrix, it is useful to employ the equivalent coefficient of moisture absorption capacity K^e:

$$K^e = \frac{K}{0{,}018\,E^d} = \frac{K}{0{,}018\,(1+K)\,E^h} \cdot \quad (10)$$

Eqn. (10) shows that the equivalent coefficient of moisture absorption capacity defines a number of millimoles of water per milliequivalent of functional groups provided the entire trapped liquid is in a bound state and does not merely fill pores, cracks, etc. and that the hydration shells of adjacent groups do not overlap [36,37].

In certain cases, the formation of cracks leads to an increase of the equivalent coefficient of moisture absorption capacity[37], which is in no way related to the expansion of the three-dimensional network. The decrease of this quantity for the usual gel cation-exchange resins may indicate a contraction of the three-dimensional network while for macroporous resins it may be evidence of a decrease of the overall porosity. In the literature on ion exchange, publications have already appeared in which the effect of heat treatment on the porometric characteristics of cation-exchange resins is considered[38,39]. Similar studies have not so far been made on anion-exchange resins.

Infrared spectroscopic methods are particularly important for the investigation of the changes in the chemical structure of anion-exchange resins on heat treatment and irradiation. The basic aspects of the application of infrared spectroscopy to anion-exchange resins have already been considered[14,140]; in addition, interesting experimental results have been presented in other publications[41-44].

In many cases, comparison of the results of different workers is difficult owing to the absence in the reports of a detailed description of the resins investigated (the degree of their cross-linking, capacity with respect to different active groups, and the coefficient of moisture absorption capacity) and sometimes due to an unduly concise description of the experimental technique. For example, such details as the proportions of the resin and solution phases are undeservedly regarded as unimportant and are usually not mentioned. Nevertheless, in cases where there is a direct interaction of the medium with the functional groups[44], when the products of the reaction affect its rate[27], and for reversible changes in resins, the kinetics of the decrease of exchange capacity depend on the quantitative proportions of the phases. Naturally, there are no grounds for being dogmatic about these relations, but it is important that each investigator base his treatment on something concrete.

III. THE STABILITY OF ANION-EXCHANGE RESINS ON HEATING IN AIR

The study of the thermal stability of anion-exchange resins in air was begun in 1952 [45] and was confined to the observation of an endothermic effect associated with the evolution of water and an exothermic effect associated with the combustion of the resin. In another, more sophisticated study[46], the thermal stability of an anion-exchange resin based on methylvinylpyridine and divinylbenzene was investigated but in this case the change in the content of acid groups was not determined by chemical analysis.

Two endothermic effects observed on the thermogram for AV-17 anion-exchange resin in the OH-form have been interpreted[47]: the first (at 120–150°C) was attributed to the desorption of water and the elimination of active groups and the second (at 190–280°C), to the thermal degradation of the resin itself. Together with the decrease of exchange capacity, heat treatment results in a decreased capacity of the anion-exchanger for hydration, but it is not surprising that below 140°C these effects are not observed.

Comparative thermographic data for the stability of anion-exchange resins of different basicities have been published[48,49]. In studies on EDE-10P, Dowex-1 × 4 and Dowex-2 × 4 resins, differences between the stabilities of strongly and weakly basic active groups have been clearly demonstrated: a decrease of exchange capacity is observed mainly in relation to strongly basic groups. EDE-10P anion-exchange resin in the OH-form is stable in air up to 150°C, but in the range 160–200°C strongly basic groups are converted into weakly basic groups without loss of the total exchange capacity[48]. Strongly basic polymerisation anion-exchange resins lose thier active groups completely after heating for 3 h at 220°C.[49]

As shown by one of the present authors and Shaburov[5], even simple drying of AV-17 anion-exchange resin at room temperature entails an appreciable decrease of the total exchange capacity with a simultaneous accumulation of weakly basic groups. Following Dybczynski[50], the authors explained these changes by deamination:

$$R{-}CH_2{-}N(CH_3)_3OH + H_2O \rightarrow R{-}CH_2OH + NH(CH_3)_3OH \qquad (11)$$

and degradation

$$R{-}CH_2{-}N(CH_3)_3OH + H_2O \rightarrow R{-}CH_2{-}NH(CH_3)_2OH + CH_3OH\ . \qquad (12)$$

However, one cannot rule out the possibility that reactions (11) and (12) are of subsidiary importance and that the main cause of the changes in the capacity of AV-17 anion-exchange resin is interaction of two active groups with formation of a tetramethylammonium base and of two polymeric molecules, one of which should be a weakly basic anion exchanger:

$$\begin{matrix} R{-}CH_2{-}N(CH_3)_3OH \\ R{-}CH_2{-}N(CH_3)_3OH \end{matrix} + H_2O \rightarrow \begin{matrix} R{-}CH_2{-}NH(CH_3)_2OH \\ R{-}CH_2OH \end{matrix} + N(CH_3)_4OH\ . \qquad (13)$$

Mechanism (13) is supported primarily by the fairly high basicity of the aqueous extracts from AV-17 anion-exchange resin dried *in vacuo*, which may be attributed to the tetramethylammonium base the volatility of which is known[51] to be low in aqueous solutions. Furthermore, mechanism (13) is confirmed by the finding that the rates of deamination and degradation of anion-exchange resins depend little on the method of drying[5].

Thus AV-17 × 2 anion-exchange resins dried at room temperature *in vacuo*, at room temperature in the presence of $CaCl_2$ and Anhydrone, and at 110°C to constant weight lost 1.69, 1.57, and 1.96 milliequivalents of strongly basic groups per gramme of dry resin as a result of deamination and 1.42, 1.15, and 1.89 mequiv. g^{-1} as a result of degradation. Under the same drying conditions, AV-17 × 16 resin lost 0.44, 0.37, and 0.68 mequiv. g^{-1} as a result of deamination and 0.39, 0.39, and 0.56 mequiv. g^{-1} as a result of degradation. All these findings make it possible to regard the deamination and degradation of the OH-form of AV-17 anion-exchange resin as coupled and not as independent processes.

Bearing in mind the comparatively low volatility of the conversion product of AV-17 anion-exchange resin according to mechanism (13), it is easy to explain the finding of Soldatov et al.[52] that its exchange capacity remains unchanged when dried at 60°C. Indeed, this constancy is only an apparent consequence of the equivalent relations between the number of strongly basic groups eliminated and the tetramethylammonium base formed and remaining in the resin phase under mild drying conditions. If the analysis of liquid extracts is neglected it is thus possible to arrive at completely incorrect ideas about the stability of the anion-exchange resin.

In AV-27 anion-exchange resins, the ethanol group is linked to the nitrogen atom less strongly than the methyl groups[13] and therefore the main cause of the changes in the

resin is degradation with elimination of ethylene glycol according to the equation

$$\begin{matrix}RCH_2N(CH_3)_2OH\\ |\\ CH_2CH_2OH\end{matrix} + H_2O \rightarrow \begin{matrix}RCH_2N(CH_3)_2OH\\ |\\ H\end{matrix} + HO{-}CH_2CH_2{-}OH \ . \quad (14)$$

Shaburov and Saldadze's studies[53] on the behaviour of the polyfunctional AV-16 anion-exchange resin in the OH-form involving a large scale employment of chemical-analytical methods showed that at 110°C the capacity decreases mainly in relation to the strongly basic pyridinium groups, which the authors believe to undergo tautomeric transformations. The changes in exchange capacity during the drying process lead to a marked contraction of the three-dimensional network and to a decrease of swellability almost by a factor of two.

The salt-forms of AV-17 anion-exchange resin[44,49,54-56] and of anion exchangers based on polyallylamine and epoxide ethers[57] are in general more resistant to heat treatment in air than the corresponding resins in the hydroxide-form. The salt-forms derived from acids with non-oxidisable anions can be arranged in the following sequence in terms of the decrease of thermal stability: $RCl > R_2SO_4 > R_3BO_3$. The relative thermal stability of the nitrate-form depends on temperature[49,58]. At 140°C it is more resistant to heating than the hydroxide-form, while at 160–200°C it undergoes pyrolytic decomposition and self-ignition. The self-inflammation temperature decreases with increased degree of cross-linking of Dowex-1 anion-exchange resin and with the concentration of the nitric acid employed for its regeneration. Barghusen and Jonke[58] do not recommend the employment of the nitrate-form of the resin above 60°C and note that, other conditions being equal, the thermal stability of anion-exchange resins in this form decreases in the series Dowex 2 > Permutit SK > Amberlite IRA-401.

Anion-exchange resins of type AV-17 in the Cl-form are entirely stable on heating in air up to 70°C [55] and, according to Shaburov[54], up to 100°C; they even withstand brief heating at 160°C.[35]

On prolonged heating at a temperature as low as 130°C, active groups of different basicities are split off, tentatively[55] in accordance with the mechanisms

$$RCH_2N(CH_3)_3Cl \rightarrow RCH_2Cl + N(CH_3)_3 \ , \quad (15)$$

$$RCH_2NH(CH_3)_2Cl \rightarrow RCH_2Cl + HN(CH_3)_2 \ . \quad (16)$$

A further increase of temperature from 130° to 180°C leads to a sharp fall of exchange capacity in relation to strongly basic groups with a possible accumulation of weakly basic groups owing to degradation:

$$RCH_2N(CH_3)_3Cl \rightarrow RCH_2N(CH_3)_2 + CH_3Cl \ . \quad (17)$$

It has been shown[35,44] that the number of weakly basic groups formed on heating AV-17 resin in a mixed Cl–OH-form to 150–170°C is smaller by a factor of two than the number of strongly basic groups split off under these conditions and it has been established that the scission of these groups is not due to the reactions (15)–(17) but is a result of hydrolysis involving the residual water. In the presence of a high water content, one amino-group is involved in the hydrolysis:

$$RCH_2N(CH_3)_3Cl + H_2O \rightarrow RCH_2OH + HN(CH_3)_3Cl \ , \quad (18)$$

and in the presence of a deficiency of water two amino-groups are involved:

$$\begin{matrix}RCH_2N(CH_3)_3Cl\\ RCH_2N(CH_3)_3Cl\end{matrix} + H_2O \rightarrow \begin{matrix}RCH_2OH\\ RCH_2NH(CH_3)_2Cl\end{matrix} + N(CH_3)_4Cl \ . \quad (19)$$

If the anion-exchange resin is dried *in vacuo* at 100°C, reaction (18) altogether fails to take place owing to the insufficiency of water and hydrolysis via mechanism (19) probably involves the interaction of two amino-groups via the following mechanism:

$$\begin{matrix}RCH_2N(CH_3)_3Cl\\ RCH_2N(CH_3)_3Cl\end{matrix} \rightarrow \begin{matrix}RCH_2\\ RCH_2\end{matrix}\!\!>\!N(CH_3)_2Cl + N(CH_3)_4Cl \ . \quad (20)$$

When AV-17 anion-exchange resins in the Cl-form are heated in open tubes to 150–180°C, partial decomposition of tetramethylammonium chloride is possible[44]. An increase of temperature to 270°C leads to the total loss of exchange capacity and to the appearance of inactive nitrogen[55], possibly owing to the oxidation of the amino-groups by atmospheric oxygen to nitro-groups.

EDE-10P anion-exchange resin in the Cl-form is less resistant to heating than in the mixed Cl–OH-form[35], since the HCl evolved in the hydrolysis of the weakly basic groups decomposes the anion-exchanger macromolecule. Condensation anion-exchange resins of type AT are more stable than EDE-10P resin[57], the increase of stability in the series AT-7 < AT-8 < AT-6 being explained (without convincing evidence) by different relative contents of primary, secondary, and tertiary amino-groups. The above anion exchangers were investigated by the thermographic method[57], which showed the presence of an endothermic effect in the range 160–200°C corresponding to the degradation of the functional groups. The differential thermal (DTA) curves for a number of strongly basic anion exchangers in salt-forms are quoted in a number of publications[48,49,52].

The resistance of anion-exchange resins in salt- and hydroxide-forms to frost has been investigated[59,60] and it has been established that the main result of the action of low temperatures is disruption of some of the polymeric chains, the cracking of grains, and deamination; degradation was not observed[59].

The thermal stability of anion-exchange resins with phosphonium and sulphonium groups[61] is appreciably lower than that of quaternary ammonium bases with an analogous matrix structure.

IV. THERMAL STABILITY OF ANION-EXCHANGE RESINS IN WATER AND AQUEOUS SOLUTIONS

Isolated data for the thermal stabilities of anion-exchange resins in water were obtained incidentally by the authors of the first studies of the properties[62,63] and behaviour of anion-exchange resins under the conditions of their industrial employment[64-68]. A general characteristic of these investigations is the random choice of the objects of study, the inadequate reliability of the experimental methods employed, and the formal nature of the results, which do not always yield a consistent picture of the main phenomenon during heat treatment—the decrease of the exchange capacity of the anion-exchange resin.

Systematic studies on the thermal stability of a wide range of different types of anion-exchange resins were undertaken by Pashkov et al.[3] On the basis of extensive experimental data, the authors showed that the thermal stability of anion-exchange resins depends on the matrix structure and on the nature of the active groups and the counterion. Thus weakly basic resins proved to be more stable than strongly basic resins and their salt-forms proved to be more stable than the hydroxide-forms. Other conditions being equal, polymerisation anion-exchange resins are more stable than condensation resins, although

individual examples of the latter, for instance EDE-10P resin [3] and particularly AT-6 resin [69], exhibit a high stability. Unfortunately all the experiments were carried out by Pashkov et al. [3] only at a single temperature (100°C) and for a single duration of heating (60 h) and the chosen criterion of thermal stability was the static exchange capacity, which is known [70] to depend on the conditions of its determination.

Table 2. Thermal stabilities of a series of anion-exchange resins in the OH-form

Type of anion-exchange resin	Active groups	Temp., °C	Time, h	Relative change in exchange capacity, %			References
				total	w.r.t. strongly basic groups	w.r.t. weakly basic groups	
AV-17	$-\overset{+}{N}(CH_3)_3$	100	48	+33	+18	+60	73
		100	120	+36	+29	+48	73

Additional information about the thermal stability of various anion-exchange resins in the OH-form can be found for a wider temperature range in studies by Ol'shanova and coworkers [71-73]. The most important results obtained in the above investigations are presented in Table 2, where the plus sign before the value of the relative change in exchange capacity of the anion-exchange resin as a result of its heat treatment corresponds to a decrease and the minus sign to an increase of exchange capacity.

Comparison of the results in Table 2 reveals primarily a poor agreement between the values of exchange capacity losses established by different workers. This is most probably due to the non-equivalence of the resins investigated, which might have differed in the degree of cross-linking and in the composition of the samples used. For example, 6% of the exchange capacity corresponded to the contribution by the weakly basic groups of AV-17 resins in the study by Shaburov et al. [74], while in the study by Petrova and Potakova [73] the corresponding percentage was **36.** The divinylbenzene content of the AV-17 anion-exchange resins has been indicated only by Shaburov et al. [74] and is not mentioned in the other investigations. This significant omission vitiates the experimental results no less than the use of faulty research techniques.

Bearing in mind the above inconsistency, it is necessary to compare the results of the determination of the losses of capacity obtained in the same laboratory. In this connection, the data in Table 2 lead to the conclusion that the stabilities of polymerisation and condensation anion-exchange resins with weakly basic groups are different. For anion-exchange resins with strongly basic groups, these differences become blurred, since, owing to the $-I$-effect in quaternary ammonium bases [76], the linkage with $C-\overset{+}{N}$ is so highly polarised that the structure of the framework becomes of secondary importance as a factor in thermal stability. Moreover, this levelling is favoured by the poor choice by the authors of the above studies of the relative change in capacity as a criterion of the thermal stability of anion-exchange resins known to have different contents of active groups.

The decrease of the exchange capacity of anion-exchange resins in the OH-form in relation to strongly basic groups has been shown [10,12,13,77] to take place owing to the deamination and degradation processes examined above, which are usually identified with the familiar Hofmann degradation [78]. The methanol and trimethylamine formed on heat treatment of AV-17 anion-exchange resins were identified; according to Shaburov and Saldadze [12] and Roginskaya et al. [77], their amounts corresponded to changes in exchange capacity with respect to strongly and weakly basic groups. However, the data in Roginskaya's disseration [79] and in the study of Minto et al. [112] contradict this assertion.

The relative contribution by the deamination and degradation of AV-17 anion-exchange resins depends on the duration of heat treatment and on the content of divinylbenzene (DVB) in the test object [74]. In the first, rapid stage involving the decrease of exchange capacity, the ratio of the rates of these reactions changes with increase of the degree of cross-linking in favour of deamination, which has been explained [74] by a weakening of the protective effect of the hydration shells of the active groups as the swellability of the resin decreases. Generalising such data [71,72,80,84,112], we may note that in the majority of cases an increase of the content of the cross-linking agent entails a decrease of the thermal stability of strongly basic anion exchangers in the OH-form.

Not only the variation of the degree of cross-linking but also an increase in the specified purity of the starting material employed in the synthesis and the introduction of active groups into mixed aliphatic-aromatic [81] or even aliphatic [82] structures give rise to some possibility of controlling the thermal stability. For example, it has been established that [80] the anion-exchange resin based on styrene and *p*-divinylbenzene has a higher resistance to heating than the specimen synthesised from technical DVB, the impurities of which cause the formation of defects in the macromolecule. An improved thermal stability of strongly basic anion-exchange resins in which the active group is separated from the aromatic ring by the isobutyl group has been predicted [81].

AV-27 anion-exchange resin, which occupies an intermediate position as regards thermal stability, and its analogue Amberlite IRA-410, readily split off the CH_2CH_2OH group with formation of ethylene glycol and a high-molecular-weight tertiary amine (degradation) [13]. This process is faster than the overall deamination and degradation of AV-17 resin and is responsible for the higher rate of decrease of the exchange capacity of AV-27 resin in relation to strongly basic groups.

An interesting study on the thermal stability of the vinylpyridine anion-exchange resin VP-IAP in water and certain aqueous solutions has recently been made by Kiseleva et al.[43] On the basis of a large-scale experiment by the infrared spectroscopic method, they showed that heating the anion-exchanger in water at 200–230°C for 10–60 h leads not only to the usual losses of exchange capacity but also to the oxidation of the methyl groups of the ring to aldehyde and carboxy-groups and to the formation of hydroxypyridines. In alkaline solutions, the formation of a stable form of pyridones accompanied by the loss of exchange capacity is observed. If the heat treatment of the anion exchanger was carried out at 70°C, the pyridones formed were protonated to hydroxypyridines with restoration of exchange capacity on subsequent heating of the anion exchanger in water or nitric acid solutions at 200°C.

The resistance of strongly basic anion-exchange resins and model low-molecular-weight quaternary ammonium bases to heating in alkaline media has been investigated[82-87] and it has been established that resins of the phenyl type, like the corresponding low-molecular-weight bases with aromatic substituents, undergo mainly deamination (to the extent of 60–70%). Anion exchangers of the benzyl type and quaternary ammonium bases with benzyl substituents largely undergo the Hofmann degradation, its rate being higher than for aliphatic alkyltrimethylammonium bases[82]. Hence it follows that the synthesis of anion-exchange resins with aliphatic structures constitutes a likely pathway to the creation of thermostable polyme. with anion-exchange properties.

In a later study[87], it was shown that at 40–100°C macroporous ion-exchange resins are more stable in 2–10 *N* solutions of alkali than gel ion exchangers; similar observations were made in studies on the thermal stability of macroporous sulphonic acid cation-exchange resins[39]. Studies in this field should be continued and require theoretical consideration.

Data for the stability of anion exchangers in solutions of alkalis and non-oxidising acids, which are of interest for practical purposes, have been published[15,87,89]. The studies of Laskorin et al.[15] led to the establishment of a norm for the prolonged employment of a number of USSR-produced anion-exchange resins, which are listed in Table 3.

All the inorganic reagents investigated can be arranged in the following sequence in terms of their influence on the rate of decrease of the exchange capacity of anion-exchange resins: $NaOH > NH_4OH > Na_2CO_3 > HNO_3 > H_2SO_4$. Thus the disrupting capacity of alkalis is greater than that of acids (even the oxidising nitric acid). In nitric acid solutions at a concentration up to 6 *N*, AM and AMP anion-exchange resins can be used only at room temperature, while VP-IA resin can be used up to 80°C. According to other data, the exchange capacity of the anion-exchange resins AN-23, AN-25, AN-27, AN-35, AN-40, and AN-42 based on vinylpyridine is hardly altered after heating for 90 h in 5 *N* HNO_3 at 100°C.[88]

The salt-forms of strongly basic anion-exchange resins are more stable than the hydroxide-forms not only on heating in an aqueous medium[3,54,71,90,91] but also on treatment with corrosive agents such as free chlorine[62].

In hydrogen peroxide solutions at concentrations up to 1 M, the stability of AM-6, AMP, and VP-IA anion-exchange resins decreases in the order in which they have been stated. The addition of 0.2 *N* KOH to hydrogen peroxide enhances its oxidising activity and the addition of 0.2 *N* H_2SO_4 reduces it. The anion-exchange resins exhibit a particularly low stability in calcium hypochlorite solutions.

Disdar[92] and Bychkov et al.[93] made the most interesting and complete investigation of the behaviour of AV-17 anion-exchange resins in hydrogen peroxide solutions. It was shown[93] that AV-17 anion-exchange resins absorb selectively hydrogen peroxide as a result of the displacement of water and the exchange sorption of the HO_2^- ion. Hydrogen peroxide then undergoes catalytic decomposition and the anion exchanger undergoes deamination and degradation; the catalytic activity of the anion exchanger in the decomposition of hydrogen peroxide decreases faster than the exchange capacity in relation to strongly basic groups. An increase of the concentration of the oxidant leads to an increase of the loss of exchange capacity by the anion exchanger and an increase of the amount of carbon dioxide given off. Owing to their partial oxidation, the amount of amines determined is somewhat lower than the value calculated from the loss of the exchange capacity of the resin. Strongly basic anion-exchange resins in the Cl-form and weakly basic anion exchangers in the OH-form decompose to a lesser extent[93].

Table 3. The limiting permissible operational standards for anion-exchange resins in solutions of acids and alkalis.

Reagent	Standards for stable operation of anion-exchange resins

Na_2CO_3	—	—	up to 3	30	up to 3	50

Vinogradov's dissertation[94] has made a significant contribution to the elucidation of the mechanism of the action of oxidants on anion-exchange resins. He showed that the ionogenic groups are involved in reactions of three types: deamination, degradation, and inactivation. Oxidants mainly induce inactivation, i.e. the loss of the capacity of the functional groups to participate in ion exchange. Moreover, oxidants act on the matrix, causing the formation of new functional groups containing a C=O double bond. With increase of the divinylbenzene content in the anion-exchange resin, the number of these groups also increases; there is a simultaneous intensification of degradation and a decrease of the contribution by deamination. Anion-exchange resins containing pyridine or quinoline groups are the most resistant to the action of oxygen. In all the oxidants investigated, except solutions of ammonium persulphate, they withstand heating to 80°C. Weakly basic anion-exchange resins in oxidant solutions are less stable than strongly basic resins, although in pure water the opposite behaviour was observed. The change in the composition of the medium probably alters the mechanism of the processes occurring.

V. THERMAL STABILITY OF ANION-EXCHANGE RESINS IN ORGANIC AND MIXED MEDIA

Studies in this field were begun 10 years ago by one of the present authors and Shaburov [10] and were then continued by Shaburov and Saldadze [12,53,54,95,96]. The principal results of the studies on the thermal stability of anion-exchange resins in mixed and organic media are compiled in Table 4. For comparison, it also includes data characterising the thermal stability of anion-exchange resins in water.

Table 4. Thermal stabilities of anion-exchange resins in mixed and organic media.

The data in Table 4 show that all anion-exchange resins in the OH-form undergo both deamination and degradation, the relative losses of exchange capacity increasing with the concentration of the organic component in the mixed media. In absolute alcohol and acetone, the losses of the exchange capacity of AV-17 anion-exchange resins are much greater than in water. The comparatively low thermal stability of AV-17 anion-exchange resin in alcohols is easily explained by the formation of association complexes of the alcohols with the amino-groups [10,13,54] and in acetone by the polarisation of the C—N bond owing to the participation of the amino-groups in catalysis of the aldol condensation of acetone [95]; all these factors facilitate the elimination of trimethylamine from the matrix. However, the lower thermal stability of the OH- and Cl-forms of the anion-exchange resins in alcohols than in water [13,44,54] is presumably due to the direct chemical interaction between the alcohol molecules and the amino-groups of the anion exchanger catalysed by hydroxide ions. Such interaction with the anion exchanger in the Cl-form leads to deamination via the mechanism [44]

$$RCH_2N(CH_3)_3Cl + R_1OH \rightarrow RCH_2OH + R_1N(CH_3)_3Cl, \quad (21)$$

$$RCH_2N(CH_3)_3Cl + R_1OH \rightarrow RCH_2OR_1 + HN(CH_3)_3Cl. \quad (22)$$

The real composition of the mixture of nitrogen-containing compounds formed as a result of the deamination of AV-17 × 8(Cl) anion-exchange resin in various alcohols at 180°C is presented in Table 5, which shows that the proportion of alkyltrimethylammonium chloride increases with the dimensions of the alcohol molecule, i.e. in parallel with the increased steric hindrance to the formation of ordered solvation shells around the counterions of the functional groups.

Table 5. Composition of the deamination products of AV-17 anion-exchange resin in the Cl-form [97].

Alcohol	Duration of experiment, h	Content, mequiv. g^{-1}		Fraction of alkyltrimethylammonium chloride, %	Loss of capacity, %
		trimethylammonium chloride	alkyltrimethylammonium chloride		
CH_3OH	4	0.84	0.15	15	31
CH_3OH	6	1.00	0.22	18	38
C_2H_5OH	4	0.65	0.12	16	24
C_2H_5OH	6	0.85	0.26	23	35
n-C_3H_7OH	4	0.65	0.23	26	28
n-C_3H_7OH	6	0.75	0.33	30	34
i-C_3H_7OH	6	0.77	0.34	30	34
n-C_4H_9OH	4	0.77	0.32	29	34
n-C_4H_9OH	6	1.11	0.51	32	51
n-$C_5H_{11}OH$	4	0.69	0.37	35	33
n-$C_5H_{11}OH$	6	0.82	0.49	37	41

Deamination of AV-17 anion-exchange resins in the OH-form on interaction with methanol takes place via mechanism (23), as shown by infrared spectroscopy [12]:

$$RCH_2N(CH_3)_3OH + CH_3OH \rightarrow RCH_2OCH_3 + HN(CH_3)_3OH. \quad (23)$$

With increase of the size of the organic group of the alcohol, its reactivity also increases, which leads to a decrease of the thermal stability of AV-17 and AV-27 anion-exchange resins. This correlation, which is in fact between the thermal stability and the positive inductive effect of the aliphatic groups [98], persists only until steric hindrance to the penetration of alcohol molecules into the resin phase appears. When this happens the deamination reactions become more difficult and the thermal stability of anion-exchange resins in alcohols increases after having passed through a minimum [44,54]. A similar relation governs the changes in the losses of exchange capacity as a function of the degree of cross-linking of AV-17 anion-exchange resin. However, in this case it is also necessary to bear in mind the internal concentration of OH^- ions in the resin phase in relation to the sorbed alcohol, which determines (as for cation-exchange resins [99]) the rate of interaction. In particular, the decrease of the thermal stability of the resin with increased content of the cross-linking agent from 2 to 6% is related to this factor [74]. A further increase of the degree of cross-linking to 16% leads to a sharp lowering of the swellability of the resin in alcohols, which causes a corresponding decrease in the concentration of one of the reactants. As a result, the rate of deamination falls despite the increased concentration of OH^- ions relative to the sorbed alcohol. All these factors lead to a higher thermal stability of the anion-exchange resin with 16% DVB compared with less cross-linked specimens.

The relative losses of the capacity of AV-17 anion-exchange resin with respect to the strongly basic groups

in water in the range of cross-linking agent contents investigated (2–16%) are a continuous increasing function of the degree of cross-linking. The difference between this relation and that which has just been discussed for thermal stability in alcohols is undoubtedly due to the higher swellability of the anion-exchange resin in water. As a result, the rate of deamination is determined only by the concentration of the catalytically active OH^- ions in the resin in relation to the bound water, the concentration increasing with the degree of cross-linking.

The electrostatic factors discussed by Shaburov et al.[74] are probably of subsidiary importance.

Degradation involving the residual water [via reaction (12)] is always observed together with deamination when the OH-form of AV-17 anion-exchange resin is heated in alcohols[75]. The absolute decrease of the total exchange capacity of AV-16 and AV-17 anion-exchange resins as a result of their heat treatment in methanol or ethanol exceeds the amount of tertiary amine eliminated[12,13], which indicates the conversion of part of the nitrogen into an inactive state. The mechanism of the reactions occurring under these conditions still requires elucidation.

VI. THE MECHANISM AND KINETICS OF PROCESSES OCCURRING ON HEATING ANION-EXCHANGE RESINS IN WATER AND AQUEOUS ORGANIC AND ORGANIC MEDIA

Earlier it was already stated that the deamination and degradation of the amino-groups of the OH-form of type AV-17 anion-exchange resins are regarded by all investigators as the Hofmann degradation of the quaternary ammonium bases. However, the data in Roginskaya's dissertation[79] and those of other investigators[112], which unfortunately have not been interpreted in sufficient detail, are inconsistent with these ideas and throw doubt on the mechanism adopted for the deamination and degradation of the amino-groups and anion-exchange resins. The following facts are inconsistent with the Hofmann decomposition mechanism.

1. The relative contribution of deamination with a loss of capacity as strongly basic groups on heating the anion-exchange resin in sealed tubes with water falls with increased duration of the experiment, while in a mixed bed and under dynamic conditions it remains unchanged[27,77,79,96].
2. The deamination process terminates long before the strongly basic groups are completely exhausted[27,77].
3. Methanol is evolved in appreciably smaller amounts than that of the weakly basic groups formed[79,112].
4. The content of trimethylamine in the aqueous extract is lower than that of OH^- ions and the deaminated amino-groups formed[79].
5. The unsatisfactory description of the kinetics of the deamination and degradation of the amino-groups by first-order rate equations[75,77,79].
6. The presence of secondary amines among the decomposition products of the anion-exchange resin in the OH-form at 150°C.[77]

We regard the deamination and degradation processes of the amino-groups[100,101] as complex parallel-consecutive reactions involving the nucleophilic substitution of the trialkylamino-group in tetra-alkylammonium by a nucleophilic residue of the molecule of the solvent or the solute, which may consist of products split off from the anion-exchange resin. In these reactions OH^- ions exhibit a catalytic activity[102] and therefore the rate of deamination and degradation of the amino-groups in the OH-form of the anion-exchange resin is much higher than in the Cl-form.

The role of OH^- consists in the activation of the nucleophilic agent as a result of interaction with it. When anion-exchange resins in the OH-form are heated in alcohol, acetone, water, and aqueous solutions of amines the nucleophilic agents are anions (R_1O^-, $CH_3C\lesssim^{CO^-}_{CH_2}$), carbanions ($CH_3COCH_2^-$), hydrated hydroxide ions ($H_2O.OH^-$), and neutral ($R_1-\underset{R_2}{\underset{|}{N}}-R_3$) or hydrated molecules $[(R_1-\underset{R_2}{\underset{|}{NH}}-R_3)OH]$.

In order to understand the chemical reactions of the amino-groups of anion-exchange resins when these are heated in various media, one must take into account the polarisation of the bonds in the amino-group and the resulting induced charges. In the quaternary ammonium groups of AV-17 and AV-27 resins, an induced positive charge arises at the carbon atoms linked to nitrogen as a result of a powerful negative inductive effect[78]. Owing to the influence of the alcoholic hydroxyl, the positive charge induced on the carbon atom of the ethanol group in AV-27 anion-exchange resin is higher than on the other carbon atoms. The presence of an induced positive charge facilitates attack on the carbon atoms by the nucleophilic agent. Each of the carbon atoms linked to nitrogen and the second carbon atom of the ethanol group of AV-27 anion-exchange resin is subject to nucleophilic attack.

Taking into account the foregoing factors, one possible mechanism for the deamination and degradation of the amino-groups of AV-17 anion-exchange resin on heating in sealed tubes with water can be represented schematically by the following reactions[101]:

$$RCH_2\overset{+}{N}(CH_3)_3 + OH^- \rightleftarrows RCH_2N(CH_3)_3OH\ , \qquad (24)$$

$$RCH_2N(CH_3)_3OH + H_2O\cdot HO^- \begin{cases} \rightarrow RCH_2OH + HN(CH_3)_3OH + OH^-\ , & (25) \\ \rightarrow RCH_2NH(CH_3)_2OH + CH_3OH + OH^-\ . & (26) \end{cases}$$

The trimethyl- and benzyldimethyl-ammonium hydroxides evolved are readily dehydrated and converted into tertiary amines:

$$HN(CH_3)_3OH \rightleftarrows H_2O + N(CH_3)_3\ , \qquad (27)$$

$$RCH_2NH(CH_3)_2OH \rightleftarrows RCH_2N(CH_3)_2 + H_2O\ . \qquad (28)$$

Part of the trimethylamine formed dissolves in the aqueous phase and, after Donnan sorption, can participate in the nucleophilic substitution reaction:

$$RCH_2N(CH_3)_3OH + N(CH_3)_3 \rightarrow RCH_2N(CH_3)_2 + N(CH_3)_4OH\ . \qquad (29)$$

When the OH-form of the anion-exchange resin is heated in trialkylamine, the formation of trialkylmethylammonium hydroxide via a reaction of type (29) is probably accompanied also by the substitution of the amino-group of the resin:

$$RCH_2N(CH_3)_3OH + R_1-N\lesssim^{R_3}_{R_2} \rightarrow \left(RCH_2N\lesssim^{R_1}_{R_3}R_2\right)OH + N(CH_3)_3\ . \qquad (30)$$

The above reactions explain some of the contradictions noted above which do not fit within the framework of the old hypotheses. Thus the formation of tetramethylammonium hydroxide via reaction (29) should lead to an increased contribution of the degradation process to the overall loss of capacity by the anion exchanger with increase of the duration of heating and to the appearance of a deficiency of methanol and trimethylamine compared with the content of the weakly basic groups accumulating in the resin and of

OH^- ions in solution. Naturally the deficiency should correspond to the amount of tetramethylammonium hydroxide formed. The cessation of the deamination of strongly basic groups on heating can be explained by postulating that an equilibrium is established between the deamination and amination processes. The amination of the polymeric alcohol produced in reaction (25) by trimethylamine can be represented thus:

$$RCH_2OH + N(CH_3)_3 \rightarrow RCH_2N(CH_3)_3OH\ . \qquad (31)$$

When AV-17 anion-exchange resin is heated in alcohols [101], the following reactions probably occur together with reaction (24):

$$RCH_2N(CH_3)_3OH + R_1O^- \rightarrow RCH_2OR_1 + N(CH_3)_3 + OH^-\ , \qquad (32)$$

$$RCH_2N(CH_3)_3OH + R_1O^- \rightarrow RCH_2N(CH_3)_2 + CH_3OR_1 + OH^-\ . \qquad (33)$$

The involvement of trimethylamine in reactions of types (29) and (31) is in this case less likely than in water owing to its binding by the alcohol molecules into complexes [105].

The heating of AV-17 anion-exchange resins in water under dynamic conditions is accompanied by the removal from the reaction zone of all the products of the conversion of the amino-groups and the processes should be restricted to reactions (25) and (26). In a mixed bed, only trimethylammonium ions are removed, and methanol, which remains partly in the anion-exchanger phase, participates in reactions of types (32) and (33).

The deamination and degradation of AV-17 anion-exchange resin on heating in acetone are due primarily to the interaction of the amino-groups with the solvent and not with the water evolved in the Aldol condensation or contained in the resin. This is confirmed by the much greater losses of capacity by the anion exchanger in acetone than in water. The changes in AV-17 anion-exchange resin in acetone can be represented schematically as follows:

$$CH_3C(O^-)(CH_3)(CH_2) \rightarrow RCH_2OC{=}CH_2 + N(CH_3)_3 + OH^-\ , \qquad (34)$$

$$RCH_2N(CH_3)_3OH + CH_3COCH_2^- \rightarrow RCH_2N(CH_3)_2 + CH_3COC_2H_5 + OH^-\ , \qquad (35)$$

$$RCH_2N(CH_3)_3OH + CH_3COCH_2^- \rightarrow RCH_2CH_2COCH_3 + N(CH_3)_3 + OH^-\ . \qquad (36)$$

When AV-27 anion-exchange resin is heated in water and alcohols the following reactions are likely, disregarding secondary processes involving the products (for example under dynamic conditions):

$$RCH_2N(CH_3)_2OH + H_2O \cdot OH^- \rightarrow RCH_2NH(CH_3)_2OH + HOCH_2CH_2OH + OH^-, \qquad (37)$$

$$RCH_2N(CH_3)_2OH + H_2O \cdot OH^- \rightarrow RCH_2OH + HN(CH_3)_2OH + OH^-\ , \qquad (38)$$

$$RCH_2N(CH_3)_2OH + H_2O \cdot OH^- \rightarrow RCH_2N(CH_3)_3OH + H_2CO + OH^-\ , \qquad (39)$$

$$RCH_2N(CH_3)_2OH + H_2O \cdot OH^- \rightarrow RCH_2NH(CH_3)OH + CH_3OH + OH^-\ , \qquad (40)$$

$$RCH_2N(CH_3)_2OH + R_1O^- \rightarrow RCH_2OR_1 + N(CH_3)_2OH + OH^-\ , \qquad (41)$$

$$RCH_2N(CH_3)_2OH + R_1O^- \rightarrow RCH_2N(CH_3)_2 + R_1OCH_2CH_2OH + OH^+\ , \qquad (42)$$

$$RCH_2N(CH_3)_2OH + R_1O^- \rightarrow RCH_2N(CH_3)CH_2CH_2OH + CH_3OR_1 + OH^-\ . \qquad (43)$$

The first attempts at a kinetic treatment of the experimental decrease of the exchange capacity with respect to strongly basic groups on heating AV-17 and AV-27 anion-exchange resins in the OH-form in water and organic media reduced to the derivation of formal empirical relations of the type $\lg E^{SBG} - f(\lg\tau)$ [13] or to the application of the equation for first-order reactions [75,77,79,106]. We must emphasise that in almost all cases the kinetic curves were found to consist of two sections with different linear slopes. The presence of two stages were explained [10,106] by the energy non-equivalence of the bonds between the amino-groups and the anion-exchanger matrix, while other workers [13,17] suggested that the reaction is inhibited by the deamination product—trimethylamine.

According to Bauman's data [106], the second, slower stage in the decrease of the exchange capacity of Amberlite IRA-400 anion-exchange resin in water is described satisfactorily by a first-order rate law with a 50% conversion time equal to 43 days at 90°C. The authors of later investigations [77,79] adopted the first-order equation for the entire range of deamination and degradation processes involving AV-17 anion-exchange resin in water, but the resulting scatter of the observed rate constants about the mean was unduly great (±60%) and therefore one can hardly regard this attempt as successful.

The change in AV-17 and AV-27 anion-exchange resins in the OH-form on heating in water and ethanol is described satisfactorily by a linear relation between $\lg E^{SBG}$ and $\lg\tau$. [13] However, in acetone the relation becomes more complicated and, when the anion exchanger is re-used, the rate of change of the exchange capacity falls. This feature of the properties of the anion-exchange resin was attributed [95] to its catalytic activity and reactions of the medium.

It follows from the foregoing that the above kinetic equations for the description of the processes involved in the decrease of the exchange capacity of anion-exchange resins are approximate and apply to special cases only.

In recent years a new promising trend appeared in studies on the kinetics of the elimination of functional groups from ion-exchange resins, the principles of which were laid down in a number of investigations [36,37,97,107,108]. The main idea of these studies is that the molecules of the solvent (water or organic liquid) in the solvation shells in the resin phase participate in the process involving the removal of the functional groups. The total amount of solvent in the solvation shells is proportional to the exchange capacity throughout the experiment, since during the heat treatment part of the solvation shell of the functional group split off is removed with it from the resin phase.

The above principles were used in a general treatment of the kinetic data for the deamination of AV-17 anion-exchange resin in the Cl-form, which is the only factor in the decrease of its exchange capacity [54]. Taking into account the foregoing, the rate of deamination in water is defined by the equation

$$-dE/d\tau = k'\,E\,\bar{C}_{H_2O}\ . \qquad (44)$$

Since

$$\bar{C}_{H_2O} = nE\ , \qquad (45)$$

Eqn.(44) is converted into the equation for a reaction which is second-order with respect to the concentration of the functional groups:

$$-dE/d\tau = k'E^2n = kE^2, \qquad (46)$$

where n is the solvation number of the functional group (mmoles H_2O mequiv.$^{-1}$). Under the initial conditions ($\tau = 0$, $E = E_0$),

$$E = E_0/(1 + kE_0\tau). \qquad (47)$$

The agreement between the experimental data for the deamination of AV-17 anion-exchange resin in the Cl-form

and the values calculated by Eqn.(47) has been demonstrated convincingly[107]. The temperature variations of the apparent rate constant for the deamination reaction obeys the Arrhenius equation quite satisfactorily with a pre-exponential factor of $(4.3 \pm 0.1) \times 10^{17}$ kg matrix mole^{-1} h^{-1} and an activation energy of 40.2 ± 0.2 kcal mole^{-1}.

The mechanism[44] and kinetics of the processes occurring[107] change with decrease of the water content of the anion-exchange resin, deamination being supplemented by degradation.

A detailed study of the kinetics of the deamination of AV-17 anion-exchange resin in the Cl-form in alcohols has been made[97]. It might have been expected that in alcohols, as in water, the deamination of the Cl-form of the resin could be described by the equation for second-order reactions. This is indeed the case for all the alcohols except methanol[97]. The kinetics of the deamination of AV-17 anion-exchange resin in methanol obey a first-order rate law. Evidently in this case the effect of the high affinity of methanol for the active groups operates, as a result of which the nucleophilic substitution reaction involves the same mechanism as under homogeneous conditions. The amount of trimethylammonium chloride[97] varies with time according to a curve with a maximum, which indicates its consecutive transformation via the reaction

$$HN(CH_3)_2Cl + CH_3OH \rightarrow N(CH_3)_4Cl + H_2O \ . \qquad (48)$$

This concept is fully consistent with the correspondence of the overall content of nitrogen-containing compounds in the resin decomposition products both to the loss of exchange capacity and to the total amount of Cl^- ions in the liquid phase. Bearing in mind that the kinetics of reaction (48) are described by a first-order equation[109] the decrease of the exchange capacity of AV-17 anion-exchange resin (E) in methanol via reactions (21) and (22) and of the accumulation of trimethylammonium (C_1) and tetramethylammonium (C_2) chlorides is described[97] by the equations

$$-dE/d\varepsilon = (k_1 + k_2)E \ , \qquad (49)$$

$$dC_1/d\tau = \frac{k_1^2}{k_1 + k_2} \cdot E - k_3 C_3 \ , \qquad (50)$$

$$dC_2/d\tau = \frac{k_2}{k_1 + k_2} \cdot E + k_3 C_1 \ , \qquad (51)$$

where k_1, k_2, and k_3 are the apparent rate constants for reactions (22), (21), and (48). For the initial conditions ($\tau = 0$, $E = E_0$, $C_1 = 0$, and $C_2 = 0$), the solution of Eqns. (49)–(51) is

$$E = E_0 \cdot \exp[-(k_1 + k_2)\tau] \ , \qquad (52)$$

$$C_1 = \frac{k_1^2 E_0}{(k_1 + k_2)(k_1 + k_2 - k_3)} \{\exp(-k_3\tau) - \exp[-(k_1 + k_2)\tau]\} \ , \qquad (53)$$

$$C_2 = \frac{E_0}{(k_1 + k_2)} \left\{ \frac{k_1^2}{(k_1 + k_2 - k_3)} [1 - \exp(-k_3\tau)] - \left[\frac{k_1^2 \cdot k_3}{(k_1 + k_2)(k_1 + k_2 - k_3)} + \frac{k_2^2}{(k_1 + k_2)} \right] [1 - \exp[-(k_1 + k_2)\tau]] \right\} \ . \qquad (54)$$

The apparent rate constants for the above reactions at different temperatures and the results of calculations using the Arrhenius equationare presented in Table 6.[97]

The subscripts 1, 2, and 3 to the symbols k, ΔU, and A show that they refer to reactions (22), (21), and (48) respectively.

More complete information about the process kinetics on heating anion-exchange resins in the OH-form may be obtained taking into account the mechanism proposed[101] and the characteristics of the behaviour of the swollen resin. The resin is then regarded[111] as a pseudohomogeneous system consisting of the hydrocarbon matrix, fixed ions, counterions, hydration (solvation) shells, and the molecules sorbed from the external solution. During the heat treatment, the ions and molecules sorbed by the resin phase (by the hydration shells) are expelled from it by the elastic forces of the matrix together with the functional groups eliminated and the hydration shells. Thus during the heat treatment of the resin, the content of all the components, except the weight of the matrix, changes. Hence it follows that, in calculations on the kinetics of the elimination of functional groups from resins, the method of expressing the concentrations of the remaining components per litre of the solvent, which is generally adopted in physical chemistry, is inapplicable and the method proposed previously[37] in which they are referred to 1 g (1 kg) of the matrix treated formally as a "solvent" is the most reliable. The dilution of the mobile counterions and sorbed molecules by the solvent in the resin phase is then taken into account by the molality $\bar{m} = \bar{C}d_S/\bar{C}_S\epsilon_S$, where $\bar{C}$ and $\bar{C}_S$ are the concentrations of the dissolved component and the solvent in the resin phase [mequiv. (mmole)/g matrix] and d_S and ϵ_S are the density and the molecular weight of the solvent.

Table 6. Kinetic parameters of reactions (22), (21), and (48) in methanol[97].

Temp., °C	Reaction rate constant, h^{-1}			Activation energy, kcal mole^{-1}	Pre-exponential factor in Arrhenius equation, h^{-1}
	10^2k_1	10^2k_2	10^2k_3		
160	3.66±0.08	0.79±0.06	2.70±0.06	$\Delta U_1 = 35$	$A_1 = 1.2 \cdot 10^{16}$
170	7.6 ±0.2	2.14±0.14	5.45±0.17	$\Delta U_2 = 40$	$A_2 = 6.0 \cdot 10^{17}$
180	20.0 ±1.4	6.3 ±0.5	10.7 ±0.8	$\Delta U_3 = 26$	$A_3 = 4.1 \cdot 10^{11}$

Taking into account reactions (24)–(27), (29), and (31) and the analogies with the treatment of Tulupov and Shaburov[101], the kinetics of the processes involving the decrease of the exchange capacity with respect to strongly basic groups (E^{SBG}), deamination (q_1), and degradation (q_2) of AV-17 anion-exchange resin on heating with water in sealed tubes are described by the following equations:

$$-dE^{SBG}/d\tau = (k'_{25} + k'_{26})\bar{C}_b\bar{C}_a/\bar{C}_{H_2O} + k'_{29}\bar{C}_b\bar{C}_e/\bar{C}_{H_2O} - k'_{31}\bar{C}_f\bar{C}_e/\bar{C}_{H_2O}, \qquad (55)$$

$$dq_1/d\varepsilon = k'_{25}k'_{26}\bar{C}_b\bar{C}_a/\bar{C}_{H_2O}(k'_{25} + k'_{26}) - k'_{31}\bar{C}_f\bar{C}_e/\bar{C}_{H_2O} \ , \qquad (56)$$

$$dq_2/d\tau = k'_{26}k'_{26}\bar{C}_b\bar{C}_a/\bar{C}_{H_2O} + k'_{29}\bar{C}_b\bar{C}_e/\bar{C}_{H_2O} \ . \qquad (57)$$

The material balance equation is

$$E_0^{SBG} = E^{SBG} + q_1 + q_2 \ . \qquad (58)$$

Assuming that the strongly basic groups of the anion-exchanger are fully dissociated, like alkalis of the NaOH type, and that $\bar{C}_{RCH_2\dot{N}(CH_3)_3} = E^{SEG}$, Eqns.(55)–(57) can be reduced to the following form by simple rearrangements:

$$-dE^{SBG}/d\tau = (k''_{25} + k''_{26})(E^{SBG})^2(1 + \alpha)\bar{m}_{OH^-} + k''_{29}E^{SBG}\bar{m}_e\bar{m}_{OH^-} - k''_{31}(E^{SBG})^2 \cdot \bar{m}_{OH^-}\bar{m}_e \ , \qquad (59)$$

$$dq_1/d\tau = \frac{k''_{25} \cdot k''_{26}}{k''_{25} + k''_{26}}(E^{SBG})^2(1 + \alpha)\bar{m}_{OH^-} - k''_{31}(E^{SBG})^2\bar{m}_e\bar{m}_{OH^-}(1 + \alpha) \ , \qquad (60)$$

$$dq_2/d\tau = \frac{k''_{29} \cdot k''_{26}}{k''_{25} + k''_{26}}(E^{SBG})^2(1 + \alpha)\bar{m}_{OH^-} + k''_{29}(E^{SBG})\bar{m}_e\bar{m}_{OH^-} \ . \qquad (61)$$

The following notation is employed: $a = H_2O.OH^-$; $b = RCH_2N(CH_3)_3OH$; $e = N(CH_3)_3$; $f = RCH_2OH$; $g = RCH_2\overset{+}{N}(CH_3)_3$; α = content (mmole mequiv.$^{-1}$) [108] of tetramethylammonium hydroxide in the hydration shell of the functional group sorbed by the Donnan mechanism;

$$k''_{25} = k'_{25}K_{24}K_e \cdot 55{,}5\,\bar{\gamma}_g\bar{\gamma}^2_{OH^-}/\bar{\gamma}_a\bar{\gamma}_b;\ k''_{26} = k'_{26}k''_{25}/k'_{25},$$
$$k''_{29} = k'_{29}K_{24} \cdot 55{,}5^2\bar{\gamma}_g\gamma_{OH^-}/\gamma_{H_2O}\bar{\gamma}_b;\ k''_{31} = k'_{31}k'_{25}k''_{25}/(k'_{25} + k'_{26}).$$

The numerical subscript to the rate constant k or the equilibrium constant K corresponds to the number of the reaction, K_e is the equilibrium constant for the hydration of hydroxide ions, γ is the activity coefficient, and a bar over a symbol implies that it refers to the resin phase.

The solution of Eqns. (59)–(61) involves considerable difficulties, since the molalities of the hydroxide ions and trimethylamine in the resin phase vary continuously as the deamination and degradation of the anion-exchange resin proceed.

The molality of trimethylamine in the resin phase found from the Donnan equilibrium [110] depends on the proportions of the external solution and the resin in the experiment and on the solubility of trimethylamine in the external solution:

$$\bar{m}_e = \frac{-0.018E^{SBG}}{2\bar{C}_{H_2O}} + \sqrt{\left(\frac{0.018E^{SBG}}{2\bar{C}_{H_2O}}\right)^2 + \beta\frac{0.018C_e}{C_{H_2O}}} \quad (62)$$

As the limiting solubility of triethylamine in the external solution is approached, its molality in the resin phase will tend to a constant value. The molality of OH^- ions in the anion-exchange phase is determined by the capacity for hydration of the strongly basic amino-groups† and tetramethylammonium hydroxide sorbed as a result of the Donnan distribution:

$$\bar{m}_{OH^-} = \frac{0.018E^{SBG}}{2\bar{C}_{H_2O}} + \sqrt{\left(\frac{0.018E^{SBG}}{2\bar{C}_{H_2O}}\right)^2 + \beta_1\frac{0.018C_{N(CH_3)_4OH}}{C_{H_2O}}}, \quad (63)$$

where β and β_1 are the ratios of the activity coefficients of trimethylamine and tetramethylammonium hydroxide in the resin phase and in the external solution.

As tetramethylammonium hydroxide accumulates, the molality of OH^- ions in the resin phase and the rates of the deamination and degradation processes should increase. However, in the presence of a large excess of "external" water and also on heating the anion-exchange resin under dynamic conditions and in a mixed bed, the Donnan sorption of trimethylamine and tetramethylammonium hydroxide may be neglected. In such experiments the contribution of reactions (29) and (31) to the decrease of the exchange capacity of the anion exchanger will be reduced to a minimum and Eqns. (59) to (61) simplify to

$$-dE^{SBG}/d\tau = (k'_{25} + k'_{26})(E^{SBG})^2\bar{m}_{OH^-}, \quad (64)$$

$$dq_1/d\tau = \frac{(k'_{25})^2}{(k'_{25} + k'_{26})} \cdot (E^{SBG})^2\bar{m}_{OH^-}, \quad (65)$$

$$dq_2/d\tau = (k'_{26})^2(E^{SBG})^2\bar{m}_{OH^-}/(k'_{25} + k'_{26}). \quad (66)$$

The change in the molality of OH^- ions in the anion-exchanger phase during the experiment may be neglected (as in experiments with cation exchange resins [111]) and, having assumed that the activity coefficient ratio in the resin is constant, we obtain the following solution of Eqns. (64)–(66) for the initial conditions ($\tau = 0$, $E^{SBG} = E^{SBG}_0$, $q_1 = q_2 = 0$):

$$E^{SBG} = E^{SBG}_0/[1 + (k_{25} + k_{26}) \cdot E^{SBG}_0 \cdot \tau], \quad (67)$$

$$q_1 = k_{25} \cdot E^{SBG}_0/[k_{25} + k_{26} + 1/\tau \cdot E^{SBG}_0], \quad (68)$$

$$q_2 = k_{26} \cdot E^{SBG}_0/[k_{25} + k_{26}) + 1/\tau \cdot E^{SBG}_0], \quad (69)$$

where $k_{25} = k'_{25}\bar{m}_{OH^-}$ and $k_{26} = k'_{26}\bar{m}_{OH^-}$ are the apparent rate constants for the deamination and degradation of the anion exchanger amino-groups.

One must note that Eqns. (67)–(69) make it possible to carry out calculations on the process kinetics even when there are difficulties in the determination of the molality of OH^- ions (macroporous and condensation resins) or in the interpretation of published experimental data containing insufficient information about the capacity of the functional groups for hydration. In such cases one can find the constant k, which includes the molality of hydroxide ions.

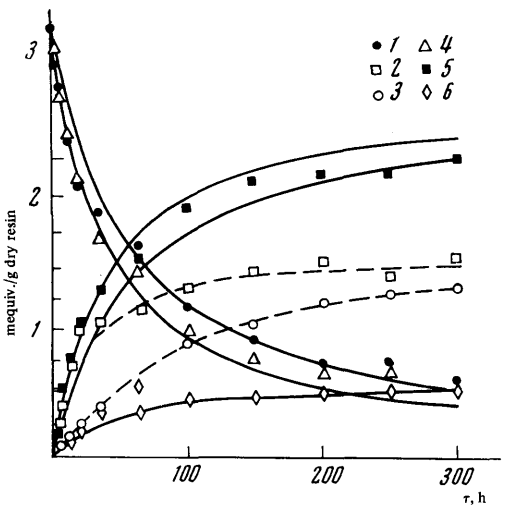

Figure 1. Decrease of E^{SBG} (*1* and *4*), deamination (*2* and *5*), and degradation (*3* and *6*) of the amino-groups of AV-17 anion-exchange resin in the OH-form at 125°C in water (*1*–*3*) and in a mixed bed (*4*–*6*). The continuous curves have been calculated by Eqns. (67)–(69) and the dashed curves have been drawn on the basis of the experimental data; points *1*–*6* have been taken from Roginskaya' et al. [27]

Thus interpretation of the experimental results obtained on heating AV-17 anion-exchange resin under dynamic conditions [98] and in a mixed bed [27] demonstrated the satisfactory applicability of Eqns. (67)–(69). The discrepancy between the experimental and calculated data for high degrees of decomposition of the amino-groups of AV-17 anion-exchange resin in a mixed bed is due to the conversion of the functional groups from the OH-form into the sulphate-form as a result of the neutralisation of the sulphuric acid evolved on desulphonation of KU-2 cation-exchange resin [27]. Reactions (29)–(31) have a compensating effect on the decrease of E^{SBG} and therefore, even when the anion-exchange resin is heated with water in sealed tubes, there is a satisfactory agreement between the experimental data and the values calculated by Eqn. (67) (Fig. 1).

† The dissociation of the weakly basic groups is neglected.

The deamination and degradation curves calculated by Eqns.(68) and (69) did not then of course coincide with the experimental curves, since the contributions of the second terms in Eqns.(56) and (57) cannot be neglected. The contribution of reactions (29) and (31) to the deamination and degradation processes increases with the duration of heating and also with decrease of the degree of cross-linking of the matrix and of the ratio of the volumes of the external solution and the resin in the experiment. In studies by Shaburov and coworkers [13,74,75], the relative content of water was probably significantly higher than in the work of Roginskaya and coworkers [27] and therefore in the first case even deamination and degradation of amino-groups are frequently described satisfactorily by Eqns.(68) and (69). This can be illustrated by the data in Fig. 2.

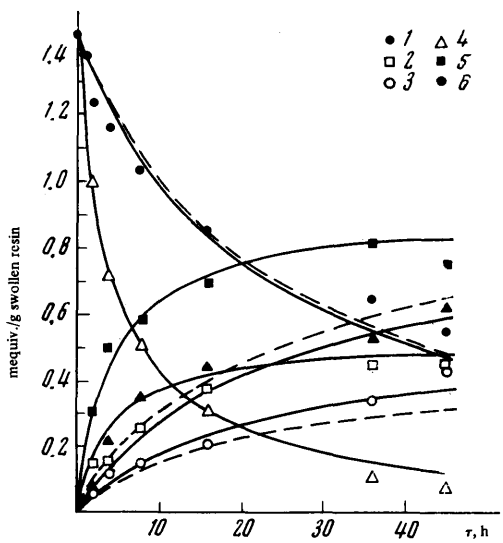

Figure 2. Decrease of E^{SBG} (*1* and *4*), deamination (*2* and *5*), and degradation (*3* and *6*) of the amino-groups of AV-17 × 6 anion-exchange resin in the OH-form on heating in water at 135°C (*1–3*) and 150°C (*4–6*). The continuous and dashed curves have been calculated by Eqns.(67)–(69) and (67)–(71) respectively. The experimental points have been taken from Shaburov [75].

The sum of the apparent rate constants $k_{25} + k_{26}$ was found from the relation $1/E^{SBG} - 1/E_0^{SBG} = (k_{25} + k_{26})\tau$. The constants k_{25} and k_{26} were found from the sum of the constants and the contributions of the deamination and degradation processes under the initial conditions when reactions (29) and (31) may be neglected. The rate constants calculated by this method, the ranges of variation of the exchange capacity at different temperatures, and the calculated exchange capacities E_0^{SBG} (in mequiv./g matrix) (from the formulae in Table 1) are listed in Table 7.

The data in Table 7 show that the deviations from the mean values of the apparent rate constants for the deamination and degradation of the amino-groups found with the aid of the equations proposed amount to 10–25% and are appreciably smaller than those found using the equations for first-order reactions (±60%). [77,79] This finding is undoubtedly evidence in support of the new principles underlying the treatment of the thermal stability of the functional groups of ion-exchange resins.

One must note that in the kinetic treatment of published data about 13% of amino-groups, which were split off in water and alcohols at an appreciably higher rate than the remaining groups, were detected only for the anion-exchanger specimen with 16% DVB.

Table 7. Apparent rate constants for the deamination (k_{25}) and degradation (k_{26}) of the amino-groups of anion-exchange resins on heating in water.

[a]The exchange capacity was quoted in the original paper in mequiv./g dry resin. [b]The exchange capacity in the original paper was quoted in mequiv./g swollen resin. [c]These constants in the Arrhenius equation correspond to $t = 190°C$. [d]The resin was heated in a mixed bed with KU-2 cation-exchange resin in the H-form. [e]The resin was heated under dynamic conditions.

The kinetic parameters in the Arrhenius equation obtained for the experiments in water on the basis of the data of Shaburov and coworkers [75] and Roginskaya and coworkers [77] are virtually identical. Thus the deamination of AV-17 × 6 (Shaburov [75]) and AV-17 × 8 (Roginskaya et al. [77]) anion-exchange resins in water is characterised by activation energies of 27 ± 2 and 26 ± 3 kcal $mole^{-1}$ and pre-exponential factors of (3.9 ± 2.5) × 10^{12} and (1.2 ± 0.2) × 10^{12} kg matrix $mole^{-1}$ h^{-1}; the corresponding parameters for their degradation are 26 ± 6 and 25 ± 3 kcal $mole^{-1}$ and (8.5 ± 6.3) × 10^{11} and (9.9 ± 3.6) × 10^{11} kg matrix $mole^{-1}$ h^{-1} respectively.

Eqns. (67)–(69) can be successfully extended to other media. Thus their use yielded satisfactory results for experiments in which AV-17 anion-exchange resin was heated not only in alcohol but also in aqueous alcoholic media and in acetone, as shown by the slight scatter of the apparent rate constants about the mean (Table 8) and the satisfactory agreement between the calculated and experimental kinetic curves (Fig. 3).

Table 8. Apparent rate constants and the contribution of deamination to the loss of capacity of anion-exchange resins in the OH-form at 100°C in organic media and aqueous methanol.

Anion-exchange resin	Medium	Deamination, %	Rate constant, 10^4 kg matrix mole^{-1} h^{-1}		References
			deamination k_{32}	degradation k_{23}

AV-27	CH_3COCH_3	27±1	53±19*	87 ±31**	94

Note. In acetone, the deamination (*) and degradation (**) constants are $k_{34} + k_{36} + k_{35}$ respectively.

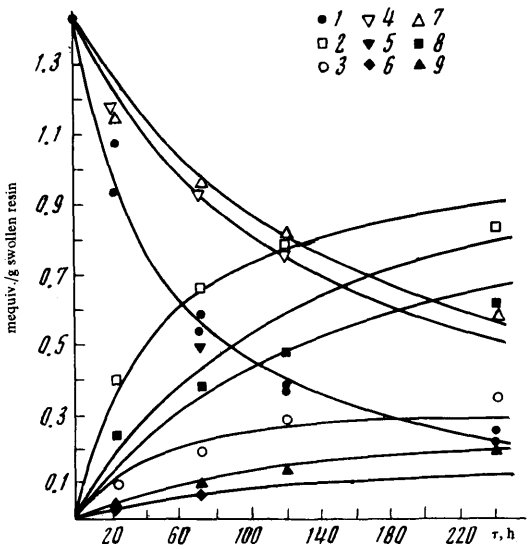

Figure 3. Decrease of E^{SBG} (*1*, *4*, and *7*), deamination (*2*, *5*, and *8*), and degradation (*3*, *6*, and *9*) of the amino-groups of AV-17 × 6 anion-exchange resin in the OH-form at 100°C in methanol (*1–3*), pentanol (*4–6*), and 50% aqueous methanol (*7–9*). The curves have been calculated by Eqns. (67)–(69); the experimental points *1–9* have been taken from Shaburov and coworkers [13,75].

According to Shaburov [75], in ethanol the deamination process has an activation energy of 28 ± 2 kcal mole^{-1} and a pre-exponential factor of (5.2 ± 0.6) × 10^{13} kg matrix mole^{-1} h^{-1}; the corresponding parameters for its degradation are 28 ± 3 kcal mole^{-1} and (2.6 ± 0.4) × 10^{13} kg matrix mole^{-1} h^{-1}.

Despite the expected wide variety of reactions on heating AV-27 anion-exchange resin, the overall processes involving a decrease of E^{SBG}, deamination, and degradation are satisfactorily described by Eqns. (67)–(69) in all the media investigated, as shown by the small deviations of the rate constants from the mean values (Tables 7 and 8) and by the satisfactory agreement between the experimental points and the calculated kinetic curves (Figs. 4 and 5).

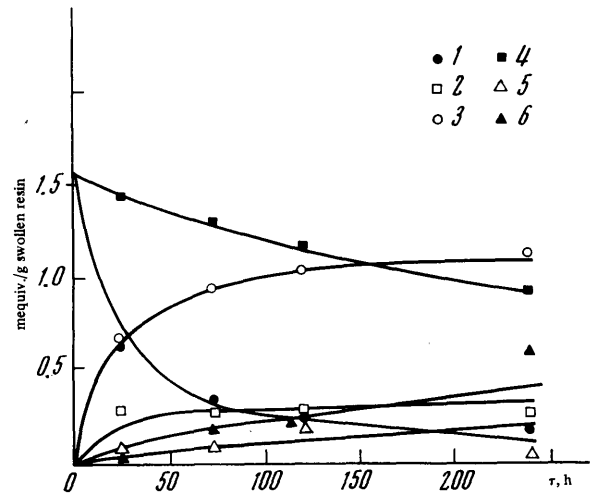

Figure 4. Decrease of E^{SBG} (*1* and *4*), deamination (*2* and *5*), and degradation (*3* and *6*) of the amino-groups of AV-27 anion-exchange resin in the OH-form in water at 100°C (*1–3*) and 75°C (*4–6*). The curves have been calculated by Eqns. (67)–(69); the experimental points *1–6* have been taken from Shaburov and Saldadze [13].

Eqns. (67)–(69) show that there should be a direct proportionality between the apparent rate constants for deamination and degradation and the molality of OH^- ions in the anion-exchanger phase in relation to the sorbed solution for resins with different contents of the cross-linking agent. The molalities of hydroxide ions in AV-17 resin specimens with 2.6 and 16% DVB calculated from the initial equivalent coefficients of moisture absorption capacity quoted by Shaburov et al. [74] are 1.52, 2.41, and 4.34 equiv.OH^-/litre water.

The linear relation between the constants k_{25} and k_{26} and the pre-exponential factors in the Arrhenius equation on the one hand and the molality of the hydroxide ion in the anion-exchanger phase on the other (Fig. 6) leads to a realistic method for the theoretical calculation of the thermal stability of the resins in water at any temperature. A similar relation was found earlier also for sulphonic acid cation-exchange resins [111].

The apparent rate constants for the deamination and degradation of the amino-groups may be calculated from equations which follow from Fig. 6:

$$k_{25} = (3.51 \cdot \bar{m}_{OH^-} - 2.50) \cdot 10^{12} \cdot \exp(-28 \cdot 10^3/RT) , \quad (70)$$

$$k_{26} = (1.36 \cdot \bar{m}_{OH^-} - 0.40) \cdot 10^{12} \cdot \exp(-28 \cdot 10^3/RT) . \quad (71)$$

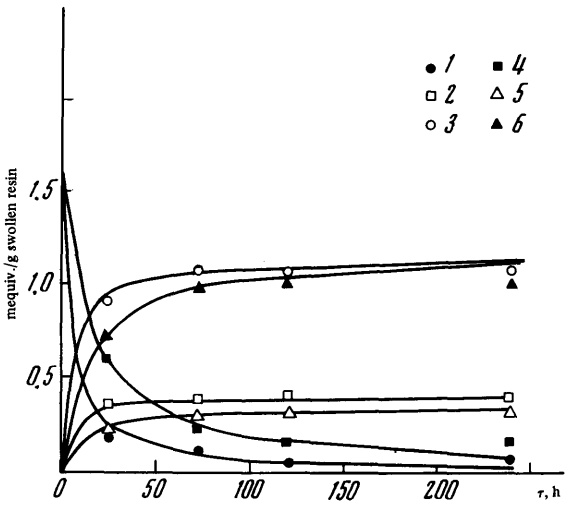

Figure 5. Decrease of E^{SBG} (*1* and *4*), deamination (*2* and *5*), and degradation (*3* and *6*) of the amino-groups of AV-27 anion-exchange resin in the OH-form at 100°C in ethanol (*1*–*3*) and pentanol (*4*–*6*). The curves have been calculated by Eqns. (67)–(69); the experimental points *1*–*6* have been taken from Shaburov and Saldadze [13].

The applicability of Eqns. (70) and (71) combined with Eqns. (67)–(69) for the calculation of the curves describing the decrease of E^{SBG}, deamination, and degradation may be illustrated by the data presented in Fig. 2 for experiments in which AV-17 anion-exchange resins were heated in water at 135°C.

The present stage in the development of studies on the thermal stability of anion-exchange resins is characterised by an endeavour on the part of investigators to extend the range of instrumental methods for the solution of many problems concerning not only the fate of the functional groups but also the changes in the matrix itself; they will provide a key to the creation of mechanically stable ion-exchange resins.

Another characteristic feature of such studies is an endeavour to unify and standardise the research techniques. Unfortunately little has yet been done in this important field.

A third and most important feature of the present stage in the development of studies on the thermal stability of resins is the concentration of the efforts of investigators on the elucidation of the mechanisms of processes involving the elimination of functional groups. The results presented in this review have demonstrated quite clearly the effect of the medium and its capacity to undergo changes under the influence of the anion-exchange counterions on the stability of the functional groups of the resin itself. This view concerning the relation between the catalytic activity and thermal stability of sulpho-groups was formulated in the previous review [1] and in this review has been developed further and given a more clear-cut theoretical basis.

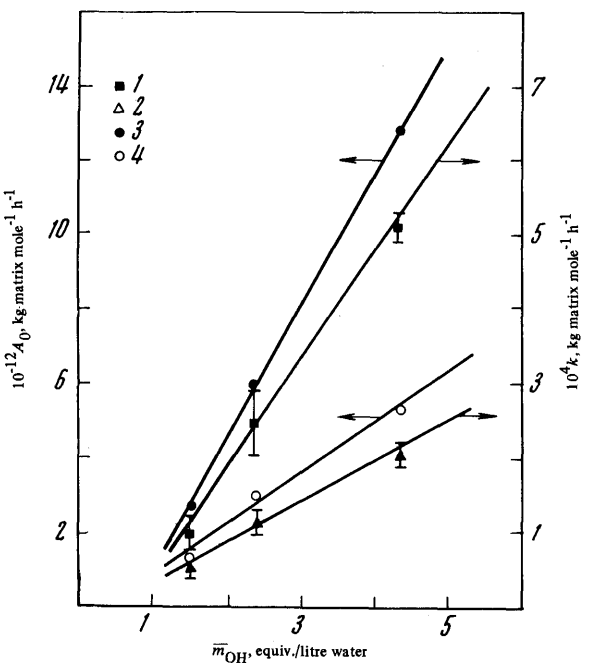

Figure 6. Variation of the apparent rate constants k at 100°C (*1* and *2*) and the pre-exponential factors A_0 in the Arrhenius equation (*3* and *4*) for the deamination (*1* and *3*) and degradation (*2* and *4*) of the amino-groups of AV-17 anion-exchange resin in water as a function of the molality of OH^- ions in the resin phase (points *1*–*4* have been obtained from the data of Shaburov et al. [74]).

The endeavour by investigators to give a mathematical description of the conversion of functional groups on the basis of a kinetic approach we believe to deserve all possible encouragement and further development.

The new ideas about the mechanisms of the deamination and degradation of anion-exchange resins in which the bond polarisation in the unit cell and the involvement of OH^- ions as reaction catalysts in the formation of intermediates are taken into account may not correspond to the true situation in all details and in this sense remain controversial. However, the fruitfulness of this approach is evident. With its aid, kinetic equations have been obtained giving a satisfactory description of earlier experimental data and allowing theoretical calculations, based on the known exchange capacities and molalities of the counterions in the resin phase, on the kinetics of the decrease of the content of strongly basic groups, deamination, and degradation of anion-exchange resins at any temperature. There is no doubt that further development

of studies in the field of the thermal stability of ion-exchange materials and (as model substances) of their low-molecular-weight analogues will create firm foundations for the synthesis of such materials in which the structural elements will be correctly combined and new resins with satisfactory operational properties will be created.

Organophosphorus Fungicides

A.F.Grapov and N.N.Mel'nikov

The review examines the applications of organic derivatives of phosphorus as agricultural fungicides. Trends in the development of research in this field have been noted and data are presented on the mechanism of the action of certain preparations. The bibliography includes 263 references.

I. INTRODUCTION

The use of organic derivatives of phosphorus as fungicides and herbicides constitutes a new and promising field of their application in the national economy [1-8]. The first studies in which the microbiological action of organic derivatives of phosphorus was noted were made at the beginning of the 1940's, but systematic investigations of their fungicidal and bactericidal properties were begun much later [9-11]. By 1972, 450 publications had been devoted to organophosphorus fungicides, some preparations found practical application, and others are being tested as experimental fungicides.

At the present time the main advances in the field of phosphorus-containing fungicides have been made in combating diseases of rice caused by the fungi *Piricularia* and *Pellicularia sasaki*. The reduction of the rice crop due to infection by *Piricularia* in the countries of South East Asia reaches 10%. As a result of vigorous measures taken to protect rice from disease, the losses in Japan have been reduced to 3%. Nevertheless they have been estimated at 250 000–350 000 tons of rice per year in an overall crop of 12–14 million tons [12,13].

The main preparations for the treatment of the infection of rice by Piricularia in Japan are phosphorus-containing fungicides (kitazin, kitazin P, inezin, hinosan, and cerezin) and antibiotics (kasugamycin and blasticidin). The industrial manufacture of these preparations was begun in 1966 [14] and in 1970 the manufacture of kitazin and kitazin P reached a total output of 1600 tons and that of hinosan 700 tons.

Phosphorus compounds with microbiological activities have a wide variety of chemical properties. Among these one encounters potential alkylating, acylating, and phosphorylating agents, oxidants, reductants, and complex-forming agents. These findings show that their action on the fungal cell is not unambiguous.

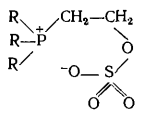
The advances in the chemistry of organic phosphorus-containing insecticides are in many ways related to the creation of a reliable model of the mechanism of the insecticidal action. For the mechanism of the fungicidal action, such a model has not been established so far. In view of the different types of action of organophosphorus preparations on the fungal cell, it is probably necessary to develop not one but several models. Unfortunately there have been virtually no biochemical studies on the action of phosphorus-containing preparations on processes in the fungal cell.

The bulk of the information on the fungicidal action of organic derivatives of phosphorus is concentrated in patent publications. The present review covers only the literature for the period 1967–1971 inclusive, since earlier studies on this question have been examined in a previous review [4].

II. DERIVATIVES OF PHOSPHOROUS AND PHOSPHINOUS ACIDS

The fungicidal and bactericidal activities of phosphorus(III) derivatives are probably associated with their reducing properties [4]. Dialkyl-, dicyclohexyl-, diphenyl-, and di(phenylethyl)-phosphinites exhibit bactericidal and bacteriostatic activities [15,16]. Cyclohexylammonium, piperidinium, and furfurylammonium salts of *O*-methyl- and *O*-phenyl-phosphorous acids also show germicidal properties [17]. It has likewise been noted that triaryl, tri(naphthylmethyl), and tri-(α-cyanopentachlorobenzyl) phosphites [19,20,21], dinitrophenyl phenylene phosphites [22], and a mixture of β-aminoethyl phosphite and *N*-β-hydroxyethyl phosphoramidite, obtained from *OO*-dimethylphosphorous acid and monoethanolamine [18], exhibit a high fungicidal activity against phytopathogenic fungi and also as antiseptics for the protection of wood.

The anhydrides of phenylphosphonous and arenesulphonic acids and dialkyl trimethylstannyl phosphites have been patented as agents effective against *Pellicularia sasaki* on rice [23,24].

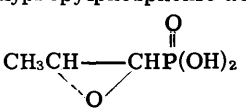


III. PHOSPHINES AND PHOSPHONIUM SALTS

Substituted phosphines show a low fungicidal activity. Chlorotri(diphenylphosphino)methane at a concentration of 30–100 mg litre^{-1} destroys the spores of *Venturia inaequalis* on apple seedlings [25]. Trialkylstannylhydroxyethyldialkylphosphines have been patented as germicidal preparations [26].

Trialkylbenzylphosphonium, triarylbenzylphosphonium, tetra-(α-hydroxybenzyl)phosphonium, and tetra(arylamino)phosphonium salts suppress the growth of pathogenic micro-organisms much more effectively than

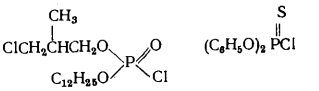
phosphines and aminophosphines [27-31]. Thus trialkylbenzylphosphonium salts suppress the growth of the spores of *Alternaria solani*, *Monilinia fructicola*, and *Stemphylium sarcinaeforme* and are effective against anthracnose and tomato blights [29]. The structure of both the cationic and anionic components of the molecule has a marked influence on its activity and the selectivity of its action. For example, alkyltriphenylphosphonium phosphorothioates and phosphorodithioates are several times as effective as the corresponding salts with inorganic anions in their action on the fungi *Alternaria* and *Botrytis* [30]. The considerable phytocidal activity of the preparations, which limits the scope of their application in plant cultivation, must be regarded as a disadvantage of this group of compounds [4].



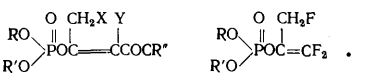
Phosphonium zwitterions, obtained by the reaction of trialkylphosphines with cyclic sulphates, suppress the growth of *Bacillis subtilus* and *Pullularia pullulans* [32].

IV. ACIDS OF TETRACOORDINATE PHOSPHORUS AND THEIR SALTS

O-Alkyl-, *O*-aryl-, and *OO*-diaryl-phosphorous acids and their salts show a moderate fungicidal activity against the fungi *Fusarium*, *Phytophthora*, *Pythium*, and *Aspergillus* [33-36]. For example, *O*-(1-diethylamino-2-propyl)*O*-dodecylphosphorous acid protects cucumber plants from mildew under greenhouse conditions at a dose of 2 kg per hectare [32]. The salts of alkylaminomethylphosphonic, *N*-substituted *O*-(α-aminobenzyl)phosphoric, phosphanilic, and difluorophosphanilic acids as well as laurylammonium *N*-laurylchloromethylphosphonamidate have been patented as germicides [37-39].



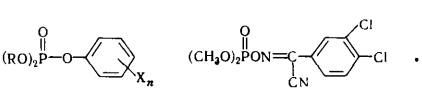
Studies on the microbiological activities of 1,2-epoxypropylphosphonic acid and its salts have been made in the laboratories of the Merck Company. The acid itself at a concentration of 0.01% completely suppresses the growth of the spores of *Macrosporium sarcinaeforme* and *Sclerotinia fructicola* [40-45]. The geometrical and optical isomers of 1,2-epoxypropylphosphonic acid



and its salts may be synthesised by the reaction of formylphosphonates and substituted ethylides [46], the thermolysis of sodium dioxolan-4-ylphosphonate [47], the reaction of α-hydroxypropionaldehyde with phosphorus tribromide followed by a rearrangement [48], by the oxidation of vinylphosphonates [49], and by other methods [44,50-53].

V. ESTERS OF TETRACOORDINATE PHOSPHORUS ACIDS

The halides of *O*-alkyl- or *O*-arylphosphoric and phosphorothioic acids are rarely used as organophosphorus pesticides in view of their low stability. However, some of them have been patented as the active principles of fungicidal preparations against *Alternaria* and *Tilletia* [35,54]:

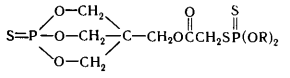


Phosphoric acid esters as a rule exhibit a moderate toxicity with respect to fungi. Among these, mention should be made of halogenovinyl phosphates obtained by the Perkow reaction from trialkyl phosphites and α-halogenocarbonyl compounds [55-57]:

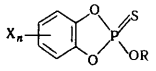
Dialkyl 2-alkoxycarbonyl-1,2-dibromoalkyl phosphates can be used as soil fungicides and in the treatment of seeds to prevent root rot. They are synthesised by the addition of bromine to the double bond of the corresponding vinyl phosphates [58]:

Nitrobenzyl, pentachlorophenyl, cyanophenyl, and cyanohalogenophenyl esters of phosphoric acid (with two other alkyl groups) [59-61] and the dimethylphosphate derivative of the oxime of 3,4-dichlorophenylglyoxylonitrile [62] also exhibit a fungicidal activity:

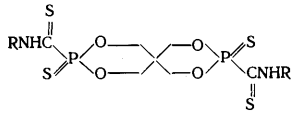
The last preparation effectively destroys the soil fungi *Fusarium oxysporum*, *Pythium debarianum*, *Rhizoctonia solani*, and *Sclerotium rolfsii*.



Among the esters of phosphonic and phosphinic acids, tested as fungicides, mention may be made of dialkyl 1,2-epoxyalkylphosphonates [63-65], alkyl halogenophenyl phenylphosphonates [67,69], dialkyl halogenobenzylphosphonates [68], and substituted amidines of dialkoxyphosphinyldichloroacetic acid [69]. These preparations are effective against various Gram-negative and Gram-positive microorganisms, the infection of rice by *Piricularia*, and tomato blight (due to *Phytophtora*); the majority of the preparations show little toxicity for warm-blooded animals and fish. Dialkyl sulphonylcarbamoylphosphonates are most toxic towards fungi; for example at a concentration of 0.01% diethyl toluene-*p*-sulphonylcarbamoylphosphonate suppresses the growth of more than 20 species of various phytopathogenic fungi [70,71]. Preparations of this group have been obtained by the addition of dialkyl phosphites to sulphonyl isocyanates:

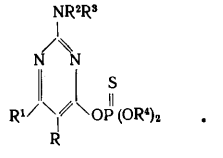


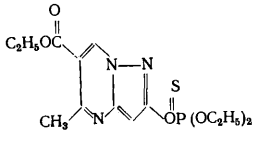
There are only isolated data about the fungicidal properties of the aryl esters of phosphorothionic and phosphonothionic acids containing various substituents in the aryl group—halogeno-, alkylthio-, alkylsulphonyl, alkylsulphonyl, trichloromethylthio-, β,β-dicyanovinyl, and certain others [72-80].



Cyclic phosphorothionates exhibit a moderate fungicidal activity in the treatment of diseases of fruit caused by

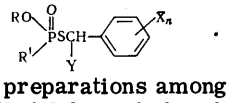
Phytophthora and *Fusarium* and of wheat smut in the *Graminae* [81-84].





Bisthiocarbamoyl spirophosphonothioates can be used as soil fungicides and fungicides for the treatment of green plants [85]:

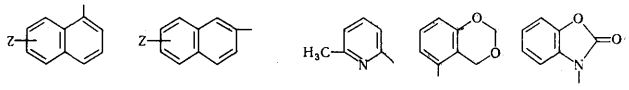
Phosphorothioic acid esters containing pyrimidine residues exhibit a high funcigidal activity against *Erysiphe cichoracearum* on cucumbers, *Phytophtora infestans* on tomatoes, *Puccinia recondita* and *Erysiphe graminis* on wheat, *Uncinula necator* and *Plasmopara viticola* on the vine, and *Podosphaera leucotricha* on the apple tree [86,87]:



The Hechst Company has proposed a new fungicide for the treatment of the mildew of wheat and other agricultural plants—diethyl 6-ethoxycarbonyl-5-methylpyrazolopyrimidine-2-phosphorothionate (Hoe 2873) [88].

Its toxicity is 140 mg kg^{-1} for rats, 435 mg kg^{-1} for rabbits, and 184 mg kg^{-1} for guineapigs. The preparation exhibits systemic activity.

Almost all the industrial phosphorus-containing fungicides which are being manufactured in Japan belong to the group of phosphorothiolic and phosphorodithiolic acids.



The fungicidal activity of *S*-benzyl derivatives of phosphorus acids has been investigated in detail mainly as an agent against the infection of rice by *Piricularia* [89-114]:

The most effective preparations among compounds of this class are *OO*-diethyl *S*-benzyl phosphorothiolate (kitazin), *OO*-di-isopropyl *S*-benzyl phosphorothioate (kitazin P), and *O*-ethyl *S*-benzyl phenylphosphonothioate (inezin).

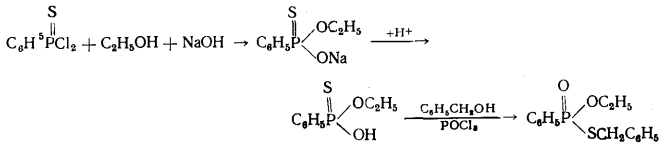
The phosphoric, phosphorothioic, and phosphotodithioic analogues of kitazin are much less effective. The methyl and higher homologues also exhibit a lower fungicidal activity. The introduction of various substituents (alkyl, halogeno-, nitro-, methylthio-, dialkylamino-, and alkanesulphonyl) into the phenyl ring or the introduction of the COOR and CN groups in the α-position of the benzyl residue decrease the fungicidal activity of these compounds.

Kitazin analogues containing the groups indicated below in place of the phenyl ring were investigated [111-114]:

as well as analogues with various electronegative groups [115,116]:

The effect of a change in the distance between the phosphorothiolic group and the phenyl ring was also studied [99]. All the preparations investigated exhibited a very moderate antipiriculariasis activity.

Kitazin, kitazin P, and inezin possess systemic fungicidal activity and are used against the diseases of rice caused by the fungi *Piricularia orizae* and *Pellicularia sasaki* at a dose of 1 kg per hectare. The toxicity of kitazin for rats is LD_{50} = 320 mg kg^{-1}, that of kitazin P is LD_{50} = 640 mg kg^{-1}, and that of inesine is LD_{50} = 750 mg kg^{-1}.

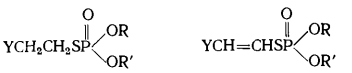


Studies on the mechanism of the action of kitazin showed that it acts on the permeability of the cell membrane of *Piricularia* fungi preventing the passage of carbohydrates and aminosugars, in particular glucose and glucosamine, into the fungal cell and promotes the loss of intracellular substances. Probably kitazin interferes with the biosynthesis of phytin in the fungal cell. It has almost no influence on the synthesis of proteins, phosphorylation processes, and endogenic and exogenic respiration [117-119].

It is noteworthy that *OO*-diethyl *S*-benzyl phosphorothioate was obtained for the first time by Kabachnik, Mastryukova, and Kurochkin in 1956 by the Michaelis–Bekker reaction [120,121]. At that time no one could even suggest that the compound might have fungicidal properties.

The industrial synthesis of kitazin and kitazin P consist in the benzylation of the ammonium salts of dialkyl phosphorothioates by benzyl chloride [122]:

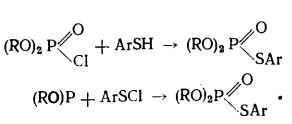
In the manufacture of inezin, the dichloride of phenylphosphonothioic acid is treated with 3.4–3.6 moles of NaOH in 80% alcohol. The alcohol is distilled off, the residue dissolved in water, and the small amount of the *OO*-diethyl phenylphosphonothioate formed is extracted with ether. The aqueous layer is acidified and the hydrogen *O*-ethyl phenylphosphonothioate formed is esterified by benzyl alcohol in the presence of phosphoryl chloride [108,122,123]:



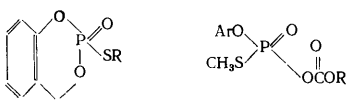
An interesting method for the preparation of inezin consists in the high-temperature *S*-benzylation of *OO*-diethyl phenylphosphonothioate by Pishchimuka's method [124]:

To extend the spectrum of fungicidal activity, it is suggested that mixtures of *OO*-dialkyl *S*-benzyl phosphorothioates with pentachlorobenzyl alcohol[125] or *O*-naphthyl-(*O*-aryl) *N*-methylcarbamates and also mixtures[126] of inezin with the antibiotic kasugamycin[127] be employed.

A number of studies have been made on the biological properties of β- and αβ-substituted *S*-ethyl phosphorothiolates and also *S*-vinyl phosphorothiolates:



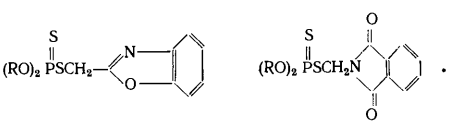
where Y = halogeno-, aryl-, alkoxy-, arylthio-, and arenesulphinyl groups and the *O*-ethyl phenylphosphorothiolate residue. All the compounds tested showed a moderate fungicidal activity in relation to *Piricularia oryzae*[128-132]. Apart from *S*-benzyl derivatives *S*-aryl esters of phosphorus acid are also effective against fungal diseases of plants[133-140]. The most active preparation in this series is *O*-cyclohexyl *O*-ethyl *S*-(4-chlorophenyl) phosphorothiolate—the active principle of cerezin. It destroys fungi of the *Corticium*, *Cochliobolus*, *Piricularia*, *Cercospora*, *Alternaria*, *Botrytis*, *Fusarium*, and *Verticillium* species:



The toxicity of cerezin *per os* is 160 mg kg^{-1} for rats. *O*-Cyclohexyl *O*-ethyl *S*-(4-chlorophenyl) phosphorothiolate synergises the fungicidal activity of another preparation—hinosan. Their use in a mixture ranging from 1 : 3 to 3 : 1 makes it possible to lower the active concentrations and to improve the effectiveness of the treatment[141].

Double decomposition reactions of dialkyl phosphorochloridates (phosphonochloridates) with thiophenols or the interaction of trialkyl phosphates with arenesulphinyl chlorides have been suggested for the synthesis of *S*-aryl phosphorothiolates and phosphonothiolates[134,136-138]:

2-Alkylthio-2-hydroxy- or 2-arylthio-2-hydroxy-4-*H*-1,3,2-benzodioxaphosphorine[142-144] and the mixed anhydride of dihydrogen *S*-methyl phosphorothiolate and carbonic acid[145] have also been patented as funcigides:



The simplest phosphorodithioates and phosphonodithioates do not exhibit a significant funcigidal activity[4]. The introduction of various electronegative substituents (halogeno-, nitro-, alkylthio-, arylthio-, alkylseleno-, trichloromethyl, alkynesulphonyl, acyl, alkoxycarbonyl, carbamoyl, and trialkylstannyloxycarbonyl groups) into the α-position of the *S*-alkyl group improves the fungidical properties of the preparations[116,146-152]. For example, *OO*-diethyl *S*-trichloromethyl phosphorodithioate at a concentration of 110 mg kg^{-1}, frees soil from infestation by *Fusarium solani*[147].

In the series of carbamoyl methyl phosphorodithioates, fungicidal activity increases on passing from *OO*-dialkyl to *O*-alkyl *O*-phenyl and further to *O*-alkyl *O*-(4-chlorophenyl) derivatives[151]:

OO-Dimethyl *S*-carbamoylmethyl phosphorodithioate forms with phenols molecular compounds the bactericidal activity of which towards *Staphylococcus aureus* and *Escherichia coli* exceeds that of the initial phenols by a factor of 10-30.[153]

Methyl phosphorodithioates containing heterocyclic residues have fairly pronounced fungicidal properties[154,155]

One should also note the fungicidal properties of *OO*-dialky *S*-(ω-dihalogenovinylalkyl) phosphorodithioates[156], αα-bis(dialkoxyphosphinodithioyl methyl)naphthalenes[157], 1-alkoxy-2,4-bis(dialkoxyphosphinothioylmethyl)benzenes[158], *OO*-dialkyl *S*-dialkylarsinophosphorodithioates[159], *OO*-dialkyl *S*-*O*-allylphenoxyphosphorodithioates[160], and bis(dimethoxyphosphinothioyl) sulphides and disulphides[161].

The study of the fungicidal properties of phosphorodithiolic acid derivatives led to the synthesis of the preparation quinosan—*O*-ethyl *SS*-diphenyl phosphorodithiolate[162-169]. Alkylphosphonodithiolate, phenylphosphonodithiolate, and benzylphosphonodithiolate esters have much weaker fungicidal properties[170-175]. The toxicity of hinosan for rats *per os* is LD_{50} = 150-340 mg kg^{-1}, for mice LD_{50} = 218 mg kg^{-1}, and for guineapigs and rabbits LD_{50} = 350-400 mg kg^{-1}.[176]

Hinosan is used to combat the diseases of rice caused by *Piricularia orizae*, *Pellicularia sasaki*, *Cochliobolus myiabeamus*, *Helminthosporium*, and *Hormodendrum* in doses of 0.7-1 kg of the emulsified concentrate, the treatment being repeated 2-4 times. At high concentrations the preparation is phytotoxic for the cabbage, tomatoes, and radishes[166,167]. Quinosan may be combined with cerezin (as stated above) and ethylenethiuram monosulphide as synergistic agents[176].

In the industrial synthesis of hinosan, ethyl phosphorodichloridate is treated with sodium thiophenoxide obtained from diphenyl disulphide or thiophenol[162,177]:

OS-Dialkyl *S*-phenyl phosphorodithioates are effective fungicides against the diseases of rice caused by *Piricularia*, *Helminthosporium*, and *Rhizoctonium*[178,179]. *O*-Alkyl *S*-alkyl *S*-benzyl phosphorodithiolates and *O*-alkyl *SS*-dibenzyl phosphorodithiolates have a relatively weak fungicidal activity[171,180,181].

Only a few studies have been made in recent years on the fungicidal properties of phosphorotrithioate and phosphorotetrathioate esters. *SSS*-Trialkyl, *SSS*-triaryl, and *SSS*-tribenzyl phosphorotrithioates, *SS*-diaryl chloromethyl phosphonotrithioates, and *SS*-di(alkylcarbamoylmethyl) phosphorotrithioates exhibit a moderate fungicidal activity[182-186].

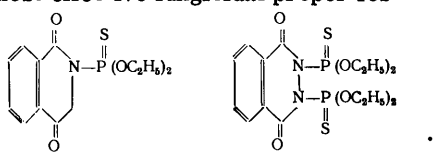
The most effective preparation of this group is *O*-(2,4,5-trichlorophenyl) *SS*-di(methylcarbamoylmethyl) phosphorotrithioate, which, at a concentration of 0.003%, causes 100% suppression of the growth of the mycelia of the *Botrytis*, *Aspergillus*, *Fusarium*, and *Venturia* fungi

but it is completely non-toxic for the spores of the same fungi. It can be used against brown spot of leguminous plants and wheat grain mildew [187-190].

Products prepared by the addition of 1–8 atoms of sulphur to phosphorotetrathioates [191] and bis(dialkoxyphosphinothioyl) tri- and tetra-sulphides [192] have also been patented as fungicides.

VI. PHOSPHORUS ACID AMIDES

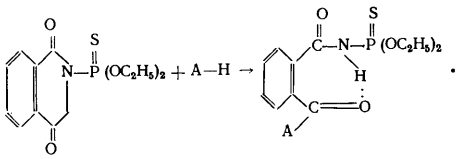
In the series of monoamides of phosphoric and phosphonic acids, *O*-aryl alkylphosphonamidates, phosphorylureas, and phosphorylthioureas, *OO*-dialkyl *N*-(β-aminoethyl)phosphoramidothioates, and 2-amino-2-oxo-1,3,2-benzodioxaphosphorines exhibit appreciable fungicidal activity [193-208].



O-Pentachlorophenyl and *O*-(2,4,5-trichlorophenyl) *NN*-diethylmethylphosphonamidates suppress the growth of *Botrytis cinerea*, *Fusicladium dendriticum*, and *Fusarium oxysporum* [193]. 2,4-Dichlorophenyl derivatives exhibit a lower activity [205,206]. *OO*-Diarylphosphorylthioureas are active against *Piricularia* on rice [197-199]. *N*-Phosphorylated derivatives of 6-aminopenicillanic acid exhibit antistaphylococcal properties [201].

Phosphoramidates and phosphonamidates with alkenyl, benzyl, phosphorylalkyl and triazolyl groups attached to the oxygen or sulphur atoms as well as *N*-phosphorylated iminoesters of dihalogenocarboxylic acids proved to be weak fungicidal agents [204-208].

Among the group of amides of phosphorothiolic and phosphonothiolic acids, kitazin and inezin analogues have been patented as fungicides, but they have no advantages over their ester analogues [209-211].

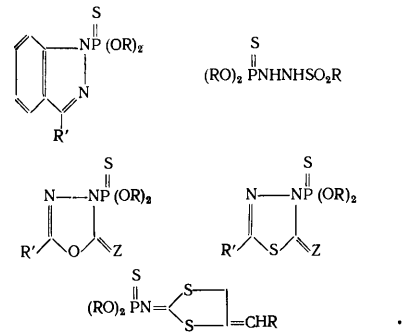


The fungicidal activity of the amides of *S*-benzyl benzylphosphonothiolic acid and ethoxycarbonyldichlorophosphoramidylmethyl disulphide and *S*-alkyl *NN*-dialkylphenylphosphonamidothiolates [212-216], which are effective against *Piricularia orizae*, *Pythium*, *Fusarium*, and *Verticillium*, is also noteworthy.

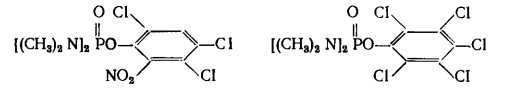
Among the large number of compounds which Tolkmith synthesised and tested in the study of *N*-acylated and *NN*-diacylated phosphoramidothioates, *OO*-diethyl phthalimidophosphonothioate (Dowco 199 preparation) and *NN'*-bis(diethoxyphosphinothioyl)benzopyridazinedione exhibit the most effective fungicidal properties [217-226]:

The Dowco 199 preparation is used against apple scab, powdery mildew of cucumbers, *Sphaerothaeca* on rose bushes, and certain other diseases at a concentration of 0.015–0.06%. The preparation is highly toxic for warm-blooded animals (5000–5500 mg kg^{-1}).

In order to explain the mechanism of the fungicidal activity of *OO*-diethyl phthalimidophosphonothioate, Tolkmith suggests that it acylates amidases interfering thereby with vital metabolic processes in the fungal cell:



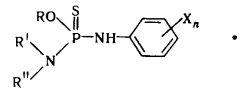
The high activating capacity of the Dowco 199 preparation accounts for its low anticholinesterase activity.



Several methods have been described for the synthesis of *OO*-diethyl phthalimidophosphonothioate: by the interaction of phthaloyl chloride with *OO*-diethyl phosphoramidothioate and triethylamine, by treating potassium phthalimide with *OO*-diethyl phosphorochloridothioate, and by the reaction of phthalic anhydride with the *OO*-diethyl phosphoramidothioate anion obtained from the corresponding amide and sodium hydride in dimethylformamide [219,221,225].

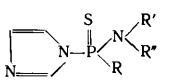
In the study of the effect of the chemical structure of chemical analogues of the Dowco 199 preparation on their biological activity, it was shown that the introduction of substituents into the phenyl ring and its hydrogenation decrease the fungicidal activity by a factor of 10–20.

In the series of phosphonamidothionates and phosphonothionates, *OO*-diethyl indazolylphosphonothioates [227,228], *N*-(*OO*-diethylphosphorothioyl)-*N'*-sulphonylhydrazines [229], *N*-(*OO*-dialkylphosphorothioyl)oxadiazines and *N*-(*OO*-dialkylphosphorothioyl)thiadiazines [230], and 4-alkylene-2-(*OO*-dialkylphosphorothioylimino)-1,3-dithiolanes [231] also possess fungicidal properties:



Among phosphoric acid diamides, *O*-aryl *NNNN'*-tetramethylphosphorodiamidates containing electronegative atoms and groups in the aryl substituent exhibit a high fungicidal activity [232-237]:

The above two preparations are now being tested as experimental fungicides. The first was developed in the Czechoslovak Socialist Republic. Its toxicity for warm-blooded animals is 10 mg kg^{-1} when introduced to rats via the stomach. The second preparation was patented as early as 1962 (Schoot et al. [236]), but its field tests were reported only at the Fifth British Conference on Insecticides and Fungicides [237]. The preparations are effective against the fungi (*Erysiphe graminis* and *Erysiphe cichoracearum*) responsible for the powdery mildew on barley and cucumbers.

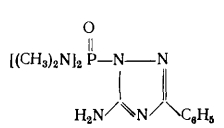


Mel'nikov and Vladimirova made a systematic study of the fungicidal activity of *N*-arylphosphorodiamidothioate esters [238,239]:

The introduction of the methyl group and of chlorine atoms in the aryl substituent increases the fungicidal activity of the preparation; alkyl esters are more active than aryl esters and *N*-alkylamido-derivatives are more effective than the dialkylamido-derivatives. *O*-Ethyl *N*-(4-chlorophenyl-*N*-methylphosphoramidothioate yielded satisfactory

results against the *Peronospora* infection of tobacco and the wilting of fodder beans caused by *Fusarium*[238].

Imidazolylphosphoramidothioates and imidazolylphosphonamidothioates possess a high fungicidal activity[220,230-246]:



In a study of the biological activity of this group of preparations against the powder mildew of cucumbers and the potato disease caused by *Phytophtora*, it was shown that in such cases the fungicidal activity of the compounds is maximal when R is a planar substituent, for example phenyl. Derivatives of dihydrogen *O*-ethyl and dihydrogen *O*-aryl phosphorothioates and also of cyclohexylphosphonothioic acid are less effective[220,246]. The influence of the polarity and steric properties of the substituent at the phosphorus atom on the fungicidal activity of imidazolylphosphoramidothioates is more complicated than for cholinergic preparations.

It is interesting to note that the toxicity of the optical isomers of *NN*-diethylaminophenyl imidazolylphosphonothioate for *Phytophtora infestans* is independent of the sign of the optical rotation of the isomer, while the toxicity of the (−)-isomer for white mice is twice as high as that of the (+)-isomer (147 and 316 mg kg^{-1} respectively)[241]. Probably the mechanism of the fungicidal activity is related to the dissociation of the P–N bond, the elimination of the imidazole residue, and its inclusion in the metabolic processes of the fungus[244].

2-Aryloxy-2-thionobenzo-1,2,3-diazaphospholens, *O*-aryl *N*-acylphosphorodiamidothioates[247], *S*-benzyl phosphorodiamidothioates[248], 3-[*O*-alkyl-*N*-alkylphosphoramidothioyl]-5-alkoxy-1,3,4-thiadiazol-5-ones[249], and 1-(*O*-alkyl-*NN*-dialkylphosphoramidothioyl)imidazolidine-2-thiones[250] have also been proposed as fungicides.

There are only isolated data about the fungicidal activity of phosphorodiamidodithioic acid. *NNNN'*-Tetraalkyl-*S*-thiocarbamoylphosphorodiamidodithioates[251] and 2-anilino-2-thiono-3-phenyl-4,5-benzo-1,3,2-thia-aza-phosphorin-6-one possess fungicidal properties[252].

The study of the fungicidal activity of phosphorus acid triamides is associated mainly with the work of van den Bos on the *N*-phosphorylation of nitrogen-containing heterocycles by phosphorodiamidochloridates and phosphorothioates. Among this group of compounds, the preparation "Wepsyn", 2-amino-4-phenyl-1,3,5-triazolylphosphonic acid *NNNN'*-tetramethyldiamide, is used on a small scale against the fungi responsible for the powder mildew on decorative and fruit-bearing cultivated plants. The preparation is active both on spraying the leaves and when administered through the roots. It exhibits a systemic activity. Wepsyn makes the plants resistant or, in other words, it stimulates the synthesis of phytoalexins[253,254]:

Some of the Wepsyn analogues are effective against *Erysiphe cichoracearum* on cucumbers and *Erysiphe graminis* on barley and oats[255].

In order to enhance their fungicidal activity and decrease their phytotoxicity, imidazolylphosphonodiamidothioates can be used as complexes with calcium, cobalt, copper, iron, manganese, nickel, and zinc salts[256].

The fungicidal properties of phosphorodiamidoyl- and phosphorothioyl-sulphonylhydrazides are also noteworthy[257]:

Among other classes of organic phosphorus compounds, tetra-arylalkylenebisphosphine oxides[258], triphenylphosphinomethylenes[259], di-iodotriphenylphosphorane[260], arenesulphonylphosphazo-compounds[262], derivatives of cyclotriphosphazine[262], and 5-alkyl-1,1,3,3-tetraphenyl-1,3-diphospha-5-bora-2,4,6-triazines[263] have been patented as fungicides.

The review has shown that intensive studies on the fungicidal properties of organophosphorus compounds are being made in different countries. One of the useful properties of phosphorus compounds is their relatively low stability and rapid metabolic breakdown in plants, in animal organisms, in soil, and other components of the environment with formation of products which are safe for man and domestic animals. Another important feature of these compounds is the high selectivity of their action.

Phosphorus-containing fungicides act on metabolic processes within the fungal cell, on the permeability of the cell membrane, as well as on the inter-relation between the host plant and the parasitic fungus.

For a specific synthesis of new fungicidal preparations, it is necessary to extend biochemical research on the mechanism of the action of phosphorus-containing fungicides on the fungal cell.

Polarography in Organic Media

S.I.Zhdanov

Brief consideration is given to fundamental aspects—the technique of a polarographic experiment in an organic medium, factors producing a change in polarographic behaviour when water is replaced by an organic solvent, and specific features of the polarographic behaviour of inorganic and organic depolarisers—and a list of 42 references is included.

CONTENTS

1. Introduction 782
2. Experimental technique 782
3. Causes of change in behaviour of depolarisers on passing from aqueous to organic media 784
4. Inorganic depolarisers 785
5. Organic depoarisers 785

1. INTRODUCTION

Polarography was discovered in 1922 by the well known Czechoslovak Nobel prizewinner J. Heyrovský during the investigation of aqueous solutions. This method yielded much valuable information on the mechanism and the kinetics of electrode processes in aqueous media. But soon after the discovery it became necessary to use the method also to investigate solutions in mixtures of water with organic solvents and in pure organic solvents. The original reason was the limited solubility in water of many organic and inorganic substances (e.g. elementary sulphur), whose polarographic behaviour was of interest. At the present time, however, the use of organic solvents in polarography is dictated also by the valuable information on the mechanism and kinetics of electrode processes and on the properties of solutions obtainable by working with organic solvents. The elucidation of the mechanism of the electrochemical reduction and oxidation of many classes of organic compounds, the generation and investigation of the radical-ions of organic and inorganic substances (oxygen, sulphur), the establishment of the differentiating action of organic solvents for strong inorganic acids, and other surprising results obtained with organic solvents struck the imagination and initiated a powerful new stream of investigations on these lines. It is therefore of interest to examine some fundamental aspects of the use of organic solvents in polarography. More detailed, specific information will be found in numerous reviews and also in a monograph [1].

2. EXPERIMENTAL TECHNIQUE

The development of polarography in organic media has been stimulated by advances in the chemistry and electrochemistry of organic solvents and solutions in them [2-5], by the preparation of new organic solvents having very interesting properties (propylene carbonate, an aprotic solvent having a high dielectric constant; hexametapol, in which solvated electrons exist for quite a long time; etc.), and by the production of new polarographic apparatus, especially potentiostatic instruments, which enable perfectly satisfactory polarograms to be recorded with poorly conducting solutions.

Considerable experience has accumulated of working with organic solvents. The purity of the supporting electrolyte is of primary importance for polarography in organic media. In practice it must be freed mainly from contamination with electrochemically active substances (depolarisers) and proton-donors, in particular water, if the experiment is to be conducted under aprotic conditions. On storage the purified solvents again accumulate undesirable impurities as a result of their hygroscopicity and decomposition. It is therefore advisable to work with freshly purified solvents. In some solvents peroxy-compounds, which give sharp reduction waves, appear on storage. Oxolan, for example, is best freed from peroxides by being boiled with potassium permanganate [6].

Oxygen is usually more soluble in organic solvents than in water, and is more difficult to displace from organic media than from aqueous solutions. The rate of expulsion of dissolved oxygen is increased by passing fine bubbles of an inert gas through the solution; this is achieved by inserting porous glass plates at the gas inlet into the cell. Nitrogen and electrolytic hydrogen from cylinders must be freed from traces of oxygen by combustion over catalysts or adsorption on metallic copper or other adsorbent. It is considerably more convenient to use argon, which requires no further purification, since its oxygen content lies within permissible limits. Sulphate is not employed to remove oxygen from solutions in organic solvents, since either it is sparingly soluble or it reacts slowly with oxygen.

The solvents are rigorously dried by means of powerful drying agents—alkali metals, molecular sieves, electrolysis, etc.—followed by fractionation under reduced pressure and in an inert atmosphere to avoid decomposition and oxidation, especially with high-boiling solvents.

Water of crystallisation in a salt used to prepare the supporting electrolyte or as depolariser may seriously moisten the electrolyte and nullify all efforts to dry the solvent. The salt must therefore be dried no less thoroughly. It is very difficult to remove the last traces of moisture from salts. The latter must be heated in the presence of strong drying agents in a vacuum for a long time or else melted preferably in a vacuum. But not all salts are completely freed from moisture by vacuum melting (lithium perchlorate, for example, still contains 0.1% of water [7]). Where maximum dryness is required

during an experiment, therefore, it is useful to treat the final electrolyte with such drying agents as molecular sieves or alkali metals. Salts of strongly hydrolysed multivalent metals (titanium, zirconium, hafnium, thorium, aluminium, etc.) are difficult to dry, since they decompose on dehydration of the crystalline hydrates, with formation of sparingly soluble oxy-salts. In such cases either the behaviour of the hydrates is studied [8] or the anhydrous salts are prepared under conditions excluding access of moisture.

The dehydrated solvents and solutions rapidly absorb moisture from the surroundings. It is therefore best to conduct all operations with them in an atmosphere of a dry inert gas in hermetically sealed boxes.

The water content of solvents and solutions is most often determined by titration with the Karl Fischer reagent. The Reviewer's experience has shown that water can be determined considerably less laboriously and no less accurately from the volume of hydrogen evolved on contact of a portion of the solution with calcium hydride [9]. A very sensitive ($\ll 0.01\%$) method proposed [10] for the determination of water is based on its reaction with lead tetra-acetate, the precipitated lead dioxide being estimated spectrophotometrically. Pure calcium carbide is required for the determination of small concentrations of water by gas–liquid chromatography.

The above procedures enable solutions to be prepared whose water content can be lowered to 10^{-4} M or below. In most cases, of course, such rigorous drying of the solutions is not required, since even large quantities of water by no means always effect the polarograms. The radical-anion of piazthiole, for example, is protonated by water so slowly that, in admixture with dimethylformamide, the first reduction wave of piazothiole to the radical-anion still remains completely unchanged even with water contents up to 40 vol.%, [11] and this case is by no means exceptional. The insensitivity of many electrode processes to traces of moisture enables us to work with organic solvents under ordinary laboratory conditions. Since many methods of pretreating solvent, salts, and solutions are laborious, they must be applied only where necessary.

Quite often, however, the whole arsenal of means must be used for removing moisture from the solutions. If the depolariser reacts with water, the presence of traces of moisture will lower its concentration and produce other complications. Dessy et al. [12] pointed out the need for careful drying of aprotic solutions for this reason in the investigation of organometallic compounds. Experimental conditions of maximum dryness are extremely desirable also because they may lead to the detection of radical species and also unusual valency states of elements that are otherwise too unstable.

In the choice of salt for the preparation of supporting electrolytes it is quite insufficient to assess solubility from the dielectric constant ϵ of the solvent. Experience shows that solubility and solvation often depend not only on the polarity of the solvent molecules but also on specific interaction of the ions with the solvent. The relatively non-polar pyridine ($\epsilon = 12.5$), for example, is a fairly good solvent for ionic salts, whereas formamide ($\epsilon = 113$) is comparable only with pyridine in solvent power, but is inferior to water [8].

Cations are solvated by coordination with electron-donor solvent molecules (whence the high solubility of salts in pyridine), whereas anions, which themselves are electron-donors, may be solvated by electron-acceptor solvent molecules or by hydrogen-bonding. Since hydrogen bonds are weaker than bonds in the solvates of cations, the nature of the anion strongly influences the solubility of the salt as a whole. The solubility of halides falls on passing from iodides to chlorides, while fluorides are usually sparingly soluble. Perchlorates, nitrates, nitrites, and thiocyanates are more soluble, whereas sulphates, carbonates, phosphates, oxides, and sulphides are in general insoluble [8].

Lithium perchlorate and chloride as well as tetra-alkylammonium iodides and perchlorates, which are very soluble, are most often used as supporting electrolytes in organic solvents. The maximum potential range within which mercury is polarised ideally (the polarographic range) is provided by a tetra-alkylammonium perchlorate. Thus with tetraethylammonium perchlorate in dimethylformamide we can work at potentials from +0.45 to −2.8 V relative to the saturated calomel electrode (s.c.e.). [8] This supporting electrolyte is interesting also because it exhibits the least tendency to form ion-pairs with radical-ion products of electrode reactions.

The electrical conductivities of the best electrolytes in organic solvents are considerably inferior to those of aqueous solutions. An optimum salt concentration, ensuring maximum conductivity of the solution, exists for most solvent–salt pairs. This concentration is usually close to molar, which it is desirable to ensure. With a solvent of low ionising strength, nevertheless, even fairly concentrated salt solutions are comparatively poor conductors, since a considerable proportion of the ions are combined as ion-pairs, and are not involved in the transport of current through the electrolytes. For this reason it is difficult to work with anhydrous solvents such as oxolan and dioxan.

It is often necessary to correct the polarograms for the voltage drop iR in the solution. This is best done by calculating the resistance R of the cell at the required instant t in the life of the drop from the resistivity ρ of the electrolyte [13]:

$$R = \frac{0.191\rho}{m^{1/3}t^{1/6}} \qquad (1)$$

where m (g s^{-1}) is the rate of efflux of mercury from the capillary. A reversibly dischargeable pilot ion, whose half-wave potential $E_{\frac{1}{2}}$ is independent of its concentration, can be used [14]. Inclusion of a Luggin–Haber capillary in a potentiometric cell, e.g. in work with a potentiostatic polarograph, can eliminate only part of the voltage drop, since the latter is largely concentrated near the mercury drop [13]. Rather better elimination can be achieved by arranging auxiliary, indicator, and standard electrodes in that order in a straight line.

Potentiostatic polarographs completely eliminate the effect of instability of the potential of the mercury floor as auxiliary electrode, which is especially marked in the presence of perchlorates. When polarograms are recorded by means of the usual polarograph, the potential of the indicator electrode relative to a reliable reference electrode must be measured periodically, and the polarogram must then be replotted on a linear potential scale, in order to avoid stretching of the waves and the appearance of spurious inflections, falls in current, and hysteresis phenomena.

Various electrodes of the first or second kind are used as reference electrodes, either in the test solution or externally. Very often an external aqueous calomel electrode is employed. A diffusion potential of unknown magnitude appears at the junction between aqueous and non-aqueous solutions. This is of no importance when the behaviour of different compounds in the same solvent is

compared, but it prevents a quantitative comparison of the behaviour of a given depolariser in different solvents. In this connection an electrode of the second kind may be useful, e.g. a silver chloride electrode placed in a saturated solution of a salt having a common anion (chloride). The potential of such an electrode will be independent of the composition of the medium, since the activity of the potential-determining ion will remain constant [15,16].

Several redox systems having large, weakly solvated, univalent cations, whose potentials can be regarded to a first approximation as independent of the nature of the solvent, have also been proposed for this purpose. On Pleskov's suggestion [17] the potential of the Rb/Rb^+ electrode is taken as standard, but Strehlow introduced the ferrocene–ferricinium and cobaltocene–cobalticinium systems [3,18], of which the former has become more widely used. It must be borne in mind, however, that the potential of such an electrode is only approximately independent of the nature of the solvent. The use of such systems to reveal fine effects is therefore inadmissible. In aqueous–alcoholic solutions, for example, the limiting current of the ferricinium ion changes not only with the viscosity η of the medium but also with the degree of solvation [19].

By means of such standard systems it has been established that the liquid junction potential between an aqueous saturated calomel electrode and acetonitrile, propionitrile, isobutyronitrile, phenylacetonitrile, and acetone is 0.25 V, which must simply be subtracted from the potential measured in the organic solvent relative to the aqueous reference electrode [20].

One of the most important properties of an organic solvent for polarography is its proton-donor activity. On this principle solvents can be classified as protic, aprotic, and non-protic [21]. Solvents which are proton-donors can be divided into three groups: (i) hydroxylated solvents include water, alcohols, glycols, and phenols; (ii) protogenic solvents are considerably stronger acids than water; and (iii) protophilic solvents are considerably stronger bases than water. Aprotic solvents possess neither acidic nor basic properties by definition, but in fact, with the exception of pyridine and similar compounds, they (dimethylformamide, dimethyl sulphoxide, acetonitrile, oxolan, etc.) exhibit nevertheless weak acidic or basic properties. For example, dimethyl sulphoxide is a considerably weaker acid than water, but is comparable with it in basic strength. Finally, non-protic solvents contain no hydrogen at all in their structure (sulphur dioxide, carbon tetrachloride) and cannot act as Brønsted acids, but exhibit Lewis acid–base properties.

3. CAUSES OF CHANGE IN BEHAVIOUR OF DEPOLARISERS ON PASSING FROM AQUEOUS TO ORGANIC MEDIA

Several factors influence the change in polarographic behaviour on passing from aqueous solutions to solutions in organic solvents.

1. Since the mercury-solution interfacial tension depends on the composition of the latter, change of solvent affects the drop time τ of the electrode. The effect of τ on the limiting diffusion current i_d is fully represented by the Ilkovič equation and its modifications. The change in τ may have some effect on the half-wave potentials of irreversible waves.

2. The viscosity of the medium changes on passing to another solvent, and this entails a change in diffusion coefficients. It is easy to show by means of the Ilkovič equation and the Stokes–Einstein equation ($D = kT/6\pi\eta r$) that

$$i_d \eta^{1/2} r^{1/2} = \text{const}. \qquad (2)$$

Systematic data on the effect of solvent composition on the limiting diffusion current through variation in diffusion coefficient will be found in Schwabe's publications [22–24]. Change in diffusion current is usually produced by changes not only in viscosity but also in solvation of the depolariser particles r.

3. Replacement of the solvent affects the acid–base and other equilibria in the solution (solvation, association, complex formation). This effect has many important consequences.

(*a*) Acids and acidic components of buffer mixtures are usually weaker in organic solvents, and the pH is higher. The half-wave potential of a reversible reduction wave involving ν hydrogen ions and n electrons becomes more negative [22–24]:

$$\partial E_{1/2}/\partial \mathrm{pH} = -59.1 \frac{n}{\nu}. \qquad (3)$$

(*b*) If the depolariser becomes less strongly solvated, the reversible reduction wave undergoes a positive shift, whereas weakening solvation of the product produces a shift in the opposite direction along the potential axis. The energy of interaction with the solvent depends on the dielectric constant ϵ of the medium and the particle size r. From the Born equation the standard reversible discharge potential of cations can be written [25]

$$E_0 \simeq E_{1/2} \simeq A + eZ/2r\epsilon. \qquad (4)$$

If r is assumed to be independent of the composition of the medium, i.e. if we neglect the role of specific interaction between cation and solvent, it follows from Eqn. (4) that the half-wave potential should become less negative with decrease in dielectric constant, while the product $E\frac{1}{2}\epsilon$ remains constant. In practice, however, this product is rarely constant: strictly speaking, the product $E\frac{1}{2}\epsilon r$ should be constant. Weakening solvation of the depolariser diminishes the degree of irreversibility: processes quite often occur reversibly in organic solvents that are completely irreversible in aqueous solutions [8].

(*c*) Ionic interactions are strengthened by weakening solvation of the cations of the supporting electrolyte. Much experimental information has accumulated on the effect of the nature and concentration of these cations on the reduction waves of aromatic hydrocarbons in aprotic solvents, which is governed by the formation of ion-pairs with radical-anions and dianions of the hydrocarbons [26–30]. The formation of ion-pairs displaces the waves to less negative potentials. The effect is greater the higher the charge on the hydrocarbon anion ($R^{\cdot-}$ or R^{2-}) and the cation of the supporting electrolyte, the smaller the crystallographic radius of the cation, and the higher its concentration. It is supposed that the radical-ions do not interact with tetra-alkylammonium cations; dianions interact most strongly with lithium ions. Multiply charged cations produce a very large displacement of the waves even at low concentrations: thus 0.002 M $Nb(ClO_4)_3$ displaces the half-wave potentials of the first and second waves in 0.003 M quinone in acetonitrile by 550 and 950 mV respectively [28]! Both this phenomenon and solvation are analogous to complex formation, and the composition p of the ion-pair and its equilibrium formation constant K_{eq} can be calculated from the displacement

of the half-wave potential by means of the equation[28]

$$(E_{1/2})_{cat} - (E_{1/2})_0 = \frac{RT}{F} \ln K_{eq} + \frac{RT}{F} p \ln [M^+] \quad . \qquad (5)$$

For example, the radical-anion of anthraquinone forms a 1 : 1 complex with lithium ion in dimethylformamide, having Keq = 39 M^{-1}, whereas the dianion associates with three lithium ions[28].

4. Adsorption of the solvent on the mercury may retard tangential movement of the electrode surface, and thus eliminate polarographic maxima, which are suppressed e.g. by aliphatic alcohols[22,31]. Adsorption of the solvent can in principle inhibit electron transfer.

5. An organic solvent diminishes the adsorbability of other substances, primarily organic, and is thereby able to produce various effects.

(*a*) Surface-active substances, which suppress polarographic maxima in aqueous solutions, are largely ineffective in organic solvents. In order to eliminate tangential movement in the latter, therefore, use must be made of such strong surface-active agents as dodecyl sulphate, dodecylamine hydrochloride, dodecylammonium dodecyl sulphate, octadecyl sulphopropionate, etc.[8]

(*b*) Weakening of the adsorption of depolariser and reaction product in reversible systems leads to the disappearance of adsorption waves preceding and following Brdička waves.

(*c*) With self-inhibition due to the adsorption of depolariser or reaction product, the weakening of adsorption in organic solvents leads to an increase in current, i.e. to elimination of the self-inhibition effect[32].

(*d*) Weakening of adsorption of the depolariser produces a cathodic shift in irreversible reduction waves[22-25,33].

(*e*) Kinetic and catalytic surface waves undergo greater changes in organic solvents also because of decrease in the surface concentration[33].

(*f*) In several cases the decrease in adsorbability changes the mechanism of the process. Stradyn' and Kravis have shown that, in alkaline aqueous–ethanolic solution, the first four-electron wave of nitrobenzenes separates into one- and three-electron waves. The splitting of the wave is caused by insufficiently rapid protonation of radical-anions in the surface layer of solution owing to their desorption[34].

(*g*) Elimination of adsorption phenomena by organic solvents improves the correlation between half-wave potentials and substituent constants, and permits more accurate establishment of the composition and stability of complexes with ligands that from aqueous solutions are adsorbed on mercury.

6. Organic solvents influence the structure of the electrical double layer. This undoubtedly affects the kinetics of electrode processes involving slow discharge.

4. INORGANIC DEPOLARISERS

In many organic solvents alkali-metal ions are reduced reversibly. Only the lithium ion, the most strongly solvated, exhibits some irreversibility[35]. Most bivalent cations are Lewis acids, and can be solvated by a basic solvent. In aprotic solvents they are more weakly solvated than in water, and are reduced more easily[20].

Readily hydrolysed multiply charged ions (Ti^{4+}, Th^{4+}) are reduced considerably more easily in acetonitrile than in water. Whereas in aqueous solutions the waves are attributed to the discharge of water molecules constituting the hydrate sheaths of ions, with the evolution of hydrogen, in acetonitrile thorium, for example, forms an amalgam, though not in high yield[8].

Many anions are stabilised in protic solvents by hydrogen bonds. This possibility does not arise in aprotic solvents. Therefore the activity of anions is higher in such solvents than e.g. in water. Anions may be stabilised in aprotic solvents by interaction with a Brønsted acid (HX^{2-}) or with a Lewis acid, i.e. with cations. The stability of anion–cation complexes is considerably greater in aprotic solvents than in water. This is evident from the cathodic shift in the anodic dissolution potential of mercury. Thus on passing from water to acetonitrile with an anion concentration of 0.001 M this potential shifts from 0 to −1.16 V in the presence of the hydroxide ion, from −0.1 to −0.71 V in the presence of the iodide ion, and from +0.1 to −0.61 V in the presence of the chloride ion[20].

An especially interesting result was obtained for the reduction of oxygen in aprotic solvents. Polarography cyclic volt–ammetry, and electron spin resonance established that in dimethyl sulphoxide the first stage consists in transfer of a single electron to the oxygen molecule with formation of a superoxide radical-anion $O_2^{\cdot-}$. This highly reactive species is quite stable in aprotic solvents. It is curious that the electron is transferred almost reversibly under these conditions, whereas in aqueous solutions transfer of the first electron is assumed to be the limiting stage[36].

On platinum, graphite, and gold electrodes in dimethyl sulphoxide, oxolan, and dimethylformamide elementary sulphur S_8 also undergoes one-electron reduction with formation of the radical-ionic species $S_8^{\cdot-}$, which is stable for several days[37]. Sulphur reacts with mercury to form mercury sulphide. The mechanism of the reduction of sulphur is therefore different at a dropping mercury electrode.

It is remarkable that strong mineral acids are differentiated in solvents, such as acetonitrile, that are weaker bases than water and dimethyl sulphoxide. Perchloric, sulphuric, and hydrochloric acids give identical hydrogen-evolution waves in water, but separate waves in acetonitrile, and can be determined when present together[20,21]. A linear relation exists between the pKa value of the acid in water (with p$K < 3$) and the half-wave potential of hydrogen evolution in pyridine[38].

The use of organic solvents in polarography shows promise for the analysis of metals after extraction by organic solvents without a re-extraction stage.

5. ORGANIC DEPOLARISERS

The use of aprotic organic solvents in the polarography of organic compounds has led to fundamental changes in our views on the mechanism and the kinetics of electrode processes involving them. It had previously been assumed, when many-electron and completely irreversible waves were observed in aqueous and waterlike solvents, that the limiting stage was slow transfer of the first electron. The use of aprotic solvents enabled these many-electron processes to be separated into individual elementary stages. Alternating-current polarography and cyclic volt-ammetry showed that the first electron is transferred immeasurably rapidly in organic electrochemistry, but transfer of the second electron is sometimes slow[39,40]. The irreversibility of processes in protic solvents is due to secondary chemical reactions,

mainly protonation of radical-anions and dianions. One of the few exceptions to date is the reduction of halogeno-derivatives, which is irreversible also in aprotic solvents. However, the probable cause of irreversibility even in this case is rupture of a carbon–halogen bond after or during transfer of the first electron, not slowness of the actual electron-transfer stage.

In conclusion we note that maximum accuracy of correlation of half-wave potentials with substituent constants may be ensured by the use of aprotic solvents and supporting electrolytes with cations of large radius, since only under such conditions does the half-wave potential best represent the electron affinity of the molecule. In protic solvents such correlations are complicated by preceding and following chemical reactions, as well as by simultaneous transfer of more than one electron [41,42].

It follows also from the above account that the use of aprotic solvents in a.c. polarography opens up great new possibilities for highly sensitive analysis of inorganic and organic compounds, since in many cases processes take place reversibly under these conditions.

Physicochemical Foundations of Micellar Catalysis

I.V.Berezin, K.Martinek, and A.K.Yatsimirskii

The structure and the properties of micelles of surface-active substances in aqueous solution are briefly surveyed. Attention is paid mainly to solubilisation and methods for investigating the location of solubilised molecules. Kinetic concepts of micellar catalysis are examined and compared. The role of various factors (concentration effect, orientation, shift in pK_a of reactants, change of environment) in the micellar effects observed in organic reactions is analysed. A list of 113 references is included.

V. Effect of micelles on reaction equilibrium	799

I. INTRODUCTION

Research on the effect of surface-active agents on the kinetics of organic reactions in aqueous solution has recently become a separate branch of physical organic chemistry. Interest in this problem has arisen mainly from the fresh opportunities both for controlling the rates of chemical reactions and for studying their mechanism[1,2].

The presence of a surface-active agent usually produces a 10–100-fold acceleration or deceleration of the reaction; in individual cases reaction velocities are increased by factors of 10^3–10^4.[1-4] It has now been finally established that these effects are due to the presence not of individual molecules but of association complexes (micelles) containing a large number of molecules of the surface-active agent. This fact has been responsible for the appearance of the term "micellar catalysis".

Micellar catalysis is also of interest to biochemists, for several aspects of this phenomenon exhibit features recalling the mechanism of the action of enzymes[5-8].

Surface-active agents may also be used in organic syntheses[1,2], e.g. in reactions between water-insoluble substances in aqueous solution (the most important application of this is emulsion polymerisation[9,10]).

Micellar catalysis may also be assumed to play some part in the bactericidal action of surface-active agents mixed with other bactericidal preparations. An example is the dependence of the time of destruction of *Bacillus coli* bacteria by a solution of phenol (0.54%) on the concentration of a dialkyl sulphosuccinate anionic surface-active agent (Aerosol MA).[11] The efficiency of the phenol is greatly increased by the formation of micelles in the solution of the surface-active agent (when the critical micelle concentration (c.m.c.) is reached), after which it passes through an optimum. As will be shown subsequently, both these features are characteristic of micellar catalysis.

The number of papers on the kinetics of chemical reactions in the presence of micelles of surface-active compounds began to increase sharply after 1960, and now exceeds fifty (excluding papers on emulsion polymerisation). An exhaustive survey of work on micellar catalysis

(up to 1970) was made by E. and J. Fendler[2], who reviewed systematically all available published information on the mechanisms of the catalysed reactions. The present paper attempts to discuss the physicochemical basis of micellar catalysis†. Attention will be paid mainly to explaining the kinetics of chemical reactions occurring in the presence of the micelles of surface-active compounds and to establishing the rôle of the principal factors—the close approach (concentration) of reactants attached to the micelle, their mutual orientation, the change in the environment, and with ionic micelles the effect of the micellar charge on the transition state in the reaction—causing the change in reaction velocity in the presence of micelles. An analysis of these factors must take into account the structure of the micelles and the laws governing their formation and interaction with other solutes. The first part of the Review will therefore report the necessary information on the physicochemical properties of aqueous solutions of surface-active agents.

II. PHYSICOCHEMICAL PROPERTIES OF AQUEOUS SOLUTIONS OF SURFACE-ACTIVE AGENTS

Among the many aspects connected with the problem of the physicochemical properties of aqueous solutions of surface-active agents[12-15] we shall consider only those which are directly related to micellar effects in the kinetics of chemical reactions.

1. Formation and Structure of Micelles in Aqueous Solutions of Surface-active Agents

Surfactant molecules possess well defined diphilic properties: i.e. they contain both hydrophobic and hydrophilic groups. They usually have the structure RX, where R is a hydrocarbon chain containing 8–18 carbon atoms, an alkylaromatic radical, or other type of hydrophobic residue, and X is a hydrophilic group. Depending on the nature of X surface-active agents can be divided into non-ionic, anion-active, and cation-active. In the last case the hydrophilic residue is usually a quaternary ammonium, pyridinium, or phosphonium group; the anion-active compounds contain a sulphate, sulphonate, phosphate, or carboxylate group; in non-ionic surfactants X represents a polyoxyethylene residue. Zwitterionic surface-active compounds constitute a special class[13].

Surface-active substances are characterised by several specific features—(i) the ability to lower the surface tension in solutions by adsorption and orientation at interfaces, (ii) very low maximum concentration of the molecular form in solution, (iii) formation of micelles above a certain concentration (critical micelle concentration, c.m.c.), and (iv) ability to solubilise water-insoluble substances within and on the surface of the micelles—all of which are closely interrelated[12,14]. The last two properties are of interest in connection with micellar catalysis, and will be considered in greater detail below.

In fact the formation of micelles takes place in a narrow range of surfactant concentrations around the c.m.c. and is accompanied by a sharp change in several properties of the solution (light scattering, viscosity, electrical conductivity, surface tension, solvent power for certain substances, etc.), which is used for determining the c.m.c. The "experimental" value of the c.m.c. may depend significantly on the property and on the method of measurement; when a third component (e.g. a dye) is used, its presence may cause a shift in the c.m.c. [16]

Theoretical statistical-mechanical models of micelle formation[17,18] are by no means perfect, and merely enable the presence of a minimum in the dependence of the free energy of the system on the aggregation number to be established. Nevertheless, the rôle of several factors which lead to micelle formation can be traced on the basis of these models. The main driving force causing the association of surfactant molecules is the hydrophobic interaction of their hydrocarbon chains.

The following generalisations apply to micelle formation. The shorter the hydrocarbon chain the smaller the decrease in free energy of the system resulting from aggregation and the higher the concentration at which the surfactant molecules have the same chemical potential in the dissolved state and in the micelle, and hence the higher the critical micelle concentration. Factors that diminish the electrostatic repulsion of the hydrophilic groups favour micelle formation. Thus increase in the concentration of gegenions considerably lowers the c.m.c. of ionic surfactants. With the non-ionic compounds micelle formation is promoted by rise in temperature, which diminishes the hydration of their hydrophilic groups. Higher alcohols also lower the surface charge density on an ionic micelle and diminish the c.m.c. On the other hand, methanol and similar compounds (dioxan, ethylene glycol), which do not penetrate a micelle to the same extent, have a weak effect on the c.m.c., raising it in high concentrations by decreasing the energy of hydrophobic interaction between the hydrocarbon chains of the surfactant molecules.

Enlargement of the micellar aggregates, i.e. separation of the surfactant as a macrophase, is prevented by hydration of the hydrophilic group, steric factors, entropy losses, and electrostatic repulsion of head groups in the case of ionic surfactants. In terms of the general theory of the thermodynamic stability of two-phase disperse systems the stability of micelles is probably determined by two factors—sufficiently low interfacial tension and its rapid increase with decrease in particle radius[19].

Micelle formation can be regarded thermodynamically as resembling the formation of a new phase, with the c.m.c. as saturation concentration[12]. However, the resulting micelles do not coalesce into a continuous phase, but are uniformly distributed in the aqueous medium, forming a "pseudophase". Micelle formation actually possesses several properties characteristic of phase separation. Many properties of surfactant solutions undergo an abrupt change at the critical micelle concentration (see above). The increase in solubility of certain substances in surfactant solutions above the c.m.c. can be regarded as similar to dissolution of the substance in a separate phase. At the Kraft point—the temperature above which micelle formation is possible—the first derivative of the solubility of the surfactant with respect to temperature exhibits a discontinuity, which is also characteristic of one type of phase transition. The variation in the c.m.c. caused by various substances can be regarded, on the basis of the pseudophase model of micelle formation, as variation in the true solubility of the surfactant.

† Several aspects of this problem have already been touched upon in monographs[8,7] or have formed the subject of separate reviews[1,5], many conclusions from which we shall use in the subsequent discussion. The relation between micellar catalysis and processes involving macromolecular catalysts (both synthetic polymers and biopolymers—enzymes) was subjected to detailed examination by Morawetz[5].

Another approach is to describe micelle formation as an equilibrium process using the law of mass action. On this model a sharp change in the properties of the system can be expected only if a sufficiently large number of molecules are bound into the micelle[12,20].

Micelles are dynamic structures having times of formation and destruction of a few milliseconds[21]. Ionic micelles usually comprise roughly 50–100 surfactant ions. In dilute solutions they are supposed to be spheroidal with the polar groups on the surface and the hydrophobic chains at the centre. A spherical micelle is shown diagrammatically in Fig. 1. The ionic "head" groups in the diphilic surfactant molecules and some of the gegenions form a compact Stern layer[22], in which about 60–70% of the micellar charge in neutralised. The remaining gegenions form a diffuse Gouy–Chapman layer. The mean surface potential (the ζ-potential) of the micelle can be estimated from the electrophoretic mobility, although the exact value of ζ depends to some extent on the model used for interpreting the experimental data. It usually varies in the range 50–100 mV. A critical examination of the estimation of surface potential from the shift in pK_a of dyes adsorbed on the micelle showed[23] that the potential measured is rather higher than the ζ-potential but less than the total potential difference between micelle and water.

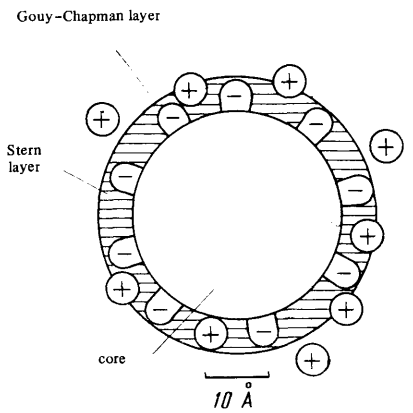

Figure 1. Schematic representation of a micelle of an ionogenic surfactant according to Stigter[22] (micelle of sodium dodecyl sulphate shown as example).

The behaviour of ionic surfactants is greatly complicated by interaction between micelles and gegenions. The concentration of the latter in the aqueous phase can be supposed to remain almost constant and equal to the concentration of molecularly disperse surfactant (i.e. to the c.m.c.[24]) in the vicinity of the critical micelle concentration, but further increase in surfactant concentration is accompanied by an increase in the concentration of gegenions in the water. This tends to depress the c.m.c. and the surface potential of the micelle, and also increase the size and change the shape of the micelles[12,15].

The micellar surface is not uniform[25]. Nuclear magnetic resonance data[26] indicate that some of the hydrocarbon chains are turned towards the solvent, or at least come into contact with it periodically. It must also be borne in mind that micelles contain a considerable quantity of water, e.g. 33–46 vol.% in those of sodium dodecyl sulphate[27]. The water is probably located not only in the surface layer but also in the hydrophobic core of the micelle, the content decreasing with distance from the polar head group into the interior of the micelle[28,29]. On the whole it may be supposed that the micellar surface is a polar environment differing in properties from water itself. For example, the effective dielectric constant of the micellar surface was estimated as 36[30] from the position of the charge-transfer band in the surface layers of micelles formed by dodecylpyridinium iodide.

The hydrophobic core of a micelle is closely similar to a liquid hydrocarbon in properties, although rather more ordered. Results obtained by means of a fluorescent probe group[31] indicate that the core closely resembles a liquid hydrocarbon in nature, although the microviscosity is considerably higher in micelles than in hydrocarbons. The whole micelle, although evidently possessing some solid character[32], is more in the liquid state. This last view is consistent with the facts (*a*) that micelle-forming ions are able to form mixed micelles with various additives[12], and (*b*) that solubilisation takes place in micellar systems. This process resembles in many respects the extraction of organic substances from an aqueous phase, with the micelles acting as the second phase.

2. Distribution of Simple Substances between Aqueous and Micellar Phases

A specific feature of solutions of surface-active agents is their ability to dissolve within the micelles substances that are sparingly soluble in water, with the formation of thermodynamically stable isotropic solutions[12,33,34]. This explains the sharp increase in solubility of certain substances when the critical micelle concentration is reached in a surfactant solution (the phenomenon of solubilisation). With further increase in the surfactant concentration the solubility increases in proportion to the latter, mainly because of the increase in the total number of micelles in unit volume. Solubilisation is affected by the many factors which in turn influence the properties of micelles (temperature, presence of foreign non-electrolytes, concentration of gegenions), and is further complicated by the effect of the solubilised substance itself on the micelles[35]. Nevertheless, data on solubilisation can be analysed with some caution by means of a simple model, in which micelles are regarded as a separate phase from the rest of the solution[36].

We postulate that a solute A is distributed between micellar and aqueous phases in conformity with the simple distribution law:

$$[A]_M/[A]_W = P_A \qquad (1)$$

Here and subsequently the subscripts "M" and "W" denote quantities relating to micellar and aqueous phases respectively. The total concentration of A, averaged over the volume of the whole system, is

$$[A]_0 = [A]_M CV + [A]_W(1 - CV), \qquad (2)$$

which with (1) gives

$$[A]_0/[A]_W = 1 + (P_A - 1)CV, \qquad (3)$$

where C is the surfactant concentration (molarity) less the c.m.c., and V is the molar volume of the surfactant, the factors CV and $1 - CV$ being the fractions by volume of micellar and aqueous phases respectively. Provided that the distribution (1) is satisfied at concentrations up to S_W, the solubility of A in pure water, its solubility $S_{M,W}$ in the

presence of the surfactant is related to S_W by Eqn. (3), which can be conveniently written

$$S_{M,W}/S_W = 1 + K_A C, \quad (4)$$

where the constant K_A is given by

$$K_A = (P_A - 1)V \quad (5)$$

and thus has the dimensions (M^{-1}) of an ordinary binding constant. From general considerations, however, Eqn. (1) would be satisfied only for dilute solutions. Therefore Eqn. (4) is applicable only to sufficiently sparingly soluble substances, whose saturated solutions can still be regarded as dilute.

(*a*) Determination of binding constants of solutes with micelles

Binding constants of type K_A are convenient measures of efficiency of solubilisation. Examples of the use of solubilisation data for various substances to determine their binding constants with micelles can be found in Refs. 36–40. Fig. 2[4] shows plots of Eqn. (4) illustrating the typical dependence of the solubility of several *p*-nitrophenyl carboxylates on surfactant concentration. A more general method applicable to substances whatever their solubility is to determine their binding with the micelles by gel filtration[40]. However, this method is restricted to fairly large partition coefficients ($P \geqslant 10$).

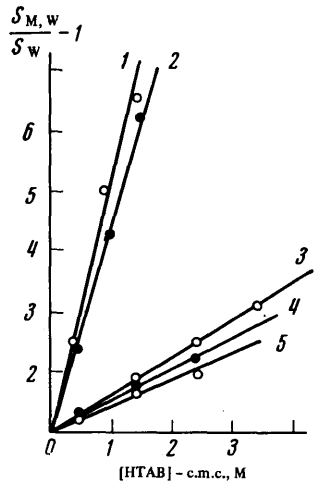

Figure 2. Effect of hexadecyltrimethylammonium bromide on solubility of *p*-nitrophenyl carboxylates: 1) heptanoate; 2) β-phenylpropionate; 3) salicylate; 4) butyrate; 5) αα-dimethylpropionate[4].

The binding constant of a substance with a micelle can readily be found also when the variation in some molecular property on passing from water to the micellar medium can be followed. Such properties may be the visible and ultraviolet spectra[41], the nuclear magnetic resonance[42] and electron spin resonance[43] spectra, or also e.g. the reactivity towards solvolysis[37,38,44]. Since their variation is connected with the change in the microenvironment in the vicinity of the molecule undergoing solubilisation, data of this type can be used to solve the important problem of the arrangement of the solubilised molecule in the micelle.

(*b*) Location and orientation of solubilised molecules in micelle

A solute can be arranged in various ways in the micelle: it may pass completely inside the hydrophobic core, or penetrate a particular depth into the surface layer; it can be adsorbed on the surface of the micelle or—what is most probable for molecules containing polar substituents—be oriented with the polar portion of the molecule situated in the surface layer and the non-polar portion directed into the micelle. In order to solve the problem of where a solubilised molecule had entered—into the hydrophobic core or into the hydrated surface layer—it was usual to compare the spectra (ultraviolet, e.s.r., n.m.r.) observed in the presence of the detergent with the spectra in water and in an organic solvent (hydrocarbon, alcohol). However, the interpretation of such results is usually complicated, because the observed effects may depend on various factors.

An instructive example is the investigation of the polarity of the sorption centre in the enzyme α-chymotrypsin, on which the colorant proflavin is bound. The "red shift" of the visible absorption spectrum of proflavin on interaction with the enzyme was interpreted as resulting from the low polarity of the sorption site in the protein globule, since the same shift occurs in aqueous dioxan[45]. It has since been shown[46], however, that the shift in λ_{max} of proflavin is determined not by the dielectric constant of the medium but by the refractive index. Thus the shift relative to water ($\epsilon = 81$ and $n_D = 1.33$) is the same in dioxan (2.4 and 1.42) and in formamide (109.5 and 1.44). Detailed analysis of the spectral changes undergone by proflavin in various systems suggests[46] the presence of orientation interaction in its complex with chymotrypsin on excitation of the colorant molecule, and hence that the corresponding sorption site in the enzyme is highly polar.

Parallel studies by several methods of the arrangement of solubilised molecules in the micelle[47,48], giving consistent results, are therefore especially valuable. In general aliphatic molecules or side-chains are immersed in the hydrophobic core of the micelle[12,49]; aromatic molecules or parts thereof are probably (but not always[50]) situated in the surface layer of cationic micelles[49], but in the hydrophobic core of anionic and non-ionic[50,51] micelles. Molecules with polar substituents (alcohols, phenols, acids, amines, etc.) are oriented with their polar groups in the surface layer and the non-polar portions immersed in the core[12,47]; ions are adsorbed on the surface of the micelles[12,22].

The efficiency of chemical interaction between solubilised molecules should obviously be strongly dependent on their mutual orientation. The arrangement of solubilised molecules in the micelle must therefore be examined in rather greater detail.

The most widely used method for investigating the microenvironment of solubilised molecules is n.m.r. spectroscopy‡, for the chemical shifts of protons and

‡ The lifetime of solubilised molecules in micelles has also been estimated from n.m.r. spectral data. That of the benzene molecule in micelles of sodium dodecyl sulphate was determined[42] as ~ 10^{-4} s from the broadening of the n.m.r. band of benzene on solubilisation.

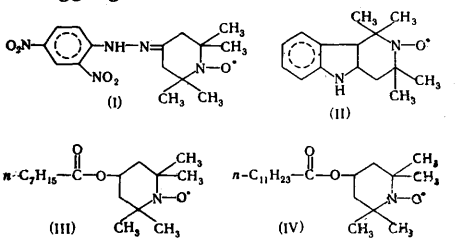
especially fluorine-19 atoms are fairly sensitive to the medium. Muller and Birkhahn[52] suggested as a quantitative measure of the closeness of the environment of a molecule to a liquid hydrocarbon the function

$$Z=(\delta_M-\delta_W)/(\delta_{HC}-\delta_W) \quad (6)$$

where δ_M, δ_W, and δ_{HC} are the chemical shifts of hydrogen or fluorine atoms in the test molecule solubilised by micelles and in aqueous and hydrocarbon solutions. The quantity Z can obviously be calculated also from ultraviolet, visible, or e.s.r. spectroscopic data. The Table gives values for benzene and certain derivatives in the presence of a number of surfactants. Sufficiently reliable interpretation of Z is evidently possible only in comparative experiments examining the variation in Z resulting from variation in some parameter of the system, whereas the absolute value of Z may firstly contain a systematic error[28] and secondly be a non-linear function of the composition of the medium.

Values of Z for aromatic molecules solubilised by micelles of various surfactants[51].

Surface-active agent	Z	Substance
Polyoxyethylene dodecyl ether	0.06-0.16	benzene
Hexadecyltrimethylammonium bromide	0.18	benzene
Sodium dodecyl sulphate	0.20-0.22	radicals I and II
Sodium laurate	0.52	trifluoromethylbenzene
Sodium decanoate	0.29-0.33	benzene
Sodium decanoate + 1 M NaCl	0.55	benzene



Important information on the nature of solubilisation can be obtained simply by comparing the position of the chemical shift of the solubilised molecule with the position in aqueous and hydrocarbon solutions. Such investigations[49] suggest that aromatic molecules are arranged in the surface layer of the cationic micelles n-hexadecyltrimethylammonium bromide, whereas aliphatic molecules and aliphatic side-chains of aromatic molecules enter the hydrocarbon core. The shielding constants of the fluorine nuclei in *para*-substituted fluorobenzenes (with formyl, acetyl, methoxyl, trimethoxymethyl, and diethoxymethyl as substituents) show that these molecules are arranged in the micelles of sodium dodecyl sulphate in such a way that the hydrogen bonds with water are preserved[53]. From this it might be concluded that these molecules are located in the surface layer of the micelle, but since water may be partly enclosed also in the inner regions of the micelle (see above), they may nevertheless be immersed to some extent in the hydrophobic core.

The permeability of micelles for molecules of substances possessing no well defined hydrophobic properties can be studied by means of the n.m.r. spectra of fluorine present in the surfactant (sodium 12,12,12-trifluorododecyl sulphate)[54]. Glycerol, glycine, and urea hardly penetrate the hydrocarbon core of the micelle at all; methanol and acetamide enter only to a slight extent; and ethanol, acetone, and dioxan freely enter the inner regions of the micelles.

The ultraviolet and visible spectra of solubilised molecules can be used only with aromatic compounds. Reigelman et al., in their pioneering work[50], were the first to pose the problem of determining the site of a solubilised molecule in a micelle. In their view four modes of solubilisation—penetration into the hydrocarbon core, deep immersion in the surface layer, shallow immersion in the surface layer, and adsorption on the micelle surface—must be distinguished. They investigated the nature of solubilisation in micelles of three types of surfactants—anion-active (potassium laurate), cation-active (dodecylammonium chloride), and non-ionic (Brij 35—oxyethylated dodecanol). From an analysis of the fine structure and the positions of the maxima in the spectra of several aromatic compounds they concluded that solubilised molecules are arranged in the same way in all three types of micelles: ethylbenzene penetrates into the hydrocarbon core; naphthalene, anthracene, and *trans*-azobenzene are deeply immersed in the surface layer; *o*-nitroaniline effects shallow penetration of the surface layer; and dimethyl phthalate is adsorbed on the surface of the micelles.

A more quantitative result was obtained by Rehfeld[41], who studied the solubilisation of benzene in the presence of sodium dodecyl sulphate. The spectrum of the solubilised benzene, whose concentration in the micelle was 0.47 ppm, was roughly equivalent to the spectrum of a solution of benzene in hydrocarbons and dodecanol or methanol at a concentration of 0.5 ppm. Certain differences in the spectra were due, according to this author, to various non-equivalent positions of the benzene molecule in the micelle, between which dynamic equilibrium was rapidly established.

Investigations using electron spin resonance require that the molecule undergoing solubilisation shall contain a "paramagnetic label", for which purpose iminoxyl radicals have been widely used[55]. The e.s.r. spectra of the "label" enable at least the following information to be obtained—concentration of radicals, polarity of solvent surrounding the radical, rotational mobility of radical, and degree of aggregation of radicals§.

Solubilisation of the radicals (I)–(IV) by micelles of sodium dodecyl sulphate has been investigated by Waggoner and his coworkers[57]. Since both ends of radicals (I) and (II) can be watched (one end by means of the e.s.r. spectra and the other by the ultraviolet spectra), these workers attempted to distinguish three situations—adsorption on the micelle surface, radial orientation in the micelle, and submersion in the hydrocarbon core—but the results were consistent with none of these static models of solubilisation. It was therefore concluded that the observed parameters were mean values resulting from rapid exchange between the different positions, and on the average the radicals were in a fairly polar environment. Data on radicals (III) and (IV) also indicate that the solubilised molecules are subject to relatively rapid rotational motion.

Information on the nature of the bonding of solubilised molecules by micelles was obtained also by studying the effect of salts on solubilisation. Additions of salts lower the degree of solubilisation of octanol and benzaldehyde by

§ A critical survey has been published[56] of factors complicating the interpretation of e.s.r. spectra of solubilised radicals.

hexadecylpyridinium[58], and of dimethyl phthalate by potassium laurate and Triton X[59] (oxyethylated octylphenol). This indicates that solubilised molecules of these substances interact with polar groups of the surfactant molecules. On the other hand, the solubilisability of octane and benzene by hexadecylpyridinium increases in the presence of salts[58], which is interpreted as a change in structure of the micelles produced by the salts, although this phenomenon can probably be explained as an ordinary salting-out effect.

The above brief review shows that the interrelation between the molecular structure of organic compounds and their arrangement and orientation in the micelle on solubilisation cannot yet be regarded as adequately studied. A future kinetic study of organic reactions occurring in micelles may reveal fine effects of micellar structure and the orientation of solubilised molecules.

(*c*) Nature of interactions during solubilisation and free energy of transfer from water into the micelle

Hydrophobic and ionic interactions with non-polar and charged groups of the solubilised molecules are responsible for binding to micelles[12,33,34,60]. In the case of aromatic molecules interaction between charged groups in the micelle surface and the π-electron system of the aromatic ring also plays a part[49]. We give some very rough estimates of the partition coefficient P to be expected for various types of molecules. We start from the usual relation for the equilibrium constant

$$P = e^{-\frac{\Delta\mu_0}{RT}} \qquad (7)$$

where $\Delta\mu_0$ is the change in the standard chemical potential of the partitioned substance on passing from water to the micelle.

If a molecule is bound to a micelle mainly by hydrophobic interactions, $\Delta\mu_0$ can be either calculated theoretically[61,62] or estimated from data on the free energy of transfer of the molecule from water to a non-aqueous solvent, e.g. octanol[60,63]. The correctness of such estimate is confirmed in particular by data[36] showing that the partition coefficients of several dyes between the micelles of a non-ionic surfactant (Triton X-100) and water are close to the values for these dyes between octanol and water. We have found that the increment in the free energy of transfer of an aliphatic or a phenylalkyl group from water into the micelle of a cation-active surfactant (hexadecyltrimethylammonium bromide) is practically equal to the increment for transfer of the same group from water to n-octanol[4] (0.6–0.7 and 2.9 kcal mole^{-1} for a methylene group and for benzene respectively). The latter value yields for benzene $P \simeq 100$; experimental data give calculated values of $P = 75$ and 280 for sodium dodecyl sulphate[41] and for hexadecyltrimethylammonium bromide[64].

The contribution of the electrostatic interaction of an ion or an ionic group in a molecule with the micellar charge of an ionogenic surfactant can be estimated from the expression for the electrostatic free energy $Ze\Psi$, where Z is the ionic charge, e the electronic charge, and Ψ the surface potential of the micelle[12]. If Ψ is expressed in millivolts, as is usual, the contribution of electrostatic interaction to the partition coefficient can be written $\exp(-Z\Psi/25.2)$ (at 20°C).[65] With the usual values of the ζ-potential of 50–100 mV (see above) this factor is 10–50. However, the actual potential at the site of a solubilised molecule is usually higher than the ζ-potential[23].

The energy of interaction with dipolar molecules, even those possessing large dipole moments (e.g. Zwitterionic amino-acids), is probably insignificant, and for systems of this type (interaction of amino-acids with macroions) is comparable with RT.[66]

III. KINETICS OF CHEMICAL REACTIONS IN THE PRESENCE OF MICELLES OF SURFACE-ACTIVE AGENTS

In the discussion of the kinetics of micellar reactions the micelle M is most often regarded[2] as an additional species, which on combination with a reactant A can change its reactivity both in a unimolecular reaction and on reaction with another substance B dissolved in water:

$$\begin{array}{ccc} A + M & \overset{K}{\rightleftharpoons} & AM \\ \downarrow k_W[B] & & \downarrow k_M[B] \\ \text{Products} & & \text{Products} \end{array} . \qquad (8)$$

The association constant in (8) has its usual significance ($K = [AM]/[M][A]$), while k_W and k_M are the conversion rate constants of A in water and in the micelle. The effective reaction rate constant measured experimentally (as the ratio of the rate of the process to the total concentration of the reactant: $k_{exp} = v/[A]_0$) depends in this case on the surfactant concentration:

$$k_{exp} = \frac{k_W + k_M[M]}{1 + K[M]} . \qquad (9)$$

provided that $[M] \gg [AM]$. The concentration of the micelles is given by the ratio $[M] = C/N$, where N is the aggregation number.

According to the principles discussed in Section II, however, the binding of the reactant molecules to the micelles involves physically a partition of the substance between micellar and aqueous phases rather than association in the stoichiometric proportions 1 : 1. In other words, the kinetic scheme of the reaction must be written differently:

$$\begin{array}{ccc} (A)_W & \overset{P}{\rightleftharpoons} & (A)_M \\ \downarrow k_W[B] & & \downarrow k_M[B] \\ \text{Products} & & \text{Products} \end{array} \qquad (10)$$

where the partition coefficient P is given by Eqn. (1). When the surfactant concentration greatly exceeds the reactant concentration, the two approaches lead to formally indistinguishable kinetic equations. A formula for the effective rate constant based on scheme (10) was probably first given by Grunwald[67]:

$$k_{exp} = \frac{k_W + k_M P \varphi_M}{1 + P\varphi_M} \qquad (11)$$

where the volume fraction of the micellar phase $\varphi_M \ll 1$. Since $\varphi_M = [M]NV$, a relation can easily be established between the equilibrium constants in Eqns. (9) and (11):

$$K = P \cdot N \cdot V \qquad (12)$$

Equations (9) and (11) are quite correct for first-order reactions, but there are fundamental objections to their application to higher-order reactions. With a bimolecular reaction, in fact, the constant k_M in these equations has the significance of a rate constant for interaction of one reactant, attached to the micelle, with the other, unattached reactant, uniformly distributed throughout both phases. However, the latter condition can hardly be satisfied in general, since the second reactant may also

interact with the micelle, and will then have different concentrations in aqueous and micellar phases. In this case, moreover, the fractions of the second reactant in aqueous and micellar phases would depend on the concentration of micelles, so that in principle Eqns. (9) and (11) give an incorrect dependence of k_{exp} on the surfactant concentration. This is evident from the monotonic increase in k_{exp} with the volume fraction of the micellar phase indicated by Eqn. (9): actually, the dependence of k_{exp} on C observed experimentally for a bimolecular reaction usually passes through a maximum[1]. The occurrence of an optimum surfactant concentration is easily explained (see below) if the distribution of the second reactant is taken into account.

The situation is simpler in the particular case in which the second reactant has a very high concentration (in comparison with the surfactant) or is a component of a buffer solution. Its concentrations in micellar and aqueous phases then remain almost constant but are unequal and are independent of the surfactant concentration. As a consequence, Eqns. (9) and (11) give a correct formal description of the dependence of k_{exp} on the surfactant concentration. In comparing the constants k_M found by means of these equations with the constants k_W, however, we must bear in mind that the former are effective values, since they contain the ratio of the concentrations of the second component in water and in the micelle.

The effect of micelles on the kinetics of bimolecular reactions when both reactants are bound to the micelle has been discussed qualitatively by Heitmann[68]. A quantitative treatment of this concept and its experimental verification have been undertaken by the Reviewers[4,69], and will be considered in detail below.

1. Kinetic Concept of Micellar Effects in a Bimolecular Reaction

Regarding a surfactant solution above the critical micelle concentration as a two-phase system, in conformity with the above discussion, we can express the observed reaction velocity v, averaged over the whole volume of the system, in terms of the reaction velocities in micellar and aqueous phases v_M and v_W:

$$v = v_M CV + v_W(1 - CV) = k_{exp}\,[A]_0[B]_0. \qquad (13)$$

Assuming that the law of mass action is satisfied in each phase, we obtain

$$\left.\begin{aligned} v_M &= k_M [A]_M [B]_M \\ v_W &= k_W [A]_W [B]_W \end{aligned}\right\}. \qquad (14)$$

The relation between the total concentrations of the reactants $[A]_0$ and $[B]_0$ and their true concentrations in the corresponding phases is established by means of Eqns. (1) and (2) for each reactant. This involves the postulate that the equilibrium distribution of the reactants between the phases is not displaced by the occurrence of the chemical reaction. The justification is that the exchange of molecules between the phases occurs very rapidly (see above). From Eqns. (1), (2), (13), and (14) it follows that

$$k_{exp} = \frac{k_M P_A P_B CV + k_W(1 - CV)}{(1 + K_A C)(1 + K_B C)} \qquad (15)$$

where the constants K_A and K_B are defined by formula (5).

Molecules of the same kind can in general be differently arranged and oriented in the micelle (above). The observed effective rate coefficient k_M is therefore in fact "averaged" over the volume of the micelle. We consider as a limiting case the situation in which the observed reaction velocity includes not only the rates in micellar and aqueous phases but also the rate of a reaction between solubilised and unsolubilised reactants:

$$v = k_M [A]_M [B]_M CV + k'_M [A]_M [B]_W CV + k''_M [A]_W [B]_M CV + k_W [A]_W [B]_0 (1 - CV)$$

whence we obtain

$$k_{exp} = \frac{(k_M P_A P_B + k'_M P_A + k''_M P_B) CV + k_W(1 - CV)}{(1 + K_A C)(1 + K_B C)}$$

This equation is similar in form to (15), and when P_A, $P_B \gg 1$ (strong binding of reactants) and $k_M \simeq k_M' \simeq k_M''$ it shows approximately the same dependence of k_{exp} on P_A, P_B, and C as does Eqn. (15).

In the case of dilute surfactant solutions, in which the volume fraction of the micellar phase is small, Eqn. (15) can be simplified to

$$k_{exp} = \frac{k_M P_A P_B CV + k_W}{(1 + K_A C)(1 + K_B C)}. \qquad (16)$$

This equation¶, first given in Ref. 69, enables the nature of micellar effects to be analysed as functions of the relation between the "elementary" rate constants in the two phases and the binding constants of the reactants. We shall consider some important particular cases.

Case 1. Both reactants are weakly bound to or are repelled from the micelle: i.e. P_A, $P_B \leq 1$. Then K_A and K_B vary from zero to $-V$, and when $C < 0.1$ M (corresponding to dilute surfactant solutions) we have

$$k_{exp} \cong k_M P_A P_B CV + k_W. \qquad (17)$$

In this case an appreciable increase in k_{exp} in comparison with k_W is possible only with $k_M \gg k_W$, since $CV \ll 1$. In rare cases, however, k_M exceeds k_W hundredfold, but usually $k_M \simeq k_W$ (see below). Even in the most favourable case (when $P_A \simeq P_B \simeq 1$ and at higher surfactant concentrations of ~ 0.1 M), therefore, k_{exp} is able to exceed k_W only about fourfold, since for the usual surfactants V is around 0.3 M^{-1}.[4,6,70] Evidently this case is in general of no special interest.

Case 2. One reactant is strongly bound to the micelle, while the other is weakly repelled from it. This implies e.g. that $P_A \gg 1$, while $P_B \leq 1$. In this case Eqn. (16) can be simplified to

$$k_{exp} = \frac{k_M P_A P_B CV + k_W}{1 + P_A CV} \qquad (18)$$

since from (5) we have $K_A \simeq P_A V$. If the reactant B is very strongly repelled from the micelle $P_B \simeq 0$, or the reaction rate constant in the micelle is small $k_M \simeq 0$, the micelles inhibit the reaction, since in this case k_{exp} would fall with increase in C:

$$k_{exp} \approx \frac{k_W}{1 + P_A CV}. \qquad (19)$$

If, however, $P_B \simeq 1$, it follows from (18) that $k_{exp} \simeq k_W$ in the absence of a specific effect of the micelles on the reaction, i.e. with $k_M \simeq k_W$, and therefore the reaction

¶ When the reactant concentrations are far smaller than the surfactant concentration, the concept of a distribution of the reactants between micellar and aqueous phases and the less rigorous hypothesis of association of reactants with micelles give the same results. We have already seen this for a first-order reaction. The mathematics for a second-order reaction is similar.

velocity is almost independent of the presence of the surfactant. But when $k_M > k_W$, or conversely $k_M < k_W$, increase in C produces an increase or conversely a decrease in k_{exp}, in conformity with the equation

$$k_{exp} \approx \frac{k_M P_A CV + k_W}{1 + P_A CV} \qquad (20)$$

and in both cases k_{exp} reaches the limiting value k_M.

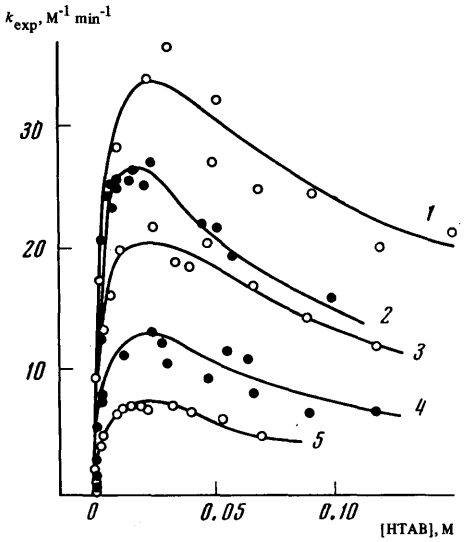


Figure 3. Dependence of experimental rate constant for reaction between fluoro-2,4-dinitrobenzene and the methyl ester of *N*-benzoyl-L-histidine on surfactant concentration at various temperatures (°C): 1) 55; 2) 48; 3) 40; 4) 32; 5) 25.[71]

Case 3. The case in which both reactants are strongly bound to micelles is of especial interest. Considerable acceleration of the reaction is now possible in the presence of surfactant micelles even if they have no specific influence on reaction velocity. The reason is that the reactants become concentrated in the micellar phase. When P_A, $P_B \gg 1$, Eqn. (16) can be written

$$k_{exp} = \frac{\bar{k}_M K_A K_B C + k_W}{(1 + K_A C)(1 + K_B C)} \qquad (21)$$

where

$$\bar{k}_M = k_M / V. \qquad (22)$$

If the reaction hardly occurs at all in the micelle ($k_M \simeq 0$), the micelles have an inhibiting effect, since k_{exp} falls monotonically with increase in C:

$$k_{exp} \cong \frac{k_W}{(1 + K_A C)(1 + K_B C)}. \qquad (23)$$

In all the remaining cases in which reaction is accelerated in the presence of micelles, the dependence of k_{exp} on C passes through a maximum (Fig. 3 illustrates a typical case). The physical significance of the presence of an optimum is that increase in the volume of the micellar phase is accompanied both by an increase in the quantity of substance passing into it from water and by a decrease in the concentration of this substance in the micellar phase. The first process tends to accelerate the reaction by increasing the relative proportion of the more rapid micellar reaction, and it predominates at low surfactant concentrations, while the quantity of substance passing into the micelles is small. The second process—dilution of the reactants in the micellar phase—slows down the reaction, and predominates at high surfactant concentrations, when the reactants are mainly present in the micellar phase.

This aspect can be analysed in greater detail for the most important particular case, in which the reaction velocity in the aqueous phase can be neglected. Putting $\bar{k}_M K_A K_B C \gg k_W$, we can then simplify Eqn. (21), and obtain the formula[4]

$$C_{opt} = (K_A K_B)^{-1/2} \qquad (24)$$

for the optimum surfactant concentration, corresponding to the maximum value of k_{exp}. The maximum acceleration of the reaction is then

$$(k_{exp}/k_W)_{max} = \frac{k_M}{k_W} \frac{K_A K_B}{V(\sqrt{K_A} + \sqrt{K_B})^2}. \qquad (25)$$

The ratio k_M/k_W represents the change in reactivity when the reactants are transferred from water into the micelle, and hence the specific effect of the micelles on the transition state of the reaction. The factor following the ratio on the right-hand side of (25) represents the "trivial" acceleration produced by the localisation of the reactants in the micelle.

2. Shift in pK_a of Ionogenic Reactant in presence of Surfactant Micelles

Acceleration or retardation of a reaction may also be caused by a shift in the pK_a of an ionogenic reactant in the presence of micelles. General consideration has already been given[4] to the kinetics of a bimolecular reaction involving an ionogenic reactant. Taking into account the dissociation of the reactant

$$AH \overset{K_a}{\rightleftharpoons} A^- + H^+ \qquad (26)$$

and assuming that the reactive form is, for instance, the anion

$$A^- + B \xrightarrow{k_W^0} \text{Products} \qquad (27)$$

we can write the effective rate constant of the reaction in the form

$$k_W = k_W^0/(1 + [H^+]_W/K_a). \qquad (28)$$

Formally the same relation applies in the presence of a surfactant:

$$k_{exp} = k_{exp}^0/(1 + [H^+]_W/K_{a,exp}), \qquad (29)$$

where

$$k_{exp}^0 = \frac{\bar{k}_M^0 K'_A K_B C + k_W^0}{(1 + K'_A C)(1 + K_B C)} \qquad (30)$$

and

$$K_{a,exp} = K_a \frac{1 + K'_A C}{1 + K_A C}. \qquad (31)$$

Here K_A and K'_A are the binding constants of undissociated and ionic forms of the reactant A, and K_B is the binding constant of reactant B. Analysis of Eqn. (29) yields for

the maximum acceleration of the reaction the expression[4]

$$(k_{exp}/k_W)_{max} = \frac{k_M}{k_W}\frac{K_A K_B}{V(\sqrt{K_A}+\sqrt{K_B})^2}\frac{K'_A}{K_A} \quad (32)$$

As with the simpler equation (25), the second factor on the right-hand side represents the localisation of the reactants (substance B and the non-ionic form of A) into the micellar phase. The last factor on the right-hand side of Eqn. (32) represents the effect of the shift in the pK_a of the ionogenic reactant in the presence of the micelles, as can be seen from Eqn. (31), whence it follows that $K_{a,exp}/K_a$ tends to K'_A/K_A at sufficiently high values of C. With a cationic micelle, which would obviously bind the anion A^- more strongly than the non-ionic form A, we have $K'_A > K_A$, so that the shift in pK_a makes an additional contribution to the acceleration of the reaction in the presence of micelles (this effect is discussed in greater detail in Ref. 4).

3. Determination of Binding Constants of Reactants with Micelles from Kinetic Data. Experimental Determination of Second-order Rate Constant in Micellar Phase

It is a simple matter to analyse the dependence of the rate of a first-order reaction on C, for which purpose we convert Eqn. (11) to the form

$$k_{exp} = \frac{k_M P_A C V + k_W}{1 + P_A C V} \quad (33)$$

on the assumption that $\varphi_M = CV$. The value of k_M can then be found as the limiting dependence of k_{exp} on C at high C, and the binding characteristic of the reactant PV as the reciprocal of the abscissa for which $k_{exp} - k_W$ has half its limiting value. Graphical methods, based on the linearisation of Eqn. (33), are normally used[2] to evaluate k_M and PV.

Binding constants of reactants with micelles and the true reaction rate constant in the micellar phase can also be found for a bimolecular reaction. We shall consider this for one of the most important particular cases of micellar catalysis†, when $k_M K_A K_B C \gg k_W$. For this purpose we write (21) in the form

$$C/k_{exp} = \alpha + \beta C + \gamma C^2, \quad (34)$$

where

$$\alpha = 1/k_M K_A K_B,$$
$$\beta = \alpha(K_A + K_B),$$
$$\gamma = \alpha K_A K_B. \quad (35)$$

A graphical method is convenient for determining α, β, and γ from experimental data. The value of α is then the intercept made on the vertical axis by the curve representing the dependence of C/k_{exp} on C according to Eqn. (34). With α determined, the experimental results are conveniently plotted as the linear equation

$$\frac{C/k_{exp} - \alpha}{C} = \beta + \gamma C \quad (36)$$

which follows from (34). The intercept on the vertical axis and the slope of the straight line obviously give β and γ respectively. Finally, knowing α, β, and γ, we can use Eqns. (35) to calculate the required quantities K_A, K_B, and k_M.

A study[71] of the effect of cationic micelles of hexadecyltrimethylammonium bromide on the aminolysis of fluoro-2,4-dinitrobenzene by *N*-benzoyl-L-histidine has shown[71] agreement between the binding constants of the reactants with the micelles K_A and K_B found by the above method from kinetic data and measurements in an independent experiment on the solubilisation of the reactants by the micelles. Such agreement proves the correctness of the above kinetic concept of micellar effects in bimolecular reactions.

The molar volume V of the surfactant must be known in order to calculate the true rate constant k_M of a bimolecular (but not a unimolecular) reaction in the micellar phase from the measured effective value $\bar{k}_M$. This independent parameter must be known also in order to calculate partition coefficients P from experimental binding constants K. Certain difficulties arise as a consequence, since the molar volume V occurring in Eqn. (5) or (22) is in fact an effective quantity, representing that portion of the surfactant molecule which forms the region of the micelle where the reactants are actually solubilised and the chemical reaction takes place. However, difficulties already arise in estimating the total molar volume of the surfactant. The estimation usually starts[4,6,40] from the density of the micelles calculated from the partial specific volume of the surfactant above the critical micelle concentration, which varies from 0.9 to 1.1 g ml^{-1} for different surfactants[70]. On this basis an estimate of the total molar volume of the surfactant in the micelles which started from a density of ~ 1.0 g ml^{-1} might have been regarded as quite acceptable. However, this density applies to the "dry" surfactant, and does not allow for the hydration of the micelles, which is very considerable (see above). Nevertheless, the use of such a value for the density of the micelles probably does not lead to serious errors.

As example we estimate the size of micelles of the well studied sodium dodecyl sulphate[22,25]. The probable radius of the hydrocarbon core of its spherical micelles is 16.6 Å, the thickness of the Stern layer 4.6 Å, and the aggregation number 62. Hence the volume of the whole micelle is 4.0×10^4 Å^3,[5] or the molar volume of the surfactant in the micelles is 0.4 M^{-1}. Using the molecular weight 288 and density of the "dry" surfactant in the micelles 1.1 g ml^{-1},[70] we find that the corresponding molar volume is 0.26 M^{-1}. Since sodium dodecyl sulphate micelles contain 33 vol.% of water[27], the molar volume of the hydrated surfactant in the micelles is 0.39 M^{-1}, almost identical with the estimate obtained above from the dimensions of the micelles.

Estimating the effective molar volume is a more complicated task. All the reactions that have hitherto been studied in the presence of micelles involve polar molecules, which on solubilisation are probably located in the surface layers of the micelles. In most cases the reaction is assumed to occur in some surface region of the micelle, which covers the Stern layer and a further 3–4 methylene groups of the hydrocarbon chain in the surfactant molecule[1]. In the case of sodium dodecyl sulphate this means that ~ 4 Å must be added to the 4.6 Å thickness of the Stern layer. The volume of such a layer is 3.6×10^3 Å^3, which gives a molar volume of 0.32 M^{-1}, only slightly less than the above estimate of the total molar volume of the surfactant. It may be expected that this difference will also be small in the remaining cases.

† A general analysis of Eqn. (21) has been given previously[71]. The general equation (16) is analysed similarly to (21).

4. Micellar Catalysis in Reactions of the *n*th Order

The contribution made by concentrating the reactants to accelerating the reaction should increase with increase in the kinetic order of the reaction. We can show this for the *n*th-order reaction

$$nA \rightarrow \text{Products}, \qquad (37)$$

When the concentrating effect in the micellar phase is strongly marked ($P_A \gg 1$), while the surfactant concentration is not too large ($CV \ll 1$), the effective reaction rate constant $k_{exp} = v/[A]_0^n$ is given by[8]

$$k_{exp} = \frac{k_M P_A^n CV + k_B}{(1 + P_A CV)^n}. \qquad (38)$$

With $n = 1$ the dependence of k_{exp} on the surfactant concentration tends to the limiting value k_M. With other values of n this function has a maximum. With sufficiently large accelerations, when the rate of reaction in the aqueous phase can be neglected $k_M P_A^n CV \gg k_W$, the optimum surfactant concentration is‡

$$C_{opt} = 1/P_A V(n-1). \qquad (39)$$

At this surfactant concentration the maximum acceleration reaches[8]

$$(k_{exp}/k_W)_{max} = \frac{k_M}{k_B} \cdot \frac{(n-1)^{n-1}}{n^n} P_A^{n-1}. \qquad (40)$$

Equation (40) shows that two factors—change in reactivity of A on passing from water to the micellar phase and the concentrating of A into the micelle—are responsible for accelerating the reaction. The first factor k_M/k_W depends on the mechanism of the reaction and the orientation of the reactants in the micelle; the second factor is determined [not] only by the partition coefficient of the substance between micelle and water but also by the order of the reaction. Values of P usually lie in the range 10^2–10^3. Then the maximum acceleration due solely to the concentration effect, i.e. with $k_M/k_W = 1$, is shown by Eqn. (40) to lie in the range 10–10^2 for a bimolecular reaction, and 10^3–10^5 for a termolecular reaction.

Since the factor $(n-1)^{n-1}/n^n$ in Eqn. (40) varies only slightly with n, the involvement of each new species in the reaction (i.e. unit increase in the order of the reaction) increases the efficiency of micellar catalysis approximately P-fold. This was confirmed by studying the effect of micelles of sodium dodecyl sulphate on the kinetics of the hydrolysis and the formation of benzylideneaniline[8]

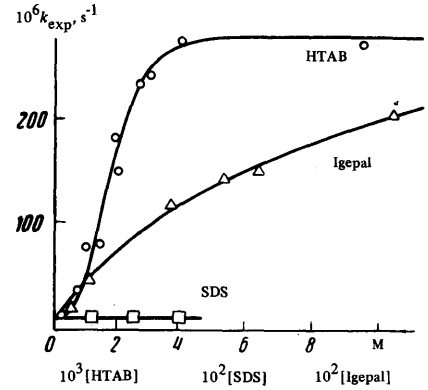
$$C_6H_5NH_2 + C_6H_5CHO \rightleftharpoons C_6H_5N{=}CHC_6H_5 + H_2O. \qquad (41)$$

At pH < 9 this reaction is acid-catalysed, whereas at pH 9–12 its progress is independent of pH. Hence the efficiency of micellar catalysis when the reaction order varies from 1 to 3 could be followed by studying the rates of forward and reverse reactions in various pH ranges. Micelles of sodium dodecyl sulphate were found to produce a 3-fold retardation of the pseudounimolecular (pH-independent) hydrolysis of benzylideneaniline, whereas the pseudobimolecular reaction (acid-catalysed hydrolysis) underwent 20-fold acceleration. The effect of micelles on the bimolecular formation of benzylideneaniline was in turn 3-fold acceleration, but the termolecular (acid-catalysed) reaction was accelerated 125-fold. Thus the efficiency of micellar catalysis increases by factors of 40–60 with unit increase in the order of the reaction. This is consistent with the above kinetic concept, since the partition coefficients of the reactants lie in the same range (P = 30–80).[8]

The facts cited in this Review together with the detailed investigation of the effect of surfactant micelles on the kinetics of several other reactions[1,2] demonstrate that the kinetic concept of micellar catalysis that has been developed has the following merits: (i) the dependence of reaction velocity on surfactant concentration can be correctly described for reactions of different kinetic orders; (ii) the binding constants of reactants with the micelle can be calculated from kinetic data, and the reaction rate constant in the micellar phase can be estimated with satisfactory accuracy; and (iii) the acceleration of the reaction due to the concentrating of reactants in the micelle can be predicted and calculated theoretically.

IV. NATURE OF MICELLAR CATALYSIS

Two types of physicochemical factors—(1) change in reactivity of reactants on transfer from water to the micellar phase and (2) the concentrating of reactants into the micellar phase (Eqn. 25) in the case of reactions of the second and higher orders—can be distinguished as responsible for the efficiency of micellar catalysis. The above effect of the shift in the pK_a of an ionogenic reactant is essentially of the second type, since it represents the preferential concentrating of one ionic form relative to the other. Effects of the first type are characterised by the ratio of the rate constants k_M/k_W and may be caused by the environment (including electrostatic interaction of the transition state of the reaction with the surface charge of the micelle) and by orientation of the reactants in the micelle. The contribution of the concentration effect in accelerating reaction is determined mainly by the strength of ionic and hydrophobic interactions between reactant molecules and micelles (by the partition coefficients of the reactants).



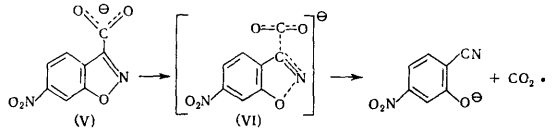


Figure 4. Effect of various surfactants on rate of decarboxylation of the 6-nitrobenzisoxazole-3-carboxylate anion (42).[72]

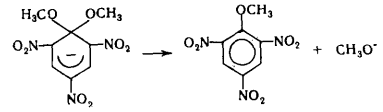
The most reliable information on the effect of micelles on the true reaction rate constant in the micellar phase

‡ Equations essentially equivalent to (38) and (39) were probably first given in Ref. 9, in connection with the kinetics of emulsion polymerisation.

will be provided by the study of *unimolecular reactions*, when k_M can be found without any assumptions concerning V (see above). Unfortunately, very little work has been done on such reactions. Data obtained by Bunton and Minch[72] on the effects of hexadecyltrimethylammonium bromide (HTAB), the non-ionic surfactant Igepal (an oxyethylated alkylphenol), and sodium dodecyl sulphate (SDS) on the kinetics of the decarboxylation of the anion (V) are plotted in Fig. 4. These workers assume[72] that the catalytic effect of the first of these surfactants is due to the action of the positive charge of the micelle in stabilising the anionic transition state (VI), in which the charge is more delocalised than in the initial species (V):

(42)



In our view this interpretation is not entirely satisfactory, since firstly it does not explain the catalytic action of a non-ionic surfactant, and secondly it is not entirely clear why a more delocalised charge on the substrate should be subject to stronger electrostatic interaction with the micelle. Probably in this case direct electrostatic interaction with the micellar charge is manifest only in binding the reactant to the micelles. This is indicated by our treatment of the kinetic data (Fig. 4) by means of Eqn. (33). Closely similar values of k_M were obtained for the quaternary bromide and Igepal (2.9×10^{-4} and 3.0×10^{-4} s^{-1}). On the other hand, the binding constants of the initial reactant with the corresponding micelles actually differ substantially (1400 and 20 M^{-1} respectively). The lack of effect of sodium dodecyl sulphate on the reaction is clearly due to electrostatic repulsion of the reactant from the anionic micelle. With cationic and non-ionic micelles the most probable factor tending to increase k_M in comparison with k_W is in our view replacement of the aqueous environment by the comparatively non-polar environment of the micelle. The direction and the magnitude of the observed effect ($k_M/k_W \simeq 100$) are fully consistent with those to be expected for processes involving delocalisation of the charge, and may be due both to stronger hydration of the localised charge in water and to stronger dispersion interaction of the delocalised charge with its environment in the micelle[73,74].

The breakdown of the 2,6-dinitrophenyl phosphate dianion[75]

$$ArOPO_3^{2-} \rightarrow [ArO^- \ldots PO_3^-] \rightarrow ArO^- + PO_3^- \qquad (43)$$

is an analogous process. In the presence of hexadecyltrimethylammonium bromide the reaction is accelerated, with $k_M/k_W = 29$ and $K = 1250$ M^{-1}. The substrate remains almost completely unattached to micelles of a non-ionic surfactant, let alone to an anionic agent; this may explain the lack of effect of non-cationic surfactants on the reaction velocity. The considerable contribution of electrostatic attraction to the efficiency of binding of a doubly charged ion (see above) may be responsible for the absence of binding. However, as in the preceding example, electrostatic interaction between reactant and micellar charge has only a very slight effect on the reaction in the micellar phase. An indication of this is the "competitive" inhibition of micellar catalysis produced by the introduction of gegenions leading to neutralisation of the surface charge on the micelle: i.e. the binding constant decreases, but the rate constant k_M remains almost constant. It is interesting that micelles do not catalyse hydrolysis of the *p*-nitrophenyl phosphate monoanion or the glucose 6-phosphate dianion, which involves transfer of a proton to the resulting negative charge and hence is not accompanied by delocalisation of charge in the transition state.

E. and J. Fendler studied the effect of surfactants on the kinetics of the unimolecular decomposition of Meisenheimer complexes[76]. They examined in greatest detail the reaction

(44)

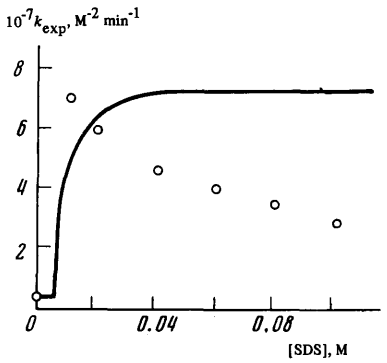
which is retarded in the presence of hexadecyltrimethylammonium bromide and Igepal, but whose rate is unaffected by sodium dodecyl sulphate. This latter fact is easily explained by electrostatic repulsion of the reactant from the anionic micelle. Although the data given[76] are unfortunately insufficient for detailed analysis of the kinetics, nevertheless even qualitative comparison of the effects observed with different surfactants indicates that here, too, interaction of the substrate with the micellar charge has no decisive effect on the reaction rate constant in the micelle k_M.

The above facts suggest that in general, when the sole difference between initial and transition states is the degree of delocalisation of the charge, the rate constant k_M is mainly affected merely by the change in reaction medium when the reactant passes into the micellar phase. A specific effect of the micellar charge on the rate of a unimolecular reaction can probably be expected only when ionisation occurs in the transition state, as e.g. in the hydrolysis of t-butyl chloride[73].

Most *bimolecular reactions* studied hitherto involve the interaction of appreciably hydrophobic neutral molecules with ions. They comprise mainly the acid and alkaline hydrolysis of carboxylic esters, phosphoric and sulphuric esters, acetals and orthoesters, Schiff bases, and aryl and alkyl halides, as well as nucleophilic substitution of the latter compounds with anions. Data on the effect of micelles on the kinetics of these reactions have been assembled in Ref. 2. The recently investigated reduction of iminoxyl radicals by iron(II) ions[77,78] and the reaction of benzene with the hydrated electron[79] are of the same type. Micellar effects on these processes exhibit several characteristic general features, although there are exceptions[1,2,80]. The reaction is usually accelerated by a surfactant whose micelles are oppositely charged to the reactant ion; when micelles and reactant ions bear like charges, the reaction is inhibited. Non-ionic surfactants generally have no significant influence on the rates of these reactions. The efficiency of ionic surfactants is in turn greatly diminished by increasing the concentration of gegenions.

The simplest explanation of the regularities observed is that a hydrophobic reactant is attached to a micelle by hydrophobic interactions, independently of the charge on the latter. If the second reactant is oppositely charged to the micelle, it also becomes bound to the latter, and thus the reactants are concentrated, which is responsible for accelerating the reaction. If, however, the ion bears a like charge to the micelle, it is repelled from the latter, and reaction is retarded owing to separation of the reactants (Eqn. 19). Since the binding of ions is determined by the surface potential of the micelle, the lowering of the potential with increasing concentration of gegenions tends to diminish the attachment of a reactant ion and hence decreases the efficiency of micellar catalysis.

A fundamental difficulty is encountered when Eqn. (16) is used to analyse the kinetics of these reactions. In fact increase in surfactant concentration is accompanied by an increase in the concentration of gegenions and thus a fall in the surface potential, which entails a decrease in the binding constant for the ionic reactant and a consequent divergence between theoretical and experimental variations of k_{exp} with C (Fig. 5). At large values of C this disregarded effect may be very considerable[8]. The method sometimes used, of maintaining a constant total concentration of gegenions[81], is not entirely correct, since these ions attach to the micelles, so that their concentration in the aqueous phase, which should have been maintained constant, falls with increase in C.



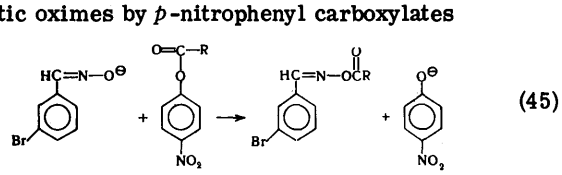


Figure 5. Dependence of experimental rate constant for the acid hydrolysis of benzylideneaniline on concentration of sodium dodecyl sulphate[8]. The theoretical curve has been drawn on the assumption that the surface potential of the micelle remains constant with increase in the surfactant concentration.

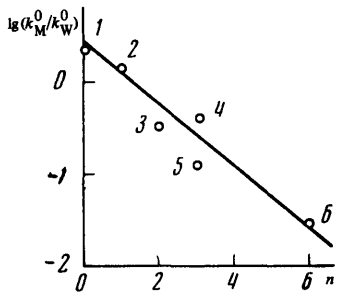
The above kinetic concept of micellar catalysis has formed the basis for a most detailed study[4] of the acylation of aromatic oximes by p-nitrophenyl carboxylates

(45)

in the presence of hexadecyltrimethylammonium bromide. Analysis of the experimental results by means of Eqn. (29) shows that the acceleration of the reaction due to the shift in the pK_a of the oxime is about 15-fold. The effect of concentrating the reactants—ester and undissociated form of oxime—in the micellar phase varies from 60 for the acetate to 2000 for the heptanoate. The two effects enable substantial accelerations to be achieved, up to 17 000 in the case of the salicylate.

An extremely interesting dependence of k^0_M/k^0_W on the structure and dimensions of the aliphatic portion of the hydrocarbon radical R has been found in the latter investigation[4] (Fig. 6). Since the mechanism of reaction (45) should not depend on the size of R, so that the same change in reactivity on transfer of the reactants to the micellar phase should be produced by the environment and by interaction with the micellar charge, the most probable reason for the observed dependence of the ratio on the size of the side-chain R may be *orientation of the reactants in the micelle*.



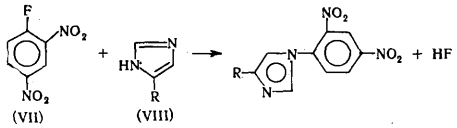


Figure 6. Dependence of logarithm of ratio of rate constants in micellar k^0_M and aqueous k^0_W phases for the acylation of m-bromobenzaldehyde oxime on number n of methyl and methylene groups in acyl portion of p-nitrophenyl carboxylate acylating agent: 1) salicylate; 2) acetate; 3) β-phenylpropionate; 4) $\alpha\alpha$-dimethylpropionate; 5) butyrate; 6) heptanoate[4].

A semi-quantitative interpretation of this effect is that ions and aromatic molecules are sorbed in the surface layer of the quaternary ammonium micelles, whereas the aliphatic chains on solubilisation by the micelle are immersed in the hydrophobic core. Thus increase in size of the aliphatic portion R will secure an orientation of the ester molecule such that both R and the ester group will be drawn into the hydrophobic core of the micelle. This, of course, would prevent its interaction with the oxime ion. It may be postulated as a first approximation that every methyl or methylene group makes a roughly constant positive contribution, equal to the incremental free energy of transfer of this group from the hydrophobic core to the hydrated surface layer, to the free energy of activation of the reaction in the micellar phase. The validity of such a view is indicated by the linear relation between $\lg(k^0_M/k^0_W)$ and the number n of methyl and methylene groups in the radical R (Fig. 6), whose slope gives +0.43 kcal $mole^{-1}$ (for each methylene or methyl group) as the increment in the free energy of transfer.

This phenomenon is remarkable in indicating the possibility of specificity in micellar catalysis. Indeed this is a case not of "trivial" specificity due to the concentration effect (the stronger the binding the greater the acceleration) but of finer "tuning" of the catalyst, when substantially different acceleration effects are obtained with similarly bound substrates.

The situation with regard to research on micellar catalysis in bimolecular reactions involving only uncharged molecules is far worse, although this particular case is far easier to analyse theoretically because of the absence of effects due to variation of the surface potential. A reaction of this type—between fluoro-2,4-dinitrobenzene

(VII) and the methyl ester of *N*-benzoyl-L-histidine (VIII) [sic]

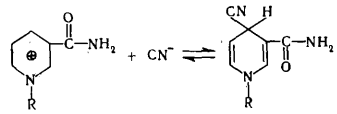
(46)

has been used[71] to solve the important problem of activation energy in micellar catalysis. "Experimental" values E_{exp}, obtained from the temperature dependence at some constant value of C

$$E_{exp} = -R\left(\frac{\partial \ln k_{exp}}{\partial (1/T)}\right)_C \qquad (47)$$

have normally been employed. However, this quantity is equal to the true activation energy of the reaction occurring in the micellar phase only for a unimolecular reaction, provided that limiting values of k_{exp} are used at sufficiently large values of C. In all other cases E_{exp} is composite (as will be shown below), and therefore its value must be interpreted with caution. From the decrease in E_{exp} in the presence of hexadecyltrimethylammonium bromide, which catalyses the alkaline hydrolysis of chloro-2,4-dinitrobenzene, and its increase when the same reaction was inhibited in the presence of sodium dodecyl sulphate, it was concluded[37] that the transition state of the reaction is stabilised by the surface charge of the micelle during catalysis, and destabilised during inhibition. However, it is then difficult to explain why E_{exp} passes through a minimum with increase in C in the catalysis of the alkaline hydrolysis of fluoro-2,4-dinitrobenzene by the quaternary bromide[38], whereas it increases with increase in C during micellar catalysis of the alkaline hydrolysis of *p*-nitrophenyl diphenyl phosphate[82]. Similarly, the lower value of E_{exp} for the acid hydrolysis of sodium dodecyl sulphate as compared with that of sodium ethyl sulphate led to the conclusion that the transition state is stabilised by the anionic micelle of this surfactant (whose rate of hydrolysis exceeds that of sodium ethyl sulphate by a factor of 60)[83]. But it then remains obscure why the acid hydrolysis of the surfactant is characterised by the same value of E_{exp} before and after the c.m.c.[84] Yet all these facts can be explained perfectly satisfactorily by using the above simple concepts of the approach or separation of ionic and hydrophobic reactants. From Eqn. (21) with $\bar{k}_M K_A K_B C \gg k_W$ and Eqn. (47) it follows that

$$E_{exp} = E_M + \frac{\Delta H_A}{1 + K_A C} + \frac{\Delta H_B}{1 + K_B C} \cdot \qquad (48)$$



The composite quantity E_{exp} is seen to include also the heats of binding of the reactants by the micelles and to depend on C. For reaction (46) between uncharged reactants it was found that $E_M \simeq E_W$, and the very considerable decrease in E_{exp} observed is due to negative heats of binding of the reactants[71].

The binding by micelles of reactants containing no charged groups is due mainly to hydrophobic interactions. Therefore cation-active, anion-active, and non-ionic surfactants should act as catalysts, with the action of ionic surfactants unaffected by the concentration of the gegenions. This occurs in the case of reaction (46),[71] and also for the reaction of aniline with chloro-2,4-dinitrobenzene or fluoro-2,4-dinitrobenzene[85].

However, very considerable specific electrostatic effects are nevertheless possible in the micellar catalysis of reactions between uncharged molecules. An example is the reaction of (VIII) or other imidazole derivative with *p*-nitrophenyl carboxylates[71]. These reactions are accelerated by hexadecyltrimethylammonium bromide, retarded by sodium dodecyl sulphate, and slightly dependent on the concentration of a non-ionic surfactant. Catalysis by the quaternary bromide is sharply depressed in the presence of gegenions. At the present time it is difficult to establish whether these effects are due to orientation of the reactant in the micelle or are a direct effect of the surface charge of the micelle on the transition state of the reaction. In any case, the presence of such effects indicates the existence of extremely untrivial ways in which surfactant micelles influence the kinetics of organic reactions.

V. EFFECT OF MICELLES ON REACTION EQUILIBRIUM

The influence of micelles on ionic equilibria is well known. The effect of surfactant micelles has been most fully studied on the dissociation constants of acids and bases[2,23]. The shift in pK_a produced by ionic surfactants can in general be satisfactorily described on simple electrostatic concepts, of the type applied by us to the kinetics of ion–molecule reactions. The shift usually reaches 1–2[2,23], corresponding to the observed 10–100-fold acceleration of such reactions. The most considerable changes in ionic equilibrium constants have probably been found in the reaction

(49)

where the equilibrium constant increases by a factor of 25 000 in the presence of hexadecyltrimethylammonium bromide[86].

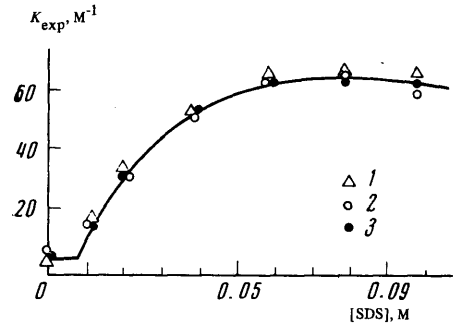


Figure 7. Effect of sodium dodecyl sulphate on experimental equilibrium constant for the formation of benzylideneaniline: 1) values calculated from equilibrium concentration of benzylideneaniline; 2) ratios of rate constants of forward and reverse reactions at pH 7; 3) ratios at pH 10.[8]

An example of the displacement of a non-ionic equilibrium[8] is the effect of sodium dodecyl sulphate on the equilibrium constant of the formation of benzylideneaniline by reaction (41). Fig. 7 illustrates the dependence of the experimental equilibrium constant on the surfactant concentration. These results were discussed on the basis of

a rapidly established distribution of reactants between aqueous and micellar phases. The experimental equilibrium constant

$$K_{exp} = \frac{[AB]_0}{[A]_0[B]_0} \quad (50)$$

is then related[8] to the surfactant concentration by the formula

$$K_{exp} = K_W \frac{1 + K_{AB}C}{(1 + K_A C)(1 + K_B C)} \quad (51)$$

where K_A, K_B, and K_{AB} are binding constants of the reactants with the micelles and K_W is the equilibrium constant in water. The true equilibrium constant in the micellar phase is

$$K_M = \frac{[AB]_M}{[A]_M[B]_M} = \frac{[AB]_0}{[A]_W[B]_W} \cdot \frac{P_{AB}}{P_A P_B} = K_W \frac{P_{AB}}{P_A P_B}. \quad (52)$$

The binding constants of the reactants with the surfactant micelles were found from Eqn. (51) by analysing the dependence of K_{exp} on C (Fig. 7). The results were almost identical with independent measurements using the gel filtration of the reactants in an aqueous solution of the surfactant[8]. This demonstrates the validity of the theoretical equation (51). Moreover, it was found that $K_M \leqslant K_W$. Despite a more than tenfold increase in the experimental equilibrium constant K_{exp} (Fig. 7), the true equilibrium constant in the micellar phase K_M is thus roughly equal to K_W (or even less). This phenomenon is directly analogous to the acceleration of reactions by the localisation of the reactants.

In view of these facts the term "micellar catalysis" is not entirely correct, since a "true" catalyst should not displace an equilibrium appreciably[87]. Nevertheless, this term has become established and is a quite happy choice, for it reflects the facts firstly that a surfactant has a substantial effect on reaction velocities when added in low concentrations ($\leqslant$0.01 M) and secondly that the surfactant is not used up in the reaction.

ADDENDUM

A considerable number of studies of micellar effects in various organic reactions have been published since the appearance of the review[2]. Some of them are covered in the present Review (see above), but several investigations, not specially concerned with physicochemical aspects, have not been mentioned. Among them we may note the following—alkaline decolorisation of triphenylmethane dyes[88-90], hydrolysis of carboxylic esters[91-93] and ethers[94], hydrolysis and aminolysis of phenyl sulphates[95], acylation of thiols[96], interaction of the hydroxide ion with tetranitromethane[97] and of the cyanide ion with 3-carbamoylpyridinium ions[98], azo-coupling[99], deamination of amines[100] and hydroxylamines[101], decarboxylation[102], addition of cyanide to haemin[103], reactions of Cl_2^- and hydroxyl radicals[104,105], activation of complex ions[106], and other reactions[107,108]. Catalysis by "reversed" micelles in non-aqueous solvents is especially interesting. The mutarotation of 2,3,4,6-tetramethyl-α-D-glucose in benzene and in cyclohexane[109], the aquation of complex ions in benzene[110], and other reactions[111-113] have been studied in such systems.

Heat Capacity of Aqueous Solutions of Electrolytes

V.A.Latysheva

The present review deals with studies of the heat capacity of aqueous solutions of electrolytes. The material has been selected to show the extent to which the studies which have been carried out reveal the relationship between the heat capacity of the solutions and their internal chemical character, with reference to the dependence of the heat capacity of solutions on their structure, the hydration and hydrolysis of ions, the formation of acido-complexes, etc. Some promising possibilities provided by the study of the heat capacity of aqueous solutions of electrolytes have been noted. The bibliography contains 264 references.

I. INTRODUCTION

The study of the heat capacity of aqueous solutions of electrolytes is being initiated in various spheres of theoretical and practical research. In the period 1960–1971, heat capacity was studied in connection with the development of efficient adsorption refrigerating machines [1], the technology of wet spinning [2], methods of distilling and processing sea water [3–8], and the rationalisation of the production of alumina [9–17] and other materials [18–28]. In most of the works cited, narrow problems of a practical character were resolved, but an incomparably greater number of studies were aimed at determining the relationship between heat capacity and the nature of solutions. This tendency is natural, since the search for general regular features, directed in the final analysis towards the development of a theory of solutions, should be much more effective than utilitarian studies in leading to the rapid elimination of the marked inadequacy of data on the heat capacity of solutions, which makes itself felt everywhere—from the non-ferrous metal industry [29] to the study of the functions of nucleic acids [30].

II. SOME THEORETICAL IDEAS

Essentially no development of fundamentally new theories of the heat capacity of solutions has taken place in recent years. We can only say that attempts have been made to develop, verify, or discuss the theoretical ideas previously put forward by Born [31] and Webb [32], Everett and Wynne-Jones [33], Everett and Coulson [34], Eley [35], Frank and Evans [36], Frank and Wen [37], Eucken [38–40], Kapustinskii [41,42], and others.

The application of the Born–Webb theory invariably encounters difficulties, associated with the fact that this theory does not take account of the molecular nature of the solvent [35,43–48]. Thus for example it has been shown convincingly [43,44] that the equation for the dependence of the partial molar heat capacity of ions at infinite dilution $\overline{C}^0_{p_2}$ on the radius of the ion:

$$\overline{C}^0_{p_2} = f_1\left(\frac{e^2}{r}\right) + f_2(e) \qquad (1)$$

where e is the charge and r the radius of the ion, derived by Kapustinskii [41,42] using only the Born equation, does not show even qualitative agreement with experiment. The slope of the theoretical curve is the opposite of that observed experimentally. Agreement with experiment can be obtained only by taking account of "the effect of the long-range action of ions on water, which should be negative and should increase with increase in the ionic radius and with increase in the complexity of the configuration of the ion" [43]. Eqn.(1) should then be replaced by:

$$\overline{C}^0_{p_2} = f_1\left(\frac{e}{r}\right)^2 + f_2(e) + f_3(r\varkappa), \qquad (2)$$

where $\varkappa$ is a coefficient characterising the configuration of the ion.

At the present time the Born–Webb theory is sometimes used only as a means of estimating the electrostatic components of the thermodynamic characteristics of ions in solution. The use of this method in practice is based on the need to know the effective dielectric constant of water in solutions, and its derivatives with respect to temperature. Thus some authors start from the converse;

they use some independent method of estimate these electrostatic components, and then calculate the effective dielectric constant and its derivatives[49]. In the case of heat capacity, compressibility, and thermal expansion, however, the attempts to carry out these estimates appear unsuccessful, partly because of the lack of accurate data[49], but chiefly because of the complexity of the interpretation of these properties[45,46]. The significant correction which was introduced into the electrostatic theory by Everett and Coulson[34] and which takes account of the unique state of the water molecules closest to the ion, did not lead to agreement with experiment[34,45]. Conway and coworkers[45] showed that the change in heat capacity ΔC associated with the effect of the restriction of the liberations of the water molecules closest to the ion is relatively small in magnitude and has the same sign as the change in entropy ΔS in the corresponding process, and that ΔC and ΔS should change in the same sense on going from one system to another. At the same time the order of change in the values of $\overline{C}_i^0$ for the ions of the alkali and alkaline earth metals and the halogens, and also the values of ΔC_V (the changes in heat capacity at constant volume) for the ionisation of methylammonium ions, obtained from the experimental data, are opposite to the corresponding orders for $\overline{S}_i^0$ and ΔS, and the signs of the quantities $\overline{C}_i^0$ and ΔC may be the opposite of the signs of $\overline{S}_i^0$ and ΔS (Fig.1). On this basis, Conway and coworkers[45] exclude the effect indicated by Everett and Coulson from the factors determining the magnitude of $\overline{C}_{pi}^0$ and give preference to the influence of ions on the structure of water. They assume that the positive values of $\overline{C}_{pi}^0$ for cations and the negative values for anions may be due to the structure-forming influence of cations and the destructive influence of anions.

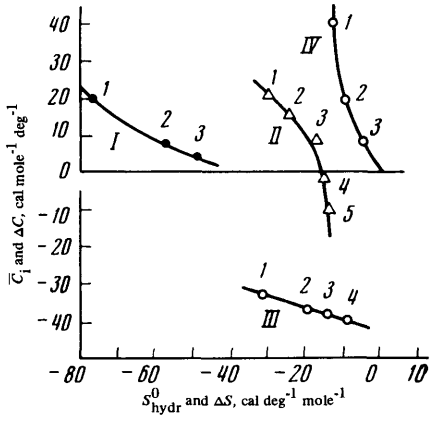

Figure 1. Comparison of the partial g-ion heat capacity of monatomic ions $\overline{C}_i$ (curves *I*–*III*) and the change in heat capacity in the protolytic dissociation of alkylammonium ions ΔC (curve *IV*) respectively with the entropy of hydration of the monatomic ions S^0_{hydr} and the change in entropy ΔS in the protolytic dissociation: *I*) Mg^{2+} (*1*), Ca^{2+} (*2*), Ba^{2+} (*3*); *II*) Li^+ (*1*), Na^+ (*2*), K^+ (*3*), Rb^+ (*4*), Cs^+ (*5*); *III*) F^- (*1*), Cl^- (*2*), Br^- (*3*), I^- (*4*); *IV*) $(CH_3)_3NH^+$ (*1*), $(CH_3)_2NH_2^+$ (*2*), $(CH_3)NH_3^+$ (*3*).

It should however be noted that Conway and coworkers use the values of $\overline{C}_{pi}^0$ on Eucken's scale, without justifying its use in preference to other scales. It is quite possible that scales in which the values of $\overline{C}_{pi}^0$ for cations are not positive but negative will prove more correct (this will be discussed later). Moreover, the changes in the opposite sense noted by the authors cited for $\Delta\overline{S}_i^0$ and $\overline{C}_{pi}^0$ may indicate merely that the effect of partial freezing of the degrees of freedom of the water on hydration overlaps the effect of change in structure, but not complete absence of the first effect.

In order to reveal the existence of the first effect, it is necessary to compare the heat capacities of ions not within the vertical groups of the periodic system but along the horizontal periods of elements with similar steric and electrostatic parameters (*d* or *f* elements). This approach has been made by a number of authors[50-55]. Study of the heat capacity of aqueous solutions of the perchlorates of the 3*d* metals (Mn^{II}, Co^{II}, Ni^{II}, Cu^{II}, and Zn) showed that the values of $\overline{C}_p^0$ for these electrolytes, on going from one ion to another, change in the same sense as the values of ΔH, ΔG, and ΔS for the hydration of the cations (Fig. 2).[50-53] Thus the strength of binding of water by the ions still has significant importance for the heat capacity. The study of the heat capacity of solutions of salts of the rare earth elements led to similar conclusions[54,55]. The concept of the influence of ions on the structure of water has attracted the greatest attention from research workers[35-37,56-58]. In particular, the ideas of Frank and coworkers[37] on the cluster structure of water and solutions have provided the basis for several recent theoretical and experimental studies[59-70]. Nemethy and Scheraga[59] suggest that the water molecules inside the clusters, on the surface, and outside the clusters differ from one another in the number of hydrogen bonds which they form and in the changes which they bring about in the vibrational spectrum of water. On the basis of this premise, Nemethy and Scheraga developed a statistical method for calculating the concentration and size of the water clusters and the thermodynamic properties of water from data on the vibrational spectra. The calculations do not show complete agreement with experiment for pure water (the method has not been used for aqueous solutions of electrolytes); in the opinion of Vand and Senior[60], this is due to underestimating the number of straight and branched chains in the structure of water. Attempts have been made to develop a theory of aqueous solutions of electrolytes from the semi-empirical theory of Eucken[38-40,71,72], based on the view that in solutions an equilibrium is established between monomers, dimers, tetramers, and octamers of water molecules and hydrated ions. Wicke compared new experimental data on the heat capacity of aqueous solutions of a number of alkali metal halides, alkylammonium salts, and aliphatic acids and their salts at temperatures in the range 0–130°[61,73] with the results of studies of other properties of the solutions carried out by different authors, and concluded that Eucken's theory is inadequate and that it is necessary to take into account the existence, in water and aqueous solutions, of structural units of the "flickering cluster" type, in Frank's terminology[37]. However, in the opinion of Wicke (and many others[46,61,74-76]) Frank's two-structure model is inadequate for a satisfactory description of the heat capacities of solutions. Wicke puts forward the so-called combined model of the structure of water, which as it were combines elements of the models of Eucken and Frank.

On the basis of this model, Wicke[61] and Rueterjans and coworkers[69] put forward an explanation of the form of the

temperature dependence of $\bar{C}_p^0$ for a number of simple halides (the existence of a maximum at temperatures in the range 50–90°) and the characteristic features of the heat capacity of solutions of tetra-alkylammonium halides ($\Phi C > 0$).

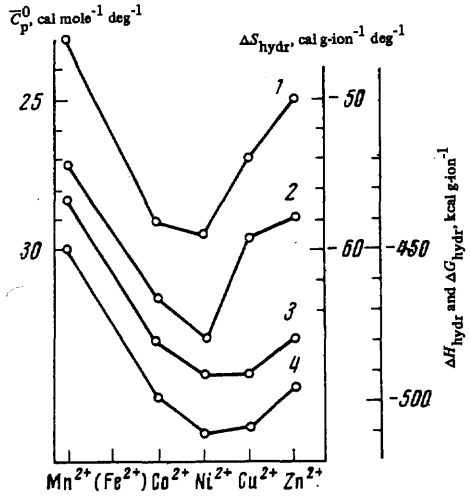

Figure 2. Comparison of the values of $\bar{C}_p^0$ for the perchlorates of the 3*d* metals (*1*) with the entropy ΔS_{hydr} (*2*), free energy ΔG_{hydr} (*3*), and enthalpy ΔH_{hydr} (*4*) of hydration of the corresponding cations.

The theoretical studies of Lovett and Ben-Naim [77], devoted to solutions of the inert gases in water, have proved of interest in the elucidation of the nature of the structure-forming influence of the non-polar parts of electrolytes on water. The one-dimensional model of aqueous solutions of the inert gases put forward in the work cited, and statistical calculations using this model, lead to the unambiguous conclusion that the introduction of inert gas molecules into heavy water (D_2O) should lead to less stabilisation of the structure than their introduction into ordinary water (which is less structured than heavy water). This difference is in fact observed and is based on the fact that (according to the model) the inert gas can stabilise the structure only when the water contains open cavities into which the gas can penetrate. The less structured water has more of these cavities.

Krestov and coworkers [78,79] approached the problem of heat capacity from the viewpoint of the theory of positive and negative hydration, developed by Samoilov [80]. Like Noyes [49], Krestov and coworkers [79] assume that the change in heat capacity accompanying the hydration of ions ΔC_phydr can be broken down into two parts, one of which, ΔC_{pI}, is not related to the electrostatic parameters of the ion and is equal to the effect of the hydration of an inert gas atom having the same radius as the ion, whereas the other, ΔC_{pII}, depends on the nature of the effect of the electrostatic field of the ion on the structure of the surrounding water. Arguing within the framework of Samoilov's theory, the authors cited represent the quantity ΔC_{pII} as resulting from the partial compensation of two effects of the influence of ions on water: 1) the orientation of the nearest molecules in the field of the ion, and 2) the breakdown of the bonds between further-removed water molecules. The first effect should be accompanied by a decrease in heat capacity as a consequence of the decreased mobility of the molecules, and the second should be accompanied by an increase, since the water molecules become more mobile. Since the first effect predominates for ions with positive hydration, and the second effect predominates for ions with negative hydration, it is to be expected that for the former $\Delta C_{pII} < 0$, whereas for the latter $\Delta C_{pII} > 0$. The results of calculations carried out by Krestov and Klopov [79] confirm these suggestions, but they contradict the widely held opinion that the rupture of bonds in the structure of water should lead not to an increase in heat capacity but to a decrease; this is confirmed by the experimentally observed decrease in the values of $\bar{C}_p^0$ for alkali and alkaline earth metal salts and for the halides of the sub-groups with increase in the size of the ions [43,81]. On examination it was found that the contradiction was due to errors in the calculation of ΔC_{pI}, [79] carried out using data on the solubility of the inert gases in water [82]. The correct calculation leads to positive values of ΔC_{pI}, which within the limits of error are the same for all the inert gases (~40 cal mole^{-1} deg^{-1}) and to values of $\Delta C_{pII\,corr}$ which in all cases are negative and decrease with increase in the size of the ions in the sub-groups (column 4 of Table 1).

Table 1. Values of ΔC_{pI} and ΔC_{pII} for various ions (cal g-ion^{-1} deg^{-1}).

Ion	ΔC_{pI} [79]	ΔC_{pII} [79]	$\Delta C_{pII\,corr}$ (for $\Delta C_{pI} = 40$)
Li^+	—4.8	—3.7	—48.5
Na^+	—17.8	+4.1	—53.7
K^+	—25.2	+5.8	—59.4
Rb^+	—35.0	+14.8	—60.2
Cs^+	—48.6	+27.6	—60.8
Mg^{2+}	—18.4	—23.5	—81.9
Ca^{2+}	—25.6	—18.1	—83.7
Sr^{2+}	—39.6	—8.0	—87.6
Ba^{2+}	—49.2	—1.7	—90.9
F^-	—15.2	—3.3	—58.5
Cl^-	—23.6	+4.8	—58.8
Br^-	—37.8	+17.6	—60.2
I^-	—47.9	+27.1	—60.8

If in addition we take account of the tendency, noted by some authors (see, for example, Ref. 82), for ΔC_p to increase from He to Xe, we obtained an even greater decrease in ΔC_{pII} with increased size of the ions in each sub-group.

This result confirms the view [43,83] that Samoilov's theory does not provide an understanding of the heat capacity of solutions, since "the thermostatics of solutions is related not to fluctuations in the structure, produced by the translational movements of the molecules, but to the average statistical characteristics of the systems".

The results of theoretical studies of the influence of the concentration of an electrolyte on $\bar{C}_p^0$ (in the range of medium and high concentrations) have been published by Mikulin (p. 44 of Ref. 23). In Mikulin's opinion, the nature of the dependence of the partial molar heat capacity of the electrolyte on concentration in concentrated solutions is determined by the form of the concentration dependence of the so-called electrostatic component of the free energy of the solution G^{el}. The latter is related to "the nature and magnitude of the electrostatic forces" (the interaction of the ions and the polarisation of the water molecules) which

lead to the formation of the "ionic atmosphere" and bring about a change in the properties of the solvent close to the ion" (p. 49 of Ref. 23). It has the form:

$$G^{el} = -RTm(a + b\sqrt{c}) \quad (3)$$

where C is the molarity of the electrolyte, and a and b are constants which are characteristic of each electrolyte and which depend on temperature and pressure.

An extremely interesting feature of Mikulin's approach is the model of the hydrated ion, which takes account of the possibility that around the primary hydrated ion there is a layer of water molecules for which the dielectric constant value is greater than that for pure water (p. 126 of Ref. 23). The magnitude of the increase in the dielectric constant of this layer depends on the individual nature of the ions, and this is responsible for the specific character of the values of a and b in the equation for concentrated solutions. This unique layer is limited to a distance of 10–12 Å from the centre of the ion, so that in the range of highly dilute solutions it does not determine the form of the concentration dependence of G^{el}, which becomes the same for all electrolytes of the same valency type, in accordance with the Debye–Hückel theory.

Mikulin's theory has been critically reviewed[43]. The work cited also summarises the theoretical ideas previously developed by Mishchenko and coworkers on the factors determining the concentration and temperature dependence of the partial molar heat capacities of water and electrolytes in solution.

Drakin and coworkers[84] suggested that there is a linear relationship between the heat capacity of the hydration of ions ΔC_h on the one hand and the charge of the ion z and its hydrate coordination number n on the other

$$\Delta C_h = -Azn, \quad (4)$$

where A is a proportionality coefficient, the magnitude of which is determined empirically, and ΔC_h is the difference between the partial molar heat capacity of the ion at infinite dilution and the heat capacity of the ion in a vacuum.

This dependence is based on the idea that each of the n water molecules surrounding the ion can be bound by hydrogen bonds to two other molecules and hence can act as the starting point for a chain of hydrogen-bonded water molecules. The ion, which possesses a charge, will influence the vibrations of the chain. The total effect of the ion should be proportional to nz. This idea is attractive for its simplicity, and at first sight it might seem to provide a basis for a new method for determining the coordination numbers of ions in solution. As shown below, however, not all of the ions studied by these authors[84-87] obey this relationship, and the authors themselves conclude that it is only approximate[87]. We doubt whether all the change in heat capacity when ions pass into solution can be attributed to the formation of the hydration sheaths of the ions.

The results of these theoretical studies show clearly that the heat capacity of solutions is sensitive to the most varied characteristics of the interaction between the components of solutions. Thus in order to develop a general theory it is necessary first of all to accumulate sufficiently extensive and reliable experimental data on the relationship between heat capacity and the various forms of interaction in solution, such as the hydration of ions, their association, their action on the structure of water, hydrolysis, complex formation, etc.

Data on the partial molar heat capacities of electrolytes in highly dilute solutions are of exceptional importance for the development of the theory.

III. THE PARTIAL MOLAR HEAT CAPACITIES OF ELECTROLYTES AT INFINITE DILUTION $\bar{C}^0_{p_2}$

1. Experimental Determination of $\bar{C}^0_{p_2}$

The values of $\bar{C}^0_{p_2}$ are usually determined by extrapolating the apparent molar heat capacities of the electrolyte ΦC_{p_2} to zero concentration. For this extrapolation to be successful, the experimental data on the specific heat capacity of the solutions c_p should be as accurate as possible[88].

In recent years there has been an increase in the number of laboratories in which precision heat capacity measurements are being made. There has been an increased number of materials for which accurate c_p values have been obtained for the first time or for which earlier inaccurate values have been accurately determined[84-87,89-128]. Only a few papers[106], however, cover the range of solutions with concentrations less than 0.1 m. This means that the values of $\bar{C}^0_{p_2}$ obtained by extrapolation are still unreliable, since at lower electrolyte concentrations a change in the slope of the plot of ΦC_{p_2} against $\sqrt{m}$ is still quite possible[43,51,53,87,113,118,119,122,129].

Parker[130] proposed a way out of situations of this kind; in this approach, the slope for very dilute solutions is calculated from the Debye–Hückel theory, after which the ordinate of the initial point of the calculated section is determined by assuming that the change from the calculated straight line to the experimental line should take place along the smoothest and shortest curve. This method was used to calculate $\bar{C}^0_p$ for a number of uni-univalent electrolytes, and also to estimate the heat capacities of various solutions of electrolytes which have been little studied (NH_4Br, NH_4I, RbI, and MX, where M = Rb or Cs, and X = OH, Cl, Br, or NO_3). The application of Parker's method to electrolytes of the 1:1 valency type, which are chemically relatively "simple", is apparently justified at present, but it can hardly be used in the case of electrolytes with highly charged ions, which often tend to undergo hydrolysis, or, by strongly polarising the nearest water molecules, bring about structural effects in dilute solutions, not taken into account by the Debye–Hückel theory. A number of authors who have carried out the precise determination of the heat capacity of aqueous solutions of the chlorides of the elements of the beryllium side group at 25°[90-94] suggest that $\bar{C}^0_{p_2}$ be determined by use of interpolation equations giving the concentration dependence of the specific heat capacity. This method has some advantages over graphical extrapolation, but it also is unreliable in the absence of data for dilute solutions.

Work devoted specifically to the question of the extrapolation of the values of ΦC_p to $m = 0$ [113] has shown that even such a relatively "simple" 1:1-valent electrolyte as NaI can show quite unexpected behaviour in the range of low concentrations.

The difficulties associated with the extrapolation of ΦC_{p_2} to $m = 0$ have led to the search for new methods of determining $\bar{C}^0_{p_2}$. One of these is known as the "method of integral heats", due to Cobble[131]. In this method, the values of $\bar{C}^0_{p_2}$ are determined from data on the heat capacity of an individual electrolyte C_{p_2} and the change in heat

capacity on dissolution ΔC^0_{pS}. The latter are found by differentiating, with respect to temperature, the first heats of dissolution of the electrolyte in water ΔH^0_S, found by extrapolating the integral heats of dissolution ΔH_S to zero concentration using the extended Debye–Hückel equation [132]. An advantage of this method is the greater reliability of the extrapolation of ΔH_S to $m = 0$ (m = molality) compared with the usual extrapolation of the apparent molar heat capacities of the electrolyte Φ_{C_2}, since the function which Criss and Cobble use in the extrapolation is linearly dependent on the molality. Nevertheless, even this extrapolation does not always give good results, as apparently indicated by the insufficiently "smooth" temperature dependence of ΔH^0_S, observed by these authors in a number of cases. The artificial smoothing of this dependence, undertaken by Criss and Cobble, is hardly justified for all systems, since the existence of an incompletely smooth temperature dependence for ΔH^0_S is apparently possible in principle (see p. 1779).

If in addition we take into account the unavoidability of error in the determination of the heat capacity of an individual electrolyte C_{p_2}, which sometimes reaches several cal mole^{-1} deg^{-1}, we can understand why the accuracy of the measured values of $\overline{C}^0_{p_2}$ obtained by Cobble's method in a number of cases differs little from that for the values of $\overline{C}^0_{p_2}$ obtained by extrapolating the Φ_{C_2} values (Table 2).

Table 2. Comparison of the values of $\overline{C}^0_{p_2}$ (cal mole^{-1} deg^{-1}) obtained by the method of integral heats (m.i.h.) and by measurement of the heat capacity of the solutions (m.h.c.s.). $t° = 25°$.

The method of integral heats is being used in many studies at the present time [65,68,69,95–103,121,126,133–137]. The lack of reliable data on the heat capacity of most individual electrolytes (particularly crystal hydrates), however, restricts the possibilities provided by the use of this method.

2. Semi-empirical Methods for Separating $\overline{C}^0_{p_2}$ into Ionic Components $\overline{C}^0_{p_i}$ and the Calculation of $\overline{C}^0_{p_i}$ for Different Temperatures

The problem of separating the heat capacity of an electrolyte into ionic components is even further from solution than the analogous problems of resolving into components the heats of hydration, volumes, and various other properties. There coexist ionic heat capacity scales which differ considerably from one another not only in the absolute values but also sometimes in the signs of the heat capacities [43,81]. In the resolution of heat capacities it may be necessary to use criteria different from those used in the separation of the enthalpy of hydration, since the heat capacity, which is the derivative of the enthalpy with respect to temperature, may be distributed between the ions in a way which is quite different from that for the actual integral heat [43]. The method of resolving the heat capacities proposed by Mishchenko and coworkers is based on the relationship between the heat capacities and the volumes of the solutions. The authors cited assumed that the values of $\overline{C}^0_p$ are equal for those ions for which Fajans and Johnson established that the partial molar volumes are equal, namely NH_4^+ and Cl^-. The scale of ionic heat capacities obtained on this basis is given in Table 3. Drakin and coworkers [84] suggested that the separation of $\overline{C}^0_{p_2}$ into ionic components be based on the assumption that $\overline{C}^0_{pCl^-} = -8$. [84] The authors cited obtained this quantity by selecting a value which would satisfy the equation (4) which they put forward for the relationship between the heat capacities and the hydration coordination numbers of ions.

Table 3. Values of $\overline{C}^0_{p_i}$ for various ions (cal mole^{-1} deg^{-1}) on different scales. $t° = 25°$.

De Ligny and coworkers [143] put forward an original method for finding the heat capacity for the individual hydrogen ion, involving the determination of ΔC_p for the hydration of the H^+ ion from the cycle:

$$\begin{array}{ccc} H^+(aq) + Foc(aq) & \rightarrow & Fic^+(aq) \rightarrow {}^1/_2 H_2(gas) \\ \uparrow 4 & & \downarrow 2 \\ H^+(gas) + Foc(gas) & \leftarrow 3 & Fic^+(gas) \rightarrow H^+(gas) + \bar{e}(gas) \end{array} \qquad (5)$$

where Fic^+ represents the ferrocinium ion $(C_5H_5)_2Fe^+$, and Foc represents ferrocene.

In the calculation of this cycle it is assumed that the heat capacity of the hydration ΔC_p hydr of large ions of the type Fic^+ ($r = 3.8$ Å) is additively made up of electrostatic and non-electrostatic components, so that the difference ΔC_p hydr $Fic^+ - \Delta C_p$ hydr Foc is equal to the electrostatic component of the hydration of Fic^+ and can be calculated

from the Born equation. The other quantities are determined rigorously. This gave $\Delta C_{hydr\,H^+} = -8 \pm 8$ and $\overline{C}^0_{p\,H^+(aq)} = -3 \pm 8$. The values of the heat capacities of other ions calculated on this basis are given in Table 3.

Latysheva[81] proposes a method for estimating ionic heat capacities which is based on the analysis of vibrational spectra of hydroxonium and hydroxyl ions in aqueous solutions. The results of such an analysis have shown that the nature of motion of particles in hydrate shells, and also the characteristics of hydration of H_3O^+ and OH^- ions, are very similar[144]. Latysheva therefore assumes that $\overline{C}^0_{p\,H_3O^+}$ will differ from $C_{p\,OH}$ only by an amount equal to the difference between the internal specific heats of non-hydrated ions, and separates $\overline{C}^0_{p_2}$ into ionic components. The starting values of $C^0_{p_2}$ are taken from the work of Criss and Cobble[146]. The resulting scale is shown in Table 3.

In papers by Cobble[146,147], Naumov and coworkers[148-152], and Krestov and coworkers[135,145,153], the question of the separation of $\overline{C}^0_{p_2}$ into ionic components is examined at the same time as, and in relation to, the temperature dependence of the entropies and heat capacities of ions.

Criss and Cobble[146,147] took as a basis the possibility of calculating rigorously the mean partial molar heat capacity of an electrolyte $\overline{C}^0_{p_2}]_{t_1}^{t_2}$ in the temperature range t_1-t_2 using the thermodynamic relationship

$$\overline{C}^0_p|^{t_2}_{t_1} = \frac{\overline{S}^0(t_2) - \overline{S}_0(t_1)}{\ln T_2/T_1}. \qquad (6)$$

The authors cited took account of the lack of the necessary experimental values of $S^0(t)$, and tried to establish a quantitative relationship between the values of $\overline{S}^0$ at different temperatures for individual groups of ions, classified according to structural type (simple or complex) and sign of charge (cations or anions). As a result, Criss and Cobble formulated the correspondence principle: "A standard state can be chosen at every temperature such that the partial molar entropies of one class of ions at this temperature are linearly related to the corresponding entropies at some reference temperature":

$$\overline{S}^0(t_2) = a(t_2) + b(t_2)\,\overline{S}^0(t_1) \qquad (7)$$

where $a(t_2)$ and $b(t_2)$ are empirical constants for a given class of ion†. By choice of standard state at each temperature is meant the specification of $\overline{S}^0$ for the hydrogen ion at this temperature. Having assumed that at 25° $S^0_{H^+} = -5.0$ e.u. (in accordance with published data), Criss and Cobble had to assume that at 60, 100, and 150° this quantity had the values −2.5, 2.0, and 6.5 e.u. respectively, otherwise the simple linear correspondence principle was not obtained.

The authors cited showed that with this choice of conditions, for simple ions, the principle applies with a range of ±0.5 cal mole^{-1} deg^{-1} up to 150°, and on this basis they assumed that extrapolation to 200° is possible. The use of the correspondence principle makes it possible to estimate, simply and rapidly, unknown entropies of electrolytes at different temperatures, and average heat capacities within the temperature ranges indicated. The values of the entropies and heat capacities of individual ions obtained by this calculation can hardly be the true values, however, since it has not been proved that the form of the correspondence principle is necessarily linear.

† It is obvious that the analytical form of the expression of the correspondence principle corresponds to one of Karapet'yants' comparative calculation methods.

It is therefore not accidential that the values of $\overline{C}^0_{p\,H^+}$ at 25°, obtained by differentiation of the curve giving the dependence of $\overline{S}^0_{H^+}$ on T and equal to 28 cal mole^{-1} deg^{-1}, and also the complete scale of ionic heat capacities based on this value by Criss and Cobble (see Table 3), have been criticised by a number of authors[81,135,153]. The high positive values of $\overline{C}^0_p$ for cations, and the large negative values of $\overline{C}^0_p$ for anions appear unjustified, if we take into account the more energetic binding, on the average, of water molecules by cations, and their larger hydration numbers. The increase in the values of $\overline{S}^0_{H^+}$ with increase in temperature also appears unnatural, since for a positively hydrated cation, such as the H^+ ion, the effect of the ordering of the structure when the ion is placed in water should predominate over the destructive influence to a still greater extent at higher temperatures[43].

Khodakovskii and coworkers[148-152] critically reviewed available published data on the equilibrium constants of processes involving the participation of different ions at different temperatures, calculated the heat capacities of many ions over a wide range of temperatures, and concluded that the temperature dependence of $\overline{C}^0_{p_2}$ is described satisfactorily by the equation

$$\overline{C}^0_{p_2} \cong bT. \qquad (8)$$

This approximation is applicable only for calculations in the temperature range 200−300°, that is at temperatures at which most of the hydrothermal processes in which these authors were interested took place, but it does not describe the extremal form of the dependence of $\overline{C}^0_{p_2}$ on $t°$ in the temperature range from 20° to 80°.[135] Having shown convincingly that the values of $\overline{S}^0_2$ obtained by Cobble and Criss are not absolute, the authors cited proposed new equations for the relationship between $\overline{C}^0_{p_2}$ and $\overline{S}^0_2$ for ions. These equations are not rigorous either, however, since they are based on the approximation $\overline{C}^0_{p_2} \simeq bT$ examined above.

An interesting attempt to obtain consistent values of the partial molar heat capacities and entropies of ions in infinitely dilute solutions in the temperature range 0−100° was described by Krestov and Kobenin[135,145,153]. On the basis of the concepts of the electrostatic and non-electrostatic contributions to the entropy and heat capacity of hydration of ions, developed by Krestov and coworkers[78,79,155-158], Krestov and Kobenin derived an equation for the partial molar entropy of the hydrated ion‡ at a temperature T, $S^T_{aq.i}$

$$\overline{S}^T_{aq\ i} = S^{298}_{aq\ i} + 45.7 \ln T/298 + \Delta a_T + \Delta b_T |z| + \Delta d_T \frac{|z|}{r_{aq}} \qquad (9)$$

and from this, by appropriate differentiation, they obtained the relationship

$$(C_p)^T_{aq\ i} = 45.7 + \left(\frac{\partial \Delta a_T}{\partial T} + \frac{\partial \Delta b_T}{\partial T}|z| + \frac{\partial \Delta d_T}{\partial T}\frac{|z|}{r_{aq}}\right) T \qquad (10)$$

where $S^{298}_{aq.i}$ and $(C_p)^T_{aq.i}$ are respectively the partial molar entropy at 298°K and the partial molar heat capacity at T for the ion in an infinitely dilute solution; z is the charge of the ion; r_{aq} is the radius of the hydrated ion, equal to $r_{crystallographic}$ + an increment q; and Δa_T, Δb_T, and Δd_T are constants at a temperature T.

‡ In the works cited, the quantities $\overline{C}^0_{pi}$ and $\overline{S}^0_i$ are meant, although the corresponding terms are not introduced in the text.

To determine the constant coefficients, the authors cited wrote Eqn. (10) in the form

$$(C_p)'^{T}_{aq\ i} = 45.7 + \left(\frac{\partial \Delta a_T}{\partial T} + \frac{\partial \Delta b_T}{\partial T}|z| + \frac{\partial \Delta d_T}{\partial T}\frac{|z|}{r_{aq}}\right)T - (C_p)'^{T}_{H^+\,aq}\ z \quad (11)$$

and solved the system of equations (11) for several ions. Here, $(C_p)'^{T}_{aq.i}$ is a conditional quantity which is smaller than the "absolute" heat capacity of the hydrated ion by the "absolute" heat capacity of the hydrated proton at the temperature T, multiplied by the charge of the ion. The $(C_p)'^{T}_{aq.i}$ values were determined from experimental data on the heat capacity of the hydrogen halides and other halides, with the condition that $(C_p)'^{T}_{aq.H^+} = 0$. By integrating the temperature dependence of the coefficients in Eqn. (11), the authors cited calculated Δa_T, Δb_T, Δd_T, and $S^T_{H^+}$ in the range 0–100°.

The values of $\overline{C}^0_{pi}$ for a large number of ions were obtained by this method [145]. Some of these values are given in Table 3. The values of $\overline{S}^0_{H^+aq}$ obtained by Cobble and by Krestov and Kobenin are compared in Table 4. It can be seen that with increase in temperature the values of $\overline{S}^0_{H^+}$ being compared change in opposite directions; there is a stronger physical justification for the direction of the change in $\overline{S}^0_{H^+}$ given by Krestov and Kobenin, so that more reliance can be placed on the value of $(C_p)^{298}_{H^+aq}$ obtained by Krestov and Kobenin. An interesting feature is that this value practically coincides with the corresponding value obtained by Latysheva [81] by a completely different method. The method of Krestov and Kobenin, unlike that of Cobble and Criss, does not require the artificial fixing of the values of $S^T_{H^+}$ at several temperatures, so that it appears more "absolute".

The only conditional quantity introduced into the calculation by Krestov and Kobenin is $\overline{S}^{298}_{H^+} = -2.1$ e.u. This method also, however, can only be regarded as approximate, since it is based on the assumption that the non-electrostatic components of the thermodynamic characteristics of the hydration of ions and inert gases are equal. This assumption is obviously incorrect for ions which are not of the noble gas type, as confirmed by the significant discrepancies between the calculated and experimental values of ΔC_p for the hydration of the chlorides of the rare earth elements (REE). [135]

In the case of ions of the noble gas type this assumption is of course more justified, but even in this case the calculation cannot be accurate, since it is known that a change in the charge of the nucleus can alter significantly the ratio of the electronic terms for the same number of electrons in the atom [159], and hence may influence the nature of the interaction of the ion with water.

To summarise, it may be stated that despite vigorous attempts to obtain real values of $\overline{C}^0_p$ for individual ions, this problem cannot yet be regarded as solved. The conditional scale of heat capacities ($\overline{C}^0_{pH^+} = 0$) therefore apparently has not lost its value completely, and it is still being used [43,130] (Table 3).

IV. THE RELATION OF THE HEAT CAPACITY OF SOLUTIONS TO THE VARIOUS TYPES OF REACTION OCCURRING IN THEM

1. Heat Capacity and the Hydration of Ions

The hydration of ions leads to changes in the state of not only the ions themselves and the nearest water molecules but also, in the great majority of cases, to a change in the structure of all the remaining water. The changes in heat capacity associated with the effects of the so-called short-range and long-range hydration may sometimes differ even in sign. In this connection, a number of papers emphasize one or other of these aspects of the phenomenon.

One of the most important characteristics of the short-range hydration of ions is the number of water molecules coordinated directly around the ion. Since the chemical binding of liquid water by salts on the formation of crystal hydrates [35,160] and even the covalent hydration of carbonyl groups [161] lead to a significant decrease in heat capacity, it was natural to expect the observation of a distinct relationship between the number of water molecules coordinated to the ions and the heat capacity of solutions. Attempts to find a quantitative relationship of this kind in analytical form were made by Drakin, Karapet'yants, and coworkers [84,86,87,122]. The relationship which they put foward was mentioned above [see Eqn. (4)]. To verify this equation, the heat capacities of aqueous solutions of a number of nitrates were studied. The values of n appearing in this equation for most cations were chosen on the basis of an analysis of the values of the coordination numbers in crystalline compounds of the corresponding elements [162,163] and for Cd^{2+} and Pb^{2+} by analogy with strontium and barium, in the same periods§. It was found that not all the ions are covered by this form of relationship. Apart all together from ions which do not have the inert gas structure, other ions such as Na^+ and Sr^{2+} are not covered. This may be due to insufficiently reliable estimation of the coordination numbers of the ions in solution and to the lack of justification for the view that the magnitude of the change in heat capacity on hydration is determined entirely by this single parameter. In actual fact, when the ions of elements belonging to different periods and sub-groups are compared, we can observe not only a change in the coordination numbers of the ions but also a change in the energy of the attachment of water molecules to the ions and in the extent to which ions influence the structure. The influence of the first of these factors was demonstrated in a study of the heat capacity of solutions of the perchlorates of the bivalent 3d elements, which have identical cation coordination numbers and similar structural parameters (see p. 1759). It is only for the ions of the REE, for which the structural similarity is even greater, that almost complete agreement is observed between the Φ_{C_p} values for their salts, if we consider the first and second halves of the REE series separately (Fig. 3). The difference between the Φ_{C_p} values for the two groups of elements in this case can in fact be attributed chiefly to the change in the coordination number of the cations [54,55]. The apparent absence of a correlation between the hydration energy of cations and the heat capacity of solutions in this case indicates the existence of some compensation effect, and

§ This analogy appears insufficiently justified in the case of Pb^{2+} and Ba^{2+}, in view of the marked difference in the electronic structure of these ions.

not that the heat capacity is independent of the binding energy of the water for the cations. This is possibly due to an intensification of the structure-forming action of the ions with increase in their field strength, particularly since the values of the standard entropy of the ions $\bar{S}_i^0$ decrease in the same direction, and in the alkali and alkaline earth metal series the action of the ions on the structure of water evidently becomes of primary importance (as already noted on p. 804).

Attempts have been made to consider heat capacity only in relation to structural changes. An original approach to the study of the influence of ions on the structure of water was made by Mrevlishvili and Privalov [164,165], who studied the temperature dependence of the heat capacity of frozen aqueous solutions of a number of electrolytes during heating, in order to estimate ΔS for the fusion of ice in the presence of various electrolytes. These values of ΔS differ significantly from the values of ΔS for the fusion of pure ice. In the opinion of the authors cited, this indicates a change in the structure of water under the influence of the ions. Thus for example it was found that Na^+ and Cl^- ions produce little change in the structure of water, whereas the K^+ ion destabilises it. The cations can be arranged in the following sequence of increasing ordering influence on water: $Mg^{2+} < Ca^{2+} < H^+ < Li^+ < Na^+$. A marked ordering influence on the structure is also shown by OH^- ions.

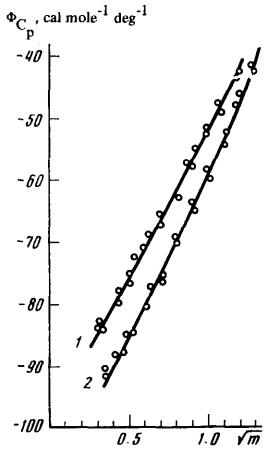

Figure 3. Dependence of ΦC_p for the chlorides of dysprosium, erbium, ytterbium (curve *1*), lanthanum, and neodymium (curve *2*) on the concentration of the solutions (m is the molality) at 25°. [54]

Papers by Mishchenko and coworkers, summarised in two reviews [43,116], emphasise the need to make simultaneous allowance for the binding of water in the hydrate sheaths of ions and the structural changes brought about in water, and examine the ratio of the contributions from these effects over a wide range of concentrations. In particular, it was shown that the role of structural changes is especially marked in dilute solutions and at low temperatures. At the same time the binding of water by ions becomes weaker at higher concentrations, as a consequence of the increase in the electrical viscosity in the solution, and this explains the increase in $\bar{C}_{p_2}^0$ with increase in concentration. In the region of the complete distribution boundary (CDB), a decrease in the energetic hydration of ions is possible, and this should lead to a further increase in $\bar{C}_{p_2}^0$. Further increase in concentration may be accompanied by a redistribution of the hydrate water in favour of the more hydrophilic partner. This should decrease the slope of the $\bar{C}_{p_2} = f(\sqrt{m})$ isotherm and may even lead to the production of a maximum. The possibility of the production of maxima in the range of "extremely high concentration" in the solutions was also predicted by Drakin and coworkers [166], who suggested that the production of maxima should be due to association in solution. In actual fact, maxima on the $\bar{C}_{p_2} = f(\sqrt{m})$ isotherms were observed for the salts of various REE. [54] Spedding and Jones attribute this to the possible formation of acido-complexes in concentrated solutions. In the section on heat capacity and complex formation it will be shown that this explanation is erroneous. The observation being discussed apparently corresponds more closely to the prediction of Mishchenko and coworkers.

The relative decrease in the role of the disruption of the water structure with increase in temperature and concentration was also demonstrated by Mashovets, Puchkov, and coworkers [9-17]. Mishchenko and Stagis were the first to study the heat capacity of solutions at the complete distribution boundary [167,168].

In an examination of the heat capacity of comparatively simple electrolytes (consisting of inorganic, generally monatomic, ions), only the breakdown of the intrinsic structure of water on the hydration of ions is discussed, whereas in the study of solutions of electrolytes including organic ions there is frequently encountered a phenomenon which is attributed to a strengthening of the intrinsic structure of water under the influence of the ions (see p. 805).

Ahluwalia and coworkers [65-67] determined the values of ΔC_p^0 of dissolution and $\bar{C}_{p_2}^0$ for a number of tetra-alkylammonium halides at 25° and 35°, and found that the ΔC_p^0 values increase in the order:

Me_4NI	$<$	Me_4NBr	$<$	Et_4NBr	$\simeq$	Et_4NI	$<$	Pr_4NBr	$\leqslant$	Pr_4NI	$<$	Bu_4NBr
-10.5 ± 6		-10.4 ± 4		33.0 ± 3		37.5 ± 4		112.5 ± 2		119 ± 4		179 ± 3

They conclude that Me_4N^+ cations break down the structure of water, and that the other cations strengthen it. The $C_p = f(T)$ and $\Delta C_p = f(T)$ curves are not monotonic [65] (Fig. 4). The minimum at 50° was explained in terms of "hydrophobic" interactions, and the maximum at 70° was explained on the assumption that the heat capacity of the structuring process decreases above 70°. The idea that large ions have a structuring action was confirmed by Boyd and coworkers [68], who studied the values of ΔC_p^0 for ion exchange by examining the temperature dependence of the values of ΔH^0 for the exchange of Na^+ and Bu_4N^+ on ion exchange resins.

Kresheck [169] determined $\bar{C}_p^0$ values for several amino-acids in infinitely dilute aqueous and heavy-water solutions at 25° and concluded that the non-polar side chains of methionine and norvaline promote structure formation in water, the effect being greater for light water than for heavy water, in agreement with the theoretical predictions of Lovett and Ben-Naim [77] (see p. 805). Kay and coworkers [62,63] compared the results of the study of many properties (thermodynamic and transport properties) of aqueous and non-aqueous solutions at several temperatures in terms of the theory of Frank and Wen; this enabled Kay

to divide ions into three classes: electrostrictional structure-forming (Li^+, F^-, Ca^{2+}), hydrophobic structure-forming (Bu_4N^+, Ph_4B^-, etc.), and structure-destroying (Cs^+, I^-, Me_4N^+).[62] The ion classification made by Kay leaves open the question of the possibility of an increased heat capacity due to the hydration of hydrophilic ions of inorganic character. Moreover, the opinion has grown in the literature that the dissolution of these electrolytes in water is always accompanied by a decrease in heat capacity[43,170]. Recently, however, it was found[171-175] that the temperature coefficient of ΔH for the dissolution of manganese and zinc perchlorate crystal hydrates is positive over an appreciable range of concentration, that is the ΔC_p values for the dissolution of these salts are positive and not negative. It was suggested that this effect is due to the formation, around the aquo-cations, of associates of water molecules, joined by hydrogen bonds. The formation of associates depends on the nature of the ions and the state of water in the corresponding aquo-complexes, and on this basis suggestions have been put forward regarding the cases in which ΔC_p for the dissolution of an electrolyte may be greater than 0 or less than 0. In the work cited, attention was drawn to the existence of characteristic features in the properties of dilute solutions, which can be understood qualitatively by assuming that the effect of the structuring of water by many ions is particularly marked in highly dilute solutions.

The question of the unique behaviour of heat capacity in the range of very dilute solutions was also dealt with in papers by Mishchenko and Novoselova[107-109,113], and agrees with studies of other properties of dilute solutions[129,176,177].

2. Heat Capacity and Hydrolysis of Ions

No special studies of heat capacity in relation to the hydrolysis of ions have been made in the period under review. It is possible only to try to estimate this effect from data on the change in heat capacity on the ionisation of water[178-180], ammonium ions and some of their derivatives[181,182], and acids[150,178,180-191], and also from the results of individual studies of the temperature dependence of the hydrolysis constants of metal cations[192-201].

Table 5 gives the values of ΔC_p for the ionisation of water for various acids and for the ammonium ion and its derivatives, obtained either as the temperature coefficients of ΔH for the reaction[178,180,181,186-188] or from the temperature dependence of the ionisation constants[150,181-185,190,191]. The values of ΔC_p for the hydrolysis of the anions formed on the dissolution of the uncharged acids listed in Table 5 are obviously equal to the difference between ΔC_p for the ionisation of water and ΔC_p for the protolytic dissociation of the acid. The corresponding values are given in column 5 of Table 5. It can be seen that the values of ΔC_p hydrol for the anions may be negative or positive.

Table 5. Values of ΔC_p for protolytic dissociation, ΔC_p p.d., for compounds, and values of ΔC_p for hydrolysis, ΔC_p hydrol, for the corresponding acid residues, at 25° (cal mole^{-1} deg^{-1}).

The hydrolysis of metal cations involves essentially the protolytic dissociation of their aquo-complexes, so that subsequently we can try to estimate the values of ΔC_p for these processes by analysing the accumulated data for other acids.

Examination of the data in Table 5 reveals the following features.

1. The protolytic dissociation of uncharged molecules and anions is generally accompanied by a decrease in heat capacity, but the dissociation of positive ions almost always corresponds to an increase in heat capacity or to very little change.

2. The value of ΔC_p for the first stage of the dissociation of the uncharged molecules of many acids lies in the range between -22 cal mole^{-1} deg^{-1} and -38 cal mole^{-1} deg^{-1}. An exception is provided by acids which tend to decompose (HNO_2, H_2CO_3, H_2SO_3, H_2S) or polymerise (H_3BO_3, H_4GeO_4, H_6TeO_6), or which have a complex branched structure (THAM¶ or substituted carboxylic acids). It is also possible that some of these deviations are due to a large error in the determination of ΔC_p.

3. The value of ΔC_p for each successive stage of the step-wise dissociation of H_3PO_4, H_3AsO_4, and H_4SiO_4 is more negative than the previous one (Fig. 5).

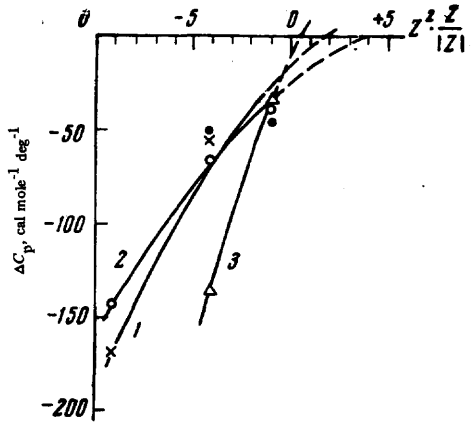

Figure 5. Values of ΔC_p for the successive stages of the acidic dissociation of H_3PO_4 (*1*), H_3AsO_4 (*2*), and H_4SiO_4 (*3*) as functions of the charge z of the conjugated base.

4. In the series of methylammonium ions, an increase in ΔC_p for the dissociation is observed with increase in the number of methyl groups.

The existence of several independent regular features, not to speak of the exceptions, indicates that the values of ΔC_p for the ionisation of protolytes are determined by various factors. One is the change in the electrostatic parameters of the particles in the dissociation process. This is obviously confirmed by the first three of the above regular features.

King [181] attempted to described ΔC_p for protolytic dissociation on the basis of Born's electrostatic model of hydration. He showed that, according to this model, ΔC_p for ionogenic reactions (corresponding to the dissociation of uncharged or anionic acids) should be negative, and should be more negative, the higher the charge of the anion. In the case of isoelectric reactions (for example the dissociation of NH_4^+), the absolute value of ΔC_p should be slightly greater, and possibly positive. Verification of the theory by experiment led King to the conclusion that the simple electrostatic model does not make it possible to predict ΔC_p quantitatively for protolytic dissociation [181]. It is necessary to take account of other factors influencing ΔC_p. Many authors consider that the most important of these factors is the hydration of the particles, including the rearrangement of the solvent as a result of the dissociation of the solute [180-184,186]. The temperature dependence of ΔC_p for the ionisation is particularly sensitive to these changes [180,182,184]. Thus if our aim is to estimate ΔC_p for the protolytic dissociation of the aquo-cations of metals

$$M(H_2O)_n^{z+} + H_2O \rightleftarrows MOH(H_2O)_{n-1}^{z-1} + H_3O^+$$

or in other words the hydrolysis of M_{aq}^{2+} cations, it is necessary to have not only the electrostatic parameters of the components of the reaction but also data (which are usually not available) on their hydration and action on the structure of the solution.

If we nevertheless assume that the electrostatic approach should be most applicable to metal ions of spherical shape, we may expect (following King's method [181]) for the hydrolysis of singly-charged metal ions ΔC_p close to zero, that for doubly-charged ions about 20–40 cal mole^{-1} deg^{-1}, and that for triply-charged ions 60–80 cal mole^{-1} deg^{-1}. It is difficult to verify this suggestion, since no direct calorimetric measurements of ΔC_p have been made. The known dependence of pK† for the hydrolysis of cations [192-201] on the reciprocal of the absolute temperature $1/T$ in most cases is linear, irrespective of the charge of the cation. Thus within the limits of error of the measurement of pK, the value of ΔC_p for the hydrolysis is equal to zero. The error in the measurement of pK, however, is nowhere less than ± 0.02 pK units; according to King's estimates [181], this would correspond to an error of several tens of cal mole^{-1} deg^{-1} in the determination of ΔC_p.

In a spectrophotometric study [191] of the hydrolysis of $FeCl_3$, $Fe(NO_3)_3$, and $Fe(ClO_4)_3$ it was found that ΔH for the reaction $Fe^{3+} + H_2O \rightleftarrows FeOH^{2+} + H^+$ in the temperature ranges from 21° to 50° and from 50° to 90° has the values 3.4 kcal mole^{-1} and 8.6 kcal mole^{-1} respectively. This gives the value $\Delta C_p \sim 150$ cal mole^{-1} deg^{-1}, which does not agree with the value -16.5 cal mole^{-1} deg^{-1} calculated on the basis of data on $\bar{C}_p^0$ for the components of the reaction, equal to -61 (Fe^{3+}), -39 ($FeOH^{2+}$), 18 (H_2O), and -20.5 (H^+) cal deg^{-1} mole^{-1}. [81]

From data on ΔS for the reaction $Al^{3+} + 2H_2O \rightleftarrows AlOH^{2+} + H_3O^+$, [201] the value of ΔC_p for this reaction can be estimated at about 30 cal mole^{-1} deg^{-1}. This value is also greater than the error in its determination, since it is found from the change in ΔS with temperature, which in this case is commensurate with the error in the determination of ΔS.

Thus the question of the values of ΔC_p for the hydrolysis of cations remains open. Nevertheless, it can hardly be assumed that the magnitude of this quantity has in fact the same zero value for all cations, since the state of the components of the solution changes quite markedly on

¶ THAM = tris(hydroxymethyl)aminomethane.

† $pK = \lg K$, where K is the hydrolysis constant.

hydrolysis and is different for different systems. This is indicated, for example, by the values of ΔS for hydrolytic processes, taken from a review by Arnek [202] (Table 6). The values of ΔS for the reactions of the same type involved in the formation of the complexes $CdOH^+$, $HgOH^+$, and $FeOH^{2+}$ vary from −2.7 e.u. to +23 e.u., those for complexes of the type $M_4(OH)_4^{4+}$ from −20.8 e.u. [for $Pb_4(OH)_4^{4+}$] to +14.0 e.u. [for $Ni_4(OH)_4^{4+}$], etc. It is difficult to believe that such marked differences in the entropy of the reaction are not associated with differences in the change in heat capacity. In actual fact, data on the measured heat capacity of aqueous solutions of the perchlorates of Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} at 25° [50,51,81,171] showed that in the range of high concentrations there is a correlation between the degree of hydrolysis of the cations and the apparent (and partial) molar heat capacity of the salts in solution (Fig. 6).

Table 6. Change in entropy ΔS accompanying the hydrolysis of cations $qM^{n+} + pH_2O \rightleftharpoons M_q(OH)_p^{(nq-p)+} + pH^+$ at 25° in 3 M $NaClO_4$. [202]

Hydrolysis product	ΔS, e.u.	Hydrolysis product	ΔS, e.u.	Hydrolysis product	ΔS, e.u.	Hydrolysis product	ΔS, e.u.

$FeOH^{2+}$	23.0			$Hg(OH)_2$	4.6	$Pb_6(OH)_8^{4+}$	−27.0

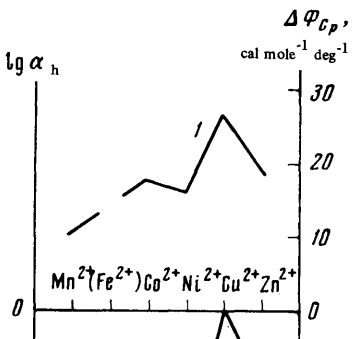

Figure 6. Correlation between the increase in the apparent molar heat capacity of the perchlorates of the 3*d* metals with increase in concentration from 0 to 4 *m*, $\Delta\Phi C_p$ (*1*) and the logarithm of the degree of hydrolysis $\lg\alpha_h$ for the corresponding cations in concentrated solutions of their chlorides (*2*).

If this correlation is not accidential, it indicates a positive change in heat capacity in the hydrolysis of these electrolytes in concentrated solutions. In the works cited it was suggested that a positive change in heat capacity may accompany the localised hydrolysis and hydrolytic polymerisation of cations, that is the processes which take place preferentially at high concentrations of the salt.

3. Heat Capacity and the Formation of Acido-complexes

The question of the change in heat capacity on the formation of acido-complexes in solution has been examined many times [7,10,11,54,203-228]. In all the works cited, with some exceptions [54,209,212-216,223,226], an indirect method for determining ΔC_p for complex formation from the temperature coefficients of the values of ΔH and ΔG was used. The main results are given in Table 7. It can be seen that the values of ΔC_p for ion association ΔC_{pk} vary over a wide range, depending on the specific ions, but are always positive.

Table 7. Change in heat capacity ΔC_{pk} on formation of various acido-complexes (cal $mole^{-1}$ deg^{-1}).

[a] Suc^{2-} = succinate anion; [b] A^- = β-alanite anion; [c] Gl^- = glycinate anion; [d] Mal^{2-} = malonate anion.

The large positive change in heat capacity on complex formation is also indicated by the study of ΔH for the formation of $FeBr^{2+}$ [210] and $CdBr^+$ [211] at different temperatures and by the study of heat capacity in the H_2SO_4—HNO_3—H_2O system [212]. In view of this characteristic

feature of the ΔC_{pk} values, it must be assumed that Spedding and Jones' conclusion that complex formation is responsible for the production of the maximum on the $\Phi Cp = f(m)$ curves for the REE chlorides at high concentrations is incorrect[54,55] (see p. 810).

The positive change in heat capacity on the formation of acido-complexes is attributed to the partial liberation of water from the hydrate sheaths of simple ions and to a reduction of the range over which ions affect the heat capacity of the surrounding water due to a decrease in the overall charge of the particles[209,213-216]. Vasil'ev[207,208,210,217-222] explains this phenomenon on the basis of the view that "icebergs" of water molecules are formed around simple and complex ions, and that these icebergs undergo rearrangement on complex formation.

An interesting feature is that the effect of temperature on ΔC_{pk} in the cases studied[207,208,217] is relatively small (Table 7); at $I = 0$, with increase in temperature from 0° to 50°, the value of ΔC_{pk} decreases by only a few calories. With increase in I the effect of temperature becomes even smaller. This suggests that the decrease in ΔC_{pk} with increase in temperature is due chiefly to the decrease in the heat capacity of the free water. With increase in the ionic strength, the quantity of free water becomes smaller, with a corresponding decrease in the effect of temperature on ΔC_{pk}.[223]

ΔC_{pk} has been determined by the direct calorimetric method for the $Zn(ClO_4)_2-CaCl_2-H_2O$ and $Cd(ClO_4)_2-CaCl_2-H_2O$ systems[209,214-216,226] for several values of the total electrolyte concentration and for different ratios of the quantities of complex-forming species and ligand. The values obtained are the overall values for a mixture of several species of complex, but at high ratios m_{Cl}/m_M they correspond almost completely to the formation of the complexes $ZnCl_4^{2-}aq$ and $CdCl_4^{2-}aq$. After analysing the dependence of ΔC_{pk} on m_{total}, on m_{Cl}/m_M, and on $[Cl^-]_{free}$, the authors cited concluded that the greatest increase in ΔC_{pk} corresponds to the formation of the neutral species, and that ΔC_{pk} is sensitive to the state of the species in the outer sphere.

4. Change in Heat Capacity on the Formation of Ternary and Multi-component Solutions

In addition to the paper already cited[3-6,9-12,15,16,22,23], work in this field has been published by Karapet'yants, Vasilev, and coworkers[91-94,229-237], Latysheva and Andreeva[209,214-216,223,226], and Anderson and coworkers[238,239].

The paper by Karapet'yants, Vasilev, and coworkers are devoted to the study and interpretation of those deviations from additivity which accompany the formation of ternary solutions from two binary solutions when these are isomolal (sometimes isopiestic). Most of the systems studied (mixtures of solutions of alkali and alkaline earth metal halides) do not contain acido-complexes, and the changes in heat capacity accompanying their formation from the binary solutions are extremely small. The authors cited attributed them to slight changes in the structure of the solution and to the redistribution of water between the ions. Work by Anderson and coworkers[238,239] has been carried out in approximately the same direction.

Latysheva and Andreeva[209,214-216,226] studied ΔC_p for the formation of the ternary non-complex-forming solutions $Ca(ClO_4)_2-Zn(ClO_4)_2-H_2O$, $Ca(ClO_4)_2-Cd(ClO_4)_2-H_2O$, and $CaCl_2-Ca(ClO_4)_2-H_2O$ from the corresponding (isomolal) binary solutions. The values obtained are small compared with ΔC_p for the formation of ternary complex-forming systems. The values of ΔC_p are slightly greater in the system formed by solutions of zinc and calcium perchlorates than in the other two systems; in the opinion of the authors cited, this indicates an appreciable redistribution of water between Zn^{2+} and Ca^{2+} cations, which differ significantly in their ability to undergo hydration. Nevertheless, it follows from these papers, and also from the others listed above, that the changes in heat capacity associated only with the redistribution of water between the dissolved electrolytes or with the structural changes in the system on the formation of the ternary solution from the binary solutions are generally small compared with the changes in heat capacity on the dissolution or ionisation of electrolytes, or the formation of acido-complexes. This is evidently related to the fact that the effect of the ions on the heat capacity of the more distant layers of water molecules is much less than that for the nearest molecules.

5. Sharp Change in Heat Capacity within Narrow Ranges of Temperature and Concentration

The few papers which have been published in this field[65,240-245] indicate the possibility of fairly sharp changes in the heat capacity of certain solutions within a narrow range of temperature or concentration. Smirnova and coworkers[240] observed the existence of a maximum on the $\Phi Cp = f(\sqrt{m})$ curve in the range of high concentrations (80–82%) of polyphosphoric acids, and attributed it to a change in the structural form. Latysheva and coworkers[241,242] studied the influence of heating through several degrees on the heat capacity of solutions of strontium perchlorate and manganese sulphate, saturated at temperatures close to the temperature of the change in the composition of the solid phase. The transformations studied were $Sr(ClO_4)_2.4H_2O \rightarrow Sr(ClO_4)_2.2H_2O + 2H_2O$ ($t° = 25.5°$) in the case of strontium perchlorate, and $MnSO_4.5H_2O \rightleftharpoons MnSO_4.4H_2O + H_2O$ ($t° = 27°$) in the case of manganese sulphate. Both systems showed sharp changes in heat capacity, but the form of the curve and the displacement of the temperature of the sudden change with change in concentration are specific for each system. Typical examples of curves for the two systems are shown in Fig. 7. With increase in concentration, the temperature of the sudden change increased in the $Sr(ClO_4)_2-H_2O$ system, and decreased in the $MnSO_4-H_2O$ system. The heat capacity isotherms for these systems also show sharp changes in heat capacity (within a narrow range of concentrations). The phenomena are attributed to a change in the structure of the solutions due to the partial dehydration of the cations, accompanied in the case of the $MnSO_4-H_2O$ system by the formation of acido-complexes. Labowitz and Westrum[243], in a study of the heat capacity of solutions of NH_4F in water at concentrations of 0.005 to 0.50 m and temperatures in the range 55–325°K, found that the heat capacity of the solutions varies very smoothly with temperature at some concentrations, whereas at other concentrations a heat capacity surge is observed at the eutectic temperature. The change from the first solutions to the second apparently corresponds to a significant rearrangement of the solutions within a finite range of concentrations.

In the cases examined, the heat capacity surges were observed at fairly high electrolyte concentrations, so that

they must have been due to changes in the structure of the solution as a whole. At the same time the possibility of a sharp rearrangement in only one component is not excluded. For example, in pure water, breakdown of the collective structure was observed close to 34°.[244] This effect increases when non-polar substances of the benzene type are dissolved in water: the curve giving the temperature dependence of ΔC_p for the dissolution of benzene shows a distinct maximum in the region of 30° (Fig. 8).[245]

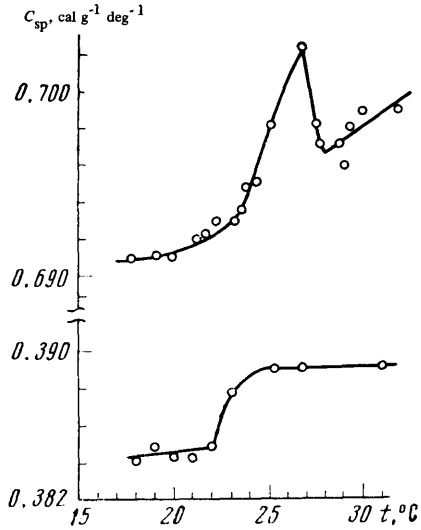

Figure 7. Examples of the form of the temperature dependence of the heat capacity of solutions of $Sr(ClO_4)_2$ (1) and $MnSO_4$ (2) under conditions close to those corresponding to the change in the composition of the solid phase in equilibrium with the solution.

In solutions of strong electrolytes this effect disappears, since the dissolution itself in this case leads to breakdown of the collective structure of water[244]. On the dissolution of substances with a strong ordering influence, on the other hand, the extremal values on the curves giving the temperature dependence of the heat capacity may become even sharper.

Solutions of polyribouridylic, polyriboadenylic, and deoxyribonucleic acids showed sharp heat capacity λ-surges at two temperatures[246]. The cause in this case is apparently the change in the collective hydrophobic interaction of the protein molecules. According to some estimates[247], the hydrophobic interaction between two protein side chains in solution at 25° is characterised by values of ΔC_p in the range from −10 cal mole^{-1} deg^{-1} to −50 cal mole^{-1} deg^{-1}. Berendsen even suggests that hydrophobic bonds are a more important factor in the stabilisation of the native conformation of a protein than intermolecular hydrogen bonds[247]. Breakdown of the hydrophobic interaction is associated with a sharp change in the structure of the surrounding water.

The marked contribution of changes in structure to the value of the heat capacity of solutions may be related to the heat capacity of activation, and moreover it must obviously have a decisive influence on the difference between the isobaric and isochoric heat capacities.

6. Heat Capacity of Activation

This problem was studied by Cobble[248-250], who showed that for the successful development of the theory of reaction rates in aqueous solution there is an extreme lack of data on the relationship between the nature and structure of the activated complexes on the one hand and the values of the energy $\Delta E^{\neq}$, enthalpy $\Delta H^{\neq}$, and entropy $\Delta S^{\neq}$ of activation on the other.

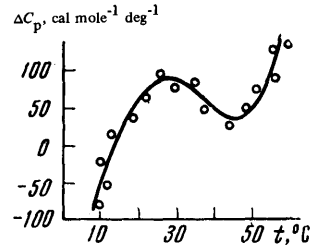

Figure 8. Temperature dependence of ΔC_p for the dissolution of benzene in water.

Cobble assumes that this gap can be filled by studying the heat capacity of activation $\Delta C_p^{\neq}$, which can be determined experimentally (as the temperature coefficient of $\Delta H^{\neq}$) or calculated for an activated complex with a given structural model using the principles of statistical thermodynamics. Additional verification of the description of the symmetry and internal motion in the activated complex is possible by means of a statistical calculation of the $\Delta S^{\neq}$ values, which are related to $\Delta C_p^{\neq}$ by the familiar equation

$$\left(\frac{\partial \Delta S^{\neq}}{\partial T}\right)_p = \frac{\Delta C_p^{\neq}}{T}. \qquad (12)$$

On the other hand, in Cobble's opinion, $\Delta C_p^{\neq}$ can be extimated from experimental data on $\Delta S^{\neq}$ by means of the correspondence principle (p. 808). The results of this estimate for a number of reactions are given in Table 8.

Table 8. Estimated values of $\Delta C_p^{\neq}$ for various reactions[249] at 25°.

Rate-determining reaction	$\Delta C_p^{\neq}]_{25}^{100}$, cal mole^{-1} deg^{-1}
$OCl^- + OCl^- \rightarrow [OClOCl]^{2-\neq}$	98
$[S\dot{O}_3]^{2-} + [S_2O_3]^{2-} \rightarrow [O_3S\dot{O}_2S_2]^{4-\neq}$	75
$[Fe^{\cdot}(CN)_6]^{4-} + [Fe(CN)_6]^{3-} \rightarrow [Fe^{\cdot}(CN)_6 Fe(CN)_6]^{7-\neq}$	52
$HO_2^- + Co^{3+} \rightarrow [HOCo]^{2+\neq}$	$\leqslant 0$
$[Pu^{\cdot}(OH)]^{3+} + Pu^{3+} \rightarrow [Pu^{\cdot}(OH)Pu]^{6+\neq}$	−29
$[Fe^{\cdot}(OH)]^{2+} + Fe^{2+} \rightarrow [F\ddot{e}(OH)Fe]^{4+\neq}$	−35
$Cr^{2+} + [(H_2O)Co(NH_3)_5]^{3+} \rightarrow [Cr(H_2O)Co(NH_3)_5]^{5+\neq}$	~ −40
$H^+ + VO_2^+ + Fe^{2+} \rightarrow [HVO_2Fe]^{4+\neq}$	−53

Unlike reactions in gases, reactions in aqueous solutions may have very large $\Delta C_p^{\neq}$ values, which may be

either positive or negative. In the last case it is possible in principle that above a certain inversion temperature the activation energy will be not positive but negative, since

$$\Delta H^{\neq}_{(T_1)} = \Delta H^{\neq}_{(T_1)} + \Delta C^{\neq}_p (T_2 - T_1) \qquad (13)$$

and the kinetics will become retrograde. The problem of retrograde kinetics is now being studied in Cobble's laboratory.

In the opinion of Arnett and coworkers [251], the fluctuations and irregularity in the experimentally determined values of $\overline{C}^0_{p_2}$ for some substances may be due to fluctuations in the values of $\Delta C^{\neq}_p$.

V. HEAT CAPACITY AT CONSTANT VOLUME C_V

Kozhevnikova and Latysheva [50,171,252] determined C_V and $C_p - C_V$ for aqueous solutions of Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} perchlorates. Contrary to the previously held opinion, the difference $C_p - C_V$ was found to be fairly large. In addition, the form of the dependence of $\Phi C_p - \Phi C_V$ on the concentration, previously unknown for electrolytes, was determined. All the perchlorates are characterised by a maximum on the $\Phi C_p - \Phi C_V = f(m)$ curve (Fig. 9). To explain the results obtained, these authors put forward a model of the structure of these solutions at different concentrations.

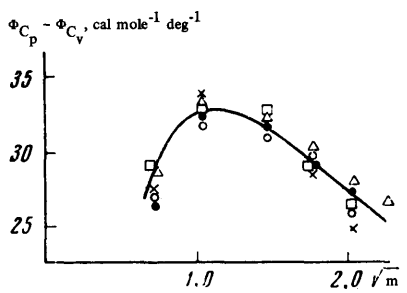

Figure 9. Dependence of the difference $\Phi C_p - \Phi C_V$ for the perchlorates of doubly-charged 3*d* metals (Mn, Co, Ni, Cu, and Zn) on the concentration of the solution.

The determination of C_V has been carried out by Gucker [105,253], but the numerical data [253] are unfortunately not yet available to Soviet readers.

C_V values for solutions of several electrolytes at 25° and 230° have been determined under the direction of Galinker [254,255]. An interesting observation is the marked increase in the difference $C_p - C_V$ with increase in temperature. At the same time there is a sharp decrease in the difference between water and electrolyte solutions. The magnitude of $C_p - C_V$ decreases with increase in concentration at high temperatures, in contrast to the behaviour at low temperatures. The authors cited assume that $C_p - C_V$ is related to the sharp increase in the entropy of the liquid at constant pressure, that is "it is found that a small decrease in the volume of the liquid brings about a marked decrease in the freedom of the thermal motion of the molecules".

---o0o---

The material reviewed demonstrates the deep and complex relationship between the heat capacity of aqueous solutions of electrolytes and the chemical character of the dissolved ions and the solvent. Without establishing the essential features of this relationship we cannot hope to develop the theory of the problem and solve the corresponding applied problems. At the same time the most rigorous route—from the quantum-mechanical description of the ion–molecule interactions to the macro-properties of solutions via statistical thermodynamics—is as yet too difficult. A method which is more accessible at the present time and therefore more promising (the establishment of the relationship between the chemistry of the micro-reactions in solutions and their properties) involves the search for and the thorough analysis of the regular features of the change in properties from one solution to another on the basis of the periodic classification of the elements. It is the (temporary) impossibility of predicting theoretically all the contributions to the heat capacity of a solution with a given composition which makes necessary an analysis of the regular features for a number of systems related to one another by the periodic classification, since in an analysis of this kind the probability that one of the constituent macro-properties will be missed is decreased sharply [129]. For example, the important contribution of the destructive influence of ions to the heat capacity was detected only in analysis of the regular features of the change in the values of $\overline{C}^0_p$ for series of ions of the alkali and alkaline earth metals and the halogens [36,37,50,171], and not from the heat capacity of solutions of any single electrolyte. The addition of the series of 3*d* metal ions [50–53,81,129,171,175,252,256,257] to these series revealed the effect of the interaction energy of the ions with water on heat capacity, and the study of REE ions revealed the influence of the coordination number of the cations [54,55]. A comparative study of the heat capacity of solutions of the chlorides and perchlorates of the elements of the second main group and side group provided further information on the relationship between heat capacity and the formation of acido-complexes in solution [209,213–216,226].

Thus in order to develop the theory of the heat capacity of solutions, the studies must not be restricted to solutions of the simplest salts, that is the alkali halides, and it is necessary to extend the range of materials studied even further, using the logic of the periodic classification. The fruitful results to be obtained from the use of the periodic classification for practical purposes by the method of comparative calculation have been proved convincingly in a large number of papers [124,154,231,232,258,259]. The method makes it possible in many cases to predict the properties of solutions of compounds which are difficult to obtain.

Nevertheless, the problem of increasing the accuracy of experimental methods for the determination of heat capacity, particularly in dilute solutions, remains urgent. The lack of accurate heat capacity data is at present holding back its theoretical analysis. In view of the exceptional complexity of the interpretation of the heat capacity of solutions, it would be extremely useful to have the results of investigations combining a study of heat capacity with an examination of other properties over a wide range of temperatures and pressures [254,255,260].

The development of new methods for estimating individual contributions to the heat capacity of solutions from the results of spectroscopic measurements of different kinds would be extremely useful. Spectra characterising the weak intermolecular interactions and rotations of molecules would be highly important, since the change in intramolecular vibrations as a result of interactions in aqueous solutions of electrolytes makes only a relatively small contribution to the heat capacity [181]. We can also apparently expect to obtain interesting information from studies of the changes in heat capacity in non-equilibrium processes, for example the so-called heat capacity of transfer C^*, determined in the study of the Soret effect [261-264]. In the opinion of Kennerley and coworkers [262], the effect of transfer makes it possible to obtain a pecture of the state of water which is external with respect to the moving particle, that is the hydrated molecule or ion, whereas an overall property of the solution includes the characteristics of all the particles simultaneously.

One of the most important problems related to the study of the heat capacity of aqueous solutions of electrolytes undoubtedly remains the problem of the development of the theory of the liquid state of water.

Double Molybdates and Tungstates of the Rare Earth and Alkali Metals

A.A.Maier, M.V.Provotorov, and V.A.Balashov

Data on the preparation, structure, and various properties of the double tungstates and molybdates (EO_4) of the alkali (M) and rare earth (R) metals with the composition $RM(EO_4)_2$ have been summarised and systematised. The regular features of the change in the symmetry, polymorphism, and nature of the fusion with change in the nature of the alkali and reare earth metals have been examined. The bibliography contains 82 references.

I. INTRODUCTION

Double molybdates and tungstates of the type $R^{3+}M^{+}(EO_4)_2$, where R represents a rare earth element (REE) or any other tervalent element, M represents an alkali metal, and E represents molybdenum or tungsten, are of considerable interest in connection with their possible use as laser matrices. Up to the present, lasing has been achieved in single crystals of $LaNa(WO_4)_2$,[1] $LaNa(MoO_4)_2$,[2-8] $PrNa(MoO_4)_2$, $TbNa(MoO_4)_2$,[8] $GdNa(MoO_4)_2$,[7] $GdLi(MoO_4)_2$,[9] and $YK(MoO_4)_2$,[10,11] containing Nd^{3+}. The transparency of these crystals over a wide range of wavelengths of the spectrum (0.4–5.0 μ), the high thermal conductivity [22 mW cm^{-1} deg^{-1} for $LaNa(MoO_4)_2$], low lasing threshold [5.5 J for $LaNa(MoO_4)_2$–Nd^{3+}], and the possibility, in principle, of obtaining single crystals with any concentration of active ion, have been noted.

The crystals of many double tungstates and molybdates are characterised by structural disorder, involving the random distribution of R^{3+} and M^{+} in the lattice[12]; the disorder is apparently greater, the closer the radii of these two ions[13,14]; it is revealed in the indistinct nature of the birefringence pattern and in the broadening of the bands in the vibrational absorption, luminescence, and paramagnetic resonance (PMR) spectra[2,3,7,12,15,16]. Two important possible applications of these disordered crystalline systems have been noted: the production of extremely short ($<10^{-11}$ s) giant pulses of coherent radiation in optical quantum generators (OQG) with phasing of the modes; and high-temperature lasing[17].

Almost all double molybdates and tungstates $RM(EO_4)_2$ have now been prepared, their structures and polymorphism have been studied, and their melting points and other physicochemical properties have been determined. Most of these compounds have been obtained in the form of small single crystals suitable for the study of their structures and optical, magnetic, and various other properties. Large single crystals for lasers have been grown for only a few of these compounds, however. The lack of a well-developed technology for the growth of large crystals is retarding the further study of this interesting class of laser material.

The wide variety of properties shown by this group of compounds on the one hand provides the possibility, in principle, of an extensive selection of methods for the preparation of active solids with desirable properties, and on the other hand complicates this selection. In this connection, we have attempted to analyse and systematise the available (in many instances contradictory) data.

As compounds derived from scheelite (by replacing two calcium atoms by R and M atoms), the double compounds $RM(EO_4)_2$ can be classified naturally according to the extent to which the dimensions of the ions R^{3+} and M^{+} differ from those of the calcium ion. This replacement, in addition to the scheelite-like structure, produces a whole set of new structural types. Thus the properties of the double compounds must be related not only to the disordered character of the structure, but also to the actual structures and structural types.

According to Goldschmidt's rule[18], the crystal structure of a compound depends chiefly on the polarisation properties, geometric parameters, and relative numbers of the ions present. The polarisation properties (the nature of the hybridisation) of the ion in complex compounds (to which class the double molybdates and tungstates belong) are suppressed by the large total energy of the lattice[19]. It may therefore be assumed that the structure of $R^{3+}M^{+}(EO_4)_2$ is determined chiefly by the ratio of the dimensions of the ions, which in turn may change with change in temperature, so that it also determines the polymorphism. In the series of normal double molybdates and tungstates $R^{3+}M^{+}(EO_4)_2$, the variable species are R^{3+} and M^{+}, so that the structure and also the degree of disorder will depend on the values of the ionic radii $r_{R^{3+}}$ and $r_{M^{+}}$ (naturally, within the approximation indicated).

Existing systems[20] of ionic radii characterise the values at room temperature, so that it is justifiable to examine the dependence of the symmetry of the structures on $r_{R^{3+}}$ and $r_{M^{+}}$ only for the low-temperature phases. We cannot however reach completely reliable conclusions regarding the crystal system of the low-temperature phase in those cases where some authors have established a polymorphic transition, and others have not detected it, and the problem of whether the crystal systems which they have established correspond to the high-temperature or low-temperature modifications remains open. This ambiguity can be resolved on the basis of the working hypothesis that there is a certain probability of quenching or stabilisation of high-temperature phases at low temperatures either as a consequence of the presence of impurities or as a result of

insufficiently slow cooling in the region of the temperature of the phase transformation.

Comparison of the results obtained by different authors leads to the conclusion that the ability of the high-temperature phases to undergo quenching or stabilisation is a characteristic feature of double tungstates and molybdates, so that the production of a particular modification depends on the method of preparation and subsequent thermal treatment.

II. PREPARATION OF DOUBLE MOLYBDATES AND TUNGSTATES $R^{3+}M^{+}(EO_4)_2$

A bibliography of various methods for the preparation of the double molybdates and tungstates formed by the alkali metals with the REE and Y is given in Tables 1 and 2. The compounds are prepared by precipitation from aqueous solutions (O), by the hydrothermal method (Г), by crystallisation from solutions in melts (P), and by heating mechanical mixtures of the oxides and salts (T). (The preparation of large single crystals by the Czochralski method is denoted by the letter C in the Tables.)

1. Precipitation from Aqueous Solutions

The double compounds $RM(EO_4)_2$ are precipitated by mixing aqueous solutions of M_2EO_4 and a salt of the tervalent element. Both the direct (addition of M_2EO_4 solution to a solution of the REE salt) and the reverse order of mixing are used. The second alternative appears less reliable, as a consequence of the hydrolysis of the salt of the tervalent element when it is added to the MEO_4 solution, which has an alkaline reaction [61].

It has not been possible to obtain the sodium double tungstates with the REE from La to Sm, or any of the lithium double tungstates, by simply mixing the solutions [61]. $RNa(WO_4)_2$ (R = La, Ce, Pr, or Nd) have been obtained only in neutral medium; for this purpose, nitric acid was added to Na_2WO_4 solution to pH 8, so that on mixing with $R(NO_3)_3$ solution the mother-liquor had pH 7. [35] The corresponding double molybdates are formed by simply mixing the solutions.

In all cases the normal tungstate or molybdate is precipitated first; on standing, this reacts with the excess of M_2EO_4 in the solution to form the double salt [36,61]. The double molybdates with sodium and potassium (unlike those with rubidium and caesium) are readily decomposed by water. Since departures from stoichiometry take place when these precipitates are washed with water, the removal of mother-liquor in a press has been proposed [61]. At low concentrations of the REE salt (≤ 0.01 M), the sodium and potassium double molybdates (unlike the

rubidium and caesium compounds) are not formed[61].

The data given show that the stability of the double tungstates, under the conditions of preparation from solution, increases from Li to Cs. In view of the similarity in the chemical properties of molybdates and tungstates, it may be assumed that the same regular features are observed for the double molybdates

The precipitated double molybdates formed by sodium with the REE from La to Nd contain one molecule of water of crystallisation[34-36]. The removal of water and the crystallisation of anhydrous $NdNa(MoO_4)_2$ begin at 540°.[34]

The compositions of the hydrated tungstates, and the temperatures of their dehydration and crystallisation with the formation of the anhydrous double compounds are given in Table 3.

Table 3. Characteristics of double tungstates $RM(WO_4)_2$ obtained by precipitation from aqueous solutions.

2. Hydrothermal Preparation of $RM(EO_4)_2$

This method has been used for the preparation of the double compounds $RM(EO_4)_2$ only by Klevtsov and Kharchenko[71] (Table 2). They prepared crystals of $RLi(WO_4)_2$, $RNa(WO_4)_2$, and $RK(WO_4)_2$ (where R = Ce, Pr, or Nd), and also $LaK(WO_4)_2$, by spontaneous nucleation under isothermal conditions in 8—12 cm^3 capacity autoclaves with titanium linings.

For the lithium—REE double tungstates, the best results from the viewpoint of yield (70%) and crystal size (up to 3 mm) were obtained with a charge consisting of a heated mixture of the oxides R_2O_3 and WO_3 with molar ratio 1 : 2, and 20—30% LiCl solution as solvent, at 525—550° with a filling factor of 50—60%.

The compounds $RNa(WO_4)_2$ were obtained under hydrothermal conditions in the form of fine crystals with dimensions up to 0.3 mm. The optimal conditions of crystallisation were the same as those for $RLi(WO_4)_2$.

The potassium double compounds were prepared under hydrothermal conditions at 500—600° in 50% KCl solution. At lower concentrations, non-stoichiometric crystals with variable composition $R_{1-x}K_{1-3x}(WO_4)_2$ are formed.

At the comparatively low temperatures characteristic of the hydrothermal method of preparation, the lithium double molybdates crystallise in the triclinic modification, and the potassium compounds in the monoclinic form. When heated above 800°, these phases undergo monotropic conversion into the tetragonal (scheelite) and monoclinic [analogous to $Nd_2(WO_4)_3$] modifications respectively, which are obtained when other methods of preparation are used (Table 2). The sodium REE tungstates are tetragonal for all methods of preparation. The similarity in the ionic radii of Na^+, R^{3+}, and Ca^{2+} evidently facilitates the preservation of the $CaWO_4$ structure[68].

3. Crystallisation of $RM(EO_4)_2$ from Molten Solutions

This method was used to prepare the first double compounds of the type $R^{3+}M^+(EO_4)_2$ [66] (if we exclude the work of Carobbi[36], who precipitated $LaNa(MoO_4)_2$ from aqueous solutions). Several versions of the method are now employed, and in most cases spontaneous crystallisation is used.

Alkali metal chlorides or tungstates (or molybdates) are used as solvents. The latter are more convenient, since they undergo little volatilisation[63] under the crystallisation conditions, have lower melting points, and do not contaminate the crystals with foreign ions.

The high volatility of chlorides can be used to grow crystals by evaporation of the solvent (chloride) from the corresponding molten salts at a constant temperature (700—750°, 10 h).[29,31,40,54] Most frequently, after being heated for 3—20 h in the superheated (1100—1250°) state, the solution is cooled slowly (2—3 deg h^{-1}) to a temperature below the melting point of the eutectic (~700°). The subsequent cooling is carried out more rapidly (~25 deg h^{-1}).

The charge is introduced into the solvent in all possible forms: the oxide R_2O_3, mixtures of the oxides R_2O_3 + $3EO_3$, R_2EO_4, $RM(EO_4)_2$, etc. The only condition is that the ratio of the components of the molten mixture should ensure the formation of the double compound and the solvent in the optimal proportions.

Sometimes, in order to obtain large crystals of $RM(EO_4)_2$, sufficient EO_3 is added to the solvent M_2EO_4 to form $M_2E_2O_7$, which has a higher "capacity" as solvent, as a consequence of the decrease in the EO_4^{2-} concentration with the formation of $E_2O_7^{2-}$.[26] This also explains the existence, on the ternary diagram of the $Na_2O—Gd_2O_3—Mo_2O_6$ system[77], of optimal composition ranges for the production of relatively large crystals. The solidified $M_2E_2O_7$ solvent, however, can be washed from the crystal only with concentrated MOH solution[26], whereas M_2EO_4 is readily removed with water. Moreover, the crystallisation from highly concentrated solutions takes place at a high rate, a large number of crystallisation centres are produced, and entrainment of the solvent by the rapidly growing faces of the crystals takes place. Transparent crystals without inclusions have been obtained only at a molar ratio $R_2(WO_4)_2 : Na_2WO_4 \leq 1 : 9$ (R = Y, La, Lu), at a rate of growth equal to 0.020—0.025 mm h^{-1}.[63] Reverse rotation (60 r.p.m.) of the crucible, beginning at a temperature 10—15 deg below the temperature of the start of crystallisation, made it possible to reduce by an order of magnitude the quantity of crystals of these compounds forming spontaneously.

Individual attempts to grow single crystals on seed crystals and by pulling (Czochralski method) from the melt solutions have been made. $EuCs(MoO_4)_2$ [49] and $RNa(WO_4)_2$, where R = Y, La, and Lu,[63] have been prepared in this way. In the last cases, growth took place in the upper part of a cylindrical quartz vessel containing the melt under conditions of a temperature gradient or a temperature drop (with the use of a diaphragm).

4. Preparation by Heating a Mechanical Mixture

The phase composition of the original mixture can represent any stoichiometric combination of thermally unstable salts of the rare earth and alkali metals and the products of their reaction with one another. It determines the chemistry of the process and hence the minimal temperature of heating.

It has been suggested [25,46] that the preparation of $RNa(EO_4)_2$, where R = La or Nd, by the action of heat on $R_2O_3 + 4EO_3 + Na_2CO_3$ and $R_2O_3 + EO_3 + Na_2EO_4$ mixtures involves the formation of amorphous sodium molybdates and tungstates $Na_2E_4O_{13}$ with their subsequent active reaction with R_2O_3, and that the preparation by the action of heat on an $Nd_2(MoO_4)_3 + Na_2MoO_4$ mixture involves the formation of the intermediate compound $NdNa_5(MoO_4)_4$. The formation of the molybdate $NdNa(MoO_4)_2$ is complete at 500° in the first case and at 600° in the second case. It has also been noted that the formation of the double tungstates takes place at higher temperatures (~750° for the ternary mixture). Other authors (see bibliography in Tables 1 and 2) prepared double molybdates and tungstates by heating at 500–900° and 600–1100° respectively for periods of 8–100 h. The possibility of carrying out the preparation over a wide range of temperatures makes it possible in some cases to obtain various polymorphic modifications immediately [21,43,57].

III. POLYMORPHISM

Comparison of the results obtained by different authors in the thermographic study of polymorphism with the methods of preparation of the compounds which they studied reveals a curious feature. In some cases, transformations which could not be detected in the study of compounds obtained from solutions in a melt have been clearly revealed when the same compounds were prepared by the sintering of solid mixtures.

For sodium and lithium double molybdates it has been possible to establish the existence of transitions (Tables 4 and 5) only after they had been prepared by heating mechanical mixtures with subsequent fusion and slow cooling of the melt. Crystals of the same compounds grown from molten solutions do not show any effects. It may therefore be assumed that in the first case a low-temperature form is obtained, and in the second case a high-temperature form. Both were found to be tetragonal (scheelite type). The weak reversible effects observed on the DTA curves when these compounds are heated indicate only slight rearrangement of the structure [52].

Table 4. Structures and polymorphism of double molybdates of the REE (R) and alkali metals (M) $RM(MoO_4)_2$ (1).

Footnotes to Tables 4 and 5.

(1) The following symbols are used in Tables 4 and 5: T—tetragonal, P—orthorhombic, M—monoclinic, Tp.—triclinic, Г—hexagonal.
The Tables are divided into blocks, each of which corresponds to a particular double compound. The lower part of each block contains the low-temperature modification, the upper part the high-temperature modification, and the central part the intermediate phase; the temperature (°C) of the phase transformations are given on the right. The values of Δr and r_{av} are given in the lower right-hand corner of the block.
(2) The ionic radii are taken from Ref. 18.
(3) According to Ref. 27, there is no polymorphic transformation.
(4) In our opinion, polymorphism is observed here, and the authors cited obtained the quenched high-temperature forms.
(5) According to Ref. 39, there is no polymorphic transformation.
(6) According to Ref. 43, the temperature of the transformation is 690°.
(7) According to our ideas, the low-temperature phase should have monoclinic or orthorhombic symmetry.
(8) In Ref. 21, a single polymorphic transformation was observed at 700°.
(9) In Ref. 48 it is reported that the high-temperature phase is isostructural with the high-temperature modification of $NdK(WO_4)_2$.
(10) In Refs. 21 and 43 the symmetry was not determined, but it was established that the compound is isostructural with PrRb molybdate, which has orthorhombic symmetry.
(11) We assume tetragonal symmetry here.
(12) Examination of the diagram in Fig. 1 indicates that this is apparently an orthorhombic phase.
(13) According to Ref. 41 there is no polymorphic transformation.
(14) The authors' suggestion.
(15) Quenching of the specimens from temperatures close to the melting points[74] gave a mixture of a tetragonal phase (isostructural with the high-temperature phases of $RRb(MoO_4)_2$ with R = La–Gd) and an orthorhombic phase.
(16) In Ref. 43, a single polymorphic transformation was established at 730° (the measurements were made up to 800°). The low-temperature phase was found to be tetragonal, and the high-temperature phase was found to be isostructural with $PrPb(MoO_4)_2$, orthorhombic[44]. Quenching of $ErRb(MoO_4)_2$ from 650–700° into liquid nitrogen gives a monoclinic modification of the same type as the low-temperature modifications of the rubidium molybdates formed by thulium, ytterbium, and lutetium.
(17) The second polymorphic transformation at 640° in Ref. 52 was not established.
(18) If the orthorhombic structure is stable above 640° [see (12)], then the phase between 515° and 640° is also orthorhombic, since it cannot have a lower symmetry than the low-temperature phase, which has been found to be orthorhombic[41,48,52].
(19) In Refs. 21 and 43, the compound was found to have a tetragonal low-temperature modification, and a low-temperature polymorphic transformation was not detected.
(20) In Ref. 58 the temperature of the phase transformation was found to be 904°.
(21) In Ref. 28 it was suggested that the high-temperature modification has a tetragonal structure.
(22) In Ref. 8 the high-temperature phase was found to have a tetragonal structure with monoclinic distortion.
(23) According to Refs. 65 and 79, polymorphic transformations are not observed.
(24) Hydrothermal preparation[68,69] gave monoclinic crystals.
(25) According to Refs. 43 and 71, the low-temperature form of $RK(WO_4)_2$, where R = La–Nd, has a monoclinic structure. According to Ref. 8, these phases are isostructural with the high-temperature modifications of $RK(WO_4)_2$, where R = Sm–Lu. They are therefore monoclinic, since the symmetry of the high-temperature modification is never lower than that of the low-temperature phase, and the latter, for $RK(WO_4)_2$, where R = Sm–Lu, are monoclinic[15,65,79]. In the case of Lu, the high-temperature modification is apparently hexagonal (see section headed "Fusion").
(26) The low-temperature phase is isostructural with the low-temperature modification of $PrCs(WO_4)_2$.[54]
(27) This phase is isostructural with the low-temperature modification of $YK(WO_4)_2$.[15,65]
(28) In Ref. 76, the structure was found to be triclinic.
(29) The low-temperature phase is isostructural with the low-temperature modification of $YCs(WO_4)_2$.[54]
(30) In Ref. 58 it is suggested that the temperature of the phase transformation is so close to the melting point that the low-temperature monoclinic modification crystallises immediately.
(31) The low-temperature phase is isostructural with the low-temperature modification of $YCs(WO_4)_2$.[54]

It is probable that almost all other $RLi(MoO_4)_2$ and $RNa(MoO_4)_2$ have been obtained in the form of stabilised or quenched high-temperature phases.

The RK molybdates are characterised by a large number of clearly defined polymorphic transitions. The isostructural tetragonal phases $RK(MoO_4)_2$, where R = La–Nd,

prepared from solution in a melt[41] and by sintering mechanical mixtures[21], are probably high-temperature phases, since $NdK(MoO_4)_2$, prepared by the methods of ceramic technology[48], was obtained in two forms: a high-temperature monoclinic distorted scheelite form, corresponding to the tetragonal form[41], and a low-temperature monoclinic form.

$YK(MoO_4)_2$ crystals, obtained from solution in a melt, were found to be orthorhombic[41]. When heated, they underwent a polymorphic transformation[28]. The orthorhombic structure can therefore be regarded as the low-temperature form, although there is still some doubt regarding this conclusion, since the X-ray diffraction pattern for this compound, obtained by sintering mechanical mixtures, contains a large number of lines, the splitting of which indicates a low-symmetry, apparently triclinic, structure[21].

The RK molybdates from Dy to Lu [41,48] and the high-temperature (orthorhombic) modification of $TbK(MoO_4)_2$ [48] are isostructural with the double molybdate $YK(MoO_4)_2$. Crystallisation from solution in a melt[41] gave only this structure of $TbK(MoO_4)_2$, which does not exhibit polymorphism. In this case, therefore, stabilisation of the orthorhombic phase takes place under the conditions of growth. This phenomenon is of undoubted importance for the growth of single crystals.

The crystals obtained from solutions in a melt[41] for the most part undergo high-temperature polymorphic transformations (Table 3). Low-temperature transformations have been detected in the study of the equilibrium diagrams[51] of compounds obtained by sintering mechanical mixtures with subsequent fusion of the sinter and slow cooling[51,52]. The low-temperature transitions in all cases are accompanied by weak thermal effects.

Mokhosoev and coworkers[21] assumed for the potassium molybdates from Er to Lu not the orthorhombic structure, as all other authors have done (Table 4), but a hexagonal structure. At the same time, X-ray diffraction studies[78] of the orthorhombic crystals of $YK(MoO_4)_2$ have shown that their structure is close to hexagonal. From the analogy between the rubidium and caesium double molybdates, we have classified the hexagonal phases as high-temperature phases (Table 3).

Most rubidium and caesium REE molybdates show low-temperature phase transformations (Table 3), which give weak endothermic effects on the thermograms obtained by heating[31], and which do not lead to marked changes in structure.

At high temperatures, the rubidium and caesium double molybdates of the heavy REE become hexagonal (Table 4). In the three-dimensional diagram of phase transformations (Fig. 1), which we constructed from published data, the right-hand upper corner shows the range of existence of the high-temperature hexagonal phase, bounded below by the surface *1*, *2*, *3*, *4*, *5*, *6*, *7*. It can thus be seen that the high-temperature phases of the potassium molybdates of Lu and Yb (and possibly also Tm and Er) should be similar to the high-temperature phases of the caesium and rubidium double molybdates with the heavy REE, that is they should be hexagonal.

A noteworthy feature is that the temperatures of the low-temperature transformations for almost all double molybdates are approximately the same (the surface *14*, *15*, *16*, *17*, *18*, *19*, *20*, *21*, *22*, *23*, *24*, *25*, *26* in Fig. 1). In the diagram, a single overall surface has been drawn through the points corresponding to these transitions (in some regions it is "split" into two surfaces close together). In fact, these transformations have much in common: they are difficult to detect, apparently as a consequence of stabilisation of the high-temperature phase; they give weak thermal effects; and they do not lead to a change in symmetry. Their nature has not yet been established. It is quite possible that this surface has a "gap" in the region of the lithium and sodium double molybdates of the light REE, and their low-temperature transformations are even more difficult to detect.

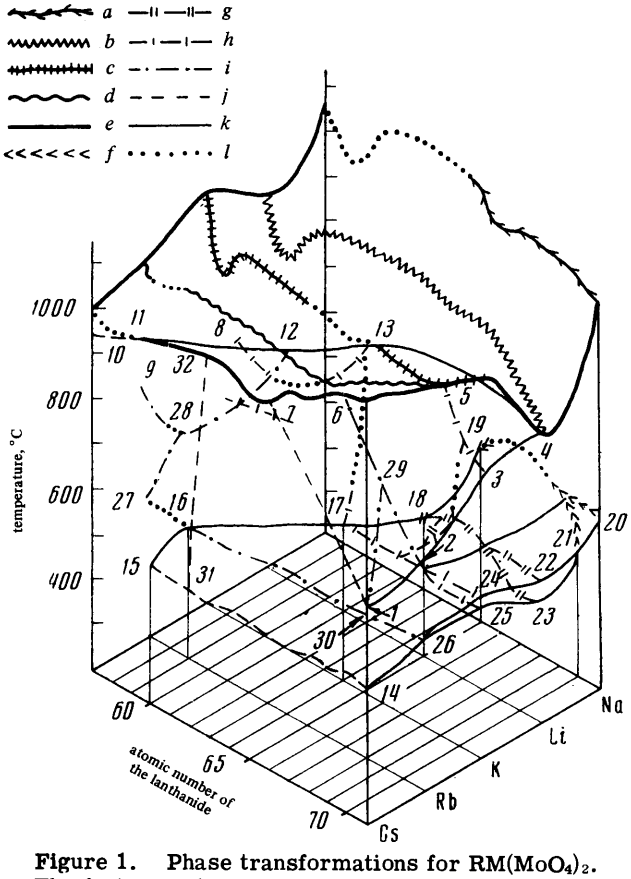

Figure 1. Phase transformations for $RM(MoO_4)_2$. The fusion surface is indicated by the lines: *a*) Na, *b*) Li, *c*) K, *d*) Rb, *e*) Cs. The surfaces of the other phase transformations are shown by the lines: *f*) Na, *g*) Li, *h*) K, *i*) Rb, *j*) Cs. *k*) Guide lines; *l*) assumed lines.

The range of existence of the phases with a tetragonal structure is occupied by all the lithium and sodium double molybdates. On going to the potassium, rubidium, and caesium compounds, this range (which is bounded below by the surface *8*, *9*, *10*, *11*, *12*, *13*) becomes narrower towards lanthanum and becomes the high-temperature region.

The dependence of the type of structure at low temperatures on $r_{R^{3+}}$ and r_{M^+} can be characterised by the extent to which these radii differ from one another ($\Delta r = |r_{M^+} - r_{R^{3+}}|$) and from the radius of the calcium ion in the scheelite structure [$r_{av} = (r_{M^+} + r_{R^{3+}})/2$]. The greater

this difference, the lower the symmetry of the low-temperature modification (Table 3).

For the potassium, rubidium, and caesium double compounds, the parameter Δr increases towards Lu, whereas r_{av} decreases, that is the two factors act in opposite directions. If the low-temperature potassium and rubidium double molybdates with the $YK(MoO_4)_2$ structure did in fact have orthorhombic symmetry, and not a lower symmetry, r_{av} would obviously have a greater influence on the structure than Δr, since on going towards Lu the symmetry increases to orthorhombic. The fairly large values of Δr, however, have a stronger influence than r_{av}: the heavy rubidium and all the caesium REE molybdates have monoclinic symmetry.

It should also be noted that with increase in the deviation from the "scheelite" radius ratio ($r_{R^{3+}} \simeq r_{M^+} \simeq r_{Ca^{2+}}$) there is an increase in the variety of structural types and in the tendency for polymorphism to be observed (Table 3). As a rule, the symmetry of the high-temperature phase is higher than that of the low-temperature phase. This suggests that with increase in temperature, equalisation of the ion dimensions takes place. Thus it has been shown [49] that the large difference in the ionic radii of Pr and Rb causes these cations to be distributed in separate layers on transformation of the high-temperature modification of $PrRb(MoO_4)_2$ into the low-temperature form.

The high-temperature phase of $LaCs(MoO_4)_2$ has not been identified, and the low-temperature phase is assumed to be tetragonal [31]. It is not excluded, however, that this tetragonal phase is in fact the high-temperature phase, and that the effect on the thermograms at 950° [31] is due merely to partial phase transformation. In this case, $LaCs(MoO_4)_2$ would not be an exception in the diagram (Fig. 1) and would complete the range of tetragonal phases in regular fashion. If this is the case, the low-temperature form of $LaCs(MoO_4)_2$ should have either a monoclinic or an orthorhombic structure, depending on whether it completes the monoclinic range, bounded below by the surface *13*, *17*, *27*, *28*, or the orthorhombic range, bounded on the left by the same surface, and on the right by the surface *29*, *30*, *31*, *32*.

The monoclinic low-temperature modifications of $RRb(MoO_4)_2$, where R = Tm–Lu, and $RCs(MoO_4)_2$, where R = Pr–Lu, have been assigned to the $PrCs(MoO_4)_2$ structural type [31,74]. The X-ray powder diagrams of the caesium molybdates from Pr to Sm can be indexed satisfactorily in the orthorhombic system. The heavier REE show appreciable splitting of some of the lines, which increases with increase in the atomic number of R.

The double tungstates $RM(WO_4)_2$ are characterised by the same regular features as were noted above for the molybdates, but reveal them much more sharply (Table 4).

In fact, the crystals of the NaREE tungstates, as a consequence of the similarity in $r_{R^{3+}}$, r_{M^+}, and $r_{Ca^{2+}}$, have the tetragonal (scheelite) structure and do not exhibit polymorphism, whereas the low-temperature modifications of the lithium double molybdates of the heavy REE have monoclinic symmetry. When heated, they undergo reversible transformations into high-temperature tetragonal phases.

In the case of the scheelite-like lithium double molybdates of the light REE, a polymorphic transformation has been established only for $NdLi(WO_4)_2$ (Table 4). At 665° it gives a weak thermal effect, which is not accompanied by a change in symmetry. Similar transformations can apparently be detected for the other light RLi tungstates.

The decrease in symmetry towards Lu can be attributed to the large contribution of the influence of change in r_{av} compared with Δr. The low-temperature phases of the other double tungstates are monoclinic.

The diagram for the phase transformations of the double tungstates (Fig. 2) is approximately the same as that for the molybdates. Instead of the horizontal surface corresponding to the low-temperature transformations, however, it has a steep sloping surface (*3*, *7*, *8*, *14*, *15*, *16*). In the region where this surface approaches the melting point surface (RK molybdates), the polymorphic transformations are accompanied by marked thermal effects [65] and mechanical stresses leading to breakdown [79]. In the low-temperature region of the surface (RCs tungstates) the transformations correspond to weak effects on the thermograms and do not lead to significant changes in structure.

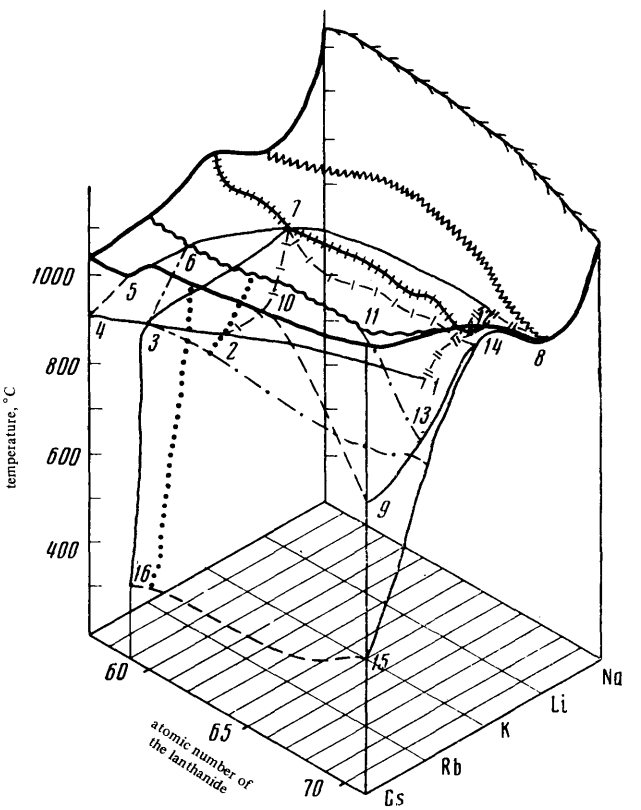

Figure 2. Phase transformations for $RM(WO_4)_2$. For symbols see Fig. 1.

This relationship between the "strength" of a transformation and its proximity to the melting point can be readily followed for other double compounds from all those papers which give DTA curves. On the other hand, it makes it possible to estimate the disruptive tendencies of the phase transformation in the selection of compounds and procedures for the growth of single crystals.

The ranges of existence of the tetragonal and hexagonal modifications are bounded below by the surfaces *1*, *2*, *3*, *4*,

5, *6*, *7*, *8*, and *9*, *10*, *11*, *12*, *13* respectively, and are bounded above by the fusion surface. The reverse order of the positions of Li and Na in Fig. 2 was chosen for the sake of clarity in the representation of the actual diagram as a whole, and also to set off the regular increase in the width of the range corresponding to the tetragonal phases from the caesium double tungstates to the sodium compounds. Although this last feature is not of importance for the double molybdates (since all the phases $RLi(MoO_4)_2$ and $RNa(MoO_4)_2$ are tetragonal), the positions of Li and Na are also represented in Fig. 1, for convenience in comparing the two diagrams. The monoclinic phases lying above and below the sloping surface *3*, *7*, *8*, *14*, *15*, *16* correspond to at least six structural types [15,54,65,74]. Thus as in the case of the molybdates, increase in Δr and r_{av} is accompanied by an increase in the variety of tungstate structures. The symmetry of the high-temperature structure is always higher than that of the low-temperature structure.

It should also be noted that the crystals of the low-temperature forms of the potassium, rubidium, and caesium double tungstates and molybdates exhibit perfect cleavage, and this creates additional difficulties in the growth of large crystals and their use in lasers. The anisotropy of the mechanical properties can be attributed to the tendency for R and M with a large value of Δr to distribute themselves in layers. This increases the degree of order in the structure, however, and hence decreases the width of the luminescence lines, as noted above for the $YK(MoO_4)_2$–Nd^{3+} system.

The existence of "smooth" surfaces on the three-dimensional diagrams giving the phase transformations of $RM(MoO_4)_2$ and $RM(WO_4)_2$, bounding the ranges of existence of related structures, means that we are dealing not with a simple set of compounds, but with systems. This feature makes it possible to represent regularities, to estimate the reliability of published data in those cases where they are contradictory, and to predict various properties which have not yet been established.

IV. FUSION

The "smooth" form of the fusion surfaces on the diagrams (Figs. 1 and 2) makes it possible in many cases to estimate melting points which have not yet been determined: $RNa(MoO_4)_2$ from Nd to Gd ~1160°; $CeNa(MoO_4)_2$ and $PrNa(MoO_4)_2$, apparently, ~1080°; $SmK(MoO_4)_2$ ~ 990°; $GdK(MoO_4)_2$ ~ 960°; $TbRb(MoO_4)_2$ ~ 980°; $TbCs(MoO_4)_2$ ~ 1010°; $CeNa(WO_4)_2$ ~ 1270°; $CeLi(WO_4)_2$ ~ 1060°; and $CeRb(WO_4)_2$ and $CeCs(WO_4)_2$ ~ 1040°.

The melting points of the double tungstates are always higher than those of the corresponding molybdates, so that the high melting points found by Heindl and coworkers [8] for the sodium molybdates of La, Pr, and Nd (Table 5) contradict the values found by other workers [38,58,80].

Data on the fusion of double molybdates and tungstates are contradictory (Tables 6 and 7). It has been suggested [60,61,74] that there exists a boundary of congruent fusion, separating the congruently melting double molybdates and tungstates of the light REE from the incongruently melting double compounds of the heavy REE. For molybdates containing sodium, potassium, and rubidium, this boundary passes through gadolinium or terbium and is then displaced towards the end of the REE series in the case of caesium. For the tungstates it passes through $ErNa(WO_4)_2$, $LaK(WO_4)_2$, $HoRb(WO_4)_2$, and $DyCs(WO_4)_2$. According to other sources [41,65], however, all the compounds $RK(EO_4)_2$ (obtained from solution in a melt) melt congruently.

The suggestion that there is a relationship between the position of the boundary of congruent fusion and the fairly sharp decrease in melting point on going into the range of incongruent fusion, put forward for the rubidium and caesium double tungstates [61], is apparently justified in individual cases. The fusion surface for the double molybdates (Fig. 1) in fact shows a curvature due to a decrease in the melting points along the REE series, beginning at Tb for the rubidium and caesium compounds, at Gd for the potassium compounds, and at Dy for the lithium and sodium compounds, corresponding approximately to the boundary of incongruent fusion (Table 6). The fusion surface of the double tungstates also shows corresponding curvatures in the region of $HoCs(WO_4)_2$, $ErRb(WO_4)_2$, $HoK(WO_4)_2$, $HoLi(WO_4)_2$, and $ErNa(WO_4)_2$. These compounds apparently also form the boundary of incongruent fusion for the tungstates.

Table 6. Temperatures and nature of the fusion of the double molybdates of the REE (R) and alkali metals (M) $RM(MoO_4)_2$*.

*In Tables 6 and 7, the minus sign denotes congruent fusion, the plus sign denotes incongruent fusion, and the absence of a sign denotes that the nature of the fusion has not been established.

The very sharp decrease in the melting points of the double molybdates formed by cerium with lithium and potassium apparently cannot be related to the nature of the fusion until more information is obtained. The increase in the melting points of the hexagonal high-temperature phases for both the double tungstates and the double molybdates of the heavy REE (Figs. 1 and 2) is evidently not accidental.

The high-temperature modification of $LuK(MoO_4)_2$ should be hexagonal.

In the other cases, the relationship between the melting points and the structures of the high-temperature phases is not so clear.

---o0o---

Almost all compounds of the type $RM(EO_4)_2$, where R = the REE and Y, M = an alkali metal, and E = Mo or W, have been prepared, but only a few of them have been obtained in the form of large crystals.

Single crystals of double tungstates and molybdates containing REE exhibit valuable laser properties. Their luminescence characteristics depend on the ratio of the dimensions of the R^{3+} and M^+ ions and on the structure. The low-temperature structure of $RM(EO_4)_2$ is determined chiefly by the quantities $\Delta r = |r_{M^+} - r_{R^{3+}}|$ and $r_{av} = (r_{M^+} + r_{R^{3+}})/2$, which characterise the extent of the departure from the scheelite radius ratio of the ions $r_{M^+} \simeq r_{R^{3+}} \simeq r_{Ca^{2+}}$. With increase in Δr and r_{av}, the symmetry of the low-temperature modification decreases, the number of structural types increases, the tendency to exhibit polymorphism becomes greater, and the R and M atoms tend to distribute themselves in individual layers, leading to the production of perfect cleavage in the crystals. At the same time, increase in these two parameters leads to a decrease in the disorder of the low-temperature structure and a corresponding decrease in the width of the luminescence line.

Δr and r_{av} change in opposite directions along the REE series, so that in some cases the symmetry of the low-temperature phase increases towards lutetium.

The symmetry of the high-temperature modification is never lower than that of the low-temperature phase.

The formation of a given modification depends on the method of preparation and the subsequent thermal treatment. This constitutes the chief difficulty in the deduction of the above regular features from an analysis of published material.

The construction of phase transformation diagrams on the basis of published data has made it possible to compile a fairly complete picture of the polymorphism and fusion of the rare earth metal double tungstates and molybdates, to reveal the regions with identical symmetries, and in some cases to estimate the structures, melting points, and polymorphic transitions where these have not yet been established.

A relationship evidently exists between the nature of the fusion and the form of the fusion surface; the boundary of incongruent fusion passes in "steps" over this surface.

I. INTRODUCTION

Since the discovery of Raman scattering (RS), many investigators based their explanation of the characteristics of the spectra of solids, liquids, and gases on Placzek's work. Despite the fact that the first studies on Raman scattering were carried out by physicists, during the period from 1935 until the introduction of the laser, this type of spectroscopy has been used extensively by chemists as a means of establishing molecular structures. The vibrational and rotational Raman spectra have been almost always excited by a low-pressure mercury lamp which precluded a direct comparison of specific experimental data with theory. For example, it was difficult to obtain information about the individual elements of the scattering tensor, since the direction of propagation of the exciting radiation was not exactly parallel or perpendicular to the direction of the observation of the scattered radiation. The measured degrees of depolarisation of the Raman lines of liquids and gases almost always differed from the theoretical values, so that the calculation of the degrees of depolarisation of vibrations of a particular type or the *a priori* calculation of absolute intensities constituted a cumbersome procedure.

Most of the experimental studies during the above period dealt with the excitation of Raman transitions in the vibrational or rotational molecular levels. All these levels are linked to the electronic ground state of the molecule. Electronic Raman scattering was observed only for the NO molecule[1]. In 1932 Rasetti attributed the 121 cm^{-1} Raman line for this molecule to the $^2\Pi_{1/2}-{}^2\Pi_{3/2}$ transition. According to Gerding's evidence, Gorter undertook experiments with lanthanide ions during the second world war and it was not until 1964 that Hougen and Singh[3] succeeded in exciting Raman scattering in the electronic transitions of Pr^{3+} in $PrCl_3$. Immediately before the publication of this paper, Elliott and Loudon[4] predicted the possibility of observing electronic Raman scattering by lanthanide ions. In addition, Chau observed Raman scattering for Ce^{3+} in $CaWO_4$.[5] In all the experiments the mercury lamp still served as the light source and photographic plates were used to record the spectra. Very little information was obtained about the intensity of this effect relative to the intensities of strong Raman lines for certain well known liquids.

† This is an English translation of the review published by the author in Russian (Ed. of Translation).

Placzek pointed out that the scattering tensor for electronic transitions differs from the scattering tensor for vibrational and rotational transitions[6,9]. In the latter case the tensor is symmetric, whereas the tensor for electronic transitions may become antisymmetric.

Numerous crystalline compounds containing lanthanide ions are now available and, when it is necessary to separate the phonon Raman spectrum from electronic effects, the elements of the scattering tensor must be investigated.

In 1966 the author of the present review began a programme devoted to the excitation of electronic Raman scattering of lanthanide ions in certain crystals using the radiation from a helium–neon laser at 6328 Å. By that time it became clear that the individual elements of the Raman scattering tensor for vibrational transitions can be measured and there was hope that measurements of this type might be carried out also for electronic transitions. The helium–neon laser was chosen because, as can be seen from the energy level diagram for lanthanide ions, only a few of them have excited states with energies equal to those of the laser emission (Fig. 1). By employing a more sensitive recording system, the author succeeded in 1966 in exciting the Raman spectra of tervalent lanthanide ions in the lattice of the yttrium–gallium garnet[6,7]; this was followed by a series of experiments on the same ions in other crystals[8–12].

In Placzek's theory of polarisability for vibrational Raman scattering, attention was concentrated on the polarisability of the molecular ground state and the role of the intermediate states was to a considerable degree limited. The matrix elements of the electrical dipole moment operator for transitions between the ground and intermediate states appear in the expressions for the elements of the scattering tensor. In the general case, our knowledge of the wave functions for these states is insufficient to calculate the matrix elements and hence we have also to calculate the elements of the scattering tensor for vibrational transitions. The situation is almost completely different for tervalent lanthanide ions. The wave functions for the states of the lanthanide ions—free or in an environment of specified symmetry—have been calculated and Axe[13] used these wave functions in the calculation of the absolute Raman intensities in the electronic transitions of certain lanthanide ions. In these calculations the effect of the antisymmetry of the scattering tensor was neglected.

However, Mortensen and the present author[14] showed that a large contribution by antisymmetric tensors to the total intensities may be expected from many ions. Indeed,

in certain cases the contribution from antisymmetric tensors is greater than that from symmetrical tensors and at least one case has been found where the Raman transitions are due to a completely antisymmetric tensor[9]. Apart from the absolute intensities, the ratio of the intensity of Rayleigh scattering to the intensity of electronic Raman scattering of all the lanthanides has also been calculated[15] and in subsequent reports a relation was established between the force and symmetry of the crystal field on the one hand and the polarisation characteristics of the complete electronic Raman spectra on the other[16,17].

Following the appearance of the argon and krypton ionic lasers towards the end of 1970, more detailed experimental data were obtained[18] and electronic Raman scattering was observed for all lanthanide ions with two exceptions[19,20]. The experimental results confirmed the theoretical prediction that the intensity of the electronic Raman lines is lower than the intensity of scattering by the crystal matrix phonons. It was also noted that the intensities depend greatly on the electronic configuration of the ions. However, the contribution of antisymmetric tensors to the intensity is less marked, with the exception of the Eu^{3+} ion, where the scattering is entirely due to the antisymmetric tensor[21]. The appearance of this tensor is unique in physics and chemistry and in Raman spectroscopy is a result of profound changes in selection rules.

A glance at the energy level diagrams (Fig. 1) shows that many levels have been designated by the quantum number J which is a multiple of 1/2. This implies that representations of binary groups must be used for the investigation of the symmetry of the levels in the crystal field and of the scattering tensor components. The main result is that the tensors for electronic and vibrational transitions are completely different in all the crystals[22].

We shall conclude the introduction with general remarks concerning the selection rules for Raman scattering[23]. All the states arising from the same electronic configuration have the same parity—they are either even or odd. The scattering operator $\hat{\alpha}_{\rho\sigma}$ (where ρ and $\sigma = x, y, z$) is an even operator and the integral $\int \Psi_n \hat{\alpha}_{\rho\sigma} \Psi_m d\tau \neq 0$, where Ψ_n and Ψ_m are the wave functions of these states. Thus, like vibrational and rotational scattering, electronic scattering is formally allowed.

II. VIBRATIONAL AND ELECTRONIC RAMAN SCATTERING[14,15]

We shall suppose that a photon flux is incident on atoms, molecules, or a crystal. Most of these photons will not interact with the species but some of them (less than 1%) will be involved in an elastic interaction. The frequency of the electromagnetic radiation then remains unchanged and the elastic interaction leads to the so-called Rayleigh scattering. However, a much smaller number of protons are scattered inelastically. An atom, ion, or molecule may be excited from the ground to the first or second excited state and, when this has happened, the law of conservation of energy shows directly that the scattered photons have an energy and consequently a frequency differing somewhat from that of the incident photons. It is of course also possible that a species can return from the excited to the ground state, whereupon the [liberated] energy is added to the energy of the incident photons, which leads to a decrease of the wavelength of the scattered radiation. Thus the Raman spectrum appears in the form of emission lines corresponding to greater and smaller energies than the undisplaced Rayleigh scattering lines. Since in the excited states there are fewer species than in the ground state, the intensity of the so called anti-Stokes Raman lines is lower than of the Stokes Raman lines. The intensity ratio of these lines is specified by the Boltzmann distribution law. However, in order to obtain a clear description of the Raman intensity, it is necessary to examine this process in greater detail.

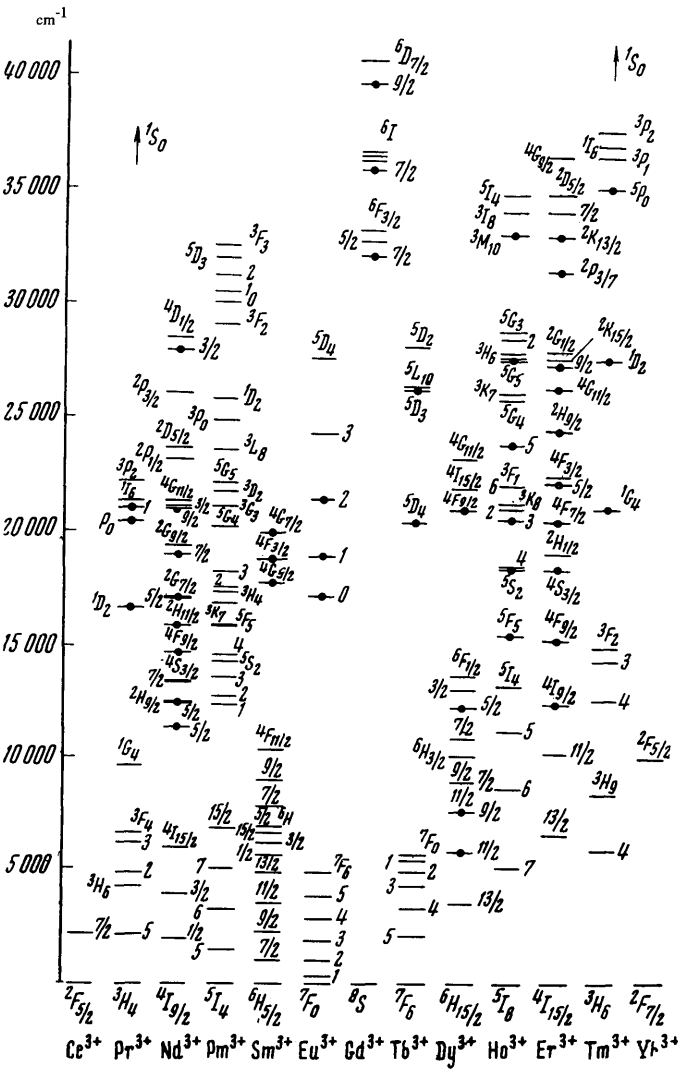

Figure 1. Energy level diagrams for tervalent lanthanide ions. The emission energy of the He—Ne and Ar^+ lasers is between 15 000 and 22 000 cm^{-1}. Certain lanthanide ions absorb this radiation with a consequent appearance of fluorescence, which precludes the observation of electronic Raman scattering.

Fig. 2 represents the case where the incident radiation is propagated along one of the axes of the rectangular coordinate system and the scattered radiation is observed in

the direction perpendicular to that of the propagation of the incident light rays. We shall suppose that at the origin of the rectangular coordinate system there is a single crystal with cubic symmetry and that its macroscopic axes coincide with the x, y, and z axes of the coordinate system. The electric field of the incident wave may induce a dipole moment in the atom or molecule of the crystal. In the general case, the direction of this induced moment will not be parallel to the electric vector of the incident wave. Raman scattering may be described by the tensor

$$\mu^i = (\alpha)\, E,$$

where

$$\begin{aligned} \mu_x^i &= \alpha_{xx}E_x + \alpha_{xy}E_y + \alpha_{xz}E_z, \\ \mu_y^i &= \alpha_{yx}E_x + \alpha_{yy}E_y + \alpha_{yz}E_z, \\ \mu_z^i &= \alpha_{zx}E_x + \alpha_{zy}E_y + \alpha_{zz}E_z. \end{aligned} \qquad (1)$$

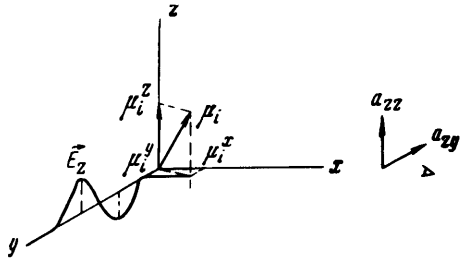

Figure 2. Raman scattering in a cubic crystal the a, b, and c axes of which are parallel to the axes of the cartesian coordinate system. The laser radiation enters the crystal in the direction of the y axis and the scattered Raman radiation is observed along the x axis. The induced dipole moment μ_i and its components μ_i^z, μ_i^y, and μ_i^x are shown. By placing an analyser in front of the monochromator, it is possible to resolve the α_{zz} and α_{zy} components. They appear in the $y(zz)x$ and $y(zy)x$ polarisation Raman spectra.

In each specific case different components of the scattering tensor can be determined by a suitable choice of direction of the polarisation of the incident radiation, the crystal orientation, and the direction of observation of the scattered radiation. Hitherto, we have not discussed the types of Raman scattering. Raman spectroscopy has proved to be a very successful method for the determination of molecular structures in the gas phase, in liquids, and crystals using rotational or vibrational spectra.

The induced moment for vibrational Raman scattering is the transition moment between the ground and excited vibrational states. In order to relate the intensity of the Raman line to the elements of the scattering tensor, the polarisability of the molecule in the ground state $(\alpha_{\rho\sigma})$ is formulated in the form of an expansion in terms of the coordinates of the normal vibrations of the molecule. The intensity of the Raman lines is related to the derivatives of the polarisability[24] of the molecule in the ground state with respect to the normal coordinates (Q). Recently another model was proposed[25] for vibrational Raman scattering. The following expression, obtained for the components of the scattering tensor $(\alpha_{\rho\sigma})_{kn}$ (where ρ and $\sigma = x, y, z$), was used for the transition between the states k and n of the system:

$$(\alpha_{\rho\sigma})_{kn} = h^{-1}\sum_r \frac{\langle n|e\sigma|r\rangle\langle r|e\rho|k\rangle}{\nu_0 - \nu_{kn}} + \frac{[\rho \leftrightarrow \sigma]}{\nu_0 + \nu_{kn}}. \qquad (2)$$

The subscripts k and n in Eqn. (2) show that Raman scattering begins from the state k and terminates at the state n, ν_0 is the frequency of the incident light, $\langle n|e\sigma|r\rangle$ is a matrix element of the electric dipole moment, and the summation with respect to r is carried out over all the excited states of the system. The electric dipole moment can be formulated as follows:

$$\int \Psi_n^* e\sigma \Psi_r d\tau.$$

In the general case, the wave function Ψ_n is defined as the product of the electronic wave function $\Psi_n(\mathbf{r}Q)$ and the vibrational wave function $\varphi_v(Q)$, where n is the electronic quantum number, v the vibrational quantum number, and Q the normal coordinate. The electronic motions may be sensitive to the motions of the nuclei in the molecule. Assuming that this interaction is weak, the following form may be used for the Hamiltonian $\mathcal{H}$:

$$\mathcal{H} = \mathcal{H}_0 + \left(\frac{\partial \mathcal{H}}{\partial Q}\right)_{Q=0} Q + \ldots$$

and the wave function

$$\begin{aligned} \Psi_n(\mathbf{r}, Q) &= \Psi_n^0(\mathbf{r}, Q=0) + \\ &+ \sum_{l\neq n} \frac{\int \Psi_l^0(\mathbf{r}, Q=0)\left(\frac{\partial \mathcal{H}}{\partial Q}\right)_{Q=0} \Psi_n^0(\mathbf{r}, Q=0)\, Q d\tau}{E_l^0 - E_n^0} \Psi_l^0(\mathbf{r}, Q=0), \end{aligned} \qquad (3)$$

where $\mathcal{H}_0$ is the Hamiltonian of the vibrating molecule in the equilibrium configuration and E_l^0 is the energy of the first excited electronic state of the molecule.

The electronic wave functions in the form of a series [Eqn. (3)] can now be substituted in the expression for the matrix elements of the electric dipole moment, which enters into the component of the scattering tensor in Eqn. (1). Fortunately, it is possible to make certain simplifications and to obtain the following relations.

I. Electronic Raman scattering $(n;\ v = 0 \rightarrow k;\ v = 0)$:

$$(\alpha_{\rho\sigma})_{nv=0;kv=0} = h^{-1}\sum_r \left\{ \frac{(M_\rho)_{nr}(M_\sigma)_{rk}}{\nu_{rk} - \nu_0} + \frac{[\rho \rightarrow \sigma]}{\nu_{rn} + \nu_0} \right\}. \qquad (4a)$$

II. Vibronic Raman scattering $(n;\ v \rightarrow k;\ v')$:

$$(\alpha_{\rho\sigma})_{nv;kv'} = h^{-1}\langle \varphi_{v'}|Q|\varphi_v\rangle \sum_r \left\{ \frac{(M_\rho)_{kr}[(M_\sigma)_{rl}h_{ln}^Q + (M_\rho)_{ln}h_{lr}^{Q*}]}{\nu_{rk} - \nu_0} + \ldots \right\}. \qquad (4b)$$

The constant h_{ln}^Q is defined by the integral

$$\int \Psi_l^0(\mathbf{r}, Q=0)\,(\partial\mathcal{H}/\partial Q)_{Q=0}\Psi_n^0(\mathbf{r}, Q=0)\, d\tau/(E_l^0 - E_n^0).$$

If the vibronic interaction is weak, it follows automatically that the constants h_{ln}^Q are small. As a result, we find that the main contribution to the intensity of electronic Raman scattering levels comes from the elements of the scattering tensor $(\alpha_{\rho\sigma})_n$; $v = 0 \rightarrow k$; $v = 0$. Vibronic Raman scattering is probably insignificant compared with the more intense electronic Raman scattering in the transition between the states k and n.

It is interesting to replace the quantum number n by k in Eqns. (4a) and (4b). The first of these equations becomes identical with the expression for Rayleigh light

scattering. The replacement of n by k in Eqn. (4b) leads to the relation

$$(\alpha_{\rho\sigma})_{nv;nv'} = \hbar^{-1}\langle\varphi_{v'}|Q|\varphi_v\rangle \sum_r \left\{\frac{(M_\rho)_{nr}[(M_\sigma)_{rl}h^Q_{ln} + (M_\rho)_{ln}h^{*Q}_{lr}]}{\nu_{rn}-\nu_0} + \ldots\right\}, \quad (5)$$

which gives the elements of the Raman scattering tensor for the transition between the vibrational levels v and v' linked to the same ground electronic state n. Thus vibrational Raman scattering has now been described in terms of a model where interaction with vibrations has been introduced. This model, incorporating vibronic interactions, was proposed, as already stated, by Albrecht[25], who also showed that the selection rules for Raman scattering may be obtained by examining the conditions under which the constants h^Q_{nl} and h^Q_{lk} are not zero.

Eqns. (4a) and (5) may be used directly to investigate the symmetry of the scattering tensor. The tensor is symmetric if the element $(\alpha_{\rho\sigma})_{nk}$ is equal to the element $(\alpha_{\sigma\rho})_{nk}$. For vibrational Raman scattering levels, the tensor is symmetric, but for electronic Raman scattering it is found that this condition is not obligatory. One should probably note here that the antisymmetry of the scattering tensor at vibrational levels can also obtain if (a) the wave function entering into the matrix elements of the electric dipole moment operator are not real or (b) the electronic ground state of the molecule is degenerate. The vibrational model loses validity for a degenerate ground state and the considerations employed to obtain expressions for a non-degenerate ground state are inapplicable in this instance.

The transition between the states k and n is allowed in Raman scattering if the matrix element $\langle k|\hat{\alpha}_{\rho\sigma}|n\rangle \neq 0$. The operator $\hat{\alpha}_{\rho\sigma}$ can be formulated as follows:

$$(\hat{\alpha}_{\rho\sigma})_{kn} = \sum_r \frac{|e\sigma|r\rangle\langle r|e\rho|}{\nu_0 - \nu_{kn}} + \frac{[\rho\rightarrow\sigma]}{\nu_0 + \nu_{kn}}. \quad (6)$$

In order to find the conditions under which the matrix element does not become zero, it is necessary to know the transformation properties of the wave functions of the states k and n and the symmetry properties of the scattering tensor itself. The matrix element does not become zero if the direct product of the irreducible representations of the wave functions of k and n and the tensor contains a fully symmetric representation of the point groups. The symmetry properties of the electronic levels may be obtained, for example, from crystal field calculations. The transformation properties of the elements of the scattering tensor are sometimes quoted in the tables of characters of various point groups. However, these data refer only to the special case of vibrational or rotational Raman scattering and above it was shown that in this case the tensor is symmetric. Thus the question arises of what changes occur in the transformation properties when the tensor becomes antisymmetric.

III. THE RAMAN SCATTERING TENSOR

The transformation properties of the antisymmetric part of the scattering tensor are specified by the symmetry of the $\alpha_{\rho\sigma} - \alpha_{\sigma\rho}$ (σ, $\rho = x, y, z$) combinations. The transformation properties of these combinations are not quoted directly in the tables of characters of various point groups. It can be shown that the antisymmetric combinations for all rotations transform as an ordinary vector, and in inversion the transformation is more as an axial vector than a polar vector. This is also valid for the transformation properties of the rotations about the axes of the cartesian coordinate system (R_Z, R_Y, and R_X), so that the transformation properties of the transformation of the antisymmetric part of the scattering tensor and of the rotations about R_Z, R_Y, and R_X are analogous. They can be found directly from the character tables, for example those quoted by Wilson et al.[26]

Ions in crystals occupy positions with specific symmetry. Thus the components of the tensor and the wave functions of the electronic levels may be designated in accordance with the representation of the known point groups. However, the angular components of the electronic wave functions are formulated in terms of the polar coordinates r, θ, and φ, while the symmetry of the tensor was considered above in terms of cartesian coordinates.

The intensity of Raman scattering in an electronic transition is proportional to the square of the matrix element $\langle n|\hat{\alpha}_{\rho\sigma}|m\rangle$, but the n and m wave functions of the operator $\hat{\alpha}_{\rho\sigma}$ have still not been defined in terms of the same coordinate system.

The tensor $(\alpha_{\rho\sigma})$ can be transformed into one in terms of spherical coordinates. These new tensors are irreducible and their components are designated by α^K_Q. The difference between the cartesian and irreducible tensors is that the components of the latter can be combined into three separate sets. In an arbitrary rotation, the members of each set are transformed into one another (or into their combinations), which does not happen for the components of the tensor in terms of cartesian coordinates. The relation between $\alpha_{\rho\sigma}$ and α^K_Q is indicated in Table 1.

Table 1. Relation between the components of the tensor in the cartesian coordinate system and the components of irreducible tensors.

$\alpha^0_0 = -(1/\sqrt{3})(\alpha_{xx}+\alpha_{yy}+\alpha_{zz})$,	$\alpha^2_2 = \frac{1}{2}(\alpha_{xx}-\alpha_{yy}+i\alpha_{xy}+i\alpha_{yx})$,
$\alpha^1_1 = \frac{1}{2}(-\alpha_{xz}+\alpha_{zx}-i\alpha_{yz}+i\alpha_{zy})$,	$\alpha^2_1 = -\frac{1}{1}(\alpha_{xz}+\alpha_{zx}+i\alpha_{yz}+i\alpha_{zy})$,
$\alpha^1_0 = (1/\sqrt{2})(i\alpha_{xy}-i\alpha_{yz})$,	$\alpha^2_0 = (1/\sqrt{6})(2\alpha_{zz}-\alpha_{xx}-\alpha_{yy})$,
$\alpha^1_{-1} = -\frac{1}{2}(\alpha_{xz}-\alpha_{zx}-i\alpha_{yz}+i\alpha_{zy})$,	$\alpha^2_{-1} = \frac{1}{2}(\alpha_{xz}+\alpha_{zx}-i\alpha_{yz}-i\alpha_{zy})$,
	$\alpha^2_{-2} = \frac{1}{2}(\alpha_{xx}-\alpha_{yy}-i\alpha_{xy}-i\alpha_{yx})$.

It is useful to compare the three sets of irreducible tensor components and the s, p, and d orbitals defined in terms of polar coordinates. Like the s orbitals, the irreducible tensor component α^0_0 is completely invariant for all rotations, while the $\alpha^1_{1,0,-1}$ components are mainly transformed like the p orbitals: p_X, p_Y, and p_Z. However, there is a small difference: the orbitals change sign following the inversion of the coordinate system, while the tensor components are invariant in this operation. There is also an analogy between the transformation properties of the d orbitals and the five α^2_Q components ($Q = 2, 1, 0, -1, -2$).

Suppose, for example, that an electronic Raman transition has been induced between the states ^1S and ^3P with the electronic configuration $(p)^2$. We assume that an atom or ion is located in the crystal in a position where

the symmetry is very high, for example O_h. A necessary condition for the Raman scattering in the electronic transition to be allowed is that the fully symmetric representation of the point group is contained in the direct product of the representations:

$$\Gamma_i \times \Gamma_{\alpha_Q^K} \times \Gamma_i .$$

The state (i), which is the lowest in Raman scattering, transforms as the fully symmetric representation of the point group and it is therefore seen that the non-zero components of the scattering tensor transform as the representation to which the finite state p belongs. This finite state is a spectroscopic P state ($l = 1$) and the non-zero components of the scattering tensor α_Q^K are those which transform as the p orbitals. The α_Q^1 components constitute the antisymmetric part of the scattering tensor (see Table 1); Raman scattering in the transition between these states is related to the scattering tensor, which is partly asymmetric. The components of the irreducible tensors may be used not only to establish the selection rules but also they are important for the calculation of the absolute Raman intensities.

In translational Raman scattering, such calculation is very difficult, since in the expression for the tensor element [Eqn. (1)] it is necessary to carry out a summation over all the states r of the system. For electronic Raman scattering, these states are purely electronic and not vibrational, which simplifies the calculations. If the average frequency $\tilde{\nu}_{\chi k}$ is determined by the centre of gravity of the energy $h\tilde{\nu}_{\chi k}$ of one specific excited configuration, the denominator in Eqn. (1) becomes

$$(\nu_{kr} - \nu_0)^{-1} = (\tilde{\nu}_{\chi k} - \nu_0)^{-1}(1 + x + x^2 + \ldots), \qquad (7)$$

where

$$x = (\tilde{\nu}_{\chi k} - \nu_{rk})/(\tilde{\nu}_{\chi k} - \nu_0).$$

The $4f-5d$ transition in Ce^{3+} has a frequency of about 50 000 cm^{-1}. If the Raman spectra are excited by light with a frequency $\nu_0 = 20\,000\ cm^{-1}$, then $x > 1$, since all the states r have almost the same energy. Moreover, the frequency dependence of the summation is now found from the terms ν_{rk}, where r are the states of an individual electronic configuration.

We now have

$$\langle r|[\mathcal{H}\sigma]|k\rangle = \langle \mathcal{H}r|\sigma|k\rangle - \langle r|\sigma\mathcal{H}|k\rangle = (\nu_{rk}/h)\langle r|\sigma|k\rangle \quad , \qquad (8)$$

where $\mathcal{H}$ is the Hamiltonian of the system and σ is the electric dipole moment of the operator. Combination of Eqns. (7) and (8) with Eqn. (4a) yields

$$(\alpha_{\rho\sigma})_{kn} \approx \sum_r \frac{1}{h}\frac{\tilde{\nu}_{\chi k}\langle n|\rho|r\rangle\langle r|[\mathcal{H}\sigma]|k\rangle}{\tilde{\nu}_{\chi k} - \nu_0} + \frac{\tilde{\nu}_{\chi n}\langle n|[\mathcal{H}\sigma]|r\rangle\langle r|\rho|k\rangle}{\tilde{\nu}_{\chi n} + \nu_0} . \qquad (9)$$

If the Raman intensity is now specified by the integral $\langle k|\hat{\alpha}_{\rho\sigma}|n\rangle$ then the operator $\hat{\alpha}_{\rho\sigma}$ becomes

$$\hat{\alpha}_{\rho\sigma} \simeq \sum_r \frac{\tilde{\nu}_{\chi k}\{|\rho|r\rangle\langle r|[\mathcal{H}\sigma]|\}}{\tilde{\nu}_{\chi k} - \nu_0} + \frac{\nu_{\chi n}\{|[\mathcal{H}\sigma]r\rangle\langle r|\rho|\}}{\tilde{\nu}_{\chi n} + \nu_0} . \qquad (10)$$

The wave functions $|r\rangle$ and $|n\rangle$ of tervalent ions are in the general case characterised by the quantum numbers $nLSJJ_Z$. Under the influence of the crystal field, the LSJ sets split into $2J + 1$ components, as a result of which the states of the crystal field are no longer pure J_Z substates but represent a mixture of J_Z substates resembling that formulated below:

$$|\Psi\rangle = a_{nLSJJ_z}|J, J_z\rangle + a_{nLSJJ'_z}|J, J'_z\rangle + \ldots + a_{nLSJ-J_z}|J, -J_z\rangle \qquad (11)$$
$$\rangle \sum_{J_z} a^2_{nLSJJ_z} = 1.$$

If the coefficients a are introduced into Eqns. (9) or (10), then the single summation with respect to the states r assumes the following form:

$$\sum_{nLSJJ_z}\sum_{nLSJJ'_z}\sum_{n''L''S''J''J''_z} a(nLSJJ_z)\, a(nLSJJ'_z)\, a(n''L''S''J''J''_z) , \qquad (12)$$

where all the wave functions have been normalised. Consequently, similarly to Eqn. (11), we have

$$\sum_{J_z \in \chi} a^2(n''L''S''J''J''_z) = 1. \qquad (13)$$

We can now introduce the components of the irreducible tensors and employ Judd's sums rule, since two operators $\hat{\rho}$ and $[\mathcal{H}\sigma]$ appear in the operator $\hat{\alpha}_{\rho\sigma}$ [Eqn. (10)]. We obtain the following final expression for the element α_Q^K:

$$\hat{\alpha}'^K_{knp} = \sum_{\nu SLJM}\sum_{\nu' SL'J'M'} a^*(n;\gamma'SL'J'M')\, a(k;\gamma SLM)\langle\gamma'SL'J'M'|U^K_Q|\gamma SLJM\rangle + \\ + \sum_\chi\left[\sum_{i=0}^{p}\binom{p}{i}\left(-\frac{1}{h}\right)^i\left\{\frac{(\tilde{\nu}_{\chi k})^{p-i}}{(\tilde{\nu}_{\chi k} - \nu)^{p+1}}(nl\|r\|n'l')(n'l'\|[\mathcal{H}^i r]\|nl)\times\right.\right. \\ \left.\left.\times(-1)^i\frac{(\tilde{\nu}_{\chi n})^{p-i}}{(\tilde{\nu}_{\chi n} + \nu)^{p+1}}(-1)^K(nl\|[\mathcal{H}^i r]\|n'l')(n'l'\|r\|nl)\right\}\right]\times \\ \times(2K+1)^{1/2}\begin{Bmatrix} 1 & K & 1 \\ l & l' & l\end{Bmatrix}(-1)^K \qquad (14)$$

and for the matrix element

$$\langle\gamma'SL'J'M'|U^K_Q|\gamma SLJM\rangle = (-1)^{J'-M'}\begin{pmatrix} J' & K & J \\ -M' & Q & M\end{pmatrix}\times \\ \times\langle\gamma'SL'J'\|U^K\|\gamma SLJ\rangle \quad . \qquad (15)$$

Raman scattering has now been formulated for transitions between the crystal field states $|SLJJ_Z\rangle$ and $|SL'J'J'_Z\rangle$; here

$$(nl|r|n'l') = \int R_{nl}(r)\, R_{n'l'}\, d\tau \quad .$$

$|n'l'\rangle$ are wave functions for the excited configuration. The values of the matrix elements $\langle n'SL'\|U^K\|nSL\rangle$ have been published by Nielson and Koster[27].

One can gain a better understanding of the essential feature of the selection rules for Raman scattering from the knowledge of the conditions under which the j-symbol is non-zero:

$$\begin{pmatrix} J' & K & J \\ -J'_z & Q & J_z\end{pmatrix} \quad . \qquad (16)$$

The $3j$-symbol is automatically zero if $-J'_Z + Q + J_Z$ and $J' + K + J$ do not simultaneously satisfy the usual triangle conditions (for $J = 0$, this implies that $J' = K$). The selection rules with respect to J are $\Delta J \leq 2$ and also $\Delta S = 0$ and $\Delta L \leq 2$. Thus the additional conditions in the calculation of the scattering tensor are as follows: (a) expansion (7) must be valid and (b) all the states involved in Raman scattering must be those of the crystal field and not the ligand field.

IV. INTENSITY OF RAMAN SCATTERING AND THE CRYSTAL FIELD

Having an expression for α_Q^K, it is possible to calculate the ratios $\alpha_0^0/(\alpha_Q^1 + \alpha_Q^2)$ and α_Q^1/α_Q^2. The first represents the ratio of the intensities of Rayleigh and Raman scattering and the second the ratio of the antisymmetric and symmetrical parts of the Raman scattering tensor. Fig. 3 presents the Rayleigh and Raman intensity ratios for all the lanthanides where there is a transition between

the lowest and subsequent manifold LSJ states of the free ions. These manifold states for Ce, Pr, Nd, Sm, Eu, Tb, and Dy have an energy greater by 2500 cm^{-1} than that of the ground state, while for Tm and Yb the energy is greater by 10000 cm^{-1}. In the general case, the ratio is between 10^2 and 10^3, i.e. approximately the same as for Raman scattering in vibrational transitions.

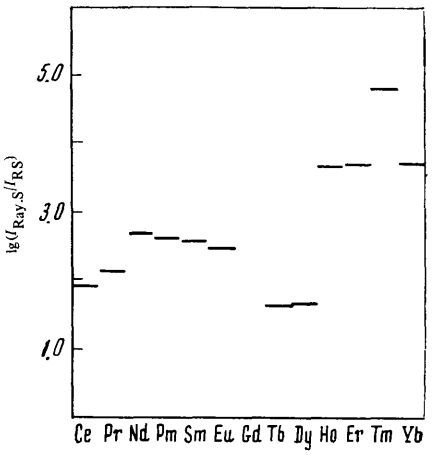

Figure 3. The ratio of the Rayleigh and electronic Raman scattering intensities of tervalent lanthanide ions. The Raman scattering takes place between the set of levels of the ground state and the first higher set of levels. For Yb^{3+}, the difference between the energies of these levels is about 10000 cm^{-1}, which accounts for the higher Rayleigh and Raman intensity ratio, since the intensity of the Raman lines (Stokes lines) is proportional to $(\nu_0 - \nu_{kn})^4$.

Table 2 lists the scattering cross-sections for certain electronic effects. The absolute value of 10^{-32} cm^2 for electronic scattering may be compared with 10^{-28} cm^2 [the experimental value for the $\nu_1(C_6H_6)$ line at 992 cm^{-1}] for vibrational Raman scattering[28]. Thus the intensity of the electronic transitions is lower than that of the majority of the vibrational Raman bands. The fact that one cannot neglect the antisymmetry of the scattering tensor becomes evident when the theoretical results in Fig. 4 are compared. The degree of antisymmetry diminishes if the transition is between states with different values of J; however, lanthanide ions with less than seven f electrons show a higher degree of antisymmetry. It was shown in Section III that the transition associated with the $\alpha_{\rho\sigma} - \alpha_{\sigma\rho}$ ($\alpha_Q{}^1S$) tensor combination is possible only for electronic Raman scattering.

Table 2. Absolute cross-sections[a] of Rayleigh and electronic Raman scattering of Pr^{3+} and Tm^{3+} ions.

Ions	Rayleigh scattering, cm^2	Raman scattering	Transition in Raman scattering
Pr^{3+}	$0.9\cdot10^{-29}$	$0.6\cdot10^{-31}$	$^3H_4 \rightarrow {}^3H_5$
Tm^{3+}	$1.3\cdot10^{-30}$	$0.2\cdot10^{-39}$	$^3H_6 \rightarrow {}^3H_4$

[a]The calculation was made for exciting radiation at a wavelength of 6328 Å.[15]

The relation between the transitions in electronic Raman scattering and the symmetry of the crystal field, which is shown for ions in solids, is also specified by Eqn. (14). The linear combination of the substates J_Z, which are the wave functions of the crystal field levels [Eqn. (10)], is in fact determined by the crystal field symmetry and the strength and symmetry of the field appear in the expressions for the mixing coefficients a.

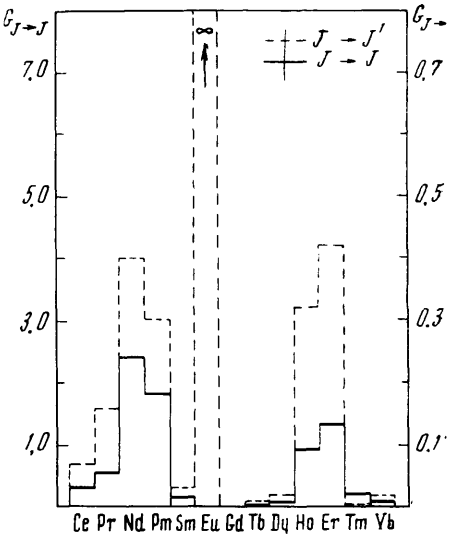

Figure 4. The calculated degree of antisymmetry of the tensor for electronic Raman scattering of tervalent lanthanide ions.

These coefficients and therefore the correct wave functions may be found by diagonalising the matrix comprising the elements $\langle J, J_Z | H_{CF} | J', J'_Z \rangle$, where H_{CF} denotes the effective potential due to neighbouring ions at the site of the jth electron of the lanthanide ion located in the centre. H_{CF} can be expressed in the following form:

$$H_{CF} = -e\sum_j V(r_j, Q_j, \varphi_j) \quad . \tag{17}$$

In the calculation of the crystal field, the perturbation Hamiltonian is usually formulated thus:

$$\mathcal{H}_{CF} = \sum_n \sum_{m=-n}^{n} \sum_j B_n^m r_j^m Y_j^m(\theta_j, \varphi_j) \quad . \tag{18}$$

The B_n^m are constants and their values are in principle determined by the positions and charges of the ions surrounding the lanthanide ions, r_j is the expectation radius of the jth $4f$ electron, and Y_n^m are spherical harmonics. The expansion for f electrons should include terms up to $n \leq 6$ subject to the condition $n \leq 2J$.

The eigenvectors, eigenvalues, the values of α_Q^K, and the elements of the tensor in terms of cartesian coordinates for the tervalent europium ion in a crystal field with tetragonal symmetry, determined by the parameters B_2^0, B_4^0, B_4^4, and B_6^0, are given in Table 3. Figs. 5, 6, and 7 illustrate the calculated polarised spectra of this ion in certain crystal fields.

The electronic transitions in Raman scattering are $^7F_0 \rightarrow {}^7F_1$ (<600 cm^{-1}) and $^7F_0 \rightarrow {}^7F_2$ (>600 cm^{-1}). All the

tensors for the transitions $J = 0 \rightarrow J = 1$ are fully antisymmetric and all the tensors for the transitions $J = 0 \rightarrow J = 2$ are fully symmetric. Such tensors may be separated from one another by the rotation of the entire crystal about the fourfold axis; the differences in Raman intensity under the conditions of the observation of $z(xy)x$ for the symmetrical tensor and the fully antisymmetric tensor are presented in Fig. 8. Table 3 shows that the coefficients a are completely independent of the crystal field parameters and consequently the number of Raman lines in the spectra obtained for different polarisations is the same for all the crystal fields with tetragonal symmetry, but the frequency of the Raman lines depends in all cases on the parameters B_n^m.

Table 3. The eigenvalues, eigenvectors, and scattering tensors for the Eu^{3+} ion in a tetragonal crystal field[a,b].

Eigenvalue	Eigenvector	Controlling element α_Q^K	$\alpha_Q^K/F(K,\nu)$	Scattering tensor
		$^7F_0 \rightarrow {}^7F_2$		
$2\alpha A_2 + \beta(A_4^0 - A_4^4)$	$(1/\sqrt{2})(\lvert 2,2\rangle - \lvert 2,-2\rangle)$	α_{-2}^2	$+(1/70)^{1/2}$	$\alpha_{-2}^2\begin{bmatrix} 1/2 & -i/2 & 0 \\ -i/2 & -1/2 & 0 \\ 0 & 0 & 0 \end{bmatrix}$
$2\alpha A_2^0 + \beta(A_4^0 + A_4^4)$	$1/\sqrt{2}(\lvert 2,2\rangle - \lvert 2,-2\rangle)$	α_2^2	$+(1/70)^{2/2}$	$\alpha_2^2\begin{bmatrix} +1/2 & -i/2 & 0 \\ -i/2 & -i/2 & 0 \\ 0 & 0 & 0 \end{bmatrix}$
$-\alpha A_2^0 + 4\beta A_4^0$	$1(\lvert 2,1\rangle \lvert)$	α_1^2	$-(1/35)^{1/2}$	$\begin{bmatrix} 0 & 0 & -1/2 \\ 0 & 0 & -i/2 \\ -1/2 & -i/2 & 0 \end{bmatrix}$
$-\alpha A_2^0 - 4\beta A_4^0$	$1(\lvert 2,-1\rangle \lvert)$	α_{-1}^2	$+(1/35)$	$\alpha_{-1}^2\begin{bmatrix} 0 & 0 & -1/2 \\ 0 & 0 & -i/2 \\ -1/2 & -i/2 & 0 \end{bmatrix}$
$-2\alpha A_2^0 + 6\beta A_4^0$	$1(2,0\rangle)$	α_0^2	$-(1/35)$	$\alpha_0^1\begin{bmatrix} -2/\sqrt{6} & 0 & 0 \\ 0 & -1/\sqrt{6} & 0 \\ 0 & 0 & 2/\sqrt{6} \end{bmatrix}$
		$^7F_0 \rightarrow {}^7F_1$		
$-2\alpha A_2^0$	$1(\lvert 1,0\rangle \lvert)$	α_0^1	$-(1/21)^{1/2}$	$\alpha_0^1\begin{bmatrix} 0 & i/\sqrt{2} & 0 \\ -i/\sqrt{2} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$

[a] For $^7F_2$, $\alpha = -11/315$ and $\beta = 2/189$. For $^7F_1$, $\alpha_1 = -1/2$.

[b] All the A_n^m are expressed in cm^{-1}.

A complication is observed for lanthanide ions with an odd number of electrons. The assignment of the crystal field levels with respect to the symmetry of the scattering tensor elements and the wave functions is now based on irreducible representations for binary groups. All the crystal field levels are Kramers doublets and the double degeneracy may be removed when the ions are placed in a magnetic field. Table 4 gives the tensors and designations of the Raman lines shown for two Ce^{3+} transitions in $CeCl_3$—one from the $J_Z = \pm 5/2$ level to $J_Z' = \pm 3/2$ and another from the $J_Z = \pm 5/2$ level to $J_Z' = \pm 1/2$.

Thus, when a field is superimposed, it is possible to observe the individual components and the spectra for different polarisations may be constructed on the basis of the contributions of the scattering tensors to individual transitions. For one of the transitions in a zero field, the tensor is somewhat asymmetric. The frequency dependence of the degree of antisymmetry for the Ce^{3+} ion in $CeCl_3$ has been calculated[29]. It is illustrated in Fig. 9. The results depend greatly on the position of $\tilde{\nu}_{\chi k}$ which is ν_{4f5d} in our case. The presence of Kramers doublets in fact leads to a scattering tensor which differs from the normal tensors. Table 5 lists the characters of the binary group D_2 representations. All the crystal field states of the split LST manifold of a lanthanide ion with an odd number of f electrons belong to the representation Γ_5. Thus the transformation properties of the irreducible tensors $\Gamma_{\alpha_Q^K}$ are contained in the direct product of the representations $\Gamma_5 \times \Gamma_5 = \Gamma_1 + \Gamma_2 + \Gamma_3 + \Gamma_4$. The resultant overall tensor is therefore more complicated than the tensor for the vibrational transition of the system, which belongs to the usual point group D_2.

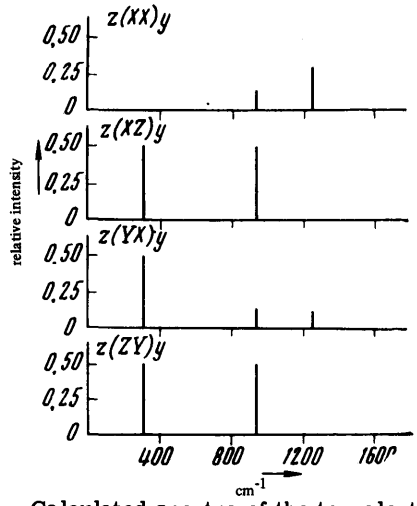

Figure 5. Calculated spectra of the tervalent europium ion in a crystal field of cubic symmetry for different polarisations. The intensities of the Raman lines with frequencies of about 800 cm^{-1} in Figs. 5 and 6 should be divided by 30 if the first excited electronic configuration has an energy of about 110000 cm^{-1}. The crystal field parameters are $A_4^0 = -250$ cm^{-1} and $A_4^4 = 5A_4^0$, where $A_n^m = \langle r^n \rangle B_F^m$.

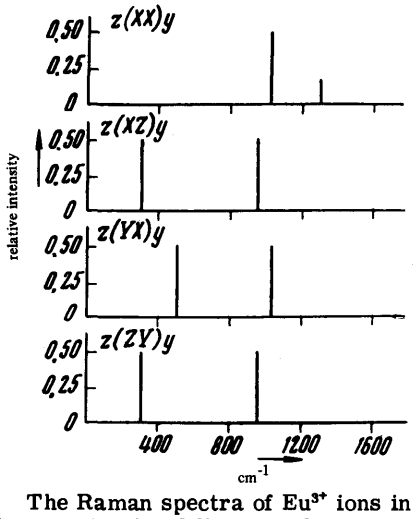

Figure 6. The Raman spectra of Eu^{3+} ions in a field with hexagonal symmetry for different polarisations. The crystal field parameters are $A_2^0 = 250$ cm^{-1} and $A_4^0 = -250$ cm^{-1}.

The calculation of the Raman spectrum for a specific polarisation presented here presupposes that the crystal unit cell contains one lanthanide ion and that the local axes of this ion are parallel to the macroscopic axes of the crystal. In most cases the situation is more complicated: the unit cell may contain more than one ion and the ions may occupy different sites with their own crystal field symmetry.

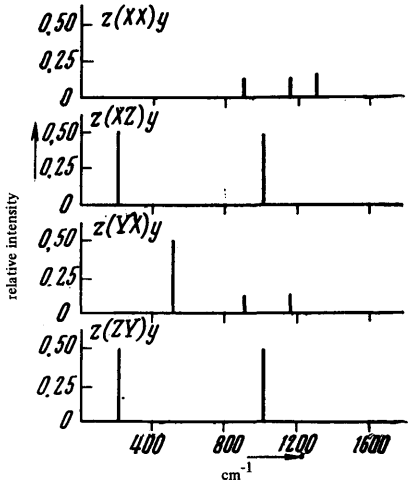

Figure 7. The Raman spectra of Eu^{3+} ions in a crystal field of tetragonal symmetry for different polarisations. The crystal field parameters are $A_2^0 = 250\ cm^{-1}$, $A_4^0 = -250\ cm^{-1}$, and $A_4^4 = -1000\ cm^{-1}$.

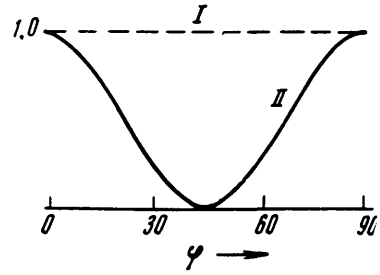

Figure 8. Variation of the Raman line intensity determined by the tensor element α_{yz} with the angle of rotation $\varphi°$ about the z axis of the crystal. Curves I and II refer to the asymmetric tensor $\begin{matrix}0\,a\,0\\-a\,0\,0\\0\,0\,0\end{matrix}$ and the symmetric tensor $\begin{matrix}0\,a\,0\\a\,0\,0\\0\,0\,0\end{matrix}$ respectively.

It is readily seen that the characteristics of the scattering by lanthanide ions are obtained for the entire crystal by the transformation of the scattering tensors $(\alpha_{\rho\sigma})^S_{kn}$ for each of the ions occupying different sites S in the laboratory coordinate system. This can be done with the aid of the rotation matrices R_S and R_S^{-1}, subsequent squaring of the individual tensor components, and their addition. The following scattering tensor is then obtained for the crystal:

$$[(\alpha_{\rho\sigma})_{kn}]^2_{\text{crystall}} = \sum_{\text{sites}} [R_s (\alpha_{\rho\sigma})^S_{kn} R_s^{-1}]^2.$$

Although this procedure is simple, it is clear that the interaction between various lanthanide ions is not taken into account. Indeed, it is possible to consider this case as one where there is incoherent scattering by the ions, in contrast to the case of coherent scattering. As has been shown by the present author and Schaack[12] it is then important to take into account the similarity between the factor-group interaction and the correlation between various phases of the scattering centres—lanthanide ions.

Table 4. The eigenvalues, eigenvectors, and Raman line intensities for the $^2F_{5/2}$ set of levels in a hexagonal crystal field.

$J_z - J'_z$ transition	Energy	Controlling element α_Q^K	$\alpha_Q^K/F(K,\nu)$	Intensity matrix

Γ_5	all the levels of the crystal field of the LSJ manifold	

Suppose that $\mathcal{H}_0$ is the Hamiltonian of an ion with a definite local symmetry, Φ_{ks} the wave function for the state k, and H_i the perturbation Hamiltonian describing the interionic energy. In the space group symmetry operations, H_i is transformed in the same way as H_0. The eigenfunctions Ψ_k for the $H_0 + H_i$ states with $k = 0$, which are important and of interest only in the case of first-order Raman scattering considered here, belong to an irreducible representation of the factor-group. In

terms of the zeroth approximation, these wave functions have the following form

$$\Psi_k = (1/N)\sum_s A_{ks}\Phi_{ks}.$$

With the exception of A_{ks}, these symbols have the usual significance. The A_{ks} are constants which have been chosen in such a way that the wave functions Ψ_k have been transformed in terms of the factor-group representations. Evidently the determination of A_{ks} is of primary importance.

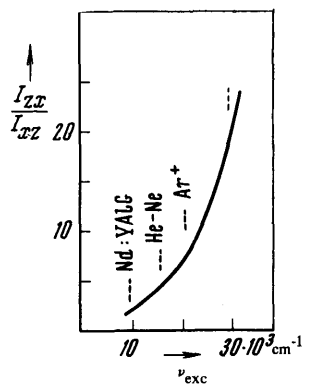

Figure 9. The ratio of the intensities I_{ZX} (related to the α_{ZX} element) and I_{XZ} (related to the α_{XZ} element) for Raman scattering in the electronic transitions of the Ce^{3+} ion in $CeCl_3$ for various frequencies of the exciting radiation.

For example, it follows from Table 6 that there is a unique relation between the representations of the local group D_2 and those of the factor-group O_h, since the representations of the group C_h appear once in each case. This makes it possible to set up the wave functions Ψ_k on the basis of symmetry considerations alone. If the irreducible representation γ is one-dimensional, then A_{ks} will be a character of γ referring to the symmetry elements which transform the site k into the site s. For two- or three-dimensional representations, it is necessary to employ the rules for finding the symmetry coordinates employed in molecular physics[17].

Table 6. Relation between the local irreducible representations and the representations of the factor-group for lanthanide ions in garnets.

D_2 representations	O_h^a representations	D_2 representations	O_h^a representations
A	$A_{1g}+E_g+T_{2g}$	B_2	$T_{2g}+T_{1g}$
B_1	E_g+T_{1g}	B_3	$T_{2g}+T_{1g}$

[a]Only the transformation properties of the Raman scattering tensor are quoted.

If the wave functions Ψ_k are used to calculate in the usual way (the integral $\langle\Psi_n|\alpha|\Psi_k\rangle \neq 0$) the scattering tensor components, the tensor for the crystal unit cell may be evaluated by the superposition of site tensors but now one must take into account the different phase factors. In this instance one must also consider the orientation of local axes, the following expression being obtained for the Raman intensity:

$$[(\alpha_{\rho\sigma})_{kn}]^2_{\text{crystal.}} = \Big[\sum_{\text{sites}} A^*_{ns}A_{ks}R_s \times (\alpha_{\rho\sigma})^s_{kn}R_s^{-1}\Big]^2.$$

The angles of rotation, which are important for the R_S and R_S^{-1} matrices for different sites of the unit cell, are obtained most simply when the directions of the local axes are known.

Calculation of the incoherent and coherent scattering tensors leads in general to the same results, but there is also a difference. In the first case one finds that the tensor for the Raman lines is determined by tensors associated with definite representations of the factor-group. It is then impossible to obtain information about the site tensors. On the other hand, in the case of coherent scattering, such information may be obtained and there is a relation between the crystal scattering matrix elements and the analogous values for the sites.

V. THE BREAKDOWN OF SELECTION RULES

In previous sections it was stated that the low electronic levels of the tervalent europium ion belong to the states ^7F_J, where $J = 0, 1, 2, \ldots, 6$. The $^7F_0$ state is the lowest and the $^7F_1$, $^7F_2$, and $^7F_3$ states are at about 300, 900, and 1800 cm^{-1} respectively.

The selection rules for electronic Raman scattering of lanthanide ions are as follows[4,5]: $\Delta S = 0$, $\Delta L \leqslant 2$, and $\Delta J \leqslant 2$; according to the $\Delta J \leqslant 2$ rule[4], the $^7F_0 - {}^7F_3$ transition is forbidden. However, this selection rule is valid only when J can still be regarded as a "good" quantum number, i.e. in those cases where the distances between the crystal field components are small compared with the distances between the energy levels for the state of the free ion. For strong crystal fields, "good" quantum numbers yield only the representations of the local symmetry group, so that different values of J may become mixed in a single eigenstate. However, the mixing of the J depends not only on the strength of the crystal field but also on its symmetry, since certain values of J cannot become mixed in the crystal if the crystal field symmetry is sufficiently high (for example states with $J = 0$ and $J = 3$ are not mixed for D_4 symmetry). Thus a good example of the breakdown of the $\Delta J \leqslant 2$ rule is provided by a crystal with a strong crystal field and a low local symmetry of the lanthanide ion. Among all the lanthanide ions, the free Eu^{3+} ion has the lowest levels; in this case mixing of the J can be achieved most readily. On the other hand, the aluminate crystal matrix gives rise to a strong crystal field with the point group having the C_S symmetry for the position of the lanthanide ion[6]. Table 7 shows that the states of the crystal fields with $J = 3$ belongs to the representations A' (Hougen and Singh[3]) and A'' (Elliott and Loudon[4]), but the wave functions of these states presumably contain an admixture of states with other values of J (particularly with $J = 2$). As a result, the Raman scattering in the $^7F_0$—$^7F_3$ electronic transition becomes allowed and the non-zero components of the scattering tensor again belong to the representations A' and A'' of the group C_S. It is possible to show in the same way that the Raman scattering in the $^7F_0$—$^7F_4$ transition is also allowed, but the intensity of these transitions

will presumably be much lower, because (1) the difference between the energies of the $^7F_2$ and $^7F_4$ levels is now about 2000 cm^{-1} and the states are mixed to a smaller extent than are the $^7F_3$ and $^7F_2$ levels where $\Delta E \simeq 800$ cm^{-1} and (2) the Raman intensity is proportional to the fourth power of the frequency of the emitted radiation.

Table 7. Symmetry properties of the crystal field levels for the ^7F_J set of $EuAlO_3$.

^7F Set	Representations of C_S groups	^7F Set	Representations of C_S groups
0	A'	2	$2A' + 3A''$
1	$A' + 2A''$	3	$3A' + 4A''$

α_{xx}, α_{yy}, α_{zz}, and α_{xy} enter into A'. α_{yz} and α_{xz} enter into A''.

The effect of the mixing of the J states has also certain interesting consequences for antisymmetric and isotropic tensors. Eu^{3+} ions provide a good example of the former. According to theory, the $^7F_0 - ^7F_2$ transitions are related to the more usual symmetric tensors. If the wave functions of the $^7F_1$ and $^7F_2$ states are mixed, then evidently the scattering tensors for the $^7F_0 - ^7F_1$ transitions now become partly antisymmetric and correspondingly some of the tensors for the $^7F_0 - ^7F_2$ transitions may change from symmetric to partly antisymmetric. The degree of antisymmetry depends on the percentage admixture of the corresponding states. The isotropic scattering tensor α_0^0 cannot contribute to transitions for the free ion either within the limits of a single configuration or to interconfigurational transitions. This follows from an examination of the conditions for a non-zero value of the $3j$-symbol introduced previously. However, as in the breakdown of the selection rule for the transitions with $\Delta J = 3$ and 4 in Raman scattering, the isotropic tensor can also contribute to the intensity under the influence of the mixing of the J states. From the theoretical standpoint, it is useful to recall that the absolute magnitude of $|\alpha_0^0|$ is about 100 times greater than $|\alpha_Q^{1,2}|$ and in the case of $^7F_0 - ^7F_2$ transitions it is easier to observe the presence of the isotropic tensor than that of the antisymmetric tensor.

In formulating the expressions for the scattering tensor, it was postulated that the frequency of the incident radiation (ν_0) is strongly displaced in relation to the frequency of the absorption band of the system. In this instance, when ν_0 is close to the value for the absorption band of the lanthanide ion, the Raman intensity for the transition between the ground stage g and the final state e is determined by the following scattering tensor:

$$(\alpha_{\rho\sigma})_{gl} = \sum_r \frac{\langle e|\rho|r\rangle\langle r|\sigma|g\rangle}{h\nu_0 - h\nu_{gr} + i\gamma_r} + \frac{[\rho \leftrightarrow \sigma]}{h\nu_0 + h\nu_{rl} + i\gamma_r} \quad . \qquad (19)$$

Here $\langle e|\rho|r\rangle$ and $\langle r|\sigma|g\rangle$ are the matrix elements of the operators ρ and σ of the electric dipole moment ($\rho, \sigma = x, y, z$; γ is the decay operator related to the line width of the electric dipole transition from the state g to the state r). In the derivation of Eqn. (19), we must assume that the matrix elements of the dipole operator become zero for transitions between states of the same parity. Thus only transitions between states with the $4f^n5s^25p^6$ configuration contribute, since owing to the crystal field states with configurations of other parities, similar to $4f^{n-1}5s^25p^65d$, become mixed in. If we designate by $|\alpha\rangle$ the lowest (as regards energy) configuration $|4f^n5s^25p^6\rangle$ and by $|\beta\rangle$ the first of the higher configurations $|4f^{n-1}5s^25p^65d\rangle$ of opposite parity, then one can write for the low states of the crystal field

$$|\Psi_1\rangle = a_1|\alpha\rangle + b_1|\beta\rangle + \ldots,$$
$$|\Psi_2\rangle = a_2|\alpha\rangle + b_2|\beta\rangle + \ldots,$$

where $\alpha_1 \simeq \alpha_2 \simeq 1$, $b_1 \simeq b_2 \simeq V_C/(E_\beta - E_\alpha)$, V_C determines the crystal field strength, and $E_\alpha - E_\beta$ determines the energy difference between the two configurations, equal to approximately 10^5 cm^{-1}. Here we are dealing with cases where V_C is between 10^2 and 10^3 cm^{-1} Then the values of b_1 and b_2 are also somewhere between 10^{-3} and 10^{-2}.[3]

An estimate of the matrix elements of the dipole moment operator is

$$\langle\Psi_1|\rho|\Psi_2\rangle \approx (a_1b_2 + b_1a_2)\langle\alpha|\rho|\beta\rangle \approx 10^{-2} \div 10^{-3}\langle\alpha|\rho|\beta\rangle.$$

Resonance implies that $\nu_0 \simeq \nu_{gr}$ and, if one assumes that the denominator of the first term in Eqn. (19) becomes equal to approximately ten, then this term has an order of magnitude somewhere between 10^{-5} and 10^{-7} in units of $|\langle\alpha|\rho|\beta\rangle|^2$. The second term in Eqn. (19) may be neglected.

If we consider the part of the sum for which the intermediate state $|r\rangle$ belongs to the configuration $4f^{n-1}5s^25p^65d$, then the denominator, which depends on the energy, will be 10^5 and we obtain 10^{-5} in units of $|\langle\alpha|\rho|\beta\rangle|^2$ for the contribution of this part of the sum. Hence we see that, although the matrix elements $\langle\Psi_1|\rho|\Psi_2\rangle$ are in fact very small, they can have an appreciable influence in the case of resonance. One can reach the following two conclusions.

1. The resonance effect depends on the admixture of states with a different parity from the states of the lowest conformation of the crystal field and consequently should be more intense for stronger crystal fields.

2. When the symmetry point group contains an inversion centre, there should be no resonance effect, since a crystal field of this type does not involve the mixing of configurations of different parities.

The matrix element $\langle\Psi_1|\rho|\Psi_2\rangle$ depends also on whether ρ is equal to x, y, or z. Thus the properties of the polarisation of the transition from the ground state to the resonance state have a direct influence on the Raman scattering tensor. In the special case where a direct transition between the two states is forbidden, we would not observe any resonance effect. However, the corresponding absorption line will of course also be missing under these conditions.

VI. EXPERIMENTAL METHODS

The apparatus for the investigation of Raman scattering is illustrated schematically in Fig. 10. It can be seen that the direction of propagation of the laser radiation is at right angles to the direction of the scattered light. In the general case the laser is focused in a very narrow beam within the crystal. Estimates of the beam diameter in our experiments yielded about 150—200 μm. The crystal was placed at the top of the cold finger of the experimental helium Dewar vessel fitted with windows for the illumination of the specimens and the observation of the scattered light. The light from the laser beam within the crystal was reflected onto the slit of a double monochromator.

Double monochromators are now used in Raman spectroscopy, since they are particularly effective in eliminating the scattered light and make it possible to observe Raman lines displaced by less than 10 cm^{-1} from the unperturbed Rayleigh line. In most cases a photomultiplier is used as a detector; in our experiments we employed a photomultiplier with an S20 cathode. The signal from the photomultiplier was transferred to an integrating digital voltmeter, the time constant of which was set in the range from 1 to 60 s. By reducing the scanning rate of the monochromator to 1.25 Å min^{-1}, it is possible to employ time constants of about 20 s. In order to prevent the distortion of the line form of the radiation, the slit width S, the time constant t, and the scanning rate v must be related as follows: $tv/S = 1/2$. The details of the detector are shown schematically in Fig. 10. A photomultiplier of type EMI 9558B was used in the experiments. The solenoid was placed directly around the photocathode; the light emerging from the output slit of the monochromator was focused by lenses onto a small section of the photocathode. The magnetic lines of force generated by the solenoid prevented the incidence on the first dynode of the photoelectrons emitted from different parts of the cathode, except its centre on which the scattered light impinged. This gave rise to an effective amplification of the signal to noise ratio by a factor of approximately six compared with the case where the magnetic field was switched off and the entire area of the photocathode was illuminated. The crystals employed in the experiments were very small and the length of the path traversed by the laser beam within the crystal hardly exceeded 4 mm in all cases. It is well known that the width of the electronic levels depends greatly on the temperature of the specimen. The lower the temperature, the smaller the width of the electronic level. For this reason, transitions between electronic levels were investigated at low temperatures.

However, such investigations suffer from the disadvantage that the principal characteristic of the Raman spectrum, the presence of anti-Stokes and Stokes lines, is lost if the specimen is cooled to very low temperatures. Nevertheless, for electronic levels in the region up to 150 cm^{-1} even at specimen temperatures below 77°K, there are excited lines with sufficient populations to ensure an adequate intensity of the anti-Stokes spectrum. In order to determine which line in the Raman spectrum of the crystal is due to Raman scattering in an electronic transition, the phonon spectrum of the lattice-matrix was compared, for example, with the spectrum of a lanthanide compound. The appearance in the latter of new lines might have been an indication that Raman scattering in electronic transitions takes place. However, the study of the phonon spectra of lanthanide compounds of the garnet type showed that marked differences are observed in the positions of the phonon bands for different lanthanide garnets. This implies that additional lines observed in the spectra of lanthanide compounds are not necessarily electronic Raman lines. A reliable method for determining which lines in the Raman spectrum belong to electronic transitions involves placing the specimen in strong magnetic fields. The low electronic levels of lanthanide ions in the crystal are sensitive to the influence of external magnetic fields; this is of course not the case for phonon lines. Fig. 10*c* presents details of the experimental apparatus in which the crystal is placed within a superconducting magnet fitted with the necessary apertures whereby it is possible to illuminate the crystal with laser light and to observe the scattered radiation at right angles to the direction of propagation of the laser beam. The specimen

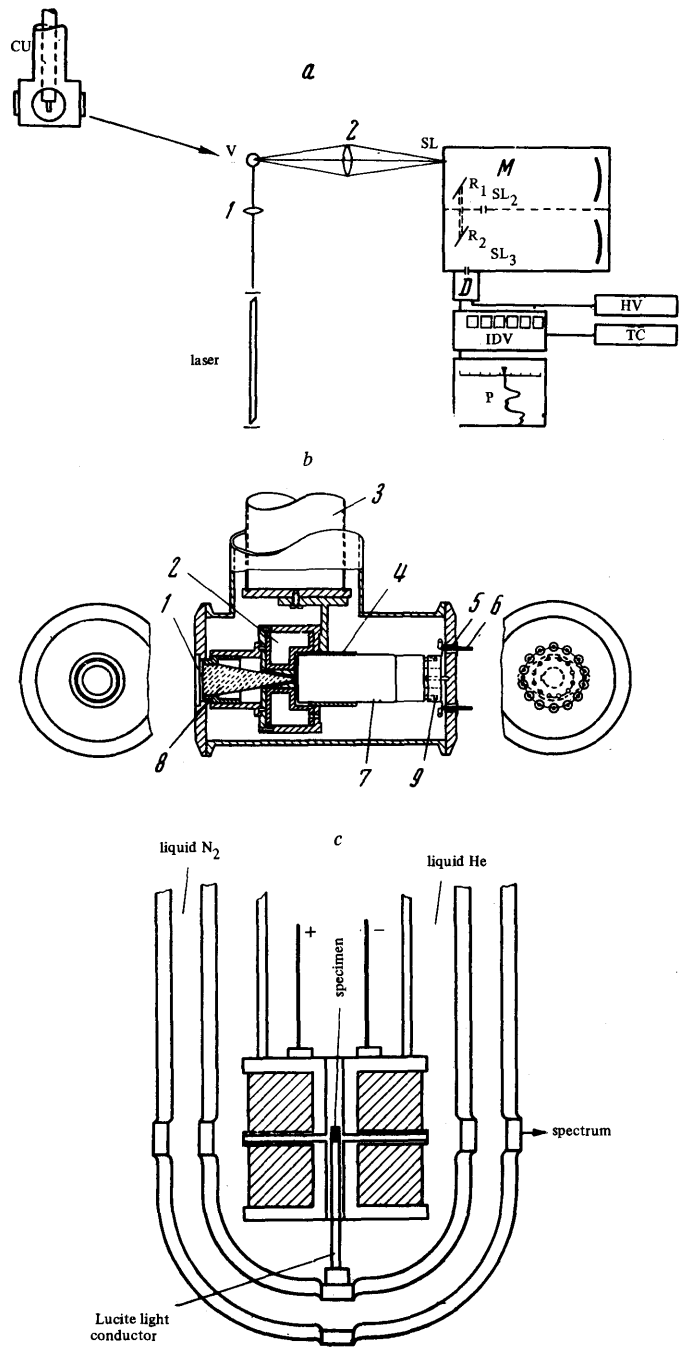

Figure 10. *a*) Diagram of apparatus for the measurement of Raman spectra with laser excitation: V—Dewar vessel containing the single crystal [the laser radiation is focused by the lens (*1*) into the interior of the crystal]; D—detector; HV—high voltage source; IDV—integrating digital voltmeter; P—pen recorder; TC—device for the measurement of the voltmeter time constant; M—double monochromator; CU—cuvette; SL—slit; R—replica gratings. *b*) Detector with cooling system and magnetic defocusing: *1*) Pyrex window; *2*) coil; *3*) to Dewar vessel; *4*) copper tube; *5*) glass—metal seal; *6*) photomultiplier terminals; *7*) photomultiplier; *8*) Pyrex light conductor. *c*) Schematic illustration of the position of the specimen in the superconducting magnet.

is now immersed in liquid helium and, needless to say, at this low temperature the anti-Stokes Raman lines should not be observed. An advantage of experiments at such temperatures is of course that the electronic levels under these conditions are very narrow. Care must be taken to screen the photomultiplier from the magnetic field generated by the superconducting magnet.

Having discussed the theory and the experimental conditions in the study of electronic Raman scattering, we now proceed to Section VII, which discusses the experimental aspects of electronic Raman spectroscopy.

VII. EXPERIMENTAL RESULTS‡

The Raman spectra of lanthanide ions in single crystals are discussed in this section. Consequently, apart from the excitation of the electronic levels, the phonons of the crystal–matrix will play a certain role. In the theoretical Section IV it was shown that the scattering cross-section for electronic transitions is lower than for vibrational Raman scattering and therefore it is more convenient to investigate lanthanide compounds which contain a high percentage of lanthanide ions. Such systems may be found in the series of rare-earth chlorides ($RECl_3$) [3,30] or their aluminates ($REAlO_3$). The phonons for the latter lattice-matrix are observed at frequencies <600 cm^{-1} and Fig. 11 illustrates part of the $SmAlO_3$ spectrum containing Raman lines in the range 1000–1550 cm^{-1}. According to the energy level diagram presented in Fig. 1, transitions of the type $^6H_{5/2} - {}^6H_{7/2}$ are to be expected in this region. The width of these transitions depends on the crystal temperature, which distinguishes between them and phonons and the data presented in Fig. 11 make it possible to establish immediately the position of the four crystal field components for $J = 7/2$. Raman scattering in electronic transitions within the limits of the $^6H_{5/2}$ configuration cannot be observed as they coincide in position with the intense phonons of the aluminate crystal. Another example of such systems has been found in the series of RE_2O_3 crystals[31]. The compounds Yb_2O_3 and Er_2O_3 were investigated and electronic transitions at a frequency of about 41 cm^{-1} were found for the erbium compound. The phonon level of the Yb_2O_3 and Er_2O_3 crystals differ also in their width which may indicate the occurrence of an electron–phonon interaction. The crystals of lanthanide oxides are cubic, another series of crystals of the same symmetry being provided by lanthanide garnets. Here we are interested in the lanthanide aluminium and gallium garnets with the general formulae $RE_3Al_5O_{12}$ or $RE_3Ga_5O_{12}$. The unit cell contains 80 atoms and the 237 degrees of freedom of the species may lead to a complex spectrum. By virtue of the cubic symmetry of the crystals, the appearance of only 21 vibrations active in Raman scattering is expected in the spectrum; the corresponding lines were observed in the spectra of many crystals containing aluminium and gallium in the range 40–900 cm^{-1}. Thus, as for the aluminates, here too it is convenient to investigate the electronic effects outside the phonon region.

Fig. 12 presents the spectra for different polarisations of the compound $Tb_3Al_5O_{12}$ with cubic symmetry. The spectrum arises as a result of transitions from the ground state (which is one of the levels of species $^7F_6$) to levels of species $^7F_5$. The local symmetry of the lanthanide ions in the garnet crystals is determined by the point group with D_2 symmetry since all the levels belong to one of the representations A, B_1, B_2, or B_3 of this group. For a transition of the type $A(^7F_6)$–$A(^7F_5)$, the tensor is determined by components transformed in accordance with the representations $A_{1g} + E_g + T_{2g}$; the tensor is the same also for transitions between levels with the symmetry $B_1(^7F_6)$ and $B_1(^7F_5)$, etc.§ However, since the symmetry of the crystal field is known, it is possible to predict how many times tensors of the type $A_{1g} + E_g + T_{2g}$, $E_g + T_{1g}$, and $T_{2g} + T_{1g}$ will appear. By altering the illumination conditions, it is possible to show that the symmetry of the ground state is A or B_1.

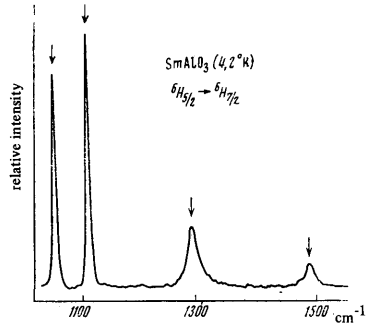

Figure 11. Low-temperature Raman spectrum of a non-oriented $SmAlO_3$ single crystal; the arrows indicate the $^6H_{5/2}$–$^6H_{7/2}$ electronic transitions.

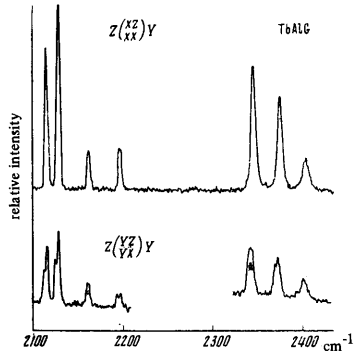

Figure 12. Raman spectrum of terbium aluminium garnet at 4.2°K. The lower spectrum is that of a crystal placed in a magnetic field of about 2.5 kG.

Having thus at one's disposal two possible sets for the assignment of states of the type $^7F_5$ in a crystal field with D_2 symmetry, it is now possible to employ the mathematical procedure used in crystal field calculations. In such calculations it was assumed that the ground state has the A symmetry and that the excited state with B_1 symmetry lies more than 10 cm^{-1} above the ground state.

‡The results presented in this section have been selected from data which have already been published[3,10,18,19,21,23].

§ See also Table 6.

It is most convenient to assign particular symmetries to the electronic levels using a spectroscopic technique based on electronic Raman scattering. The transitions in luminescence or absorption are usually largely related to the electric dipole moments and the moments in the directions x, y, and z for a cubic crystal cannot be distinguished. The dipole moment operator is transformed in accordance with one of the representations of the factor-group and therefore one cannot achieve a symmetry assignment for the crystal field levels. The electronic transitions for the $^7F_5$ levels in Raman scattering have frequencies below 600 cm^{-1} and this region also contains the phonons of the garnet crystal. Electronic Raman scattering can be separated from the phonon spectrum by comparing the spectrum in Fig. 13 with that of the yttrium–aluminium garnet. The positions of the corresponding phonons for the two crystals are established with the aid of identical polarisation measurements in Raman spectra. The high intensities of the electronic transitions in the range from 60 to 90 cm^{-1} are somewhat surprising. The general conclusion from data for TbAlG is that not all possible electronic transitions are observed. Evidently the width of the transitions continues to increase if the difference between the energies of the electronic levels reckoned from the lowest set of levels increases. Thus the width of the excited levels remote from the lowest level may be so great that it is difficult to observe the transitions, particularly if the phonons of the crystal-matrix are present.

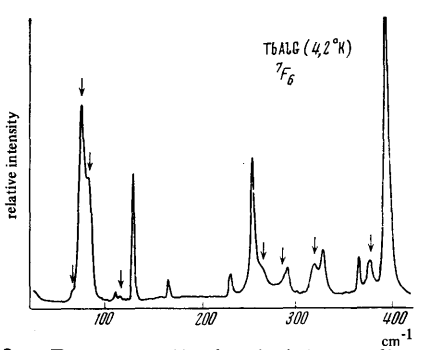

Figure 13. Raman scattering in interconfigurational electronic transitions of the type $^7F_6$ in TbAlG.

The foregoing considerations are confirmed by the data in Fig. 14. Like the main set of Tb^{3+} levels, Tm^{3+} ions also have the quantum number $J = 6$ in the ground state. Thus the crystal field with D_2 symmetry has 13 components but only two transitions have been observed for TmAlG. Under the same experimental conditions (power of the laser, quality of the crystal, recording system, etc.), it was found that the scattering at the electronic levels of the Tm^{3+} ion is definitely smaller than for the Tb^{3+} ion in the aluminium garnet crystal. This is at least consistent with the *ab initio* calculations of the absolute cross-sections presented in Table 2.

The changes in the spectra arising because the levels and the tensor components belong to representations of binary groups can be most satisfactorily demonstrated for $DyAl_5O_{12}$. The tensors for the phonons of this compound belong to the factor-group O_h. The space group of the garnet is O_h.[10] Fig. 15 illustrates part of the low-temperature Raman spectrum of DyAlG. Experiments showed that the upper spectrum is due to phonon (and electronic) levels with the E_g symmetry only. The lower Raman spectrum reflects only the transitions with T_{2g} symmetry. Evidently the phonons have the E_g or T_{2g} symmetry.

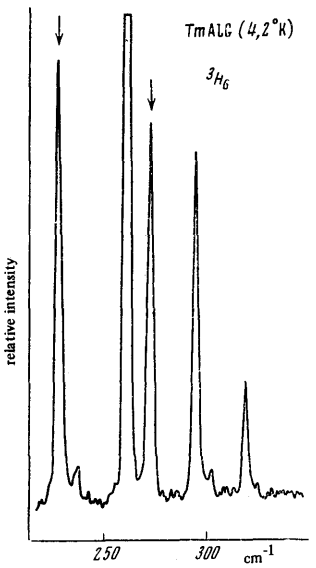

Figure 14. Raman scattering in two electronic transitions in thullium aluminium garnet.

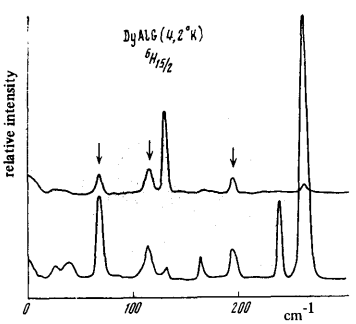

Figure 15. Polarisation Raman spectrum of an oriented crystal of dysprosium aluminium garnet. The difference between the polarisation characteristics of the electronic (↓) and phonon transitions becomes clear when the upper and lower spectrograms are compared.

The tensor for electronic transitions is contained in the representation $\Gamma_5 \times \Gamma_5 = \Gamma_1 + \Gamma_2 + \Gamma_3 + \Gamma_4$ of the binary group D_2 (see also Table 5). Thus we find that, as a result, the tensor for the transitions between electronic levels with Γ_5 symmetry no longer belongs either to the E_g representation or to the T_{2g} representation. This tensor is more complex and the spectra shown in Fig. 15

confirm the theoretical predictions. The Raman spectroscopic data for the electronic transitions in DyAlG have also been used to determine the crystal field strength expressed in terms of the coefficients A_n^m. The results of the calculation of the crystal field using data for electronic Raman scattering are important not only for the prediction on the basis of the crystal field parameters of the positions of the crystal field levels but also for the determination of the symmetry of the states. Thus there are more experimental data than the parameters to be determined and such data are now being used to find the parameters for all possible lanthanide garnets. Fig. 16 presents part of the Raman spectrum of $EuGa_5O_{12}$ (europium gallium garnet). According to theory, the observed electronic transitions of the type $^7F_0 - ^7F_1$ are due to a fully antisymmetric tensor. For cubic crystals, there are several methods for the determination of the tensor symmetry. It is impossible to distinguish symmetrical and antisymmetric tensors when the crystal is oriented in such a way that the excited radiation is propagated along the a axis of the garnet crystal and the scattered radiation is observed along the b and c axes. This situation differs radically from the case where the crystal is rotated by 45° about the c axis so that the direction of propagation of the incident radiation makes an angle of 45° with the a and b axes and the direction of observation of the scattered light is at right angles to them, as in all normal cases.

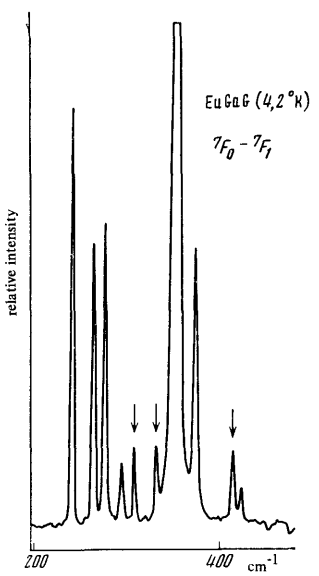

Figure 16. Electronic Raman scattering of Eu^{3+} in europium gallium garnet. The scattering corresponds to fully antisymmetric tensors.

Lanthanide ions occupy sites with D_2 symmetry and in the unit cell there are six such sites. Using the theory of the incoherent and coherent Raman scattering tensors, it is possible to set up the corresponding matrices taking into account the rotations; they are presented in Table 8.

Evidently, if the entire intensity is internally related to a phonon with E_g symmetry, then the intensity ratio $R = I_{yx+yz}/I_{zx+zz}$ becomes zero for the Raman line with A_g symmetry, 8/3 for the line with T_{1g} symmetry (antisymmetric tensors), and 4/3 for the line with T_{2g} symmetry (symmetrical tensors). The tensors which transform as the T_{1g} representation of the factor-group are of the form $(\alpha_{xy} - \alpha_{yx}, \alpha_{yz} - \alpha_{zy}, \alpha_{xz} - \alpha_{zx})$ and those which transform as the T_{2g} representation are $(\alpha_{xy} + \alpha_{yx}, \alpha_{yz} + \alpha_{zy}, \alpha_{xz} + \alpha_{zx})$.

Table 8. Scattering matrices for an oriented EuGaG crystal.

Tensor symmetry	Scattering matrix	Tensor symmetry	Scattering matrix
A_{1g}	$\begin{bmatrix} a^2 & & \\ & a^2 & \\ & & a^2 \end{bmatrix}$	T_{2g}	$\begin{bmatrix} c^2 & 0 & c^2 \\ 0 & c^2 & c^2 \\ c^2 & c^2 & 0 \end{bmatrix}$
E_g	$\begin{bmatrix} b^2 & 3b^2 & 0 \\ 3b^2 & b^2 & 0 \\ 0 & 0 & 4b^2 \end{bmatrix}$	T_{1g}	$\begin{bmatrix} 0 & d^2 & d^2 \\ d^2 & 0 & d^2 \\ d^2 & d^2 & 0 \end{bmatrix}$

It has been found experimentally that $R = 2.6 \pm 7\%$ for the 308 cm^{-1} line and $R = 2.6 \pm 10\%$ for the 329 cm^{-1} line. Owing to the presence of the phonon with T_{2g} symmetry close to the electronic transition at 411 cm^{-1}, it is impossible to determine the ratio R in this case. The experimental results show that two of the $^7F_0 - ^7F_1$ transitions indeed involve antisymmetric tensors. The first electronic Raman spectrum obtained on laser excitation was that of yttrium gallium garnet doped with europium[6] so that it is now evident that transitions due to the antisymmetric tensor were recorded as early as 1966.

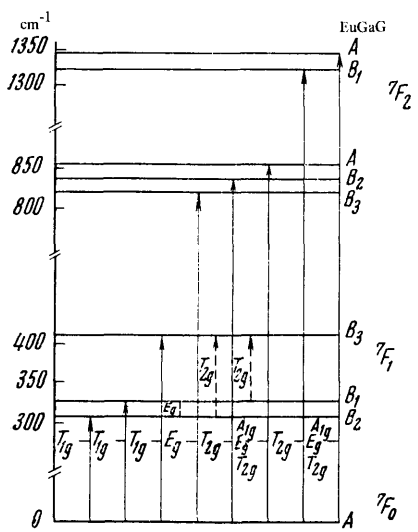

Figure 17. Low energy levels of Eu^{3+} in EuGaG.

Raman scattering has also been observed in electronic transitions of the type $^7F_0 - ^7F_2$; according to theory,

these transitions are linked to symmetrical tensors. The low energy levels of EuGaG obtained from Raman spectroscopic data are presented in Fig. 17. The presence of a level with B_1 symmetry in the gap between the levels with B_3 and B_2 symmetries for $^7F_1$ suggests that the crystal field is orthorhombic and the deviation from tetragonal symmetry is large. Thus, although the crystal is in fact cubic, the europium ion is in a crystal field determined by the local orthorhombic symmetry. Using in the analysis the mathematical procedures of the crystal field theory, it is possible to calculate the eigenvectors of the crystal field levels; the results of the calculation are presented in Table 9.

Table 9. Energies and assignments with respect to symmetry and the wave functions of the low-lying ^7F set of energy levels for EuGaG.

Calculation of all the Raman lines presupposes, as stated in the theoretical section, a complete analysis of the diagrams of energy levels belonging to set ^7F_j.

The selection rule $\Delta J \leq 2$ for electronic transitions does not hold either for EuGaG or $EuAlO_3$. The results of the study of the Raman and fluorescence spectra of $EuAlO_3$ are presented in Table 10 and Fig. 18 also shows the spectra and the energy level diagram.

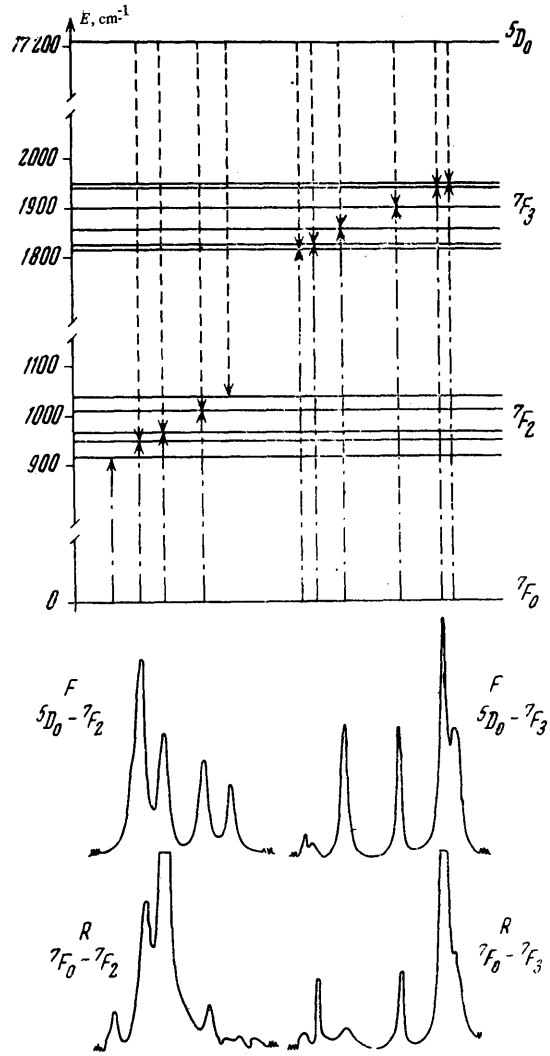

Figure 18. Transitions associated with the fluorescence and Raman scattering in europium aluminate.

The breakdown of the selection rule $\Delta J \leq 2$ occurs owing to the mixing of the J states, since the europium ion in the garnet and aluminate crystals is subjected to powerful crystal fields. The theory of the calculation of Raman intensities was applied to $CeCl_3$ and $PrCl_3$ crystals. A good agreement with experiment was found for $CeCl_3$. It was discovered that one of the Raman lines is linked with a partly asymmetric tensor. The calculated degree of asymmetry agrees satisfactorily with experimental data, possibly owing to the simplicity of the energy level scheme for Ce^{3+}. There is a good agreement between theory and experiment also for $PrCl_3$. The calculations are simple,

since the crystal field is determined by a small number of parameters.

We shall now turn our attention to the results of studies on resonance Raman scattering and the Zeeman effect in Raman scattering. The observation of electronic Raman scattering involved serious experimental difficulties. Firstly, it was necessary to find a system where at least one of the electronic absorption bands coincides with the available laser lines. The majority of absorption spectra of crystals with lanthanide ions contain a large number of lines in the green and blue regions of the visible spectrum and therefore there is some probability of a coincidence with the emission lines of the argon laser. Indeed a fairly large number of such cases have been found but only some of them are suitable for the investigation of resonance Raman scattering.

It was discovered that under these conditions not only the frequencies but also the oscillator strength of the chosen transition must satisfy special requirements. If the oscillator strength is too low, there is no interaction and consequently there is only a slight increase of the Raman intensity, while in the opposite case the entire exciting laser light is absorbed in a thin layer on the surface of the crystal. Although the resonance effect can in fact occur under these circumstances, the Raman scattering is too weak to be detected. Thus the optimal conditions should be sought when (a) the laser line coincides with an absorption band of moderate intensity and (b) when the specimen does not absorb in the part of the spectrum containing the Raman lines.

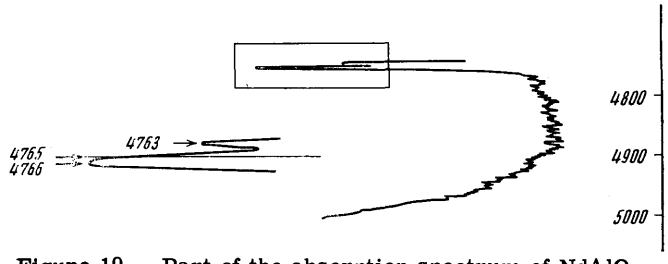

Figure 19. Part of the absorption spectrum of $NdAlO_3$ in the region of the 4765 Å line of the argon laser.

In our particular case the most serious difficulty involved making sure that the observed lines are indeed due to electronic Raman scattering and not to fluorescence. Fig. 19 presents the absorption spectrum of Nd^{3+} in $NdAlO_3$, which is involved in resonance with the 4765 Å line of the argon laser. Fortunately there is no complete coincidence in this case. The laser line is located at the wing of the absorption line on the high-energy side and it is displaced by approximately 4 cm^{-1} relative to its centre. If the observed emission lines (Fig. 20) were due to transitions caused by fluorescence from this level to lower levels, there would have been a 4 cm^{-1} shift relative to the Raman spectrum. Such a shift is not observed. The positions of the two low levels were known from the Raman spectrum obtained on excitation by the 4880 Å laser line; they were established for the first time by Scott[5]. Fig. 19 shows that there is a window in the absorption spectrum of the crystal between 4770 and 4950 Å. The intensity of the Raman lines in this region does not change owing to partial absorption. The Raman lines excited by those of the argon laser at wavelengths of 4765 and 4880 Å, which occur in this region, can therefore be compared directly with one another.

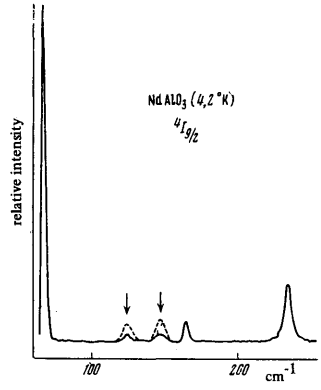

Figure 20. Raman spectrum of $NdAlO_3$ excited by light corresponding to the line at wavelengths of 4765 Å (shown dashed) and 4880 Å.

The spectra obtained with and without resonance, i.e. excited by laser lines at wavelengths of 4765 and 4880 Å, are compared in Fig. 20. The 53 and 147 cm^{-1} lines are due to phonons, while the 125 and 146 cm^{-1} lines are associated with electronic Raman scattering at the electronic levels. The phonon lines can be used as a standard in adjusting the spectra illustrated in Fig. 20 to the same intensity scale. Indeed the Raman spectrum excited by the 4765 Å line has a lower intensity owing to the partial absorption of the laser emission. Fig. 20 shows that the intensity of the electronic line increases approximately by a factor of five in the case of resonance. This small increase of intensity is inconsistant with the considerations put forward in Section V. It is found that not all the components of the scattering tensor increase in resonance Raman scattering. The symmetry of the resonating excited levels plays a role here, but, owing to the low symmetry of the $NdAlO_3$ crystal and because of the complexity of the tensor for scattering in electronic transitions (binary groups!), no attempts were made to determine the components of this tensor. Resonance scattering has also been observed for the Nd^{3+} ion in yttrium gallium garnet and for the Dy^{3+} ion in garnet crystals. All the data indicate that the dipole transitions within the limits of the $(4f)^n$ configuration have a weak influence on the elements of the scattering tensor for electronic transitions compared with the contributions having a direct bearing on the matrix elements. The case where the exciting line is in resonance with an interconfigurational transition has been observed for the Ce^{3+} ion in CaF_2; the enhancement of the electronic transitions was more marked, since the oscillator strength for the absorption band was much greater than for the $4f-4f$ transitions forbidden according to the Laporte rule.

The first studies on the Zeeman effect in Raman scattering were reported for the tervalent ytterbium ion in

yttrium gallium garnet. Here we shall consider the influence of this effect on the positions of the very intense electronic transitions of ytterbium aluminium garnet centred at 80 cm^{-1} (Fig. 13). The Zeeman spectrum of this Raman line is illustrated in Fig. 21, which shows that, for a zero magnetic field, cooling of the specimen from 77°K to 4.2°K alters the shape of the line. The intensity of the B transition at a frequency of 81.5 cm^{-1} decreases on the side of high energies. Since it has a higher energy than the A transition with a frequency of 74.6 cm^{-1}, one may reach certain conclusions concerning the energy level scheme; the relative positions of the levels are illustrated in Fig. 21. When a magnetic field is imposed, the distance between the two lower levels of the $^7F_6$ set of the TbAlG crystal field increases. The temperature of the crystal was 4.2°K, being immersed in liquid helium and the first excited state was unpopulated. Accordingly, the transition between levels with A (in group D_2) and B_3 or $B_2(D_2)$ symmetry disappears if the field and the distance between the levels increase. The single transition from the ground state shifts from 74.6 cm^{-1} to 79.5 cm^{-1} in a field of about 48 kG. In the crystal lattice unit cell of the garnet there are six sites for lanthanide ions, but the above experiments failed to reveal a fine structure. To some extent, this has also been observed for Dy^{3+} in garnets and one can now assume that the Zeeman Raman spectroscopic technique may be important, particularly in those cases where it is necessary to distinguish phonons and electronic transitions.

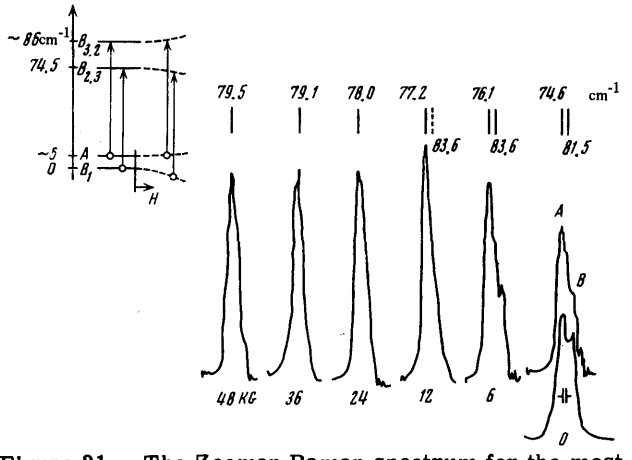

Figure 21. The Zeeman Raman spectrum for the most intense electronic effects in terbium aluminium garnet.

---o0o---

The present review deals exclusively with the interpretation and observation of light scattering at low electronic levels of lanthanide ions in solids. This type of light scattering is weaker than the usual scattering at vibrational levels but it has certain theoretical (and experimental) features which are not encountered in the usual Raman spectroscopy. All the experimental results presented are to some extent related to the effect of the crystal field on the lanthanide ion. It has been established that these results are particularly important for the elucidation of the nature of the crystal field in certain cubic crystals. Investigations of this kind have now been extended, particularly to the crystal field of transition metal ions in solids. Only limited information is available on this subject, but it appears that the main interest lies in the magnetic properties of transition metal compounds reflected in the characteristics of the scattering spectra.

The Reactivities of .OH, $.O^-$, and HO_2. Radicals and Oxygen Atoms in Aqueous Solutions of Aromatic Compounds

N.A.Vysotskaya

This review considers the results of studies on the reactivities of hydroxy- and perhydroxy-radicals and oxygen atoms with respect to aromatic derivatives of benzene, pyridine, and furan. The rate constants for the reactions investigated have been compared and a relation between them and the structure of compounds oxidised has been demonstrated.
The bibliography includes 60 references.

I. INTRODUCTION

The ·OH, $\cdot O^-$ and $HO_2\cdot$ radicals and atomic oxygen are formed in many oxidation-reduction processes used in the manufacture of important organic products, biochemical oxidation, and purification of sewage. Owing to their high reactivity, these radicals react rapidly with substances in solution and with one another and therefore their concentration in solutions is very low, which makes it difficult to investigate reactions involving them. Competitive methods, which make it possible to determine by comparatively simple procedures the relative rate constants for these reactions, and also pulse radiolytic methods, whereby the absolute rates may be determined, have been extensively applied to the study of processes of this kind.

The review presents the data obtained in recent years on the kinetics of reactions of ·OH and $\cdot O^-$ radicals with aromatic compounds; this makes it possible to revise many generally accepted hypotheses concerning the mechanisms of these reactions and the properties of the radicals themselves. The results of kinetic studies on the reactions of $HO_2\cdot$ radicals and atomic oxygen in the $O(^3P)$ state, which are as yet very few, have been examined.

II. REACTIONS OF ·OH RADICALS

Catalytic and photochemical decomposition of hydrogen peroxide or the radiolysis of water are used to generate ·OH radicals in aqueous solutions.

It was established in recent years that the active oxidising species formed in the decomposition of H_2O_2 by the above procedures and in the radiolysis of water are identical. This conclusion is based on a comparison of the relative rates of oxidation of the same substrates (benzene and many of its derivatives, methyl and ethyl alcohols, and certain other compounds) in the radiolysis of water and in the catalytic or photochemical decomposition of hydrogen peroxide in the presence of the same ·OH radical traps. *NN*-Dimethyl-*p*-nitrosoaniline (DMNA),[1,2] thymine[3], or H_2O_2 (Armstrong[4]) were used as the ·OH radical traps. The absolute rate constants listed in Table 1 were calculated from the ratios found.

Table 1 shows that the rate constants for the oxidation of substrates by products of the photochemical and catalytic decomposition of hydrogen peroxide are very close to the values obtained for the radiation-induced oxidation. This is consistent with the formation of free hydroxy-radicals in the photochemical and catalytic decomposition of hydrogen peroxide, since the generation of ·OH radicals in the radiolysis of water is not in doubt[6]. In $H_2O_2 + M^{+n}$ systems in the absence of organic additives, the hydroxy-radicals formed are captured by metal ions or their complexes with H_2O_2, which leads to the appearance of new paramagnetic complexes as shown by ESR spectroscopic data[7-10]. The results presented extend the scope of studies on the reactions of ·OH radicals.

Table 1. Comparison of the rate constants for the oxidation of various substrates by products of the photochemical or catalytic decomposition of H_2O_2 and the radiolysis of water.

Substrate	$10^{-9}k$, litre mole^{-1} s^{-1}			
	$H_2O_2 + h\nu$	$H_2O_2 + Fe^{2+}$	$H_2O_2 + Ti^{3+}$	$H_2O \xrightarrow{\gamma^{60}Co}$
Benzene	4.2[5]	4.1[5]	—	4.3[3], 3.8[1]
Benzyl alcohol	2.8[5]	—	—	4.1[1]
Benzoate ion	3.8[5]	—	—	4.1[1]
Anisole	5.0[5]	—	—	4.9[1]
Phenol	8.3[5]			7.5[1]
Methanol	—	0.8[5]; 0.89[4]	0.77[4]	0.75[3] 0.69[4]
Ethanol	—	1.1[5]; 1.7[4]	1.5[4]	1.6[3]
Formic acid	—	0.12[4]	0.12[4]	0.14[4]
Oxalic acid	—	0.016[4]	0.015[4]	0.02[4]

A number of studies were made recently on the interaction of these radicals with various organic acceptors[1-3,11-14]. The kinetics of these reactions with benzene and pyridine derivatives were investigated in detail by Shevchuk et al.[1] and with benzene also by Neta and coworkers[14,15]. Shevchuk et al.[1] and Neta and coworkers[14] employed the method of competitive kinetics using DMNA as the hydroxy-radical acceptor[2]. The systems

were irradiated with cobalt-60 γ-rays. The concentrations of DMNA before and after irradiation were determined spectrophotometrically.

For the competing reactions,

$$\text{Ac} + {}^{\cdot}\text{OH} \xrightarrow{k_1} \text{product},$$

$$\text{RH} + {}^{\cdot}\text{OH} \xrightarrow{k_2} \text{product},$$

it was shown that

$$\frac{1}{G_{(-\text{Ac})}} = \frac{1}{G_{\text{OH}}}\left[1 + \frac{k_2[\text{RH}]}{k_1[\text{Ac}]}\right].$$

where Ac = DMNA, RH = hydrocarbon and $G_{(\text{Ac})}$ and $G_{(\text{OH})}$ are the radiation-chemical yields for the disappearance of the acceptor and the formation of the ·OH radicals respectively.

This equation makes it possible to find the ratio k_2/k_1. Table 2 lists the relative rate constants for substituted benzenes and pyridines obtained by Shevchuk et al.[1] using this method. The logarithms of the $k_{\text{RH}}/k_{\text{benzene}}$ ratios are correlated with Hammett's σ constants. Shevchuk et al.[1] found a satisfactory correlation for substituted benzenes with $\rho = -0.31$. A similar value $\rho = -0.41$ was found by Neta and coworkers[14] using the same acceptor. Dorfman and Neta[15] determined the absolute rate constants for the hydroxylation of substituted benzenes by pulse radiolysis, from the formation curves for hydroxycyclohexadienyl radicals. The correlation between the logarithms of $k_{\text{RH}}/k_{\text{benzene}}$ and Hammett's σ constants yielded $\rho = -0.5$, which is fairly close to the values of ρ obtained by the method of competitive kinetics.

Table 2. Relative rate constants for the reactions of substituted benzenes, furans, and pyridines with hydroxy-radicals.

Substrate		$k_{\text{substrate}}/k_{\text{acceptor}}$
Substituted benzenes

CHO		0.62±0.04

Mention must be made of the discrepancies between the absolute rate constants obtained by pulse radiolysis and the values calculated from the relative constants obtained by the method of competitive kinetics. The former are as a rule higher by a factor of 2–3. The reason for the discrepancy is so far obscure. It may be related to the use of defective techniques in the first or second case[16] and possibly in both. However, comparison of the coefficients for the linear correlations of the rate constants obtained by different methods for series of identical derivatives shows a fairly satisfactory agreement between them.

The negative sign of ρ shows that the hydroxylation reactions are electrophilic; this is in turn consistent with data on the relative amounts of isomers formed[17] and demonstrates the electrophilic properties of the ·OH radicals. The low value of ρ, lower than in the usual electrophilic substitution reaction, suggests a high reactivity of the hydroxy-radicals as a result of which they are less sensitive to the polar influences of the substituents. Table 2 shows that the rate constants for the reactions of substituted pyridines are several times smaller than for benzene, in agreement with the lower reactivity of the pyridine ring in relation to attack by the electrophilic hydroxy-radicals. Accordingly, the absolute value of ρ is higher than for the series of benzenes and reaches 0.73. However, these reactions are also accelerated by electron-donating substituents and are retarded by electron-accepting substituents. A satisfactory correlation has been found only for β-substituted pyridines ($\rho = -0.73$).

The results obtained for the effect of substituents in the α-position are probably distorted by the adjacent electronegative nitrogen atom. The rate constants for the reactions of pyridine derivatives with electron-donating substituents in the α-position are higher than for the γ-substituted pyridines (Table 2). For compounds with electron-accepting substituents, the opposite relation between the rate constants for the oxidation of α- and γ-derivatives is observed. This may be because, as shown by Cercek and Ebert[18], hydroxy-radicals add not only to the ring but also partly to the pyridine nitrogen atom. In this process, the inductive effect of α-substituents at the nitrogen atom leads to the observed behaviour of the overall reaction rate constants and is of primary importance.

In contrast to the pyridine ring, furan derivatives readily undergo electrophilic substitution reactions and do not exhibit a tendency towards reactions with nucleophilic species. The relative rate constants for the reactions of furan and some of its derivatives[19] have been obtained by a method of competitive kinetics analogous to that employed by Shevchuk et al.[1] using the DMNA acceptor and were found to be higher by a factor of 2–3 than the corresponding constants for benzene derivatives and be a factor of 7 than for substituted pyridines (Table 2). This demonstrates an enhanced sensitivity of furan derivatives to attack by ·OH radicals. A satisfactory correlation has been found between $k_{\text{RH}}/k_{\text{furan}}$ and Hammett's σ constants with $\rho = -0.81$. The absolute value of ρ is relatively small and does not exceed those encountered in homolytic reactions ($1.5 > \rho > 0$). However, it is higher than the values found for reactions of substituted benzenes and pyridines, which may indicate a greater ease of transmission of the electronic effects of substituents in the furan series[20].

The high reactivity of hydroxy-radicals is consistent with the low activation energies for their reactions. The relative rate constants for reactions of ·OH radicals with various organic substrates have been determined[21] in the temperature range 20–70°C. Thymine was employed as the hydroxy-radical acceptor[3]. The observed activation

energies for reactions involving the abstraction of a hydrogen atom by hydroxy-radicals did not exceed 5 kcal mole^{-1} and those for addition reactions did not exceed 2 kcal mole^{-1}. The variations in activation energy in the benzene series relative to DMNA have been determined[19]. They are of the order of 0.08—0.56 kcal mole^{-1} and do not exceed the experimental error. The activation energies for β-substituted pyridines were found to be about ten times larger: 1.7 ± 0.2 kcal mole^{-1} for pyridine, 1.6 ± 0.3 kcal mole^{-1} for β-nicotinic acid, 2.1 ± 0.3 kcal mole^{-1} for β-nicotinamide, and 1.2 ± 0.1 kcal mole^{-1} for β-hydroxypyridine. It is evident from the above results that the activation energies for pyridine derivatives increase with the electron-accepting properties of the substituents and decrease as their electron-donating properties become more pronounced.

The data for the reactions of ·OH radicals with *ortho*-, *meta*-, and *para*-substituted phenols[22] are presented in Table 3. In order to determine the relative rate constants the DMNA acceptor was employed at pH 9 and isopropyl alcohol at higher pH values[23]. The logarithms of the relative rate constants for *para*-substituted phenols at pH 9 are satisfactorily correlated with Hammett's σ constants ($\rho = -0.32$). This value of ρ hardly differs from that obtained for the oxidation of benzene derivatives, which indicates a similarity of the mechanisms of these reactions. The correlation between the rate constants for *meta*-substituted phenols yielded $\rho = -0.18$. For *ortho*-substituted derivatives, there was virtually no correlation at pH 9 but it was observed at pH 13 with $\rho = -0.61$. This finding may be attributed to the influence of the dissociation of phenols at pH 13 on the *ortho*-effect.

Comparison of the relative rate constants for the reactions of substituted phenols with the analogous constants for the corresponding benzene derivatives shows that the former are higher by a factor of 2—3 (see the data in Tables 2 and 3). This is consistent with the powerful activating effect of the hydroxy-group in reactions with ·OH radicals.

Table 3. Relative rate constants for the reactions of substituted phenols with ·OH radicals at pH 9.

	Substituent	$k_{substrate}/k_{acceptor}$
para	$C(CH_3)_3$	1.49±0.26
	OCH_3	1.15±0.23
	CH_3	1.04±0.09
	CHO	0.82±0.2
	COO^-	0.70±0.06
	H	0.68±0.02
	NO_2	0.61±0.08
	OH	0.44±0.12
meta	OH	0.97±0.12
	Cl	0.58±0.05
	NO_2	0.57±0.05
ortho	CH_3	0.90±0.15
	OH	0.89±0.14
	NO_2	0.74±0.06
	CHO	0.69±0.16
	COO^-	0.69±0.09
	Cl	0.66±0.12

The introduction of a second hydroxy-group into the benzene ring activates the latter still further for reaction with ·OH radicals, but the introduction of a third ·OH group deactivates it, as can be seen from a comparison of the following absolute rate constants ($10^{-9}k$, litre mole^{-1} s^{-1}): 3.8 for benzene[1], 7.5 for phenol[1], 10.7 for 1,3-dihydroxybenzene, and 5.7 for 1,3,5-trihydroxybenzene[22].

This effect may be attributed to a change in the hydroxylation mechanism, for example, the site of attack by ·OH radicals changing from the benzene ring to the hydrogen atom of the phenolic hydroxyl.

The relative rate constants (with DMNA as the acceptor) for the reactions of ·OH radicals with carbohydrates, polysaccharides, and certain aromatic compounds have been determined[24,25]. The authors believe that the protective properties of radioprotectors (inositol, propyl gallate, trihydroxypyridine derivatives) can be accounted for by the high rate of their interaction with ·OH radicals.

III. REACTIONS OF ·O$^-$ RADICAL-IONS

The ·OH radicals are known to dissociate at high pH according to the mechanism

$$\dot{O}H + OH^- \underset{k_2}{\overset{k_1}{\rightleftarrows}} \dot{O}^- + H_2O \ ;$$

the pK_a for the dissociation is 11.8 ± 0.2 (Rabani and Matheson)[11] and the rate of the forward reaction is a thousand times higher than that of the reverse reaction[26]:

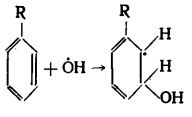
$$k_1 = (1.2 \pm 0.3) \cdot 10^{10}\ M^{-1}\ s^{-1},$$
$$k_2 = (9.2 \pm 0.2) \cdot 10^{7}\ s^{-1},$$

The study of the kinetics of the hydroxylation of organic substances in alkaline media at increasing pH values yielded information about the relative reactivity of the ·OH radical and its conjugate base ·O$^-$. It was found for reactions with phenols[22] that the relative rates of hydroxylation decrease with increase of pH (Tables 4 and 5). The following changes in the relative rate constants for the reactions of ·OH radicals with phenols have been found: 0.68 ± 0.02 at pH 9, 0.46 ± 0.10 at pH 12, and 0.28 ± 0.04 at pH 13. The constants at pH 13 are more than a factor of 2 lower than those at pH 9 (Table 4).

Table 4. Comparison of the relative rate constants for *ortho*-substituted phenols at pH 9 and 13.

Substituent	$k_{phenol}/k_{acceptor}$(pH 9)	$k_{phenol}/k_{acceptor}$(pH 13)
$-COO^-$	0.69±0.09	0.32±0.05
—CHO	0.69±0.16	0.27±0.06
$-CH_3$	0.90±0.15	0.33±0.03
$-OCH_3$	1.18±0.15	0.46±0.09

This is not related to the dissociation of the *ortho*-substituted phenols themselves, since, firstly, the formation of phenoxide ions would accelerate the addition of ·OH radicals because phenoxide anions are more powerful electron donors than the undissociated phenols and, secondly, at pH 12 and 13 phenols are completely ionised, while the ·OH radical is hardly dissociated at pH 9, at pH 12 the degree of dissociation is 50%, and at pH 13 the dissociation is almost complete. Consequently the decrease of the rate constants can be accounted for only by a lower reactivity of the radical-ions ·O$^-$ radicals compared with ·OH radicals. The data obtained for phenols agree with the conclusion[23] (Table 5) that ·O$^-$ is



much less reactive in both addition and electron transfer reactions, while reactions involving the abstraction of a hydrogen atom take place with equal efficiency when either of the two species is involved.

Table 5. Comparison of the relative rate constants for the reaction of ·OH radicals in acid, neutral, and alkaline media[23].

Substrate	0.05 *M* H_2SO_4	pH 6.98	0.1 *M* NaOH	1.0 *M* NaOH	Substrate	0.05 *M* H_2SO_4	pH 6.98	0.1 *M* NaOH	1.0 *M* NaOH

IV. THE MECHANISM OF HYDROXYLATION BY ·OH RADICALS

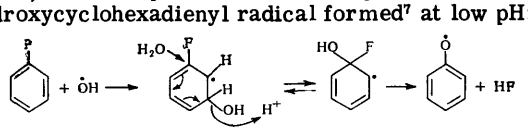
One may regard it as established that in the first stage hydroxy-radicals add to aromatic rings with the intermediate formation of hydroxycyclohexadienyl radicals[27-33] according to the mechanism

and do not abstract hydrogen from then with formation of phenyl radicals as suggested previously[34-38]. This is supported by the results of studies on the radiolysis of solutions of benzene in heavy water (D_2O) [29,30] and also by the direct observation of the spectra of hydroxycyclohexadienyl radicals in studies by pulse radiolysis[33] or by ESR in flow systems[32]. Hydroxy-radicals can also add initially to the substituent with a subsequent rearrangement involving a shift to the ring. It has been shown by pulse radiolysis[39] that ·OH radicals react with *p*-nitrophenol, adding to the nitro-group via the mechanism

$$\dot{O}H + OHC_6H_4NO_2 \rightarrow OHC_6H_4N\dot{O}_2 + H^+$$

with $k = (3.8 \pm 0.6) \times 10^9$ litre mole^{-1} s^{-1} and subsequent isomerisation of the resulting radical-ion into a hydroxycyclohexadienyl radical via the reaction

$$OH—C_6H_4N\dot{O}_2 + H^+ \rightarrow OH(OH)\dot{C}_6H_4NO_2 \quad ,$$



the pK_a of which is 14 ± 2 s^{-1}.

Hydroxy-radicals can also displace a ring substituent. For example, in the reaction between ·OH radicals and anisole, the methoxy-group is substituted with retention in the resulting phenol of the oxygen from anisole[40], in agreement with the following mechanism[41]:

$$C_6H_5OCH_3 + \dot{O}H \rightarrow C_6H_5\dot{O}CH_2 + H_2O \quad ,$$

$$C_6H_5\dot{O}CH_2 \xrightarrow{\dot{O}H} C_6H_5OCH_2OH \rightarrow C_6H_5OH + HCHO \quad .$$

However, such substitution also can occur with incorporation in the resulting phenolic hydroxyl of oxygen from water, for example via the acid fragmentation of the hydroxycyclohexadienyl radical formed[7] at low pH:

with subsequent conversion of the resulting phenoxy-radical into phenol containing oxygen from water.

A similar reaction can probably occur with benzene and many of its derivatives. For some of these, the incorporation of oxygen from water into the product of their oxidation by Fenton's reagent has been established[40,42]. The transfer of oxygen from water is not associated with a rapid exchange of hydroxy-radicals with water, as frequently suggested in the literature[43-45]. Indeed, calculation of the upper limit of the rate of exchange of hydroxy-radicals with water showed that it is slower by 3—4 powers of ten than the rate of reaction of these radicals with organic substances[46]: $0 \leq k < 7 \times 10^6$ litre mole^{-1} s^{-1}.

V. REACTIONS OF HO_2· RADICALS

The participation of HO_2· radicals in the hydroxylation of an aromatic ring has been postulated in a number of studies[47,48]. It has also been suggested that they do not possess electrophilic properties[47] and therefore yield different proportions of the isomeric products in the hydroxylation of the aromatic ring as compared with ·OH radicals and are less reactive than ·OH radicals towards aromatic compounds[49]. The reactivity of HO_2· radicals in aqueous solutions of aromatic compounds has been little investigated quantitatively. This is due to the difficulty of determining the rate constants for their reactions in the presence of the more reactive hydroxy-radicals, the mode of reaction of which is similar. There are only data for the oxidation of the sulphonates of indigo and certain other dyes, which have been obtained by the method of competing acceptors[50,51]. The relative rate constants for reactions of the dyes with HO_2· radicals generated by the γ-radiolysis of water were determined in such studies.

These reactions were carried out in the presence of oxygen in order to convert all the reducing species into HO_2· radicals; the pH was kept at 0.4 to avoid the dissociation of the HO_2· radicals (pK = 4):

$$H\dot{O}_2 \rightleftarrows H^+ + \dot{O}_2^-$$

and the reaction was carried out in the presence of added 2,5-dichlorohydroquinone which trapped quantitatively the ·OH radicals.

The rate constant for the reaction of HO_2· with the dye was calculated by considering the competition between the reactions

$$D + H\dot{O}_2 \xrightarrow{k_1} \text{colourless product} \quad ,$$

$$H\dot{O}_2 + H\dot{O}_2 \xrightarrow{k_2} H_2O_2 + O_2 \quad ,$$

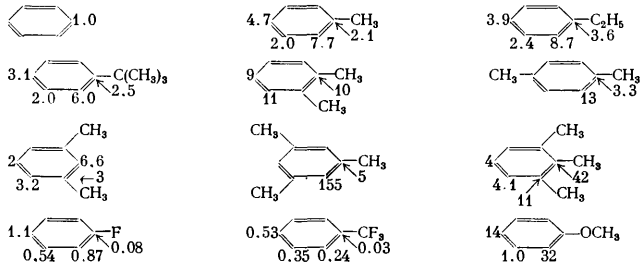
where D is the dye, using the equation

$$k_1 = \frac{0.693}{D^0_{1/2}} \sqrt{\frac{2k_2 I}{\alpha G_{HO_2}}} \quad ,$$

where $k_2 = 2.2 \times 10^6$ litre mole^{-1} s^{-1},[52] I the dose rate, $G_{HO_2} = 3.6$ the radiation yield in the formation of HO_2· radicals,[53] $\alpha = 1.66 \times 10^{-23}$ mole ml mol.$^{-1}$ litre^{-1} a conversion factor, and $D^0_{1/2}$ the dose at which the concentration of the dye diminished by 50%.

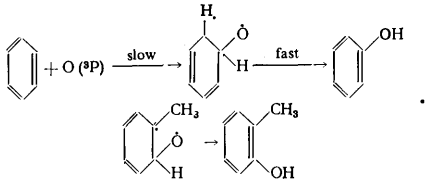
Table 6 lists the rate constants obtained in this way. They are approximately a million times smaller than the rate constants for the reactions of ·OH radicals with aromatic compounds, which indicates a much lower reactivity of HO_2· radicals compared with hydroxy-radicals.

VI. REACTIONS OF ATOMIC OXYGEN



The hypothesis of the intermediate formation and involvement of atomic oxygen in the ground $O(^3P)$ state in chemical and radiation-chemical processes in aqueous solutions has already been put forward in the literature[47,54]. Certain studies have also been made on the reactivity of $O(^1D)$ atoms in solutions. These atoms were generated by the photolysis of ozone at 2537 Å.[55,56] However, since the reaction of $O(^1D)$ with water is very rapid, high concentrations of the corresponding traps are required.

Table 6. Rate constants for the reactions of $HO_2^{\cdot}$ radicals with indigo sulphonates.



Dye	k_1, litre mole^{-1} s^{-1}
Indigo tetrasulphonate	$7.7 \cdot 10^2$
Indigo trisulphonate	$4.5 \cdot 10^3$
Indigo disulphonate	$8.5 \cdot 10^3$

The reactions of $O(^3P)$ oxygen in the ground state with aqueous solutions of aromatic compounds have been studied by the method of competing acceptors[57] developed by Amichai and Treinin[58]. $O(^3P)$ atoms were generated by the flash photolysis of BrO_3^- ions in the presence of molecular oxygen playing the role of the trap for $O(^3P)$. The partial rate factors for the formation of phenols in the reactions of $O(^3P)$ with substituted benzene were determined in the same study. The results are presented in Table 7.

Table 7. Partial rate factors for the formation of phenols in reactions of substituted benzenes with $O(^3P)$ at 30°C.

These data show that $O(^3P)$ atomic oxygen is electrophilic. The *ortho*-position is more reactive than the *para*-position, which is characteristic of radical reactions, for example those of ·OH radicals. A satisfactory correlation has been obtained ($r = 0.95$) with the logarithms of the partial rate factors for the *meta*- and *para*-positions and Hammett's σ^+ constant for $\rho = -1.15$. The negative sign of ρ indicates the electrophilic nature of $O(^3P)$, while the fairly high absolute value of ρ compared with the corresponding value for ·OH radicals is evidence of a greater selectivity of atomic oxygen compared with hydroxy-radicals. The following mechanism, analogous to that for hydroxylation by ·OH radicals, has been proposed for hydroxylation by atomic oxygen:

The low isotope effect found in the oxidation of an equimolar mixture of benzene and deuteriobenzene ($k_H/k_D = 1.14 \pm 0.04$) shows that the C—H bond is not dissociated in the rate-determining step of the reaction, in agreement with the proposed mechanism.

The absolute rate constant for the oxidation of benzene by atomic oxygen, determined by Grovenstein et al.[57], is $k_{25°} = 1.2 \times 10^7$ litre mole^{-1} s^{-1}.

Comparison of the reactivities of the radicals ·OH, $\cdot O^-$, and $HO_2^{\cdot}$ and the $O(^3P)$ oxygen atoms has shown that the hydroxy-radicals are the most reactive among them (Table 8). The reactivity of their dissociated form $\cdot O^-$ is somewhat lower (by a factor of 3—4). The oxygen atoms are less reactive than ·OH radicals approximately by a factor of 300 and the reactivity of the $HO_2^{\cdot}$ radicals is lower still—by 5—6 powers of ten.

In conclusion, we may mention that the rate constants for the reactions of hydroxy-radicals with organic compounds in aqueous solutions have been compiled by Metelitsa[48], Denisov[59], and Anbar and Neta[60].

Table 8. Comparison of the rate constants for the reactions of ·OH, $\cdot O^-$ and $HO_2^{\cdot}$ radicals and $O(^3P)$ oxygen atoms.

Species	k, litre mole^{-1} s^{-1} Compound oxidised		
	benzene	phenol	indigo disulphate
·OH	$3.8 \cdot 10^9$ [1]	$7.5 \cdot 10^9$ [1]	—
$\cdot O^-$	—	$2.1 \cdot 10^9$ [22]	—
$O(^3P)$	$1.2 \cdot 10^7$ [57]	—	—
$HO_2^{\cdot}$	—	—	$8.5 \cdot 10^3$ [61]

New Aspects of Polycyclisation

E.S.Krongauz

The review deals with a comparative discussion of polycyclisation processes and the prospects of the polycyclisation method in the synthesis of thermostable polymers. The bibiography includes 221 references.

I. INTRODUCTION

During the last 10–15 years, increasing attention has been devoted in many world scientific centres to an active search for new ways of synthesising polymers containing various cyclic groups in the macromolecules. The reason for this is, on the one hand, the ease of their formation due to the favourable thermodynamics and kinetics of such reactions (particularly of the formation of five- and six-membered systems) and, on the other hand, the importance and wide variety of their applications in man's practical activities.

The rapid development of these investigations is largely related to the fact that they are directed to the solution of one of the most urgent problems in the modern chemistry of macromolecular compounds presented by modern engineering techniques now being developed, namely the creation of materials with special properties.

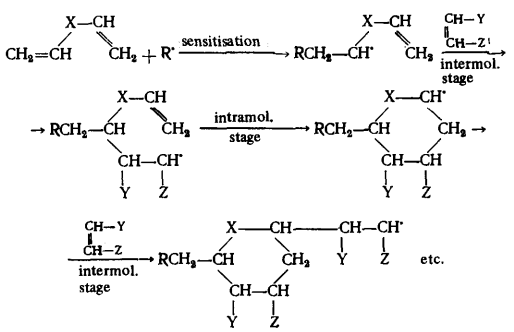
The development of new macromolecule formation reactions led to the appearance of the class of polyheteroarylenes—polymers the macrochains of which consist of aromatic carbocycles and heterocycles. Many of these polymers have a high heat resistance and thermal and chemical stability, useful deformation-strength characteristics, satisfactory electrical conductivity and photoconductivity, etc.

A significant role of the same reactions in natural processes can be postulated with a high degree of probability, since, for example, cyclic forms are known to be important in the structure of protein. The pathways leading to the formation and decomposition of macromolecular compounds in nature are still obscure. However, the synthesis of high polymers which are the most important biologically—proteins, higher carbohydrates, and nucleic acids—and the study of their nature, metabolism, etc. are virtually impossible without simulating the functions of these natural compounds by synthetic polymers.

Studies in the field of cyclic polymers have been very numerous; the reactions used for their synthesis have also been extremely varied. Nevertheless, despite the different nature of these reactions, they can be combined under the single concept of polycyclisation, because they lead to polymeric structures the final form of which is in fact determined by cyclisation processes. The synthesis of a cyclic polymer can occur in a single-stage or via the formation in the first stage of an intermediate linear macromolecule containing fragments capable of subsequent cyclisation.

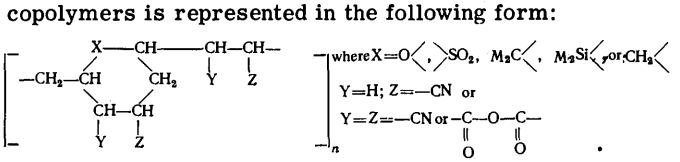
Processes already familiar, such as cyclopolymerisation and cyclocopolymerisation, the Diels–Alder reaction, 1,3-dipolar cycloaddition, polycyclotrimerisation, and polyheterocyclisation, are also polycyclisation reactions. The reactions enumerated above can be divided into two groups: (1) processes in which chain propagation is coupled to the formation of rings, as, for example, in Butler cyclopolymerisation and in polycycloaddition reactions and (2) single- or two-stage polyheterocyclisation processes (including the synthesis of ladder and parquet structures) and polycyclotrimerisation in which the stages involving the formation of linear and cyclic polymers may be separated.

The formation of polycyclic compounds constitutes an irreversible process and may be regarded as an example of non-equilibrium polymerisation reactions. The energy relations of these reactions and also their feasibility are mainly determined by the structural changes in the chemical bonds and by the appearance of qualitatively new bond systems.



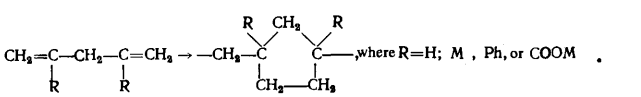
In the course of studies on these reactions, there has been a significant change in traditional ideas about functionality, introduced into polymer chemistry by its founder (Staudinger [1]), according to which it was believed that linear macromolecules can be formed only by the interaction of bifunctional polymers, while monomers with a large number of functional groups give rise to the formation of branched and cross-linked products. Polycyclisation is virtually based on tetrafunctional starting materials and leads ultimately to cyclolinear polymers.

In recent years investigators have paid increasing attention to the mechanism and kinetics of the formation of cyclochain polymers and also to a more detailed study of the properties of the latter. The results of the investigation of cyclochain polymers are described in an extensive original literature, in many review articles [2-14], and monographs [15-20].

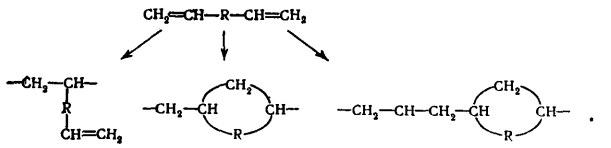


This review deals with a comparative discussion of polycyclisation processes and their influence on the properties of polymers, attention being concentrated on methods whereby thermostable polymers may be synthesised.

II. CYCLOPOLYMERISATION AND CYCLOPOLYMERISATION

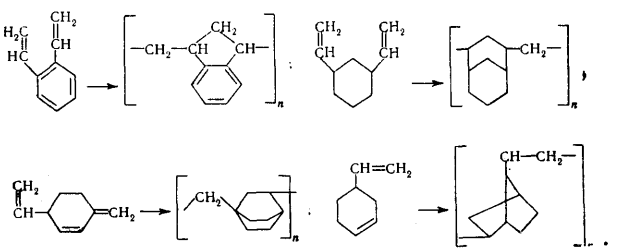


In 1951 Butler and Ingley [21] established that, contrary to theoretical predictions [1], dialkyldiallylammonium salts form non-cross-linked linear polymers and, in order to account for these results, put forward an intramolecular–intermolecular mechanism, which proved to be common to reactions involving the conversion of 1,6-dienes into cyclopolymers [22,23]. Later Butler [24,25] reported the copolymerisation of certain dienes with mono-olefins proceeding via an alternative intramolecular–intermolecular mechanism:



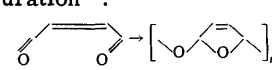
The first example of this kind was the cyclopolymerisation of vinyl ether and maleic anhydride; subsequently the reaction was extended to a wide range of dienes, alkynes and SO_2. [26-29] The general structure of the resulting copolymers is represented in the following form:

Apart from the fundamental work of Butler and coworkers, mention should be made of the wide range of studies by Marvel's school and many other investigators in which the scope of cyclopolymerisation was greatly extended and its kinetics and mechanism were investigated. Thus it was shown that symmetrical 1,5-dienes are polymerised similarly to 1,6-dienes with a high degree of cyclisation, forming polymers containing five-membered rings in the macromolecules [30-32]:



Asymmetric 1,5- and 1,6-dienes and other non-conjugated dienes are capable of homopolymerisation and cyclisation, particularly in those cases where the reactivities of the two double bonds are comparable; otherwise cyclopolymerisation, branching, and cross-linking reactions compete and the contribution of each to the overall process may vary considerably [33-35].

It was noted that the polymerisation of asymmetric dienes and the copolymerisation of two monomers have many features in common and the relation between the cyclisation and copolymerisation parameters is determined by the nature of the multiple bonds of the monomers [35]. Polymers containing different macrorings in the chain were obtained by the cyclopolymerisation of higher $\alpha\omega$-diolefins in which the double bonds are separated by 4–18 methylene groups [36-40].

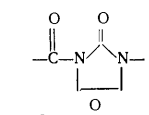


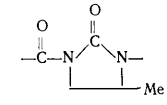
The polymerisation of dienes containing cyclic groups, which leads to the formation of bicyclic structures in the absence of steric hindrance, has been described. Thus *o*-divinylbenzene [41], *cis*-1,3-divinylcyclohexane and *cis*-1,3-divinylcyclopentane [42], and 1-methylene-4-vinylcyclohexene and 4-vinylcyclohexene [43] polymerise according to the following equations:

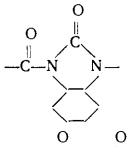
The formation of bicyclic and tricyclic structures is also possible in polymerisation of branched open-chain trienes and tetraenes; thus Trifan and coworkers [44] reported the synthesis of soluble polymers with a low degree of unsaturation from triallylethyl- and tetraallyl-ammonium bromides and also from 3-vinylhexa-1,5-diene.

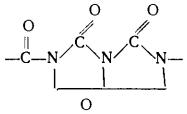
The polymerisation of monomers containing double bonds between carbon atoms and heteroatoms, for example, dialdehydes [45-50], di-isocyanates [7,51], dinitriles [7,52], and epoxy-compounds, has been investigated in recent years.

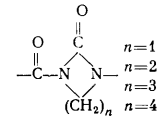
Systematic studies on the effect of temperature, solvents, catalysts, and monomer concentration on the rate of polymerisation and on the molecular weight of the polymer formed have shown that the mode of reaction, its rate, and the polymer structure are determined not only by the nature of the monomer, but also to a considerable degree by the type of catalyst employed, its amount, the presence of water, and other factors [7]. Thus the studies of the structure of the polymer obtained by the cyclopolymerisation of maleic aldehyde by infrared and NMR spectroscopy have shown that, in contrast to cationic and Ziegler catalysts, anionic catalysts promote the formation of the *cis*-configuration [45]:





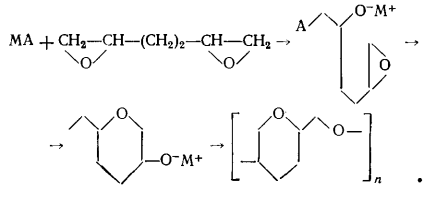






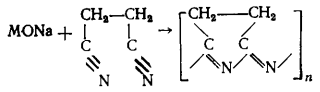
In the case of *o*-phthalodialdehyde, the amount of the *cis*-form is also determined by the catalyst employed,

decreasing in the following sequence: γ-irradiation > cationic catalysts ≥ anionic catalysts > coordination catalysts [50].



Anionic catalysts, polar solvent, and a temperature in the range between −50° and −75°C are most suitable for the cyclopolymerisation of di-isocyanates [7]. Polymers of this type are listed in Table 1.

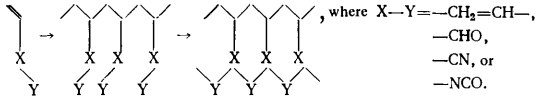
Table 1. Cyclopolymers of aliphatic di-isocyanates [7].



Monomer [a]	Structure of polymer unit	M.p., °C	β_{int} [b]	Solvent
1,2-Diethylene di-isocyanate [c]		365	0.85	H_2SO_4, TCE–phenol (40:60)
1,2-Triethylene di-isocyanate		287	1.35 0.56 [c] 0.72 [d]	HCOOH, DMSO, DMF, nitromethane
1,2-Cyclohexylene di-isocyanate		303	0.38	Pyridine, nitromethane, DMSO
1,2,3-Triethylene tri-isocyanate		365—400	0.28 [e]	H_2SO_4
αω-Polymethylene di-isocyanate		350 270—280 350 350		DMSO DMSO *m*-Cresol Ethylene carbonate

[a] Polymerisation in DMF between −30° and −50°C with NaCN as catalyst.
[b] β_{int} of 0.5% solution in 40:60 TCE–phenol mixture at 30°C.
[c] Polymerisation without catalyst.
[d] The molecular weight, determined osmometrically in nitromethane solution, is 45 000.
[e] Polymerisation in bulk at 0°C in a stream of nitrogen.
[f] In sulphuric acid.

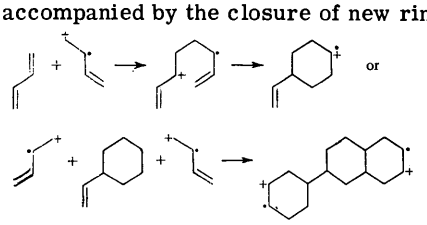
The cyclopolymerisation of diepoxy-compounds can be achieved in the presence of a wide range of catalysts, which may include tri-isobutyl and tri-isopropyl-aluminium, PF_5–H_2O, diethylzinc, and others. Depending on the structure of the initial monomer, tetrahydrofuran or pyran rings are formed. The polymer having the highest molecular weight (η = 0.45 dl g^{-1}) but with limited solubility is that of 1,2,5,6-diepoxyhexane obtained in the presence of the $ZnEt_2$–H_2O system; the author suggested an anionic polymerisation mechanism [52]:



The cyclopolymerisation of various dinitriles in methanol in the presence of sodium methoxide via the mechanism

has been described [52]. n may vary, depending on the reaction conditions, from 6 to 65. There is a possibility of the incorporation in the polymeric skeleton of other structures, including the triazine structure.

Interesting results have been obtained in the study of the cyclopolymerisation of three types of bifunctional monomers with fixed (in the 2-position of the six-membered ring) double bonds [54]: (a) monomers with two C=C bonds (*o*-divinylbenzene, *cis*-1,2-divinylcyclohexane); (b) monomers containing two C=O bonds (*o*-phthalodialdehyde, *o*-formylphenylacetaldehyde); (c) monomers containing one C=O bond and one C=C bond (*o*-vinylbenzaldehyde). Although the structural characteristics of the monomers favour cyclopolymerisation, chain propagation in these polymers is different and is determined in the present case by the nature of the monomer. A stepwise chain propagation has been suggested for the cationic polymerisation of *o*-divinylbenzene; the polymerisation of monomers such as *cis*-1,2-divinylcyclohexane and *o*-phthalodialdehyde takes place, according to the author, via a concerted mechanism, while in the cationic polymerisation of *o*-vinylbenzaldehyde both mechanisms operate [53].



A very interesting and important aspect of the cyclopolymerisation reaction from the standpoint of the synthesis of thermostable and semiconducting materials is its employment for the synthesis of ladder and doubly cross-linked structures. Polymers of this type may be obtained both by the cyclopolymerisation of the corresponding linear polymers containing terminal multiple bonds within the framework (for example *cis*- and *trans*-polybuta-1,4-dienes [54], polyisoprenes [55,56], polyacrylonitrile [57], and polycyanoacetylene [58]) and directly by the cyclopolymerisation of diene or diyne monomers in the presence of cationic catalysts [59–65], which may be represented as follows in a general form:

The most probable mechanism of the conversion of conjugated diene monomers (or polymers) into ladder structures is one of the cationic-radical type [63,64], according to which the formation of active centres takes place via the transfer of one electron from the monomer molecule to the electron-accepting component of the catalyst A^+:

The radical-cations formed react further either with a monomer molecule or with a double bond of the polymer, this being accompanied by the closure of new rings:

It was established that identical structures are formed as a result of the cyclopolymerisation of *cis*-1,4-, *trans*-1,4-, *cis*-3,4-, and *trans*-3,4-polyisoprenes by a Ziegler-Natta catalyst [62]. At the same time, depending on the structure of the radical-cation (1,2- or 1,3-), the polymers formed have the perhydroanthracene or perhydrophenanthrene structures respectively [63,64].

In principle, cyclopolymerisation can be achieved by radical, ionic, or coordination mechanisms depending on the catalyst employed (Tables 2 and 3) and also under the influence of ultraviolet light or γ-radiation. Under these conditions, monomers containing non-conjugated double bonds show a greater dependence on the catalyst, since the different reactivities of the double bonds require more favourable conditions for the intramolecular reaction. Thus allyl acrylate reacts with azobisisobutyronitrile to form polymers containing 60 mole % of lactone groups [39], whereas anionic catalysts give rise exclusively to polymerisation involving the double bond of acrylic acid [92,93]. At the same time, a monomer such as 2,6-diphenylhepta-1,6-diene forms only a cyclopolymer in the presence of catalysts of any type [68].

Usually the cyclopolymerisation of monomeric compounds is carried out in an emulsion or in dilute solutions (at a concentration of about 0.1 M), which tends to increase the yield of soluble polymers; only a few examples of the cyclopolymerisation of monomer in the solid state are known [83].

Interesting results have been obtained in the study of the controlled and directed cyclopolymerisation of butadiene [89] and the anhydride of methacrylic acid [93,94] with radical sensitisation of the process. On the basis of data for the mechanism of free-radical polymerisation at different temperatures and after a comprehensive investigation of the specimens obtained [95–97], it was concluded that the intermolecular stage of the cyclopolymerisation process takes place stereoselectively. Reaction temperature and the predominance of one of the pyramidal structures of the strained cyclic radical formed are then of decisive importance; the axial mode of addition leads to syndiotactic stereoregularity which in the ideal case involves the presence of *ddll*-sections throughout the chain [98].

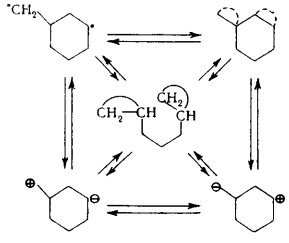
Numerous studies, particularly on cationic and radical systems, have been undertaken to elucidate the cyclopolymerisation mechanism. Nevertheless there is at present no theory which would yield a clear explanation of the alternation of intramolecular and intermolecular "cyclopolymerisation" steps. The latest advances in the field of anionic cyclopolymerisation and their comparison with the results quoted in a number of publications concerning radical and cationic systems, enabled Butler and coworkers [7] to make certain generalisations concerning the cyclopolymerisation mechanism.

In a general form, the cyclopolymerisation mechanism can be represented by the following scheme:

Scheme 1

where R* may be a radical, cationic, or anionic catalyst.



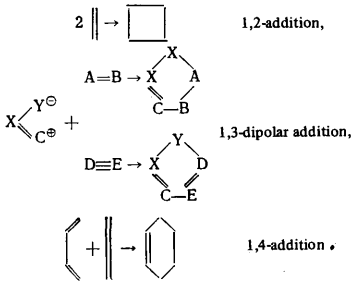
The initiator R* reacts with the terminal carbon atoms of the diene yielding the structure (II), the remaining double bond of which is involved in a further intramolecular cyclisation. The cyclic structure (III) then reacts intermolecularly with another diene molecule, this being continued until the formation of the polymer (IV). Nor can one rule out the possibility of the conversion of structure (II) via intermolecular propagation into a linear polymer (V). Therefore the most important factors here are the stability of structures (II) and (III) and the relative rates of reactions B and C.

Evidently, if the intramolecular process takes place more slowly than intermolecular reactions, the polymer will contain a large number of unsaturated groups; on the other hand, if the intramolecular process is faster than the intermolecular process, a linear and saturated polymer is obtained. It was found that the cyclisation constant k_c is then independent of the concentration of monomers and the degree of cyclisation of the polymer is determined by the ratio k_c/k_p.

Statistical calculations on the cyclopolymerisation reactions carried out by Butler and Raymond [99] for 1,6-dienes selected as model compounds showed that theoretically the monomer concentration required for the attainment of 95% cyclisation must be reduced to 0.10 M. However, in practice, polymers with 95–100% cyclisation have been obtained at a monomer concentration of 1.9–8.0 M. To account for this contradiction, the authors proposed two schemes taking into account electronic effects and steric factors; however, none of these can provide an answer to questions such as, for example, why the activation energy for cyclisation is equal to or greater than the activation energy for linear chain propagation and why the reactivity of diolefinic monomers is frequently higher than that of the analogous mono-olefins.

Therefore the only possible conclusion has now been reached that steric and entropy effects, the probabilities of the intramolecular and intermolecular steps, thermodynamic stability, and electronic effects in the transition states make a contribution to the cyclopolymerisation mechanism. The ease of cyclisation may be due to the electronic interaction between the double bonds of the 1,6-dienes or between the reaction centres formed on attack by the sensitiser and the intramolecular double bond, as can be seen from the scheme below [3,100]:

Scheme 2



The steric resonance interaction, which constitutes the driving force of the cyclopolymerisation reaction, leads to a bathochromic shift in the ultraviolet spectra.

Similar investigations carried out on allylsilanes showed that the magnitude of the shift is satisfactorily consistent both with calculations by the molecular orbital method and with experimental observations on the polymerisation of diallyl-, [80,81,101] triallyl- and tetra-allyl-silanes [102]. The activation energy for the cyclopolymerisation of allylsilanes calculated per double bond is 9 kcal mole^{-1}. [103]

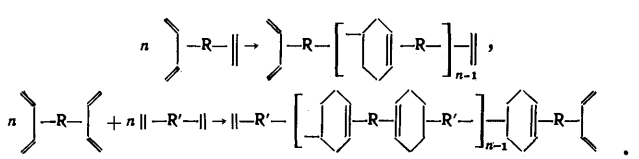
Further development of hypotheses concerning the cyclopolymerisation mechanism involves the accumulation of new data in the field of anionic processes and also the verification with the aid of new experimental techniques of the results obtained in radical and cationic systems.

III. POLYCYCLOADDITION

The use of cycloaddition reactions, which are well known in organic chemistry, for the synthesis of polymers may be regarded as a further development of methods for the synthesis of macromolecules [15];

The 1,2-addition reactions are little used in the synthesis of polymers owing to difficulties in the synthesis of the monomers and because the strain in the resulting cyclobutane ring gives rise to instability of the polymers.

1. 1,3-Dipolar Cycloaddition



1,3-Dipolar cycloaddition reactions have found some application in the synthesis of polymers, since the bifunctional monomers are relatively easily synthesised and the majority of dipolar addition reactions take place quantitatively. Moreover, the above method is interesting because it makes it possible to introduce into the polymer chain the greatest variety of five-membered heterocyclic systems and is frequently used in those cases where other methods are less effective; if the dipolarophiles contain triple bonds, for example acetylenes or nitriles, and the dipole has an atom Y with a lone electron pair, the resulting heterocycle is aromatic (it includes a π-electron sextet), which is the reason for the high thermal stability and heat resistance of the corresponding polymers.

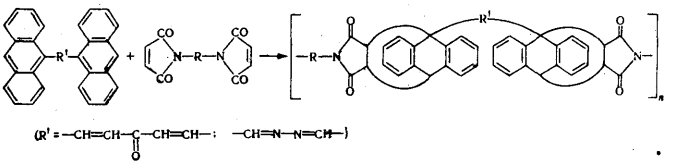
The main types of polymers synthesised by the 1,3-dipolar addition reaction are listed in Table 4. It is noteworthy that the formation of a mixture of polymeric products with different positions of substituents in the heterocycles is possible in many cases.

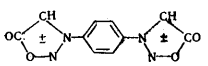
2. The Diels–Alder Reaction

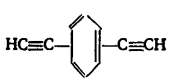
The Diels–Alder reaction is achieved by the interaction of a diene and a dienophile; the latter include maleic anhydride, acrolein, vinyl monomers, and also various quinones. The Diels–Alder polymerisation can be achieved starting with monomers containing in a single molecule both diene and dienophile functional groups or via

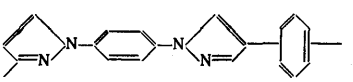
the copolymerisation of bisdienes with bisdienophiles according to the following mechanisms [11]:

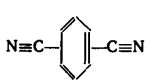
Polymers with high softening temperatures have been obtained by the interaction of 1,5-di-(9-anthryl)penta-1,4-diene and anthryl azine with benzidine-bismaleimide [11]:

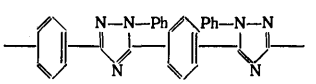


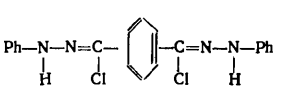


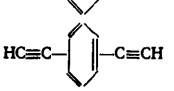


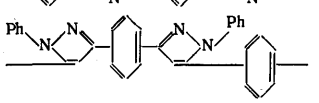


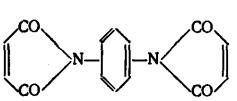


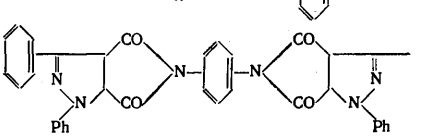


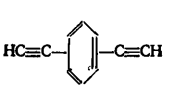


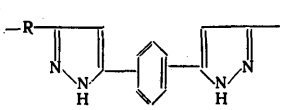


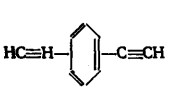


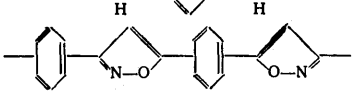


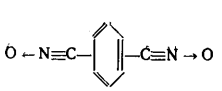


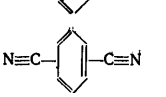


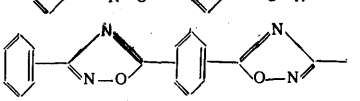


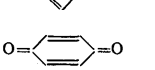


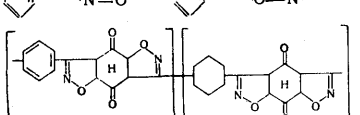


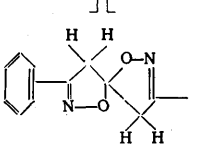


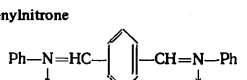


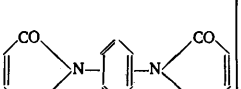


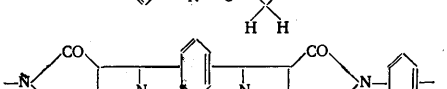


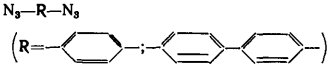


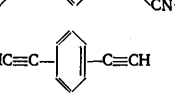


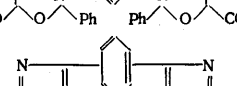


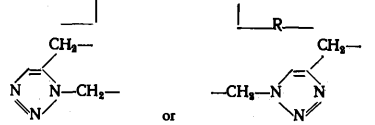


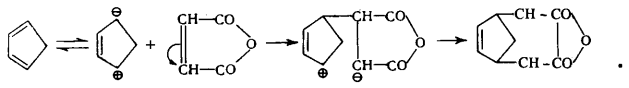












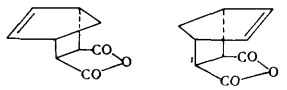


Table 4. Types of polymer synthesised by the dipolar 1,3-addition reaction.

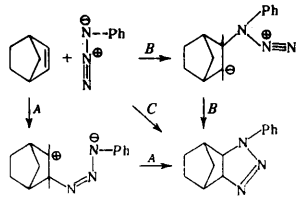
Although the Diels–Alder polymerisation includes reactions of unsaturated compounds and the resulting polymers do not have a structure typical for condensation products, the synthesis of the polymer itself resembles polycondensation. In a general form, this reaction involves the π electrons of both components and the formation of a dimeric product according to the mechanism

In the interaction of cyclopentadiene with maleic anhydride, two forms of addition are possible, but the *endo*-form is produced preferentially [11]:

exo-form *endo*-form

In many cases, the synthesis of polymers with regular structures has been achieved by the Diels–Alder reaction [11]. Thus the polymers obtained by the reaction of cyclopentadienes, α-pyrones, or thiophen dioxides with bismaleimides contain bicyclo[2,2,2]octene rings in which the imide groups are in the *exo*-position. Even reactions in which both these forms are produced should lead to chains with a certain degree of order in the distribution of *endo*- and *exo*-groups in relation to the chain.

Polymers obtained by the Diels–Alder reaction are as a rule amorphous, but their amorphous nature does not rule out the possibility of stereoregularity [11].

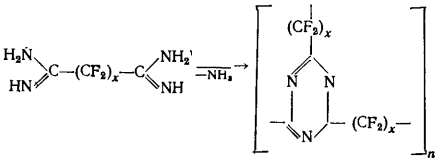


Kinetic studies have shown that polymerisation includes a number of individual reactions and is a stepwise and not a chain process. Therefore, the equation for second-order reactions $-dc/dt = KC^2$, where C is the concentration of the terminal diene and dienophile groups, should hold for the Diels–Alder reaction. The decrease of the rate on dilution of the solutions and on decrease of the molecular mobility of the reactants is typical for the Diels–Alder reaction.

The degree of polymerisation in the Diels–Alder reaction depends on its duration, since at the beginning oligomers accumulate in the reaction mixture and are gradually converted into products with a higher molecular weight. However, one should bear in mind that the Diels–Alder reaction is reversible and that at high temperatures the polymeric products may decompose into dienes and dienophiles. It is postulated that the dissociation takes place more readily in the centre of the molecular chain than at its ends, which leads to a narrowing of the molecular weight distribution [11].

Despite the fact that in many cases a biradical mechanism has been postulated for the Diels–Alder reaction [113], the vast majority of experimental data are consistent only with a synchronous mechanism [114] of the $[\pi 4 + \pi 2]$-cycloaddition type with retention of orbital symmetry [115,116].

The mechanism of the 1,3-dipolar cycloaddition reaction involving polymers has not yet been investigated. However, since there is sufficient information about 1,3-dipolar addition reactions of low-molecular-weight substances, certain comparisons may be made and conclusions reached [112]. 1,3-Dipolar polyaddition has much in common with polymerisation via the Diels–Alder reaction: it is an example of ionic [4 + 2]-cycloaddition, because, although the molecules of 1,3-dipolar compounds involved in cycloaddition reactions are formally neutral, they usually behave as three-orbital 4π-electron species [117].

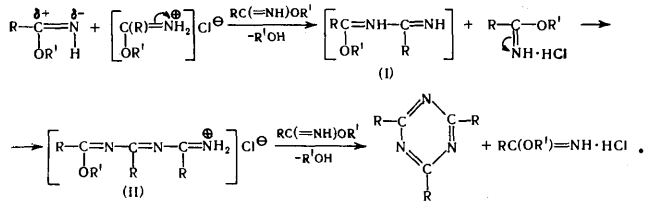


Analysis of 1,3-dipolar addition [115–118] and Diels–Alder reactions on the basis of the rule of conservation of orbital symmetry [119] has demonstrated the similarity of these two processes, which makes it possible to classify the former as pseudo-Diels–Alder reactions and suggests that they have similar kinetics and mechanism. Of the three theoretically possible mechanisms for the addition of a 1,3-dipole to double and triple bonds, illustrated for the interaction of phenyl azide with bicycloheptene as an example, the most likely is mechanism (*C*) with cyclic electron transfer and simultaneous formation of two new bonds [117]:

[(*A*) the positive end of the dipole initiates attack; (*B*) the negative end of the dipole initiates attack; (*C*) the addition takes place simultaneously]. According to mechanism (*C*), the synchronous electron shift leads to the formation of two new σ bonds and enables all three nitrogen atoms to reach octet stability without carrying a formal charge.

IV. POLYCYCLOTRIMERISATION

Polycyclotrimerisation can be achieved both as a polycondensation and a polymerisation process, which results in the formation of carbocyclic or heterocyclic polymers. The polycyclotrimerisation reaction was used for the first time to synthesise polymers by Brown [120–122], who described the polycondensation of diamidines with evolution of ammonia and the formation of cross-linked polytriazines:

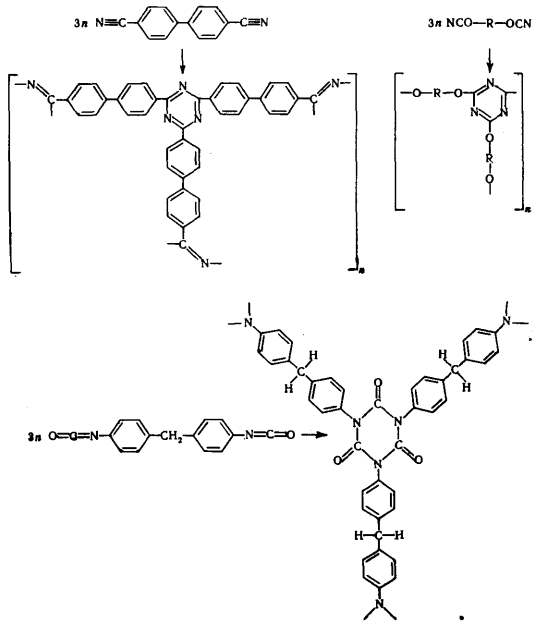


The addition of monoamidines appreciably suppresses the structure-formation process but nevertheless does not altogether rule it out owing to the considerable difference between the reactivities of mono- and bi-functional monomers.

In the course of further studies, the characteristics of this reaction and of the polycyclotrimerisation of fluorinated and non-fluorinated iminoesters were investigated in the presence and absence of catalysts, namely the dependence of the thermal degradation and other properties of the polymers obtained on the nature of the group linking the triazine rings; much attention has been devoted to problems of the processing and applications of triazine rubbers [123–134].

Yakubovich et al. [131] believe that the condensation of iminoester groups into triazine rings proceeds via a series of consecutive stages leading to the formation of a

linear "dimer" (I) and "trimer" (II). The resulting hydrochloride of the linear "trimer" (II) cyclises into the more stable *s*-triazine systems via the mechanism [135]

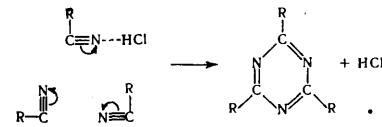


Presumably the electrophilic properties of the carbon atom in iminoesters are insufficient to ensure the effective addition of a second iminoester molecule to the C=N double bond; therefore the cyclisation of the free bases of the iminoesters takes place only in the presence of the iminoester hydrochloride, in which the electrophilic properties of the carbonyl carbon atom are enhanced owing to the presence of 'onium nitrogen and the associated shift of the π-electron density of the double bond:

The substitution of hydrogen atoms in the alkyl group of bisiminoesters by fluorine increases the electrophilicity of the carbonyl carbon atom to such an extent that the triazine ring is formed also in the absence of a catalyst [134]. In order to obtain linear polytriazines under these conditions, it is necessary that one position in the triazine ring should be substituted by a non-reactive side group and the remaining two should be involved in the formation of the polymer chain.

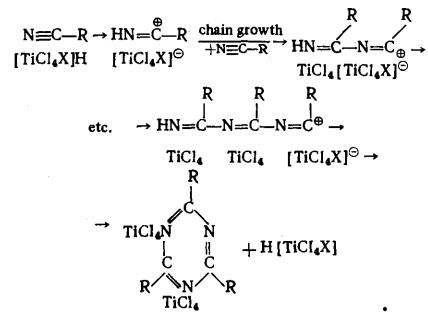
Examples of polycyclotrimerisation are provided by the formation of polymers with triazine rings from aromatic dinitriles, aryl cyanurates, or aryl di-isocyanates [14].

Scheme 3



The reason for the tendency of compounds containing C=N bonds to form stable cyclic trimers is that, on conversion of monomers into trimers, the enthalpy of the π bond is lost; moreover, the cyclic trimer is stabilised owing to the combination of the most favourable valence angles (120°) and the planarity of the resulting ring, which makes possible the existence in the trimer of a stable aromatic system [136-139]. The inclusion of stable aromatic systems between triazine rings is responsible for the high thermal stability of the polymers [138].

The cyclotrimerisation of nitriles may be accelerated by many catalysts, for example, by the halides of coordination-unsaturated metals. The presence of a lone electron pair and of π bonds in the C≡N group promotes the formation of highly electrophilic molecular complexes with Lewis acids. It is suggested that the addition of more than one equivalent of the electrophilic compounds to a nitrile is due to the formation of the so called π complexes [140].



Hydrogen halides are used most often among compounds inducing the cyclotrimerisation of nitriles [141], but reactants such as sulphuric and chlorosulphonic acids, Lewis acids, and others can also serve as catalysts [142-145]. The ease of formation of the *s*-triazine ring in the presence of HCl is probably due to the possibility of a cyclic electron transfer via Scheme 4: [146,147]

Scheme 4

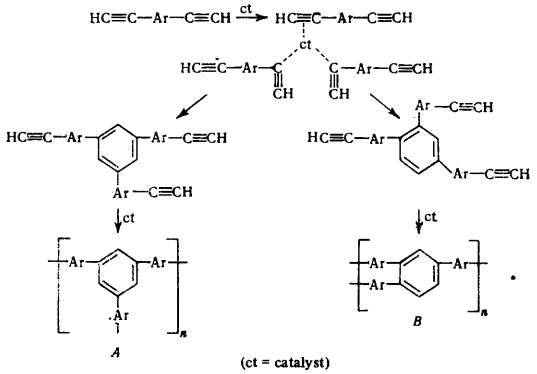
According to Scheme 4, both the free nitrile and its complex with the hydrogen halide is involved in the formation of triazines.

Interesting results have been obtained by Kargin and coworkers [148-153] in a study of the mechanism and kinetics of the polymerisation of benzonitrile with compounds such as $TiCl_4$, $ZnCl_2$, and BF_3. [149] They also showed that triphenyltriazine is an intermediate in the formation of a linear polymer with a polyene structure and that the complex $[TiCl_4X]H$, formed in the interaction between the complex-forming agent and proton-containing additives, serves as a centre for chain initiation [152]:

Petrov et al. [154] studied the kinetics of the cyclotrimerisation of di-isocyanates by infrared spectroscopy using as a test object the polymer obtained by the interaction of one mole of low-molecular-weight polybutadiene (mol. wt. 4000) containing terminal OH groups with 2 moles of 2,4-tolylene di-isocyanate in the presence of a catalytic system including glycidyl phenyl ether and dimethylbenzylamine in different proportions. It was shown that the cyclotrimerisation of isocyanate groups corresponds to a quasi-monomolecular reaction up to 70–90% conversion; the rate of cyclotrimerisation is directly proportional to the product of the initial concentrations of the tertiary amine and the epoxyalkane. The author suggested that the cyclotrimerisation reaction is a special case of anionic polymerisation [154].

The results have been explained in terms of the stepwise Beitchman mechanism [155], according to which the addition of the first, second, and third isocyanate (M) molecules to the catalytic complex (N) takes place in the same way:

$$N + M \xrightarrow{k} NM,$$



$$NM + M \xrightarrow{k} NM_2,$$

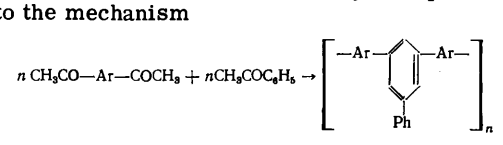
$$NM_2 + M \xrightarrow{k} M_3 + N.$$

Although the closure of the isocyanate ring, accompanied by the elimination of the catalyst, is most likely in the trimer stage, in principle the formation of a linear polymer or the arrest of reaction at the dimer stage are possible.

Korshak, Sergeev, and coworkers [156,157] achieved the polycyclotrimerisation of diethynyl compounds in bulk and in solution in the presence of complex catalyst which consisted of various complexes of cobalt, nickel, and other transition metals capable of catalysing the cyclisation of acetylenes into benzene and its derivatives. The overall mechanism of the polycyclotrimerisation of diethynyl compounds may be regarded as involving the consecutive trimerisation of ethynyl groups leading to chain propagation, branching, and cross-linking (see Scheme 5).

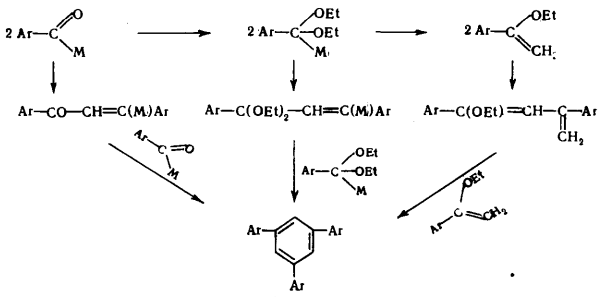
Scheme 5

(ct = catalyst)



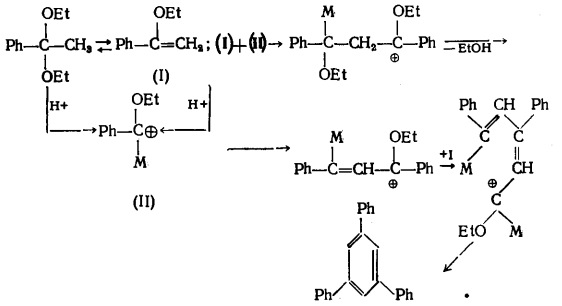
The study of the infrared and NMR spectra showed that polycyclotrimerisation results in a decrease of the intensity of the absorption band corresponding to the stretching vibrations of the ≡C–H linkages (3300 cm^{-1}) and an increase of the vibration frequency of the hydrogen atoms linked to the benzene ring.

The formation of 1,3,5- and 1,2,4-substituted benzenes depends on the nature of the catalyst metal and the ligand [156,157]. The use of a mixture of diethynyl and monoethynyl compounds make it possible to regulate the degree of branching of the polymer formed:



On heat treatment, oligomeric polycyclotrimerisation products are converted into an infusible and insoluble state.

Korshak, Teplyakov, and coworkers [158,159] proposed a new method for the synthesis of polyphenylenes via the polycondensation of aromatic diacetyl compounds according to the mechanism



However, as in the trimerisation of acetylenic compounds, it was found that the use of diacetyl monomers alone leads rapidly to the formation of three-dimensional products. Therefore, one usually employs equimolar mixtures of di- and mono-acetyl compounds, although in this case too gel formation is observed in the course of the reaction.

The authors showed that the formation of the benzene ring is a fairly complex process including as an intermediate stage the crotonic condensation of the acetyl groups, resulting initially in the formation of a dimer and then a trimer, the intramolecular cyclisation of which yields 1,3,5-substituted benzene rings. The catalytic effect on the reaction by ethyl orthoformate, which apparently promotes the conversion of acetyl compounds in an acid medium into more reactive ketals, has been noted. In this case, the mechanism of the possible fundamental steps in the formation of polyphenylenes can be represented as follows [158]:

A detailed study has been made of the cyclocondensation of acetophenone ketal, which can serve as a model for the synthesis of polymers. Mass-spectrometric analysis established that a certain amount of α-ethoxystyrene, dypnone [1,3-diphenyl-2-buten-1-one], and 1,3,5,7-tetraphenylcyclo-octatetraene is formed in the course of the reaction together with triphenylbenzene [159]. Kinetic investigations established that the cyclocondensation of acetophenone ketal is described by the equation for second-order reactions with a rate constant of $(1.2-1.4) \times 10^{-1}$ litre $mole^{-1}$ min^{-1} at 20°C.

The authors proposed the following mechanism for the condensation of acetophenone ketal on the basis of the results obtained:

The employment of diacetylarylene bisketals together with acetophenone ketal makes it possible to achieve polycondensation and to obtain soluble linear polyphenylenes consisting of oligomers with a molecular weight up to 3000. The oligophenylenes are hardened by heat treatment in an inert atmosphere at 300°C using toluene-*p*-sulphonic acid as the catalyst; the hardened polyphenylenes are infusible and insoluble; they are decomposed vigorously in air at about 400°C. The infrared spectra

of the heat-treated polyphenylenes show no absorption whatever due to the vibrations of the terminal ketal groups.

V. POLYHETEROCYCLISATION

Polyheterocyclisation is a typical polycondensation process, which can be achieved in different ways. (1) In two stages (the first stage involves the formation of linear polymers containing in their macromolecules fragments capable of cyclisation and the second stage, the cyclisation proper, leads to a cyclochain polymer with repeating heterocycles in the chain); (2) in one stage—in polyphosphoric acid (PPA). The most interesting polyheterocyclisation products from the standpoint of thermal stability and heat resistance are polyheteroarylenes—polymers containing only aromatic carbocyclic and heterocyclic groups in the macrochains.

Certain polyheteroarylenes can be formed also on direct fusion of the starting compounds; however, this method is not preparatively useful, since it requires a high temperature at which secondary processes (degradation, cross-linking) may occur in the polymers and alter their properties.

The majority of polyheteroarylenes can be obtained by both methods; each of these has its advantages and disadvantages, largely associated with the properties of the final product. Since the majority of polyheteroarylenes do not melt and do not dissolve in the usual organic solvents, an advantage of the two-stage method is the formation in the first stage of soluble prepolymers, which can be worked into finished articles by the usual methods and then cyclised by heat treatment.

An advantage of the synthesis in PPA is primarily the occurrence of the process in a single stage, its relative simplicity, cheapness, and the ready availability of the starting compounds. Moreover, PPA, which provides a unique combination of the properties of an effective solvent for polymers, a proton donor (this promotes the condensation), and a cyclodehydrating agent, frequently makes it possible to synthesise polymers with a higher molecular weight and with a higher degree of cyclisation. In the two-stage process, the cyclisation usually occurs in the solid phase and, as the reaction proceeds, the macromolecular chains become increasingly rigid, which greatly hinders the occurrence of total cyclisation; PPA, which in this case behaves as a plasticiser, promotes the attainment of a higher degree of cyclisation.

A wide variety of different classes of polyheteroarylenes have been obtained by the above methods and the most important among them are the following: (1) *polyazoles*—polymers containing repeating five-membered heterocycles in the macromolecules: oxadiazole, triazole, pyrazole, thiadiazole, and other units; (2) *polybenzazoles*

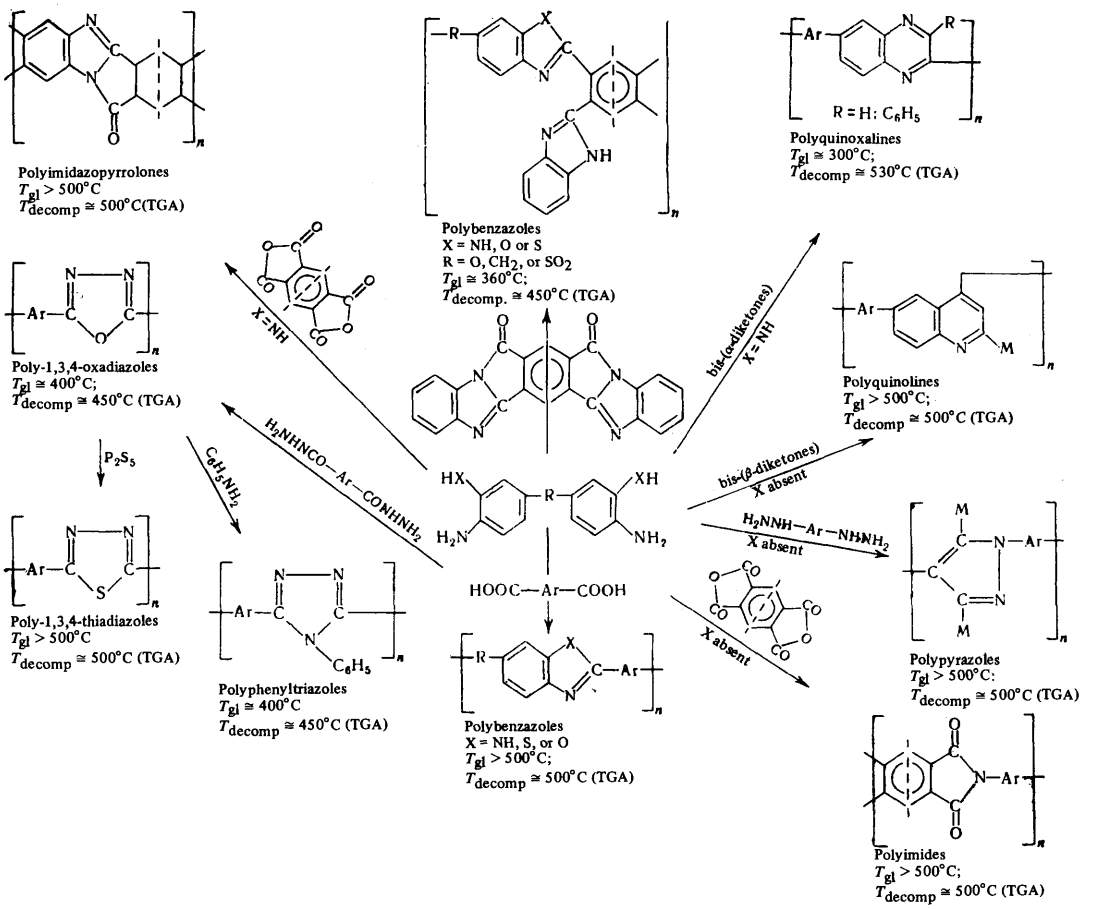


Figure 1. Scheme for the formation and main thermal characteristics of the principal types of polyheteroarylenes.

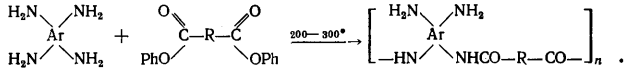
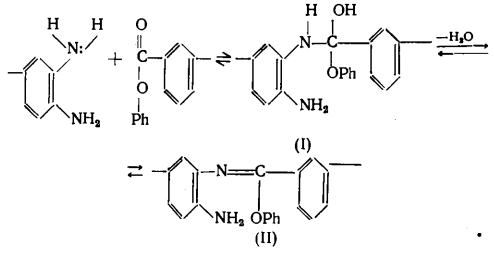


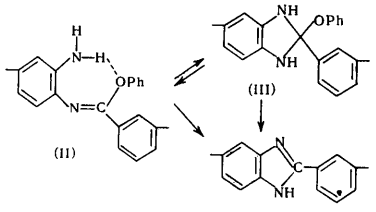
and *polybenzazines* —polymers containing condensed heterocycles: benzimidazole, benzoxazole, benzothiazole, benzimide, indole, quinoline, quinoxaline, benzoxazine, and other units; 3) ladder polymers of different structures.

Fig. 1 presents a general scheme for the formation of the main polyheteroarylenes indicated above and some of their thermal characteristics.



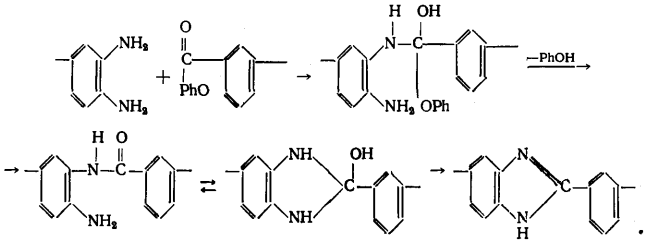
1. Two-stage Method of Synthesising Polyheteroarylenes

The first stage of this process has been investigated in many systems and such studies have led the majority of investigators to the conclusion that at this stage the reaction is reversible and obeys relations characteristic of equilibrium polycondensation [160–165]. Since the second stage is the cyclisation proper and the properties of the final polyheteroarylenes are to a large extent determined by the structure of the prepolymers, we shall consider in this section also the mechanism of the reactions occurring in the first stage.

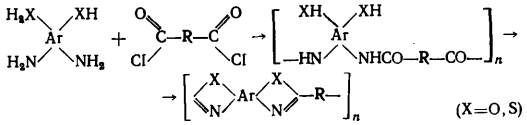


According to the literature [166,167], the formation of polybenzimidazoles on interaction of 3,3′-diaminobenzidine with diphenyl esters of dicarboxylic acid takes place via the formation of a polyaminoamide as an intermediate:

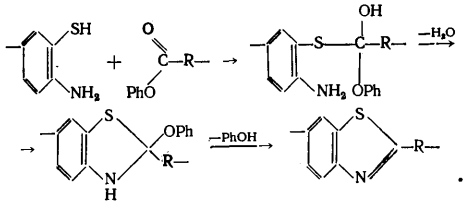
However, Wrasidlo and Levine [168] believe that such interaction begins with the nucleophilic attack by the amine on the carbonyl carbon atom of the diphenyl ester, leading to the formation of an intermediate aldol type product (I), which after dehydration gives rise to a new intermediate with the structure of a Schiff base (II):



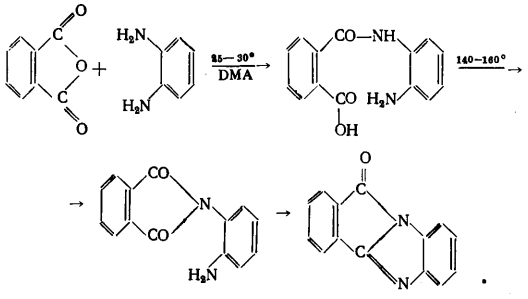
The *syn*-form of the intermediate (II) can produce intramolecular hydrogen bonds, which promote the intramolecular formation of phenol and prevent the formation of cross-linked and branched structures. The authors postulate the possibility of an equilibrium between the intermediate (II) and the benzimidazole structure (III):



The consecutive elimination of phenol from structures (II) and (III) leads to the final benzimidazole. The electronic absorption spectra of the prepolymer and the fact that water is formed before the phenol are quoted in support of the proposed mechanism.



However, Grey et al. [169], who studied the reaction in a flow system in contrast to the earlier investigators, demonstrated on the basis of spectroscopic data and elemental analysis that water and phenol begin to form simultaneously and that half the theoretical amount of water and the entire phenol are produced in the first stage and only water in the second stage. This led them to the conclusion that the reaction intermediate has a hydroxyimidazoline structure formed via the following mechanism:

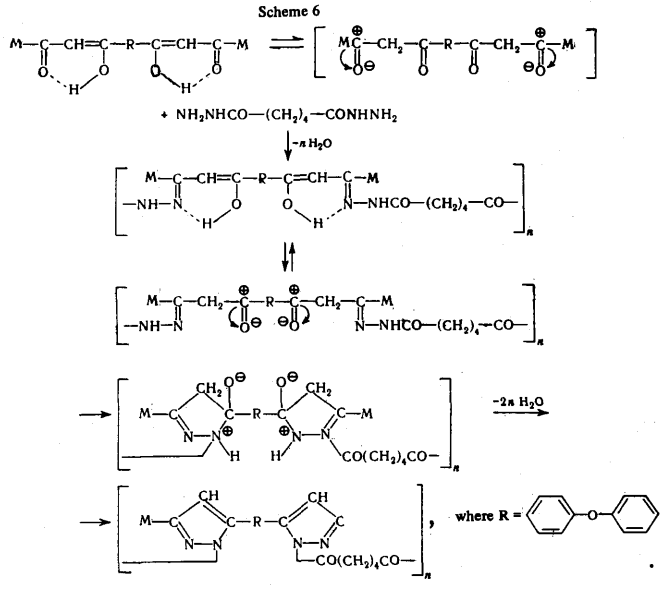


Many workers believe that polybenzoxazoles [170–172] and polybenzothiazoles [173] are formed via a polyhydroxamide and a polymercaptamide respectively as intermediates in the first stage:

It has been suggested that the reaction of 3,3′-dimercaptobenzidine with diphenyl esters in diethylaniline solution proceeds via a different mechanism [174]:

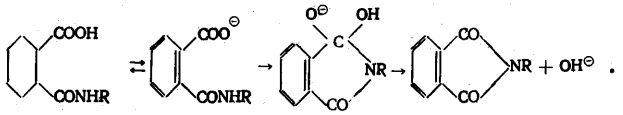
The synthesis of ladder polymers (for example pyrrone type polymers) by the two-stage method proceeds via the formation of a polyaminoamidoacid in the first stage, which has been demonstrated convincingly by Colson et al. [175], using NMR, for the reaction of phthalic anhydride with *o*-phenylenediamine:

The study of the reaction of bis-(β-diketones) with dicarboxylic acid dihydrazides by Korshak and coworkers [176] in order to synthesise polypyrazoles showed that polyacylhydrazones are formed as intermediates in the first stage. The kinetic data obtained by the authors for this stage contradict the earlier idea according to which the interaction of amines with carbonyl compounds is regarded as a bimolecular process, the rate-limiting stage of which is



the formation of an intermediate adduct [177,178]. The interaction of 4-acetoacetylphenyl ether and adipodihydrazide under the chosen conditions was irreversible and obeyed the equations for first-order reactions. The activation energy was 17 kcal mole^{-1} and at first sight greatly exceeded the usual activation energy for a keto–enol transformation. Therefore, the hydrogen bond energy in 4-acetoacetylphenyl ether was determined by 1 H NMR and was indeed found to be 23 ± 4 kcal mole^{-1}. Such unusually marked stabilisation of the intramolecular hydrogen bond is probably due to the conjugation of the enol ring with the benzene rings, as in benzoylacetone and dibenzoylmethane [179].

On the basis of their results, the authors proposed a mechanism for the formation of polypyrozoles according to which bis-(β-diketones) and the intermediate hydrazones react in the keto-form (see Scheme 6).



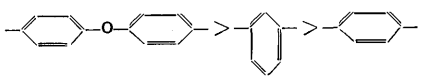
The second stage in the synthesis of polyheteroarylenes—dehydrocyclisation—consists in the intramolecular formation of water from the intermediate product with formation of a cyclochain polymer and may be achieved both in solution and in the solid phase. These processes are being vigorously investigated since they have a direct influence on the properties of the polymers [180–194].

A study of the kinetics of the imidisation of a polyamidoacid in solution in dimethyl acetamide at 80°C on the basis of the amount of water formed, both chromatographically and from the change of the absorption intensity in the region of 1780 cm^{-1}, showed that the process is first-order with a rate constant $k = 3.87 \times 10^{-3}$ litre mole^{-1} s^{-1}. The reaction is very rapid and after 11 min the degree of imidisation is 98.5%. [180] The reaction rate depends on the nature of the diamine and the dianhydride: polyamidoacids comprising more basic diamines and aromatic dianhydrides are cyclised more readily.

Scheme 6

It was observed that the cyclisation of a polyamidoacid in the form of the ammonium salt proceeds much faster (by a factor of 5–10) compared with the cyclisation of the free polyamidoacid. Therefore, it has been suggested that the mechanism of the cyclisation reaction includes a stage in which the carboxy-group is ionised [184]:

On the other hand, the cyclisation of the methyl ester of a polyamidoacid proceeds much more slowly than that of the acid itself [187], which constitutes indirect confirmation of the above hypothesis.



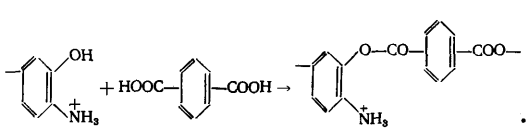
A characteristic feature of the kinetic curves for the cyclisation of polyamidoacids is the presence of two stages, the first of which corresponds to rapid cyclisation and the second to a very slow process. The activation energies for the two stages are almost the same, but the activation entropy for the second stage is significantly higher [184]. If the water formed in the cyclisation process is not removed from solution, then hydrolytic cleavage of the macromolecules and a decrease of the molecular weight of the polymer are possible at the reaction temperature [180]. Therefore, in solid-phase cyclisation, which takes place at higher temperatures (250–300°C), it is necessary to remove water rapidly from the reaction zone; consequently, the cyclodehydration of solid prepolymers is carried out in thin layers *in vacuo* [183–187].

The studies showed that the mechanism of solid-phase cyclisation is more complicated in solution. Regardless of the prepolymer cyclised (polyamidoacid, polyhydroxamide, polyhydrazide, and others), the kinetics of these reactions have the following common feature: regardless of the fact that all such reactions are unimolecular and are treated as first-order processes, the rate constant calculated from the first-order kinetic equation decreases monotonically with conversion. Thus, with increase of the degree of cyclisation of a polyamidoacid from 0.2 to 0.8, the absolute reaction rate constant increases by a factor of 10–12. The decrease of the imidisation (and in general cyclisation) rate constant with increase of the degree of reaction may be accounted for by the fact that the energy and time parameters of the constant k in the Arrhenius equation do not remain constant in the solid-phase process [183]. The decrease of the reactivity of the macromolecules in consequence of the increased rigidity of the polymer chains and their decreased mobility with increase of the degree of cyclisation may be regarded as one of the causes of this phenomenon.

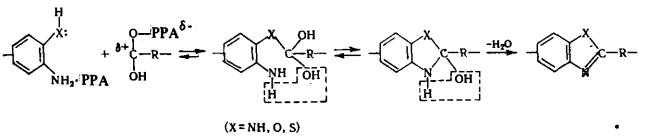
An attempt has been made to estimate quantitatively the change in mobility (increase of rigidity) of polymer chains during cyclisation using as an example the polyhydrazide obtained from the dihydrazide of 4-carboxyphenyl ether and the dichloride of diphenylphthalide-4,4′-dicarboxylic acid [188]. It was shown that the glass temperature of the resulting intermediate exceeds the experimental temperature, the solid-phase reaction is sharply inhibited and virtually comes to a stop; under these conditions, the degree of cyclisation does not reach the maximum possible value. In this case, one observes "self-inhibition" of the reaction owing to a continuous change in the mobility of the polymer chains during the solid-phase polycyclisation caused by the increase of their rigidity due to the increase in the content of cyclic fragments.

The authors suggest that the specific behaviour of these polymers is due to the non-indentity (according to the thermodynamic parameters) of the polymer chains involved in the reaction; this is responsible for the change in the reactivity of the hydrazide groups in the cyclisation [188–190].

The cyclodehydration of polyhydroxamides takes place at 250–300°C. Despite the fact that the decrease of molecular weight during cyclisation corresponds to the calculated values, amide units may persist under these conditions in the polymer, as shown by the presence in the infrared spectra of a weak absorption band at 1660 cm^{-1}. This band disappears only after heating the polymer at 420–430°C, which is accompanied by the formation of a small amount of water and carbon dioxide and the loss of solubility of the polymer in sulphuric acid [192]. The study of the kinetics of the cyclisation of polyhydroxamides showed that the chemical structure of the initial polyhydroxamide influences the rate of the process in a manner similar to that observed for other polymers: with decrease of the mobility of the macromolecular chains in the cyclisation process (i.e. with decrease of the number of units capable of rotation), the cyclisation rate constant falls and the pre-exponential factor increases. It has been established that the rate of cyclisation decreases in the following sequence as a function of the groups linking the benzoxazole rings [193]:



The authors suggest that the mechanism of the cyclodehydration of polyhydroxamides does not include a preliminary amide–imidoyl rearrangement, as shown by the formation of 2-phenylbenzoxazole from *o*-hydroxy-*N*-methylbenzanilide in which such tautomerism is impossible. The presence of a strong intramolecular hydrogen bond, which probably plays an important role in cyclodehydration, has been detected in the infrared spectra of *o*-hydroxamides [194].

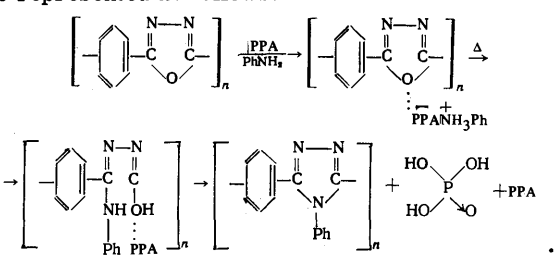


2. Single-stage Method of Synthesising Polyheteroarylenes in Polyphosphoric Acid

The elucidation of the mechanism of polyheterocyclisation in PPA was preceded by a detailed study of the acid properties of PPA itself as the P_2O_5–H_2O system [195-198] and also of the mechanism of the ring closure of a number of low-molecular-weight compounds [198,199], which led to the hypothesis that PPA acts simultaneously as a protic acid, a Lewis acid, and a phosphorylating agent [200]. This is the reason for the change in the reactivity of various compounds when the reaction is carried out in PPA.

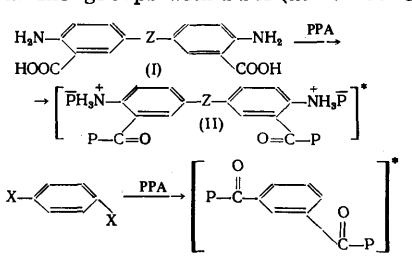
Thus, it has been shown that, being a strong Lewis acid, PPA increases the positive charge on the carbon atom of the carbonyl group and thereby leads to an increase of its electrophilic reactivity. It is also interesting to note that, in reactions in PPA, the basicity of the hydroxy-group is higher than that of the amino-group; therefore, the reaction of bis-(*o*-aminophenols) with dicarboxylic acids in PPA involves the initial selective formation of a polyester [170]:

Taking these facts into account, Iwakura and coworkers [170] achieved for the first time the synthesis of polyheteroarylenes in PPA and proposed the following general mechanism for the formation of polybenzazoles:



(X = NH, O, S)

It has been suggested that the intermediates formed are hydroxyimidazolines in the synthesis of polybenzimidazoles in PPA and the corresponding hydroxy-derivatives in the synthesis of polybenzoxazoles and polybenzothiazoles. It was noted that a high molecular weight is attained more rapidly in the last two cases than for polybenzimidazoles. According to the authors, this is due to the higher basicity of the hydroxy- and mercapto-groups in PPA compared with the amino-group and this is in fact the reason for the higher rate of formation of the polymer [201,202].

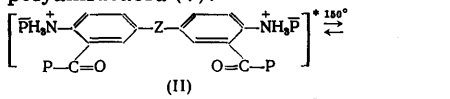


Probably the mechanism of the formation of poly-1,3,4-oxadiazoles from dicarboxylic acids and hydrazine derivatives in PPA is analogous to that quoted above [203], but this requires experimental proof.

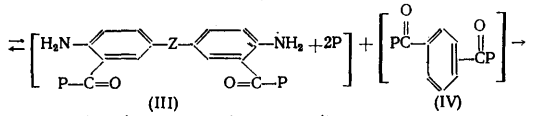
The data obtained by Meiboom and coworkers [204] in a study of the rate of proton transfer in an acid medium to substituted ammonium ions proved to be important for the elucidation of the mechanism of their reactions in PPA. It was shown that the formation of the free base is the rate-limiting stage in this process. Later Holsten and Liliquist [205-207] determined by NMR spectroscopy the temperature range in which the aniline–PPA salt dissociates into the free acid and aniline. Accordingly, the mechanism of the formation of polyphenyltriazoles by the reaction of a polyhydrazide or polyoxadiazole with aniline may be represented as follows:

Kurihara and coworkers [208-210] made a detailed study by spectroscopic and chemical methods of the mechanism of the formation of polybenzoxazinones in PPA by the polycondensation of bisanthranilic acids and their copolycondensation with dicarboxylic acid derivatives. They demonstrated convincingly that the synthesis of polybenzoxazinones in PPA proceeds via the formation of phosphorylated intermediates in the following way.

First stage—phosphorylation of both initial compounds with formation of mixed anhydrides and the interaction of the amino-groups with PPA (at 40–80°C):

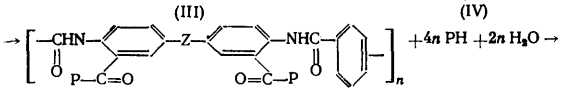


where Z = CH_2 or O, X = COOH, COCl, CN, C(=NH)OR,

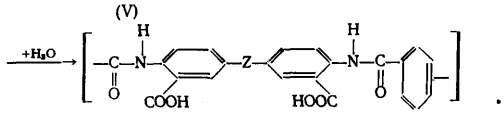


COOR, $CONH_2$, or CHO, R = CH_3, C_2H_5 or C_6H_5,

P = $H[OP(OH)_n]O$, and [ ]* = activated complex.

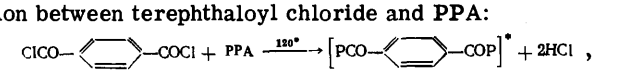


Second stage—the formation of the polyamidoacid (V). At 150°C the salt (II) dissociates and an equilibrium is established between the salt and the free amino-form of the phosphorylated product. The reaction is initiated by the nucleophilic attack by the free-amino groups on the carbonyl group of the mixed anhydride and leads to the formation of the polyamidoacid (V):

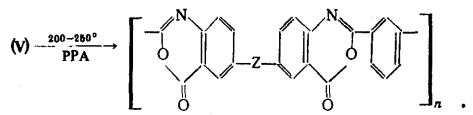


(II)

(III) (IV)



(V)



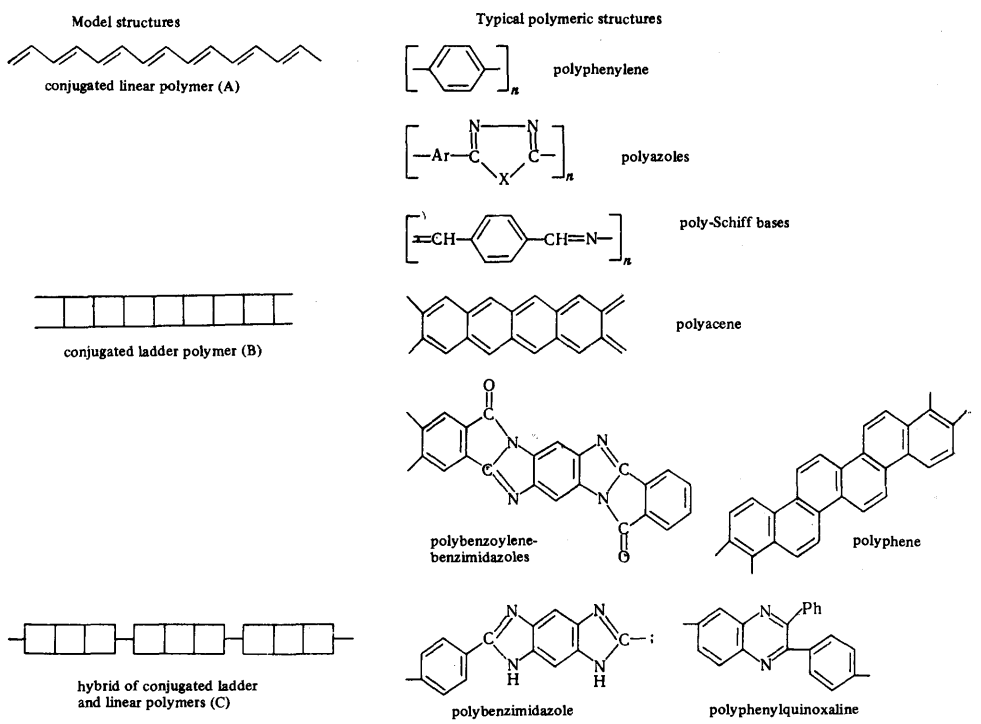
(VI)

The presence of the mixed anhydride (IV) in the reaction mixture has been demonstrated by carrying out the reaction between terephthaloyl chloride and PPA:

which resulted in the formation of a stoichiometric amount of hydrogen chloride. The carbonyl group in such a mixed phosphorylated anhydride is more sensitive to nucleophilic attack by amino- or phosphoramido-groups. The presence of free NH_2 groups, which appear as a result of the dissociation of the amine salt (II) in PPA, has been demonstrated by NMR. The polyamidoacid (V) was isolated from the reaction mixture and characterised by elemental analysis and infrared spectroscopy.

Third stage—cyclodehydration in PPA. This occurs on further heating and leads to polybenzoxazinones:

(VII)



VI. LIMITS OF THE APPLICABILITY OF THE POLYCYCLISATION METHOD

Examination of the above data permits the following conclusions.

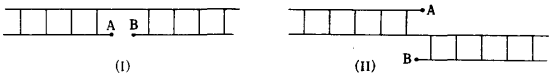
1. Despite the apparent wide variety of methods described, they are all based on well known polymerisation and polycondensation processes.
2. Methods leading to polymers with continuous conjugation or pseudo-conjugation of the aromatic (carbocyclic and heterocyclic) structural skeleton, i.e. polyheterocyclisation, polycyclotrimerisation, and 1,3-dipolar addition, are the most suitable for the synthesis of thermostable and heat-resistant organic polymers.
3. The two-stage method of synthesising polyheteroarylenes, whereby it is possible to obtain in the first stage soluble polymers capable of being worked, has nowadays been developed to the greatest extent.

All the above types of polyheteroarylenes can be represented by models[211] (see Scheme 7).

Scheme 7

The presence in the polymer macromolecules of aromatic carbocyclic and heterocyclic groups alone, which are responsible for the rigidity of the main chain and the strong interchain interaction, should lead to high softening temperatures (heat resistance) and resistance to high temperatures (thermal stability) and chemical reagents; when the molecular weight is fairly high, all these qualities give rise to satisfactory operational properties of polymers of this class.

The softening temperatures of polymers, which constitute the upper limits of the region where they can be employed, are related to thermal stability as follows [212]:

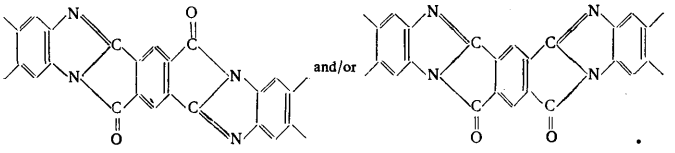


$$T = \frac{\Delta Q}{\Delta S} ,$$

where T is the melting point (or the phase transition temperature), ΔQ the amount of heat absorbed on decomposition of the polymer (or in the transition), and ΔS the entropy of decomposition of the polymer (or the entropy of the transition).

This formula takes into account the following factors: the intermolecular interaction, which determines Q, and the rigidity of the polymer chain responsible for the change in the entropy of the system.

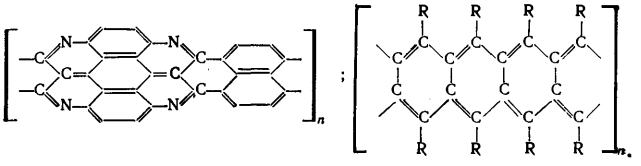
Examination of the thermal stability of polyheteroarylenes of different structures from these standpoints suggested that aromatic polymers with a ladder structure should be more resistant to high temperatures and should be degraded more slowly, since this requires the dissociation of not one but two single bonds [212]. At the same time it was found that despite the differences in structure all the known polyheteroarylenes have similar thermal stabilities, according to dynamic thermogravimetric analysis, which are appreciably lower than suggested. The majority of the polymers begin to decompose in the temperature range 450–500°C with a simultaneous loss of mechanical and other valuable properties (Fig. 1).



This apparent contradiction between the expected and actual thermal stabilities can evidently be accounted for by the presence of single bonds in the macromolecules, i.e. structural defects in the polymer due to incomplete cyclisation. Analysis of data for the properties of polyheteroarylenes and the study of the process in which they are formed (polyheterocyclisation reactions) showed that it is extremely difficult to attain complete polycyclisation in the polymer macromolecules. This applies particularly to the two-stage synthesis of polyheteroarylenes, in which the cyclisation process takes place in the solid phase, and also to the synthesis of ladder polymers.

In order that the reactive groups A and B should react with formation of a completely cross-linked (ladder) structure, it is necessary that they should be coordinated as in Scheme (I). When Scheme (II) obtains, the formation of a bond requires rotation by 180°, which is extremely difficult for polymers with a high softening temperature owing to the low mobility of the main chain segments. This difficulty increases with increase of the degree of cyclisation.

The study of the polycyclisation kinetics in the solid phase demonstrated differences between the initial and final rates of cyclisation, which is consistent with the entropies of the initial and final stages; the process activation energy does not change appreciably under these conditions [188].



The lower than expected thermal stability of polyheteroarylenes may be caused, apart from the defects in the structure containing non-cyclised sections, by the branching of the polymer, which lowers the packing density and reduces the interchain interaction and also by the configurational and conformational disorder arising in polymer chains owing to the possibility of geometrical isomerism, which also leads to a loss of crystallinity and a decrease of interchain interaction. This can be illustrated using as an example polybenzoylenebenzimidazole obtained from pyromellitic dianhydride and 3,3′-diaminobenzidine, which consists of a mixture of *cis*- and *trans*-isomers (in relation to the benzene ring of pyromellitic acid) [175]:

Among the known polyheteroarylenes, phenylated polyquinoxalines have been attracting special attention; the closure of the quinoxaline ring is apparently favoured so much by thermodynamic and kinetic factors that these polymers are formed extremely readily at room temperature, have high molecular weights, and are fully cyclised, being at the same time fusible and soluble, i.e. capable of being worked [213–215].

A comparative study of the thermo-oxidative degradation of polyphenylquinoxalines and some of the most thermostable polymers—polybenzothiazoles—(under isothermal conditions, since the oxidation processes develop over a period of time) demonstrated a clear advantage of the phenylated polyquinoxalines both over polybenzothiazoles and over unsubstituted polyquinoxalines [215] (Fig. 2). The latter finding confirms the earlier hypothesis that the C–H bonds are very readily activated on heating and are the most susceptible to oxidation, particularly in heterocycles [216].

Such high thermal stability of polyphenylquinoxalines is probably related to the freedom from defects in the polymer chains, which can probably be regarded as the maximum attainable for true linear organic polymers. A further improvement of the thermal characteristics of polymers can be partly achieved by creating more condensed polymeric structures of the type

In this case chain termination at one point cannot cause any appreciable changes in the adjacent regions; under these conditions, there is also a high probability of the destruction of the radicals formed, which increases the resistance of the polyconjugated polymer to thermal oxidation [217–220]. However, the thermal characteristics of condensed polymers of this kind are not markedly improved either; this is probably because, with increase in the complexity of polymer structure, it is increasingly more difficult to attain a high degree of cyclisation and freedom from structural defects.

At the same time the requirements of modern engineering for articles based on thermostable polymers (for example, fibres, fabrics, coatings, plastics, etc.) are increasing continuously. Therefore further heat treatment

of finished articles is being employed to an increasing extent. With the aid of structure-forming processes such as carbonisation and graphitisation, it is possible to increase appreciably the thermal stability and heat resistance of the articles. Consequently, for the formation of satisfactory polycyclic structures, it is very important that the heat-treated cyclopolymers should have a defect-free structure, which makes it possible to avoid undesirable degradative processes [221].

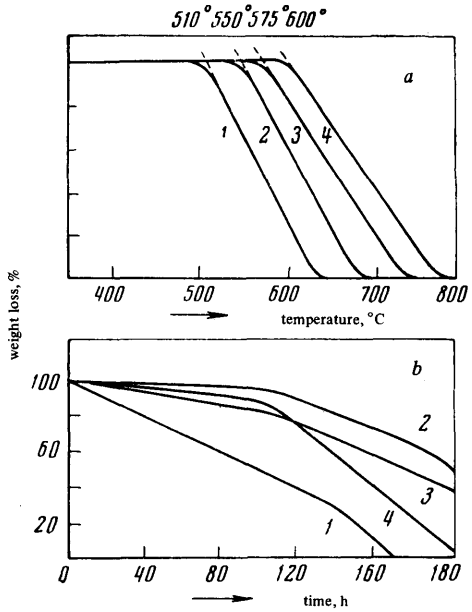


Figure 2. a) Weight loss according to dynamic thermogravimetric analysis in air at a heating rate of 6.67 deg.min^{-1}; particle size 140–240 mesh [1) diether polyquinoxaline; 2) diether polyphenylquinoxaline; 3) polybenzothiazole of type AA–BB; 4) polybenzothiazole of type A–B]; b) weight loss according to isothermal thermogravimetric analysis of the polymers in air at 371°C.

Graphitisation, which involves a more far-reaching heat treatment than carbonisation, leads to materials which should approach, to some extent, carbon structures which also consist of polymers with a very high molecular weight, a two-dimensional and three-dimensional network, and an infinite C/H ratio [218–220].

Thus, depending on the purpose of the final article, an appropriate method should be used for the synthesis of the polymer and for its subsequent heat treatment.

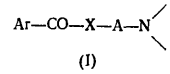
Advances in the Chemistry of Anaesthetics (1961 - 1971)

E.M.Cherkasova, N.T.Pryanishnikova, S.V.Bogatkov, and G.S.Erkomaishvili



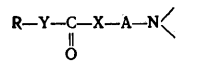
The most important studies on the chemistry of anaesthetics during the last decade are reviewed. Anaesthetics belonging to different classes of organic compounds (aminoalcohol esters, aminoamides, aminoacid amides, aminoketones, etc.) are considered mainly in terms of the relation between structure and physiological activity. Much attention has been devoted to the consideration of the available literature data on the mechanism of the action of anaesthetics.
The bibliography includes 411 references.

CONTENTS

I. Introduction	876
II. Anaesthetic activity of compounds containing amino- and carbonyl groups	877
III. Anaesthetic activity of compounds containing one functional group	881
IV. Some hypotheses about the mechanism of the action of anaesthetics	883

I. INTRODUCTION

During the ten years which have elapsed since the publication of our previous review[1], the total number of reports dealing with anaesthetics† has continued to increase. More than two hundred publications now appear on this subject every year, more than half of which deal with the problems of the mechanism of anaesthetic action, while the syntheses of new preparations are published in brief patent reports with increasing frequency. The result of electrophysiological, physicochemical, biochemical, and other studies discussed below make it possible to formulate fairly definite ideas about the mechanism of the action of anaesthetics with aminoester and amide structures at the cellular and subcellular levels. However, by no means all problems may be regarded as solved. In the first place this applies to the mechanism of the action of anaesthetics at the molecular level and to the determination of the relative role of factors responsible for the quantitative differences in the strength of anaesthetics. The latter problem is closely related to that of the specificity of their action. An enormous amount of experimental data have shown, on the one hand, a high specificity–small changes in structure lead to a sharp decrease in activity up to its complete disappearance[1-9], while at the same time drastic structural changes—for instance, transition from aminoesters to aminoketones or amines involving a complete change in all chemical characteristics—do not deprive the preparation of its capacity to interrupt the nerve pulse. Admittedly, the absence of experimental data makes it impossible to rule out the hypothesis that in such cases the mechanism of action at the cellular or molecular level is different and such substances cannot then be called anaesthetics, although the final physiological result is the same. So far we are forced to treat these substances together with "typical" anaesthetics having ester and amide structures in accordance with the terminology adopted by the authors who describe them. However, considerable difficulties then arise in the classification of published data. Therefore, in the present review the available results are described on the basis of ideas which may be regarded as a development of the old concept of the "anaesthesiophoric group" (I), although its limitation has already been noted[1]:



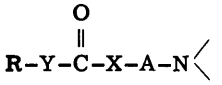
(I)

Statistical data have shown that, despite the wide variety of structures investigated, certain groups are nevertheless encountered most frequently in reactive compounds. These include the amino-group (about 98%) and the carbonyl group (about 80%). Most anaesthetics, including the most active preparations which have found applications, contain both these groups. This suggests that the above combination of functional groups is important for the formation of the steric structure and distribution of electron density in the molecule which is responsible for anaesthetic activity. The environment of these groups, particularly that of the carbonyl group, may be extremely varied and the "structure–activity" problem reduces mainly to the analysis of the nature and mechanism of the influence of substituents in various parts of the molecule on pharmacological activity. There are many views on this topic. Thus, according to Löfgren[10], the strength of anaesthetics is related to the electron density at the oxygen atom of the carbonyl group, which behaves as an electron donor. In many cases, this factor is undoubtedly important—in particular it can account for the increase in the strength of anaesthetic action following the introduction of electron-donating groups (NHR, OR) in the *para*-position of diethylaminoethyl benzoate and the opposite effect of electron-accepting groups such as NO_2. Similar observations have been made for aminoacid amides[11,12] and a number of other types of anaesthetic substances[13] and sometimes it was even possible to observe a quantitative correlation between anaesthetic activity and electron density at the C=O bond[14]. The increase of the activity of the compounds on replacing the ester group by the amide group can itself be related to the increase of electron density at the carbonyl oxygen atom[11].

On the other hand, many facts demonstrate the inadequacy of this hypothesis. Thus when the compounds

†A terminology somewhat different from that current abroad is used nowadays in the Soviet literature; instead of the terms "local anaesthetic" and the Russian equivalent "mestnyi anestetik" employed previously, the term "anaesthetic" is now used, while "narcotic" corresponds to the term "general anaesthetic". This terminology will be used in the present review.

under consideration are represented by the general formula (II)

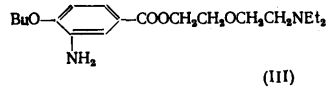


(II)

where X and Y can represent NH, NR, O, S, or C< and A is an alkyne chain or an aromatic residue, it is found that the anaesthetic activity is retained not only on replacement of O by NH but in many cases also on their replacement by the CH_2 group. These groups are isoelectronic and in most cases isosteric, whence one may conclude that geometrical (steric) effects play a considerable role. Numerous data concerning the high activity of compounds containing an *ortho*-disubstituted benzene ring—amino-esters [15-17], anilides [8,9,18,19], and many others—support this view.

Thus, although at present the mechanism of the action of anaesthetics can be regarded as established in broad outline, it is as yet impossible to determine unambiguously the general relation between the structure of the compounds and their anaesthetic activity—different factors are of primary importance in different cases. The "kind" of atoms and their relative positions are probably not the only important (and possibly not the most important) factors; other significant factors are physical parameters characteristic of the molecule as a whole: the relation between hydrophilic and lipophilic properties, the general distribution of the electron cloud, and other features which are related to molecular structure in a complex manner. Recognising this, in classifying anaesthetics we are nevertheless obliged to employ the structural principle as the only one possible at present. It is based on formula (II) and the classification has the form shown in Table 1.

Table 1. Classification of compounds of the type

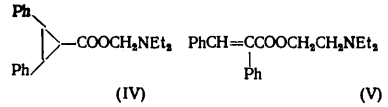


X	Y	Type of compound	X	Y	Type of compound
O	C<	Aminoalcohol esters	C<	NH	Aminoacid amides
NH	C<	Aminoamides	O NH	NH O	Carbamates
C<	O	Aminoacid esters	C<	C<	Aminoketones

II. ANAESTHETIC ACTIVITY OF COMPOUNDS CONTAINING AMINO- AND CARBONYL GROUPS

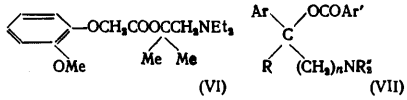
1. Aminoalcohol esters (X = O, Y = C<)

As before, most attention is devoted to varying the acid component of the molecule in esters of diethylaminoethanol $RCOOCH_2CH_2N(C_2H_5)_2$ and related aminoalcohols. Studies on the classical series of substituted benzoic acids—aminobenzoic [20-23], alkylbenzoic acid [15,24], alkoxybenzoic [16,25-31], and others [32,33]—are being continued. It has been found that the increase of activity in the series *ortho* < *meta*- < *para*-alkoxybenzoic acids [26] and on enlarging R from C_1 to C_4 as well as its decrease when R is branched take place in parallel with the change in the surface activity of these compounds and in many cases (for positional isomers) a parallel variation with partition coefficients is observed.



Promising preparations have been found among *p*-alkoxyethoxybenzoates [25] and 2,6-dimethylbenzoates [15]. The latter act over longer periods, possibly owing to steric hindrance to hydrolysis due to the *ortho*-methyl groups, which is characteristic also of other *ortho*-substituents [17]. Among alkoxybenzoic acid derivatives, it was possible to find a substance (III) combining high anaesthetic and vasoconstrictor activities [21]:

(III)

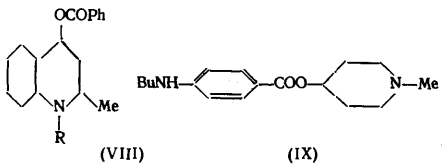


On the other hand, despite their high activity, the aminoesters of halogenobenzoic acids were found as a rule to be unsuitable owing to their considerable toxicity and side effects [29,32].

The esters of certain other aromatic [34-36] and heterocyclic acids [37-42] and also of cinnamic acid and its analogues [43,44] were found to exhibit anaesthetic activity. The derivatives of 2,3-diphenylcyclopropane-1-carboxylic acid [45] may be included among acids of this type. It is interesting to note that the (−)-isomer of (IV), which is a compound in this series, was found to be twice as active as the (+)-isomer. Shah and Ketcham [43] observed that the *trans*-form of compound (V) has a higher anaesthetic activity than the *cis*-isomer:

(IV) (V)

Finally, a high activity has been found in many aminoesters of diarylacetic and similar acids [16,46-51] and also in phenoxyacetates [52-54]. Thus compound (VI), the toxicity of which is smaller by a factor of 7, gives rise to an anaesthetic effect lasting twice as long as that of xylocaine [54]. This confirms the earlier conclusion [1] that the presence of a conjugated chain is not always necessary for anaesthetic activity and that the substituent R in compounds (II) need not necessarily be an aromatic group or its vinylogue:



(VI) (VII)

Relatively less attention has been devoted in recent years to varying the alkyl and amino-components of the aminoester molecules. The esters of aliphatic-aromatic aminoalcohols [44,52,53,55-63], including derivatives of type (VII), [52,55-60] were studied in greater detail in this respect. As in many other series, it was found that the shape of the molecule and the dimensions of its constituent units play a significant role in the activity of these compounds [52]. Thus compounds with a trimethylene chain proved to be the most effective, while derivatives of aminoethanols and aminobutanols are relatively inactive [52,56,57]. The accumulation of alkyl substituents round the ester group promotes a high activity, which may be attributed to their electron-donating influence, leading to an increase of electron density at the C=O group and to steric effects,

for example in consequence of the resulting hindrance of hydrolysis. On the other hand, the introduction of various substituents in Ar or Ar′ does not have satisfactory results [52,55,59]. The activity decreases sharply when Ar or Ar′ are replaced by saturated residues [52,58,60,61].

The role of the geometrical structure may be followed by analysing data for the activities of the stereoisomeric esters of γ-piperidinols and γ-decahydroquinolinols [64-68]. It was found that, among benzoates of type (VIII), the esters with a *cis*-diaxial disposition of the CH_3 and C_6H_5COO groups and the *trans*-junction of the rings are much less toxic and more active in terminal [caudal!] and conduction anaesthesia than their epimers. In infiltration anaesthesia the behaviour is somewhat different—here the highest activities are shown by the *trans*-isomers with an equatorial C_6H_5COO group [65,68]. The change from the *trans*- to the *cis*-junction of the rings reduces both activity and toxicity in all cases.

(VIII) (IX)

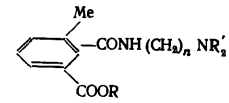
Similar conclusions were reached by Nobuo [69] in a study of decahydroisoquinoline derivatives. Among piperidine derivatives, the axial isomers show the most effective properties [68,70]. All these data confirm the earlier hypothesis [52] of the importance of the geometrical structure of the molecule in view of the necessity for similarity (isomorphism) of the anaesthetic and a receptor surface for the activity of the preparation.

In conclusion we may note a few other aminoesters which exhibit a high anaesthetic activity—"paridocaine" (IX) [23] which has a more prolonged and intense action than novocaine, 2-piperidinoisopropyl diphenylacetate which is 40 times more effective than xylocaine in surface anaesthesia and 3 times more effective in infiltration anaesthesia [71], 2-diethylaminoethoxyethyl benzoate ("kallocaine") which is twice as effective as xylocaine on surface administration and four times as effective on administration by infiltration [72], and also certain other preparations containing ester oxygen in the alkyl chain [73,74].

Other ways of varying the alkyl and amino-components of the aminoester molecules, involving the doubling of the number of functional groups, the introduction of sulphur atoms or the hydroxyamino-group, and the use of various heterocyclic structures, were not appreciably successful [16,27,75-80].

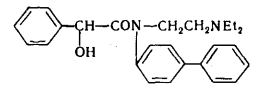
2. Aminoamides (Y = C<, X = NH)

Among aminoamides (i.e. diamines in which one amino-group is acylated), the amides of the heterocyclic acids, which include the familiar anaesthetic sovcaine (cinchocaine, dibucaine, percaine), have been investigated in greater detail [3,5b,81,82]. The activity of these compounds increases as a rule after the introduction of bulky alkyl and alkoxy-groups [81]. It is interesting that the amides of 3-alkoxycinchoninic acid do not exhibit anaesthetic activity, in contrast to the 2-alkoxy-derivatives [39].



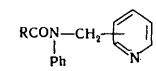
Alkyl and alkoxy-groups promote the appearance of pharmacological activity not only in the series of sovcaine analogues but also among the amides of substituted benzoic acids, which were previously frequently regarded as relatively unpromising [1]. Thus *o*-alkoxybenzamides, particularly the *o*-butoxy- [83,84], *o*-benzyloxy- [85], and *o*-allyloxy-derivatives [86], for example compound (X), proved to be effective, their anaesthetic activity being close to that of xylocaine; 2,4,6-trimethyl- [87,88] and 6-alkoxycarbonyl-2-methylbenzamides (XII) [89] are also active. The activity of the diamide (XI) [90]

(X, Z=OCH2CH=CH2)
(XI, Z=NHCOC6H17)



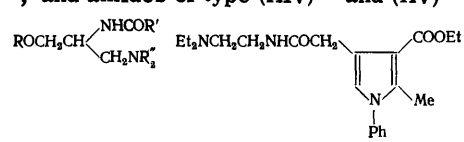
exceeds that of novocaine by a factor of 200.

Compounds containing substituents in the *para*-position are usually less active, but some of them, for example *p*-$ClC_6H_4OCH_2CONHCH_2CH_2NR_2$, are nevertheless used in view of their low toxicity [91].



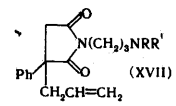
(XII)

A number of studies have been made on aminoamides with an arylated amide group [92,93]; according to the authors, compound (XIII) is a powerful anaesthetic:

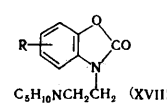


(XIII)

(XIV)

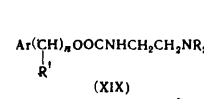


Among other active aminoamides, mention may be made of 4-alkoxyphthalimides [94], 3,3-diphenylacrylamides [95], and amides of type (XIV) [96] and (XV) [97]:



(XV) (XVI)

Compound (XIV), in which the structures of an aminoamide and aminoacid ester are combined, and which is said to induce rapid, stable, and prolonged anaesthesia [98] is interesting. Among dibasic acid imides, which attracted attention recently, compounds (XVII) [99], (XVIII) [100], and a number of others [101,102] proved to be active anaesthetics.

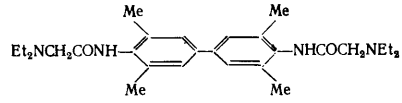


One can also mention the aminoamides of carbamic acids of type (II) (X = NH, Y = O), the infiltration activity of many of which is equal to that of xylocaine. As in other classes of compounds, in the series of substances of type (XIX) the maximum activity is attained with Ar = 2,4-$(CH_3)_2C_6H_3$ and 2,6-$(CH_3)_2C_6H_3$, while *p*-CH_3O, *p*-NH_2, and *p*-Cl substituents reduce it [103]:

(XVII)

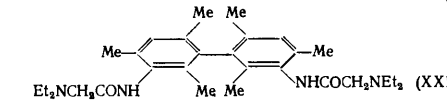
(XVIII)

(XIX)



3. Aminoacid imides (X = C<, Y = NH)

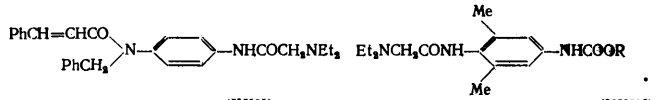
Aminoacid amides are a class of compounds to which most attention has been devoted during the last decade. This is due to the abundance of very active preparations



belonging to this class. It is sufficient to mention xylocaine, trimecaine (mesocaine), prilocaine (cytanest) and others. Starting with the structure of xylocaine, detailed studies were made on a wide variety of its analogues[8,9,104]. Studies involving the changes in amide moiety of the molecule, primarily by the introduction of various substituents into the anilide group, have been particularly numerous. As already mentioned, one of the most important factors here are the general lipophilic properties of the molecule, the enhancement of which by the introduction of additional methyl groups (for example in trimecaine[8,9,18]) or by replacing a methyl group by larger substituents[19] leads to an increase of activity; in the last case the fact that the structure of the amide group is sterically hindered may also play an important role.

Numerous compounds containing groups more polar than alkyl substituents in the benzene ring have been investigated. Alkoxy- and aryloxy-derivatives proved to be the most interesting[88,104-108] and, whereas the C_6H_5O group has the most marked effect in the *meta*-position, the $C_6H_5CH_2O$ and $C_6H_5CH_2CH_2O$ groups are most effective in the *para*-position[8,9]. Introduction of the more hydrophilic OH, $OCOCH_3$, and SH groups as well as halogen atoms or the NO_2 group in the benzene ring increases the activity sharply or completely abolishes it[12,88,107,109]. In contrast to other hydrophilic groups, the amino-group has a promoting effect on pharmacological properties, particularly in the 4-position[12,88].

Interesting data were obtained in the study of compounds which may be regarded as "dimeric" analogue of xylocaine (XX) or trimecaine (XXI)[8,9,45]. It was found that, when the distance between the nitrogen atoms in such a structure,

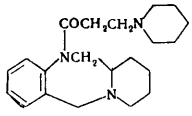


(XX)

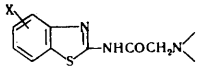
(XXI),

is about 10.3 Å, the activity of the preparation is extremely high, when the distance is greater than this it is approximately equal to the activity of the monofunctional compound, and when it is less the activity falls sharply. These results partly indicate the possibility of many-centre addition of the anaesthetic to the receptor.

Certain other combinations of two amide groups in the molecule lead to highly effective anaesthetics, for example in compound (XXII)[110] or (XXIII)[111] whose toxicity is low, the activity of the latter exceeding that of xylocaine by a factor of 10, 20, and 60 respectively for R = C_4H_9, i-C_5H_{11}, and C_6H_{13}:

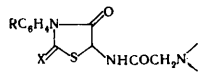


(XXII) (XXIII).



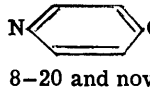
However, in most cases additional carbonyl-containing groups do not improve the properties of aminoacid amides[112-116].

Together with a substituted benzene ring as the aromatic residue, other aromatic and heterocyclic fragments have been frequently introduced into the aminoacid amide molecule. It was found that high activity and its long duration are characteristic of certain aminoacylamide derivatives of naphthalene[117,118] and phenothiazine[50,119-122]. However, the latter frequently exhibit an irritant action on the tissues and for this reason are unsuitable. Unexpectedly the results[120,121] show that, despite the generally held view, certain quaternary salts of 10-aminoacylphenothiazines are not inferior to tertiary amines in their anaesthetic activity or actually superior to them, The author claims that the activity of the preparations depends mainly on the dimensions of the group introduced on quaternisation. Bearing in mind the low activity of the preparations and their considerable irritant action, one might have doubted these claims, but recently a further report has been published[123] in which it is shown that xylocaine methochloride acts like xylocaine itself and the "dose–response" relation is approximately the same for both preparations. Possibly the mechanisms of the action of the base and the quaternary salt are nevertheless different, although so far there are no literature data on this question.

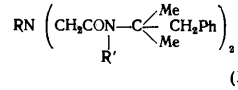


The interesting tricyclic amide (XXIV) has an anaesthetic activity equal to that of xylocaine and its toxicity is low (LD_{50} = 500–1250 mg kg^{-1}),[124]

(XXIV)



(XXV)



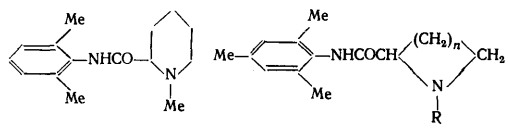
(XXVI).

A number of very active preparations have been discovered by Indian investigators[125-129] and other workers[130-131] among aminoacyl derivatives of thiazoles, benzothiazoles, and thiazolidinones [(XXV)–(XXVI)] and also among the analogous bispiperazine derivatives. The absence of conjugation between the NH–CO group and the aromatic ring in compounds of type (XXVI) is striking. Such conjugation is probably not obligatory, which does not apply only to the above types of compounds—the number of active local anaesthetics discovered in the series of benzylamides[132-137] and compounds with an aromatic terminal group still more remote from the amide moiety has increased in recent years[138-141]. Some of these, for example the bisamides (XXVII), are extremely active[139,140,142]; in particular, the compound with R = $HOCH_2CH_2$ ("oxethazine) and also its analogues with R = $HOCH_2CHC_2H_5$, *p*-$NO_2C_6H_4COOCH_2CH_2$ and

$COOCH_2CH_2$ surpass sovcaine by a factor of 8–20 and novocaine and xylocaine by a factor of 2000 to 4000, while their toxicity is low (for oxethazine, LD_{50} = 400 mg kg^{-1}) and their irritant action is only slight. It is interesting that the activity disappears completely with R = $HO(CH_2)_3$.[140] Thus the position of the benzene ring in a molecule is not always of primary importance:

(XXVII).

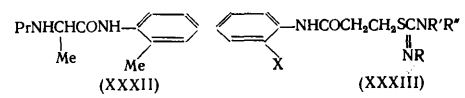
However, the norbornane and cyclohexane analogues of xylocaine exhibit only an extremely weak anaesthetic effect[143]. These data as well as a number of others described above suggest that the aromatic moieties in the molecule of the anaesthetic are not important solely because of their direct influence on the properties of the carbonyl group. Probably their role is largely to ensure that the compound is soluble in lipids and is capable of



binding to the receptor via non-covalent bonds (hydrophobic binding, π-complex formation, etc.).[11]

Studies[144,145] on the pharmacological properties of *N*-aminoacylephedrines, which are interesting because all eight possible isomers of the amides formed by D- and L-*NN*-dimethylphenylalanines with D- and L-ephedrine and pseudo-ephedrine were investigated and it was shown that derivatives of L-*NN*-dimethylphenylalanine are the most active, merit consideration. On this basis, the authors put forward certain hypotheses concerning the structure of the receptor with which the above substances can interact. It was also shown for compounds (XXVIII) and (XXIX)[146] that the L-isomer has a much higher anaesthetic activity than the D-isomer. Recently this was observed for the anilides of *NN*-dimethylalanine[147]. On the other hand appreciable differences between the activities and toxicities of the D-, L-, and DL-isomers of prilocaine (see below) were not observed[148]:

(XXVIII) (XXIX) .



Together with studies on the amide component, much attention has been devoted in recent years to varying the aminoacyl component in aminoacid amides[108,132,135,149-180]. Thus many piperidinoacetamides, particularly those containing several methyl groups in the piperidine ring, proved to be highly active anaesthetics with low toxicity[132-135,149,150]. Together with carbocaine (mepivacaine), which has been known for a long time, its *N*-butyl analogue bupivacaine (marcaine) (XXX), which has a very prolonged anaesthetic action and low toxicity, has been actively investigated recently[151-153]:

(XXX) (XXXI) .

Studies on a series of mesidides of azacycloalkane-α-carboxylic acids (XXXI)[8,9,154-156] showed that, with increase of ring size (n = 2, 3, 4), the surface anaesthetic activity increases and the infiltration activity falls. The activity also increases with increase in the size of the group R, the optimal properties being obtained with R = C_4H_9, i-C_4H_9, and cyclo-C_6H_{11}. As a result of these investigations, two new highly active anaesthetics of type (XXXI) (n = 2)—pyrromecaine (R = C_4H_9) and cyclomecaine (R = cyclo-C_6H_{11})—have been proposed and introduced into clinical practice.

Compounds with other heterocyclic groups (pyrrole, nortropane, morpholine, and piperazine[133,149,157-161] and also with branched or polar aliphatic substituents at the nitrogen atom[162,163] are as a rule relatively inactive or toxic and behave as tissue irritants.

(XXXII) (XXXIII) .

On the other hand, substances with a secondary amino-group, particularly so called prilocaine (propitocaine, cytanest, L 67) (XXXII), continue to attract interest[118,151,164-169]. According to a number of investigators, the activity of prilocaine is equal to that of xylocaine *in vivo*, while the duration of its action is longer and its toxicity lower, although in tests on an isolated neuromuscular preparation it was inferior to xylocaine[168]. The difference is attributed to the lower rate, compared with xylocaine, at which it is washed out by blood, although its *in vivo* decomposition is faster, which accounts for its lower toxicity[168]. Certain *N*-butyl derivatives, for example α-butylamino-3-chloropropionanilide, which according to Malatesta et al.[170] is 79 times more active than xylocaine, are not inferior to prilocaine. Compounds with an NH_2 group are as a rule inactive.

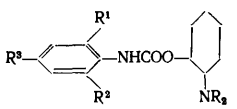
Compounds (XXXIII), which can be classified as aminoacid amides only by convention, have an unusual structure. Some of them [for example, compound (XXXIII) with X = R′ = R″ = H and R = cyclohexyl] are much more active than xylocaine on surface and subcutaneous administration[171,172].

The data on the role of alkylation of the amide nitrogen are contradictory. Thus, according to Kurihara et al.[173], the introduction of an alkyl group into the amide group of xylocaine analogues increases their activity, while the toxicity remains constant. Similar results have been obtained for *N*-benzyl derivatives[174]. On the other hand, according to other workers[132,175], *N*-cyclohexyl and *N*-ethyl derivatives of mesocaine are relatively inactive.

The branching of the aminoacid chain structure appears to have a mainly favourable effect, most probably as a result of an enhancement of lipophilic properties and a change in molecular geometry. This can be seen for the dimethyl analogue of priplocaine (LA - 012) which is superior to xylocaine and prilocaine both as regards activity and duration of action[176], as well as for certain other compounds[177,178]. Many derivatives of β-aminopropionic[179], γ-aminobutyric[106], and β-aminoisobutyric acids[180] are active, although the increase of their activity is frequently accompanied by an increase of their irritant properties and toxicity.

In conclusion mention should be made of the anaesthetic properties of the polypeptide (XXXIV)[181], which can be reasonably considered in this section, since it contains amide bonds:

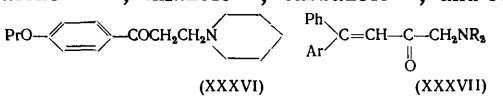
Unfortunately quantitative data concerning its activity have not been quoted, although it has been stated that it also exhibits a vasoconstrictor activity and that its activity is potentiated by other anaesthetics.



Aminoacid sulphonamides, some of which [for example, $ArNHSO_2CH_2CH_2(C_2H_5)_2$] have anaesthetic properties, can also be probably included in the class of compounds considered here[182].

4. Aminoacid esters (X = C<, Y = O)

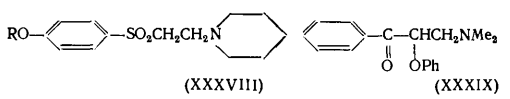
In contrast to aminoacid amides, there has been a considerable decrease of interest in aminoacid esters without an amino-group in the alcoholic component. These compounds can be regarded as analogues of aminoalcohol esters with an "inverted" carboxy-group, such structural transformation being apparently unfavourable for pharmacological properties. Among the few substances that have been investigated[183-188], only preparations belonging to the group of aryl esters of *N*-morpholine- and *N*-methylpiperazine-α-carboxylic acids are of interest[183-185]. While their structures are similar to that of xylocaine, their activity is higher for the same toxicitv but they do cause appreciable tissue irritation. The other aminoacid esters investigated recently do not show an appreciable anaesthetic activity.



5. Carbamates (X = O, Y = NH)

The Czech school of investigators have been investigating compounds of this class most vigorously [186-193], concentrating attention mainly on 2,6-disubstituted carbanilates. As in many other instances discussed above, it was found that, together with physicochemical properties, the steric influence of *ortho*-constituents plays a significant role, since 2,6-dichloro-, 2,6-dimethyl-, 2-alkoxy-, and 2-aryloxy-derivatives have all been found to be active [103,186-180,194]. Some of them are 5–17 times more active than cocaine in surface anaesthesia and 7–20 times more active than novocaine in administration by infiltration, while having approximately equal toxicities [190]. 2-Butoxy-4,6-dimethylcarbanilate [195], 2-chloro-6-methylcarbanilate [194], and also the carbamates (XXXV) with a somewhat modified ester moiety are extremely active [192,196]. Among them, compound (XXXV) with R′ = CH_3, R^2 = Cl, R^3 = H and R_2N = NC_5H_{10} is 35 times more active than cocaine. Other carbamates with anaesthetic activity which may be mentioned are derivatives of *N*-pyridylcarbamic acids [197,198], phenothiazine-10-carboxylic acid [199], phenothiazine-10-dithiocarboxylic acid [200], and certain carbamoylazepines [201].

(XXXV)



6. Aminoketones (X = C<, Y = C<)

A detailed review of aminoketones with anaesthetic activity was published quite recently [202]. Investigators concentrated attention mainly on the modification of the structure of falicain (XXXVI)—an active anaesthetic discovered at the beginning of the 1950's. It was found that, instead of the benzene ring, it was possible in principle to employ almost any aromatic residue—naphthalene [203,204], thiazole [205], carbazole [206], and others:

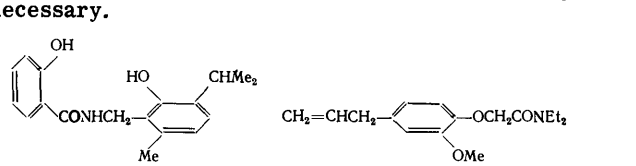
(XXXVI) (XXXVII)

The vinylogues of (XXXVII) are several times more active than xylocaine [207,208], in contrast to their hydrogenated analogues [207]. One should mention that, in contrast to falicain, the ketone (XXXVII) is an α-amino-derivative. Certain other α-aminoketones [209-211] and γ-aminoketones [212,213] were found recently to have anaesthetic activity. It was discovered that a sulpho-analogue of falicain—the aminosulphone (XXXVIII)—has a higher anaesthetic activity [214].

Among compounds produced by varying the amino-group, derivatives of hexamethyleneimine proved to be promising in this respect [202,215,216], particularly p-propoxy- and p-butoxy-β-*N*-hexamethyleneiminopropiophenones, the activity of which exceeds that of falicain and dicain, while their toxicity is lower and they do not give rise to side effects. The second preparation has been called "hexacaine"; the *p*-ethoxy-derivative ("ethamine") is somewhat less active [202].

(XXXVIII) (XXXIX)

A further increase in ring size is undesirable—derivatives of heptamethyleneimine are completely inactive [217]. The best results are obtained by the introduction of propyl [218] and butyl [219] substituents in the 4-position of the piperidine ring; substituents in the 2- and 3-positions are less effective [218]. Compounds with acyclic nitrogen are as a rule relatively inactive, although the activity increases sharply after the introduction of the phenyl [220] or phenoxy-group [16] in the α-position—for example, compound (XXXIX) is three times more active than cocaine in surface anaesthesia and five times more active than novocaine in infiltration anaesthesia [16].

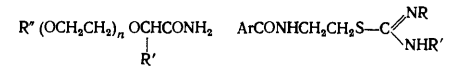


Compounds containing a carbonyl group attached directly to the heterocycle, which in this case combines the function of the amino-group and the carbon skeleton, may be classified as aminoketones with a structure somewhat different from that of falicain. Among these substances, 3-acylpiperidines [221] and 4-acyldecahydroisoquinolines [222] proved to be anaesthetics. Attempts to enhance the anaesthetic effect by doubling the aminoketone structure were unsuccessful—the aminoketones obtained by the Mannich reaction from diacetylbenzene are much less active than the corresponding monoaminoketones [223].

III. ANAESTHETIC ACTIVITY OF COMPOUNDS CONTAINING ONE FUNCTIONAL GROUP

Although the majority of active anaesthetics contain both amino- and carbonyl groups, nevertheless many studies dealing with compounds containing only one of these functional groups have been published.

1. Amides



The amides of acids without a second amino-group have been known for a fairly long time as anaesthetics. Usually anaesthetic activity is observed either in acylated anilines [224,225] or in aromatic acid amides [226,227]. As in many other instances, the general lipophilic properties of the molecule and the steric environment of the amide group play a significant role here. Thus among amides of the type $CH_3(CH_2)nCONHAr$, compounds with n = 5–7 are the most active, while derivatives of lower acids are inactive [225]. Among aromatic acid amides, *o*-substituted derivatives are the most active, for example salicylamides of type (XL) [226]. However, the contiguity of the aromatic ring and of the amide group is not obligatory—many other derivatives show anaesthetic activity, including the amides of phenoxyacetic acid, among which an interesting preparation "detrovel" (XLI) has been discovered. It causes rapid anaesthesia, the intensity of which is equal to that induced by dicain but the duration of its action is much shorter [228], which is frequently necessary.

(XL) (XLI)

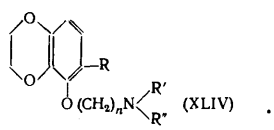
In subsequent investigations it was shown that the anaesthetic activity disappears when the acetamide moiety is eliminated from compound (XLI) or when an ethylene

group is introduced. The degree of anaesthesia diminishes sharply also after various modifications of the acetamide moiety, after the displacement of methoxy- and allyl groups to other positions in the aromatic ring, or after replacing the allyl group by the ethoxycarbonyl group [229,230].

Among other amides, anaesthetic activity has been found in *N*-acylated derivatives of heterocycles [231,232] and in certain derivatives containing a ring carbonyl group [233-235]. Readily water soluble polyglycol ethers of type (XLII) containing an amide group have also been patented as anaesthetics [236]:

(XLII) (XLIII)

2. Amidines and Derivatives of Guanidine, Isothiuronium, etc.

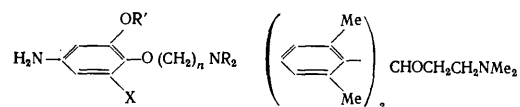


Earlier, it was noted [1] that compounds containing amidine, guanidine, and similar groups possess anaesthetic activity. Active amidines [88,237] and guanidines [238,239] have also been synthesised in recent years. Isothiuronium derivatives, anilides [171,172], and benzamides (XLIII) [240,241] are likewise powerful anaesthetics. Certain isothiuronium derivatives have an activity exceeding that of xylocaine by a factor of 4-20 in surface administration and by a factor of 2-6 in administration by infiltration. Regan et al. [241], who compared this structure with 2-aminothiazoles which also exhibit anaesthetic activity, assert that the $-S-C\begin{matrix}N-\\ \diagdown\\ N-\end{matrix}$ group can be regarded as a new anaesthesiophoric structure.

Finally, there exists yet another group, resembling the carbonyl group and related to it genetically, namely the aldoxime group, which also gives rise in many cases to anaesthetic activity in compounds containing it [242,243]. It has been noted [242] that, together with the aldoximes $ArCH{=}NOCH_2CH_2NR_2$, the isomeric *N*-oxides are active.

3. Amines

Despite the fact that anaesthetics employed in midical practice have not been found as yet among simple amines, these substances are apparently of interest by virtue of a number of advantages—relative simplicity of synthesis and resistance to hydrolysis-which are in many instances combined with high anaesthetic activity.

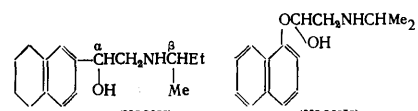


Compounds containing an ether oxygen atom (or several such atoms) together with the amino-group are most widely used. Thus Daukshas and coworkers made a detailed study of benzodioxan derivatives (XLIV) [244-246]:

(XLIV)

They showed that, in order to exhibit anaesthetic activity, compounds of this type must contain hydrocarbon substituents with a specified "bulk". The introduction of additional polar groups (OH, NR'_2) destroys their activity, apparently as a result of the enhancement of the hydrophilic properties, since the activity may be restored by the removal of the polar dioxan ring. The preparation with $n = 2$, $R = CH_2CH{=}CH_2$, $R' = H$, and $R'' = CH_3$ ("benzodiocaine") the activity of which exceeds that of dicain by a factor of 2.2 in terminal [caudal?] anaesthesia, while its toxicity is smaller by a factor of 2, proved to be the most active.

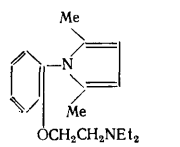
Anaesthetic properties have also been found in a series of phenyl [247-258], benzyl [259], and diphenylmethyl ethers [260-263], particularly those with *ortho*-substituents. It may be that the oxygen atom in these compounds simulates in some way the carbonyl group, which gives rise to similar structural characteristics. Thus it has been found that the activity, toxicity, and irritant properties of the series of compounds (XLV) become more marked with increase in the size of the group R', while substitution of a hydrogen atom in amino-group by an acyl group lowers both their activity and toxicity [250,251]. Basic ethers with a polyoxyethylene chain, $R(OCH_2CH_2)nNR'_2$, where R = 2-guaiacyl or 2-thyminyl residue ($n = 2-4$) [254], the analogous diphenylmethyl ethers [260], and also the diphenylmethyl ether (XLVI), which is 10 times more active than novocaine but causes irreversible tissue changes [261], were found to be active. Phenyl ethers substituted in the *meta*- and para-positions exhibit anaesthetic properties much more rarely [255,256].

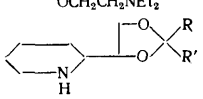


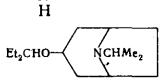
(XLV) (XLVI)

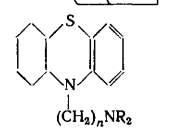
It is important to note that amines, aminoethers, and analogous compounds, which do not have an "anaesthesiophoric" structure, as a rule exhibit another kind of pharmacological activity (spasmolytic, antihistamine, cholinolytic, etc. [257,262,264-282]), as well as anaesthetic activity, which may be regarded as evidence in support of the non-specific mode of their action. Some of the most active (according to the data of the investigators who described them) amines, are listed in Table 2. Judging from the wide variety of structures of these preparations, the position of the oxygen atom in the molecule is not too significant and its role probably reduces to imparting to the substance the required physicochemical properties.

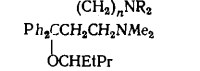
The mechanism of the anaesthetic activity of aminoalcohols is still obscure. Presumably the hydroxy-group of these compounds influences mainly their lipophilic properties. However, one cannot rule out the possibility that certain aminoalcohols do not act directly in the organism but are initially rapidly oxidised to the corresponding aminoketones, which then exhibit anaesthetic properties. Evidence in support of this hypothesis is provided by the finding that anaesthetic activity is as a rule shown by secondary aminoalcohols containing the group ArCHOH, which can be readily oxidised to ArC=O; for example, the tetrahydronaphthalene derivative (XLVII) has an anaesthetic effect comparable to that of xylocaine and novocaine [283,284].

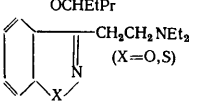


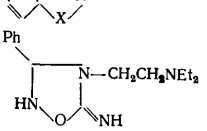






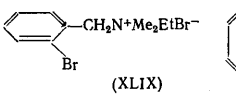






It is interesting that among the four stereoisomers (XLVII), which have been called "butydrine", the αSβS-isomer shows the highest anaesthetic activity, while the αRβR- and αRβS-isomers exhibit a β-blocking activity [284]:

(XLVII) (XLVIII)



Certain other aminoalcohols of this type are also active as anaesthetics[207,285-288]; on the other hand, active preparations with a hydroxyl remote from the aromatic rings are fairly common[288-295], in particular propranolol (XLVIII) the activity of which is close to that of xylocaine[294,295].

Table 2. Physiological activity of certain oxygen-containing amines.

Compound	Anaesthetic activity	Other types of activity	Refs.
	3 times and 20 times higher than the activities of cocaine and novocaine respectively	Antagonist of pilocarpine, morphine, and $BaCl_2$; 30 times more effective than papaverine	257
	50-80 times higher than the activity of novocaine	Spasmolytic	265
	100 time higher than the activity of cocaine	Antihistamine and atropinemimetic	266
	2-10 times higher than the activity of cocaine	Spasmolytic, sedative, antihistamine, analgesic, etc.	268-270
	Lower by a factor of 1.5 than the activity of dicaine	Cough suppressant midriatic	271
	Exceeds the activity of xylocaine	Spasmolytic, antihistamine	272
	3 times and 5 times higher than the activities of cocaine and novocaine respectively	Vasodilator, analgesic	273,274

The activity of certain phenolic compounds[296,297] and also of aminoalcohols of the diphenylmethanol series[298], which are altogether incapable of being converted into carbonyl compounds, have likewise been mentioned. Therefore the role of the OH group as well as that of the C–O–C bond in the anaesthetic activity of amines remains obscure, particularly since amines without other functional groups have shown such activity in fairly numerous instances.

Thus 2-naphthylalkylamines, which exhibit pronounced surface-anaesthetic properties, for example $Ar(CH_2)_nN(CH_3)C_5H_{11}$ (Ar = β-naphthyl), are more active than novocaine by a factor of 16.[299] The relations discovered between the physiological properties of these compounds and their structures are approximately the same in surface and conduction anaesthesia and are close to those observed in other series of compounds. β-(4-Methyl piperidinoethyl)naphthalene is 13 times as active as cocaine (in 0.5% solution)[300]. Anaesthetic properties have been found also in cyclohexylphenylamines[301], in bretilium (ornid) (XLIX)[302], although this compound does not in fact contain a quaternary nitrogen atom, in the diamine (L) which is 20 times as active as xylocaine and 4 times as active as dicain[303], in α-amino-4-dimethylaminodiphenylmethane, which gives rise to prolonged and intense anaesthesia[304], in many aromatic[305-310] and heterocyclic amines[311-322], and also in certain saturated amines[323,324]. However, all these compounds are as a rule non-specific and exhibit several types of physiological activity.

(XLIX) (L)

4. Compounds without Nitrogen Atoms

The anaesthetic activity of alcohols, particularly that of benzyl alcohol, has been known for a long time. The activities of more complex alcohols[325] and their derivatives, in particular of polyethers of the type $C_nH_{2n+1}(OCH_2CH_2)_mOH$ (Zipf and Dittmann[326]), and many others[327] have been mentioned in a number of studies. It was found that the anaesthetic activity of these compounds increases in parallel with chain length and with enhancement of their lipophilic properties and increase of the partition coefficient. It was discovered that the anaesthetic activity of the ether $(C_6H_{13}OCH_2OCH_2CH_2)_2O$ ("efiran") is close to that of cocaine, but the compound is less toxic and does not have an irritant action[328]. The alkyl esters of *p*-hydroxybenzoic[329] and gallic[330] acids were found to be active, the anaesthetic effect increasing with the size of the alkyl group; for example, the activity of dodecyl *p*-hydroxybenzoate is 6 times as great as that of novocaine[329]. However, the available data are too fragmentary to reach any conclusions concerning the mechanism of the action of compounds of this type.

IV. SOME HYPOTHESES ABOUT THE MECHANISM OF THE ACTION OF ANAESTHETICS

Until recently ideas about the mechanism of the action of anaesthetics were extremely speculative and indefinite and were based exclusively on empirical relations between structure and activity and therefore could hardly be regarded as of general validity. Direct electrophysiological investigation of the action of anaesthetics as substances acting on the generation and transmission of nerve excitation became possible only as a result of advances in the study of the generation and transmission of the nerve pulse in the last decades. Furthermore, detailed physicochemical and biochemical studies on anaesthetics were made in recent years.

As shown above, substances with a wide variety of structures and consequently differing in reactivity exhibit anaesthetic properties. All these findings suggested that the physicochemical processes determined by the physicochemical properties of the anaesthetics play an important role in the mechanism of anaesthetic action. For blocking action to take place, the anaesthetic must initially penetrate to the reaction site and must then interact with the receptor. At least three factors are therefore important for anaesthetic activity: (1) the capacity of anaesthetics to pass through various biological membranes (not linked directly to the nerve tissue) to the nerve fibres and to be adsorbed on their surface; (2) the capacity of anaesthetics to penetrate the membrane of the nerve fibre and their behaviour in the excited membrane; (3) the interaction

of anaesthetics with specific (in the chemical sense) receptor structures. The mechanism of the action of anaesthetics can be usefully considered on these lines.

Almost all anaesthetics are organic bases and therefore their capacity for ionisation is important for their activity. It was believed for a long time that the unionised base is in fact responsible for the anaesthetic effect. This conclusion was readily confirmed by well known data according to which the minimal effective blocking concentration of anaesthetics decreases with increase of the pH of the medium [331-334]. However, it was shown comparatively recently that there is no direct relation between basicity and anaesthetic activity [8,335] and, since with the majority of active preparations in the region of physiological pH values the concentration of the cation is more constant than that of the base, it was concluded that the cation is the active form of the anaesthetic [335-340]. On the other hand, it is evident that anaesthetics penetrate the myelin sheath of the nerve fibre [336-338] or the axon membrane [341] in the uncharged form. In a study of the effect of two lidocaine derivatives (pK_a = 6.3 and 9.8) on the membrane of the squid axon at different pH it was shown that the anaesthetics penetrate the membrane in the uncharged form but block the action potential only in the form of the cation [341]. The majority of anaesthetics employed in practice have pK_a = 7.0 to 9.0. [8,335,340] This limitation also suggests that both forms of the anaesthetic are important for its action: the unionised base is responsible for the migration of the anaesthetic to the reaction site and its cationic form is responsible for the direct interaction between the anaesthetic and the receptor [337,339,341-343].

For the anaesthetic substance to be able to reach the site of its activity (the axon membrane) it must have a definite solubility in water and lipids. The earlier attempt to relate the anaesthetic activity of substances to their partition coefficients between aqueous and lipid phases were unsuccessful [10,11]. However, recently it was possible to observe such a relation [8,344]. On the other hand, it has been discovered that the anaesthetic and surface-active properties of anaesthetics vary in parallel [345-347]. The surface and interfacial activities of compounds, their capacity to penetrate liquid monolayers and at the same time their anaesthetic activity increase when the pH of the medium is raised from 3.5 to 7.35. [335,348] It has been shown that anaesthetics are not only adsorbed by phospholipid layers but are also capable of interacting with certain phospholipids in cell membranes via ion–ion and ion–dipole mechanisms forming a 1 : 2 complex like Ca^{2+} ions [349]. They are probably bound to the phosphate groups of the lipids which interact with Ca^{2+} ions [349,350].

Thus, by virtue of their lipophilic properties and surface activity, anaesthetics penetrate the neural membrane and alter its physicochemical properties: hydrophobic properties [351], electrical resistance [352] and pH, while at high concentrations they coagulate aqueous phospholipid dispersions. The change in physicochemical properties alters the functions of the membrane, which is reflected in physiological processes. The parallel variation of the physicochemical properties (lipophilic properties, partition coefficient in the nerve, capacity for adsorption in the nerve, surface and interfacial activities, and capacity for adsorption) and of anaesthetic activity mentioned above is related to these factors, which has made it possible to explain certain empirical relations between the structure of the compounds and their pharmacological activity and even to predict the activity of many new preparations [8,335].

Clearly no serious investigation is now conceivable without taking into account the influence of the physicochemical factors discussed above. The action of anaesthetics is nowadays treated mainly on the basis of the generally accepted theory of the generation and propagation of electric potentials in neuromuscular tissue [353,354].

Experimental studies have shown that anaesthetics interfere with the transmission of the nerve pulse, mainly by their capacity to inhibit the increase of permeability to sodium in the region of the Ranvier node in the axon membrane [355-364].

There are divergent opinions in the literature concerning the specific action of anaesthetics on the sodium system of the membrane. The majority of investigators believe that anaesthetics reduce the "maximum permeability to sodium", i.e. block the sodium channels in the membrane [355,357,360,365-369]. On the other hand, there are data [370,371] showing that anaesthetics can activate the systems governing the permeability of the membrane to sodium. This is supported by the known ability of anaesthetics to "interfere" with the motion not only of Na^+ but also of other ions: potassium [359,360,372,373], calcium [360-362,371,374-378], lithium [363,379], nickel, cobalt, cadmium [380], and magnesium [381]. In this respect the study of the effect of Ca^{2+} ions, to which much importance is attached in the mechanism of the change in the ionic permeability of the membrane on excitation [354,381-383], is of particular interest.

The most common view held at present is that Ca^{2+} ions and anaesthetics act at the same sites in the membrane and therefore compete for the sodium "pores" or "transferring agents" in the conducting system of the membranes [351,361,270,383-386]. Such sites are probably the phosphate groups of lipids [349] acting as agents transferring Na^+ and K^+ ions across the membrane.

The charged molecules of anaesthetics can strongly inhibit this process by combining with the anionic centres of phospholipids [349,375]. However, the hypothesis of a direct competitive interaction of anaesthetics and Ca^{2+} is not free from contradictions [349,371,385].

There are numerous data indicating the capacity of anaesthetics to react not only with phospholipids, the role of which in the mechanism of the action of anaesthetics has been proved, but also with other natural substances—thiamine [387], RNA [388], adenine, and ATP. [389] It has been shown that anaesthetics are antagonistic to various amino-acids and alkaloids [390,391], nucleotides [389,392,393], and proteins [386,394,395], which has led to the hypothesis that such interactions are in fact responsible for anaesthetic activity [6,396]. One of the most thoroughly developed hypotheses of this kind is that of the competitive antagonism of anaesthetics and acetylcholine in their interaction with a specific receptor [397-400]. Such antagonism has indeed been demonstrated in a number of experiments [401-403]. However, despite a number of attempts, the result of numerous investigations on different lines contradict the acetylcholine theory of the generation and transmission of the nerve pulse in the peripheral nerve [396,404,405].

Theories which explain the action of anaesthetics by their influence on cell metabolism should also probably be treated with much caution. This explanation is unlikely primarily because even the fastest of the enzymatic processes involving the decomposition or synthesis of lipids known at present take place at a rate the order of magnitude of which is much lower than that of the blocking of ion transport, which constitutes the basis of the generation and transmission of the nerve pulse. Next it was shown that neural conduction and its blocking by

anaesthetics can be achieved equally in the presence of natural axoplasm and after its replacement by an artificial salt solution[406]. Hence one may conclude that a specific effect of anaesthetics develops in the membrane and does not depend significantly on intracellular oxidation-reduction processes. Therefore, despite the numerous data showing the influence of anaesthetics on cell respiration[407-409] and its coupling with phosphorylation[410], there are no grounds for the belief that these processes are responsible for specific anaesthetic action, since many anaesthetics are central nervous system depressants and their effect on the oxidation-reduction processes in the nerve tissue can be in no way fully related to the observations made on the axon membrane. So far it is difficult to assess the role of enzymes in the effect of anaesthetics on the Na^+ and K^+ transport systems, since hitherto it has not been established exactly what types of enzymes may be included in the operation of the sodium-potassium pump in the membrane[411]. Moreover, so far there have been no quantitative estimations of the reactivity of anaesthetics in their interaction with the structures of the excited membrane (receptor), of the kind that have been made, for example, for cholinesterases, MAO [monoaminooxidase] inhibitors, cycloserine derivatives, and other substances. It appears that due consideration has yet to be given to this important problem.

Summarising the above findings, the action of anaesthetics can be represented as follows. By virtue of their surface-active and lipophilic properties, anaesthetics pass through various media to the axon, are adsorbed on the cell surface in concentrations sufficient for their activity, and penetrate the excited axon membrane in the region of the Ranvier node, altering at the same time the orientation of the molecules in the membrane. The permeability to anaesthetics is greatly influenced by the degree of their ionisation and their capacity to exist in the region of physiological pH as an equilibrium mixture of two forms—the cation and unionised base—is important for their anaesthetic action, since their activity depends on both these species. In the axon membrane anaesthetics are held by virtue of the interaction of the cation with the polar group of phospholipids and phosphoproteins and as a result of the hydrophobic interaction of the unionised base. In the course of binding to the axon membrane, anaesthetics most probably enter into a competitive interaction with Ca^{2+} ions, which play an important role in the mechanism of ion transport. The displacement of Ca^{2+} from the structure of the membrane is one of the main causes of the marked inactivation of the sodium transport system with a simultaneous retention or even some increase of the rest potential. As a result of these effects, in the presence of anaesthetics and the normal transmembrane potential difference and the normal content of bivalent ions in the medium are no longer sufficient to maintain the membrane in a state of readiness for response to stimulation. Therefore, in order to restore this capacity, it is necessary to either increase considerably the above potential difference by a hyperpolarising current or to increase the concentration of Ca^{2+} (or Ni^{2+}) in solution. Only at very high concentrations of the anaesthetic are the hyperpolarising current and Ca^{2+} or Ni^{2+} ions no longer capable of restoring fully the damaged structure of the membrane. Thus anaesthetics inactivate the mechanism of the change in permeability to sodium on depolarisation. In consequence of all the phenomena enumerated above, electrical activity ceases without depolarisation. This probably constitutes the essential feature of the action of anaesthetics.

Super-pure Materials from Metal-organic Compounds

B.G.Gribov

Work on the preparation of super-pure materials by the decomposition of metal-organic compounds is reviewed. The decomposition methods, and the factors which influence the purity of the elements and compounds obtained, are discussed. The possible applications and the advantages of the thermal decomposition method are pointed out. 69 references.

I. INTRODUCTION

The preparation of super-pure materials by using metal-organic compounds (MOC) has been intensively studied in recent years. In principle, the method is based on the decomposition of metal-organic compounds to elements or compounds whose purity is determined (depending on the experimental conditions) by the purity of the initial metal-organic compound.

The purification of substances such as metals, which are involatile and refractory by virtue of their atomic crystal lattice, has to be carried out at high temperatures and is therefore liable to cause contamination of the product by the material of the apparatus. On the other hand, the thermal decomposition of MOC (leading to the formation of elements or compounds) can be carried out at relatively low temperatures, with negligible contamination of the product by the material of the apparatus. Substances produced by thermal decomposition of MOC can be obtained either in the form of powders or as coatings on substrates of practically any composition and configuration.

Contamination with carbon is always a possibility in the preparation of pure substances by thermal decomposition of MOC, and therefore the use of volatile inorganic hydrides is preferred for the preparation of super-pure elements such as boron, germanium, phosphorus, tin, arsenic, antimony, etc.[1] However, volatile inorganic hydrides are known for only a few of the elements, and therefore the method has only a limited application. On the other hand, metal-organic compounds are known for practically all the elements; they can be synthesised by selective methods which already remove a number of impurities, and they can be intensively purified by fractional distillation, chromatography, or crystallisation. Furthermore, the carbon contamination of the product can be reduced (often to negligible proportions) by proper control of the thermal decomposition reaction and by suitable choice of the initial MOC.

In addition to their application in the preparation of highly pure substances by thermal decomposition, MOC are often used and purified on their own account. Organic derivatives of metals are very useful for the extraction of small amounts of one element from large amounts of

another element in order to concentrate the minor component or to purify the major component.

The aim of the present review is to collate the existing fund of experimental data on the preparation of pure substances from metal-organic compounds. We shall discuss the behaviour of trace impurities during the synthesis and purification of the MOC, and we shall analyse the effect of experimental conditions and of the type of MOC on the carbon contamination of the resulting elements and compounds. We shall stress the wide range of possible applications of the method, and the prospects of obtaining superpure substances from metal-organic compounds.

The review is confined to papers in which the purity of the initial metal-organic compounds and of the resulting elements and compounds is stated.

II. SELECTIVITY OF THE METHOD OF SYNTHESIS OF METAL-ORGANIC COMPOUNDS, AND PURIFICATION

In order to produce high-purity substances by thermal decomposition of metal-organic compounds we must have access to extremely pure MOC. The freedom of the resulting metals, alloys, and compounds from trace impurities of other elements is determined by the amount of these impurities present in the original metal-organic compound. Modern techniques of organic chemistry allow us to prepare metal-organic compounds of practically every element, and even to vary the type of compound produced from any one element, so that the scope of physicochemical methods of purification becomes much wider than in the corresponding inorganic systems. The most convenient and most widely used methods of purification of MOC are fractional distillation, chromatography, recrystallisation, and extraction. Zone melting, sublimation, molecular distillation, and other special methods can be used in particular cases.

One of the most important aspects of the preparation of super-pure substances by the decomposition of MOC is the tendency of the methods of synthesis to exclude originally present impurities. This is a consequence of the selectivity of the usual methods of synthesis. Thus, the preparation of alkyl derivatives of non-transition metals can be expected to yield a product in which the concentration of transition-metal impurities is lower than in the initial reagents, since transition metals do not readily form alkyl derivatives. A similar type of purification occurs also during the synthesis of organic transition-metal compounds, which tend to be purified from non-transition metal impurities.

Gribov and coworkers [2] have studied the behaviour of trace elements during the synthesis of non-transition MOC for the special case of the preparation of trimethylgallium from methyl iodide and a gallium-magnesium alloy:

$$Ga + Mg + CH_3I \rightarrow (CH_3)_3Ga + MgI_2$$

and other workers have reported similar studies of the preparation of the etherate of trimethylgallium by the Grignard reaction [3]

$$CH_3MgI + GaCl_3 \xrightarrow{(C_2H_5)_2O} (CH_3)_3Ga \cdot O(C_2H_5)_2,$$

and of bis-ethylbenzenechromium by Fischer's method [4].

The impurities in the initial gallium, chromium, and aluminium chlorides were probably present as chlorides and oxide chlorides, those in the metallic magnesium and aluminium were probably present as elements. Under the conditions used for the synthesis of these metal-organic compounds, impurities in the initial reagents could find their way into the final product as methyl, chloromethyl, oxide chloride, and arene compounds.

Table 2. Impurity content of bis-ethylbenzenechromium and of the starting reagents.

Substance	Impurity content, wt.%						
	Al	Mg	Mn	Si	Ni	Fe	Ti
$CrCl_3$	$>1\cdot10^{-2}$	$1\cdot10^{-2}$	$7\cdot10^{-3}$	$2\cdot10^{-2}$	$2\cdot10^{-3}$	$2\cdot10^{-3}$	$6\cdot10^{-3}$
$AlCl_3$	—	$1\cdot10^{-2}$	$3\cdot10^{-4}$	—	$4\cdot10^{-5}$	$>1\cdot10^{-2}$	$1\cdot10^{-3}$
Al	—	$>1\cdot10^{-2}$	$5\cdot10^{-3}$	—	$5\cdot10^{-3}$	$1\cdot10^{-2}$	$1\cdot10^{-2}$
$(EtC_6H_5)_2Cr$	$<1\cdot10^{-4}$	$3\cdot10^{-4}$	$3\cdot10^{-4}$	$<1\cdot10^{-3}$	$<1\cdot10^{-3}$	$<1\cdot10^{-3}$	$<1\cdot10^{-3}$

Analytical results for trace impurities in the initial reagents and in the final products (trimethylgallium etherate, trimethylgallium, and bis-ethylbenzene chromium) are summarised in Tables 1 and 2. It is evident that the impurity content is much lower in the MOC than in the starting materials. For example, the concentration of aluminium, magnesium, and silicon (which do not form the corresponding bis-arene compounds) is 1–2 orders of magnitude lower in bis-ethylbenzenechromium than in the starting materials. Trimethylgallium etherate and trimethylgallium contain 10–100 times less copper, magnesium, titanium, zinc, iron, nickel, aluminium, manganese, silver and silicon than the reagents used in their preparation (magnesium and gallium trichloride).

*The tabulated values are the average of 3–5 determinations.

**Technical magnesium was used to prepare this material.

Trimethylgallium and its etherate are most effectively purified from those trace elements which do not form alkyl derivatives, and whose chlorides have a volatility very different from that of the gallium MOC. Even when the elements present as impurities in the starting materials can form the corresponding metal-organic compounds (zinc, tin, silicon) their concentration is significantly lower in the final MOC.

The behaviour of trace impurities in gallium chloride during the synthesis of gallium MOC has been studied by a radioactive tracer method[2] for the particular case of zinc. The isotope ^{65}Zn was added to gallium trichloride as zinc chloride, and the gallium trichloride was used to prepare trimethylgallium etherate. Only a very small fraction of the zinc present in the gallium trichloride was detected in the final trimethylgallium etherate: most of the radioactivity remained in the still residue left after distillation of the main product.

The selectivity of the methods of preparation of aluminium, tantalum, and niobium alkoxides has been fully discussed[5,6]. Aluminium alkoxides were prepared by treating metallic aluminium with the appropriate alcohol, and the alkoxides of tantalum and niobium by treating the chlorides of the metals with alcohols.

Analysis for trace impurities in the starting materials and in the final products showed a decrease in concentration by 1–2 orders of magnitude. This purification is due both to the selectivity of the method of synthesis and to the efficiency of the separation during distillation of the alkoxides, resulting from the large difference in volatility between the main product and the impurities. The total concentration of trace impurities (Ag, Ti, Fe, Pb, Mn) in the Ta and Nb alkoxides was 1×10^{-4} wt.%.

Existing data on the behaviour of trace impurities during the synthesis of various types of MOC indicate not only that transition metals are separated from non-transition metals (and *vice-versa*), but also that the concentration of all trace elements in the final product is very substantially decreased. We can therefore conclude that the methods used to prepare MOC have a high selectivity.

The reactions used in the preparation of metal carbonyls, widely applied in the production of super-pure metals, have a specially high selectivity. With an iron ore containing a large amount of impurities as the raw material, the synthesis of iron carbonyl almost completely eliminates[7] impurities such as S, P, Mn, As, and Cu. The resulting iron carbonyl contains other metal carbonyls as the only impurity. For example, the concentration of nickel in iron pentacarbonyl is $\sim 1 \times 10^{-2}$%. The vapour pressure of nickel tetracarbonyl is appreciably higher than that of iron pentacarbonyl, which allows the nickel content to be decreased to 1×10^{-4}–2×10^{-4}% by bubbling an inert gas through the iron pentacarbonyl at 40–60° and finally redistilling the product[7].

Umilin and Tsinovoi[8] have described some interesting observations on the removal of organic impurities during the synthesis of MOC. Tetrabutyltin was prepared from stannic chloride and a butyl magnesium halide. The butyl bromide was analysed chromatographically, and found to contain various homologues and isomers (1 mole.% of combined s- and t-butyl bromides, 7×10^{-2}% of n- and isopropyl bromides, 4.0×10^{-2}% of ethyl bromide). These impurities react with magnesium to form the appropriate alkyl magnesium bromides, which then react with stannic chloride to give compounds of the general formula $R'_nSnR''_{4-n}$, where R′ and R″ are s-Bu, t-Bu, n-Pr, i-Pr, and Et. Chromatographic analysis of the resulting tetrabutyltin showed that the total amount of organotin compounds containing the isobutyl radical, the propyl radical, and the ethyl radical had been reduced to $\sim 1 \times 10^{-1}$, $\sim 5.3 \times 10^{-5}$, and 3.3×10^{-4}% respectively. These results indicate a purification from organic impurities by 1–2 orders of magnitude during the synthesis of tetrabutyltin.

The purity of the MOC used to prepare super-pure materials must be of the highest order. When the MOC is thermally decomposed any trace impurities of other elements are transferred almost quantitatively to the final metal or compound, whether produced as a powder or as a coating. Therefore the purity of the ultimate product is largely determined by the concentration of trace elements in the original MOC. Purity of the initial MOC is vitally important in the preparation of semiconductor compounds ($A^{II}B^{IV}$, $A^{III}B^{V}$, etc.). The need for extreme purity is particularly evident in the preparation of semiconductor compounds (gallium arsenide) in the form of epitaxially grown layers[9,10]. In addition to traces of other elements, the MOC may contain organic impurities such as the initial reagents or solvents used in their synthesis. These impurities are less harmful than traces of other elements to the electro-physical properties of the resulting materials. However, the contamination of super-pure materials produced by the decomposition of MOC with carbon, resulting from deep-seated chemical changes in the organic compounds, is determined mainly by the type and the structure of the MOC and by the conditions under which these compounds are thermally decomposed. These problems are discussed in detail in Section III.

Another aspect of the MOC purity problem is the "individuality" of the compound, i.e. the presence or absence of homologues of the organic compound or of any other derivative of the metal. The presence of impurities in the form of homologues is determined by the type of MOC and by the method of synthesis used. Thus, metal alkyls produced by the Grignard reaction are, effectively, individual compounds, free from other organic derivatives of the same metal, if the starting reagents are sufficiently pure. The same is not true of alkyl-substituted bis-arene compounds of the transition metals[11–14]: for example, alkyl-substituted bis-benzenechromium is always obtained as a mixture of homologues, due to transalkylation of the alkyl-substituted aromatic hydrocarbons in the presence of the aluminium chloride added to the reaction mixture. Thus, the synthesis of bis-ethylbenzenechromium yields[13,14] a mixture of mono-, di-, and trisubstituted homologues of bis-benzenechromium, as well as a series of asymmetric products such as benzene-ethylbenzenechromium. The concentration of homologues in the mixture is determined by the experimental conditions, varying from fractions of one percent to tens of percent. The preparation of chromium coatings from these complex mixtures is not an easy process: the MOC vapour from the evaporator is led into the reactor, where it flows over the objects to be coated, which are held at a temperature higher than the decomposition temperature of the organochromium compound. The MOC decomposes on the hot surface, and a chromium film is formed. However, since the various organochromium compounds present in the mixture have different boiling points and vapour pressures, and also different decomposition temperatures, it is difficult to maintain a constant concentration of chromium MOC vapour in the reactor, and therefore the rate of deposition and the electro-physical parameters (such as resistivity) of the

film are not easily controlled. Hence, it is necessary to separate the bis-arene compounds of transition metals into their individual compounds before attempting to prepare metallic coatings by the thermal decomposition of these materials.

Table 3. Organic impurities in bis-ethylbenzenechromium, and sensitivity of the gas–liquid chromatography method of analysis used.

Impurity	Impurity content, mol.%	Analytical sensitivity, mol.%
Benzene	1.0	$1.2 \cdot 10^{-2}$
Toluene	$1.0 \cdot 10^{-2}$	$1.0 \cdot 10^{-2}$
Ethylbenzene	1.8	$6.0 \cdot 10^{-3}$
o-Ethyltoluene	$1.0 \cdot 10^{-2}$	$1.0 \cdot 10^{-2}$
o-Diethylbenzene	1.0	$5.1 \cdot 10^{-3}$
Triethylbenzene	$5.0 \cdot 10^{-1}$	$7.2 \cdot 10^{-3}$
bis-Benzenechromium	$5.0 \cdot 10^{-2}$	$6.0 \cdot 10^{-3}$
bis-Toluenechromium	$4.0 \cdot 10^{-2}$	$4.0 \cdot 10^{-2}$
Benzene-ethylbenzenechromium	12.2	$1.9 \cdot 10^{-2}$
bis-Ethylbenzenechromium	66.5	—
Ethylbenzene-*o*-diethylbenzenechromium	15.7	$3.0 \cdot 10^{-2}$
bis-Diethylbenzenechromium	1.5	$5.1 \cdot 10^{-2}$
bis-Triethylbenzenechromium	$6.0 \cdot 10^{-2}$	$6.0 \cdot 10^{-2}$

The most detailed studies of the preparation of bis-arene compounds of the transition metals in a high state of purity have been made on bis-ethylbenzenechromium [13,14]. The results of a gas-chromatographic analysis of one sample of this material are summarised in Table 3.

Benzene-ethylbenzenechromium, bis-ethylbenzenechromium, and ethylbenzene-*o*-diethylbenzenechromium with an impurity content of 6×10^{-2}% have been isolated by fractional distillation of bisethylbenzenechromium.

Bis-arene compounds of chromium can be purified by recrystallisation as well as by fractional distillation. The methyl homologues of bis-benzenechromium in an oxidised form (e.g. as iodides) are crystalline compounds having different solubilities in water, and hence it is possible to prepare alkyl-substituted derivatives of bis-benzenechromium in a relatively high state of purity [5].

Intensive purification of MOC from traces of other elements can be achieved by distillation, fractionation, preparative chromatography, recrystallisation, ion exchange, or extraction. A particularly successful method [15] of extraction of small amounts of one element in the presence of large amounts of another element, whether in order to concentrate the impurity or to purify the major constituent, depends on the formation of inner complexes of the elements. An exchange reaction occurs during the extraction, and as a result the element E′ present in the aqueous phase displaces the element E″ present in the complex. These exchange reactions offer a high selectivity, since the elements which displace E″ are those which are most readily extracted.

Separation of impurities by extraction can be realised in two ways: either by extracting the impurity or by extracting the major constituent and leaving the impurity in the aqueous layer.

Pure cobalt has been prepared [15,16] by the following procedure: an aqueous solution of a cobalt salt is treated with a solution of a cobalt soap (fatty acid salt) in an organic solvent. Impurities whose soaps are more stable than that of cobalt displace cobalt by ion exchange and are transferred to the organic layer. Cobalt solutions containing only traces of iron and copper, and $2–5 \times 10^{-3}$ g litre^{-1} of nickel, have been prepared by this method.

Tetraethoxysilane has been purified from traces of copper, nickel, cobalt, iron, manganese, and other impurities by a complex-adsorption method [17], in which the starting material is treated with sodium diethyldithiocarbamate, which complexes a large number of metals, and the resulting chelates are removed (together with the excess of reagent) by sorption on activated charcoal. Hydrolysis of the tetraethoxysilane purified in this way, followed by heating the resulting silica gel at 650–750°, has yielded samples of silicon dioxide containing aluminium, iron, copper, lead, and other impurities at the $10^{-5}–10^{-6}$ wt.% level.

Clearly, only some of the impurities can be removed from the main element by exchange–extraction methods. Elements whose extraction properties are inferior to those of the main element cannot displace the latter from its compound in the organic phase, and they remain in the aqueous layer.

A more effective method, capable in principle of removing almost any impurity from the aqueous solution has been described by Zolotov and Spivakov [15]. It consists of two main steps. In the first step the main element is extracted in such a way that the whole of the reagent is used up (the excess of the main element need not be very large). All the elements which are extracted less strongly than the main element remain in the aqueous layer. The main element is then re-extracted with an aqueous solution of appropriate acidity, and the pH of the aqueous extract is adjusted to the value used for the initial extraction. The remaining impurities are then extracted (step 2) with the same reagent but in much smaller amount, so that the main element is present in large excess over the reagent. This operation removes the trace elements which can displace the main element from the complex. Practically all metal impurities in zinc chloride and indium nitrate have been removed by this method.

Some examples of the preparation of super-pure metal-organic compounds by different methods are listed in Table 4.

III. METHODS OF DECOMPOSITION OF METAL-ORGANIC COMPOUNDS AND PURITY OF THE PRODUCT

The preparation of pure substances from MOC is based on the ability of these compounds to yield pure metals or compounds under the influence of various forms of energy. The most widely used and better understood methods rely on the decomposition of MOC in the vapour phase by heat, by an electron beam, by the radiation from optical quantum generators, by a gas-discharge plasma, and also by hydrolytic methods in solution.

Depending on the chosen method of decomposition, and on the experimental conditions, the pure substances can be obtained as powders, films (amorphous or polycrystalline), or as single crystals.

The following types of MOC have been used to prepare high-purity materials: metal alkyls and aryls; alkoxides, acetylacetonates, and organic salts; carbonyls, arenes, and some other compounds.

Whereas the purity of the ultimate product in terms of traces of other elements is determined by the purity of the MOC, the problem of contamination by carbon is more complicated and depends on a number of factors.

The general use of MOC for the preparation of pure metals, oxides, and particularly semiconductors was originally thought to be unlikely because of the presence of organic side-products and of the consequent danger of contamination of the final product by carbon and hydrogen.

Table 4. Purity of metal-organic compounds purified by different methods.

This may be the reason why no attempt was made for many years to prepare semiconductor materials from MOC: only very recently has the successful use of metal-organic compounds in the preparation of semiconductor materials such as epitaxially grown $A^{II}B^{VI}$ and $A^{III}B^{V}$ structures been reported.

A number of approaches which may help to minimise or even to eliminate the risk of carbon contamination may be found in the large fund of experimental information on the decomposition of metal-organic compounds. This belief is confirmed by the many recent reports of the preparation of ultra-high purity materials from MOC. There are two ways of controlling the residual carbon content of materials prepared from MOC. The first relies on the correct choice of MOC and on appropriate control of the decomposition conditions. The second relies on special treatment of the final products obtained from the MOC.

The criteria which determine the best type of MOC structure are the mechanism of thermal decomposition and the likelihood of carbon contamination of the final product.

The decomposition reactions of MOC can be described by the following mechanisms:

1) radical $R_nE \rightarrow n\dot{R} + E$,
2) hydride or olefin $(RCH_2CH_2)_nE \rightarrow nRCH{=}CH_2 + E + H_2$,
3) molecular $L_nE \rightarrow nL + E$.

The first two types of decomposition are typical of alkyl, aryl, and cyclopentadienyl compounds, the third is typical of MOC formed by molecules containing an even number of π-electrons. The most important among the latter are arene and carbonyl compounds of the transition metals, in which the ligands are aromatic hydrocarbons or carbon monoxide.

Side reactions involving the organic radicals and molecules formed during the decomposition of the MOC may lead to contamination of the resulting metal with carbon. Among the most important secondary reactions of the radicals formed by thermal dissociation of MOC, which may influence the purity of the metal produced, are the decomposition of an organic radical to an olefin and hydrogen, or decomposition with C–C bond breaking. Both these reactions have been detected in a study [20,21] of the thermolysis of MOC of tin, germanium, and aluminium. The conclusion of this study was that the lower alkyl radicals tend to decompose by splitting a C–C bond, the higher radicals by splitting a C–H bond.

The influence of the alkyl radical on the purity of the product of MOC decomposition is clearly shown by the behaviour of aluminium-organic compounds [21]. Thus, whereas the pyrolysis of trimethylaluminium is a method of preparation of aluminium carbide, high-purity aluminium containing $\sim 1\times10^{-2}\%$ of carbon can be prepared by thermal decomposition of tri-isobutylaluminium. A similar behaviour is observed also in the thermal decomposition of organogallium compounds: whereas the decomposition of trimethylgallium is accompanied [22] by the formation of a polymeric product of composition $(CH_3Ga)_n$, high-purity gallium metal is obtained from the decomposition of tri-isobutylgallium [5].

Thus, to prepare pure metals by thermal decomposition of MOC we must choose compounds in which the E–R bond energy is small, and the side-reactions of the organic constituents of the molecule occur preferentially by β–C–H (rather than β–C–C) cleavage.

MOC which decompose by the molecular mechanism are suitable for the preparation of pure metals in the form of powders or in the form of coatings. These include bis-arene, arenecarbonyl, carbonyl, and some other organic compounds of the transition metals. The influence of the starting MOC on the carbon and hydrogen content of chromium and molybdenum films prepared pyrolytically has been carefully studied [23–25]. The study included a

series of bis-arene compounds of chromium and molybdenum, the iodides of the bis-arene derivatives of chromium, and some arenetricarbonyl compounds of both metals. The resulting metal films were found to be contaminated by carbon, hydrogen, and (in the case of chromium) oxygen. The chromium films contained between 0.5 and 10% of carbon. The carbon content increased from the arene π-complexes to the arenetricarbonyl compounds of chromium, and within the chromium arene series it increased with the number of alkyl substituents in the aromatic nucleus of the π-complex. The lowest carbon content was found in the chromium films prepared by the pyrolysis of the iodides of bisarenechromium compounds.

Molybdenum films prepared by thermal decomposition of bis-arene and arenetricarbonyl compounds of molybdenum contain more carbon than chromium films prepared under similar conditions from analogous compounds.

Oxygen analysis of the chromium and molybdenum films gave some interesting results. Thus, whereas the pyrolytic chromium films contained 8% of oxygen as Cr_2O_3, the molybdenum films prepared by pyrolysis of bisarenemolybdenum complexes under similar conditions contained no oxygen. The most likely explanation is that both chromium and molybdenum are readily oxidised in the presence of a trace of oxygen, but whereas the chromium oxide is involatile and resistant to reduction by the products of partial decomposition of the MOC, the molybdenum oxide is more volatile, and can be reduced to the metal at temperatures as low as 360–700°.

Evidently, the presence of carbides and oxides in the pyrolytic chromium films can explain their enhanced hardness, mechanical strength, and resistance to acids (as compared with chromium films prepared electrochemically or by vacuum deposition).

It is clear from these results that the purity of metals prepared by thermal decomposition of MOC is largely determined, as far as carbon contamination is concerned, by the type of compound used, and that this contamination can be partly or completely eliminated by suitable choice of the starting compound.

However, the experimental conditions under which the MOC is thermally decomposed are also a very important factor in determining the purity (and in particular the freedom from carbon) of the resulting metals and compounds. Among the most important practical conditions are factors such as the medium, the decomposition temperature, the total pressure in the reactor, the rate of removal of the decomposition products, and the possibility of catalytic reactions.

The temperature at which thermal decomposition is carried out has a profound effect on the decomposition mechanism of the MOC, on the direction and extent of side-reactions, and hence on the purity of the final product.

Work on the bis-arene compounds of chromium and molybdenum has shown that the carbon content of the metal film increases with the temperature at which the MOC is decomposed. Thus, if bis-ethylbenzenechromium is pyrolysed at temperatures in the range 450–700° the carbon content of the chromium films increases from 0.7 to 6%,[23] and in the decomposition of mesitylenetricarbonylmolybdenum it increases from 6 to 10% as the temperature is increased from 400 to 550°.[25]

The higher carbon content is the result of more deep-seated chemical changes in the aromatic hydrocarbons, leading to the formation of free carbon and metal carbides. It is important to note that the aromatic ligands in arene compounds of the transition metals suffer more drastic decomposition than the corresponding aromatic hydrocarbons. Thus, hydrogen evolution is hundreds of times more abundant during the decomposition of bis-benzenechromium than during the decomposition of benzene at the same temperature[18].

A thermodynamic analysis of the decomposition of bis-benzenechromium[26] has shown that reactions leading to the formation of chromium, chromium carbides, and free carbon have a higher probability than reactions in which the only solid products are chromium and carbon. The higher the temperature, the greater is their probability. Hence, the decomposition temperature chosen for the bis-benzenechromium should be as low as possible in order to minimise the carbon content of the chromium films.

An increase in the temperature at which metal-organic compounds are thermally decomposed does not invariably produce an increase in the carbon content of the film: the type of MOC, and the nature of the decomposition products, determine the effect of an increase in temperature. This phenomenon is clearly illustrated by the preparation of pure metals through the pyrolysis of metal carbonyls[27–29]. The decomposition of molybdenum hexacarbonyl by the reaction $Mo(CO)_6 \rightarrow Mo + 6CO$ is accompanied by the side-reaction $2CO \rightleftharpoons C + CO_2$, which is responsible for the contamination of the molybdenum with carbon. On raising the temperature, the equilibrium of the carbon monoxide decomposition reaction is shifted towards the left, and the amount of free carbon decreases. Several workers[27–29] have found that molybdenum coatings prepared by thermal decomposition of molybdenum hexacarbonyl at relatively high temperatures have a lower carbon content.

It follows that a knowledge of the decomposition mechanism of the MOC, and of the side-reactions, is an essential prerequisite to the correct choice of decomposition temperature for the preparation of pure, carbon-free metals. The decomposition temperature can be lowered very significantly by introducing various additives into the reactor: this is an interesting method of decreasing the probability of contamination of a metal or compound prepared by thermal decomposition of MOC. The effect of additives can be explained as follows. An additive can react with the starting reagent, or it can catalyse its decomposition, thus lowering the decomposition temperature of the MOC. It can also react with the decomposition products of the MOC, thus lowering the probability of the side-reactions and raising the purity of the product. Lastly, the additive may deactivate the excited metal atoms formed by the thermal decomposition of the MOC, and modify the crystallisation conditions. Thus, the addition of amines during the thermal decomposition of tetra-alkylgermanium compounds has been shown[30] to favour the growth of monocrystalline germanium "whiskers".

The decomposition temperature of bis-arenechromium compounds can be lowered by using halogen and sulphur compounds as catalytic additives[31,32].

In the thermal decomposition of tetraethoxysilane, the presence of oxygen lowers the temperature of formation of silicon dioxide by ~300°. The catalytic effect of transition-metal salts can give rise to autocatalysis in the decomposition of some MOC. Thus, a chromium halide is formed by disproportionation during the preparation of chromium coatings from halogen derivatives of bis-arenechromium compounds[23,33]; this halide catalyses the thermal decomposition, lowering the formation

temperature of the chromium film and at the same time decreasing its carbon content.

The pressure, and the rate of removal of by-products, have a major influence on the quality and the structure of deposits prepared by thermal decomposition[34]. The pyrolysis of MOC gives rise to gaseous products whose vapour pressure is much higher than the vapour pressure of the original MOC. As a result, the total pressure in the system increases, and the concentration of MOC close to the substrate surface decreases: both these effects tend to lower the rate of deposition. This rate-limitation by pressure is observed at constant rate of removal of the reaction products. If the rate of removal is zero (closed reaction vessel) there is a gradual decrease in deposition rate due to the increase in pressure in the system. If the rate of removal of the decomposition products tends to infinity the rate of growth of the deposit becomes independent of pressure, and is limited by the rate of mass transfer to the substrate or by the rate of the decomposition reaction of the MOC. In all intermediate cases the rate of deposition is pressure-dependent to a greater or lesser extent. The presence of decomposition products near the substrate surface, and the increase in total pressure, tend to favour the adsorption of the decomposition products on the solid deposit and to hinder their desorption, thus increasing the danger of contamination. These observations lead to the following practical conclusion: in the thermal decomposition of MOC, faster depositions and purer deposits are obtained by working at low pressures and by ensuring that the decomposition products are removed rapidly.

Domrachev and coworkers[34] studied the carbon content of molybdenum films as a function of the ratio of the rate of supply of molybdenum carbonyl to the rate of removal of the reaction products, and they found that the carbon content changes from 4.6 to 1×10^{-1} wt.% as the rate of removal is increased from 0.5 to 14.2 litre s^{-1} (surface temperature 602°, $P = 0.1$ mmHg).

Other factors are also known to affect the purity of metals and compounds prepared by thermal decomposition of MOC. For example, the effect of an electric field on the growth of deposits during the thermal decomposition of molybdenum carbonyl has been investigated[38]. It has been shown that the electrostatic field increases the rate of deposition of the metal, drastically lowers the carbon content (to $\sim 1 \times 10^{-2}$%), and lowers the optimum deposition temperature of high-quality films.

In addition to the thermal decomposition method, the hydrolytic method is widely used for the preparation of high-purity materials from MOC in the vapour phase. The method lends itself to the preparation of very pure oxides, mixed oxides, and compounds such as barium titanate. Hydrolysis can be induced by treating the MOC with water vapour, in solutions, or in the vapour phase. Hydrolysis in solutions occurs at room temperature, and the resulting oxides are practically free from carbon. The greatest danger of carbon contamination arises during hydrolysis in the vapour phase. The purity of silicon dioxide prepared by vapour-phase hydrolysis of tetraethoxysilane is profoundly affected by the ratio $Si(OC_2H_5)_4 : \alpha H_2O$, the optimum value of α being a function of the hydrolysis temperature[37]. Thus, the optimum values of α at 427, 727, and 1227° are 2.85, 4.85, and 6 respectively. As the temperature increases, and as α decreases, the amount of carbon incorporated in the solid deposit increases. Whereas powdered silica prepared at 350° and with $\alpha < 3$ is strongly contaminated with carbon (and black in colour), a fine white powder is obtained at the same temperature with $\alpha > 4$. No carbon is detected in the latter sample by i.r. or u.v. spectroscopy.

Thus, the carbon content of materials prepared by the decomposition of MOC can be lowered by a number of methods, including the choice of the best type of starting material and proper control of the experimental conditions. In addition, the carbon content can also be decreased by special treatment of the final product of thermal decomposition. Hydrogen (and, in particular, moist hydrogen) is a very effective medium for the post-treatment of metals such as chromium, molybdenum, tungsten, iron, nickel, and ruthenium. Thus, whereas molybdenum prepared by the pyrolysis of molybdenum carbonyl contains ~1% of carbon, a hydrogen treatment after pyrolysis lowers the carbon content to 1×10^{-2}.[38] Thermal decomposition of iron carbonyl followed by heat treatment of the resulting carbonyl iron in hydrogen yields the purest of all iron powders[7]. The heat treatment of the carbonyl iron removes nitrogen and oxygen impurities as well as carbon. The main impurities in iron powder prepared by thermal decomposition of iron carbonyl are cementite (Fe_3C), the nitride Fe_4N, and magnetite (Fe_3O_4).[7] These impurities react with hydrogen to give metallic iron and gaseous products (water, methane and ammonia). The impurity hardest to remove is elemental carbon, which begins to react with hydrogen at an appreciable rate only above 400°. The purest iron powder is obtained by treating the carbonyl iron powder in a hydrogen atmosphere at the lowest possible temperatures (in the range 300–400°) in a large excess of hydrogen and with continuous removal of the reaction products[7]. The level of purity attainable in iron powder prepared by thermal decomposition of iron carbonyl followed by heat treatment in a hydrogen atmosphere is indicated in Table 5.

IV. PREPARATION OF PURE ELEMENTS, OXIDES, AND OTHER COMPOUNDS

Elements can be prepared in a high state of purity from MOC by methods such as thermal decomposition in the vapour phase or in solutions, photolysis, and electrolysis. The ultimate freedom from trace impurities is determined by the purity of the initial MOC rather than by the method of decomposition. Contamination of the final product by carbon depends mainly, as discussed in Section III, on the type of MOC and on the decomposition conditions.

The advantages of using MOC for the preparation of pure materials are most clearly seen when the ultrapure material is required in the form of a thin coating, or when an alloy of prescribed composition is deposited as a thin film. Alloy films deposited by conventional methods do not always have the same composition as the starting material, because of differences in the evaporation temperature of the alloy components. By choosing MOC of different metals having similar physicochemical properties, or by adding controlled amounts of MOC vapours to the reactor, coatings having the desired component ratio can be deposited by thermal decomposition even on items of complicated shape.

The relatively low decomposition temperature of MOC, and the absence of other reagents or solvents, ensure that metals prepared from MOC are purer than metal prepared by other methods. Chromium prepared by the

pyrolysis of bis-benzenechromium[18] contains fewer trace impurities than electrolytic chromium. The purity of iron prepared by thermal decomposition of iron pentacarbonyl is outstandingly high[7,39].

Because of the selectivity of the methods of synthesis, and of the high purity of the resulting metals, MOC have been used on an industrial scale to prepare specially pure materials. The carbonyl process for the preparation of pure iron[7] is very widely used in industry. It can be described by the following scheme:

$$Fe_{(impure)} + 5\,CO \xrightarrow[P=100-200\ atm]{180-220^\circ} Fe(CO)_5 \xrightarrow{230-330^\circ} Fe_{(pure)} + 5\,CO\,.$$

In the first step of the process the carbon monoxide reacts selectively with an iron-containing ore to give iron pentacarbonyl: this results in considerable purification from traces of other metals. In the second step, pure iron is produced by thermal decomposition and the carbon monoxide is re-cycled.

Table 5. Summary of preparation of pure substances from metal-organic compounds.

Element or compound	Starting compound	Method and conditions	Trace impurities in the product	Reference
1	2	3	4	5
Al	Di-isobutylaluminium hydride	Pyrolysis at 340°	Carbon $< 2 \times 10^{-2}$	21
	Tri-isobutylaluminium	Pyrolysis at 200°	Purity 99.999	50
	Complex of triethyl-aluminium with sodium fluoride	Electrolysis with lead anode	High purity	50
In	Trimethylindium complexes	Electrolysis	Cu 5×10^{-5}, Cd 2×10^{-4}, Tl 1.4×10^{-5} wt.% Fe, Pb, Sn, Ag, Mg, Si, Ni not detected	51,52
Ga	Triethylgallium	Electrolysis	Pb $\ll 1 \times 10^{-4}$, Zn 4×10^{-6}, Cu 8×10^{-6}, wt.% Sn, Mn not detected	51,52
Tl	Organic complexes of thallium salts	Electrolysis	Al 9×10^{-5}, In 8×10^{-4}, Mg 3×10^{-5} wt.% Ag, Cu, Fe, Si not detected	51,52
Ge	Germanium tetra-alkyls	Pyrolysis at 400°	Carbon < 0.1%	53,54
Fe–Ni	Mixed iron and nickel carbonyls	Pyrolysis below 200°	Carbon < 0.001%	55
Fe	Carbonyl iron	Pyrolysis and heating in hydrogen	Ni $1-2 \times 10^{-4}$ C $< 3 \times 10^{-3}$ C 1×10^{-2} S, P, Cu, Mn	7
	ditto	Pyrolysis at 200–300°	Ni, Co, Cr, Mo, Zn, Si not detected	39
Ru	Dicyclopentadienyl-ruthenium	Pyrolysis at 595° in hydrogen	Ru 99.99% pure Fe 1×10^{-2}, Pd $< 5 \times 10^{-3}$, Bi, Si even smaller traces	56
W	Tungsten carbonyl	Pyrolysis at 1000°	Carbon 0.02 wt.%	57
Cr	bis-Cumenechromium	Pyrolysis at 300–400°	Carbon < 0.2%	58
	bis-Ethylbenzene-chromium	Pyrolysis	Al 6×10^{-3}, Fe 3×10^{-3}	59
	bis-Benzenechromium	Pyrolysis	Cu $6,1 \times 10^{-4}$, Mo 1.85×10^{-4}, Sn 6.9×10^{-4}, C 1.06×10^{-1}, O 2.04×10^{-2}, H 5.7×10^{-4} N 2.16×10^{-3}; Al, Cd, Fe, Mg, Si not detected	18
Mo	Molybdenum carbonyl	Pyrolysis and heating in hydrogen	Carbon 1×10^{-2}%	38
Mo	ditto	Pyrolysis in an electric field at 600–1200°	Carbon $< 1 \times 10^{-3}$%	36
Ni	Nickel carbonyl	Pyrolysis in the presence of hydrogen sulphide below 100°	C 0.01%	60,61
Ni	Nickel carbonyl	Pyrolysis and heating in wet hydrogen	Mg, Si, P, S 1×10^{-3} Co, Zn, 5×10^{-4}, Cd, Sn, Sb, Pb, Bi, Al 3×10^{-4}, Fe 2×10^{-2} C trace	62

Table 5 (cont'd)

Element or compound	Starting compound	Method and conditions	Trace impurities in the product	Reference
1	2	3	4	5
Ga	Tri-isobutylgallium	Pyrolysis at 200°	Zn $< 1 \times 10^{-3}$, Ag 2×10^{-4}, Cu 4×10^{-5}, Al 1×10^{-4}, Ni $< 1 \times 10^{-3}$, Fe $< 1 \times 10^{-3}$, Cr $< 1 \times 10^{-3}$, Mg 4×10^{-5}, Mn $< 1 \times 10^{-4}$	5
SiO_2	Tetraethoxysilane	Hydrolysis and heating at 650–750°	Al $3-8 \times 10^{-6}$, Fe 2×10^{-6} Mg $2-8 \times 10^{-6}$ Mn $1 \times 10^{-6}-3 \times 10^{-6}$ Cu $2 \times 10^{-6}-8 \times 10^{-7}$, Pb $\sim 5 \times 10^{-6}$, B 2×10^{-6}	17
HfO_2	Hafnium tetra-amyloxide	Hydrolysis, 24 h drying at 50°, 0.5 h heating at 250°	99.995%	63
Al_2O_3	Aluminium tri-iso-propoxide	Hydrolysis	Cu 7×10^{-5}, Mg 4×10^{-4}	5,6
Ta_2O_5	Tantalum penta-ethoxide	Hydrolysis	Ag $< 4 \times 10^{-4}$, Ti $< 3 \times 10^{-4}$, Fe 5×10^{-4}, Pb $< 1 \times 10^{-4}$, Mn $< 2 \times 10^{-5}$	5,6
Nb_2O_5	Niobium penta-ethoxide	Hydrolysis	Ag $< 1 \times 10^{-5}$, Fe 3×10^{-4}, Pb $< 2 \times 10^{-3}$, Mn $< 2 \times 10^{-4}$	5,6
$BaTiO_3$	Barium isopropoxide, titanium tetra-t-amyl-oxide	Hydrolysis	99.98%	44
$HfTiO_4$	Hafnium tetra-amyloxide, titanium tetra-amyloxide	Hydrolysis, 12 h drying at 50°, heating at 580°	99.95% Co $< 1 \times 10^{-3}$, Na $< 5 \times 10^{-3}$, Si $< 3 \times 10^{-3}$, Fe $< 3 \times 10^{-3}$	64
$HfO_2Y_2O_3$	Hafnium tetra-amyloxide, yttrium tri-isopropoxide	Hydrolysis, 12 h drying 60°, 0.5 h heating at 550°	99.95%	65
GaAs	Trimethylgallium, arsine	Pyrolysis	Si 8.6×10^{-5}, S 3.4×10^{-5}, Fe 6.2×10^{-5}, Cu 1×10^{-5}, Zn 4×10^{-5}, C 2×10^{-3}, Ni 1.7×10^{-5}, O 2.4×10^{-3}	10
CdS	Dimethylcadmium, hydrogen sulphide	Pyrolysis	Semiconductor purity	47–49
	ditto	Reaction in solution		46
AlAs single crystal	Trimethylaluminium	Thermal decomp. at 700° in arsine	Semiconductor purity	67
AlP single crystal	ditto	Thermal decomp. at 700° in phosphine	ditto	67
GaP single crystal	Triethylgallium, triethyl-phosphine	Thermal decomp. at 420° of a mixture of tri-ethylgallium and triethyl-phosphine	"	68
ditto	Trimethylgallium	Thermal decomp. at 700° of tri-methylgallium in the presence of phosphine	"	9
AlN	Trimethylaluminium	Decomp. at 1200° of trimethyl-aluminium in ammonia	"	69
GaN	Trimethylgallium	Decomp. at 925–975° in ammonia	"	69
Fe_2O_3	Iron carbonyl	Oxidation	High purity	7
Ge	Tetraethylgermanium	Thermal decomp. at 820° in argon–hydrogen mixture	Semiconductor purity no carbon detected	66

A study of the thermal decomposition of tri-isobutylaluminium

$$[(CH_3)_2CH{-}CH_2]_3Al \rightarrow 3(CH_3)_2C{=}CH_2 + {}^3/_2H_2 + Al$$

has shown[40] that a method of purification of aluminium similar to the carbonyl iron process could be developed by combining the dissolution of technical-grade aluminium in isobutylene in the presence of hydrogen with the decomposition of isobutylaluminium. Some complications arise from the possible contamination of the aluminium with carbon, but the carbon content can be made as low as 2×10^{-2}% by suitable choice of the conditions under which the tri-isobutylaluminium is decomposed[21].

Pure metal oxides and other compounds can be prepared from MOC by methods such as thermal decomposition in the vapour phase of one (or several) compounds, reaction of MOC in solutions or in the vapour phase with oxygen or with compounds having labile hydrogen atoms (hydrogen sulphide, arsine, stibine, phosphine), hydrolysis in the vapour phase or in solution, or decomposition in the plasma of a gas discharge.

Depending on the conditions under which the MOC is decomposed, oxides and semiconducting compounds can be obtained in the form of powders, films, or epitaxially grown layers.

The most convenient sources of pure oxides are metal alkoxides and salts of organic acids.

The hydrolytic decomposition of alkoxides is widely used for the preparation of high-purity metal oxides. This method yields not only powdered oxides and mixed oxides, but also thin films for coating optical surfaces, for protective coatings, and for use as diffusion sources in semiconductor technology[41].

The hydrolytic method has been used to prepare very pure oxides of silicon[17], germanium[42], magnesium, aluminium, and titanium[43]. Very pure mixed oxides and compounds can be obtained by hydrolysing several alkoxides simultaneously. Thus, the hydrolysis of a mixture of barium isopropoxide and titanium tetra-amyloxide yields[44] barium titanate of 99.98% purity and 50–100 Å particle size:

$$Ba(OC_3H_7)_2 + Ti(OC_5H_{11})_4 + 3H_2O \rightarrow BaTiO_3 + 2C_3H_7OH + 4C_5H_{11}OH.$$

The uniformity and stoichiometric composition of the product were confirmed by chemical analysis and electron microscopy. The powder, dried at 50° in an inert gas atmosphere, was shown to have the barium titanate structure by X-ray diffraction analysis and i.r. spectroscopy.

Powders or films consisting of mixed oxides in the required proportions can be prepared from the alkoxides of Group IV elements such as silicon and titanium, and also aluminium. Simultaneous hydrolysis of solutions of tetraethoxysilane and compounds of other elements has been used to prepare powders and glasses of various compositions[45]. Calculated compositions of the oxides in solution were found to agree satisfactorily with the experimentally observed compositions of the powders obtained by hydrolysis[45].

The film-forming component (e.g. the alkoxide) must be suitably chosen to ensure that the oxide is deposited as a film. Tetraethoxysilane and some inorganic compounds are used in solution in polar organic liquids, aqueous alcohol, or acetone–water mixtures. The water content varies between 0.1 and 10–20%, depending on the nature of the film-forming compound[41]. Mixtures of polar and non-polar solvents can also be used to prepare films from mixtures of several compounds.

One of the distinguishing features of the use of MOC for the preparation of semiconducting compounds (in contrast to the use of inorganic compounds) is that the purity problems are less intractable. This is because the preparation of semiconductor materials from MOC usually involves lower temperatures than the preparation of the same materials from inorganic compounds, thus minimising the danger of contamination from the material of the apparatus. Furthermore, the selectivity of the methods of preparation of the MOC (discussed in Section II) ensures that many undesirable impurities are eliminated from the starting material.

Like the oxides, other compound semiconductors can be prepared from MOC by decomposition in solution or in the vapour phase. The conditions under which the decomposition is carried out are determined mainly by the form in which the semiconductor is required (powder, deposited film, or epitaxially grown layer).

Pure metal chalcogenides can be prepared by treating MOC in solution with hydrogen sulphide. Hanschild and Glemser[46] have obtained very pure cadmium sulphide by the reaction between dimethylcadmium and hydrogen sulphide in liquid propane:

$$(CH_3)_2Cd + 2H_2S \rightarrow Cd(SH)_2 + 2CH_4$$
$$Cd(SH)_2 \rightarrow CdS + H_2$$

The cadmium hydrogen sulphide decomposes at −(40–50)°; the last traces of hydrogen sulphide are removed by heating the product in a vacuum. The method yields material free from traces of other metals, and it can be used to prepare other binary compounds.

The preparation of pure semiconductor materials from MOC is particularly attractive when the product is required in a special form (for example, an epitaxially grown layer). Epitaxial layers of $A^{III}B^{VI}$ and $A^{III}B^{V}$ semiconductor compounds and of their solid solutions can be prepared by decomposing a MOC in the vapour phase in the presence of the appropriate hydride at a temperature suitable for the growth of a monocrystalline layer.

Thus, epitaxial structures of gallium arsenide have been prepared[9,10] by the thermal decomposition of gallium alkyls in the presence of arsine. The impurity level of the gallium arsenide with respect to Si, S, Fe, Cu, and Zn was 10^{-4}–10^{-5}. It is interesting to note that the carbon contamination in these layers of gallium arsenide[10] is of the same order ($\sim 2 \times 10^{-3}$%) as in the layers prepared from gallium and arsenic chlorides: hence, this contamination cannot be due to the carbon from the MOC. Epitaxial structures of cadmium and zinc sulphides, selenides, and tellurides, of semiconductor purity, have been obtained by the thermal decomposition in the vapour phase of dimethylcadmium and diethylzinc in the presence of hydrogen sulphide or hydrogen selenide, or of dimethyltellurium[47–49].

We may conclude from these examples of the preparation of high-purity materials that the decomposition of MOC is a very promising method of preparation of pure metals, oxides, and compound semiconductors. It lends itself to the production of these materials not only in a pure form, but also in the special configurations required in electronics technology. Rapid developments of the MOC method can be expected in the near future.

Various examples of the preparation of high-purity materials from MOC are listed in Table 5 together with the appropriate conditions.

---o0o---

In conclusion, we have established that the thermal decomposition of MOC is a powerful method of preparation of various substances in a high state of purity as coatings, films, and single-crystal layers. The method can be applied also to refractory materials. Rapid developments, leading to widespread practical applications, can be expected.

Paramagnetic Shift Reagents in Nuclear Magnetic Resonance Spectroscopy

I.Ya.Slonim and A.Kh.Bulai

The physical foundations and the applications of a new method in nuclear magnetic resonance spectroscopy—the simplification of spectra by means of paramagnetic shift reagents, complexes of lanthanides with diketones—are examined, and data given on the properties of the most widely used reagents. The discussion covers the mechanism of interaction of the shift reagent with the organic compound (substrate), the dependence of the displacement of the signals on the concentration of the components and the temperature, the equilibrium in the reagent-substrate system, the effect of the nature of functional groups in the substrate, of the lanthanide ion, and of the ligand in the reagent on the magnitude of the shift in the n.m.r. spectra, the dependence of the shift and the line width on geometrical factors, and the effect of the shift reagent on spin-spin coupling constants. The use of shift reagents in the nuclear magnetic resonance of protons and other nuclei is considered briefly. The paper includes a summary of compounds whose spectra have been studied in the presence of shift reagents and also 348 references.

I. INTRODUCTION

Nuclear magnetic resonance spectroscopy has become probably the most powerful method for determining the structure of organic compounds, including polymers and biopolymers. However, the information content of proton magnetic resonance spectra is substantially diminished by the fact that the protons in methine, methylene, and methyl groups unaccompanied by electronegative atoms give signals having closely similar chemical shifts in the range 0.8–2.5 ppm. A new and extremely effective method, which in several cases completely overcomes difficulties due to the overlapping of signals, is the use of paramagnetic shift reagents.

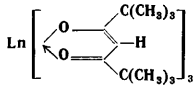
The effect of paramagnetism on nuclear magnetic resonance was detected soon after discovery of the latter [1]. Detailed theoretical and experimental studies of n.m.r. in paramagnetic systems have been reviewed [2-12]. Successful attempts were made to use nickel(II) and cobalt(II) complexes as shift reagents [13,14], but these compounds have not found wide application. A decisive step for development of the method was the change to lanthanide derivatives—complexes of europium [15,16], praseodymium [17], and other lanthanides [18-24] with 2,2,6,6-tetramethylheptane-3,5-dione, complexes with fluorine-containing [25] and with optically active [26-29] diketones.

Lanthanide shift reagents—complexes of tervalent ions Ln^{3+} with β-diketones—are Lewis acids. In solution they form complexes (adducts) with organic molecules (substrates) containing atoms having a lone pair of electrons (oxygen, nitrogen, sulphur, phosphorus), the substrates being Lewis bases. The paramagnetic ion displaces the lines in the n.m.r. spectrum. Because of rapid exchange between free and complexed molecules the observed spectrum is intermediate between those of the free and the bound substrate.

The Review will survey the physical principles underlying the action of paramagnetic shift reagents, discuss the effects of various factors on the n.m.r. spectrum of the substrate—reagent system, and briefly consider the application of paramagnetic shift reagents in organic and polymer chemistry.

II. PARAMAGNETIC SHIFT REAGENTS USED IN n.m.r. SPECTROSCOPY

Among the many known complexes of lanthanides (several hundreds were tested in a single study [25]!) only a few have found practical use as paramagnetic shift reagents. This is because shift reagents should satisfy several requirements. Such properties as great coordinating power with substrates, magnetic anisotropy, a ligand of great bulk (in order to fix the relative positions of substrate and reagent molecules in the adduct), and short electronic relaxation time (to keep the spectral lines narrow) are of considerable importance. It is also necessary that the substance should be sufficiently stable in the air, soluble in organic solvents, etc. Tables 1–3 list the properties of β-diketonatolanthanide paramagnetic shift reagents. Salts—chlorides and chlorates—can be used in aqueous solutions, and lanthanide nitrates in acetone solutions [30-34].



The solubility of the trisdipivalomethanatoeuropium(III) complex in carbon tetrachloride, hexadeuterobenzene, and deuterochloroform at room temperature is respectively [35] 200–300, 100, and 200–300 mg ml^{-1}. The solubility increases in the presence of a polar substrate [36]. The corresponding ytterbium complex is more soluble [37], as is also tris-6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dionatoeuropium(III), up to 400 mg ml^{-1} in carbon tetrachloride [25]. This last anhydrous complex, the corresponding praseodymium compound, and the tristetramethylheptanedionatoeuropium complex are strongly hygroscopic [25,38], and should therefore be kept over phosphorus pentoxide in a vacuum desiccator [25]. The solvents used in work with the shift reagents should be especially carefully dried and freed from acidic impurities: chloroform is treated with molecular sieves [35]; carbon tetrachloride is stored over caustic soda and redistilled [42].

III. EFFECT OF PARAMAGNETIC SHIFT REAGENTS ON n.m.r. SPECTRA

1. Shifts of Signals in Spectra

The shift in the n.m.r. signal of the substrate in the presence of lanthanide shift reagents is caused by the local magnetic field produced by the ion at the site of the nucleus. Most authors consider that the main contribution to the shift is made by so called "pseudocontact" (dipole) interaction appearing when the magnetic susceptibility of the complex is anisotropic: the field due to the lanthanide is not then averaged out by the molecular motion.

When the rate of molecular reorientation is large in comparison with the n.m.r. line width expressed in the same units, but small compared with the rate of electronic relaxation, and the complex has axial symmetry, the shift is given by the formula [46-49]

$$\delta_i = -10^6 \cdot \frac{1}{3N_A}(\chi_{M\parallel} - \chi_{M\perp})\frac{3\cos^2\theta_i - 1}{r_i^3} \qquad (1)$$

where δ_i (in ppm) is the shift in the signal for the ith nucleus, N_A is Avogadro's number, $\chi M\parallel$ and $\chi M\perp$ are the components of the molar magnetic susceptibility parallel and perpendicular to the symmetry axis, r_i is the length of the vector $\vec{r}_i$ between the paramagnetic ion and the ith nucleus, and θ_i is the angle between this vector and the principal magnetic axis of the complex.

The magnetic susceptibility depends on the electronic configuration of the paramagnetic ion, the ligand field, and the temperature. Equations expressing the pseodocontact shift in terms of the anisotropy of the g-factor were obtained by McConnell and Robertson [50] for ions whose magnetic properties obey the Curie law. More complicated expressions are obtained [49,54-57] for the lanthanide ions, especially for Eu^{3+}, in which the ground state (the $^7F_0$ level) is diamagnetic, and paramagnetism arises only from the excited state $^7F_1$. [51-53] Comparison with experiment shows satisfactory agreement [48,57], although difficulties are caused by the fact that magnetic susceptibilities measured on single crystals [48,58] may differ from those of molecules in solution, and furthermore the magnetic susceptibility may change on coordination of the shift reagent with the substrate [38,59,60]. The mainly pseudocontact (dipole) nature of the shift caused by lanthanide shift reagents is confirmed also by the linear dependence of the shift on the geometric factor $(3\cos^2\theta_i - 1)/r_i^3$ (see below), by the identity of proton and carbon-13 shifts in the presence of tristetramethylheptanedionatoeuropium [61,62], by the fact that the shift and the anisotropy of the g-factor have the same sign [19], and by the constancy of the ratio of shifts in the presence of the above complex to those in the presence of the corresponding praseodymium complex for several compounds [63].

Table 2. Tris-6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dionatolanthanide(III) complexes Ln fod$_3$

(preparation [43]).

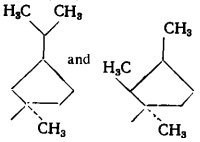
Eu	white	205—212 (decomp.)	59—67
Pr	green	218—225 (decomp.)	218—225 (decomp.)



If the electron spin density of a paramagnetic ion is delocalised, and is transmitted through a system of chemical bonds to the nucleus, a contact shift in the n.m.r. signal is observed [64]:

$$\delta_i = -10^6 \cdot A_i \frac{\gamma_e}{\gamma_n} \frac{g\beta S(S+1)}{3kT} \qquad (2)$$

where γ_e and γ_n are the gyromagnetic ratios of electron and nucleus, A_i is the isotropic hyperfine electron–nucleus coupling constant, g is the g-factor, β is Bohr's magneton, S is the spin quantum number of the electron, k is Boltzmann's constant, and T is the absolute temperature.

Table 3. Optically active paramagnetic shift reagents—tris-3-alkylhydroxymethylene-(+)-camphorato-europium(III) complexes

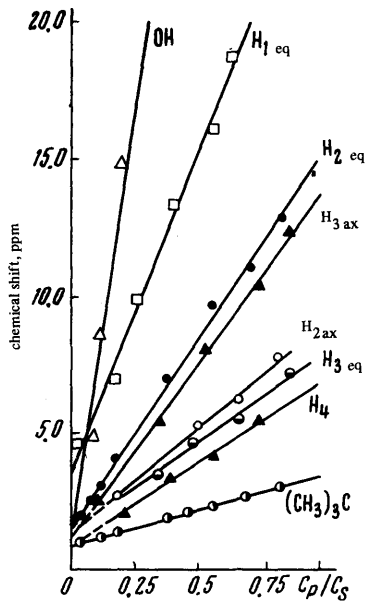
Alkyl R	Preparation—Ref.
$(CH_3)_3$—C—	26
CF_3—	28, 44, 45
$CF_2CF_2CF_3$	29
	27

The contact shift usually plays no great part in changing the n.m.r. spectra in the presence of lanthanide shift reagents. The presence of contact interaction is taken into account only in certain cases—for nuclei situated beside a coordination site, e.g. protons in the *geminal* position to a hydroxy-group [66,67] protons [68,69] and carbon nuclei [70] in strong Lewis bases having a π-bond system in the presence of shift reagents that are strong Lewis acids, and also with nitrogen-14 and phosphorus-31 nuclei.

Pseudocontact and contact interactions displace the signals in the n.m.r. spectra only of those substrate molecules that form an adduct with the paramagnetic shift reagent molecules. In addition, the introduction of a paramagnetic additive produces a large general upfield displacement of the whole n.m.r. spectrum of the solution, owing to a change in the magnetic susceptibility of the solution [71]:

$$\delta_l = 10^6\left[\chi - \chi_0 - \frac{\chi_0 (d_0 - d)}{m}\right]\frac{2\pi m}{3} \qquad (3)$$

where χ and χ_0 are the magnetic susceptibilities (g^{-1}) of the paramagnetic compound and the solvent, d and d_0 are the densities of solution and solvent, and m is the mass of the paramagnetic compound in 1 ml of solution. This shift need be taken into account only when an external standard is employed. The signal of an internal standard (tetramethylsilane) is displaced together with the whole spectrum: hence chemical shifts reckoned from the standard do not change.



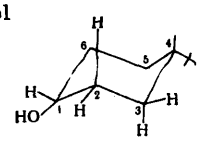


Figure 1. Dependence of chemical shift of protons in *cis*-4-t-butylcyclohexanol

dissolved in $CDCl_3$ in presence of Eudpm$_3$ on the ratio Cp/Cs (frequency 100 MHz and room temperature) [36].

2. Dependence of Shift on Composition of Solution

The shift δ of signals in the presence of a shift reagent is to a first approximation proportional to the ratio of the molar concentration of paramagnetic reagent Cp to substrate concentration Cs (Fig. 1). It has been proposed [36] that the shifts of different protons be compared by using the slopes of the linear plots of δ against Cp/Cs, i.e. by the "specific shifts" or shifts extrapolated to the ratio $Cp/Cs = 1$. For example, this shift ΔEu for the tris-tetramethylheptanedionatoeuropium complex in a solution of *cis*-4-t-butylcyclohexanol in deuterochloroform (Fig. 1) has the values 78.7, 21.7, and 1.8 ppm for OH, $H_{(1)}$, and $(CH_3)_3C$ respectively. Values of the specific shifts ΔEu, ΔPr (for the corresponding praseodymium complex), etc. are given in many papers (see reviews [72-80]). However, they are not true constants: variation in substrate concentration over the range 0.2–0.5 M produces changes in ΔEu of ±15%; values of ΔEu for alcohols and amines are 10% smaller in hexadeuterobenzene, and 20–25% smaller in deuterochloroform, than in carbon-tetrachloride solutions [35].

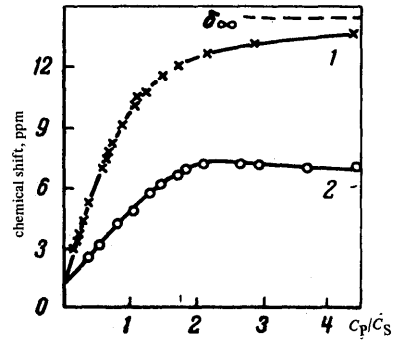

Figure 2. Dependence of chemical shift of signals in n.m.r. spectrum in presence of Eufod$_3$ on Cp/Cs ratio: 1) 0.0183 M t-butyl alcohol, calculated for K = 208 M^{-1}; [84] 2) 0.0130 M t-butylamine.

A departure from the linear dependence of δ is observed at ratios $Cp/Cs \geqslant 0.6$–0.8, the shift reaching a limiting value or even decreasing on further addition of the shift reagents [25,81-84] (Fig. 2). This dependence of the shift on solution composition is due to equilibrium complex formation

$$qP + lS \rightleftarrows P_qS_l \qquad (4)$$

with the constant

$$K = C_{PS}/(C_P - qC_{PS})^q(C_S - lC_{PS})^l \qquad (5)$$

where C_{PS} is the concentration of the complex P_qS_l. When the reagent causes rapid exchange, the shift in the substrate signal is

$$\delta = l(C_{PS}/C_S)\,\delta_\infty \qquad (6)$$

where δ_∞ is the shift of the bound substrate. At low Cp/Cs ratios almost all the reagent in solution is combined with the substrate; when the ratio approaches q/l an appreciable fraction of the reagent remains uncombined, and the dependence of δ on Cp/Cs becomes non-linear.

The parameters characterising the shift reagent–substrate system (composition of complexes (q/l), the constant K, and the shift of the bound substrate δ_∞) can be evaluated from the spectra. Methods for calculating complex-formation equilibria from n.m.r. spectra have been worked out in detail (see for instance reviews [85-88]). But difficulties are encountered in applying these methods to solutions of shift reagents. Variation of the concentration ratio of the components is restricted at high concentrations by the limited solubility of the reagents and at low concentrations by the high sensitivity to impurities, especially to small quantities of water. Calculations are complicated also by possible dimerisation of the complexes in solution [25,38,89-92].

Composition of complexes

In the trisdiketonates the Ln^{3+} ion has the coordination number 6. It can acquire up to three ligand molecules, thereby increasing its coordination number to 9; adducts of Eu dpm$_3$, Pr dpm$_3$, and other lanthanide complexes with pyridine and other substrates containing one, two, and three molecules of the Lewis base have been isolated as crystals [41,93,94]. The composition of a complex in solution can be determined by a method of continuous variation [95]. It follows from Eqn. (6) that

$$C_S\delta = C_{PS}l\delta_\infty \qquad (7)$$

If the concentrations C_P and C_S are varied while their sum is maintained constant, the graph of $C_S\delta$ plotted against $C_P/(C_P + C_S)$ passes through a maximum at

$$C_P/(C_P + C_S) = l/(q + l)$$

This method has established [84] formation of a 1 : 1 complex in the t-butyl alcohol–Eufod$_3$ system, and of 1 : 1 and 1 : 2 complexes in the corresponding t-butylamine system. The displacement of the signal is smaller in the 1 : 2 complex than in the 1 : 1 complex, which leads to the apparent paradox of a decrease in the shift on the addition of excess of the shift reagent (Fig. 2, curve *2*). If exchange in solution is slow, e.g. in the deuterated Eufod$_3$–dimethyl sulphoxide system at −80 °C, two separate signals are obtained—from free and bound substrate—the areas of which give the composition of the complex directly [96] as 1 : 2. A case of stepwise formation on 1 : 2 and 1 : 1 complexes has been examined [97].

The composition of the complex can sometimes be assessed from indirect data. For example, addition of optically active (R)-*N*-methyl-1-phenylethylamine to a solution containing Eu dpm$_3$ and racemic 1-phenylethylamine splits the signal of the CH–NH$_2$ protons of the latter [27]. Obviously this is possible only if an adduct containing both amines, e.g. 1 : 1 : 1, is at once formed with the shift reagent.

Complex-formation constant K and limiting shift δ_∞

These parameters can be found by selecting (by means of an electronic computer) values giving minimum deviation between the measured shifts and the $\delta = f(C_P/C_S)$ curve calculated by simultaneous solution of Eqns. (5) and (6) (Fig. 2, curve *1*). Good agreement confirms the formula for the complex adopted in the calculation.

With small C_P/C_S ratios the equimolecular complex is formed preferentially, and from Eqns. (5) and (6) with $C_P \ll C_S$ we obtain

$$\frac{1}{\delta} = \frac{C_S}{\delta_\infty C_P} + \frac{1}{K\delta_\infty C_P}. \qquad (8)$$

The graph of $1/\delta$ against C_S with C_P constant is a straight line [98,99]; its slope gives the parameter K, and the intercept made on the vertical axis yields δ_∞.

21	Eu (DPM)$_3$	methyladamantanone	$CDCl_3$	ditto	250	89
22	Eu (DPM)$_3$	pyridine	$CDCl_3$	27	97	108
23	Eu (DPM)$_3$	quinoline	$CDCl_3$	20	14	109
24	$EuCl_3$	ribofuranosyladenine monophosphate	D_2O	28	10±2	30
25	$HoCl_3$	ribofuranosyladenine-phosphate	D_2O	28	6±2	30
	$EuCl_3$	ribofuranosylthymine monophosphate	D_2O	28	17±3	30

Published values of K are listed in Table 4. Because of the above difficulties, they evidently cannot be regarded as entirely trustworthy. Relative determinations based on competition between substrates [100] are probably more reliable (subsection 7).

3. Dependence of Shift on Temperature

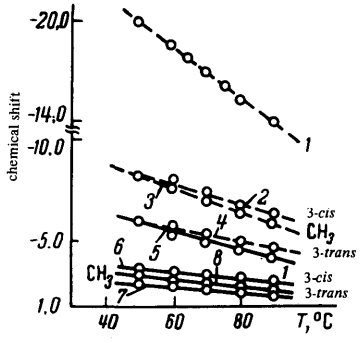
The displacement of signals caused by a shift reagent diminishes on heating. Such observations have been made for many systems, e.g. pentanol [101], heptan-2-one [42], poly(methyl methacrylate) [102], and terpenoids [81] in the presence of tristetramethylheptanedionatoeuropium, and alcohols and amines in the presence of an optically active shift reagent [29]. Quantitative measurements are few and contradictory. Tomic [103] found a linear temperature dependence of the shift between 40° and 90 °C for the methylcyclopropylmethanol system, with the slope of the $\delta-T$ straight lines different for different protons and increasing strongly with the concentration of the shift reagent (Fig. 3). The shifts in the spectra of furfuryl alcohol, octanol, and several vinylalkanones have been shown [110] to be proportional to $T^{-1/2}$ between −30° and +60 °C. If the molecular geometry is independent of temperature, a pseudocontact shift should theoretically [49] be proportional to T^{-2} for all lanthanide ions other than Sm^{3+} and Eu^{3+}.

The samarium(III) ion should exhibit a dependence on T^{-1} near room temperature, and the europium(III) ion should show a variation stronger than T^{-1} but weaker than T^{-2}. Departures from theory, observed not only with lanthanide shift reagents but also with transition-metal

complexes[111], are explained primarily by the strong influence of temperature on the equilibrium between free and complexed substrate.

4. Dependence of Shift on Nature of Functional Group in Substrate

The nature of the functional group has a decisive effect on the displacement, since it influences also the complex-formation constant and the interatomic distances and angles occurring in Eqn. (1). Different groups can be compared on the basis of the specific shift ΔEu (Table 5).



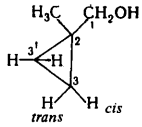


Figure 3. Temperature dependence of chemical shift (on δ-scale) in n.m.r. spectrum of 1-methylcyclopropyl-methanol

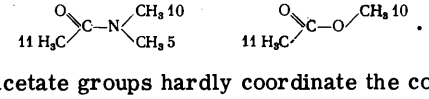
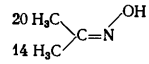


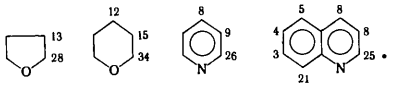
(0.02 M solution in CCl_4) in presence of Pr dpm$_3$: 1–4) 0.09 M; 5–8) 0.05 M.[103]

Table 5. Specific shift ΔEu for various functional groups (0.2–0.5 M solutions in CCl_4 at room temperature)[35].



Functional group*	Specific shift, ppm	Functional group*	Specific shift, ppm
$RCH_2\underline{NH_2}$	150	RCH_2CHO	11
$RCH_2\underline{OH}$	100	$RCH_2OCH_2R^1$	10
$RCH_2\underline{NH_2}$	30—40	$RCH_2CO_2CH_3$	7
RCH_2OH	20—25	$RCH_2CO_2CH_3$	6.5
RCH_2COR	10—17	RCH_2CN	3—7
RCH_2CHO	19		

*The proton whose signal is observed is underlined.



Amide groups bind tristetramethylheptanedionato-europium 4–5 times as strongly as do ester groups[112]; values have been found for substituted amides[113] close to those measured[114] for esters (henceforward numerals accompanying chemical formulae will indicate the values of ΔEu):

Trifluoroacetate groups hardly coordinate the complex at all[115]. Large shifts are observed with oximes[116,117]:

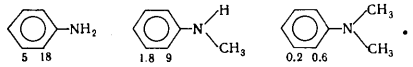
Similarly with oxygen-containing[114,118] and nitrogen-containing[79] rings:

Values of ΔEu for the *N*-oxides of pyridine and quinoline are 30–40% smaller than those for the original heterocycles[119]. Shifts in the spectra of sulphoxides are of the same order as in ketones[114,120]:

Thioacetal groups

do not combine with shift reagents[115]. The latter are successfully used to displace the signals in the spectra of compounds containing phosphoryl groups[83,121,122], e.g. phosphine oxides

Values of ΔEu decrease in the sequence[121]



$$P{=}O > C{=}O \text{ (Amides)} > C{=}S \text{ (Thioamides)} > P{=}S.$$

Nitro-groups and phosphines bind shift reagents weakly. Halides and double bonds probably do not interact with lanthanide shift reagents[35].

With compounds having the same functional groups the degree of bonding of the shift reagent depends on basic strength and steric hindrance. This rule is well observed in sulphur-containing compounds[123] and with amines[124] of general formula p-$XC_6H_4NH_2$, where ΔEu increases slowly with pKa of the amine in the sequence of substituents X

$$NO_2 < CN < Br < Cl < H < F < OCH_3.$$

The effect of steric hindrance is seen on comparing aniline, methylaniline, and dimethylaniline, which have closely similar pKa values:

Similar observations have been made with other amines[125] and with ketones and alcohols[126]. Steric hindrance may make the coordination of tristetramethylheptanedionato-europium at a hydroxy-group even less than at an ether group in the same molecule[127]. The degree of binding of the shift reagent is so sensitive to the basicity of the functional group that replacing hydrogen by deuterium *geminal* to a hydroxyl produces appreciable displacement of the signals in the spectrum ("isotope effect")[128–131].

5. Dependence of Shift on Nature of Shift Reagent

The sign and the magnitude of the pseudocontact shift (for a given substrate) are determined by the magnetic anisotropy (value of $\chi M_{\parallel} - \chi M_{\perp}$) of the shift reagent and the stability of the coordinate bond between reagent and substrate. The sign of the above difference depends mainly on the nature of the central lanthanide ion in the complex, and the degree of coordination on the nature of the ligand (diketone). The dependence of the shift on the

nature of the lanthanide has been studied in detail on the series of Ln dpm$_3$ complexes for the proton [18,20,23,24,42,132,133] and carbon-13 [22,61] n.m.r. spectra. The shift varies regularly in the series of lanthanides (Fig. 4) [19]. Complexes of cerium-group lanthanides (praseodymium, europium) give numerically smaller shifts than do those of the yttrium group (terbium, dysprosium, holmium, erbium, thulium, ytterbium), but line broadening is far less (see below).

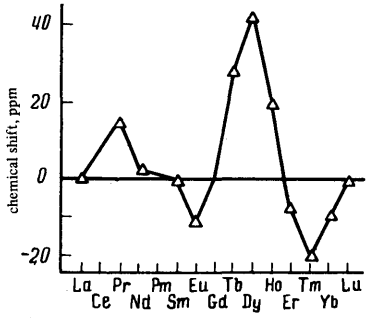


Figure 4. Shift of $H_{(1)}$ proton signal in spectra of n-hexanol (0.8 M solution in $CDCl_3$) produced by lanthanide complexes Ln dpm$_3$ at the ratio Cp/Cs = 0.125. [19]

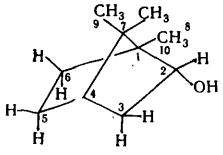
The effect of the ligand can be observed in the complexes of europium with fluorinated β-diketones [25,134]; increase in the fluorine content is accompanied by an increase in the Lewis acidity (decrease in pK_a) accompanied by increase in the displacements in the n.m.r. spectra. This is especially noticeable in the spectra of substrates that are weak Lewis bases, e.g. ethers [25]. Complexes of lanthanides with pentane-2,4-dione, 1,3-diphenylpropane-1,3-dione, and 1-phenylbutane-1,3-dione are relatively ineffective as paramagnetic shift reagents [35,128,129,135]. This may be due to insufficient bulk of the ligand, low magnetic anisotropy of the complex, or finally a small complex–substrate association constant.

6. Dependence of Shift on Geometric Factors



The dependence of the pseudocontact shift on the distance r_i from the given nucleus to the paramagnetic ion and on the angle θ_i between the vector and the axis of the complex, defined by the equation

$$\delta_i = \text{const}\ (3\cos^2\theta_i - 1)/r_i^3$$

is extremely valuable for the employment of shift reagents in practical n.m.r. spectroscopy. Its use enables signals in the spectrum of a molecule of known structure to be assigned comparatively easily; and conversely information on the geometry of the molecule to be obtained if the assignment is known.

In several cases experimental data on the dependence of δ on r and θ for "rigid" cyclic molecules are well described by Eqn. (1). Such results have been obtained, for instance, in the proton magnetic resonance spectra (Table 6) [136] and the carbon-13 n.m.r. spectra [61] for borneol in the presence of tristetramethylheptanedionatopraseodymium, for bicyclic ethers [137] and nitrogen heterocycles [109] in the presence of the europium complex, and for vinylpyridine in the presence of the corresponding complexes of several lanthanides [19].

Table 6. Comparison of specific shifts in spectrum ΔPr with geometric factor for the borneol–Pr dpm$_3$ in CCl_4 solutions at room temperature (100 and 200 MHz) [136].

Proton	*exo*-2H	*exo*-3H	*endo*-3H	4H	*exo*-5H	*endo*-5H	*exo*-6H	*endo*-6H	8CH$_3$	9CH$_3$	10CH$_3$
ΔPr	45.0	16.6	34.2	10.1	10.5	16.0	15.7	35.6	7.78	8.01	17.8
$\frac{3\cos^2\theta_i - 1}{r_i^3 \times \text{const}^{-1}}$	49.0	15.8	30.2	9.84	11.0	16.1	16.0	38.7	7.84	7.88	16.5

The importance of the angle-dependent term in (1) is supported by the fact that signals of nuclei for which $\theta_i \simeq 54°$, e.g. the aromatic protons in t-butylphenylcyclohexanol [138], are not displaced by addition of the europium complex, but when $\theta_i > 54°$ the signals shift in the opposite direction—upfield with the europium complex and downfield with the praseodymium complex [139–144].

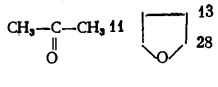
Table 7. Position of lanthanide ion in shift reagent–substrate adducts.

Shift reagent	Substrate	Ln to O (N), Å	C-O-Ln (C-N-Ln) angle	Ref.
Eu (DPM)$_3$	4-t-butylcyclohexanol	3—4	180—160	35
Eu (DPM)$_3$	adamantan-2-one	3—4	180—160	35
Eu (DPM)$_3$	quinoline	4.0	180	144
Eu (DPM)$_3$	isoquinoline	3.0	180	144
Eu (DPM)$_3$	pyridine, quinoline	4.0±0.4	180	109
Eu (DPM)$_3$	pyridine	2.9	180	156
Pr (DPM)$_3$	borneol	3.0	126	136
Yb (DPM)$_3$	acrylaldehydes	3.0	180	21
Yb (DPM)$_3$	pyridine	3.0±0.3	180	20

Many attempts have been made to plot the dependence of the shift on separation without considering the angular term, on the assumption that $\delta_i = r_i^{-n} \times$ const. The distance r_i is then measured, not to the lanthanide ion, but to the oxygen or nitrogen atom through which the shift reagent is coordinated [36,40,145–149]. Critical analyses by Rafalski [150] and by Goodisman [151] have shown that values of n = 0.2–3.6 are then obtained, with n = 2 recommended [150] for practical purposes. Such a method of calculation is convenient in not requiring the position of the lanthanide ion in the reagent–substrate adduct to be known, but the procedure should be employed with great caution.

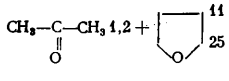
Crystallographic data can be used[152,153] to determine the distance r from nucleus to lanthanide ion, but there is no certainty that distances in solution remain the same as in the crystal. Some complication may arise also from the fact that the principal magnetic axis of the complex does not necessarily coincide with the direction of the bond between lanthanide and donor atom[154]. If we assume that the displacement is given accurately by Eqn. (1), we can determine the position of the lanthanide from the measured shifts. An electronic computer[127] or a graphical method[155] is used to select coordinates of the Ln^{3+} ion at which the deviation from Eqn. (1) is minimal.

Table 8.



Position of CH_2	1	2	3	4	5	6	7
Shift	1.00	0.58—0.60	0.40—0.42	0.20	0.12—0.14	0.08	0.02—0.05

Table 7 lists data on Ln–O (or Ln–N) distances and C–O–Ln (or C–N–Ln) angles. The appreciable divergence between results obtained by different workers is probably due to errors in measuring the shifts and in determining distances in the models.



In the case of non-rigid aliphatic molecules interatomic distances are averaged over all possible conformations. Exact calculation of the dependence of δ on r and θ is difficult, and only a gradual diminution in the displacement is observed with distance along the chain from the donor group. Table 8 gives the shifts for successive methylene groups in straight-chain aliphatic alcohols, with the shift due to the hydroxymethyl group taken as unity[35,157]. A methyl group gives a rather smaller displacement than does a methylene group in the same position[101].

7. Displacement due to Shift Reagent in presence of Several Functional Groups

Functional groups of several types may be present in a solution containing a paramagnetic shift reagent. In the simplest case they occur in different molecules: i.e. a mixture of two or more substrates is present. The shift reagent is then distributed between the substrates in proportions depending on the strength of bonding of the reagent and the concentration of the components, with corresponding changes in the shifts of the signals from each substrate. For example[114], the specific shifts

are found for acetone and for oxolan; if, however, the solution contains both compounds, in equimolecular quantities, the values

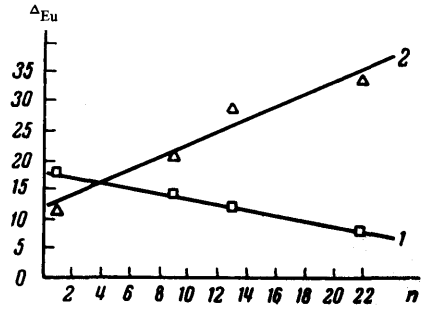
are obtained: i.e. the displacements have fallen to 11% and 89% of their initial values for acetone and oxolan respectively. From this it may be deduced that oxolan binds tristetramethylheptanedionatoeuropium eight times as strongly as does acetone.

If a solution contains two substrates forming equimolar complexes $PS^{(1)}$ and $PS^{(2)}$ with a shift reagent, we can write for the complex-formation constants K_1 and K_2 and the shifts of the signals $\delta^{(1)}$ and $\delta^{(2)}$ expressions analogous to Eqns. (5) and (6), which contain the concentrations of substrates and complexes together with the displacements of the bound substrates $\delta_\infty^{(1)}$ and $\delta_\infty^{(2)}$. Eliminating concentrations from these equations, we obtain

$$\frac{1}{\delta^{(2)}} = \frac{1}{\delta^{(1)}}\frac{K_1\delta_\infty^{(1)}}{K_2\delta_\infty^{2}} + \frac{K_2 - K_1}{K_2\delta_\infty^{(2)}} \qquad (9)$$

The plot of $1/\delta^{(2)}$ against $1/\delta^{(1)}$ for solutions of varying composition is a straight line of slope $K_1\delta_\infty^{(1)}/K_2\delta_\infty^{(2)}$, making an intercept $(K_2 - K_1)/K_2\delta_\infty^{(2)}$ on the ordinate axis. If values of the parameters K_1 and $\delta_\infty^{(1)}$ for one compound are known, this graph can be used to determine the corresponding parameters for the second compound. This "monitor" method[100] is convenient in not being as sensitive to moisture as direct methods.

When two functional groups are present in the same molecule, but sufficiently far apart not to interact, e.g. at positions 3 and 17 in a steroid molecule[66,149], the same relations hold between coordination at the two groups. The displacement of the signals is then simply the sum of the shifts caused by coordination at each group separately, and can be calculated additively either numerically[149] or graphically[66]. When the complex-formation constants of the two groups differ greatly, the competition between them ensures that the shift reagent combines initially with one group, and only then with the second group on further addition of the reagent. At low concentrations of the reagent, therefore, protons situated near the first functional group are more strongly displaced, but at high concentrations protons beside the second group take over. The signals "overtake" one another on the spectrum; the straight lines corresponding to different protons intersect on the graph of δ as a function of C_P/C_S.[122,158]



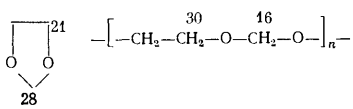


Figure 5. Dependence of specific shift ΔEu on degree of polymerisation n of polyethylene glycols in CCl_4 solution at room temperature (60 MHz) for: 1) terminal CH_2 groups; 2) central CH_2 groups[159].

More complicated relations are observed if the molecule contains different numbers of groups of each type, e.g. for functional groups in the middle and at the ends of a polymer molecule. Thus chain lengthening in the

series of polyethylene glycols $HO[CH_2CH_2O]_nH$ is accompanied [159] by increase in the proportion of tristetramethylheptanedionatoeuropium coordinated at the ether bonds in the central units, and a diminution of coordination at the terminal hydroxy-groups, with a corresponding variation in ΔEu (Fig. 5). Changes in the distribution of the shift reagent between different functional groups are observed also when the solution is heated: a group which is less effective at room temperature may be more effective at a higher temperature [160].

If two functional groups in a substrate molecule are close together, the displacements are no longer additive [146]. The bonding to the shift reagent and the magnitude of the shift depend on the distance between the groups: e.g. the bonding is considerably stronger for *o*-dimethoxybenzene than for the *meta*-derivative [130]. The displacement is influenced also by stereochemical effects. In polydioxolan, for example, the ethoxyl protons are more strongly displaced in the presence of the above shift reagent, but the formyl protons are more strongly displaced in the monomer [161]:

With a favourable conformation the substrate can evidently interact as a bidentate ligand with the lanthanide ion to form chelate complexes [162,163].

8. Effect of Shift Reagents on Width of Lines in Spectrum

A substantial advantage of lanthanide paramagnetic shift reagents is that, in contrast to complexes of transition metals containing the same ligands [164], they cause little line broadening; even when the signal is displaced by several parts per million, the multiplet structure still remains resolved.

Table 9.

Ln	Pr	Nd	Sm	Eu	Tb	Dy	Ho	Er	Tm	Yb
$\Delta\nu_{1/2}$, Hz	5.6	4.0	4.4	5.0	96	200	50	50	65	12

The broadening of an n.m.r. line in the presence of paramagnetic ions is due to acceleration of the relaxation of the nuclear spin, and also to exchange between bound and free substrate molecules. The main factor determining the substrate n.m.r. line width is the electronic relaxation time T_{1e} of the lanthanide ion. Little broadening may be expected with complexes of ions having short T_{1e} times (Eu^{3+}, Pr^{3+}, Nd^{3+}); ions having large T_{1e} values, e.g. Gd^{3+}, should produce great broadening. Table 9 gives the line widths $\Delta\nu_{1/2}$ of the methyl group in 2-methylpyridine in the presence of tristetramethylheptanedionatolanthanide complexes at the same ratio $C_P/C_S = 0.125$. [19] The broadening in the presence of the gadolinium complex is so great that the spectrum could not be obtained.

The broadening of a line is usually greater the larger the displacement. Broadening is therefore sometimes measured by the ratio $\Delta\nu_{1/2}/\delta$. For example, the values found in the spectra of t-butyl alcohol in the presence of the above lanthanide complexes are listed in Table 10. [18,24]

Table 10.

Ln	Pr	Sm	Eu	Tb	Ho	Yb
$\Delta\nu_{1/2}/\delta$	0.013—0.005	0.02	0.003	0.1	0.02	0.02

The relaxation times T_1M and T_2M of nuclei of a substrate bound in a complex having an anisotropic g-factor and a short T_{1e} time [165] are theoretically [109,166,167] given by the equation

$$\frac{1}{T_{1M}} = \frac{1}{T_{2M}} = \frac{2}{3}\gamma_n^2\beta^2 S(S+1)\frac{1}{r^6} f(g_\parallel, g_\perp, \theta) T_{1e} + \frac{4}{9}\gamma_n\beta S(S+1)\frac{A}{2\pi}(g_\parallel - g_\perp)\frac{3\cos^2\theta - 1}{r^3} T_{1e} + \frac{2}{3}S(S+1)\left(\frac{A}{2\pi}\right)^2 T_{1e} \quad (10)$$

where

$$f(g_\parallel, g_\perp, \theta) = \frac{1}{3}(g_\parallel^2 - 2g_\perp^2) + g_\parallel^2\cos^2\theta + g_\perp^2\sin^2\theta,$$

$g_\parallel$ and $g_\perp$ are components of the g-tensor, and the remaining symbols have the same significance as in Eqns. (1) and (2). The first term in (10) represents dipole–dipole interaction, the second cross relaxation, and the third hyperfine interaction. The dipole contribution predominates, since the hyperfine coupling constant is small (hence according to Eqn. (2) the contribution of contact interaction to the shift is small) in most solutions of the above europium complex and organic compounds. The observed line width is determined by the transverse relaxation time: $\Delta\nu_{1/2} = 1/\pi T_2$. For rapid exchange between bound and free substrate we have theoretically [168-170]

$$\frac{1}{T_1} = \frac{1}{T_1^0} + \frac{\sigma}{T_{1M}} \quad (11)$$

$$\frac{1}{T_2} = \frac{1-\sigma}{T_2^0} + \frac{\sigma}{T_{2M}} + \sigma(\sigma-1)^2\tau_M(2\pi\delta_\infty)^2 \quad (12)$$

where T_1^0 and T_2^0 are the relaxation times in the absence of the chemical shift reagent, σ is the fraction of the substrate combined with the reagent, and τ_M is the mean lifetime of a substrate molecule in the bound state. Equations (11) and (12) can be used to determine τ_M from the measured spin–lattice relaxation time, line width, and shift. The last term in Eqn. (12) is found to make the largest contribution to broadening the signals from protons $H_{(2)}$ and $H_{(8)}$ in quinoline dissolved in carbon tetrachloride in the presence of the europium complex; for this system $\tau_M = 2\times10^{-7}$ s. The strong dependence of line broadening and rate of spin–lattice relaxation on geometric factors (to a first approximation these quantities are proportional to r^{-6}) can be used for the determination of structure [13,30,109].

9. Effect of Shift Reagents on Spin–Spin Coupling Constants

Lanthanide shift reagents have little effect on spin–spin coupling constants J between substrate nuclei. This enables J to be determined by direct measurement of the splittings obtained in first-order spectra after addition of a sufficient quantity of shift reagent to the solution. The invariability of the spin–spin coupling constants has been confirmed by measurements of J_{H-H} in lactones [171],

carbohydrates[172], bicyclic esters[158], nitrogen heterocycles[173], by measurements of J_{Sn-H} in organotin compounds[174], etc.; little change in J has been observed with cyclic alcohols[175].

In several cases the addition of a shift reagent produces a change in J that is not connected with paramagnetism but is due to the effect of complex formation on the distribution of electron density in the molecule[176] or on the conformational equilibrium (see below).

Partial elimination of J_{23} and J_{24} spin–spin coupling in quinoline is observed at high concentrations of the europium reagent[35,109]. This phenomenon is observed also with transition-metal complexes[177–180]. It is analogous to the uncoupling of spins in double resonance, and is explained by a decrease in the relaxation time of the nuclei[181].

10. Effect of Shift Reagents on n.m.r. Spectra of Other Nuclei

The action of paramagnetic shift reagents on carbon-13 and fluorine-19 spectra conforms to the same rules as that on the proton magnetic resonance spectra[65]. Only two special features are evident. Firstly, the displacement of the signals defined by Eqn. (1) is the same as in the latter spectra, but the chemical shifts of other nuclei are far larger than those of protons. Therefore the change in the form of the spectrum is not so striking. Secondly, the n.m.r. spectra of other nuclei are strongly influenced by the change in electronic structure accompanying formation of an adduct with the shift reagent. Therefore the carbon-13 and nitrogen-14 n.m.r. spectra in the presence of the diamagnetic tristetramethylheptanedionatolanthanum exhibit a displacement of the signals comparable with that produced by the paramagnetic europium complex[22,140].

Shift reagents are used in carbon-13 n.m.r. mainly for the assignment of lines by means of the dependence of the displacement on the carbon–lanthanide distance. This method has been applied to the spectra of alcohols[182] and the complicated carbon-13 n.m.r. spectra of natural compounds—cholesterol[183], the alkaloid piperine[140], borneol[61], and isoborneol[62]. Stereoisomers have been identified[184] from the carbon-13 n.m.r. spectra of cyclopentane derivatives in the presence of the europium shift reagent. Shifts in the n.m.r. spectra in the presence of europium, holmium, and neodymium salts in aqueous solution have been used to determine the conformation of mononucleotides[30]. The increased distance between signals in the proton magnetic resonance spectrum substantially facilitates the assignment of signals in the carbon-13 spectrum by selective uncoupling of the $^{13}C-\{^1H\}$ spin–spin interaction[31].

Shift reagents find limited application in fluorine-19 n.m.r., since the introduction of fluorine into an organic molecule diminishes the basicity and weakens coordination of a lanthanide. Perfluorinated alcohols and amines do not coordinate paramagnetic shift reagents. Aromatic amines exhibit[65] the same ratios between shifts in *ortho*- and in *para*-positions as in the proton magnetic resonance spectra.

The nuclei of nitrogen-14 and phosphorus-31 atoms having a lone pair of electrons can interact with paramagnetic shift reagents by a contact mechanism[65]. Use of the tristetramethylheptanedionato-complexes of dysprosium and ytterbium has been recommended for nitrogen-14 n.m.r. (as also for fluorine-19[65]), but the great broadening of the lines makes it very difficult to record the spectra[22,185]. In phosphorus-31 n.m.r. the europium complex has been used to displace the signals in deuterochloroform solution[186], and europium and praseodymium trinitrates in aqueous solution[34].

IV. APPLICATIONS OF PARAMAGNETIC SHIFT REAGENTS IN n.m.r. SPECTROSCOPY

1. Simplification of Spectra

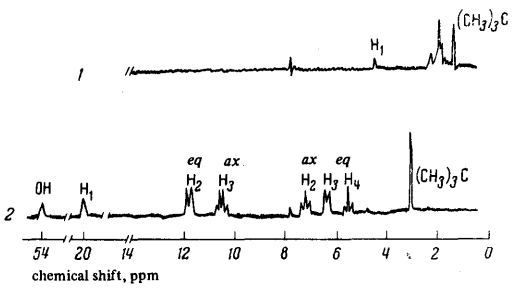

Figure 6. Nuclear magnetic resonance spectrum 100 MHz of *cis*-4-t-butylcyclohexanol in $CDCl_3$ solution: 1) in absence of shift reagent; 2) in presence of Eu dpm$_3$ with $C_P/C_S = 0.7$.[36]

The most important result of the use of shift reagents in n.m.r. spectroscopy is a remarkable simplification of the spectra. The displacement of the signals due to the reagents produces a sharp increase in the chemical shift relative to the spin–spin coupling constant J, which enables first-order spectra to be obtained even for complicated spin systems (Fig. 6)[36].

2. Assignment of Signals

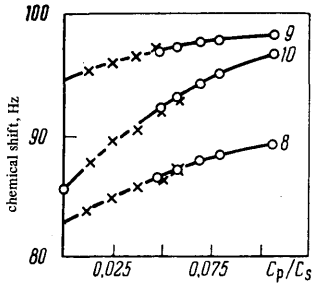
The use of shift reagents makes the assignment of signals in the spectra considerably easier. Their addition separates previously overlapping peaks, so that the signals of protons can be assigned by means of double resonance and analysis of the spin–spin coupling constants.

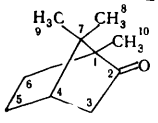
Above all, however, the method based on the dependence of the displacement on geometric factors is widely used. For example, the structure of *dextro*-camphor shows (Fig. 7) that the distance of the methyl groups from the ketonic oxygen increases in the sequence $10\text{-}CH_3 < 8\text{-}CH_3 < 9\text{-}CH_3$. The distances of the methyl groups from a europium ion coordinated at the keto-group will increase in the same sequence. Therefore the methyl signals that undergo the largest downfield displacement on addition of the shift reagent are assigned to 10-methyl protons, and the least displaced to 9-methyl protons[187]. A similar method has been used to assign signals in the n.m.r. spectra of 1,3-dimethylcyclohexylamine[148], cyclohexyl isocyanide[188], and many other compounds.

3. Determination of Chemical Shifts and Spin–Spin Coupling Constants

Extrapolation to zero shift-reagent concentration of the linear plots of δ against C_P/C_S enables us to determine chemical shifts for those substrate protons whose signals

overlap in the absence of a shift reagent[36,115,172]. Constants J, previously inaccessible because of the superposition of signals—in the n.m.r. spectra of pyrazine derivatives, for example, the couplong constants between protons of the methyl group and *ortho*-, *para*-, and *meta*-protons of the ring[173], and J_{PCH} and J_{PCCH} in those of phosphine oxides[88]—can be obtained from n.m.r. spectra in the presence of shift reagents.





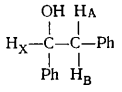


Figure 7. Dependence of chemical shift (at 100 MHz) of 8-, 9-, and 10-methyl groups of (+)-camphor in presence of $Eu\,dpm_3.2C_5H_5N$ on C_P/C_S ratio (solution

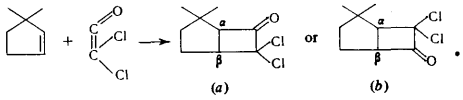
in CCl_4 at room temperature)[187].



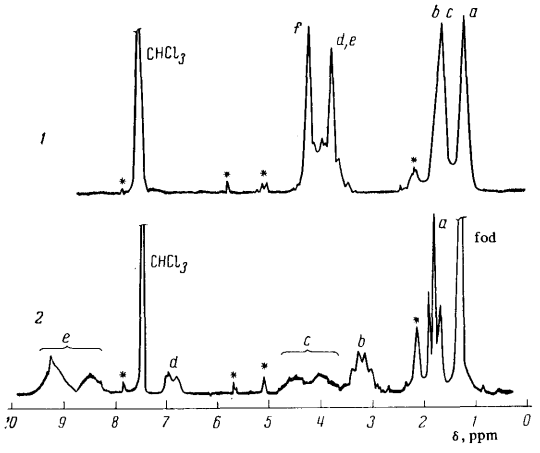
The possibility of evaluating J_{gem} for diastereotopic protons is especially interesting. In the presence of a shift reagent the signals of such protons in the α- and even in the β-position relative to an asymmetric carbon atom are sharply separated[35,115]. Thus the alkyl protons in 1,2-diphenylethanol[35]

give an n.m.r. spectrum of type A_2X, but on addition of the europium shift reagent a spectrum of type ABX is obtained, which enables J_{AB} to be determined.

4. Study of Molecular and Stereochemical Structure

In several cases molecular structure can be determined unambiguously from the dependence of the displacement on geometric factors. For example, dichloroketen can add in two ways to 3,3-dimethylcyclopentene, to yield two structures (*a*) and (*b*)[189]:

The α-hydrogen signal gives a doublet in the n.m.r. spectrum of the reaction products owing to interaction with the β-hydrogen atom, and the β-hydrogen gives a multiplet owing to interaction with the α-hydrogen and with the protons of the five-membered ring. On the addition of tristetramethylheptanedionatoeuropium, which coordinates at the ketonic oxygen, the downfield displacement of the α-hydrogen doublet exceeds that of the β-hydrogen multiplet by 50–100%, which indicates a structure of type (*a*).



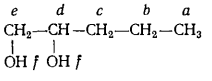


Figure 8. Nuclear magnetic resonance spectrum (at 60 MHz) of pentane-1,2-diol

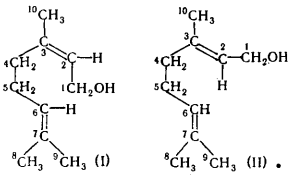
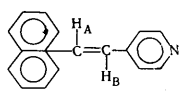


(9 wt.% solution in chloroform at room temperature): 1) in absence of shift reagent; 2) with $Eu\,fod_3$ (C_P/C_S = 1 : 3). The assignment of the lines is shown on the spectrum; the asterisks denote peaks due to impurities and satellites of carbon-13.[190]

Some difficulty has arisen[190] in establishing the structure of the pentanediol isolated from technical furfuryl alcohol. The n.m.r. spectrum (Fig. 8) may correspond to two structures (1,2- and 1,3-diols). When the spectrum is determined in the presence of trisheptafluorodimethyloctanedionatoeuropium the signal of the CH_2–OH group is strongly displaced downfield and is split into two peaks (corresponding to two diastereotopic protons), whereas the signal from the CH_2CH_3 group is not split. This means that the hydroxymethyl group is in the α-position to the hydroxymethylene group: i.e. the 1,2-diol structure is unequivocally proved.



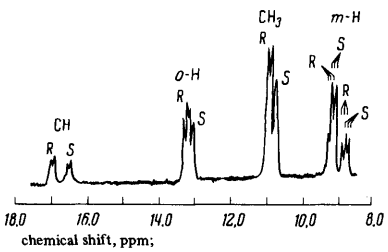
Shift reagents have been used to determine the chemical structure of polycyclic ketones[191], a bicyclic anhydride[192], etc.

Shift reagents are widely used also for identifying geometric isomers. The n.m.r. spectra of nerol (I) and geraniol (II) in the presence of tristetramethylheptanedionatoeuropium show[193] diminishing displacement of the signals of the nerol protons in the sequence $C_{(4)} > C_{(5)} > C_{(10)}$, whereas the corresponding sequence for geraniol is $C_{(10)} > C_{(4)} > C_{(5)}$, which proves that

nerol has the *cis*-configuration (I), and geraniol the *trans*-configuration (II):

In the n.m.r. spectrum of naphthylvinylpyridine

in the presence of the same shift reagent the signals of the vinyl protons no longer overlap those of the naphthalene ring protons, and give a quadruplet of type AB, so that the *cis*- or *trans*-configuration of the compound can be determined from the value of J_{AB} [194].



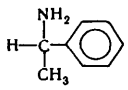


Figure 9. Nuclear magnetic resonance spectrum of solution of mixture of (*R*)- and (*S*)-isomers of 1-phenylethylamine

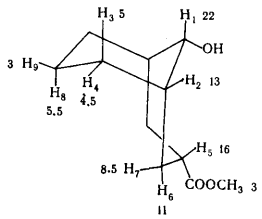
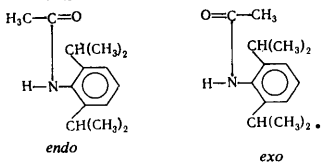


in CCl_4 in presence of 0.15 M tris-3-t-butylhydroxymethylene-(+)-camphoratoeuropium [26].

The enantiomeric purity of compounds—e.g.alcohols [28], sulphoxides [29], amines [26]—can be determined by the use of optically active shift reagents (Table 3). Fig. 9 shows the spectrum of racemic 1-phenylethylamine (mixture of (*R*)- and (*S*)-isomers) in the presence of tris-3-t-butylhydroxymethylene-(+)-camphoratoeuropium [26]. A remarkable feature of this spectrum is the considerable difference between the chemical shifts of corresponding protons in (*R*)- and (*S*)-isomers (from 0.07 ppm for the *para*-protons of the aromatic ring to 0.5 ppm for $CHNH_2$). The signals of the (*R*)-isomer are more strongly displaced than those of the (*S*)-isomer owing to the difference between the stability constants of the complexes they form with the shift reagent. The enantiomeric composition of the mixture is determined from the ratio of the areas of the signals. Tristetramethylheptanedionatoeuropium has been used to identify the *meso*-form and racemic bisphenylsulphinylmethane [195].



5. Study of Conformation

Paramagnetic shift reagents are used for the conformational analysis of flexible and rigid molecules and for the identification of rotational isomers. Analysis of the shifts of the proton signals in the n.m.r. spectrum of the *cis*-9-hydroxybicyclo[3,3,1]nonane-*endo*-3-carboxylate [158]

in the presence of tristetramethylheptanedionatoeuropium with $C_P/C_S = 0.3$ (when the shift reagent coordinates mainly through the hydroxy-group) shows that the signal of the $H_{(5)}$ proton is considerably displaced downfield, which indicates the boat–chain type of conformation. The conformation of cyclic ketones [196], griseofulvins [197], mononucleotides [30], and bicyclic alcohols [198] has been studied by the use of shift reagents.

It must be borne in mind that formation of a reagent–substrate complex is sometimes able to influence the conformational equilibrium,, e.g. that between *exo*- and *endo*-forms of the substituted amide [142]

In the absence of a shift reagent the ratio of the isomers is *endo*/*exo* = 2/1; addition of 0.1 M of the europium shift reagent changes the ratio of the rotational isomers to *endo*/*exo* = $\frac{1}{2}$. Shift reagents affect also the conformation equilibrium of other amides [133,146], the chair ⇌ chair equilibrium [199], and the equilibrium between carbohydrate anomers [31].

6. Analysis of Mixtures

Impurities can be detected by means of shift reagents, and mixtures of substances having overlapping resonance signals can be analysed by integrating individual peaks in the "stretched" spectrum. This method has been used [101] for the quantitative determination of the components in a binary mixture of 2-methylbutan-1-ol and 2-methylbutan-2-ol, in a ternary mixture of n-pentan-1-, 2-, and -3-ols, and even in a senary mixture of the C_1–C_6 straight-chain alcohols.

7. Study of Polymers

Shift reagents are used to study the stereochemical structure and sequence of units in polymers. The signals from protons in α-methyl and methylene groups are split in the n.m.r. spectrum of poly(methyl methacrylate). The presence of a shift reagent [200] not only facilitates isolation of the signals from α-methyl protons in isotactic (*i*), syndiotactic (*s*), and heterotactic (*h*) triads and the signals from methylene protons in *erythro-mmm* and *threo-rrr* tetrads but also resolves the signal from methoxy-protons into three peaks, corresponding to *i*-, *s*-, and *h*-triads in the polymer chain (Fig. 10). In contrast to this study [200] of the isotactic polymer, an investigation [102] of atactic poly(methyl methacrylate) indicates

that the displacement of the signals of methyl protons diminishes in the sequence i-CH_3 > h-CH_3 > s-CH_3-CH_2, whereas the corresponding sequence for the methoxy-protons is i-CH_3O > h-CH_3O > s-CH_3O. Such a sharp divergence of the results is evidently due to the effect of tacticity on polymer conformation, and hence on the shift, which depends on geometric factors. Resolution of the signal from the protons of a methyl group, under the influence of a shift reagent, into three peaks corresponding to i-, s-, and h-triads has been observed also with poly-(methyl vinyl ether) and polyoxypropylene [201,202].

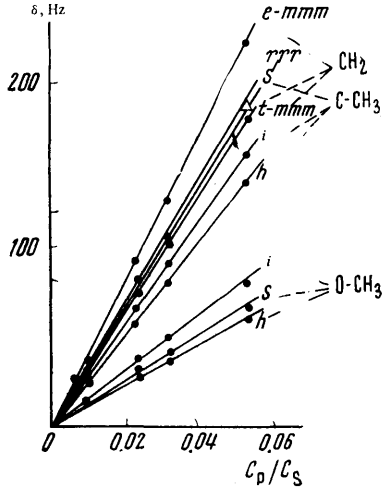


Figure 10. Dependence of shift of signals (at 220 MHz) for protons of poly(methyl methacrylate) in presence of Eufod$_3$ on C_P/C_S (solution in o-dichlorobenzene) [200].

In the n.m.r. spectrum of the trioxan–dioxolan copolymer of general formula $[OCH_2]_x[OCH_2CH_2OCH_2]_y$ the protons of the ethylene oxide group (E) give a singlet, and those of the methylenoxy-group (F) three singlets corresponding to the sequences EFE, EFF, and FFF [161]. On the addition of tristetramethylheptanedionatoeuropium to the solution the three signals due to the methylenoxy-protons coalesce into a single signal, while the peak due to protons of the ethylene oxide group split into three peaks corresponding to the sequences FEFEFEF + FEFEFFF, EFFEFFE + EFFEFFF, and FFFEFFF.

Use of the europium shift reagent enables us to determine the sequence of acid residues in the chain of a copolyester of terephthalic and isophthalic acids with ethylene glycol [203] (the signal from the glycol protons is split into three peaks).

The n.m.r. spectra of glymes—oligomers of formaldehyde and formaldehyde–dioxolan copolymers—in the presence of the europium shift reagent enable a comparative estimate to be made of the basicity of terminal and central oxygen atoms [159], which is important for an explanation of the mechanism of polymerisation. In the spectra of the copolymers $CH_3OCH_2[OCH_2OCH_2CH_2]_nOCH_3$ the signals from methylene protons adjacent to terminal oxygen atoms undergo smaller displacements than with central groups (in Fig. 11 the slope of the straight line a exceeds that of b, and line c is steeper than d): the oxygen atoms obviously become less basic from the middle towards the end of the chain. The signals from protons in methylenoxy-groups in the spectrum of the formaldehyde oligomer $CH_3O[CH_2O]_nCH_3$ are situated further downfield the closer is the group to the end of the chain, which indicates that terminal oxygen atoms have greater coordinating power (basicity). Analogous results have been obtained for glymes $CH_3O[CH_2CH_2O]_nCH_3$.

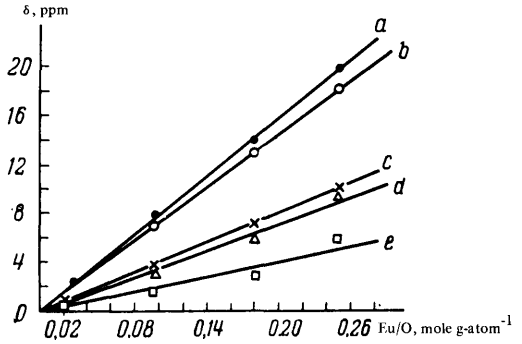

Figure 11. Dependence of shift (at 60 MHz) on ratio of Eu dpm$_3$ to oxygen for different groups in the compound $CH_3\overset{e}{O}CH_2\overset{d}{O}CH_2CH_2\overset{b}{O}CH_2\overset{a}{O}CH_2\overset{c}{C}H_2\overset{a}{O}CH_2\overset{b}{C}H_2\overset{d}{O}CH_2\overset{e}{O}CH_3$ dissolved in CCl_4 at room temperature [159].

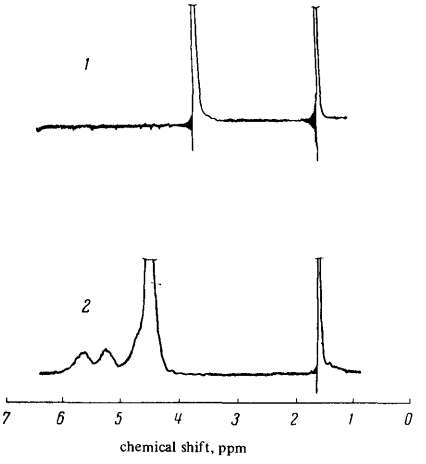

Figure 12. Nuclear magnetic resonance spectrum (60 MHz) of solution of polyethylene glycol PEG-400 in CCl_4 at room temperature: 1) in absence of shift reagent; 2) in presence of Eu dpm$_3$ with C_P/C_S = 0.4.

Use of a shift reagent facilitates determination of the molecular weights of polypropylene glycol [204] and polyethylene glycols [159] by means of the end-groups. Addition of the europium complex to a polyethylene glycol separates the signals due to terminal, penultimate, and central methylene groups (Fig. 12). The degree of polymerisation is calculated from the relative areas of the signals of terminal and central methylene groups. The resulting

molecular weights are close to the specified values (Table 11).

Table 11.

Mol. wt. from spectrum	370	550	986

8. Compounds with Spectra studied in the presence of Shift Reagents

Alcohols

Aliphatic [16,26,28,32,84,99,101,103,105,106,128,157,182,205-220].
Aromatic [35,69,214,221,222,223].
Cyclic [15,23,28,36,40,61,66,87,104,107,128,141,143,145,147,175,183,184,188,193,198,205,216,218,224-260].

Ketones

Aliphatic [33,100,106,110,161,219,220].
Aromatic [69,240,261].
Cyclic [66,89,97,110,126,127,132,160,176,189,191,196,197,215,229,232,235,237,239,240,250,252,262-274].

Ethers and esters [69,100,106,117,131,137,141,149,161,163,171,184,200,201,203,204,206,211,223,234,242,250,252,264,275-294].

Carbohydrates [23,31,203,259,290,295-300].

Other oxygen-containing compounds [20,21,32,33,97,110,112,118,140,160,192,198,218,240,263,267,281,289,292,301-310].

Amines

Aliphatic [20,26,32,99,105,125,220,303,311-313].
Aromatic [20,124,125,259,314].
Cyclic [20,82,148,315-319].

Nitrogen-containing heterocycles [20,48,69,70,84,92,109,119,140,144,150,164,173,194,238,267,268,301,305,317,320-326].

Amides [301,327-335].

Other nitrogen-containing compounds [117,142,220,301,336-339].

Sulphur-containing compounds [96,114,123,195,196,243,272,285,301,306,308,340-346].

Phosphorus-containing compounds [31,34,83,121,122,186,199,219,302,345,347].

Polymers [102,106,159,161,200,201-204,288,348].

---o0o---

Shift reagents greatly increase the possibilities of nuclear magnetic resonance spectroscopy. In some cases the information obtainable from the n.m.r. spectrum determined at a frequency of 60 MHz in the presence of the europium shift reagent is greater than that provided by the spectrum at 220 MHz in the absence of a shift reagent [173]. It may be expected that the preparation of new shift reagents, in particular with a selective action towards certain functional groups and suitable for application in polar solvents, as well as detailed physicochemical investigation of reagent–substrate–solvent systems, will still further extend the range of application of this method.

Formation and Dissociative Breakdown of Chlorophyll and Its Synthetic Analogues in Solution

B.D.Berezin and O.I.Koifman

A critical survey is made of studies on the mechanism, kinetics, and thermodynamics of the formation and the dissociation of chlorophyll, its metal analogues, and other metal porphyrins. Consideration is given mainly to results published during the past decade. Special attention is paid to complexes of the most important natural porphyrin—chlorophyllic acid. A list of 120 references is included.

I. INTRODUCTION

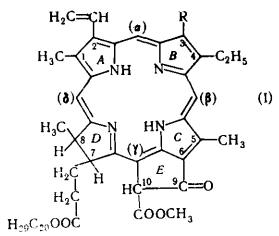
Research on chlorophyll and structurally similar complexes of other porphyrins has entered a new stage during the past twenty years. The comprehensive study of the properties of this numerous group of complexes is progressing as one of the most important links in the chain of diverse problems waiting to be solved on the path to mastery and conscious control of photosynthesis. Until recently the most intensely studied physicochemical properties were the optical and electrophysical properties of chlorophyll, its analogues, and products of their reversible chemical reactions[1-20]. Many interesting results have been obtained by infrared[3-5,10,12,18,19], nuclear magnetic resonance, and electron spin resonance spectroscopy[4-6,12]. A special place is occupied by investigations on the electronic absorption spectra and spectral luminescent properties of chlorophyll, its structural analogues, and their photoreduced forms[1,4-11]. Scale investigations on the properties of photoreduced forms of chlorophyll and other porphyrin compounds, made in the Soviet Union by Krasnovskii, Evstigneev, and others[6,11,15-17,20], have formed the basis of fertile new insights into the rôle and nature of the transformations of the inner-complex pigment system in the photosynthesising apparatus of plants while functioning in the living cell.

Products of the dark reduction and the photoreduction of metal analogues and structural analogues of chlorophyll, as well as of the complexes formed by association with metal salts, have been widely studied during recent years[10,19,20]. Results of paramount importance have been obtained in this field. However, they are not directly connected with the subject of the present Review, and therefore will not be covered. Naturally, in view of what has been said, the Reviewers do not aim to give any complete list of references on these questions. Such a list can be found in the reviews cited above.

Experimental researches on the physicochemical properties of chlorophyll and other tetrapyrrole pigments during the past decade have been accompanied by quite fruitful theoretical investigations[21-29]. A critical survey of scientific results on the structure of these molecules obtained by spectroscopic methods and theoretical calculation will be found in the monograph by Gurinovich et al.[5]

Chlorophyll and other metal porphyrins utilise their coordinating properties in their formation and decomposition, as well as their functioning in vegetable and animal organisms, so that the investigation of these properties is of considerable interest. Although the first attempts at quantitative examination of the dissociation of chlorophylls-a and -b in solution were made more than thirty years ago[30-32], since then the formation of metal analogues of chlorophyll from metal salts and the corresponding "ready made" porphyrin molecules, as well as their dissociation, have been studied almost entirely qualitatively or at best semi-quantitatively. The results of these numerous attempts were summarised in Phillips' review[33]. Systematic studies of the formation and the decomposition of chlorophyll-like inner-complex compounds were begun about fifteen years ago. They can be regarded as originating with the appearance of papers by Kukhtevich[34,35], Caughey and Corwin[36], Fleischer[37], and one of the present Reviewers[38]. Within a short time numerous data were obtained on the coordination properties of chlorophyllic acid and other porphyrins, and on the mechanism of the formation and the decomposition of structural analogues† and metal analogues‡ of chlorophyll in various solvents. There is at present no review of the porphyrins in which due attention is paid to quantitative investigations of coordination properties.

The well known and extremely comprehensive and interesting monograph by Falk[8] discusses only out-of-date results of semi-quantitative kinetic investigations of the dissociation and formation of metal porphyrins, so that judgments and conclusions based on them are often unsound. The aim of the present paper is to examine critically research results on the coordination properties of porphyrins and to elucidate the main laws governing the formation and the breakdown of chlorophyll and other metal porphyrins in solution.



---

† Structural analogues of chlorophyll are taken to be porphyrins and their derivatives of similar structure to chlorophyllic acid, i.e. most tetrapyrrole pigments with conjugation in the macro-ring.

‡ Metal analogues of chlorophyll are taken to be inner-complex compounds of metals with chlorophyllic acid other than the magnesium complex.

II. FORMATION OF METAL AND STRUCTURAL ANALOGUES OF CHLOROPHYLL IN SOLUTION

Most complexes of chlorophyllic acid (I), otherwise termed phaeophytin ($H_2\Phi$)

(I) R = CH_3; chlorophyllic-a acid; R = CHO; chlorophyllic-b acid

are formed by heating metal salts (MX_2) with phaeophytin dissolved in an organic solvent. The procedure suggested by Zalesky[39] has been widely used up to the present time. Glacial acetic acid (HOAc) is used as solvent, with a large excess of the metal acetate as the salt. The phaeophytin is complexed by heating the mixture on a boiling waterbath for 2 h. It has since been shown[40] that such treatment produces no changes in the phaeophytin molecule, and glacial acetic acid is one of the most favourable media[41] for the formation of metal analogues ($M\Phi$) of chlorophyll:

$$H_2\Phi + MX_2 \rightleftarrows M\Phi + 2HX. \quad (1)$$

Formation of $M\Phi$ takes place most rapidly in glacial acetic acid. Zalesky's method can be used to obtain stable copper(II), cobalt(II), nickel(II), iron(II), manganese(II), palladium(II), silver(II), and zinc(II) complexes. Organic solvents of other types—alcohols, esters, ethers, ketones, pyridine, quinoline, dimethylformamide—are used to prepare the cadmium(II), mercury(II), lead(II), silver(I), and certain other complexes, which are unstable even in weakly proton-donating media[41]. However, complexes of alkali and alkaline-earth metals (other than magnesium) cannot be obtained by this method, for reasons which will become clear from the subsequent discussion. Nor can treatment of the porphyrin with the metal alkoxide in alcohol or pyridine, generally adopted for other porphyrins[42], be used to prepare alkali-metal analogues of chlorophyll, owing to the instability of the cyclopentanone ring (E) of chlorophyllic acid in the presence of alkaline reagents[43]. Beryllium(II), calcium(II), strontium(II), and barium(II) analogues of chlorophyll also have not yet been prepared.

Chlorophyll itself, the progenitor of all metal phaeophytins, can be obtained by introducing magnesium into the phaeophytin molecule by means of a Grignard reagent[33,42] or a magnesium subhalide prepared from magnesium and iodine in dry pyridine[44]. Later results[45] seem to allow hope that the magnesium ion may be introduced directly into the phaeophytin molecule from solutions of its salts in organic solvents. The actual possibilities of this method will be discussed below. First we shall examine the formation of complexes from natural porphyrins—chlorophyllic-a acid.

1. Formation of Metal Analogues of Chlorophyll in Solution

The most detailed study has been made of the formation of complexes of chlorophyllic acid. The first attempt at a quantitative kinetic study of reaction (1) was made by Baker and Hodson[46], who measured the rates of formation of nickel phaeophytinate $Ni\Phi$ in methanol. They were able to obtain only empirical rate constants and an empirical kinetic equation of fractional order, which was attributed to unjustifiably severe experimental conditions and inaccurate measurements. These results were subjected to critical discussion by Berëzin and Sosnikova[38], who made a series of investigations[47-52] aimed at establishing the kinetics of the formation of metal analogues of chlorophyll in ethanol using the iron(II), cobalt(II), nickel(II), copper(II), zinc(II), silver(II), cadmium(II), mercury(II), and palladium(II) complexes as examples. Experiments were made with chlorophyllic acid under mild conditions between 15° and 50°C. The concentration of the metal salts was varied from 0.00025 M to 0.025 M. Reaction (1) took place in the presence of a considerable excess of the salt, since the concentration of phaeophytin-a did not exceed 0.000025 M. The reaction was of the first order with respect to salt concentration at all concentrations of copper(II) acetate, iron(II) chloride, and cobalt(II) chloride. With other metals the order with respect to salt concentration fell below unity as the concentration increased. The first order of reaction (1) with respect to phaeophytin was strictly maintained in ethanol with all the salts studied at all the temperatures. The general character of the kinetic dependence of reaction (1) on salt concentration is illustrated in Fig. 1 for the formation of cadmium(II) phaeophytinate[48]. Fig. 2 shows the typical dependence for most salts of the order of reaction (1) on salt concentration, illustrated by the formation of the cadmium complex from the acetate.

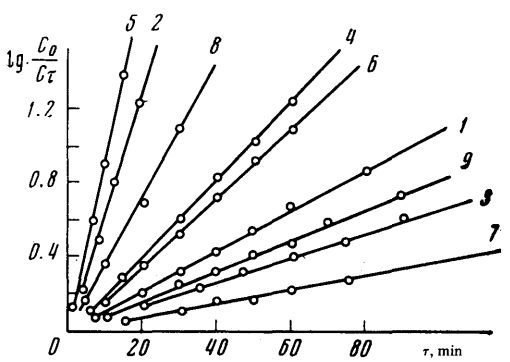


Figure 1. Rates of formation of cadmium phaeophytinate-a at different salt concentrations c and temperatures (°C): 1) 0.0025 M CdI_2 at 30°; 2) 0.0025 M CdI_2 at 40°; 3) 0.00025 M $Cd(NO_3)_2$ at 30°; 4) 0.00025 M $Cd(NO_3)_2$ at 40°; 5) 0.0025 M $Cd(NO_3)_2$ at 30°; 6) 0.0025 M $CdCl_2$ at 30°; 7) 0.00025 M $CdCl_2$ at 30°; 8) 0.0025 M $CdCl_2$ at 40°; 9) 0.00025 M $CdCl_2$ at 40°.

It was concluded from the results[38,48-50] that, at low concentrations of metal salts (below 0.0005 M), reaction (1) conforms to the second-order kinetic equation

$$-\frac{dc_{H_2\Phi}}{dt} = k_v \cdot c_{H_2\Phi} \cdot c_{MX_2}. \quad (2)$$

Values of k_V in Egn. (2) obtained at salt concentrations of 0.00025 M and below can be regarded as true rate constants. At higher concentrations k_V has smaller values, which are in some measure arbitrary (concentration rate constants).

Among the many causes of the "concentration" dependence of the rate constants discussed in the literature[53] two—the change in properties and structure of the solvent with increase in the salt concentration, and also the change in the geometrical configuration of the coordination sphere of the reactant salt with increase both in its own concentration and in that of a foreign electrolyte—must probably be regarded as the most significant. In several cases additional causes—association of the salts and also weak interaction between the salt and side-chains of the porphyrin—may no doubt operate[53]. The latter leads to "weighting" of the porphyrin molecule and changes the reactivity of its main coordination centre—the four cyclic nitrogen atoms.

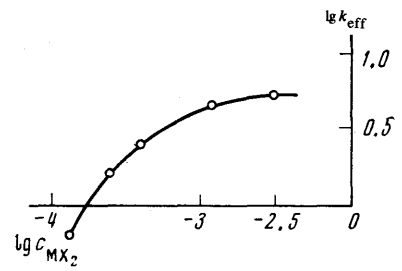

Figure 2. Concentration dependence of rate of formation of cadmium phaeophytinate.

Determinations[48-53] of the principal kinetic parameters for the formation of nine metal analogues of chlorophyll-a showed (Table 1) that "concentration" dependence of the rate constant is absent with certain salts, e.g. copper(II) acetate and cadmium(II) nitrate, iodide, and chloride; reaction (1) obeys the kinetic equation (2) at all concentrations of these salts. With other salts, e.g. cobalt(II) nitrate, the rate constant is almost independent of concentration. Finally, the "concentration" dependence is large with zinc(II) nitrate, cadmium(II) acetate, and nickel(II) nitrate. Such specific behaviour of different salts is explained by differences in the stability of particular coordination structures of the salts in organic solvents. Table 1 shows that, under comparable conditions, the rate of reaction (1) depends little on the electronic structure, charge, or radius of the cation.

The mean rate constant of reaction (1) for salts of eight metals is $(9.8 \pm 6.4) \times 10^2$ M^{-1} h^{-1}.

The rate of formation of the nickel complex is around 10%, and that of cobalt phaeophytinate around 1%, of the average for the remaining complexes. The activation energy is more sensitive to the nature of the cation than is the rate, and varies from 10.6 kcal for copper(II) acetate to 31 kcal for cobalt(II) chloride. In conformity with the kinetic compensation effect, which is strictly observed[54] in the series of metal phaeophytinates, the entropy of activation varies correspondingly from −26 to +30 e.u. for the above salts. The rate of formation of phaeophytinates depends substantially on the anionic composition of the medium[48-52]. In the case of the cadmium and cobalt salts the reaction velocity diminishes[53] in the sequence of anions $NO_3^- > Cl^- > CH_3COO^-$ (Table 1). The instability constants of the cadmium and cobalt salts with these anions decrease in the same sequence: i.e. the stability of the M–X bond in solution increases. The nature of the bond between the anion X^- and the cation probably has an indirect effect on the stability of the solvent sheath of the salt MX_2Solv_{n-2}§, determining the rate and other kinetic parameters of reaction (1). The effect of the structure of the coordination sphere in the initial salt on the formation of metal analogues of chlorophyll has been studied[50,51] by measuring the rate of formation of copper phaeophytinate at various temperatures with various complex salts of copper—malonate, succinate, citrate, and alaninate—in 90% ethanol and in ammoniacal–ethanolic media, in which the above salts have satisfactory solubility. Inspection of the experimental results (Table 2) indicates that replacing the anion X^- in the coordination sphere of the salt MX_2 changes the reaction velocity not more than tenfold, independently of the type of coordination (linear, cyclic, or inner-complex) of the organic anion as ligand, of the stability of its bond with the cation. Alanine and citrate form very stable chelate complexes with the Cu^{2+} ion[55], yet they react with chlorophyllic acid just as easily as does copper acetate. From these facts it may be concluded that reaction (1) takes place with the undissociated salt MX_2, and the stage of activation of the salt involves loss of a solvent molecule—not of an anion—from the coordination sphere of the cation.

Table 1. Kinetic parameters of the formation of metal analogues of chlorophyll

***Concentration of salt 0.00025 M.

Saturation of 90% ethanol with ammonia (Table 2) lowers the rate of reaction (1) by factors of 10–20, with increase in the energy and the entropy of activation, which was explained[50] both by rearrangement of the inner coordination sphere of the Cu^{2+} ion from a solvate to an ammine and by rearrangement of the solvent structure around this

§ Solv = solvent molecule; n = maximum coordination number of cation under specific conditions.

sphere. The high energies and entropies of activation in aqueous–alcoholic and ammoniacal–alcoholic media were explained by the formation of a second and subsequent solvation spheres in the vicinity of coordinated water or ammonia, which is impossible in the case of alcohols.

Table 2. Formation of copper phaeophytinate from various complex copper salts in ethanol at 25°C.

Cu salt	$10^{-3}k_v$, M^{-1} h^{-1}	E, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	Ethanol

Table 3. Kinetic parameters of formation of mercury(II) phaeophytinate at 25°C.

Salt	Concn., 10^3c, M	$10^{-3}k_v$, M^{-1} h^{-1}	E, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	Solvent
$HgCl_2$	0.25	28.0	13.9	−5	ethanol
$HgCl_4^{2-}$	0.25	very slow	—	—	ethanol
$HgCl_2$	0.25	0.58	56.4	+101	methanol
$HgCl_2$	0.50	0.43	48.7	+129	methanol
$HgCl_4^{2-}$	0.25	0.67	12.7	−16	methanol
$HgCl_4^{2-}$	2.50	0.046	11.3	−26	methanol
HgI_2	2.50	0.230	13.4	−14	ethanol
HgI_4^{2-}	2.50	very slow	—	—	ethanol
HgI_2	2.50	0.021	13.1	−22	methanol
HgI_4^{2-}	0.25	0.068	21.8	+14	methanol

The kinetics of reaction (1) with chloride and iodide complexes of mercury was studied in order to determine the effect of the number of coordination sites of the cation occupied by simple anions[51]. Table 3 shows that decrease in the number of solvent molecules located in the coordination sphere of Hg^{2+}, from two for HgX_2 to zero for HgX_4^{2-}, strongly inhibits reaction (1) in ethanol, whereas in methanol $Hg\Phi$ is formed at the same rate from $HgCl_2$ and $HgCl_4^{2-}$, and the rate from HgI_4^{2-} is even higher than from HgI_2. An explanation for such unusual behaviour of mercury salts will be given in discussing the mechanism of reaction (1) in later sections.

Here, however, we must note the extraordinarily strong dependence of the rate of formation of phaeophytinates on the nature of the solvent. This becomes obvious when it is remembered that the solvent forms the structure of the coordination sphere of the salt MX_mSolv_{n-m}, and determines the strength of the M–X and M–Solv bonds in solution, as well as the degree of solvation of the reactants: i.e. it determines the energy and entropy components of the free energy of activation of reaction (1). Berëzin and Smirnova[41,56–62] measured the rates of this reaction with copper(II) and zinc(II) salts in various types of organic solvents—alcohols, ketones, ethers, amides, nitrogen-containing heterocycles, and aliphatic acids—and found a thousandfold variation in the rate of formation of metal analogues of chlorophyll depending on the nature of the solvent (Table 4). The rate is maximal in glacial acetic acid, and minimal in pyridine. The effect of the solvent on the kinetics of reaction (1) was explained[56–62] by variation in the stability of the solvent coordination sphere of the salt MX_2Solv_{n-2}, i.e. in ease of rupture of the M–Solv bond, and by spatial factors, in particular steric hindrance by solvent molecules in the coordination sphere of the activated salt impeding entry of the large flat phaeophytin molecule.

Table 5. Kinetics of formation of copper phaeophytinate in ethanol–glycerol media at 25°C.

Glycerol / ethanol	Viscosity (discharge time)	$10^{-3}k_v$, M^{-1} h^{-1}	E, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.
0:100	4 s	3.42	10.6	22.7
20:80	10 s	1.81	10.8	23.4
50:50	1 min	1.46	11.9	20.0
80:20	7 min	0.44	12.8	19.4

Table 4 indicates that the reaction velocity of (1) decreases and the activation energy increases with increase in the volume occupied by the solvent in the immediate vicinity of the cation[63,64]. This is characteristic of dioxan, pyridine, quinoline, dimethylformamide, and n-pentanol. It is significant that merely strengthening the coordinate link (ethanol → methanol) does not diminish the rate, although it increases the activation energy appreciably. Another extremely interesting aspect is that change in the state of phaeophytin molecule $H_2\Phi$ has hardly any effect on the reaction velocity. Thus in glacial acetic acid, which forms a strong hydrogen bond with nitrogen atoms in the reaction centre of phaeophytin, the rate exceeds that in ethanol by a factor of 15; the latter solvent slightly blocks the nitrogen atoms. Interaction of π–π type between the aromatic rings of phaeophytin and nitrogen heterocycles (pyridine, quinoline) also has no appreciable effect on the reactivity of phaeophytin. Thus the rates of (1) in quinoline and in dimethylformamide are roughly the same. An analogous effect of nature of solvent on reactivity was established with phaeophytin and zinc salts[41,56–61]. Neither the displacement of the keto–enol equilibrium of phaeophytin-a occurring in ethanol–glycerol

solutions nor the increase in viscosity of the medium (Table 5) has a significant effect on the rate of reaction (1).[62] It was suggested that the enolic form nevertheless possesses a higher kinetic coordinating power than does the ketonic form.

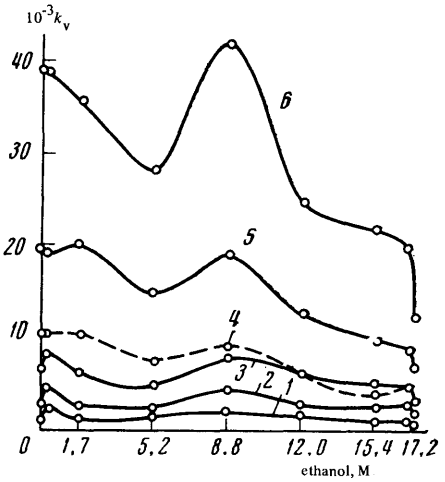

Figure 3. Dependence of rate constant of formation of CuΦ on composition of ethanolic acetic acid for different approximate $Cu(OAc)_2$ concentrations (M) at different temperatures (°C): 1) 0.0025 at 15°; 2) 0.0025 at 25°; 3) 0.0025 at 35°; 4) 0.00025 at 15°; 5) 0.00025 at 25°; 6) 0.00025 at 35°.

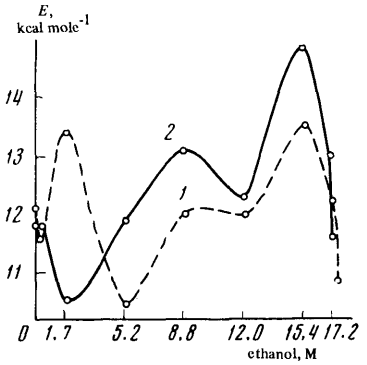

Figure 4. Dependence of activation energy of CuΦ on composition of solvent for different approximate concentrations (M) of $Cu(OAc)_2$: 1) 0.0025; 2) 0.00025.

Berëzin and Klopova[65-67] found several extremal points n the variation of rate, activation energy, and entropy of ıctivation of reaction (1) with solvent composition in ethanoic acetic acid (Figs. 3–5). The extrema were attributed[66] o resolvation, on passing from acetic acid to alcoholic nedia, of the solvate complex $[M(OAc)_2(HOAc)_{n-2}]$ through $M(OAc)_2(HOAc)_{n-2-m}(C_2H_5OH)_m]$ to $[M(OAc)_2(C_2H_5OH)_{n-2}]$; hey were attributed also to formation of an association complex $CH_3COOH...C_2H_5OH$ with a stable hydrogen bond; and in some measure to resolvation of the reaction centre of phaeophytin from >N...HOCOCH₃ to >N...HOC₂H₅ and >NH...O(H)–C₂H₅. Rearrangement of the structure of the pure solvent produced by small additions of another solvent, in particular stabilisation of the structure of methanol, is probably quite an important factor[68].

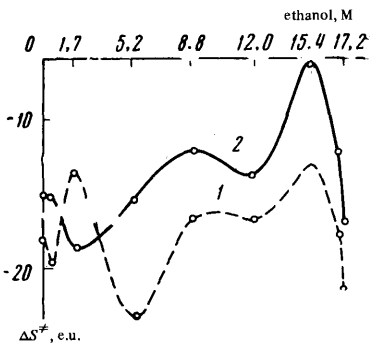

Figure 5. Dependence of entropy of CuΦ on composition of solvent for different approximate concentrations (M) of $Cu(OAc)_2$: 1) 0.0025; 2) 0.00025.

Phillips and others[69] found that the nature of the solvent had a very strong effect on the rate of formation of other metal porphyrins. Cobalt(II) salts react rapidly with porphyrins in dry acetone even at 25°C. Addition of a small quantity of water greatly retards the reaction. A still more interesting observation, which cannot yet be interpreted, was made on nickel salts: nickel(II) reacts very rapidly when the reaction is conducted in higher alcohols (butanol, pentanol) or in phenol, but very slowly in methanol, ethanol, or water. The reasons for such behaviour are now being studied in detail on complexes of cobalt(II) with chlorophyllic acid[70].

2. Formation of Complex Compounds—Structural Analogues of Chlorophyll

Quantitative investigation of the formation of porphyrin complexes—structural analogues of chlorophyll—began comparatively recently[71]. The need for their study arose from the importance and great biological activity not only of chlorophyll but also of other metal porphyrins, possessing a different system of side-chains and different central metal atoms. The selective action of metal porphyrins is probably governed precisely by the nature and range of substituents. These change the σ- and π-acceptor and the donor properties of the conjugated macrocycle, as well as the ability of the central metal atom to coordinate additional ligands involved in particular biological acts (photosynthesis, respiration, oxidation, decomposition, etc.). It is therefore a very urgent task to investigate kinetic and equilibrium aspects of the formation of metal porphyrins as a function of the nature and number of side-chains in porphin.

Choi, Fleischer, et al.[71,72] studied complex formation by αβγδ-tetrapyridylporphin (H_2TPP) with copper(II), cobalt(II), manganese(II), and nickel(II) salts in glacial and aqueous

acetic acid. This porphin possesses good solubility in proton-donating solvents, including aqueous media. The reaction, probably represented by the equation

$$H_2TPP + M^{2+}_{Solv} \xrightarrow{k_v} MTPP + 2H^+_{Solv} \quad (3)$$

has the first order with respect both to the porphin and to the metal. Unfortunately, the reaction velocity was measured only at a single concentration (~ 0.004 M) of the metal salt, and the unjustified assumption was made that copper(II) acetate is present in glacial acetic acid as Cu^{2+}. Calculation based on the second-order equation (2) gave for the rate constants of reaction (3) involving copper, cobalt, manganese, and nickel diacetates the respective values 1400, 310, 210, and 87 M^{-1} h^{-1} at 25°. The reaction takes place considerably more slowly than with chlorophyllic acid (cf. Table 4).

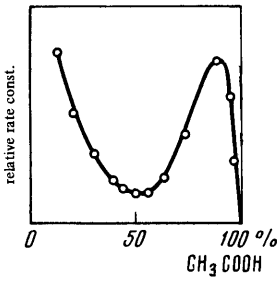

Figure 6. Dependence of rate of formation of CuTPP on acetic-acid concentration.

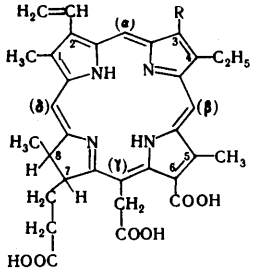
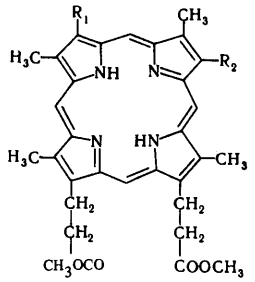


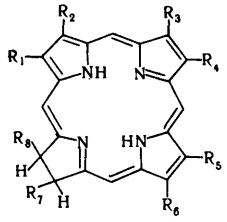
The formation (3) of copper and zinc complexes from the perchlorates in 8.3% aqueous acetic acid containing 0.01 M perchloric acid has rate constants at 25°C of 63 and 22 M^{-1} h^{-1}. Replacement of acetic acid by water molecules in the coordination sphere lowers the rate by 50–67%. The rate of reaction (1) in aqueous solution is inversely proportional[71,72] to the hydrogen-ion concentration, but in aqueous acetic acid it passes through a maximum in the 90% acid (Fig. 6). However, these facts were left unexplained[71]. It may be supposed that protonation of the pyridine residues accelerates the reaction (in concentrated aqueous acetic acid) owing to increased protonation of the pyrrole nitrogen–hydrogen bonds, while protonation of the reaction centre, i.e. of the pyrrole nitrogen atoms (aqueous perchloric acid) lowers the reaction velocity. Competition between the two processes may produce the observed variation (Fig. 6). The fact that cadmium, lead, and mercury complexes of tetrapyridylporphin are not formed under the given conditions[71] causes no surprise, since these complexes are unstable in proton-donating media.

Brisbin and Balanura[73] studied the kinetics of the reaction between manganese(II) and haematoporphyrin in glacial acetic acid, and suggested a reaction mechanism which was subjected to an impartial critique[74]. The effect of the pH of the medium on the rate of coordination of sulphonated deuteroporphyrin IX by Cu^{2+} ions was studied by Weaver and Hambright[75]; and the catalytic action of nitrogen-containing solvents on the reaction of zinc(II) with water-soluble porphyrins was investigated by Stein and Plane[76]. We shall not discuss these papers, since their results introduce nothing significantly novel into the kinetics and the mechanism of the reactions of metal salts with porphyrins.



A most interesting paper by Baum and Plane[77] deals with the direct introduction of magnesium into a porphyrin from a solution of a salt in an ordinary organic solvent (acetone, methanol). The rate of incorporation of magnesium into the dimethyl ester of deuteroporphyrin IX is given by the kinetic equation

$$\frac{d[MP]}{dt} = k_1\frac{[PH_2]}{[H^+]} + k_2\frac{[PH_2][Mg^{2+}][Py]}{[H^+]} \quad (4)$$



in which the rate constants of the uncatalysed reaction and of the reaction catalysed by pyridine or other nitrogen-containing solvent are respectively $k_1 = 4.7 \times 10^{-4}$ and $k_2 = 3.6$ M^{-1} h^{-1}, the corresponding activation energies being $E_1 = 36.5$ and $E_2 = 15.8$ kcal $mole^{-1}$. Comparison with Table 1 indicates that the rate of coordination of magnesium by porphyrins from solution is vanishingly small, but the catalytic effect of nitrogen-containing compounds is so intense that the rate of incorporation of magnesium approaches those for cobalt from the dichloride and the diacetate in ethanolic solution. These results encourage the hope of the direct introduction of magnesium into chlorophyllic acid, and also a fresh look at the formation of chlorophyll in the living cell[78].

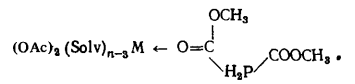
Berëzin and Koifman have reported[79-86] systematic investigations of the effect of structural units of the porphyrin molecule on the kinetics of the formation of metal porphyrins (see Table 6). To facilitate discussion of the results we give here the structural formulae of the natural and synthetic porphyrins investigated. Opening the cyclopentanone ring (ring E in structure I), i.e. the conversion of phaeophorbide-a into chlorin-e_6 (II), doubles the reaction velocity, while the activation energy and entropy remain almost unchanged. The explanation given[80] was that the substitution of carboxyl for -CO.R at $C_{(6)}$ in chlorin-e_6 changes the inductive effect exerted by the substituent on the nitrogen atoms of the macrocycle. The carboxy-group, while possessing about the same conjugation effect as the group it replaces, probably exerts a greater inductive effect, so that the nitrogen–hydrogen bond in the chlorin may become strongly protonated, with a tendency to accelerate the reaction

$$H_2P + MX_2 \rightarrow MP + 2HX. \qquad (5)$$

The suggestion that the state of the nitrogen–hydrogen bond in porphin greatly influences the coordinating power of the compound is supported[79] by a comparison of chlorophyllic-a and -b acids (structure I). Conversion of $H_2\Phi$-a into $H_2\Phi$-b is accompanied by a decrease in the rate of coordination of the Cu^{2+} ion roughly to one-seventh, with an appreciable increase in activation energy, associated with an increase in electron density on the nitrogen–hydrogen bond under the influence of the positive conjugation effect (+*C*-effect) of the 3-formyl group (structure I). The greater stability of chlorophyll-b in solution finally provides convincing evidence that the above hypothesis[74,79] is correct. An adverse effect of the 3-formyl group on the rate of formation of complexes in solution has been established also in a comparison[81] of chlorin-e_6 (II) with rhodin-g_7 (III), which have the same structural relationship as chlorophyllic-a and -b acids.

Table 6. Kinetic parameters of formation of copper complexes of natural and synthetic porphyrins in ethanol at 25°C.



Porphyrin	$10^4 c^0_{Cu(OAc)_2}$, M	$10^{-3}k_{eff}$, $M^{-1}\,h^{-1}$	*E*, kcal mole^{-1}	$\Delta S^{\neq}$; e.u.

Aetioporphyrin II	2.30	6.90	12.8	−14
Aetiochlorin II	2.30	7.50	11.3	−18

*dme = dimethyl ester.

The conversion of chlorin-e_6 (II) into mesoporphyrin (IV), involving disappearance of one carboxyl conjugated with the macro-ring at $C_{(6)}$, and of the 2-vinyl group, produces hardly any change in the kinetic parameters[84] (Table 6). Here similar electron-accepting substituents (COOH and $CH:CH_2$) have been replaced by similar alkyl and "pseudo-alkyl" substituents (C_2H_5 and $CH_2.CH_2.COOH$). The rate constants remain unchanged probably because the 2- and 6-substituents have opposite effects.

Protoporphyrin coordinates copper salts at half the rate observed with mesoporphyrin[84]. Conversion of the latter (IV) into the former (V) involves replacement of the two alkyl substituents at $C_{(2)}$ and $C_{(4)}$ by vinyl groups, which possess an analogous but weaker +*C*-effect than that of the formyl group. This leads to a diminution in the protonation of the nitrogen–hydrogen bond and a lower reaction velocity.

Completely unexpected results were obtained[82] for the coordinating properties of porphin (X) and synthetic chlorin (VI), and their comparison with the aetioporphyrins (XI) and (XII).[85] Porphin and synthetic chlorin do not differ in the kinetic parameters of coordination (Table 6). Hence the hydrogenation of one "semi-isolated" double bond of a pyrrole ring has no appreciable effect on the state of the N–H bond and the reactivity of the macro-ring. Nevertheless, porphin and synthetic chlorin coordinate copper salts at one-quarter the rate observed with chlorin-e_6 or mesoporphyrin. The favourable effect of residues of propionic acid was explained[84] by primary coordination of the metal salt on them:

Because of favourable arrangement of methoxycarbonyl groups relative to the main coordinating centre (the four nitrogen atoms of the macrocycle), primary coordination probably favours the enclosure of both reaction centres in a solvent "cage", which will increase the rate and lower the activation energy. The entropy of activation will also diminish in conformity with the compensation effect characteristic[74,83] of reaction (5). The aetioporphyrins (XI) and (XII), in which the propionic-acid residues have been replaced by alkyl groups, possess double the activation energy with the same rates of coordination. A similar result appears on comparing aetiochlorin (VII) with chlorin-e_6 (II). The high rates of reaction (5) with aetioporphyrin and aetiochlorin, relative to those with porphin (X) and chlorin (VI), are explained by the presence of a factor counterbalancing the energy factor in the coordination of porphyrins[85]. This factor is universal solvation, which is probably less favourable to alkylated than to unsubstituted pyrrole rings in porphyrins. The solvation factor is especially strongly developed when the symmetry of the porphyrin molecule and also that of the π-electron system of the macro-ring are destroyed. Pyrroporphyrin XV (VIII), which contains no 6-substituent, coordinates at double the rate observed with mesoporphyrin (Table 6). Finally, phylloporphyrin XV (IX), which unlike pyrroporphyrin has a γ-alkyl group, exhibits the maximum rate of coordination of metal salts[86]: its rate of reaction with copper(II) acetate exceeds that of phaeophytin-b by a factor of 270.

Falk's monograph[8] gives the relative rates of formation of copper(II) complexes with mesoporphyrin, protoporphyrin, and 2,4-diacetyldeuteroporphyrin in aqueous solutions of sodium dodecyl sulphate as 7 : 1.5 : 1.0. These agree well with the above results[78-85], and support the main conclusions reached.

Thus by now not only has the strong effect of structural features of the porphyrin molecule on its coordinating reactivity been established but the influence of energetic factors (variation in state of nitrogen–hydrogen bond produced by substituents), solvation factors, and primary coordination on the kinetic parameters has also been shown.

All the conclusions reached[79-85] for reaction (5) with copper(II) salts have been found to hold also for zinc(II) salts[74].

3. Mechanism of Formation of Metal Analogues of Chlorophyll and Other Metal Porphyrins

The formation of complex compounds with large planar molecules having continuous peripheral conjugation exhibits several features distinguishing such reactions from the formation of complexes (often termed ligand substitution) with simple ligands[87,88]. Several factors are responsible for such distinguishing features: (i) the ligand possesses low mobility in solution, and is a target for the more mobile reactant—the salt molecule (or ions); (ii) the ligands are acidic, and are usually extremely difficult to convert to the anionic state ($H_2P \rightarrow 2H^+ + P^{2-}$); (iii) the continuous π-cloud of the conjugated macrocyclic system (structures I–XII) shields the reaction centre of the ligand, including the four inner nitrogen atoms; and (iv) solvation of the ligand involves complicated phenomena, as the ligand carries multifarious centres of solvation.

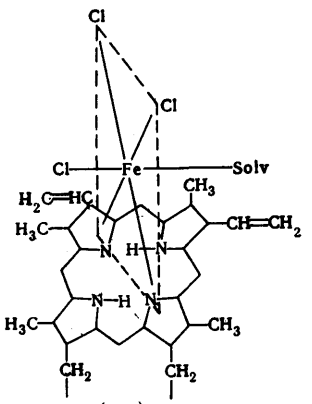
The main feature of the formation of metal porphyrins is its slowness in comparison with the coordination of other ligands. Systematic investigations of the formation of metal analogues of chlorophyll[48-51,56-62] indicated, for organic solvents possessing no appreciable ionising power, the stoichiometric equation

$$M(Solv)_{n-m}X_m + H_2\Phi(Solv)_p \rightarrow M\Phi(Solv)_q + 2HX(Solv)_s + (n-m+p-q-2s)\,Solv \quad (6)$$

which conforms to the second-order kinetic equation (2).

Reaction (6) probably takes place in a single stage in most of the solvents studied, since intermediate compounds were not detected, either kinetically or spectroscopically[48,49]. In several cases, however, formation of an intermediate complex of type $H_2\Phi.MX_2$ was a possibility[57,89,90]. Such complexes are formed in glacial acetic acid when reaction (6) is conducted with zinc(II) chloride, cobalt(II) chloride, cobalt(II) acetate, iron(II) chloride, palladium(II) chloride, and mercury(II) acetate in ethanol. They are distinguished from a phaeophytinate by a hypsochromic shift of the first two bands and a strong bathochromic shift of the other three bands in the electronic absorption spectrum. An exception is $H_2\Phi.Hg(OAc)_2$.[91] The intermediate complexes are far less stable than complexes of the bivalent metal with pyridine and with alcohols. They are converted into the corresponding phaeophytinates either at room temperature ($H_2\Phi.Co(OAc)_2$) or when the solutions are boiled ($H_2\Phi.FeCl_2$).

The stoichiometric mechanism (using Langford and Gray's classification[87]) of the formation of metal porphyrins is most probably covered by two possibilities (written here in simplified form)—(*a*) in a single bimolecular stage

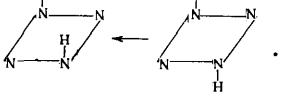


$$H_2P + MX_2 \rightarrow [MX_2 \cdot H_2P]^{\ddagger} \rightarrow MP + 2HX \quad (6a)$$

(*b*) in two stages with preliminary formation of an intermediate

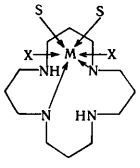
$$H_2P + MX_2 \underset{\text{(stage I)}}{\overset{\text{rapid}}{\rightleftharpoons}} MX_2 \cdot H_2P \xrightarrow[\text{(stage II)}]{\text{slow}} [MX_2 \cdot H_2P]^{\ddagger} \rightarrow MP + 2HX. \quad (6b)$$

The two reaction paths undoubtedly cross different forms of potential barrier, but the shape and height of the final peak in the potential curve, determined by the structure of the transition state $[MX_2.H_2P]\dagger\dagger$, are the same, since the latter has the same structure in reactions (6a) and (6b). According to existing schemes of classification[86,88,92,93] the stoichiometric mechanism of reactions (6a) can be regarded either as associative bimolecular S_E2[93] or as a concerted process with associative activation[87]. The mechanism of reactions (6b) can be denoted dissociative unimolecular S_E1 in Ingold's classification[92].



It is of interest to examine data on the detailed mechanism of the elementary stage of the coordination of porphyrins by metal salts. These data also deepen and refine information on the stoichiometric mechanism. It was first established[37] that the dimethyl ester of protoporphyrin in acetone, chloroform, and other weakly solvating solvents forms with iron(II), iron(III), cobalt(II), platinum(IV), tin(II), and zinc(II) salts initially a complex whose spectrum is closely similar to that of the diprotonated porphyrin $H_2PH_2^{2+}$. On this basis the structure

(XIII)



was assigned to the complex, and is probably closest to reality. This structure is supported by the results of infrared spectroscopy[37]: the vibrations of the nitrogen–hydrogen bond were shown to change in character.

In strongly solvating media, such as water, alcohols, pyridine, etc., the above cations gave metal porphyrins without forming intermediates. No intermediate complexes are formed when the cations Ni^{2+}, Cu^{2+}, Hg^{2+}, and Cd^{2+} react with the dimethyl ester of protoporphyrin in acetone. In the reaction with chlorophyllic acid the formation of intermediate complexes was only rarely observed in polar solvents, including acetone[57,89,90]. Such complexes are generally produced in glacial acetic acid, since the metal–solvent bond in the solvate coordination spheres of the salt MX_2Solv_{n-2} is not very stable. It follows from these observations that the elementary act, both in reactions (6a) and in stage (I) of reactions (6b), involves the detachment of one or two solvent molecules from the inner sphere of the salt, i.e. its activation to MX_2Solv_{n-3} or MX_2Solv_{n-4} and activation of the porphyrin, which evidently entails conversion of the *trans*-form of H_2P into the *cis*-form and its partial resolvation[50]:

The reacting system (6a) forms an activated complex (transition state $[H_2P.MX_2]\dagger\dagger$), but the reacting system (6b) forms a complex of type $H_2P.MX_2$. There is no

special reason to doubt that these two structures are the same (XIV).

(XIV)

The reacting system (6a), having reached the summit of the potential barrier, readily splits off $2H^+$, $2X^-$, and perhaps some of the solvent molecules from the inner sphere to give the metal porphyrin (MP). The reactant system (6b) remains in the potential well at the summit of the barrier, since detachment of the anions X^- and perhaps also H^+ is difficult in a weakly solvating medium, in which alone are intermediates formed. Addition of a more polar solvent leads to the displacement of H_2P molecules from the intermediate complex, and the reacting system (6b) returns to the initial state. This indicates that the intermediate is a very unstable complex. In spite of this, the second stage of reaction (6b) is difficult and is accomplished only on prolonged heating. The reason is that, as had been suggested[90], the formation of metal porphyrins in this case involves breakdown of the intermediate complex into the starting materials, which react by scheme (6a).

Thus it is highly probable[90] that metal porphyrins are not formed at all by scheme (6b). This view is supported by the analogous behaviour of the MX_2-H_2P system in strongly proton-donating solvents, in which the species $H_2PH_2^{2+}$ is formed, resembling the intermediate $H_2P.MX_2$ in properties. The rate constant for the formation of CuΦ in 95% formic acid at 25°C (6.5 M^{-1} h^{-1}) is 0.03% of its value in glacial acetic acid. The activation energy has increased from 10.5 to 29 kcal: i.e. it includes the activation energy for the breakdown of $H_2PH_2^{2+}$ to H_2P and the energy of activation of MX_2 and H_2P in reaction (6a).

Falk in his monograph[8], on the basis of results obtained by Phillips et al.,[69] concludes that the formation of metal porphyrins, like that of complexes of chlorophyllic acid, occurs predominantly by scheme (6a): i.e. it has a bimolecular mechanism¶. Some interesting results were obtained[94,95] on the detailed mechanism of reaction (6): complex formation between copper(II) and mesoporphyrin is accelerated by the presence of hydroxyquinoline (OX^-) at a concentration corresponding to formation of $CuOX^+$, after which the rate drops sharply when $Cu(OX)_2$ is formed. Thus a chelating ligand added to the MX_2-H_2P system may act either as an activator or as an inhibitor. The authors[94,95] were unable to give the true reasons for such behaviour of foreign ligands. The conclusion is suggested by data[48-51,56-62] on the complexes of chlorophyllic acid (Tables 2–4). When the reactant salt MX_2Solv_{n-2} contains the anion X^- in the inner sphere, as occurs with hydroxyquinoline, the number of coordinated solvent molecules diminishes from 4 to 0, and their bonding with the cation becomes weaker. This weakening favours the reaction, increasing the rate and lowering the activation energy. Decrease in the number of solvent molecules in the inner sphere acts in the opposite direction, and when $n - 2 = 0$ reaction may cease, as in the case of $Cu(OX)_2$.[94,95] The above considerations readily explain facts established by one of us[48-53,56-62]—that reaction (6) is not retarded by such chelating additives as malonate, succinate, citrate, and alanine (Table 2), which occupy no more than 2–4 coordination sites in the inner sphere of Cu^{2+}, leaving 2 solvent molecules in it; that reaction (6) occurs at very high rates with the very stable complex salts $HgCl_2$ and HgI_2 (Table 3); and that rates are lower in solvents having bulky molecules, such as dioxan, pentanol, dimethylformamide, pyridine, etc. (Table 4).

Nevertheless, the formation of metal porphyrins with $HgCl_4^{2-}$ and HgI_4^{2-} and the absence of reaction[53,63,64] with $[Co(NH_3)_6]^{3+}$, $[CoCl(NH_3)_5]^{2+}$, $[Co(HCOO)_2(NH_3)_4]^+$, $[Fe(CN)_6]^{4-}$, and $[Fe(CN)_5NO]^{2-}$ salts indicate a second possible detailed mechanism for reaction (6a)—displacement of ligands from their positions in the course of interaction between the porphyrin and the complex salt[51]—which is possible with HgX_4^{2-} but impossible with $[CoL_6]^{n+}$ and $[FeA_6]^{n-}$. Porphyrins can react by this mechanism with salts containing no solvent molecules in the inner sphere, provided that such salts can be distorted with contraction of the coordination sphere and the freeing of two sites for the development of interaction with two nitrogen atoms in the reaction centre of the porphyrin.

Investigation of the coordination of porphyrins (6) raises the question whether the kinetic parameters will be affected if reaction occurs with the cation of the dissociated salt:

$$M^{2+} + H_2P \rightarrow MP + 2H^+ \qquad (7)$$

a form in which the stoichiometric equation has been written[8,33,35,37]. Such a crude representation of the reaction suggests that the salt MX_2Solv_{n-2} is completely or almost completely dissociated, and is present either in the form $MSolv_n^{2+} + 2X^-$ or else as the ion-pair $[MSolv_n]X_2$. Such a state of the salt is possible with strongly solvating solvents only when weak M–X coordination interaction is present in solution (MX_2 has a high instability constant). All the results obtained for the coordination of chlorophyllic acid indicate that the kinetic parameters are little affected by change in state of the salt from $[MX_2Solv_{n-2}]$ to $[MSolv_n]X_2$ or even to $[MSolv_n]^{2+} + 2X^-$. This conclusion is based on experiment and is easily explained by the reaction mechanism (6a).

In order to understand the detailed mechanism it is necessary to know how the state of the porphyrin molecule—in particular that of the N–H bond—changes during activation. Several results tending to answer this question will be found in Refs. 50, 79, and 86. In organic solvents porphyrin undergoes the elementary act as H_2P, not as $H_2PH_2^{2+}$, PH^-, or P^{2-}.[50,90] The slight dependence of the rate of reaction (1) on the nature of the salt cation under identical experimental conditions indicates that the major component of the total activation energy resides in the stretching of the N–H bond. Investigation of the effect of structural changes in the porphyrin molecule[79-86] on the rate and on the energy and entropy of activation of reaction (6) has not only confirmed this conclusion but also established that polarisation (protonation) of the N–H bond favours the reaction.

III. DISSOCIATION OF CHLOROPHYLL, ITS METAL ANALOGUES, AND OTHER METAL PORPHYRINS IN SOLUTION

In this Section we shall discuss the heterolytic breakdown or solvolytic dissociation of porphyrin complexes,

¶ These authors[8,69] write the mechanism S_N2, not S_E2: i.e. they take porphyrin to be the reagent, which on the above considerations cannot be regarded as reasonable.

which occurs only in proton-donating media. Dissociation of the complexes into ions

$$MP + mn\,Solv \rightleftarrows M(Solv)_n^{2+} + P^{2-}(Solv)_m \quad (8)$$

is not observed owing to the very slight acidity of H_2P and the very great stability of metal–porphyrin complexes MP in solution. Appreciable dissociation begins to develop in media containing solvated protons H^+_{Solv} or molecules of strong acids. It occurs as protolytic dissociation

$$MP + 2H^+_{Solv} + 2X^- \rightleftarrows MX_2 + H_2P \quad (9)$$

but in media of high acidity

$$MP + 4H^+_{Solv} + 2X^- \rightleftarrows MX_{2(Solv)} + H_2PH^{2+}_{2(Solv)}. \quad (9a)$$

1. Dissociation of Chlorophyll and its Labile Metal Analogues

The first attempt at a quantitative kinetic study of the dissociation of chlorophyll was made by Mackinney and Joslin[30-32], who examined the reaction

$$Mg\Phi + 2HX \rightarrow Mg^{2+} + H_2\Phi + 2X^- \quad (9b)$$

in 90% aqueous acetone, using oxalic, sulphurous, sulphuric, and hydrochloric acids. The reaction was presumably of the first order with respect to the acid, but the order with respect to chlorophyll was not established, and no reliable kinetic characteristics were obtained. The failure of these experiments is explained by the choice of an unsuitable proton-donating solvent, in which partial protonation of $H_2\Phi$ to $H_2\Phi H_2^{2+}$, aggregation of $H_2\Phi$, etc. were possible. An important result[30-32] was that chlorophyll-a dissociates seven times as rapidly as chlorophyll-b†.

The kinetic experiments on the dissociation of chlorophyll and its derivatives have since been repeated by Schanderl et al.,[96] who used 80% aqueous acetone with additions of 10^{-4} M hydrochloric acid. Under the given conditions chlorophyll-a was found to dissociate more rapidly than chlorophyll-b by a factor of 5.5, while the activation energy was the same at 10.5 kcal mole^{-1}. Replacement of the phytyl residue ($C_{20}H_{39}$) in the chlorophylls by ethyl, methyl, and hydrogen, i.e. conversion of the chlorophylls into the ethylphaeophorbides, methylphaeophorbides, and phaeophorbides, produces slight acceleration of dissociation (the experimental rate constants for the a-compounds at 25°C are respectively 0.0103, 0.0127, 0.0156, and 0.0171 min^{-1}) without affecting the activation energy. The investigations provided no information on the mechanism of reaction (9) or the nature of the bond between magnesium and the porphyrin. The dissociation of chlorophyll and its analogues has therefore been studied under comparable conditions by Berëzin and Drobysheva[89,91,97-105]. The dissociation of chlorophyll-a and of cadmium and mercury phaeophytinates was examined[102] in absolute ethanol with small additions of glacial acetic acid, between 20° and 60°C. The results[102] are given in Table 7.

The dissociation of chlorophyll in ethanolic acetic acid occurs irreversibly in conformity with Eqn. (9), is strictly of the first order with respect to chlorophyll, has the activation energy $E = 13.7 \pm 0.5$ kcal mole^{-1} and the entropy of activation $\Delta S\dagger\dagger = -37 \pm 1$ e.u., and is very strongly dependent on (varies more rapidly than the fourth power of) the total concentration of acetic acid. Dissociation of the cadmium analogue of chlorophyll is reversible and of the first order with respect to the complex, with zero activation energy. Fig. 7 illustrates the dependence of the effective dissociation rate constants of chlorophyll and its cadmium analogue on the square of the total acetic-acid concentration. Dissociation of the cadmium complex is of the second order with respect to acetic acid and of the fourth order with respect to the solvated proton, whose concentration is calculated on the assumption that it is the attacking species in the act of dissociation of the complex.

† Chlorophyll-b is the magnesium complex of chlorophyllic-b acid—see structure (I).

Table 7. Dissociation of Mg, Cd, and Hg phaeophytinates in ethanolic acetic acid.

Complex	HOAc in ethanol, M	Temp., °C	k_{eff}, h^{-1}	Complex	HOAc in ethanol, M	Temp., °C	k_{eff}, h^{-1}

				HgΦ	0.02	25	very rapid

*Calculated by means of the Arrhenius equation.

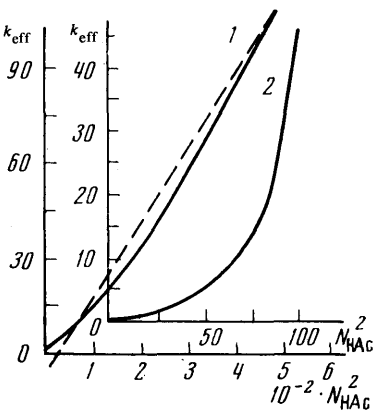

Figure 7. Dependence of effective dissociation rate constant on acidity of medium for: 1) CdΦ; 2) MgΦ.

The explanation offered[91,102] for such an unusual dependence was that not only $C_2H_5OH_2^+$ but also others, in particular CH_3COOH, may function as active protogenic species with not too stable metal porphyrins (the magnesium, cadmium, and mercury(II) complexes). Probably changes in the structure and properties of the solvent (ethanol) with increasing concentration of acetic acid should also be taken into account. These changes may have a large kinetic effect[65-67]. Since the nature of the reagent species in the act of dissociation of chlorophyll and its analogues is an important question, efforts must be directed to finding a proton-donating solvent in which one type of proton-donor would predominate, and its concentration could be calculated exactly. The Reviewers are making a search for such media in the laboratory.

Table 7 indicates an unusually large variation in the kinetic stability of the magnesium, cadmium, and mercury complexes. The mercury complex HgΦ is surprisingly unstable: in the presence of traces of acetic acid in ethanol it dissociates instantaneously. The cadmium complex is several orders of magnitude more stable. Chlorophyll is the most stable among these labile phaeophytinates. This stability is a not unimportant factor in Nature's choice as the principal complex for effecting photosynthesis.

2. Dissociation of Stable Complexes of Chlorophyllic Acid and Other Porphyrins

The stability of porphyrin complexes is of great interest for biochemistry, so that qualitative observations of this most important property were made long ago, and the results have been summarised[8,33,36]. The first quantitative data on the rates of dissociation of copper aetioporphyrin (XII) were published by Caughey and Corwin[36]. The dissociation was studied in glacial acetic acid with additions of sulphuric acid monohydrate. The results are given in Table 8.

Table 8. Rates of dissociation of copper aetioporphyrin at 30°C.

H_2SO_4, M	H_0	Expt. rate constant $10^{-6}k_{obs}$, h^{-1}
0.216	−2.02	0.715
0.267	−2.13	2.05
0.287	−2.17	2.83
0.312	−1 22	4.41
0.328	−0.328	5.00

The reaction velocity is described by the kinetic equation[36]

$$-\frac{d[\mathrm{CuAeP}]}{dt} = k\,[\mathrm{CuAeP}]^2 \cdot h_0^4 . \qquad (10)$$

The interpretation of the results[36] was subsequently criticised[37,108,107], and has not found support in investigations on other porphyrins.

Table 9. Kinetic parameters of dissociation of MΦ-a in glacial acetic acid at 25°C.

Complex	Added H_2SO_4, mole	E, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	k_{eff}, h^{-1}
AcOFeΦ	0.500	17.30	−29	$8.95\cdot10^{-4}$
NiΦ	0.500	16.50	−28	$1.20\cdot10^{-3}$
	1.00	17.00	−26	$1.67\cdot10^{-3}$
CuΦ	0.200	16.40	−28	$1.23\cdot10^{-3}$
	0.500	15.30	−31	$1.92\cdot10^{-3}$
PdΦ	1.00	17.10	−29	$2.18\cdot10^{-3}$
CoΦ		12.80	−44	$1.61\cdot10^{-3}$
NiΦ		27.40	−11	$1.3\cdot10^{-6}$
CuΦ		19.00	−29	$9.8\cdot10^{-5}$
ZnΦ		10.10	−40	0.976
AgΦ		19.60	−16	$2.25\cdot10^{-3}$

Rates of dissociation of stable complexes of chlorophyllic acid (a-series) have been measured[97–103] by a spectrophotometric method. The iron(III),[80] nickel(II),[100] copper(II),[97,100] and palladium(II)[100] complexes dissociate at a measurable rate in strongly proton-donating media (sulphuric acid monohydrate in glacial acetic acid), but the zinc(II),[98] cobalt(II),[89] and silver(II)[101] complexes are decomposed even in weakly proton-donating media (glacial acetic acid and its mixtures with ethanol). At high temperatures the rates of dissociation of the nickel and copper complexes could also be measured in glacial acetic acid. The phaeophytinates-a of iron, zinc, and silver, like those of magnesium, cadmium, and mercury, dissociate according to Eqn. (9) or (9a). Dissociation of the copper, palladium, nickel, and cobalt phaeophytinates-a is accompanied by degradation of the phaeophytin molecule $H_2\Phi$-a to slightly coloured products. It was assumed[97] that detachment of the metal ion may yield an active form of the $H_2\Phi$-a molecule, which breaks down rapidly:

$$\mathrm{M\Phi} + 2\mathrm{HAc} \xrightarrow[\text{slow}]{} \mathrm{H_2\Phi^*} + \mathrm{MAc_2}\,, \qquad (11)$$

$$\mathrm{H_2\Phi^*} \xrightarrow[\text{rapid}]{} n\,\mathrm{A}\,. \qquad (12)$$

Reaction (12) involves no change in the side-chains, but a fundamental breakdown of conjugation occurs in the macrocycle, which is impossible without preliminary detachment of the metal by reaction (11) and freeing of the reaction centre. Conditions for the mechanism of dissociation by processes (11) and (12) are at present under investigation[105]. It is favoured by a strong metal–nitrogen covalent bond in the dissociating complex, except in the iron(III) complex[91]. The occurrence of reactions according to scheme (9) or (11) and (12) depends greatly on the temperature and on the solvent. Figs. 8 and 9 illustrate the variation in the absorption spectra[91] for these reactions.

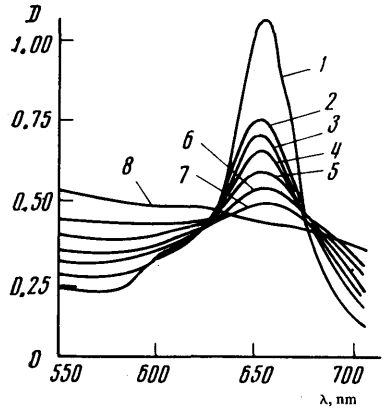

Figure 8. Dissociation of CuΦ in glacial HOAc + 0.5 M H_2SO_4 at 70°C (l = 1 cm): 1) initial CuΦ in acid mixture at 25°C; 2) initial CuΦ under experimental conditions; and after different periods of time (h): 3) 0.25; 4) 0.75; 5) 1.25; 6) 2.25; 7) 3.25; 8) 5.0.

Table 9 lists the kinetic parameters of dissociation for the stable complexes of phaeophytin-a.[91,100,108] Dissociation of stable complexes of chlorophyllic-a acid is very slow, with mean activation energies of 10–12 kcal (with the exception of the nickel complex in glacial acetic acid) and strongly negative entropies of activation, caused by the

high polarity of the transition state and the active participation of the solvent in the act of dissociation. Tables 7 and 9 indicate that the sequence of kinetic stability is

$$AcOFe\Phi \rhd Pd\Phi > Ni\Phi > Cu\Phi > Co\Phi > Ag\Phi > Zn\Phi \gg Mg\Phi > Cd\Phi > Hg\Phi.$$

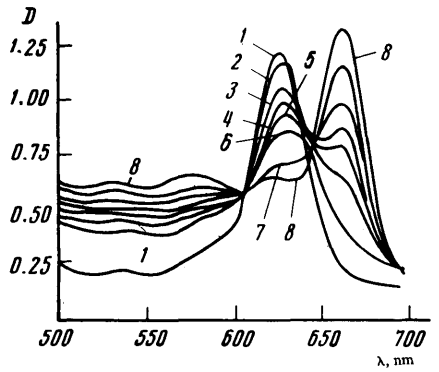

Figure 9. Dissociation of AcOFeΦ in mixture of glacial HOAc + 1.0 M H_2SO_4 at 50°C (l = 1 cm): 1) initial complex in glacial acetic acid; 2) complex under experimental conditions; and after different intervals of time (h): 3) 1; 4) 2; 5) 3; 6) 5; 7) 10; 8) 20.

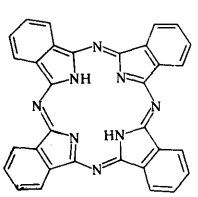
Interesting investigations have recently been made[104] on the kinetic and the thermodynamic stability of complexes of chlorophyllic-b acid with copper and zinc. Table 10 compares the kinetic stability of metal analogues of chlorophyll-a and -b. The rates of dissociation of complexes of chlorophyllic-b acid are lower than those of the a-derivatives by factors of 25–300, and their rates of formation are also lower by factors of 10–10^2. These differences are attributed[104] to the influence of the formyl group in changing the electron density on the nitrogen atoms of the reaction centre. The retarding effect of this group on the rates of formation and dissociation of the complexes is eliminated in the equilibrium constants. Therefore the a- and b-complexes differ only threefold in thermodynamic stability.

Table 10. Dissociation of complexes of chlorophyllic acid in glacial acetic acid.

Complex	k_{eff}, h^{-1}	E, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	K_{eq}
CuΦ-b	$0.38\cdot10^{-5}$	23.4	−25	$1.6\cdot10^{-9}$
CuΦ-a	$9.8\cdot10^{-5}$	19.0	−29	$5.1\cdot10^{-9}$
ZnΦ-b	$3.1\cdot10^{-3}$	10.9	−49	$2.4\cdot10^{-5}$
ZnΦ-a	0.976	10.1	−40	$7.3\cdot10^{-5}$

Iron(III) protoporphyrin (haemin) and the corresponding complex of chlorophyllic-a acid show similar kinetic stability in glacial acetic acid with additions of sulphuric acid (cf. Tables 9 and 11).



3. Mechanism of the Dissociation of Metal Porphyrins in Proton-donating Media

The first hypotheses on the mechanism of the protolytic dissociation of metal porphyrins were put forward in Ref. 36. The kinetic equation (10), showing the second order with respect to the porphyrin, was interpreted on the assumption of the improbable transition state $(MP.2H^+)_2$††. A combination of two porphyrin molecules in true solution, in which the relatively immobile "target" aetioporphyrin molecules, having no active peripheral substituents, are attacked by a proton-donating species, can hardly be taken seriously. The improbability of such a mechanism has been pointed out[97,107]. The first order of the reaction with respect to the porphyrin has since been shown convincingly[97–102,104] for the dissociation of complexes of chlorophyllic acids and also of iron protoporphyrin[105]. It follows from this that the transition state contains one molecule of the porphyrin complex.

Table 11. Dissociation of iron(III) protoporphyrin (haemin) in glacial acetic acid.

5.0	80	1.04	18.0	−24
5.0	90	1.88		

The general applicability of this principle to all complexes of tetrapyrrole ligands is supported by kinetic data on the dissociation of phthalocyanine complexes. Phthalocyanine

(XV)

is a close structural analogue of the porphyrins, and is widely used as a simple model thereof[1,3–10,14–16,110]. The complexes (MPc) dissociate in conformity with the third-order kinetic equation

$$\frac{dc_{MPc}}{dt} = -k \cdot c_{MPc} c^2_{H_3O^+}. \qquad (13)$$

Several facts have shown convincingly[109] that a termolecular mechanism is most probable. In concentrated sulphuric acid, in which a metal phthalocyanine generally dissociates at a measurable rate only at 100°C, the attacking species is not H_2SO_4 but H_3O^+. In the transition state $[MPc.2H_3O^+]$†† are two N–H bonds resulting from acid–base interaction, two coordinate links $M \leftarrow OH_3^+$ appear, and two M←N bonds are deformed and become weaker. The mechanism of dissociation can be represented by the scheme

$$MPcH^+ + H^+_{Solv} \underset{I}{\overset{k_1}{\rightleftarrows}} HN \cdots \overset{\overset{N}{\downarrow}}{\underset{Solv\ N}{M}} \leftarrow N + H^+_{Solv} \underset{II}{\overset{k_2}{\rightleftarrows}} HN \cdots \overset{\overset{Solv\ N}{\searrow\downarrow}}{\underset{N\quad Solv}{M}} \cdots NH \xrightarrow{\overset{H^+_{Solv}}{k_3}} H_2PcH^+ + M^{2+}_{Solv}. \qquad (14)$$

With stable phthalocyanines processes I and II take place in a single stage.

The close structural analogy between phthalocyanine and porphyrins suggested[100,110] that mechanism (14) applied also to stable complexes of the latter. Experimental examination of the kinetic order of the dissociation of stable complexes of chlorophyllic acid with respect to the proton-donating species has not yet given general support to this hypothesis. An unambiguous result has so far been obtained[89] only for iron(III) phaeophytinate, whose rate of dissociation in glacial acetic acid is proportional to the total concentration of sulphuric acid. In weakly ionising media such as acetic acid we have $[H_2SO_4]_{total} \simeq [H^+_{Solv}]$, which confirms the validity of Eqn. (13) for AcFeΦ and of the mechanism (14).

On the basis of the general theoretical concepts of coordination chemistry it may be predicted that it will be sufficient to break one M–N bond and convert it into M⁺...NH in the case of labile metal phthalocyanines and metal porphyrins, in which the metal–ligand bond is predominantly ionic. After the metal has been displaced from the plane of the macrocycle, subsequent rupture of the remaining bonds and transition to the structure (XIV) will take place readily. For these complexes we may not only expect the first order with respect to $[H^+_{Solv}]$ but also postulate the H_2SO_4 molecule and even HOAc as active protogenic species. This makes it clear why labile complexes dissociate instantly on the addition of traces of sulphuric acid to their acetic-acid solutions and show a high order with respect to the total concentration of acetic acid[91,100,102]. Chlorophyll itself can be included in this category: it is assumed that $k_1 \gg k_2$ in process (14).

IV. THERMODYNAMIC AND PHOTOCHEMICAL STABILITY OF CHLOROPHYLL AND ITS METAL ANALOGUES IN SOLUTION

The first paper on the thermodynamic stability of the zinc complex of the dimethyl ester of mesoporphyrin (ZnMP) appeared in 1961.[111] The instability constant in aqueous hexadecyltrimethylammonium bromide was found to be 10^{-29}. In conformity with critical comments[112] this value must be regarded as a very crude approximation. In spite of this, however, it clearly demonstrates the extraordinary stability of porphyrin complexes. In fact, zinc complexes with an instability constant of 10^{-16} are formed by one of the most strongly chelating ligands, ethylenediaminetetra-acetate[55]. Such great stability of porphyrin complexes is due to their very low rates of formation and dissociation, resulting from π-electron shielding of the four nitrogen atoms constituting the coordination centre. The first investigations in this field were made by Kukhtevich on the equilibrium formation of metal analogues of chlorophyll using an extraction method[34,35,113,114]. He studied the formation equilibria

$$M^{2+}_w + H_2\Phi_{org} \rightleftarrows M\Phi_{org} + 2H^+_w \qquad (15)$$

of bivalent zinc, cadmium, copper, and cobalt phaeophytinates by then partitioning them between the aqueous phase and an organic solvent (butanol). Kukhtevich calculated the equilibrium constants of (15) and the so called "extraction" constants

$$\frac{[M^{2+}]_w[\Phi^{2-}]_w}{[M\Phi]_{org}} = K_{M\Phi\,org/w} \qquad (16)$$

obtaining values of 2×10^{-23}, 5.2×10^{-20}, 5×10^{-20}, and 1.7×10^{-11} for CuΦ, CoΦ, ZnΦ, and CdΦ respectively. Complexes of chlorophyllic-a and -b acids had identical constants.

Kukhtevich also reported[35] so called "extraction" constants for both stages of the acid ionisation of phaeophytin:

$$K_1 = \frac{[H^+]_w \cdot [\Phi H^-]_w}{[H_2\Phi]_{org}} = 2.3 \cdot 10^{-11},$$

$$K_{1,2} = \frac{[H^+]^2_w \cdot [\Phi^{2-}]_w}{[H_2\Phi]_{org}} = 10^{-20}.$$

Data on the dissociation of phaeophytin differ sharply from the preliminary results reported by McEwen[115] for aetioporphyrin ($K_1 \simeq 10^{-16}$ and $K_{1,2} \simeq 10^{-32}$). Ionisation constants differing by a factor of 10^{12} cannot be explained in terms of molecular structure. The exact values of the acid dissociation constants of porphyrins, which are necessary for calculating the instability constants of their complexes, remain unknown, and their determination is an urgent problem in the physical chemistry of porphyrins. "Extraction" constants give only a crude indication of the order of stability of porphyrin complexes. However, these constants have correctly revealed the very great stability of the complexes, the great difference between the zinc and cadmium complexes in this respect, and the feebly developed acidic properties of chlorophyllic acid. Significant defects of the extraction method have been pointed out[116], and mention made of our ignorance of existing extraction equilibria and the absence of clarity concerning the mechanism of complex formation in a two-layer system comprising water and an organic solvent.

The difficulties associated with the direct measurement of equilibria involving porphyrin complexes led to the successful use[91,108,112] of two forms of kinetic method. The first procedure entailed calculating equilibrium constants for metal porphyrins (MP) from their known dissociation and formation rate constants obtained under identical conditions (temperature, solvent, anionic composition of the medium, etc.). The principle of detailed balancing was used[108], according to which the formation and dissociation stages of these compounds have the same transition state (Sections II and III). Dissociation equilibrium constants were found in this way for zinc, cobalt, copper, and nickel phaeophytinates in glacial acetic acid[91]. The second variant of the kinetic method was used to calculate dissociation equilibrium constants for the palladium(II), iron(II), and silver(II) phaeophytinates, since their formation rate constants could not be obtained under conditions of dissociation. This utilises the slight dependence of the formation rate constants of MΦ on the nature of the metal, i.e. that k_v^{form} is almost constant. We can then write the relation

$$\frac{K^0_{MP}}{K'_{M'P}} = \frac{k^0_v}{k'_v} \qquad (17)$$

for a complex adopted as standard and for the *i*th complex MP to be compared with it. If the equilibrium constant for the standard K^0_{MP} is taken to be unity, the relative equilibrium constant of M'P will be the ratio of the dissociation rate constants of the *i*th complex and the standard under comparable conditions:

$$K^i_{M'P} = k^i_v/k^0_v. \qquad (18)$$

Equilibrium constants were found in this way for the palladium(II), iron(III), and silver(II) complexes relative to copper(II) phaeophytinate as standard. The known true equilibrium constant of the standard enabled true constants to be obtained for PdΦ, AcOFeΦ, and AgΦ. Values obtained by both forms of the kinetic method are given in Table 12.[91]

The very great difference in stability between zinc and cadmium phaeophytinates makes it impossible to determine

their equilibrium constants in the same proton-donating medium. The constants of the cadmium complex were measured in ethanol with small additions of acetic acid, and those of the zinc complex in glacial acetic acid with small additions of ethanol. The results were then extrapolated to 50% ethanolic acetic acid. The rough values thus obtained were $K_{eq}^{Cd\Phi} \simeq 0.5$ and $K_{eq}^{Zn\Phi} \simeq 5 \times 10^{-7}$. Thus under identical conditions the complexes $Cd\Phi$ and $Zn\Phi$ would differ in stability by factors of about 10^6. Published data enable a crude estimate to be made of the dissociation equilibrium constant of chlorophyll—from the dissociation rate constant of chlorophyll measured[102] in ethanol containing 2 M acetic acid, and from the formation rate constant of magnesium mesoporphyrin, converted by means of the data in Tables 4 and 6 into the formation rate constant of chlorophyll in ethanol $k_v^{form} = 3.6 \times 10^{-5}$ M^{-1} h^{-1}—as

$$K_{eq} \approx \frac{0.013}{3.6 \cdot 10^{-6}} \approx 360$$

in ethanol–acetic acid medium. An analogous estimate of the equilibrium constant in 10 M ethanolic acetic acid yields 1.2×10^6, which exceeds the constant for zinc phaeophytinate by a factor of 10^{12}, and that for the cadmium complex by more than 10^6.

Table 12. Equilibrium constants for the dissociation of stable phaeophytinates in glacial acetic acid at 25°C.

Complex	$K_{eq} = \frac{[MOAc_2]}{[HOAc]^2} \cdot \frac{[H_2\Phi]}{[M\Phi]}$
$Zn\Phi$	$7.32 \cdot 10^{-5}$
$Co\Phi$	10^{-5}
$Ag\Phi$	$2.3 \cdot 10^{-7}$
$Ni\Phi$	$3 \cdot 10^{-8}$
$Cu\Phi$	10^{-9}
$Pd\Phi$	$8 \cdot 10^{-11}$
$AcOFe\Phi$	$5 \cdot 10^{-11}$

Several conclusions follow from the above values. Firstly, the positions of metal analogues of chlorophyll in the kinetic stability sequence (see above) and in the thermodynamic stability sequence

$$AcOFe\Phi > Pd\Phi > Cu\Phi > Ni\Phi > Ag\Phi > Co\Phi > Zn\Phi > Cd\Phi > Mg\Phi,\ Hg\Phi$$

do not coincide in those cases in which the rates of formation exhibit anomalies. The rate of formation of chlorophyll ($Mg\Phi$) exceeds those of its metal analogues by factors of 10^7–10^8. Therefore, while possessing far higher kinetic stability than cadmium phaeophytinate, chlorophyll is markedly inferior in thermodynamic stability. Certain anomalies in the rates of formation of the nickel complex make it thermodynamically less stable than the copper complex, although the kinetic stability of the former is rather greater. The same applies to cobalt(II) and silver(II) phaeophytinates: the former is kinetically the more stable, whereas the silver complex exhibits the greater thermodynamic stability. In this connection, the numerous attempts to make deductions as to thermodynamic stability from the rates of dissociation of porphyrin complexes, which have been widely undertaken both abroad[8,33,36] and in the Soviet Union[112], must be regarded as a first, very rough approximation.

Secondly, the position of a complex in the kinetic stability sequence is determined predominantly by the covalency of the metal–porphyrin bond. Kinetic stability in solution is probably a quite reliable criterion of the type of bond. The magnesium–porphyrin bond is far more covalent than the corresponding bonds with cadmium and mercury(II). This covalency is responsible for the adequate stability of chlorophyll in the plant cell. Nevertheless, chlorophyll is far less covalent than the zinc complex, one of the least stable members of the group of stable phaeophytinates. This intermediate position of chlorophyll in the covalency sequence ensures that the magnesium shall carry a sufficient effective charge to favour coordination of the various molecules forming part of the complicated photosynthetic apparatus[2].

Thirdly, the position of a metal porphyrin in the thermodynamic stability sequence is largely determined by specific aspects of its formation in solution. Consideration of the mechanism and the kinetic parameters of the formation of metal porphyrins (Section II) shows that the stability (covalency) of the complex makes no significant contribution to its rate of formation. For this reason the thermodynamic stability sequence of metal porphyrins does not reflect their covalency.

The only serious rivals to metal porphyrins in their extraordinary stability are the phthalocyanine complexes[108]. Under very severe conditions (concentrated sulphuric acid) stable metal phthalocyanines dissociate at vanishingly low rates; metal porphyrins eliminate the cation instantly under these conditions. Such a substantial difference in stability between these close structural analogues has been explained by differences in the molecular structures of the ligands[110,117,118], by differences in their electron-donating and electron-accepting powers. It must be added that probably the most significant reasons why metal porphyrins are less stable than metal phthalocyanines are some departure of the molecules from planarity[8] and the absence from the molecular periphery of nitrogen atoms, which buffer the electron density in antibonding π-orbitals of the macrocycle. Coordination of a metal with phthalocyanine removes four pairs of electrons from such orbitals of the ligand. The resulting deficiency of π-electron density is immediately filled by the lone pairs of the outer nitrogen atoms[119]. Such a possibility is not available to a porphyrin molecule.

An important problem in the chemistry of porphyrin complexes is their photochemical stability in solution and its relation to their kinetic and thermodynamic stability. The lack of work in this field is acutely felt at the present time. A parallelism between photochemical and thermodynamic stability of phaeophytin complexes was reported[120] on the basis of qualitative and semi-quantitative experiments. The general conclusion was reached that phaeophytinates of the b-series are more resistant to fading than are those of the a-series.

Detailed quantitative investigations of the photochemical stability of chlorophylls-a and -b, chlorophyllic acids, and their complexes in ethanol and glacial acetic acid[99] have enabled these conclusions to be refined. Rate constants calculated for photochemical degradation over the range 20–60°C showed that the rate is little influenced by temperature but is strongly affected by the solvent. Photochemical fading is more rapid in acetic acid than in ethanol. However, the opposite effect is observed with cadmium phaeophytinate. Phaeophytins-a and -b have the same rates of fading in ethanol; cadmium phaeophytinate-a is twice as fast to light as the b-complex. In glacial acetic acid phaeophytin-b is four times as fast as phaeophytin-a.

No correlation between photochemical and thermodynamic stability is observed in either solvent. Thus in ethanol mercury(II) phaeophytinate is more stable to light than the zinc complex, whereas the magnesium and cadmium complexes are equally fast. In glacial acetic acid cobalt(II) phaeophytinate is more stable than the palladium and copper complexes. The sequence of diminishing photochemical stability in glacial acetic acid was found[99] to be

$$AcOFe\Phi > Ni\Phi > Co\Phi > Pd\Phi > Cu\Phi.$$

This sequence does not correspond to those of kinetic and thermodynamic stability. The lack of parallelism between light fastness and resistance to ionic dissociation is not unexpected, since there is no similarity in the mechanisms of the two processes[99].

Summing up the above account, we must note an acute lack of data on several aspects, despite the substantial progress made during the past decade in investigating the conditions and mechanism of the formation and decomposition of chlorophyll and its structural analogues. This applies primarily to the fine mechanism of dissociation of the complexes and directly to measurement of the formation equilibria of metal porphyrins. The main efforts of research workers in such an important and interesting branch of chemistry should be directed to solving these problems.

Syntheses of Tetracarboxylic Acids

B.I.Zapadinskii, B.I.Liogon'kii, and A.A.Berlin

A systematic and general account of the literature data on the methods of synthesising tetracarboxylic acids capable of forming internal cyclic dianhydrides is given for the first time in the present review. These products have found extensive applications as starting materials for the synthesis of heterocyclic polymers, dyes, plasticisers, hardening agents for epoxy-resins, etc. Particular attention has been devoted to methods of synthesising aromatic tetracarboxylic acids and also products of greatest practical importance.
The bibliography includes 214 references

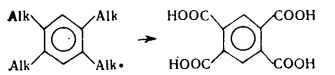
I. INTRODUCTION

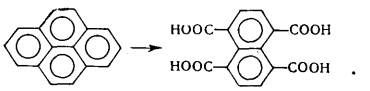
Only 10–15 years ago tetracarboxylic acids did not have practical applications although many of them had been isolated from the oxidation products of organic compounds or in the identification of diene systems by the Diels–Alder reaction. However, the situation changed radically when it became known that tetracarboxylic acids and their functional derivatives can be used as starting materials for the synthesis of thermostable products [polyimides [1] and poly(aroylenebisbenzimidazoles) [2]], plasticisers, antioxidants [3], hardening agents for epoxy-resins [4], etc. In addition, aroyleneimidazole dyes have again roused interest in recent years [5]. A systematic and general account of data on the methods of synthesising tetracarboxylic acids has therefore become necessary.

The present review deals with the methods of synthesis of only those tetracarboxylic acids whose derivatives are capable of intramolecular cyclisation. This limitation was imposed because in the main fields of their application—the synthesis of polymers and dyes—tetracarboxylic acids enter into a reaction with amines and the products of this reaction are subjected to intramolecular dehydration with formation of cyclic structures. Here it is noteworthy that the size of the ring formed corresponds to the size of the anhydride of the initial acid. Subsequently the term "tetracarboxylic acid" will be applied only to acids capable of forming five-, six-, and seven-membered internal cyclic dianhydrides.



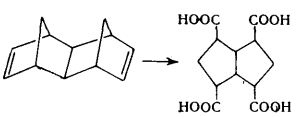
Among the numerous method of synthesising carboxylic acids [6], the following have found application in the preparation of the compounds in which we are interested: oxidation of organic compounds, cycloaddition reactions, condensation of dicarboxylic acids and their derivatives, and malonic ester syntheses. In addition there are several non-general methods, specific to the given tetracarboxylic acid.

II. OXIDATION OF ORGANIC COMPOUNDS



Hitherto the oxidation of organic compounds has been essentially the only method of synthesising tetracarboxylic acids having extensive practical applications. This is because oxidation reactions are particularly suitable for the synthesis of aromatic tetracarboxylic acids on the basis of which polymers with the most valuable properties have been obtained. The method of oxidation has already been applied on an industrial scale, although the range of products manufactured is fairly narrow.

The method can be clearly divided into three types in terms of the compound undergoing oxidation.



A. Oxidation of side chains in aromatic hydrocarbons, for example:

B. Oxidation of the rings of polynuclear aromatic compounds, for example:

C. Oxidative cleavage of olefins, for example:

The same reagents are used in laboratory practice for all three types of reactions: nitric acid, permanganates, chromates, dichromates, ozone, peroxides, and hypochlorites. Therefore initially we shall briefly characterise the scope and mechanism of the action of each of these substances.

The oxidation of hydrocarbons to acids is a multistage process and proceeds as a rule according to the following scheme: hydrocarbon → alcohol → aldehyde (ketone) → carboxylic acid. The slowest stage is the oxidation of the C–H or C–C bonds, while the subsequent stages take place with increasing ease: the alcohol is oxidised more readily than the hydrocarbon and the aldehyde more readily than the alcohol[7].

All organic compounds can be oxidised by hot nitric acid which need not necessarily be very concentrated for this purpose. This reagent is particularly active in the vapour phase[6]. The oxidation proceeds via a homolytic mechanism and includes stages involving the formation and decomposition of nitro-compounds, nitrates, and nitrites[7]. Chain reactions take place at some of the stages and nitro-compounds and nitrates do not accumulate in the course of the reaction. However, the contamination of the final product by nitrogen-containing compounds is one of the principal disadvantages of oxidation with nitric acid.

Chromic acid, chromates, dichromates, and chromyl chloride are more selective than nitric acid. They are capable of oxidising only activated C–H bonds in allyl and benzyl groups, at tertiary carbon atoms, and carbon atoms adjoining a heteroatom[7]. The reaction is usually carried out in dilute sulphuric acid solutions but aqueous solutions of alkali and glacial acetic acid can be employed.

The oxidation by chromates of the side chains in aromatic hydrocarbons and of alcohols and aldehydes constitutes a heterolytic process including a stage in which a new C–O–Cr linkage is formed. In the oxidation of alcohols by chromic acid, the first stage is rapid and reversible esterification and the rate of the overall process is limited by that of the stage of the concerted decomposition of the ester[8].

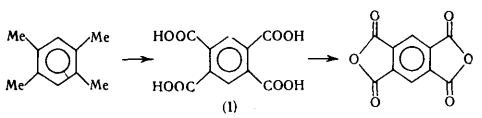
The oxidation of olefins involves a direct electrophilic attack on the π electrons of the C–C bond by one of the oxygen atoms of the reagent. The reaction is more difficult than with alcohols, so that the oxidation takes place only in acid media. Chromates attack aromatic compounds at the carbon atom with the highest electron density, for example they oxidise anthracene to anthraquinone[9].

Permanganates are very powerful reagents capable of oxidising in neutral, alkaline, and acid aqueous media and also in organic solvents—acetone or pyridine. In contrast to chromates, the oxidation of benzyl C–H bonds by permanganate involves a hydride transfer stage[7], for example:

$$MnO_4^- + H-\overset{|}{\underset{|}{C}}-O^- \rightarrow \overset{|}{\underset{|}{C}}=O + (HMnO_4)^{3-}$$

This reaction is catalysed by both acids and bases, but alkaline solutions are not used for extensive oxidation, since the process is complicated by the Cannizzaro reaction in the aldehyde formation stage.

When acted upon by permanganates in a neutral or acid medium, olefins initially give rise to acyloins, which are then rapidly oxidised until the attainment of more advanced stages[7,8]. A disadvantage of this reagent is the necessity to separate the reaction products from the manganese dioxide precipitate.

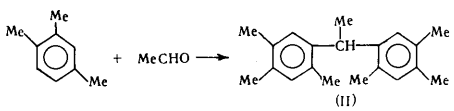


Ozone is used to oxidise condensed polynuclear hydrocarbons and for the oxidative cleavage of olefins. In the synthesis of acids, ozonides are decomposed by peroxides, peracids, oxygen, activated ozone, metal salts, etc.[10] In contrast to NO_2^+ or chromates, which attack the most nucleophilic carbon atom of the polynuclear compound, ozone is a test reagent for the most reactive double bond[11]. Thus pyrene is oxidised by ozone to biphenyl-2,2',6,6'-tetracarboxylic acid, while nitric acid and permanganate oxidise it to naphthalene-1,4,5,8-tetracarboxylic acid[12].

Hypochlorites and peroxides are effective reagents for the oxidation of polynuclear quinones to carboxylic acids. Initially one usually oxidises aromatic hydrocarbon by nitric acid, chromate, and permanganate to quinones and the latter are then treated with hypochlorite or hydrogen peroxide, which leads to acids in almost quantitative yields[13].

All the oxidation reactions enumerated above make it possible to obtain acids in yields reaching 90–95% and the oxidation methods have been fairly thoroughly developed and to some extent standardised.

1. Oxidation of Side Chains of Aromatic Hydrocarbons



Since 1851 when Erdmann[14] obtained for the first time benzene-1,2,4,5-tetracarboxylic (pyromellitic) acid (I) (PMA) and its anhydride by oxidising durene with nitric acid, PMA has been for about 100 years virtually the only readily available aromatic tetracarboxylic acid obtained by this procedure. However, this method of synthesising tetracarboxylic acids (primarily PMA) has acquired practical importance only recently as a result of the development and improvement of the oxidation technology and methods of synthesising and purifying the initial alkylbenzenes:

(I)

The principal difficulty in the synthesis of PMA is that the initial 1,2,4,5-tetramethylbenzene (durene) is very difficult to free from isomers. In this connection three procedures have been outlined for the preparation of pure PMA: by developing methods of synthesising pure durene, by obtaining PMA from sources other than durene, and by devising methods for the separation of PMA from isomeric acids and for its purification.

Pure durene is obtained by the hydrocracking of 1,1-dipseudocumenylethane (II), which is obtained by treating pseudocumene with acetaldehyde (yield 96%, purity 99.1%):[15-17]

(II)

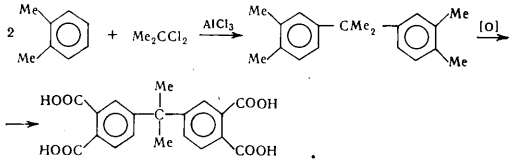
The direct oxidation of (II) or durene obtained by the hydrocracking of (II) leads to pure PMA.

The greatest success was achieved by the second procedure in the chloromethylation of crude xylene[18]:

(III)

Di(chloromethyl)xylene isomers are readily separated by simple crystallisation. The pure 1,2,4,5-isomer is chlorinated further to the tetrachloro-derivative and then oxidised. This method was modified somewhat recently[19,20]: 4,5-di(hydroxymethyl)-1,2-dimethylbenzene, obtained by treating (III) with alkali, is oxidised. In both cases the reaction product is very pure PMA.

There are also methods of synthesising PMA from $1,2,4,5\text{-}R_n\text{-}(HOOC)_{4-n}C_6H_2$, where R is a small alkyl

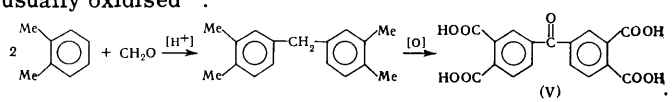


group and $n = 1-4$,[21] 2,5-di-isopropyl-1,4-dimethylbenzene obtained by propylating *p*-xylene or pseudocumene in the presence of Al_2O_3 and BF_3,[22] and also many other alkylbenzenes[17]. So far these methods have not acquired practical importance.

The possibility of isolating PMA from a mixture of isomeric acids is due to the fact that benzene-1,2,3,4-tetracarboxylic (mellophanic) acid isomerises to PMA at 330–340°C. For example, by refluxing a mixture of PMA and mellophanic acid in trichlorobenzene, one obtains fairly pure PMA.[23]

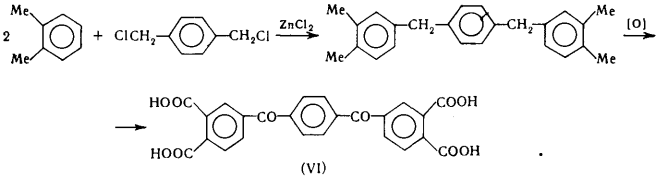
There are also methods whereby PMA obtained by oxidation with nitric acid can be freed from nitrogen-containing impurities by partition chromatography at 100 to 110°C (purity 98%),[24] by passing heated air or an inert gas through the acid melt at 300°C (purity 98.6%),[23] and by treatment with reducing agents—acetaldehyde, formaldehyde, and hydroquinone—at 200–210°C and a pressure of 45–70 atm.[25] The PMA dianhydride is purified by recrystallisation from a dioxan–acetic anhydride mixture[26] and via complexes with dimethylformamide (DMF)[27] or chlorine-containing aromatic compounds[28].

Apart from PMA, a number of other aromatic tetracarboxylic acids obtained by the oxidation of side chains have been known since the beginning of this century. These compounds were synthesised by the usual method for the oxidation or demonstration of the structures of alkyl derivatives of aromatic compounds or were obtained as intermediates. Thus mellophanic acid was obtained by oxidising the corresponding tetramethyl- and tetraethylbenzenes with permanganate[29]; biphenyl-3,3′,4,4′-tetracarboxylic acid was synthesised by oxidising 3,3′-dimethylbiphenyl-4,4′-dicarboxylic acid[30]; the oxidation of 2,3,6,7-tetramethylanthraquinone yielded anthraquinone-2,3,6,7-tetracarboxylic acid and its reduction gave anthracene-2,3,6,7-tetracarboxylic acid; pyridine-2,3,5,6-tetracarboxylic acid was obtained from 3,5-dicarboxy-2,6-dimethylpyridine[32]; benzoquinonetetracarboxylic acid was synthesised from durene via dinitropyromellitic and diaminopyromellitic acids[33]. The oxidation method has been used for the specific synthesis of products of practical value only since the appearance of new applications of tetracarboxylic acids.



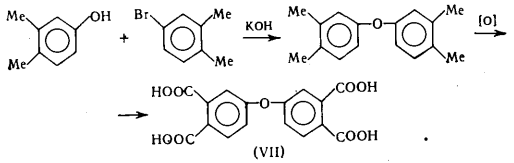
A method for the oxidation of 2,2,-di-(*o*-xylyl)propane, obtained by the Friedel–Crafts reaction between *o*-xylene and 2,2-dichloropropane, to 2,2,-di-(3,4-dicarboxyphenyl)-propane (IV) was patented as early as 1955:[34]

(IV)



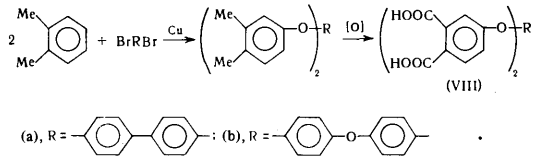
This procedure was subsequently extended to other alkylenediphthalic acids[35].

Several methods of synthesising the initial alkyl derivatives were developed in order to obtain benzophenone-3,3′,4,4′-tetracarboxylic acid (V). Di-(*o*-xylyl)methane is usually oxidised[36]:



(V)

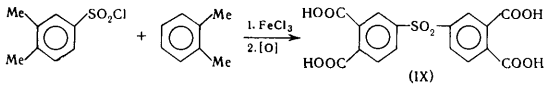
Di-(*o*-xylyl)ethane and other 1,1-di-(*o*-xylyl)alkanes[37], di-(*o*-xylyl)ethylene[38], and di-(*o*-xylyl) ketone obtained by the Friedel–Crafts reaction between *o*-xylene and phosgene[39], have also been used. The last method has been employed to synthesise a tetracarboxylic acid with two keto-groups (VI):[40]



(VI)

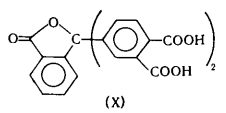
By oxidising the products of the reaction of 3,4-dimethylphenol with 4-bromo-*o*-xylene in the presence of alkali, di-(3,4-dicarboxyphenyl) ether (VII) was obtained[35]:

(VII)



The acids (VIIIa) and (VIIIb) were obtained in low yields by a similar procedure[41]:

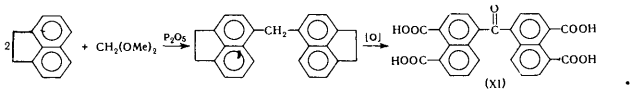
(VIII)



(a), R = ; (b), R =

Di-(3,4-dicarboxyphenyl) sulphone (IX) is formed by oxidising the corresponding tetramethyl derivative[42], which is obtained either by the reaction of thionyl chloride with *o*-xylene in the presence of aluminium chloride[43] or by the reaction of *o*-xylenesulphonyl chloride with *o*-xylene[44]:

(IX)



Korshak and coworkers[45] developed a procedure for the synthesis of the tetracarboxylic acid (X) by oxidising 3,3-di(3,4-dimethylphenyl)phthalide with permanganate in pyridine and then in water:

(X)

Yet another version of the side chain oxidation method involves the use of acenaphthene derivatives as starting materials. Thus the oxidation of 3,4-dicarboxyacenaphthene by nitrogen oxides and treatment of the resulting intermediate acenaphthenequinone with hypochlorite or hydrogen peroxide yielded naphthalene-1,2,4,5-tetracarboxylic acid[46,47].

The synthesis of the very interesting dianhydride of the tetracarboxylic acid (XI), involving the oxidation of bisacenaphthenyl derivatives, has been developed[48]:

(XI)

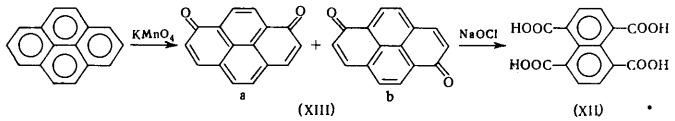
Compound (XI) is also obtained by the oxidation of diacenaphthenyl ketone synthesised by the Friedel–Crafts reaction between acenaphthene and phosgene. The

method of oxidising side chains is also suitable for the preparation of acids containing organic groups combined with various elements. The oxidation of phenyldi-(3,4-xylyl)-phosphine yielded di-(3,4-dicarboxyphenyl)phenylphosphine oxide used in the synthesis of polyimides[49], and treatment of dixylylcarboranes with CrO_3 leads to the corresponding tetracarboxylic acid in a yield of about 50% in the oxidation stage[50].

The method has been used industrially to synthesise pyromellitic dianhydride by the liquid-phase (with nitric acid) and vapour-phase oxidation of the side chains of tetra-alkylbenzenes. It is noteworthy that the principal characteristics of the oxidation of durene and other tetra-alkyl derivatives of aromatic hydrocarbons are analogous to those of the thoroughly investigated mechanism of the oxidation of *o*-xylene to phthalic anhydride[51].

The oxidation of durene with nitric acid leads to PMA in high yields, but the product contains a large amount of impurities which are difficult to separate, mainly nitro-compounds[52]. The use of nitric acid requires the application of expensive corrosion-resistant apparatus, which, together with the cost of pure durene makes this process relatively uneconomical. At present the liquid-phase oxidation of durene is hardly used to synthesis PMA. However, nitric acid is employed to oxidise chloromethylated xylenes to PMA intended for the synthesis of polyimides. In this case there is a possibility of obtaining high-purity PMA without the need for additional operations[20,53].

The industrial methods for the preparation of PMA dianhydride on the largest scale involves the catalytic vapour-phase oxidation of durene and other tetra-alkylbenzenes by atmospheric oxygen[54-57]. Vanadium pentoxide is the active component of the catalyst. The process is carried out by a continuous process and the yield of products in one cycle is 60% (90%) with respect to the alkylbenzene consumed[58,59]. There is also a method involving the almost complete oxidation of durene to PMA dianhydride in one cycle with 98% purity (the principal impurity is PMA).[60]



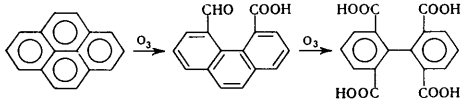
The main advantage of the vapour-phase oxidation method is the simplicity of the apparatus required for this process. The reaction is carried out in apparatus and with catalysts employed for the vapour-phase oxidation of *o*-xylene, which permits cheap large-scale manufacture of PMA. The cost of PMA obtained by the vapour-phase oxidation is lower by a factor of 3–5 than that of the product synthesised by oxidation with nitric acid[60].

The examples quoted illustrate fairly completely the scope of the method of oxidation of side chains of aromatic compounds, which is at present the principal method for the synthesis of aromatic tetracarboxylic acids. In all cases the yield of acids in the oxidation stage approaches 90%. However, we have consistently drawn attention to the synthesis of substances undergoing oxidation. The simpler and more reliable the oxidation stage the more complex are the methods of synthesising and purifying the initial alkyl derivatives. As a rule, the yield of acids barely exceeds 50% when account is taken of the synthesis of the initial compound, and the key starting materials—pure *o*-xylene and particularly durene—are at present fairly expensive.

2. Oxidation of the Rings of Polynuclear Aromatic Compounds

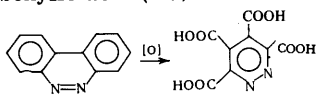
A typical example of the oxidation of condensed aromatic compounds is the treatment of graphite with hot nitric acid, which leads to a mixture of mono- and polycarboxybenzenes. The oxidation of graphitised charcoal has been suggested for the synthesis of aromatic acids[61,62]. However, this method lacks practical importance owing to the complexity of the isolation of the individual compounds, although there is a procedure for the separation of acids by fractionating the esterification products[63].

The most important reaction of this method is the oxidation of pyrene to naphthalene-1,4,5,8-tetracarboxylic acid (XII). When pyrene is oxidised by permanganate or dichromates, 1,8- and 1,6-pyrenequinones (XIIIa) and (XIIIb) are formed initially and are then oxidised by hypochlorite in an alkaline medium to (XII):[64-66]



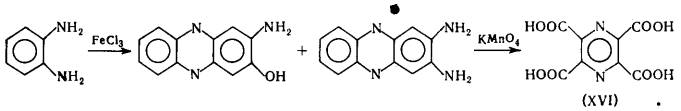
(XIII) (XII)

The method of synthesising (XII) from 1,3,6,8-tetrachloropyrene formed in high yields by the chlorination of pyrene in tetrachloroethane, is convenient. Treatment of the chloro-derivative with concentrated nitric acid or oleum leads to di-*peri*-naphthindandione, which is oxidised by nitric acid, manganese dioxide in sulphuric acid, or hypochlorite to (XII).[67,68]



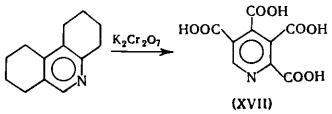
Derivatives of (XII) containing SO_3H, OH, OR, NO_2, and NH_2 groups in the ring, formed on oxidising substituted 5,6-dicarboxyacenaphthenes, are also available[69].

On ozonolysis, pyrene absorbs two moles of ozone, biphenyl-2,2',6,6'-tetracarboxylic acid (XIV) being formed in 60% yield after the decomposition of the ozonides[12,70]:



(XIV)

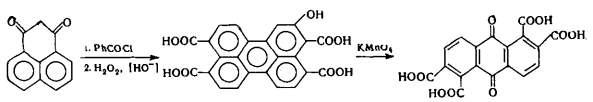
The ring oxidation method is very useful for the synthesis of heteroaromatic acids, since rings free from electronegative heteroatoms are more readily oxidised in polynuclear compounds. Thus the oxidation of phenazone by an alkaline solution of permanganate leads to pyridazinetetracarboxylic acid (XV):[71]



(XV)

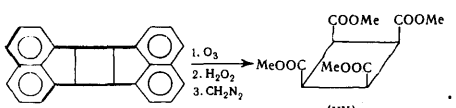
Pyrazinetetracarboxylic acid (XVI) is formed via the mechanism[72]:

(XVI)



The oxidation of phenanthridine, obtained by treating cyclohexanone with formaldehyde, ammonium acetate, and ammonium hydroxide, resulted in the synthesis of pyridine-2,3,4,5-tetracarboxylic acid (XVII):[73]

(XVII)

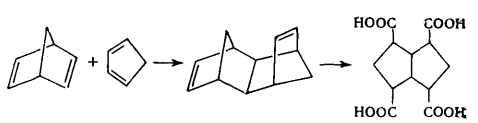


In order to illustrate the scope of this method, one may mention the synthesis of biphenyl-2,3,5,6-tetracarboxylic acid by oxidising 1-phenylnaphthalene-2,3-dicarboxylic

acid [74] and the synthesis of hydroxyperylenetetracarboxylic acid (XVIII) and anthraquinone-1,2,5,6-tetracarboxylic acid (XIX): [75]

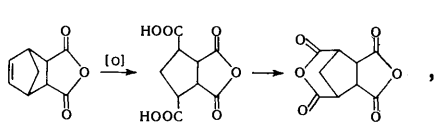
(XVIII) (XIX)

The synthesis of an aliphatic tetracarboxylic acid by the ozonolysis of β-heptacyclene—an acenaphthene dimer—constitutes an interesting example. The decomposition of the ozonide with hydrogen peroxide and treatment with diazomethane lead to the ester (XX): [76]



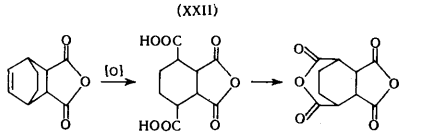
(XX)

The method of oxidation of polynuclear aromatic compounds has all the advantages and disadvantages of the side chain oxidation method discussed above. The method is of greatest value for the synthesis of naphthalene-1,4,5,8-tetracarboxylic acid—one of the cheapest and most readily available tetracarboxylic acids.



3. Oxidative Cleavage of Olefins

A classical example of the synthesis of tetracarboxylic acids by oxidative cleavage of olefins is provided by the synthesis of bicyclo[3,3,0]octane-2,4,6,8-tetracarboxylic acid (XXI) from hexahydro-1,4,5,8-*exo*,*endo*-dimethanonaphthalene [77,78]:



(XXI)

Diels–Alder adducts of maleic anhydride and cyclic dienes, for example cyclohexa-1,3-diene and cyclopenta-1,3-diene, are used as the compounds oxidised in other cases. After oxidation, a mixture of the stereoisomeric tetracarboxylic acid (XXII) and (XXIII) is formed [79]:

(XXII)

(XXIII)

The oxidation is carried out with nitric acid and permanganate, but best results have been obtained by the ozonolysis of the adducts followed by treatment with peracetic acid [80].

It is noteworthy that *endo*-methylenetetrahydrophthalic acids have recently become readily available, since a method has been devised for their synthesis by treating with maleic anhydride the C_5-fraction from the cracking of light petroleum.

The range of tetracarboxylic acids which can be readily obtained by the oxidative cleavage of double bonds is limited to the products enumerated above. Although the preparative aspect of the method is simple and the overall yield of products is close to 90%, their structures preclude their employment in the applications of tetracarboxylic acids known at present.

III. CYCLOADDITION REACTIONS

Cycloaddition reactions are understood as electrocyclisation processes involving polyenes in which new σ bonds are formed as a result of the opening of the π bonds in the groups added. Such reactions include processes involving the formation of at least two σ bonds, i.e. $2\pi \rightarrow 2\sigma$, $3\pi \rightarrow 3\sigma$, and $4\pi \rightarrow 4\sigma$ reactions. Only the most common $2\pi \rightarrow 2\sigma$ reactions have found application in the synthesis of tetracarboxylic acids. Such processes are observed in 2 + 2, 4 + 2 (the Diels–Alder reaction), 4 + 4, and 6 + 4 cycloadditions.

According to Woodward–Hoffmann rules [82-84], the mode of the concerted single-stage electrocyclisation reactions and also the stereochemistry of the adducts formed are determined by the symmetry of the π orbitals involved and formed in the reaction. This type of cycloaddition is possible only when the molecular orbitals involved in the reaction are correlated, without an energy barrier, with the molecular orbitals of the reaction product. For thermal reactions proceeding via the molecular ground state, the symmetry of the highest occupied π orbital is of decisive importance and in photochemical reactions involving excited states the mode of reaction depends on the symmetry of the lowest unfilled orbital. Since the symmetries of these orbitals are different, it follows that, when a given type of cycloaddition is allowed in the thermal reaction, it is forbidden in photochemical electrocyclisation processes.

According to the selection rules, $2\pi \rightarrow 3\sigma$ processes are thermally allowed for systems in which the number of π electrons involved in the reaction is $4n + 2$ and photochemical reactions are allowed for systems in which the number of π electrons is $4n$.

This conclusion is of fundamental importance for cycloaddition reactions, since it determines both the structure of the product formed and its stability. One may conclude that photo-adducts are thermally stable, since, in accordance with the principle of microscopic reversibility, their thermal dissociation is a forbidden process.

The characteristics of electrocyclisation reactions discovered by Woodward and Hoffmann constitute, in particular, a theoretical justification of Alder's empirical rules [85] for 4 + 2 cycloadditions and are confirmed by very extensive experimental data.

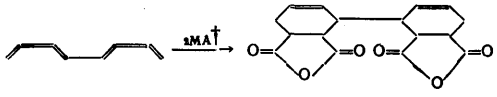
The two most common types of cycloadditions—thermal 4 + 2 and photochemical 2 + 2 processes—as well as their combinations have found the widest applications in the synthesis of tetracarboxylic acids and their functional derivatives.

1. The Diels–Alder Reactions (4 + 2 Cycloaddition Reactions)

The Diels–Alder reaction or diene synthesis involves the addition of olefins or acetylenes (dienophiles) to the

1,4-positions of *cis*-1,3-dienes with formation of unsaturated six-membered cyclic compounds (adducts):

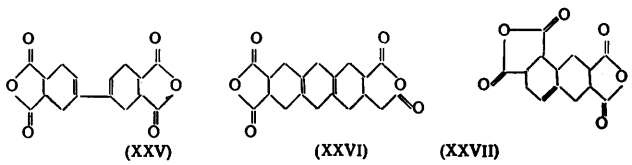
Electron-donating substituents in the diene and particularly electron-accepting substituents in the dienophile facilitate the addition and the latter factor is responsible for the extensive scope of this method in the synthesis of carboxylic acids. Indeed the carboxy-group and its functional derivatives exhibit a powerful electron-accepting effect and $\alpha\beta$-unsaturated acids are active dienophiles. The interaction of compounds containing two diene systems, or compounds capable of their formation, with $\alpha\beta$-unsaturated $\alpha\beta$-dicarboxy-derivatives constitutes a direct method for the synthesis of tetracarboxylic acids and the use of maleic anhydride—one of the most powerful dienophiles—leads directly to the anhydrides.



The Diels–Alder reaction can be carried out on a preparative scale without difficulty—by simple mixing of the components, frequently in an inert solvent—and heating to moderate temperatures leads to adducts, as a rule in high yields.

There is no need to discuss the principal characteristics and mechanism of the diene synthesis, since these problems have been considered in many monographs [85–87] and reviews [88,89]. We shall mention only one very important factor: the Diels–Alder reaction is a reversible process and elevated temperatures favour the dissociation of the adducts into the initial components (the retrodiene synthesis).

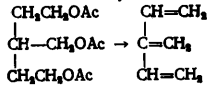
However, there are several procedures whereby one can synthesise adducts incapable of the retrodiene synthesis or requiring for dissociation temperatures at which single carbon–carbon bonds are ruptured.



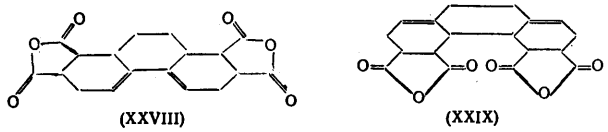
The first of these is based on the fact that the greater the energy gain on conversion of the initial compounds into the adducts the higher the temperature at which the adduct undergoes the retrodiene synthesis. Hence follows the practically important conclusion that open-chain bisdiene adducts should decompose at fairly high temperatures. Indeed acyclic bisdienes are involved in cycloaddition in a thermodynamically unstable conformation with pairs of cisoid double bonds, and their adducts are substituted cyclohexene structures with minimal Baeyer strain.

This conclusion has been confirmed experimentally. Octa-1,3,5,7-tetraene forms with maleic anhydride an adduct (XXIV) in almost quantitative yield, having a decomposition temperature in excess of 280°C: [90]

(XXIV)



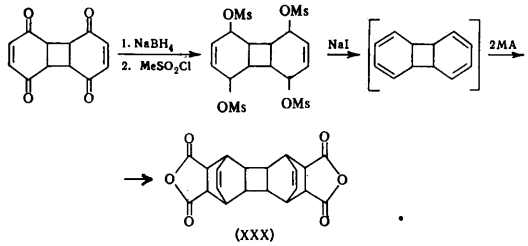
The dianhydrides (XXV)–(XXVII) also melt without decomposition at temperatures comparable to the melting points of their aromatic analogues [91–93]:



(XXV) (XXVI) (XXVII)

† In the formulae MA denotes maleic anhydride.

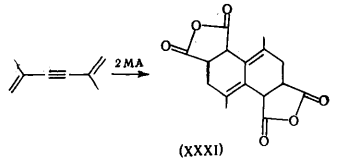
The starting compounds for the synthesis of these bisadducts are tri- and tetra-enes obtained by a general method—the pyrolysis of acetyl derivatives of tri- and tetra-hydric alcohols at 550°, for example:



Thermal isomerisation of cyclodeca-1,2,6,7-tetraene yielded 2,3-divinylcyclohexa-1,3-diene, which combined with two molecules of maleic anhydride to form the dianhydride (XXVIII). [94] In the presence of an excess of the dienophile, compound (XXVIII) forms a trianhydride:

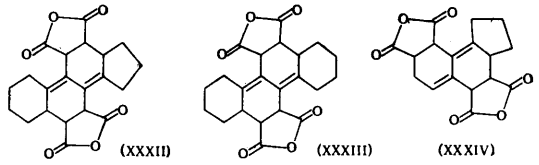
(XXVIII) (XXIX)

Similarly 1,4-divinylcyclohexa-1,3-diene (obtained from 1,4-diethynylcyclohexane-1,4-diol) yields the dianhydride (XXIX). [95]



Sometimes the difference between the thermodynamic stabilities of the diene and the adduct is so great that even with cyclic bisdienes the equilibrium in the diene synthesis reaction is completely displaced to the right. Thus the tetramethylsulphonate of the reduced photo-dimer of *p*-benzoquinone yields the dianhydride (XXX) on treatment with sodium iodide in the presence of maleic anhydride, but the corresponding bisdiene cannot be isolated [96]:

(XXX)

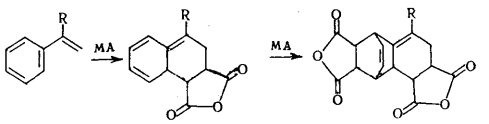


Compound (XIX) does not melt up to 360°C and sublimes without decomposition at 250°.

There is a method of synthesising dianhydrides involving the addition of two molecules of the dienophile to substituted 1,5-dien-3-ynes [97]. For example, 2,5-dimethylhexa-1,5-dien-3-yne yields the dianhydride of hexahydronaphthalenetetracarboxylic acid (XXXI): [98]

(XXXI)

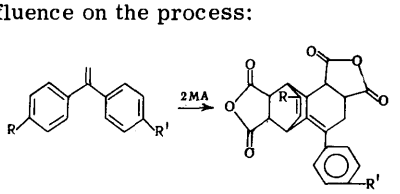
Dienynes in which one or both double bonds are in cyclic systems are also reactive in this reaction. Thus cyclohex-1-en-ylcyclopent-1-enylacetylene, di(cyclohex-1-enyl)acetylene, and cyclopent-1-enylisopropenylacetylene form with two molecules of maleic anhydride the bisadducts (XXXII)–(XXXIV) [99–101] having decomposition temperatures in excess of 260°C:



(XXXII) (XXXIII) (XXXIV)

The addition of dienophiles to 1,5-diene-3-ynes differs from the reactions of bisdienes enumerated above by the fact that in this case the adduct is formed with simultaneous addition of two dienophile molecules to the diene, i.e. via a trimolecular reaction.

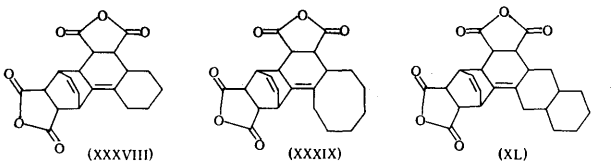
In assessing the method of synthesis of dianhydrides involving open-chain bisdienes, one should note that it suffers from a fundamental deficiency—the difficulty of obtaining the starting compounds. The achievement of a high thermal stability of the bisadducts requires in this instance thermodynamically unstable bisdienes, i.e. the very principle of the method is responsible for the difficulty of synthesising the initial compounds on a preparative scale. As a rule, acyclic bisdienes are obtained by multistage procedures with very low yields of the final products. For example, in the pyrolysis of acetates, the yield of bisdienes does not exceed 5–15% and dienynes are obtained in a yield of 10–30%.



The method of synthesising the dianhydrides by the Wagner–Jauregg reaction [102], in which substituted styrenes or 1,1-diarylethylenes are employed as the bisdienes, is free from this disadvantage. In the first stage, a molecule of maleic anhydride is added to a system including an exocyclic double bond and the π electrons of the α- and β-carbon atoms of the aromatic ring with formation of the adduct (XXXV). The addition of a second molecule of the dienophile to the newly formed diene system leads to the dianhydride (XXXVI): [103]

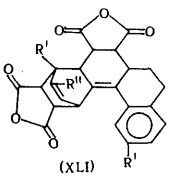
(XXXV) (XXXVI)

Although, owing to its tendency towards polymerisation, styrene itself gives low yields of adducts by this reaction [104], its α-substituted analogues form adducts in yields of 90%, particularly in the presence of polymerisation inhibitors. Many dianhydrides having the general formula (XXXVI) with R = alkyl, halogen, phenyl, naphthyl, etc., melting at 220–300°C, have been synthesised by this method [103,105,106]. β-substituted styrenes do not form bisadducts as a rule [106].



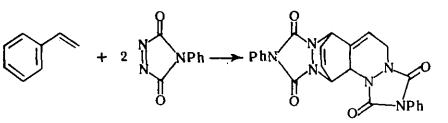
The efficiency of cycloaddition is appreciably influenced by the electronic nature of the substituents in the *para*-position of the aromatic ring. It has been shown [107] that electron-donating substituents, particularly the methoxy-group, facilitate the reaction, while electron-accepting substituents frequently make the reaction impossible, as has been observed also in other Diels–Alder reactions. Substituents in the *meta*-position hardly affect the course of the reaction, and *ortho*-derivatives are usually inactive owing to the steric hindrance to the planarity of the system. Substituents in the aromatic ring of 1,1-diarylethylenes not involved in the diene synthesis have a similar influence on the process:

(XXXVII)



Thus the yield of the dianhydrides (XXXVII) varies from 22% for the difluoro-derivatives to 90% for the di-t-butyl analogue, while the melting point varies in the opposite sense: from 350° to 240°C respectively.

Arylcyclenes—compounds with a double bond in a partly hydrogenated ring—are also reactive in the Wagner-Jauregg reaction [108,109]. For example cyclohex-1-enylbenzene, cyclo-oct-1-enylbenzene, and 2-phenyl-Δ^2-octahydronaphthalene form the adducts (XXXVIII)–(XL) respectively in high yields:

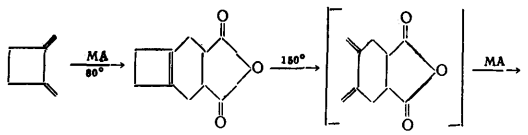


(XXXVIII) (XXXIX) (XL)

A number of substituted dianhydrides (XLI) based on 1-phenyl-3,4-dihydronaphthalene, where R, R′, and R″ are combinations of H, CH_3, C_6H_5, Cl, and OCH_3 groups, with melting points up to 300°C, have also been synthesised [108].

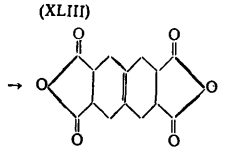
(XLI)

The use of a more powerful dienophile—4-phenyl-1,2,4-triazoline-3,5-dione—made it possible to obtain the bisadduct (XLII) by the reaction with styrene [110]:



(XLII)

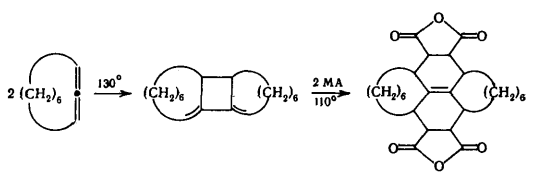
Since all the dianhydrides obtained by the Wagner-Jauregg reaction have a sterically strained tricyclic structure, they split off smoothly one dienophile molecule above the melting point. However, the melting points of the bisadducts reach 350°C and the decomposition temperatures are comparable to the temperatures at which carbon–carbon single bonds are ruptured, which, together with the ready availability of the initial compounds and the high yield of the desired products, suggests that the method is of practical value.



All the procedures for the application of the 1,4-addition reaction in the synthesis of tetracarboxylic acids enumerated above involve a reversible adduct formation stage. On the other hand, there is a fundamentally different type of Diels–Alder reaction in which, simultaneously with the addition of the dienophile to the diene, the adduct undergoes irreversible changes, in relation to the initial diene, associated with the rupture of chemical bonds.

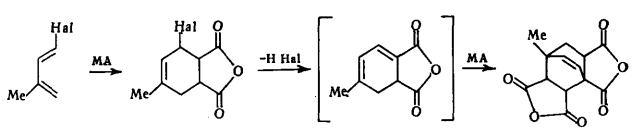
For example, 1,2-dimethylcyclobutane, obtained by the dimerisation of allene, gives the adduct (XLIII) in 94% yield on refluxing with maleic anhydride in benzene. When the temperature is raised to 150°C, a bond in the cyclobutane ring of (XLIII) is cleaved with formation of a diene

system the addition of a dienophile to which gives rise to the dianhydride (XLIV):[111]



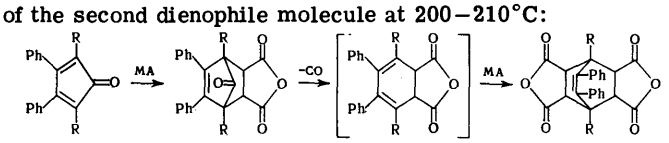
(XLIII)

(XLIV)



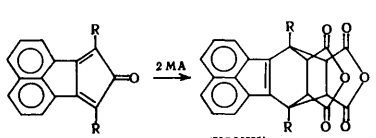
A similar procedure has been used[94] to synthesise the dianhydride (XLV), which melts without decomposition above 300°C:

(XLV)



However, irreversible Diels–Alder reactions are usually accompanied by the abstraction of volatile substances from the intermediate.

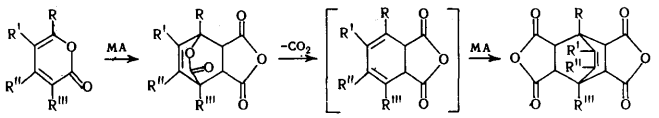
A method has been suggested[112] for the synthesis of the adduct (XLVI) using 1-halogeno-3-methylbuta-1,3-dienes (obtained from ethynyldimethylmethanol) as the bisdienes. Compound (XLVI) is obtained in an exothermic reaction with liberation of the hydrogen halide:



(XLVI)

Reactions are also known in which carbon monoxide is split off from the intermediate adduct. These reactions involve the use of cyclopentadienones (cyclones) as the dienes. 3,4-Diphenylcyclones, formed on dehydration of anhydroacetone benzils, are the most suitable for this purpose. The bisadducts (XLVII, R and R′ = H or alkyl) are formed in quantiative yields[113–116]. The decarbonylation is as a rule carried out with the simultaneous addition of the second dienophile molecule at 200–210°C:

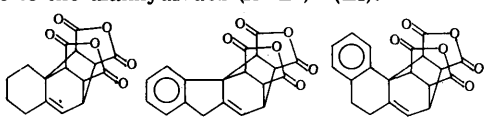
(XLVII)



Condensed cyclones react similarly; for example an acecyclone yields the dianhydride (XLVIII, R = methyl or n-hexyl)[117]:

(XLVIII)

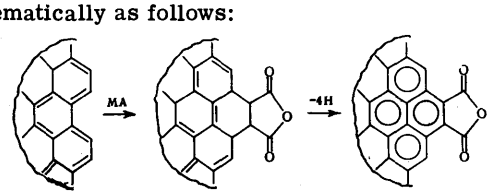
Dianhydrides of a similar type are also formed when α-pyrones or coumalins, the adducts of which split off a carbon dioxide molecule, are employed as the bisdienes[118].



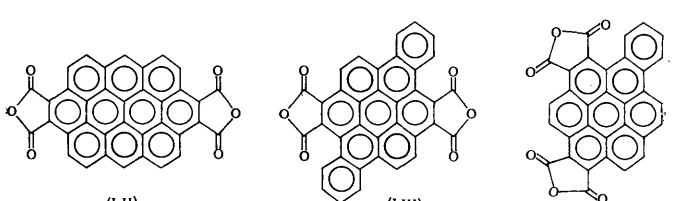
The reaction proceeds via the mechanism

(XLVII)

The synthesis of a whole series of alkyl- and phenyl-substituted derivatives (XLVII) has been described by Shusherina and coworkers[119,120]. The preparation of the perchloro-1,4-diphenyl derivative of (XLVII) and also the continuous method for the synthesis of the dianhydride of bicyclo[2,2,2]oct-7-ene-2,3,5,6-tetracarboxylic acid (XLVII, all R = H) in 99% yield have been patented[121–123].



Dianhydrides with decomposition temperatures in excess of 300°C, obtained on the basis of condensed coumalins, are also known. Thus 5,6-dicyclohexano- and 5,6-indeno-α-pyrones and 7,8-benzo-5,6-dihydrocoumarin give rise to the dianhydrides (XLIX)–(LI):[124]

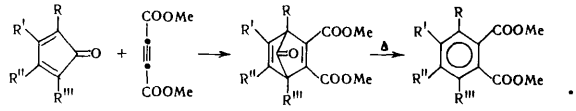


(XLIX) (L) (LI)

Adducts of type (XLVII) decompose above the melting point with liberation of maleic anhydride, i.e. reactions of this type are not strictly speaking irreversible. However, the dissociation reaction occurs at 320–350°C and is accompanied by the decomposition of the product by other mechanisms too.

Clar[125] developed a method for the synthesis of dianhydrides involving the addition of maleic anhydride to polycyclic aromatic structures with simultaneous dehydration of the adducts formed. The method can be represented schematically as follows:

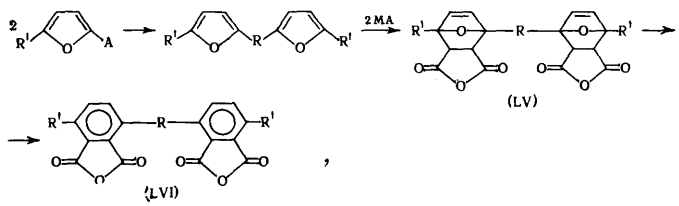
The dehydrogenation is carried out either with chloranil added to the melt of the components or by refluxing the substances to be added in an active solvent—nitrobenzene. Dianhydrides based on bisanthene, 2,3:8,9-dibenzoperylene, 1,2:4,5-dibenzopyrene, 1,2:4,5:8,9-tribenzopyrene, and di-*peri*-naphthyleneanthracene have been obtained by this method—for example the dianhydrides (LII)–(LIV):[126–129]



(LII) (LIII) (LIV)

This method is so far of purely theoretical importance, since the initial bisdienes are very difficult to obtain and most of them are very active carcinogens.

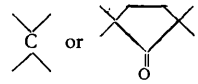
All the methods of preparation of tetracarboxylic acids by the Diels–Alder reaction known hitherto lead to products with hydroaromatic or bicyclic structures. On the



other hand, aromatic acids are necessary for the main applications of tetracarboxylic acids—the synthesis of thermostable polymers and dyes.

Certain types of monoadducts obtained in the 1,4-cycloaddition reaction propagated by thermal or chemical factors are known [85] to undergo a rearrangement into aromatic structures. For example, the adducts of dimethyl acetylenedicarboxylate and cyclones split off a carbon monoxide molecule on heating and form phthalic acid esters:

Adducts of coumalins with acetylenes, of furans with maleic anhydride, and certain others are also capable of aromatisation.



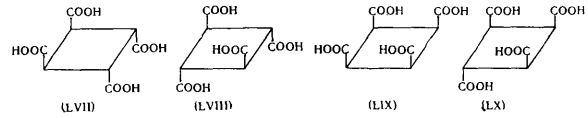
The authors of the present review [130-136] developed a method for the synthesis of tetracarboxylic acids the main idea of which involves the aromatisation of the adducts of maleic anhydride with bisfuran compounds via the general mechanism

where A is a functional group or a hydrogen atom, R = arylene,

R′ = aryl (for example phenyl) or a hydrogen atom,
R″ = arylene (*p*-phenylene, *pp*′-diphenylene, and others),

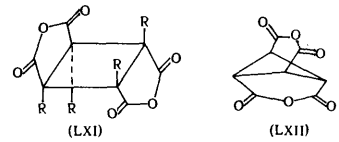
and R‴ =  .

The use of bisfuran compounds in these reactions has many advantages. Firstly, the furan ring is a fairly reactive diene in reactions with maleic anhydride and forms stable adducts in yields of 90–95%. Secondly, the synthesis of compounds containing two furan rings can be readily achieved with a high yield when readily available and cheap functional derivatives of furan are employed: furfural, furfuryl alcohol, furancarboxylic acids, etc.



Bisfuran compounds have been obtained by the decomposition of diazonium salts in furan, by the reaction of furfural with aromatic amines or tetramethoxy-derivatives, for example pentaerythritol, and by the reaction of furfuryl alcohol with aromatic dicarboxylic acid esters.

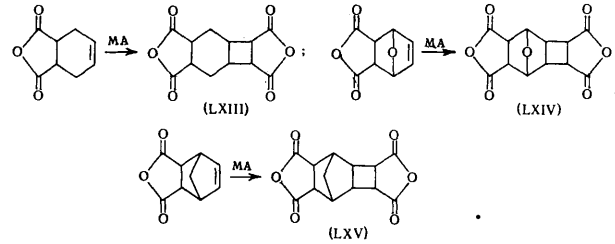
The reactions of bisfuran with maleic anhydride occur at a temperature as low as 25°C and compound (LV) is formed in a quantitative yield. The aromatisation of (LV) to (LVI) takes place in concentrated sulphuric acid at temperatures below 0°C, in polyphophoric acid at 25 to 50°C, or when acted upon by gaseous hydrogen chloride or by hydrogen bromide in glacial acetic acid.



The use of α-phenylfuran or 5-phenylfurfural in the above reactions makes it possible to obtain tetracarboxylic acids with phenyl substituents in the ring of the phthalic acid group.

2. 2 + 2 Photocycloaddition Reactions

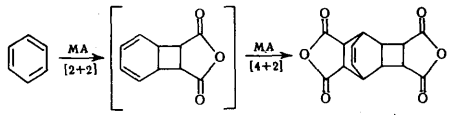
Until recently the application of the 2 + 2 photoaddition method for the synthesis of tetracarboxylic acids was restricted to the dimerisation of dimethyl fumarate and maleic anhydride and of their substituted analogues to form cyclobutane-1,2,3,4-tetracarboxylic acids. Among the four isomers of this acid, (LVII)–(LX), the first three are capable of forming the dianhydride and by virtue of this method all are known:



Irradiation at 253 nm of dimethyl fumarate in the solid phase, usually in the presence of a sensitiser, leads to the tetramethyl ester of (LVII) in the course of 7–8 days, which isomerises at 300°C to the thermodynamically more stable ester of (LVIII). [137] The hydrolysis of the esters and subsequent dehydration lead to the corresponding dianhydrides (LXI) and (LXII). [138] The dianhydride of the acid (LIX) was obtained by the ozonolysis of the acenaphthene dimer [76]. Irradiation of maleic anhydride under the same conditions leads directly [139] to compound (LXI, R = H):

The method is applicable also to methyl-, dimethyl-, and diphenyl-maleic anhydrides [139,140]. In this case, the reaction proceeds more readily. Dimethylmaleic anhydride dimerises to compound (LXI, R = CH_3) in 60% yield over a period of 6 h and the dimer (LXI, R = C_6H_5) is formed in a quantitative yield when the monomer is merely exposed to sunlight.

The scope of the 2 + 2 cycloaddition method was greatly extended recently in relation to the formation of dianhydrides [141]. The sensitised addition of maleic anhydride to tetrahydrophthalic anhydride and its 1,4-*endo*-*exo*- and 1,4-*endo*-methano-derivatives leads to the dianhydrides (LXIII)–(LXV):



This method is particularly valuable because the initial compounds are very readily available—they are adducts obtained in the Diels–Alder reaction between maleic anhydride on the one hand and butadiene, furan, and cyclopentadiene on the other. Thus there is a possibility of using for the synthesis of dianhydrides a whole class of compounds—maleic anhydride monoadducts. The yield of compounds (LXIII)–(LXV) reaches 30–35%. [142]

The high thermal stability of the 2 + 2 photocycloaddition adducts is striking, this incidentally being in full agreement with theoretical postulates. Thus the dimer

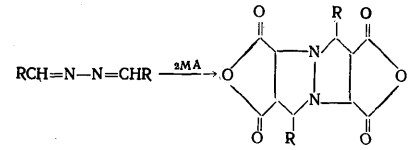
of diphenylmaleic anhydride melts without decomposition at 325°C, the dianhydride of tetramethylcyclobutanetetracarboxylic acid decomposes above 350°C, and the adduct (LXIV) has a very high decomposition temperature for non-aromatic compounds (410°C, on fusion).

3. Successive 2 + 2 and 4 + 2 Cycloaddition Reactions

Irradiation of maleic anhydride solutions in benzene leads to the formation of a 2:1 adduct which has the structure of the dianhydride of tricyclo[4,2,2,$0^{2,5}$]dec-7-ene-3,4,9,10-tetracarboxylic acid (LXVI) according to chemical and physical data [143-145]. Since thermal 2 + 2 addition reactions are forbidden on symmetry grounds and benzene does not react with maleic anhydride in the dark even under very severe conditions, a process mechanism involving successive 2 + 2 and 4 + 2 cycloadditions was proposed [144]:

(LXVI)

It has been shown [144,146] that maleic anhydride and benzene form a charge-transfer complex absorbing in the range 230–280 nm, where the photochemical reaction takes place. Irradiation in the non-sensitised process activates the charge-transfer complex and not the species to be added, the activated intermediate being insensitive to oxygen, since it is in a singlet state [147]. Cycloaddition sensitised by aromatic ketones, for example benzophenone, involves energy transfer from benzophenone in the triplet state to the charge-transfer complex. The sensitised mechanism of the intermolecular energy transfer is more effective, although the sensitiser inhibits the reaction involving the non-sensitised addition mechanism. Acetone also behaves as a sensitiser and in addition plays the role of an active solvent [148].

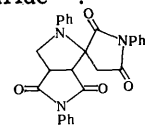


Apart from maleic anhydride, maleimide and its n-alkyl derivatives are capable of reacting with benzene. Among the *N*-aryl derivatives only those are involved in the reaction where the substituent at the nitrogen atom is not coplanar with the remainder of the molecule, for example the benzyl, *o*-tolyl, and 2,6-xylyl derivatives [149].

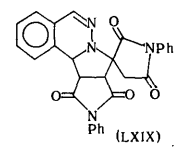
Many mono- and poly-substituted benzenes, naphthalene, and biphenylene have been employed as the aromatic component. In this group of compounds only monoalkyl- (methyl, ethyl, isopropyl, t-butyl, and C_3–C_{13} n-alkyl) and monohalogeno-benzenes, *o*- and *p*-xylenes, and biphenyl proved to be reactive [150-152]. All the substituents lower the rate of sensitised addition of maleic anhydride and the yield of products. If the rate of reaction of benzene is adopted as unity, then the rates are 0.5 for toluene, 0.25 for t-butylbenzene and chlorobenzene, 0.12 for biphenyl, 0.15 for *o*-xylene, and 0.08 for *p*-xylene [152].

From the practical point of view, the adduct of benzene and maleic anhydride is of greatest interest: it is obtained in the highest yield (70%) and has the highest melting point (350°C).

4. 1,3-Cycloaddition Reactions

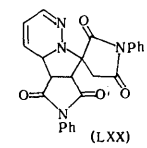


In view of the small number of examples of the application of this method for the synthesis of tetracarboxylic acids, we did not devote a separate section to reactions of this type, although the principle and mechanism of the 1,3-cycloaddition process are very different from those of the reaction discussed above. Haring and Wagner-Jauregg [153] showed that azines react with maleic anhydride via a 1,3-addition mechanism with formation of the dianhydrides (LXVII), in which R = H, phenyl, 2-furyl, *p*-chlorophenyl, *p*-methoxyphenyl, etc.:



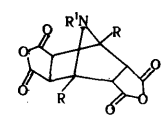
(LXVII)

When bismaleimides are employed instead of maleic anhydride, the azines can form polyimides [154].



Schiff bases are also reactive in dipolar addition reactions with many maleic acid derivatives. Benzylidenemethylamine reacts with *N*-phenylmaleimide to form the spiroadduct (LXVIII) [155] via an intermediate azomethinylide [156]. Similarly phthalazine and pyridazine form the 1:2 adducts (LXIX) and (LXX) with maleimide in very high yields [157], although previously a structure with condensed rings was proposed for the adduct of pyrazine and maleic anhydride [158]:

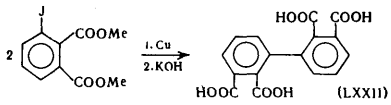
(LXVIII)



(LXIX)

(LXX)

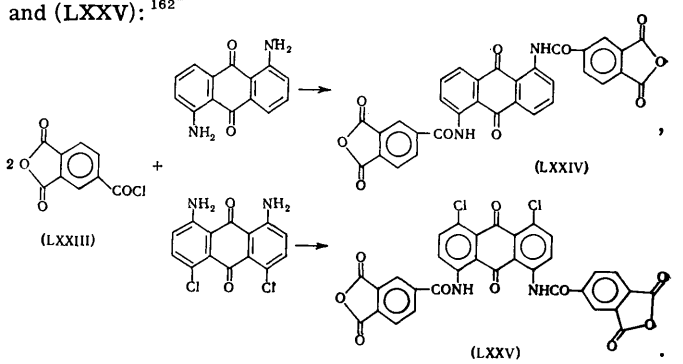
Functional derivatives of tetracarboxylic acid (LXXI) with R = phenyl or *p*-methoxyphenyl and R′ = H or methyl were also obtained by the reaction of maleic anhydride or maleimides with azlactones or mesoionic azlactones—2,4-diphenyl-5-oxazolone, *N*-(*p*-methoxybenzyl)phenylglycine, and anhydro-5-hydroxy-3-methyl-2,4-diphenyloxazolium hydroxide [159]. The reaction is carried out by 1,4-cycloaddition methods and the products are obtained in an almost quantitative yield.



(LXXI)

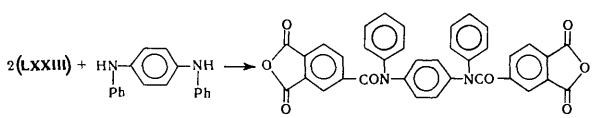
IV. CONDENSATION OF DICARBOXYLIC ACIDS AND THEIR DERIVATIVES

The methods of synthesising tetracarboxylic acids discussed in this section cannot strictly speaking be combined in a general group, since they involve the employment of a very great variety of reactions. However, in view of the general idea underlying these reactions—the employment of chemical transformations of dicarboxylic acids for the preparation of tetracarboxy-derivatives—we separated these procedures from section V below.



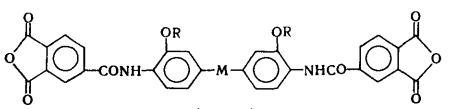
Reactions involving substituted phthalic acids are most often used for the synthesis of tetracarboxylic acids. Thus, when dimethyl 2-iodoisophthalate is heated at 240 to 250°C in the presence of powdered copper, tetramethyl biphenyl-2,2′,6,6′-tetracarboxylate is obtained [160]. The tetraester of biphenyl-2,2′,3,3′-tetracarboxylic acid was synthesised similarly from dimethyl 3-iodophthalate, the

free acid (LXXII) being produced by the hydrolysis of the ester[161]:



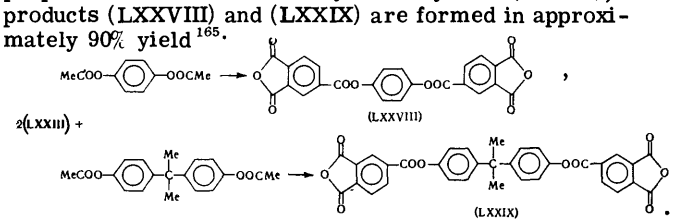
(LXXII)

Many tetracarboxylic acids specially designed for the synthesis of polymers have been obtained from trimellitic acid and its functional derivatives. The reaction of the chloride of the 1,2-anhydride of trimellitic acid (LXXIII) with 1,5-diaminoanthraquinone and 1,8-diamino-4,5-dichloroanthraquinone yielded the dianhydrides (LXXIV) and (LXXV):[162]



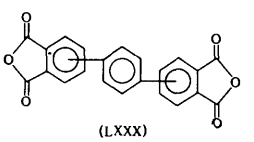
(LXXIII) (LXXIV) (LXXV)

The similar reaction of (LXXIII) with *NN'*-diphenyl-*p*-phenylenediamine leads to the dianhydride (LXXVI):[163]



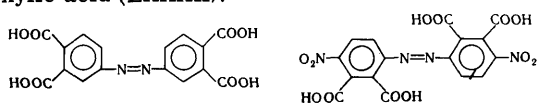
(LXXVI)

Seven dianhydrides with the general formula (LXXVII), in which R = alkyl and M = oxygen atom or a single bond, were obtained by the reaction of (LXXIII) with the hydrochlorides of di-(3-alkoxy-4-aminophenyl) ethers or 3,3'-dialkoxybenzidines[164]:



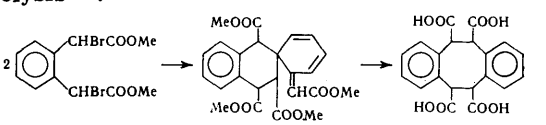
(LXXVII)

When *p*-diacetoxybenzene and 2,2-di-(*p*-acetoxyphenyl)-propane are transesterified by the anhydride (LXXIII), the products (LXXVIII) and (LXXIX) are formed in approximately 90% yield[165].



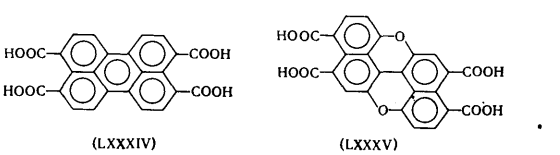
(LXXVIII) (LXXIX)

The reaction of *p*-di(chlorosulpho)benzene with phthalic anhydride has been patented as a method of synthesising a mixture of isomeric dianhydrides of terphenyltetracarboxylic acids (LXXX):[166]



(LXXX)

The reduction of nitrophthalic acids constitutes a very convenient method of synthesising azobisphthalic acids. When *p*-nitrophthalic acid is treated with aluminium powder in an alkaline solution, azobenzene-3,3',4,4'-tetracarboxylic acid (LXXXI) is formed[167]. 3,6-Dinitrophthalic is reduced by glucose in the presence of sodium thiosulphate to 6,6'-dinitroazobenzene-2,2',3,3'-tetracarboxylic acid (LXXXII):[168]



(LXXXI) (LXXXII)

On treatment with sodium iodide in DMF and further heating in boiling xylene, the ester of *o*-phenylenedi-(bromoacetic) acid gives rise to the acid (LXXXIII) after hydrolysis[169]:

(LXXXIII)

Only two examples of the dimerisation of the functional derivatives of naphthalic acid are known, but these reactions lead to very valuable products. By fusing the imide of naphthalic acid with alkalies in the presence of oxygen and subsequent hydrolysis with sulphuric acid, perylene-3,4,9,10-tetracarboxylic acid (LXXXIV) was obtained[170,171] and dehydrogenation of 3-hydroxynaphthalic anhydride in boiling nitrobenzene in the presence of copper(II) chloride yields the dianhydride of perixanthenoxanthene-3,4,8,10-tetracarboxylic acid (LXXXV).[172]

(LXXXIV) (LXXXV)

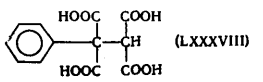
Certain reactions employed in the dimerisation method, particularly those involving trimellitic anhydride, have attracted attention by their flexibility: they make it possible to obtain many tetracarboxylic acids and their anhydrides with a wide variety of groups linking the anhydride rings. In certain cases this method permits a simplification of the synthesis of the acid.

Moreover its value lies in the fact that it allows one to synthesise compounds which cannot be prepared by other methods, for example azodiphthalic, perylenetetracarboxylic and perixanthenetetracarboxylic acids.

V. SYNTHESIS FROM DERIVATIVES OF ACIDS

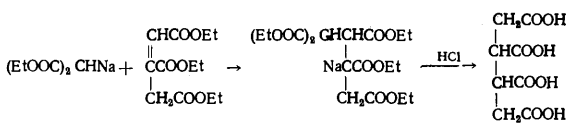
Syntheses with malonic ester are very widely used to prepare aliphatic tetracarboxylic acids with both linear and cyclic structures. However, in this case the products are mainly compounds each of which contains two carboxy-groups at the same carbon atom, for example cyclohexane-1,1,3,3-tetracarboxylic acid. Such compounds are outside the scope of the present review.

There remain only a few examples of the synthesis of tetracarboxylic acids capable of forming stable dianhydrides and only the syntheses of ethanetetracarboxylic and ethylenetetracarboxylic acids constitute examples of the classical application of this method, while the preparation of other products involves additional decarboxylation, oxidation, etc. stages.



The interaction of bromo- and dibromo-malonic esters with sodium iodide leads to the tetraesters of ethanetetracarboxylic and ethylenetetracarboxylic acids from which the free acids (LXXXVI) and (LXXXVII) were isolated by hydrolysis [173]:

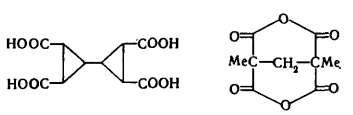
$$2\,CHBr(COOEt)_2 \xrightarrow{2NaI} (EtOOC)_2CHCH(COOEt)_2 \rightarrow (HOOC)_2CHCH(COOH)_2\ ,$$
(LXXXVI)



$$2\,CBr_2(COOEt)_2 \xrightarrow{2NaI} (EtOOC)_2C{=}C(COOEt)_2 \rightarrow (HOOC)_2C{=}C(COOH)_2\ .$$
(LXXXVII)

While treatment of compound (LXXXVI) with acetic anhydride leads smoothly to the dianhydride [174], the dianhydride of the acid (LXXXVII) is unstable and has not been isolated in a free state. However, being a powerful dienophile, it readily forms adducts with many dienes at the instant of its formation. Thus treatment of ethylenetetracarboxylic acid with acetyl chloride in the presence of 9,10-dimethoxyanthracene leads to the formation of its adduct with the dianhydride of the acid (LXXXVII). [89]

Treatment of (LXXXVII) with phenylmagnesium bromide yields phenylethane-1,1,2,2-tetracarboxylic acid (LXXXVIII): [175]

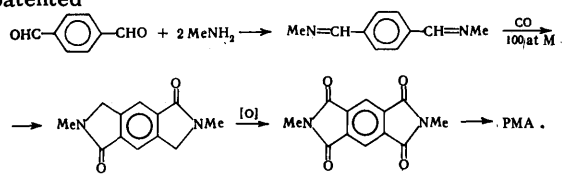


(LXXXVIII)

Butane-1,2,3,4-tetracarboxylic acid (LXXXIX) can be obtained by the reaction of sodiomalonic ester with aconitic acid ester [176,177]:

(LXXXIX)

The synthesis of dicyclopropyl-2,2',3,3'-tetracarboxylic acid (XC) also includes the decarboxylation stage [178]. The reaction of sodiomalonic ester and *trans,trans*-$CH_3OOCCCl{=}CHCH{=}CClCOOCH_3$ in methanol yields the hexamethyl ester of bicyclopropylhexacarboxylic acid, which gives rise to (XC) after hydrolysis and heating to 180°C.



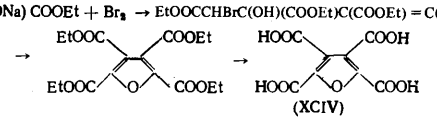
Pentane-1,2,4,5-tetracarboxylic and pentane-2,2,4,4-tetracarboxylic acids, (XCI) and (XCII), are also known. (XCI) has been obtained by the oxidation of the product of the reaction of malonic ester, methylene iodide, and sodium methoxide [179]. On treatment with diphenylketen, (XCII) is converted into the dianhydride (XCIII): [180]

(XC) (XCIII)

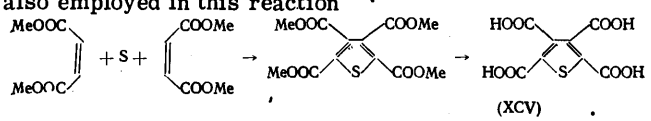
VI. SPECIFIC METHODS OF SYNTHESIS

In this section we shall consider methods of preparation of tetracarboxylic acids which are not general. However, all the examples described below satisfy one of three criteria: the method of preparation is specific, but the reaction product is of considerable interest; there is a prospect of further development of the method used at present to synthesise only one product; the method is used to synthesise many products, but the reaction mechanism has not been established.

The reactions involving the direct introduction of the carbonyl group constitute a familiar method of synthesising carboxylic acids, but it is applicable to the synthesis of only one tetracarboxy-compound—pyromellitic acid. A method of preparing pyromellitic acid by adding carbon monoxide to the Schiff base obtained from terephthalic aldehyde and methylamine and subsequent oxidation has been patented [181-183].

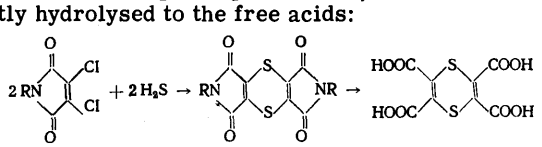


Pyromellitic acid is also formed in 35% yield on heating a mixture of sodium and potassium phthalates with calcium oxide and copper(II) chloride at a carbon dioxide pressure of 25 atm and 450°C. [184]



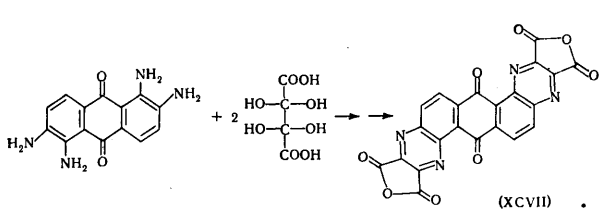
Of the tetracarboxylic acids which have already found practical applications, furan-, thiophen-, and dithiin-tetracarboxylic acids and the dianhydride of 1,2,5,6-bis-($\alpha\beta$-dicarboxypyrazino)anthraquinone were not described in the previous sections.

Furantetracarboxylic acid (XCIV) is formed on ring closure in tetraethyl dioxalylsuccinate—synthesised by treating with bromine the *O*-sodio-derivative of diethyl malate [185,186]. It has been shown [187] that the aldol $C_2H_5OOCCHBrC(OH)(COOC_2H_5)C(COOC_2H_5){=}C(ONa)COOC_2H_5$ is formed as an intermediate, splitting off subsequently NaBr and water with formation of (XCIV):



$$EtOOCCH{=}C(ONa)COOEt + Br_2 \rightarrow EtOOCCHBrC(OH)(COOEt)C(COOEt){=}C(ON_2)COOEt \rightarrow$$

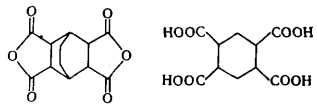
(XCIV)



Thiophentetracarboxylic acid (XCV) was obtained initially by treating dimethyl acetylenedicarboxylate with sulphur [188] and later dimethylfumarate and maleate were also employed in this reaction [189].

(XCV)

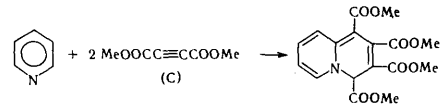
Similar cyclisation reactions have been used to synthesise dithiintetracarboxylic acid (XCVI). [190] The interaction of dichloromaleimide with hydrogen sulphide or thiourea leads to the corresponding di-imides, which are subsequently hydrolysed to the free acids:



(XCVI)

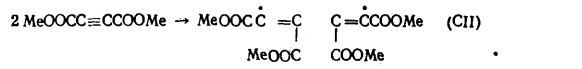
The condensation of 1,2,5,6-tetra-aminoanthraquinone with dihydroxytartaric acid leads to 1,2,5,6-bis($\alpha\beta$-dicarboxypyrazino)anthraquinone, which cyclises to the anhydride (XCVII) on refluxing in acetic anhydride [191]:

(XCVII)



The dianhydride (XCVIII), which has a very high thermal stability, was obtained[192] by oxidising the adduct of dimethyl acetylenedicarboxylate and 7,8-diacetylbicyclo[4,2,0]octa-2,4-diene—the product of the intramolecular cyclisation of cyclo-octatetraene.

The Michael reaction has been used to synthesise a tetracarboxylic acid. The dehydrobromination product of trimethyl 1-bromopropane-1,1,2-tricarboxylate yields on treatment with sodium methoxide in methanol the hexamethyl ester of cyclohexane-1,1,2,4,4,5-hexacarboxylic acid, which is decarboxylated to cyclohexane-1,2,4,5-tetracarboxylic acid (XCIX) on refluxing with concentrated hydrochloric acid[193]:



(XCVIII) (XCIX)

The adducts of pyridine with dimethyl acetylenedicarboxylate (C) [195,196] constitute a whole class of heteroaromatic tetracarboxylic acids, the first example of which was obtained by Diels[194]. Formally the reaction consists in the addition of two molecules of (C) to one molecule of pyridine with formation of the adduct (CI):

(C) (CI)

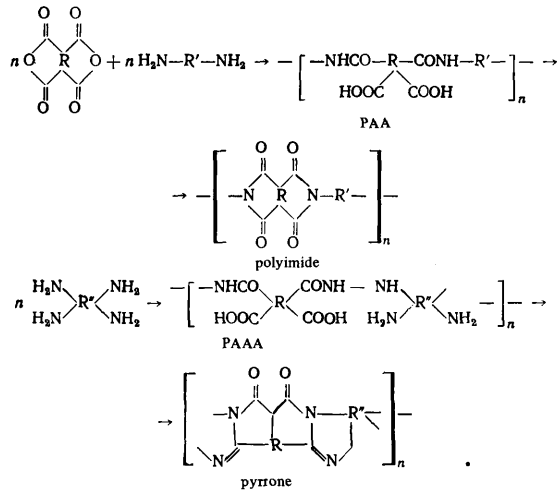
Diels proposed a mechanism for the process involving the formation of a dimer (C):

(CII)

Next compound (CII) attacks the nitrogen atom of pyridine via the positively charged centres and the intermediate is cyclised. If this mechanism were confirmed, the reaction could be classified as an example of diene synthesis, albeit of an unusual type. However, compound (CII) has not been detected by either chemical or spectroscopic methods. It is only known that the reaction at 20°C gives rise to 9*H*-quinolizine, which on heating isomerises quantitatively to the thermodynamically more stable 4*H*-isomer.

Many tetracarboxy-compounds based on substituted pyridines as well as quinoline, isoquinoline, acridine, and phenanthridine have been synthesised by this method. The tetramethyl esters are normally hydrolysed to the free acids, but the preparation of the dianhydrides has not been described.

VII. PRINCIPAL APPLICATIONS OF TETRACARBOXYLIC ACIDS



The first practical application of tetracarboxylic acids was discovered in the synthesis of dyes. The principal advances in this field are associated with the employment of the products of the condensation of naphthalene-1,4,5,8-tetracarboxylic acid and its substituted derivatives with aromatic *peri*- or *o*-diamines. The best known are Indanthren Bordeaux RR, Indanthren Brilliant Orange GR, and Indanthren Scarlet GG, which are respectively the *cis*- and *trans*-isomers of naphthoylenebisbenzimidazole and their mixture. These dyes are very stable, brillant, and have attractive tints[5].

Initially aroyleneimidazole dyes were used in vat-dying but in recent years they attracted considerable interest as disperse dyes for the dyeing of artificial fibres and Indanthren Scarlet GG and Indanthren Bordeaux RR were used to dye cotton.

Many dyes have been obtained on the basis of perylenetetracarboxylic acid (mainly di-imides) [197-199] and pyromellitic acid (benzoylenebisbenzimidazoles) [200].

The reactions of the dianhydrides of tetracarboxylic acids with diamines have been used to synthesise polyimides and the products of their reaction with *peri*-, *peri*- or *ortho*-, and *ortho*-tetramines are poly(aroylenebisbenzimidazoles) (pyrrones).

The polymers are formed via intermediate polyamidoacids (PAA) or polyaminoamidoacids (PAAA), which are then subjected to intramolecular cyclisation[1,2]:

PAA

polyimide

PAAA

pyrrone

The prepolymers (polyamidoacids, or polyaminoamidoacids), are made into articles by a two-stage method and are then subjected to solid-phase dehydration. In the one-stage method the mixture of components is heated to approximately 200°C in polyphosphoric acid or another solvent promoting dehydration, the intramolecular cyclisation processes being largely complete in the polymer isolated.

In the present review there is no need for a detailed analysis of the influence of the structure of the initial tetracarboxylic acid on the properties of the polymers, since these problems were discussed previously[1,2]. We shall only mention certain important characteristics.

The number of atoms in the anhydride rings of tetracarboxylic acids greatly influences the properties of the resulting polymers. This is due to the fact that the thermal stability and also many physicomechanical properties of polyimides and pyrrones are determined by the degree of completion of the intramolecular cyclisation processes. As stated above, in cyclisation the number of atoms in the resulting heterocycle is the same as in the initial dianhydride and therefore the degree of cyclisation in polymers based on six-membered dianhydrides, for example the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid, is higher and the resulting heterocycles are more stable than in the synthesis where five-membered dianhydrides, for example pyromellitic dianhydride, are employed [201-203].

The majority of polyimides and pyrrones have been obtained from aromatic dianhydrides and aromatic diamines or tetramines. Powerful intramolecular interactions,

which have a favourable effect on the thermal stability of the polymers but at the same time give rise to a poor solubility and absence of fluidity up to the decomposition temperature, are characteristics of such structures. It is fairly difficult and sometimes impossible to make such polymers into articles, so that usually one employs a two-stage method of synthesis with isolation of a soluble prepolymer, although this procedure suffers from a number of fundamental disadvantages [204]. On the other hand, it is known [204,205] that the introduction of bulky side groups into the polymer chain prevents close packing of the macromolecules and improves the solubility of the polymer. The employment of this procedure in the synthesis of polyimides and pyrrones, involving the use of the dianhydrides of aromatic tetracarboxylic acids containing phenyl, naphthyl, phthalide, fluorene, and other groups as substituents, permitted the synthesis of polymers capable of being made into articles when dissolved in organic solvents [206,207] without an appreciable decrease of their thermal stability.

Many methods of synthesising tetracarboxylic acids have been devised specially in order to obtain the starting compounds for the synthesis of polyimides and pyrrones. One may quote as examples the method for the preparation of adducts of maleic anhydride with caccyclones or coumalins [208], bisfuran derivatives [209], and benzene and its derivatives [210-212], the photoadducts with tetrahydrophthalic acids [3], and almost all the tetracarboxylic acids obtained by the oxidation of organic compounds and the condensation of dicarboxylic acids.

In the majority of studies dealing with the synthesis of new tetracarboxylic acids, it was stated that their dianhydrides were intended for the hardening of epoxy-resins and the preparation of plasticisers—the products of condensation with alcohols—in addition to the synthesis of polymers. However, few data have been quoted on the reactivity of the dianhydrides in these reactions and on the properties of the products.

Pyromellitic dianhydride is known [4] to be sparingly soluble in epoxy-resins and gel-formation takes place before complete dissolution of the dianhydride. On the other hand, a method has been discovered for the hardening of epoxides by the dianhydride of benzoquinonetetracarboxylic acid and its alkyl derivatives [213], whereby it is possible to raise the temperature of the onset of deformation to 288°C. The photoadducts of maleic anhydrides with ethylbenzene, cumene, and branched C_5–C_6 alkylbenzenes are highly compatible with epoxy-resins and the hardened products have very satisfactory mechanical properties, particularly at elevated temperatures [214].

Biocatalysis of the Hydrolysis of the Glycosidic Linkage under the Influence of Lysozyme

V.I.Maksimov

As a result of the advances in the X-ray diffraction analysis of enzymes, it has recently become possible for the first time to describe in a concrete form and quite unambiguously the effective factors in biocatalysis. These factors have been demonstrated by means of biochemical, physicochemical, and physical research techniques. Lysozyme is the first enzyme for which such research has been carried out on an adequate scale. This review deals in fact with such investigations. The ultimate result was not only the solution of the problem of the specific mechanism of the action of this enzyme but also the broad outlines of the mechanisms of biocatalysis were finally established in principle. Instead of the old more or less probable hypotheses, these studies led to quite definite ideas about the mechanism of biocatalysis.
The bibliography includes 98 references.

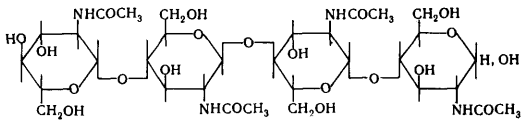
I. INTRODUCTION

Complete data on the X-ray diffraction analysis of lysozyme and its enzyme–substrate complexes with carbohydrates were published in 1967, the resolution being 2 Å.[1] At that time it was the only structure of an enzyme–substrate complex investigated in all details. It became possible for the first time to obtain for a specific example unambiguous data concerning the structure of the active centre and to put forward on the basis of these direct results a hypothesis about the mechanism of the action of the enzyme.



Chemical and physicochemical studies, which developed particularly vigorously after the above publication[1], made it possible to compare the structural data with the catalytic properties of the enzyme and the mechanism of the action of lysozyme has now been elucidated in broad outline. This example is instructive in many respects. Firstly, it shows that a problem as complex as an unambiguous description of the specific mechanism of the action of an enzyme can be solved only as a result of a combined study by various methods: chemical, biochemical, physicochemical, and physical. Secondly, it confirms the earlier view that the usual principles of physical organic chemistry underly the mechanism of biocatalysis. Thirdly, it demonstrates that the effective occurrence of a chemical process (biocatalysis) can be ensured not only by the direct action of the enzyme on the substrate linkages being dissociated but also as a result of a complex reaction pathway via intermediates, each of which is itself a substrate of lysozyme. The aim of the present review is to describe the chemical mechanism of the action of lysozyme and to show how complex the mode of interaction of the individual factors in biocatalysis can be and to attempt thereby to establish its fundamental essential features.

II. THE EARLY PERIOD IN THE STUDY OF THE ACTION OF LYSOZYME

Lysozyme became widely known as a result of Fleming's publication in 1922 describing the bacteriolytic action of a number of biological liquids and extracts[2]. Nothing was known for a long time about the chemical nature of lysozyme. A number of studies established that lysozyme can act on the polysaccharide components of cells with liberation of *N*-acetyl-D-glucosamine[3–5]. The chemical nature of the lysozyme substrate was definitely established for the first time by Berger and Weiser[6], who showed that chitin may be hydrolysed by lysozyme with formation of *N*-acetyl-D-glucosamine. It was thus shown that the lysis of bacteria takes place as a result of the hydrolysis of the polysaccharide at the β-(1–4)-glycosidic linkage connecting the *N*-acetyl-D-glucosamine residues. The first reports on low-molecular-weight substrates appeared in 1959–1960.[7–10] Salton and Ghysen[7,8] isolated a tetrasaccharide from the products of the lysozyme hydrolysis of bacterial cell walls and showed that the action of lysozyme on this substrate results in only one product—*N*-acetyl glucosamino-β(1–4)-*N*-acetyl muramic acid—a disaccharide the structure of which was finally established later[11,12]. The initial tetrasaccharide has the following structure:

The structure of another tetrasaccharide substrate, a fragment of chitin, is

The structure of the carbohydrate chain in the two cases is the same although the bacterial tetrasaccharide contains residues of D-lactic acid. Direct hydrolysis of the oligosaccharides was suggested in the above investigations[7-10] and also in later studies[13,14].

When lysozyme was allowed to act on a trisaccharide of similar structure, only two products were detected: a monosaccharide and a disaccharide[10,14]. According to Rupley[15], the glycosidic linkage is cleaved preferentially from the non-reducing end[15]. The first measurements of the rate of hydrolysis of oligosaccharides (chitin fragments) showed that the disaccharide is not hydrolysed by lysozyme at all, and the trisaccharide is hydrolysed very slowly, the rate of hydrolysis of oligosaccharides increasing with the length of the oligosaccharide[13].

III. THE MOLECULAR MECHANISM OF THE HYDROLYSIS OF SHORT OLIGOSACCHARIDES

The study of the mechanism of the action of lysozyme had two starting points. Firstly, it was established that short oligosaccharides are not hydrolysed directly, the reaction proceeding via the intermediate synthesis of longer oligosaccharides (hydrolysis via transglycosylation) and, secondly, it was shown that the hydrolysis goes almost completely to acetyl-D-glucosamine.

1. Hydrolysis via Transglycosylation

In 1964 Kravchenko and Maksimov[16] published the first report about the formation of high-molecular-weight water-insoluble products when lysozyme is allowed to act on various oligosaccharides derived from chitin. A similar phenomenon was observed by Sharon and Seifter[17], who employed a bacterial tetrasaccharide as the substrate. A number of communications confirming and extending the knowledge about the synthetic activity of lysozyme and showing that the formation of carbohydrates with a higher molecular weight proceeds via a transglycosylation mechanism (see, for example, Refs. 18–21) were published later.

It was possible to regard the transglycosylation reaction as a side process, which occurs under certain conditions (for example, at high substrate and enzyme concentrations). However, biochemical, X-ray diffraction, and physicochemical studies showed that transglycosylation is a fundamental intermediate stage in the hydrolysis of short oligosaccharides catalysed by lysozyme. Depending on the conditions, the process stops either at the stage of the total hydrolysis of the substrate to the monomer or at an intermediate stage.

The mechanism of hydrolysis via transglycosylation was formulated for the first time in 1965 by Maksimov et al.[19] The conclusion was based on the following experimental facts described for the first time in their report: (1) the induction period in the hydrolysis of short oligosaccharides; (2) the action of the seed†; (3) total hydrolysis of tri- and tetra-saccharides (involving all the glycosidic linkages). A trisaccharide is not split to the monomer and the dimer, as was believed by some investigators[10,14,15], but only to the monomer; (4) a change in the mode of reaction, towards hydrolysis or synthesis, depending on the concentrations, of the enzyme and substrate. Moreover, account was taken of the fact that the rates of the hydrolytic[13] and synthetic[16] lysozyme reactions increase appreciably with increase in the length of the oligosaccharide substrate. On the other hand, it was established that a trisaccharide cannot in principle be hydrolysed by lysozyme directly.

The hydrolysis of this substrate is a result of a complex process the mechanism of which was put forward in 1965:[19]

(1) short oligosaccharides

$$+\ \text{short oligosaccharide} \xrightarrow[\text{sylation}]{\text{transglyco-}} \text{long oligosaccharide} + \text{monomer (?)};$$

(2) long oligosaccharides

$$+\ \text{short oligosaccharide} \xrightarrow[\text{sylation hydrolysis}]{\text{transglyco-}} \text{long oligosaccharide} + \text{monomer (?)}.$$

hydrolysis

This scheme describes two reaction stages: the first is very slow, corresponding to the induction period in the course of which conditions are created for the second reaction stage. In the second stage the bulk of the substrate is digested, the process being cyclic. In a number of subsequent investigations[22-24] these findings were confirmed for other examples. The seed was regarded as a cofactor in the reaction, similar to a coenzyme[22]. It was shown that the substrate and the seed compete for the site where binding to the enzyme active centre takes place[24]. The study of the action of lysozyme on di-*N*-chloroacetylchitobiose showed that under certain conditions only one mole of monosaccharide is formed from one mole of disaccharide[23]. The following reaction mechanism was proposed[23]:

1. dimer + dimer → monomer + trimer;

2. dimer + oligosaccharide (x units) → monomer + oligosaccharide ($x + 1$ units).

According to this scheme, the first stage involves the formation of a seed by a disproportionation mechanism and in the second stage transglycosylation takes place mainly with formation of the monomer.

In 1967 Sharon published data showing that the bacterial tetrasaccharide hydrolyses only after an induction period, the duration of which is inversely proportional to the concentration of the enzyme[25]. Sharon also explains the observed lag period by the complexity of the hydrolytic process and by a molecular mechanism of the hydrolysis via transglycosylation.

In 1968 Chipman et al. published more detailed information about the molecular mechanism of the hydrolysis[26]. In their study the products formed when lysozyme was allowed to act on oligosaccharides from the *Micrococcus lysodeikticus* capsules were investigated by electrophoretic and paper chromatographic techniques and also by ion-exchange chromatography. The use of a tritium-labelled substrate permitted a simple solution of many aspects of the problem of the molecular mechanism. This study demonstrated convincingly that synthesis takes place mainly via a transglycosylation mechanism. The mechanism of the action of the seed was treated by analogy with a chain process, hexa- and octa-saccharides playing the role of the "chain carrier". In Chipman and Sharon's

† For the meaning of the term "seed" see Section IV, 3 (Ed. of Translation).

view[27], hydrolysis via transglycosylation is the most characteristic feature of catalysis by lysozyme. The study of the action of lysozyme on the glycosides of chitin oligosaccharides also led to this molecular mechanism. In 1968 the same view was adopted by Osawa[28] in a study of the hydrolysis of nitrophenyl glycosides of oligosaccharides and by Tsai et al.[29] in a study of the action of lysozyme on the glycosidic isologues of chitin disaccharides. Khorlin et al.[30] arrived at the same conclusion. A kinetic study of the molecular mechanism has been made[31].

2. Other Mechanisms

The molecular mechanism of the hydrolysis via transglycosylation has now been proved by many investigators[19,22-31]. However, many of them failed to take into account the fact in both earlier and later studies that the hydrolysis of chitin substrates does not take place directly[7-10,13,14]. The formation of transglycosylation products has been noted recently as a rule. However, the transglycosylation is regarded as a side reaction; assuming that hydrolysis and transglycosylation take place in parallel, Dahlquist and Raftery[32] reported in 1967 that, when lysozyme acts on tri-*N*-acetylchitotriose, a disaccharide and a monosaccharide are formed in molar proportions of 2 : 1 instead of 1 : 1 expected for direct hydrolysis. They suggest that part of the *N*-acetyl-D-glucosamine formed combines with the initial trisaccharide to produce a tetrasaccharide, which they detected among the reaction products. A similar mechanism was also put forward by Raftery and Rand-Mair[33], who believe that the formation of the β-methyl glycoside of *N*-acetyl-D-glycosamine, which they observed, is a result of a direct transfer of the acetylglycosamine residue from di-*N*-acetylchitobiose (the donor in the transglycosylation reaction) to methanol (the acceptor).

Rupley and coworkers also failed to take into account the necessity for the transglycosylation stage in the hydrolysis of short oligosaccharides[13,15,34]. Rupley and Gates considered a molecular mechanism according to which a productive complex of lysozyme and tri-*N*-acetylchitotriose is formed with an enzyme : substrate molar ratio of 1 : 2.[34] According to the authors, direct hydrolysis of one of the adsorbed trisaccharide molecules is then possible. Sharon and coworkers[26] regard such a mechanism as unlikely if only because two trisaccharide molecules contain one oxygen atom more than the hexasaccharide located in the active centre of lysozyme. Direct hydrolysis of tri-*N*-acetylchitotriose is also postulated in later investigations of Rupley and coworkers[35,36]. Rupley and Gates[34] attempted to determine the site of the dissociation of the glycosidic linkage in oligosaccharides in hydrolysis and transglycosylation assuming that the two processes occur in parallel. The reaction was performed with 0.001—0.05 M oligosaccharide and 0.1—0.8 M *N*-acetyl-D-glucosamine. In view of a large excess of *N*-acetyl-D-glucosamine (up to 1000-fold) the reaction must be restricted in this instance to transfer to the monomer. Some results of this investigation are presented in Table 1.

Table 1 shows that the rate of transglycosylation increases so much that the difference in rate for the dimer and hexamer is as much as 7 orders of magnitude. If one takes into account further the fact that, among the products of the reaction of the disaccharide with the monosaccharide in the presence of lysozyme, the authors observed at the end of the reaction a considerable amount of tri- and tetra-saccharides, the process in this system should presumably be self-accelerating owing to the increase of the reaction turnover with accumulation of longer oligosaccharides. Therefore, from our point of view, the mechanism of the cleavage of the dimer and trimer (and tetramer according to Sharon's data) presented in Table 1 corresponds to the induction period of the reaction.

Table 1. Characteristics of the cleavage of glycosidic bonds in chitin oligosaccharides in the reaction involving transfer to *N*-acetyl-D-glucosamine.

Oligosaccharide	Relative rate	Reaction order	Type of action
Dimer	0.003	1	
Trimer	1	1	$X_1\downarrow X_2\downarrow X_3$
Tetramer	8	1	$X_1\downarrow X_2\downarrow X_3\downarrow X_4$
Pentamer	4000	0	$X_1—X_2—X_3\downarrow X_4\downarrow X_5$
Hexamer	30000	0	$X_1—X_2—X_3—X_4\downarrow X_5—X_6$

In 1967 and 1969 Kravchenko and Kuznetsov published papers[37,38] describing the action of lysozyme on tetra-*N*-acetylchitotetraose. Together with all possible hydrolysis products, they observed the formation of a hexasaccharide the amount of which did not vary as long as the substrate remained, disappearing at the end of the reaction. On the basis of the content of hexasaccharide quoted in the figures and assuming it to be equal to 0.1 of an equivalent for the initial 8 equivalents of the tetrasaccharide, calculation of the ratio of the rates of transglycosylation (using the data of Rupley and Gates in Table 1) shows that the transglycosylation of the hexasaccharide should be 50 times faster, despite its low amount, than that of the tetrasaccharide (which behaves as the donor in this reaction). The authors suggest that the hydrolysis and transglycosylation take place simultaneously and the mechanism of hydrolysis via transglycosylation is not mentioned at all.

However, one should note that in certain cases short oligosaccharides can nevertheless hydrolyse directly. For example, the *p*-nitrophenyl glycosides of *N*-acetyl-*D*-glucosaminyl-D-glucose and *N*-acetyl-*D*-glucosaminyl-D-2-deoxyglucose can probably hydrolyse directly to disaccharides without the intermediate formation of longer oligosaccharides, as shown by appropriate techniques[39].

IV. THE CRYSTALLOGRAPHIC MODEL AND THE MOLECULAR MECHANISM

Fundamental and detailed data on the structure of enzyme—substrate complexes obtained by X-ray diffraction analysis appeared in 1967,[1] although some information had been published even earlier[40]. In these studies the complexes of lysozyme with various carbohydrates are referred to as enzyme-inhibitor complexes. This term probably arose as a result of the view, current at the time, that disaccharides are not substrates of lysozyme and trisaccharides hydrolyse slowly at concentrations corresponding to saturation (see Blake et al.[1], p. 385).

On the other hand, all these carbohydrates are capable of inhibiting the lysis of *Micrococcus lysodeikticus*. Recently the term "inhibitors", in relation to chitin or bacterial oligosaccharides, is used with decreasing frequency.

1. The Structural, Thermodynamic, and Functional Characteristics of the Binding Sites

Studies by English crystallographers have shown that the lysozyme molecule is a close-packed globule, close in shape to an ellipsoid of rotation with dimensions of $30 \times 30 \times 45$ Å. Across the globule, there is a deep cleft, which constitutes the active centre of the enzyme. In the formation of an enzyme–substrate complex, the carbohydrate is accommodated in the cleft; for each monomeric unit, there is a separate subsite—six in all. Consequently, the hexasaccharide molecule is capable of completely covering the cleft. Individual sorption subsites have been designated by the letters *A*, *B*, *C*, *D*, *E*, and *F*, starting with the subsite interacting with the non-reducing end of the hexasaccharide. Complexes with tetra-, penta-, and hexa-saccharides could not be detected by X-ray diffraction. The complex of lysozyme with a trisaccharide proved to be very stable and, moreover, the addition of the trisaccharide to the lysozyme did not affect the structure of the enzyme as a whole. Therefore, knowing the structure of lysozyme without the substrate, it was fairly easy to calculate the structure of this complex with the trisaccharide. It was found that the trisaccharide occupies subsites *A*, *B*, and *C* (*C* corresponds to the reducing end of the trisaccharide). Moreover, the retention of a certain rigidity by the enzyme structure on formation of its complexes with short substrates made it possible to obtain data concerning the structure of this enzyme–substrate complex too, by superimposing molecular models of the hexasaccharide onto the molecular model of lysozyme.

The very fact of the extrapolation of the structure of the enzyme–substrate complex to the *D*, *E*, and *F* subsites and confirmation of the validity of this extrapolation by all subsequent chemical and physicochemical data demonstrates quite clearly that the complementarity in the enzyme structure is not generated under the influence of the substrate but exists independently of the substrate. After the addition of the substrate to the lysozyme molecule, only insignificant structural changes take place. For example, a shift of the Trp 62 residue by 0.75 Å was noted.

Other residues also shift slightly, narrowing somewhat the cleft and giving rise to a closer contact between the enzyme and the substrate. However, an induced correspondence between the enzyme and substrate structures cannot be involved here. These changes in the enzyme structure can be more correctly regarded as an improvement of the existing complementarity in the interaction between lysozyme and the trisaccharide.

On the other hand, the substrate undergoes significant changes. Firstly, it loses the freedom of rotation about the C–O bonds joining the monomeric residues. Its structure becomes as rigid as that of the enzyme itself. Secondly, the rigid coupling of the enzyme to the substrate (hexasaccharide) forces the latter to alter the "chair" conformation of the pyrazine ring in one of the six subsites (*D*) and to assume a less stable and more strained "half-chair" conformation. This deformation of the structure of the carbohydrate unit at the *D* subsite is of decisive importance in catalysis by lysozyme. Measurement of the constants for the association of lysozyme with chitin and bacterial oligosaccharides by a wide variety of methods led to the determination of the energy of this interaction as the sum of the free energies of the interaction at all six subsites of the lysozyme molecule.

The results of these measurements are summarised in Chipman and Sharon's review[27] in the form of Table 2. The contributions $\Delta\Delta F_a^\circ$ introduced at each subsite separately are listed at the bottom of Table 2.

Table 2. Thermodynamic characteristics of the formation of enzyme–substrate complexes and of individual sorption subsites[27].*

Sorption subsite							ΔF_a^0, kcal mole^{-1}
X	A	B	C	D	E	F	
			NAG				−4.5(±0.3
		NAG	— NAG				−7.4
		NAM	— NAG				−7.9
	NAG	— NAG	— NAG				−9.2
	NAG	— NAM	— NAG				−9.8
	NAG	— NAM					⩾−4.2
	NAG	— NAM	— NAG	— NAM			⩾−6.9
	NAG	— NAM	— NAG	— NAM	—NAG	— NAM	−8.6
NAG	— NAG	— NAG	— NAG				−9.2
$\Delta\Delta F_a^0$, kcal mole^{-1}	0	−1.8	−2.9 ⩽−5.7	+2.9		−1.7	
			−3.4			(E+F)	

* NAG = *N*-acetyl-D-glucosamine; NAM = *N*-acetylmuramic acid.

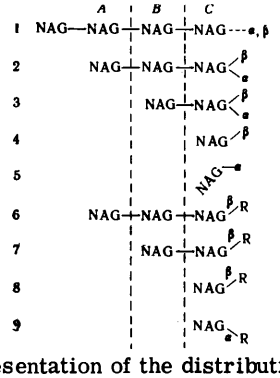


Table 2 shows that these contributions differ so significantly that they must be considered separately. The only subsite where there is a loss of energy is the *D* subsite, which can be readily explained by a change in the conformation of the carbohydrate residue at this site. On the other hand, the adjoining site is distinguished by the highest free energy gain, and hence the strongest binding of the substrate. According to data based on the crystallographic model, the sorbed *N*-acetyl-D-glucosamine is placed, as it were, in a hydrophobic "pocket".[41] In their paper dealing with the characteristics of the lysozyme complexes with various carbohydrates and related compounds, Rupley and coworkers[42] compared the free energies of formation of the lysozyme complexes with *N*-acetyl-D-glucosamine and *N*-methyl; *N*-hydroxyethyl-, and *N*-cyclohexyl-acetamides. They were found to be respectively −4.7, −2.4, −2.8 and, −3.1 kcal mole^{-1}. These and other data[42] show that the hydrophobic interaction of the acetamide group of the substrate makes a large contribution to the energy of formation of the complex. Thus a substrate with an *N*-acetamide group should always be sorbed in such a way that the *C* subsite is the first to be occupied.

It is readily seen that short chitin oligosaccharides (the dimer, trimer, and tetramer) should occupy subsites only to the left of *C* in Table 2. Phenomenologically this is shown by the finding that the affinity constant increases on passing from the monomer to the dimer and to the trimer, with very little change on further increase in the length of the substrate. The first quantitative data on this question were published by Dahlquist et al.[43], who obtained the following values for mono-, di-, tri-, tetra-, penta-, and hexa-saccharides: $(4-6)\times10^{-2}$, 1.75×10^{-4}, 6.58×10^{-6}, 9.45×10^{-5}, 9.35×10^{-6}, and 6.15×10^{-6}. The last two constants are only approximate, since even

before the attainment of equilibrium the substrates were partly hydrolysed. The data for the association constants of enzyme–substrate complexes obtained by different methods are presented in Chipman and Sharon's review[27]. The structures of the lysozyme complexes with chitin oligosaccharides and their glycosides have been investigated by NMR, which established the positions of all the residues[44].

In order to determine the positions of the remaining monomer units of the substrate in the active centre of lysozyme, measurements were made of the chemical shifts of the CH_3 protons of the acetamide groups of the chitin oligosaccharides in a free form and in their complexes with lysozyme. On formation of enzyme–substrate complexes, a shift of NMR signals towards higher fields and their broadening were observed. The acetamide groups of the chitin oligosaccharides acquire different magnetic environments on formation of the complex. This makes it possible to characterise each monosaccharide residue of the oligomer in terms of the corresponding resonance. The rule of the distribution of monomer units in the active centre of lysozyme was thereby confirmed. The *C* subsite is the first to be occupied and the remaining sites come into contact with the substrate in the following sequence: *B* first and then *A*. As shown above, this accommodation rule is fully consistent with thermodynamic characteristics. It is interesting that even the tetrasaccharide obeys this preferential accommodation rule. One of its residues is outside the region of the active centre and this disposition is more favourable, since accommodation at the *A*, *B*, *C*, and *D* subsites must lead to a loss of energy of 2.9 kcal $mole^{-1}$.

The situation involving bacterial oligosaccharides is somewhat more complex. According to X-ray diffraction data, the *N*-acetylmuramic acid (NAM) residue cannot be accommodated at the *A* and *C* subsites owing to steric hindrance[1]. For this reason, it is most probable that the NAG–NAM disaccharide is located at the *A* and *B* subsites, while the *C* subsite remains free.

Schematic representation of the distribution of *N*-acetyl-D-glucosamine (NAG) residues of oligosaccharides among the *A*, *B*, and *C* subsites of lysozyme[44].

As already mentioned, the last two subsites, *E* and *F*, were obtained by the extrapolation of X-ray diffraction data. They have been investigated experimentally much less satisfactorily. According to Sharon and coworkers[27,45], the long-lived glycosyl derivatives obtained by the elimination of the "aglycone" are located at the *A*, *B*, *C*, and *D* subsites, while the *E* and *F* subsites contain the acceptor molecules after the elimination of the aglycone residues. The formation of a lysozyme–acceptor complex cannot be recorded directly. However, this was achieved by a quantitative study of the products of the transglycosylation reaction[45]. Using as acceptors a mixture of two substances simultaneously, the authors inferred the proportions of the transglycosylation products formed from the relative rates of their formation. Comparison of two acceptors, glucose and *N*-acetyl-D-glucosamine, showed that hydrophobic interactions in the formation of the enzyme–substrate complex play an active role at the *E* subsite. Their contribution to ΔF can be estimated as -0.9 kcal $mole^{-1}$. It was discovered similarly that these interactions do not occur at the *F* subsite. Thus it was possible to estimate the overall contribution of the *E* and *F* subsites to ΔF, which is -1.7 kcal $mole^{-1}$ (Table 2). Evidently it is comparatively small and therefore, in order to drive the process towards transglycosylation, it is necessary that the acceptor concentration should be significantly higher than the donor concentration. The acceptor subsite of lysozyme as well as the donor subsite apparently do not undergo far-reaching changes on formation of the enzyme–substrate complex. Sharon and coworkers[46] tested 40 different monosaccharides and disaccharides as acceptors and showed that only those substances whose geometry corresponds to the surface of the *E* subsite may function as acceptors: only 29 acceptors were found. The remaining 11 substances are not complementary in relation to the *E* subsite and do not react at all. It is most interesting that a geometrical correspondence can be achieved by accommodating the acceptor in different ways. For this reason not only hexoses but also pentoses and even carbohydrates of the L-series can function as acceptors and the glycosidic linkages formed are not only of the β-(1–4) type but also of the β-(1–2)- and β-(1–3)- types. The reactivity of the acceptors could be predicted on the basis of data for the structure of the *E* subsite. For example, D-xylose can be accommodated at the *E* subsite in three ways, which correspond to the formation of products with 1–2, 1–3, and 1–4 glycosidic linkages[49].

2. Productive and Non-productive Enzyme–Substrate Complexes

The thermodynamic properties of the sorption subsites in the active centre of lysozyme account for the existence of the so called non-productive complexes. The very name "non-productive" complexes implies that the formation of such enzyme–substrate complexes does not lead to the dissociation or formation of covalent bonds. English crystallographers, who devised models of lysozyme, postulated that the dissociation of the glycosidic linkage in an oligosaccharide can take place only between units at the *D* and *E* subsites[1]. Further experimental studies confirmed this hypothesis and it is now generally accepted[27]. As shown above, the sorption of di-, tri- and tetra-saccharides take place preferentially at the *A*, *B*, and *C* subsites, i.e. outside the region of glycosidic linkages. Consequently all these complexes, the preferential formation of which is observed at substrate concentrations corresponding to saturation, are non-productive. For this reason, they were readily detected by X-ray diffraction analysis and a wide variety of physicochemical methods[27].

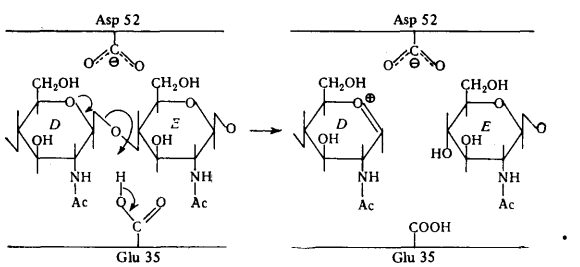
In order to form a productive complex, it is necessary to overcome the energy barrier associated with sorption

at the *D* subsite. It is readily seen that the barrier for oligosaccharides produced by the fragmentation of chitin can be overcome only as a result of the simultaneous coverage of almost all the sorption subsites in the lysozyme active centre. Productive complexes with such oligosaccharides can be obtained only with the hexasaccharide or possibly the pentasaccharide. This conclusion is proved, in particular, by the application of a competitive inhibitor such as the dye Biebrich scarlet[36], which is capable of being specifically sorbed in the region of the active centre. The affinity constants for the productive and non-productive complexes of tri-*N*-acetylchitotriose with lysozyme were determined with the aid of this inhibitor. They are respectively 1.0×10^{-2} and 1.5×10^{-5} mole litre^{-1}. The number of non-productive complexes formed is greater by almost 3 powers of ten than that of the productive complexes. The affinity constant for the productive complex of the hexasaccharide was estimated in this investigation as 5×10^{-6} mole litre^{-1}, which is very close to the affinity constant for the non-productive complex of the substrate.

Cases have been described where short oligosaccharides can form preferentially productive complexes. For example, *p*-nitrophenyl-4-O-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-β-D-glucopyranoside can be slowly hydrolysed by lysozyme without complication by the transglycosylation reaction[39]. The carbohydrate residues of this disaccharide occupy the *C* and *D* subsites and the nitrophenyl glycosidic linkage is in the cleavage zone, which makes possible direct hydrolysis without transglycosylation. A similar result was obtained for trisaccharides with D-glucose, D-xylose, and D-galactose residues at the reducing end, the last being hydrolysed much faster than all others[47]. In this case too only a productive complex of the *CDE* type (*C* = NAG, *D* = NAG, and *E* = galactose) is probably formed.

3. Interpretation of the Molecular Mechanism

Without assuming the molecular mechanism of hydrolysis via transglycosylation, it is impossible to combine the data for the structural and thermodynamic characteristics of the sorption subsites of lysozyme. These characteristics and also the hypotheses concerning the productive and non-productive complexes of lysozyme with substrates which follow from them show that in the course of the enzymatic reaction a hexasaccharide or a longer oligosaccharide functions continuously on the surface of the active centre. It is either lengthened as a result of transglycosylation or shortened as a result of hydrolysis and the cyclic process ultimately results in the hydrolysis of the short oligosaccharide involved in the reaction in the transglycosylation stage as an acceptor. The presence of a small amount of a long oligosaccharide is necessary for the effective hydrolysis of short oligosaccharides, the long oligosaccharides behaving as the "seed" in the reaction.



The degree of hydrolysis of the oligosaccharide depends on its structure. Chitin trisaccharides and tetrasaccharides are almost completely cleaved to the monomer[19], while the bacterial trisaccharide is cleaved only to the dimer[26]. This difference can be explained by the fact that the NAM residues in bacterial oligosaccharides cannot be accommodated at the *A*, *C*, and *F* subsites. Moreoever, the inhibiting action of the reaction product on the enzyme is more marked for a disaccharide than for a monosaccharide, since the former is sorbed more strongly.

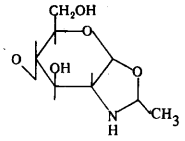
V. THE ELECTRONIC MECHANISM

1. X-Ray Diffraction Data

Analysis of the structure of lysozyme complexes with substrates also makes it possible to put forward a hypothesis concerning the electronic-conformational principles of catalysis in this specific case. Investigators began with the assumption that the lysozyme complex with tri-*N*-acetylchitotriose (at the *A*, *B*, and *C* subsites), which they detected, is unreactive or non-productive. The complex which is undetectable by this method must be reactive. The most probable site of the dissociation of glycosidic linkages is between the *D* and *E* subsites. The only ionogenic groups located within the cleft and capable of participating in proton transfer are two carboxy-groups (the β-COOH group of Asp 52 and the γ-COOH group of Glu 35), which are located on either side of the β-(1—4)-glycosidic linkage of the substrate. The Glu 35 residue is located preferentially in the non-polar region near the bottom of the cleft, which must hinder the dissociation of the COOH group. Indeed, the pK_a values for these groups are about 6 while the usual value is 4.5—4.6. The Asp 52 residue is in the polar region and is linked by hydrogen bonds to amide groups which behave as proton acceptors. This facilitates the dissociation of the COOH groups of this residue. Their pK_a values are displaced to the acid region compared with the normal value (about 4 and about 4.5 respectively). Thus, by virtue of the rigid fixation of these functional groups and the formation of a stable microenvironment around each, they are ionised to different extents.

A second feature of the conformational-electronic mechanism of the action of lysozyme is the deformation of the glucopyranose ring at the *D* subsite. The stereochemical characteristics of the *D* subsites are such that the carbohydrate residue assumes the half-chair conformation. This is associated with energy consumption (see above), which is compensated by the binding energy at other sorption subsites. However, such deformation promotes the heterolysis of the glycosidic linkage, since it corresponds to a stable conformation of the carbonium ion. The role of the carboxy-groups in this process is that one of them (Glu 35) initiates the heterolysis of the glycosidic linkage, while the other (Asp 52) stabilises the intermediate cation. The mechanism of this process can be represented as follows:

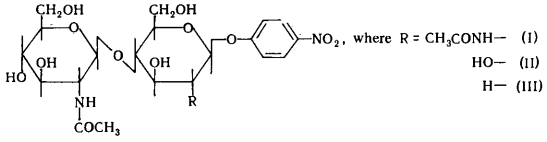
The free carbohydrate residues are desorbed from the *E* and *F* subsites and the reaction is subsequently completed either by the addition of water (hydrolysis) or by sorption of other oligosaccharides at the *E* and *F* sites and the formation of a new glycosidic linkage (transglycosylation). Thus general acid catalysis obtains in the mechanism of the action of lysozyme.



2. Chemical and Physicochemical Studies

Chemical and physicochemical studies should demonstrate the validity of the reaction mechanism put forward on the basis of structural data. Methods involving chemical modification of lysozyme established that the only groups involved directly in catalysis are the carboxy-groups[48,49]. The ϵ-NH_2 groups of the lysine residues, the terminal NH_2 group of lysozyme[43-50], the single histidine residue[50,52,54], the guanidino-groups of arginine[53], and the phenolic hydroxy-groups of tyrosine[50] can be completely blocked chemically without loss of the entire enzyme activity. In certain cases such modification led to a partial decrease of activity and in others to an increase[51,52,54]. The activity was determined as a rule turbidimetrically on the basis of the solvent action of the enzyme on a suspension of *Micrococcus lysodeikticus* bacteria. Naturally the dissolution of the bacterial suspension (lysis) is influenced by too many factors for a direct relation to be established between the quantitative changes in activity and structural factors. However, when it was possible to modify lysozyme at its carboxy-groups, a completely inactive derivative was obtained in many cases. The lysozyme molecule contains only 11 carboxy-groups (two glutamic acid residues, 8 aspartic acid residues and the *C*-terminal group). When the carbodi-imide method was used, it was possible to join to the carboxy-groups amino-derivatives such as $H_2NCH_2SO_3H$, $H_2NCH_2COOCH_3$, and $H_2NCH_2CONH_2$. One of the COOH groups of the active centre (Glu 35) cannot be amidated, while the other group (Asp 52) can be blocked, the substrate (trisaccharide) hindering the reaction[55,56]. The complete inactivation of the enzyme on blocking Asp 52 and the effect of the substrate on the reaction showed that this group is of critical importance for the activity. Similar results were obtained also on alkylation of lysozyme using triethyloxonium tetrafluoroborate as the alkylating agent[50,57]. This yielded a mixture of products, which was resolved by ion-exchange chromatography. Two monoalkylated lysozyme derivatives were isolated in a pure form, one of which was inactive but could be reactivated spontaneously at pH 2.0.[50] It was shown that this lysozyme derivative contains an alkylated COOH group of the Asp 52 residue[57]. The direct catalytic action of the carboxy-group of Glu 35 and Asp 52 is confirmed also by the finding that the blocking of all other carboxy-groups does not lead to complete loss of activity by lysozyme[55,56].

Both groups have unusual chemical properties. The Glu 35 residue is chemically inert although Lin and Koshland[56] claim that this group is sterically accessible for reaction. Ethyl-lysozyme (ethylated at Asp 52) also has unusual chemical properties. The ester linkage in this compound is incapable of involvement in nucleophilic substitution, is resistant to alkaline hydrolysis and the action of hydrazine and hydroxylamine, and is not reduced by $LiAlH_4$.[57]



The mechanism of the chemical (non-enzymatic) hydrolysis of glycosides has been described in a review[58]. Therefore, it was natural to suppose that the carboxy-group of Glu 35 exhibits a catalytic activity via the mechanism of general acid catalysis. It protonates the glycosidic oxygen, which leads to the dissociation of the glycosidic linkage and the formation of a carbonium ion. As shown in the formula illustrated above, the dissociation of the glycosidic bridge at the C_1—O bond was demonstrated using water with the oxygen-18 isotope.

Raftery and Rand-Mair examined five probable electronic mechanisms of the cleavage of glycosidic linkages[33], two of which led to the formation of α-glycosidic linkages. These two mechanisms were rejected, since the authors showed that only the β-methyl glycoside of *N*-acetyl-D-glucosamine can be detected among the products of the reaction of di-*N*-acetylchitobiose with methanol. If the α-glycoside is in fact formed, its amount cannot exceed 0.3% in relation to the total content of methyl glycosides[59]. Consequently the reaction takes place with retention of the configuration at C_1 atom. Such a reaction could take place via Koshland's double nucleophilic substitution mechanism[60]. Moreover, there is a possibility of a mechanism involving the acetamide group (anchimeric cooperation) via a stage in which an oxazoline derivative is formed[61].

In experiments with model reactions, it was shown that the involvement of the acetamide group tends to accelerate the hydrolysis of the glycosidic linkage by a factor of 1000.[62] Finally, there is a possibility of a mechanism of the cleavage of the glycosidic linkage via a stage involving the formation of a carbonium ion, but with retention of the configuration at the $C_{(1)}$ atom owing to the oriented addition to the carbonium ion of the appropriate nucleophilic agent (water in hydrolysis or another acceptor in transfer).

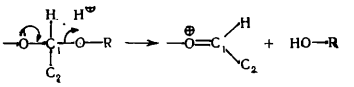
For a final solution of this problem by a kinetic method, it is important to choose the substrate correctly, since the reaction investigated must proceed via a unique pathway. For this purpose, three substances of the type

were synthesised and it was shown that, when lysozyme acts on substance (I), a mixture of different carbohydrates is formed, while only the corresponding disaccharides could be isolated chromatographically from substances (II) and (III).[39] The association constant of the complex of lysozyme with (II) was determined by NMR (K_S = $1.5 \pm 0.3 \times 10^{-2}$ mole litre^{-1}) and it was found to agree satisfactorily with the Michaelis constant (K_m = $2.3 \pm 0.8 \times 10^{-2}$ mole litre^{-1}). Bearing in mind that the NAG residue in (III) is very strongly sorbed on the *C* subsite, one must conclude that (III) forms only a productive complex with lysozyme. This substrate was found to be most suitable for kinetic studies. The method of the secondary kinetic isotope effect (α-deuterium) was used for the solution of this problem[63]. Table 3 presents the characteristics of the secondary isotope effect for the hydrolysis of compound (III) under different conditions. Typical S_N2 reactions have rate constant ratios k_H/k_D of about unity (hydrolysis by sodium methoxide) and S_N1 reactions have a ratio of about 1.14 (hydrolysis by hydrochloric acid). Over a wide pH range, lysozyme has an isotope effect which corresponds to a considerable extent to an S_N1 reaction mechanism. For comparison, the authors investigated the mechanism of the hydrolysis of compound (III) catalysed by almond β-glucosidase and found that the

mechanism of the action of this enzyme is fundamentally different.

Lowe and coworkers[61,64,65] showed in a number of studies that the hydrolysis of oligosaccharides catalysed by lysozyme proceeds via the formation of an oxazoline derivative of the carbohydrate. They found that the kinetics of the hydrolysis of the *p*- and *o*- nitrophenyl glycosides of di-*N*-acetylchitobiose obey the Michaelis–Menten equation. However, despite the extensive investigations which they carried out, their conclusions concerning the involvement of the acetamide group in the catalytic reaction cannot be regarded as reliable, since in this instance the Michaelis–Menten equation was obeyed in a purely formal manner and lacked the physical significance usually attributed to it. In the study quoted above[63], it was shown that, when lysozyme acts on compound (I), a mixture of products is formed and that this substrate is unsuitable for kinetic studies on the electronic mechanism: therefore, the conclusions of Lowe and coworkers are groundless. The digestion of such substrate proceeds via a hydrolytic mechanism involving transglycosylation, as shown for nitrophenyl glycosides by Osawa[28]. The mechanism via the oxazoline derivative is also criticised in Chipman and Sharon's review[27].

Table 3.



Conditions of hydrolysis	k_H/k_D
2 *N* HCl, 50°	1.13
3 *N* $NaOCH_3$, 70°	1.03
β-Glucosidase	1.015
Lysozyme	—
pH 5.5	1.11
pH 3.1	1.11
pH 8.3	1.11

3. Theory of Chemical Conjugation as One of the Preconditions for the Electronic Mechanism of the Action of Lysozyme

A characteristic feature of lysozyme catalysis discussed above is the obligatory action of the enzyme on the structure of the glucopyranose ring at the *D* subsite. Usually this is regarded as confirmation of the earlier hypotheses of the deformation and strain of the bonds undergoing dissociation on the surface of the active centre of the enzyme[1,27,58]. However, it is important to emphasise also the problem of the role of the conjugation of chemical bonds in biocatalysis. It is thereby possible to establish a relation between the classical concepts of organic chemistry and the concepts underlying the mechanism of biocatalysis.

The theory of bond conjugation and the effect of conjugation on reactivity were developed in organic chemistry a long time ago. One of the principal postulates concerning the conjugation of single bonds, which were developed by Nesmeyanov[68], is that specific stereochemical requirements must be met. The large class of organic reactions which occur as a result of the conjugation of single bonds, has been called "fragmentation reactions", which were studied on a wide scale both theoretically and experimentally by Grob and coworkers[68]. We have already mentioned that Grob's theory[67] of the fragmentation of organic substances is consistent in its main postulates with Nesmeyanov's theory of the conjugation of single bonds[66]. The differences between these theories concern mainly the terminology. Grob uses terms such as "stereoelectronic factor" and "frangomeric acceleration",[68,69] which reflect essentially the influence of molecular conformation on the reaction rate. It has also been suggested that the above frangomeric acceleration may be one of the factors in biocatalysis (Kossower[70]).

In the present author's studies on the fragmentation of α-aminoacids with a tertiary nitrogen atom, it was concluded that, by virtue of steric hindrance, the α-aminoacid molecule can assume a fixed conformation which is the most favourable for the conjugation of single bonds[71,72]. In this case the rotation in the aminoacid molecule about the N–C bond is hindered and the conformation is fixed in consequence of steric hindrance due to the bulky substituent at the nitrogen atom. The conformation of the substrate molecule is also fixed on formation of an enzyme–substrate complex. One cannot conclude that the fixation of the conformation is favourable for *p*, σ conjugation of the following type:

As a result of this conjugation, the transition state exists partly in the oxonium form with a double bond. The present author called this factor in biocatalysis "inclusion of conjugation" or the "steric-orientation factor".[73]

The molecular and electronic mechanisms of the action of lysozyme are interrelated. In order that the energy of the "chair–half-chair" transformation should be compensated by the energy of the formation of the enzyme–substrate complex, the involvement of six (or five) sorption centres is essential.

VI. CERTAIN UNSOLVED PROBLEMS

The study of the mechanism of the action of lysozyme constitutes an example of a combined investigation of a large research problem. For many reasons, lysozyme has proved convenient for study by X-ray diffraction. However, at the time of the completion of this review there were very few chemical and physicochemical data concerning the mechanism of its action on a substrate. Substrates with specific chemical characteristics became known only in 1960. The published X-ray diffraction data (1965–1967) on the structure of lysozyme and its complexes with substrates stimulated chemical and physicochemical research. In the course of approximately 5–6 years (1964–1969), almost all the details of the mechanism of the reaction of lysozyme were elucidated in a number of laboratories in the USSR, USA, England, Japan, France and other countries. The complete agreement between the chemical and physicochemical data on the one hand and the X-ray diffraction data on the other suggests that the mechanism of the action of lysozyme has been largely established correctly and fully.

However, there are still certain problems which require further investigation. These are related, in particular, to the nature of the structural changes in lysozyme in the pH range 6–7, which are reflected in its activity. The dissociation constants of both the imidazole group, the single histidine residue which is not involved directly in catalysis, and of the anomalous carboxy-group of Glu 35, which plays a key role in catalysis, have p*K*

values corresponding to the pH range. The dissociation of the carboxy-group, which occurs on increase of pH to 6—7 and above, is probably accompanied by changes in the details of the enzyme structure which increase the tendency towards aggregation of both native[74,75] and irradiated[76,77] protein in this pH range. It has been shown by NMR that the dimerisation of native lysozyme in solution takes place via the surface of the enzyme adjoining the region of the active centre[78]. The nature of the interaction of lysozyme with chitin is also obscure.

A detailed study showed in the first place that this interaction takes place as a result of a specific enzyme—substrate affinity. In the second place it was established that there exist two complexes between lysozyme and chitin, differing in a number of properties, particularly in the fact that one is formed preferentially at a pH below 6—7 and the other is formed under more basic conditions[79-82]. Since no other methods (differential ultraviolet spectroscopy, fluorescence, NMR spectroscopy, etc.) indicated the existence of two different lysozyme complexes with water-soluble substrates, the data obtained for the interaction of lysozyme with water-insoluble chitin can be interpreted as due to a characteristic feature of chitin itself, since, in contrast to low-molecular-weight and water-soluble substrates, chitin sorbs lysozyme molecules not only via an enzyme—substrate interaction but also as a result of forces acting on the interface between the solid (chitin) and liquid (solution) phases.

The study of the catalytic activity at high pH is also by no means complete. When lysozyme was allowed to act on *Micrococcus lysodeikticus* bacteria, it was noted that the dependence of the activity on the pH has a second maximum at pH 9.2.[83-85] Since it is unlikely that the carboxy-group of Glu 35 is protonated in this pH range, it was suggested that under these conditions general acid catalysis is not due to Glu 35 but to the ϵ-amino-group of Lys 97 located at the outlet from the cleft[84]. Later it was concluded[85] that the sorbed substrate (bacterial cell) affects the dissociation of Glu 35 in such a way that, owing to electrostatic interaction, it remains in an undissociated form even at pH 9.2. According to these data, tetra-*N*-acetylchitotetraose (an uncharged substrate) is not hydrolysed by lysozyme at pH in excess of 8.[85]

It has also been observed[86] that the pH optima for the hydrolase and transferase activities of lysozyme do not coincide: hydrolysis takes place preferentially at a lower pH and the synthetic activity is shown to a greater extent at an elevated pH (particularly at pH 8—9). The change in the type of catalytic activity of lysozyme on altering the pH may be attributed to the dissociation of the carboxy-group of Glu 35 and a correspondong change in the state of aggregation of the enzyme. The present author suggested[86] that the hydrolysis is due to the monomeric lysozyme molecule and transglycosylation is due to the dimeric molecule. One must emphasise that, over the entire region of the active centre, the *E* and *F* subsites have been most conclusively investigated; as stated above, the role of acceptor subsites is attributed to them.

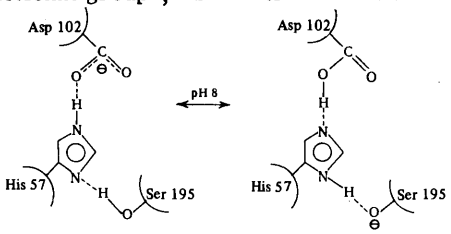
However, the interrelations between the sorption of the substrate, catalysis, and the degree of aggregation of the enzyme, proved to be more complex than might have been expected. Many data show that the degree of activation of native[87-90] and irradiated[91,92] lysozyme is reduced in the presence of a substrate. Moreover, an impression has been created that the inhibiting action of the substrate on the dimerisation of lysozyme is shown even after its complete elimination. If this is so, the substrate induces structural changes in lysozyme, which persist for a long time[93]. In this case, one may be dealing with the so called subtle conformational changes. One should probably include among them those induced by the substrate at the opposite end of the enzyme molecule, which have been detected by the paramagnetic probe method[95].

---o0o---

Lysozyme proved to be the first enzyme the most important details of the mechanism of whose action have been elucidated. It has also become clear that this mechanism cannot be extended to all related enzymes (glycosidases). Therefore, it is important to be able to isolate correctly the most general principles of biocatalysis constituting the basis of the mechanisms of the action of enzymes in general. In order to stay close to lysozyme, we shall consider as an example the hydrolysis of the glucosidic linkage. In order that the hydrolysis should follow the reaction pathway via the carbonium ion, it is necessary that (1) the glucosidic oxygen should be protonated, (2) that appropriate changes should occur in the conformation of the glucopyranose ring, and (3) that the negatively charged ion in the vicinity of the carbonium ion should assume an appropriate orientation. Each of the three conditions enumerated above is achieved with a certain degree of probability. The probability of the simultaneous coincidence of all three conditions is expressed by the products of the above three probabilities. We enumerated only the most important conditions responsible for the catalytic activity of lysozyme. In the general case the number of conditions may be even greater. The probability of the occurrence of a chemical reaction is equal to the product of the probabilities f_i of the occurrence of each condition:

$$f = f_1 \cdot f_2 \cdot f_3 \cdots f_n, \text{ where } f_i < 1$$

The greater the number of conditions involved in the mechanism of the process the smaller its overall probability. By altering the external parameters of the medium it is possible to achieve a sharp increase of the individual components of the probabilities f_i. For example, the hydrolysis of glycosides by acids implies a sharp increase of the probability of the protonation of the glycosidic oxygen (f_1) by collisions with protons (hydronium ions). An increase of temperature increases the probability of the occurrence of the transition state conformation (f_2). However, a simultaneous increase of the probabilities of the protonation (f_1) and orientation of the negative ion (f_3) in chemical systems is virtually unattainable. Only in certain individual cases, known as concerted action mechanisms, is this situation realised in non-enzymatic reactions. The familiar catalytic action of 2-hydroxypyridine on the mutarotation of glucose may serve as an example. This reaction is in fact usually regarded as one of the models of the enzymatic process. The orienting effect of the enzyme, which according to Koshland[96] ensures the mutual approach and appropriate orientation of the reacting sites in the substrate molecules, essentially reduces to an increase of the probability of occurrence of the conditions governing the transition state.



In lysozyme catalysis, the probability of each of the three conditions is very high, owing to the relatively rigid fixation of the "working" functional groups and their rigorous stereochemical correspondence to the substrate. A weak acid such as Glu 35 with $pK_a = 6—7$ protonates the glycosidic oxygen with the same high probability as, for

example, hydrochloric or sulphuric acid. The conformation of the transition state is determined by the stereochemical characteristics of the *D* subsite and its probability is probably very close to unity. The probability of the required orientation of the negative ion (of Asp 52) is just as high. The behaviour, which in a chemical process is a consequence of a random favourable combination of several conditions for the occurrence of the reaction, in an enzymatic process is programmed in the structure of the protein molecule. This in fact ensures a high efficiency of enzymatic catalysis.

The function of the enzyme is to organise the chemical process, drive it along a specific reaction pathway, and ensure a high probability of the necessary reaction conditions. This directing influence of the enzyme is possible only if the enzyme itself has a fairly rigid fixed structure. In low-molecular-weight compounds the rigidity of structure can be achieved mainly via covalent bonds, as, for example, in polycyclic steroid systems. In high-molecular-weight compounds the rigidity of structure is ensured by the compact packing of the polypeptide chain into globules and by non-covalent interactions. X-Ray diffraction analysis has shown that a wide variety of proteins have a close-packed globular structure with rigidly fixed positions of the polypeptide chains[97]. Therefore, when one speaks of the induced correspondence between the enzyme and the substrate, widely known as Koshland's hypothesis, such induction must be restricted to very small displacements of the atoms in the enzyme molecule. In lysozyme these shifts do not exceed a distance of 1 Å. Such slight structural changes in the protein can hardly serve as an adequate basis for the assertion of conformational flexibility, particularly since deformations of valence angles and distances are usually involved and not conformational changes.

The high molecular weight of the enzyme and its compact and rigid globular structure ensure the fixation of the individual functional groups, which leads to the appearance of new properties and phenomena unknown in organic chemistry. As a result of their fixed position, these groups remain in an almost unchanged microenvironment and their properties depend sharply on each specific microenvironment. In organic chemistry the functional group of any molecule is subject to the influence of a constantly varying microenvironment and the properties observed experimentally are as a rule macroproperties averaged with respect to the properties of the numerous microenvironments of the given group. Moreover, as a result of the fixation of the functional group in the rigid globule of the enzyme, there is also a possibility of the formation of structures which are unusual for organic chemistry. The above ideas can be illustrated by a number of examples.

The Asp 52 residue in the lysozyme molecule is fixed in a zone of enhanced nucleophilicity. It can be readily esterified by triethyloxonium tetrafluoroborate, but the resulting ester does not enter into nucleophilic substitution reactions (see above). The serine hydroxyl, which enters into the active centre of chymotrypsin, has unusual chemical properties. In this instance the enzyme exhibits a type of conjugation of chemical bonds which is unknown in organic chemistry. It would probably be correct to call it transannular conjugation, since it resembles most closely the transannular interaction in macrocyclic compounds. As a result of the rigid fixation of the functional groups in chymotrypsin, the geometrical disposition of Asp 102, His 57, and Ser 195 ensures chemical conjugation of their functional groups, as illustrated below:

The His 57 and Asp 102 residues are immersed in the globule and are not in contact with the solution. The Ser 195 residue projects onto the surface. As a result of this conjugation, the usual aliphatic hydroxy-group is capable of dissociation at pH 8, i.e. as regards this property it resembles the hydroxy-group of nitrophenol. As in catalysis, the probability of transannular conjugation in a mixture of the above three aminoacids is negligibly small, whereas in a protein it occurs with a probability of unity as a result of steric proximity.

The chemistry of proteins provides in addition examples of unusual structural formations. For instance, in lysozyme crystals one of the contacts between neighbouring enzyme molecules has a structure resembling the sandwich structures familiar in the chemistry of organometallic compounds. This structure is formed with participation of the benzene ring of phenylalanine in one lysozyme molecule and the phenolic ring of the tyrosine residue in another molecule. The guanidino-group of arginine in the form of a cation linked to a Cl^- anion is located between the parallel rings. Such a structure is stabilised by additional hydrogen bonds.

Biocatalysis is merely a special manifestation of the characteristics of the chemistry of proteins arising by virtue of their organised and almost time-invariant molecular structure.

Semi-empirical Quantum-mechanical Methods for the Calculation of Molecular Geometry and Conformational Energies

V.G.Dashevskii

The LCAO-MO approximation is considered in the Hartree-Fock problem for many-electron systems, and Roothaan's equations are given, various "simplifications" of which form the foundation for most current semi-empirical methods for calculating the electronic structure of polyatomic molecules. Accounts are given of the most popular semi-empirical schemes enabling the geometry of a molecule to be predicted and several related properties—conformational energies, barriers to internal rotation, and energies of formation—to be calculated. The possibilities and limits of application of these methods are discussed. A list of 171 references is included.

I. INTRODUCTION

The geometry of the ground state of a molecule is not only of purely structural interest but also, in the broad sense of the word, of chemical interest. Indeed, the thermochemical properties of molecules—differences in energy between rotational isomers, barriers to internal rotation, and heats of formation, hydrogenation, and structural isomerisation—are related to their geometry; frequencies of the vibrational spectra of polyatomic molecules, absorption in the microwave range due to transitions from one rotational level to another, and even electronic spectra are directly dependent on geometry; and finally the effect of the steric factor in reactions, especially organic, is only rarely negligible. Hence it is not surprising that calculations of molecular geometry, conformations, and the energies associated with confirmational transitions occupy an important place in current theoretical investigations.

The present Review covers calculations of bond lengths, valency angles, and conformations, mainly of polyatomic organic molecules. If a method is available for calculating the total energy of a molecule, the equilibrium geometry will clearly correspond to an absolute minimum in the total energy expressed in terms of independent geometric variables, in particular bond lengths, valency angles, and angles of rotation. The total energy surface may have not one but several minima, which, when they appear with variation of angles of rotation about bonds, are claimed to correspond to stable conformers. The difference in energy between conformers determines their

equilibrium in the gas phase (when interactions between molecules can be neglected). Saddle-points in the total energy surface, encountered on the way from one minimum to another, correspond to barriers to internal rotation or inversion, which are measured by various physicochemical methods.

Until the mid-1960s almost the sole method for calculating geometry and conformational energies was the classical model of a molecule, in which the potential energy is regarded as the sum of several contributions—deformation energies of valency bonds and angles, torsional stresses, etc.—and which has several names—the mechanical model of a molecule, the molecular force field model, and the Hill–Westheimer–Kitaigorodskii–Hendrickson–Wiberg model—the last name indicating the workers who have made the most significant contribution to the creation and development of the model[1-5]. The mechanical model has been used for numerous calculations of the conformations of organic molecules (see reviews[6-8]), macromolecules, and biopolymers[9-12], as well as energies of formation of molecules from atoms[13-15], vibrational frequencies in the spectra of polyatomic molecules[16,17], etc. Without doubt this simple model will for a long time yet be a powerful tool in the hands of physical chemists: it may be just as necessary in the present stage of the development of theoretical chemistry as three-dimensional models of molecules were necessary fifteen years ago (when methods of calculation were in a rudimentary state). It must be borne in mind, however, that a mechanical model of a molecule cannot be rigorously based on the fundamental laws of physics: it does not follow directly from the Schrödinger equation, and its constants are chosen by a purely empirical procedure. Although the predictive power of this model is very great, the fact that the nature of the interactions between electrons and nuclei is concealed in empirical constants often leaves a feeling of dissatisfaction.

Quantum-mechanical methods of calculation—both semi-empirical and non-empirical (calculations *ab initio*)—have become widespread during the past decade. This is due primarily to the creation of effective algorithms for evaluating quantum-mechanical integrals, to the elaboration of new semi-empirical methods, and finally to the development of computational technique (though electronic computers are required also for calculations based on the mechanical model) and the founding of the International Exchange Fund for Programmes on Quantum Chemistry. Quantum-mechanical methods are based on seeking approximate solutions of the Schrödinger equation, with many integrals neglected in semi-empirical methods, while many are parametrised by means of experimental data. Of course, calculations *ab initio*, in which no constants other than the fundamental physical constants—e, m, and h, (the charge and mass of the electron and Planck's constant)—are used, are preferable from any point of view, but the rapid action and the memory of present-day computers enable such computations to be made only for relatively simple molecules. Hence the need to work out semi-empirical methods, enabling results of importance for the chemist to be obtained with a relatively short machine time and by means of not very complicated programmes.

II. ROOTHAAN'S EQUATIONS AND POSSIBLE MODES OF "SIMPLIFICATION"

The non-relativistic "electronic" Schrödinger equation for a molecule containing N electrons can be written

$$H\Psi = E\Psi, \qquad (1)$$

$$H = \sum_{i=1}^{N} -\frac{1}{2}\nabla_i^2 - \sum_{i=1}^{N}\sum_{\alpha} Z_\alpha/R_{\alpha i} + \sum_{i=1}^{N}\sum_{j=i+1}^{N} 1/r_{ij}, \qquad (2)$$

where $\Psi \equiv \Psi(x_1, x_2, \ldots, x_N)$ is the wave function depending on the spatial and spin coordinates x_i of the electrons, E is the energy, and H is the electronic Hamiltonian, representing the sum (2) of the kinetic energy operators of the electrons, the potential energy of attraction of electrons to nuclei, and the potential energy of mutual repulsion of the electrons. Atomic units in which $m = e = h = 1$, have been used in Eqn. (2): the eigenvalues obtained for the energy operator H will then also be expressed in atomic units or hartrees (1 a.u. $\equiv$ 1 hartree = 27.210 eV = 627.46 kcal mole^{-1}). Furthermore, Z, R, and r in (2) denote respectively the charge on the nucleus, the distance between electrons and nucleus, and the distance between electrons; the subscripts i and j refer to electrons, and the subscript α indicates nuclei; and ∇_i^2 is the Laplace operator for the ith electron.

The electronic Schrödinger equation emerges in the Born–Oppenheimer approximation, according to which the motions of electrons and nuclei in a molecule can be regarded with sufficient accuracy as independent. In order to obtain the total energy of the molecule, however, the eigenvalue E of the electronic equation (1) must be supplemented by the potential energy of repulsion of the nuclei V_{nn}, which is given by the formula

$$V_{nn} = \sum_{\alpha}\sum_{\beta(\neq\alpha)} Z_\alpha Z_\beta/R_{\alpha\beta}, \qquad (3)$$

where the subscripts α and β refer to nuclei. Thus the Born–Oppenheimer approximation enables the problem of the quantum-mechanical calculation of a molecule to be solved with fixed nuclei, their interaction being taken into account only after the "electronic" calculation.

The difficulty in solving Eqn. (1) with the Hamiltonian (2) is due mainly to the large number of independent variables and the presence of terms of the form $1/r_{ij}$. The model of independent electrons (the Hartree–Fock model) permits considerable simplification of the problem, by introducing for each electron the mean potential V_i produced by the other electrons and the nuclei. Instead of (2) we can then write

$$H = \sum_{i=1}^{N}\left[-\frac{1}{2}\nabla_i^2 - \sum_{\alpha}\frac{Z_i}{R_{\alpha i}} + \bar{V}_i\right] = \sum_{i=1}^{N} h_i^{\text{eff}}. \qquad (4)$$

The total energy calculated with the self-consistent field (Hartree–Fock) approximation differs substantially from the true total energy, owing to the neglect of "instantaneous" interactions of the electrons (or collisions): thus for the ethane molecule this difference amounts to 0.8 a.u. or ~ 500 kcal mole^{-1}![18] However, many properties of molecules are reproduced quite well by Hartree–Fock calculation. We first note that bond angles and lengths, angles of rotation, energy differences between rotational isomers, and barriers to internal rotation can be obtained in terms of a model of independent electrons (non-empirical calculations with large basis-sets are envisaged) with an accuracy only slightly inferior to that of the best experiments. We shall therefore regard the self-consistent field approximation as almost the exact Schrödinger equation for the molecule, and use it as a basis for comparing the various semi-empirical methods.

A solution of the Hartree–Fock problem is usually sought in the form of spin orbitals ψ, each of which is written as a product $\psi_i(x_\rho)\sigma_i$, where $\psi_i(x_j) \equiv \psi_i$ is the ith molecular orbital (MO), depending only on the spatial

coordinates x_j of the jth electron, and σ_j is the spin coordinate, assuming the value either $\eta_+(j)$ or $\eta_-(j)$. The molecular orbital ψ_i is presented as a linear combination of atomic orbitals (LCAO) $\varphi\nu \equiv \varphi_\nu(x_j)$:

$$\psi_i = \sum_\nu c_{i\nu}\varphi_\nu. \tag{5}$$

Denoting the ith spin orbital of the jth electron with the spin coordinate $\eta_+(j)$ as

$$\psi_i(j) = (\Sigma_\nu c_{i\nu}\varphi_\nu)\,\eta_+(j),$$

and with the spin coordinate $\eta_-(j)$ as

$$\psi_i(j) = (\Sigma_\nu c_{i\nu}\varphi_\nu)\,\eta_-(j),$$

we write the approximate wave function Ψ for a molecule with a closed electron shell (even number of electrons N) as the antisymmetrised product of the spin orbitals or the Slater determinant

$$\Psi = A\begin{vmatrix} \psi_1(1)\,\psi_1(2) & \dots & \psi_1(N) \\ \bar{\psi}_1(1)\,\bar{\psi}_1(2) & \dots & \bar{\psi}_1(N) \\ \dots & \dots & \dots \\ \psi_{\frac{N}{2}}(1)\,\psi_{\frac{N}{2}}(2) & \dots & \psi_{\frac{N}{2}}(N) \\ \bar{\psi}_{\frac{N}{2}}(1)\,\psi_{\frac{N}{2}}(2) & \dots & \bar{\psi}_{\frac{N}{2}}(N) \end{vmatrix} \equiv A|\psi_1\bar{\psi}_1, \dots, \psi_{\frac{N}{2}}\bar{\psi}_{\frac{N}{2}}| = A\left(1,\bar{1}, \dots, \frac{N}{2}, \frac{\bar{N}}{2}\right), \tag{6}$$

where A is a normalised coefficient determined from the condition

$$\int \Psi\Psi^* d\tau = 0.$$

The variational LCAO-MO method yields Roothaan's equations[19,20], which make it possible to determine the coefficients $c_{i\nu}$, i.e. the fractional involvement of each atomic orbital in the molecular orbitals:

$$\sum_\nu F_{\mu\nu}c_{i\nu} = E_i \sum_\nu S_{\mu\nu}c_{i\nu}. \tag{7}$$

Where the E_i are the orbital energies or eigenvalues of the molecular orbital,

$$S_{\mu\nu} = \int \varphi_\mu^* \varphi_\nu\, d\tau \tag{8}$$

are the overlap integrals, and the

$$F_{\mu\nu} = H_{\mu\nu} + G_{\mu\nu} \tag{9}$$

are the matrix elements of the Fock operator, in which

$$H_{\mu\nu} = \int \varphi_\mu^* \left[-\frac{1}{2}\nabla^2 - \sum V_\alpha(r)\right]\varphi_\nu\, d\tau, \tag{10}$$

$$G_{\mu\nu} = \sum_{\lambda,\sigma} P_{\lambda\sigma}\left[(\mu\nu/\lambda\sigma) - \frac{1}{2}(\mu\sigma/\nu\lambda)\right], \tag{11}$$

$$(\mu\nu/\lambda\sigma) = \int\int \varphi_\mu^*(1)\,\varphi_\nu(1)\,(r_{12})^{-1}\varphi_\lambda^*(2)\,\varphi_\sigma(2)\,d\tau_1\,d\tau_2, \tag{12}$$

$$P_{\lambda\sigma} = 2\sum_i^{\text{occup}} c_{i\lambda}^* c_{i\sigma}, \tag{13}$$

and φ_μ^* is a complex conjugate function with respect to $\varphi\mu$. The $H\mu\nu$ in Eqns. (10)–(13) are matrix elements of the one-electron Hamiltonian, and include both kinetic and potential energy. In conformity with the fundamental idea of the self-consistent field, the potential energy is the energy of the effective electrostatic field $\Sigma V_\alpha(r)$ produced by the nuclei and by the other electrons (the summation extends over all nuclei α). The $G\mu\nu$ are the matrix elements of the effective potential resulting from interelectronic interaction. The dependence of $G_{\mu\nu}$ on the molecular orbitals is determined through the population matrix (the bond-order matrix) $P_{\lambda\sigma}$ in which the summation is made only over occupied molecular orbitals (the factor 2 indicates that each orbital is doubly occupied).

The concept of self-consistency is evident from Eqn. (13): the population matrix depends on the molecular orbitals, whereas Eqn. (7) is intended for determining the coefficients of the molecular orbitals. Self-consistency involves seeking coefficients with which these equations are satisfied. In practice self-consistency is achieved by iteration procedures.

The orbital energies E_i are roots of the secular equation

$$|F_{\mu\nu} - ES_{\mu\nu}| = 0, \tag{14}$$

while the total electronic energy is given by the formula

$$E_{\text{el.}} = \frac{1}{2}\sum_{\mu,\nu} P_{\mu\nu}(H_{\mu\nu} - F_{\mu\nu}). \tag{15}$$

Since (15) is a solution only of the "electronic" Schrödinger equation, the energy of interaction of the nuclei must be added to the energy of the electrons to give the total energy:

$$E = E_{\text{el.}} + \sum_{\alpha>\beta}\sum Z_\alpha Z_\beta / R_{\alpha\beta}. \tag{16}$$

The matrix elements $G\mu\nu$ are usually expressed in terms of Coulombic and exchange operators $K\mu\nu$ and $I\mu\nu$:

$$G_{\mu\nu} = I_{\mu\nu} - K_{\mu\nu}/2, \tag{17}$$

where explicit expressions for $I\mu\nu$ and $K\mu\nu$ can easily be found from Eqns. (11)–(13). Now writing the matrix elements of the kinetic-energy operator $T\mu\nu$ from (10) in the form

$$T_{\mu\nu} = \int \varphi_\mu^* | -\nabla^2/2 | \varphi_\nu\, d\tau, \tag{18}$$

we obtain the matrix form of the Roothaan equations

$$\mathbf{F}c_i = (\mathbf{H} + \mathbf{G})\,\mathbf{c}_i = (\mathbf{T} + \sum_\alpha \mathbf{V}_\alpha + \mathbf{I} - \mathbf{K}/2)\,\mathbf{c}_i = \mathbf{E}_i\mathbf{S}c_i \tag{19}$$

where **F**, **H**, **G**, **T**, $\mathbf{V}_\alpha$, **I**, **K**, and **S** are the matrices whose elements have been discussed above and $\mathbf{c}_i$ is a column of the matrix $c\nu i$.

A few comments on the basis-sets used in quantum-mechanical calculations. The limited (minimal) basal series corresponds to 1s orbitals of hydrogen atoms; 1s, 2s, and 2p (2p_x, 2p_y, 2p_z) orbitals of carbon, nitrogen, and oxygen atoms; etc. Extended basis-sets may involve the use of two or more functions of 1s, 2s, etc. types (i.e. there may be various orbital exponents) and also polarisation functions, e.g. functions of d- and f-types for carbon atoms. It is clear that, the larger the basal series, the better the approximation obtainable to the Hartree–Fock limit.

Semi-empirical calculations usually have a valency basis: in this case the electrons of the inner shells are assigned to the core, and are assumed to introduce a correction to the electrostatic field produced by the nucleus. In π-electron theories it is assumed, moreover, that all σ-electrons belong to the core, and only the properties of the π-electron system are examined.

Thus the first and most important "simplification" in the Roothaan equations is the general use of the valency approximation in semi-empirical theories. With regard to the resulting change in structure of the equations it is obvious that formula (10) for the effective Hamiltonian $H\mu\nu$ can then be rewritten

$$H_{\mu\nu} = \int \varphi_\mu^* \left[-\frac{1}{2}\nabla^2 - \sum_A V_A(r)\right]\varphi_\nu\, d\tau, \tag{20}$$

where the operator in the integrand is the effective potential energy of the electrostatic field due to the atomic cores $V_A(r)$ summed over all atoms A belonging to the molecule (the core of the atom is taken to be its nucleus together with the electrons of its inner shells). It therefore makes sense to replace the nuclear charges Z_α and Z_β by the core charges Z'_A and Z'_B, so that Eqn. (16) will become

$$E = E_{el.} + \sum_{A>B}\sum Z'_A Z'_B / R_{AB} . \qquad (16a)$$

In most semi-empirical methods functions of the Slater type

$$\varphi(r, \theta, \varphi) = R_{nl}(r) Y_{lm}(\theta, \varphi), \qquad (21)$$

(where n, l, m are quantum numbers (principal, azimuthal, magnetic) and r, θ, φ are the spherical coordinates of the electron) are used as atomic orbitals. For the radial part R_{nl} with $n \leq 3$ we have

$$R_{nl}(r) = (2\zeta)^{n+1/2} [(2n)!]^{-1/2} r^{n-1} \exp(-\zeta r), \qquad (22)$$

where ζ is the orbital exponent. The spherical functions $Y_{lm}(\theta, \varphi)$ characterising the angular distribution, however, are expressed in terms of Legendre polynomials. In conformity with Slater's view, the orbital exponentials are written

$$\zeta = (Z - s)/n^*, \qquad (23)$$

where Z is the nuclear charge, s the shielding constant, and n^* the effective principal quantum number. Values of s and n^* for the orbitals used in quantum-mechanical calculations of molecules have been tabulated and are given in several monographs[21-23].

Further "simplifications" of the Roothaan equations involve neglecting some integrals in Eqns. (10) and (11) and parametrising several other integrals. There would be no need for this, but for the great bulk of calculations caused by a total number of integrals of the order of N^4 (where N is the number of basal orbitals), as is readily seen from formula (11). In the evaluation of the equilibrium geometry corresponding to an absolute energy minimum or of barriers to internal rotation, however, energy calculations should be repeated several and sometimes many times (it is necessary to vary the geometric parameters). By neglecting certain integrals, semi-empirical methods enable the time, required to calculate on a computer (BESM-6 type) the "total" energy of a molecule with a fixed geometry, to be reduced to a few minutes, and then it really becomes possible to investigate various conformations for a large set of molecules.

The evolution of quantum chemistry can be regarded as a gradual transition from simple to more complicated methods, taking into account a larger number of integrals: with the years an increasingly distinct tendency has developed to obtain the best possible approximation to the Hartree–Fock limit even for organic molecules of "average" dimensions. The non-empirical calculations of the electronic structure of the pyrrole, pyridine, and pyrazine molecules made by Clementi and Davis[24,25] may be cited as example.

Ten to fifteen years ago, of course, such calculations were technically impracticable, and the Roothaan equations were applied only to diatomic molecules. The electronic structure of large unsaturated organic molecules was usually investigated by the simple Hückel method[26,27] on the hypothesis of σ–π separation. More complicated π-electron schemes then acquired popularity, in particular the Pariser–Parr–Pople (PPP) method[28,29], which took into account a rather larger number of integrals, but as before included the σ-electrons in the core. The next considerable advance was to include the σ-electrons in the scheme of calculation by means of the extended Hückel method[30]. Finally, methods appeared using the valency approximation and involving partial or complete neglect of differential overlap[22,31-34]. Since, with a sufficiently large basis-set, non-empirical calculations by Roothaan's method give reliable predictions of geometric parameters and barriers to internal rotation, as has been mentioned, it is not surprising that the improvement of semi-empirical theories has been accompanied by an increasing rôle in calculations of the geometry of polyatomic molecules.

Methods based on localised orbitals, and originating in the "old-fashioned" valence-bond method[35], were developed in parallel with LCAO-MO methods. As early as the beginning of the 1950s Lennard-Jones and Hall[36-38] showed that unitary transformations of molecular orbitals preserve the Slater determinant and enable localised to be expressed in terms of delocalised molecular orbitals (the molecular wave function remaining unchanged). Ideas developed by the above workers and independently by Fock[39] gave rise to the theory of separated electron pairs[40-43], in which the wave function is represented by an antisymmetrised product of two-electron functions (biorbitals or geminals). Although equations similar in meaning to the Roothaan equations could be obtained for such functions, for a long time no appreciable progress was made in specific calculations. Only comparatively recently have methods based on localised orbitals become widely used both in non-empirical and in semi-empirical calculations.

The following Sections will examine semi-empirical methods in order of increasing complexity. The simplest methods (of the Hückel type) make no explicit allowance for interaction between electrons, and utilise only a few of the most important integrals. Since, however, these integrals are too remote in meaning from those in the Roothaan equations, they must be parametrised by means of experimental data (the parameters are mostly found from a comparison of calculated and experimental properties of simple molecules). More complicated methods, in which interelectronic interaction is explicit (methods involving complete or partial neglect of differential overlap), require the evaluation of a considerably larger number of integrals together with a self-consistency procedure. Finally, the last Section will examine calculations with localised molecular orbitals, which in principle are already beyond the scope of the Hartree–Fock approximation. The aim is not to investigate in which cases and for which molecular characteristics a particular method should be employed: the more modest aim is pursued of discussing the results obtained by various methods for the geometry of molecules and conformational energies, and of giving a comparative assessment of the reliability and the accuracy of these methods.

III. SIMPLE HÜCKEL METHOD

The simple Hückel method is used in the π-electron approximation to investigate the electronic structure of unsaturated systems. The idea behind this method is extremely simple. If a self-consistency procedure is applied to the Hartree–Fock equations for π-electrons, the molecular orbitals will be solutions of Eqn. (9), in which the matrix elements $F_{\mu\nu}$ can be regarded as constants:

$$F_{\mu\mu} = \alpha_\mu; \; F_{\mu\nu} = \beta_{\mu\nu} \qquad (24)$$

where $\alpha\mu$ is termed a Coulombic integral, and $\beta\mu\nu$ a resonance integral.

In the Hückel method $\alpha\mu$ and $\beta\mu\nu$ are usually regarded as empirical parameters. It is assumed furthermore that the matrix of the overlap integrals is identical with the unit matrix, while the resonance integrals, corresponding to non-bonded atoms, are assumed to be zero. Since no explicit allowance for interelectronic interaction is made in the Hückel method, there is no need for a complicated self-consistency procedure. Solving the problem now reduces to finding the roots of the secular equation (14) and determining the coefficients of the molecular orbitals.

Without considering the further simplifications introduced for π-electron systems or methods of estimating the parameters $\alpha\mu$ and $\beta\mu\nu$, we merely note that this method is unsuitable for completely calculating the geometry of a molecule. In several cases, however, empirical relations between bond length and bond order, which were especially popular fifteen years ago, can be used to assess e.g. carbon–carbon bond lengths in fused aromatic systems such as naphthalene, phenanthrene, etc.

Table 1. Dependence of resonance integral (25) on internuclear distance.

Å	k^{14}	k^{15}	Å	k^{14}	k^{15}
1.20	1.71	1.38	1.45	0.83	0.91
1.33	1.23	1.11	1.54	0.57	0.78
1.397	1.00	1.00			

The Hückel method is usually applied to molecules having a planar conjugated system. If the length of a bond which transmits the conjugation (e.g. the central carbon–carbon bond in biphenyl) is changed by the repulsion of non-bonded atoms, the resonance integral is represented by the formula

$$\beta = k\beta_0, \qquad (25)$$

where β_0 is the "standard" value of the resonance integral and k is a constant, whose variation with the carbon–carbon bond length is given in Table 1. If, however, the repulsion of non-bonded atoms leads to a loss of coplanarity, a correction is made to the resonance integral of the bond relative to which the parts of the molecule are rotated. The resonance integral is then regarded as a function of the angle of rotation φ (e.g. between the planes of the phenyl rings in biphenyl) and is calculated by means of the formulae

$$\beta_\varphi = \beta_{\varphi=0}\cos\varphi \qquad (26)$$

and

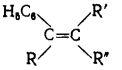
$$\beta_\varphi = \beta_{\varphi=0}\cos^2\varphi\,. \qquad (27)$$

These equations are based on the proportionality noted by Mulliken[41–46] between resonance and overlap integrals; probably their first applications were reported in Refs. 47 and 48.

Neither in accuracy nor in relative validity do expressions of such type differ from the empirical formulae used in classical calculations[49,50], where the analogue of the resonance integral is the empirical constant U_0. Nor can attempts to obtain more complicated formulae for the resonance integral by the simple Hückel method be regarded as sufficiently soundly based. This applies in particular to the suggested[51] relation

$$\beta = \beta_0 \frac{S/(1+S)}{S_0/(1+S_0)}, \qquad (28)$$

which follows from Mulliken's "magic" formula[46] (S and S_0 are overlap integrals).



Adrian[52] computed the equilibrium conformations of the triphenylmethyl radical (I), biphenyl (II), *cis*-stilbene (III), *cis*-azobenzene (IV), and the *pp'*-dimethoxyphenylnitric oxide radical (V). Resonance integrals for the carbon–carbon bonds about which rotation occurs were estimated by Wheland's method[53], which gave relations between β and φ closely similar to (27). Repulsions of non-bonded atoms compete with conjugation in these molecules (I)–(V). The H...H interactions were allowed for by means of Hirschfelder and Linnett's potential curve[54], and the C...H interactions by means of the relation $f_{C...H} = 2.3 f_{H...H}$ (interactions between carbon atoms were disregarded). The calculated angles φ of rotation of the phenyl rings for the five compounds (I)–(V) were respectively 32°, 20–30°, 30–40°, > 40°, and ~ 25°, agreeing quite well with the experimental values.

Goodwin and Morton-Blake[55] tried to solve the "converse" problem–to obtain the parameters of the H...H potential from data on the equilibrium conformation of biphenyl in the vapour (the angle between the phenyl rings is $\varphi = 42°$) and the approximate expression for the conjugation energy[56]

$$\varepsilon_\pi = 0.196\beta^* \cos^2\varphi$$

with respect to a system of two isolated benzene rings. They adopted the value $\beta^* = -32.5$ kcal mole^{-1}. The calculated H...H potential (it has no minimum, of course, since only repulsion was considered) was rather "more rigid" than other published potentials. This is due partly to the neglect of C...C and C...H interactions.

Favini and Simonetta[57] examined the conformations of the phenylated and methylated ethylenes

(R, R', and R'' are hydrogen atoms or phenyl and methyl groups). The ideal bond angles in ethylene and its derivatives were assumed to be 120°, corresponding to sp^2 hybridisation of the carbon atoms. The C–R, C–R', etc. bond lengths were computed by an iteration procedure involving calculating bond orders in the Hückel approximation for some standard geometry, and determining the bond lengths by means of Coulson's dependence[58] of bond length on bond order. Resonance integrals β were then calculated for the resulting geometry, bond orders and lengths were redetermined, and the procedure repeated until changes in bond lengths became less than 0.005 Å. Rotations of the phenyl rings relative to the plane of the ethylene system were allowed for by means of formula (26). Finally, the energy of interaction of non-bonded atoms was calculated by means of Kitaigorodskii potentials[59].

The most interesting calculated results are the angles of rotation of the phenyl rings relative to the plane of the ethylenic system (the distortions of the bond angles lay within the limits of accuracy of the calculation). Twenty compounds of this type gave angles of rotation of 17–60°.

Another paper by Italian authors [60] gave a similar calculation of the equilibrium conformation of the *trans*-$\alpha\beta$-dicyanostilbene molecule. Unfortunately, reliable structural data are as yet lacking for the large majority of these compounds.

The problem of rotation about bonds that transmit conjugation has been investigated not only by the simple Hückel method. Dewar and Harget [61] proposed a method of evaluating resonance integrals from thermochemical data and used Bartell potentials [62] to obtain a dihedral angle of $\varphi = 40°$ in biphenyl, in excellent agreement with experiment (42°). [63] Skancke [64] worked out the parametrisation of the zero differential overlap method for π-electrons (actually for the PPP method), which enabled the conformations of various fluorinated biphenyls to be predicted with good accuracy [65]. In this series of compounds the dihedral angle between the phenyl rings is increased by the entry of substituents at positions 2 and 6, reaching a maximum of 70° in decafluorobiphenyl [66]. This tendency is apparent also in calculations taking into account non-bonded interactions and the π-electron energy. A similar approach, but with use of the CNDO valency approximation (Section V), was made by Sekigawa [67] to investigating the conformations of nitronaphthalenes and certain other compounds of this type. The results of his calculations are almost identical with those obtained for the same compounds by means of the mechanical model of the molecule [49].

In the above examples empirical model methods are ultimately used, since the search for equilibrium conformations is based on the examination of non-bonded interactions. Only conjugation energies, bond orders, and certain other quantities are estimated by semi-empirical methods of quantum chemistry. The term "quantum-mechanical" should properly be applied only to calculations that give the total energy of the molecule. As already mentioned, the optimal conformers would then correspond to minima of the total energy; the heat of isomerisation is given by the difference between the total energies of the isomers; etc. Henceforward we shall consider parametric methods enabling the total energy of the molecule to be estimated.

IV. EXTENDED HÜCKEL METHOD

The extended Hückel method (EHM) uses the valency approximation and the assumption that the matrix elements of the Fock operator $F_{\mu\nu}$ are independent of the coefficients of the molecular orbitals:

$$F_{\mu\nu} = H_{\mu\nu}^{\text{eff}}. \qquad (29)$$

Comparison of Eqn. (29) with (9)–(13) shows firstly that the extended method does not allow explicitly for the interaction of the electrons (11) and secondly that the effective one-electron Hamiltonian takes account both of the kinetic energy of the electrons and of the effect on them of the electrostatic field of the core, but makes no separation of these two completely different kinds of effect. In contrast to the simple Hückel method (24), however, the extended method covers all non-diagonal elements of the one-electron Hamiltonian. This is very important in conformational analysis: it is because the non-diagonal elements differ in different conformations of such molecules as e.g. n-butane that these conformations have different energies. Another virtue of the extended Hückel method is that it takes into account all the valency electrons of the molecule, whereas methods used until the 1960s usually covered only the π-electrons, the σ-electrons being confined to the core.

Hoffmann [68], having demonstrated the great predictive power of this method, suggested using the ionisation potentials of the corresponding valency states of the atoms as the diagonal matrix elements $H_{\mu\mu}$. For hydrocarbon molecules, in particular, he used the values (in kcal mole^{-1}) $H_{\mu\mu}(1s\text{H}) = -313.6$, $H_{\mu\mu}(2s\text{C}) = -493.5$, and $H_{\mu\mu}(2p\text{C}) = -262.9$. [69,70] The non-diagonal matrix elements $H_{\mu\nu}$ are usually obtained by means of the Wolfsberg–Helmholtz relation [71]

$$H_{\mu\nu} = 0.5K(H_{\mu\mu} + H_{\nu\nu}) \cdot S_{\mu\nu}, \qquad (30)$$

where K is an empirical constant and the $S_{\mu\nu}$ are the overlap integrals of the Slater orbitals.

Choosing the value of K is the most difficult part of the whole scheme of calculation [72]. If Mulliken's approximation is adopted [46], K should be unity. But calculations for homonuclear diatomic molecules then give absurd results. It is therefore usually assumed that $K > 1$, and in Hoffmann's work and several other calculations of conformations and conformational energies the value of K is taken to be 1.75.

The non-diagonal elements $H_{\mu\nu}$ are not only estimated by means of formula (30), in which the arithmetic mean of the diagonal elements $H_{\mu\mu}$ and $H_{\nu\nu}$ is used, but sometimes from the geometric mean of these quantities [73,74]:

$$H_{\mu\nu} = K\sqrt{H_{\mu\mu}H_{\nu\nu}} \cdot S_{\mu\nu}. \qquad (31)$$

Formula (31) can be regarded as just as valid as (30). The proportionality coefficient K should exceed unity in this case, and the best agreement with experiment is obtained when $K = 1.75$.

An interesting attempt was made to avoid altogether the empirical constant K, and write the non-diagonal matrix elements of the Hamiltonian in the form [75]

$$H_{\mu\nu} = (2 - |S_{\mu\nu}|)S_{\mu\nu}(H_{\mu\mu} + H_{\nu\nu})/2. \qquad (32)$$

Calculations in the extended Hückel method are quite simple: they merely involve evaluating the overlap integrals $S_{\mu\nu}$, setting up the matrix H, and solving the set of equations

$$\sum_{\mu=1}^{n} [H_{\mu\nu} - ES_{\mu\nu}]c_{\mu} = 0, \quad \nu = 1, 2, \ldots, n, \qquad (33)$$

where n is the number of atomic orbitals. Allowing for the double occupation of each level, we take the "total" energy to be given by the sum of the orbital energies E_i of the occupied molecular orbitals:

$$E_{\text{total}} = 2\sum_{i} E_i.$$

The computer time necessary to estimate the coefficients $c_{\mu\nu}$ and compute the "total" energy is of the same order as the time required to calculate empirical potential functions. Thus only 10 s is required to calculate ethane [68]. Within the framework of the extended Hückel method, therefore, it is possible to seek the minimum total energy and calculate energy differences between rotational isomers and barriers to internal rotation.

We return to Hoffmann's parametrisation [68], and examine the results obtained in the calculation of conformations. The three conformations of propane—(I) with both methyl groups in the staggered position with respect to the methylene group, (II) with one methyl in the staggered position and the other in the eclipsed position, and (III) with both methyls in the eclipsed position—have calculated energies of −8022.32, −8016.69, and −8009.91

kcal mole^{-1}, whence it follows that (I) is the most stable form. But the calculated difference in energy between (I) and (II) is 5.63 kcal mole^{-1}, which considerably exceeds the experimental value[76]. The most favourable of the twelve conformations of n-butane is the *trans*(or *anti*)-form with the carbon–hydrogen bonds in the staggered position, which is consistent with electron-diffraction data[77]. However, the barrier to internal rotation (the difference in energy between *cis*- and *trans*-forms) is too large in comparison with the experimental value[78] (27 and 6.92 kcal mole^{-1}). The calculated barrier to internal rotation in ethane is also overestimated: 4.0 in comparison with the experimental value[79] of 2.93 kcal mole^{-1}. Calculated energies of isomerisation are also rather too high: thus for the isomerisation of n-butane into isobutane calculation gives 2.3 kcal mole^{-1}, whereas the experimental value[80] is 1.6 kcal mole^{-1}.

Calculation of the conformations of cycloalkanes has yielded interesting results. Like most empirical theories, the extended Hückel method gives for cyclobutane a minimum corresponding to the planar form. In cyclopentane the planar form is unfavoured, but the half-chair (C_2) is more favoured than the "envelope" (C_S) by 1.8 kcal mole^{-1}. This result agrees neither with empirical estimates nor with electron-diffraction data[81] proving the equivalence of these forms and the absence of hindrance to pseudorotation. The calculated difference in energy between chair and boat conformations of cyclohexane (17.7 kcal mole^{-1}) is about double the experimental value.

Hoffmann's paper was the first of a stream of predictions of the geometry and the conformational energies of molecules, and many workers regarded it as a triumph of quantum chemistry. Other authors, on the other hand, considered that the accuracy of the predictions obtained by the extended method was too poor; in any case, it is substantially inferior to that of model methods using atom–atom potentials. Subsequent Hartree–Fock calculations of the conformations of simple molecules helped to establish a moderate attitude: the extended Hückel method is useful for rough conformational calculations, but gives inaccurate values of conformational energies, and in some cases an incorrect assignment of favoured conformers.

The above examples show that the extended Hückel method in Hoffmann's parametrisation leads to a re-evaluation of the part played by the steric factor. Hoffmann calculated conformational energies for experimental bond lengths and valency angles. Strictly speaking, a minimum total energy should be sought with respect to all internal parameters, including bonds and angles. Unfortunately such a procedure does not lead to agreement with experiment: Table 2 shows that the calculated geometric parameters are far removed from the experimental values†. Conformational energies obtained with the optimised geometry are too low. Thus in Hoffmann's method optimisation of the geometry does not give agreement with experiment. Nor could better agreement be obtained by changing the parametrisation. Thus if the value 1.2 instead of 1.0 is adopted for the Slater exponent 1*s*H, calculation will give the correct barrier in ethane, but strong divergence from experiment for the difference in energy between chair and boat conformations of cyclohexane.

† The reason why the extended method may give reasonable conformational energies, while being completely unsuitable for predicting the geometry of molecules, will be indicated in Section V.

The formalism of the extended Hückel method has been compared[74,83,84] with Roothaan's formalism, and the main sources of error in the extended method have been indicated. According to Allen[74,84] a considerable proportion of the error is due to change in the electrostatic potential $\Sigma_A V_A(r)$ in Eqn. (20) during deformations of bond angles and rotations about bonds. Therefore, whereas the extended method works satisfactorily for hydrocarbons, it often predicts, for molecules whose atoms bear large excess charges, a geometry that is markedly different from the experimental geometry. Thus for the water molecule the extended method yields an HOH equilibrium angle of 140°, whereas the experimental angle is 104.5°. For the same reason the shape of the potential curve for internal rotation in the hydrogen peroxide molecule is opposite to the experimental curve.

Table 2. Geometric parameters corresponding to minimum energy in the extended Hückel method[68,82].

Molecule	Bond	Bond length, Å		Valency angle	Value of angle	
		calc.	expt.		calc.	expt.
CH_4	C—H	1.02	1.09			
$H_3C—CH_3$	C—C	1.92	1.53			
	C—H	1.00	1.10			
$H_2C=CH_2$	C=C	1.47	1.33	HCH	125°	
	C—H	0.95	1.08			
	C=C	1.52	1.33	HCH	120.7°	115.6°
	C—H	0.92	1.08			

A numerical investigation of the dependence of the non-diagonal matrix elements of the one-electron Hamiltonian on the distance between the atoms showed[83] that the proportionality of $H_{\mu\nu}$ and $S_{\mu\nu}$ expressed by Eqn. (30) is satisfied fairly accurately only if the atomic orbitals φ_μ and φ_ν are not immediate neighbours (it is probably for this reason that the extended method is suitable for conformational calculations). However, neighbouring atoms show large departures from proportionality, caused by the kinetic portion $(\varphi_\mu | -\frac{1}{2}\nabla^2 | \varphi_\nu)$ of the Hamiltonian in Eqn. (10). This non-proportionality is primarily responsible for the constant K differing from unity in the Wolfsberg–Helmholtz relation.

In spite of the obvious defects of the extended Hückel method, it is widely used for theoretical investigations of the conformations of structurally similar molecules. Van Eijck[85], who calculated the conformations of numerous carboxylic acids, concluded that the method predicts the correct equilibrium structure for these compounds in nearly every case: only the calculated barriers to internal rotation showed poor agreement with experiment. Pachler and Tollenaere[86] calculated conformational energies for substituted ethanes—fluoroethane, 1,2-difluoroethane, ethanol, propionitrile, ethylene glycol, 2-fluoroethanol, and succinonitrile—and obtained good agreement between calculated and experimental barriers to rotation by using experimental bond lengths and angles and adopting the value 1.2 for the Slater exponent 1*s*H (with exponent of 1.0 the resulting barriers were overestimated by 30–80%). In full agreement with experiment, calculation predicts preference for the gauche forms of 1,2-difluoroethane, ethylene glycol, 2-fluoroethanol, and succinonitrile. However, the calculated energy differences between the gauche and *trans*-forms are too large in comparison with the experimental differences.

Because of the simplicity of programming and the small consumption of computer time, the extended Hückel method rapidly gained popularity with biochemists investigating the conformational states of complicated bio-organic molecules. Thus conformational maps have been calculated[87] for dipeptides, the structural units of protein molecules; the conformations of amino-acids have been investigated[88]; and Long and Goldstein have predicted[89] the conformations of nicotinamide and related amides. Finally, mention may be made of work done by Kier[90], who calculated the molecular conformations of many medicinals, and claimed the start of a new line of scientific advance—quantum pharmacology.

Pullman[91-93] used the extended method to investigate the conformations of nucleosides, photodimers of thymine, and several other molecules related to components of nucleic acids. He was interested not only in the problems of finding the preferred conformers but also in the charge distribution on the atoms. The calculated charges on the atoms in nucleosides were numerically too large: although no experimental methods are available for determining charge, it is improbable that the excess charge on the oxygen atoms in β-D-ribose and in nitrogen bases would reach the calculated 1.5 electron.

An iteration procedure of the extended Hückel method (IEHM) was suggested[94,95] to obtain more realistic values of the charges and refine the conformational energies. Without going into details of the application of this procedure, we note that it yields reasonable charges on the atoms, and in some cases more reliable conformational energies. However, since the time required to calculate the total energy is appreciably increased, while the significance of the Hamiltonian is not essentially changed, the value of the procedure in conformational calculations is not very great.

V. METHODS OF ZERO DIFFERENTIAL OVERLAP

Pople[31-33] and Dewar[97,98] worked out several semi-empirical self-consistent field methods in the valency approximation. These were close in physical meaning to the Hartree–Fock LCAO-MO procedure, but were considerably simpler and accessible to many chemists having an electronic computer at their disposal.

The most laborious stage in solving Roothaan's equations consists in evaluating the two-electron integrals (11) and (12). Semi-empirical schemes have been constructed with the idea of partly or completely avoiding this complicated procedure. But simply neglecting these integrals strongly distorts the structure of Roothaan's equations: the molecular orbitals ψ_i and the orbital energies E_i become non-invariant with respect to (i) transformations of the coordinates—translation and rotation of the axes—and (ii) change in hybridisation: in particular, replacement of the $2s$, $2p_x$, $2p_y$, and $2p_z$ orbitals of the carbon atom by hybrid sp^3 orbitals will give different solutions of the equations. Although breakdown of hybridisational invariance may still be accepted in several cases, by arranging to use molecular orbitals of a certain type (this procedure is used in calculations by the extended Hückel method), loss of invariance of type (i) is simply intolerable. Indeed, any author is free to choose a system of coordinates in the molecule as he thinks fit, and non-invariance with respect to transformations of the coordinate axes makes it impossible to compare results obtained by different workers. The idea underlying methods of zero differential overlap (ZDO) is the partial or complete neglect of products of atomic orbitals of the type $\varphi_\mu\varphi_\nu$ ($\mu \neq \nu$) and the choice of approximations that leave the Roothaan equations invariant with respect both to orthogonal transformations of the basis and to change in hybridisation.

The method of complete neglect of differential overlap (CNDO)[31,32] involves neglect of integrals of the type (Eqn. 12)

$$(\mu\nu/\lambda\sigma) = 0 \text{ with } \mu \neq \nu,\ \lambda \neq \sigma \tag{34}$$

but it is assumed that

$$\gamma_{\lambda\mu} = (\lambda\lambda\,|\,\mu\mu) \neq 0. \tag{35}$$

This disrupts the invariance of the Roothaan equations, and only further approximations will restore it. It is assumed firstly that $\gamma_{\mu\nu}$ depends solely on the type of atoms to which the orbitals φ_μ and φ_ν belong, not on the type of orbital. Thus γ_{AB} is a measure of the mean repulsion of electrons in valency orbitals of the atom A and the atom B. Combining this postulate with formulae (34) and (35), we obtain instead of (9)–(13) the equations

$$F_{\mu\mu} = H_{\mu\mu} - \frac{1}{2}P_{\mu\mu}\gamma_{AA} + \sum_{B(\neq A)} P_{BB}\gamma_{AB}, \tag{36}$$

$$F_{\mu\nu} = H_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{\mu\nu}, \tag{37}$$

$$P_{BB} = \sum_{\nu}^{B} P_{\nu\nu}, \tag{38}$$

$$H_{\mu\mu} = \left(\mu\left|-\frac{1}{2}\Delta^2 - V_A\right|\mu\right) - \sum_{B(\neq A)}(\mu\,|\,V_B\,|\,\mu) = U_{\mu\mu} - \sum_{B(\neq A)} V_{AB}, \tag{39}$$

where the subscripts μ refer to the atom A ($\mu \equiv \varphi_\mu$), P_{BB} in (38) is the aggregate electron density of valency electrons on atom B, and $U_{\mu\mu}$ is the energy of the atomic orbital φ_μ regarded as an empirical parameter. Equations (36)–(39) restore the invariance with respect to orthogonal transformations. A further simplification has been introduced into Eqn. (39): the matrix elements $(\mu\,|\,V_B\,|\,\nu)$, where φ_μ and φ_ν belong to the same atom A, are zero if $\mu \neq \nu$; if, however, $\mu = \nu$, we have $(\mu\,|\,V_B\,|\,\mu) = V_{AB}$.

The non-diagonal matrix elements $H_{\mu\nu}$ in (37) are found empirically on the assumption that they are proportional to the overlap integrals $S_{\mu\nu}$:

$$H_{\mu\nu} = \beta_{\mu\nu} = \beta^0_{AB}S_{\mu\nu}, \tag{40}$$

where β^0_{AB} is an empirical parameter depending on the nature of the atoms A and B. Increments β^0_A and β^0_B are adopted for each atom, and β^0_{AB} is then computed as the arithmetic mean of these increments:

$$\beta^0_{AB} = (\beta^0_A + \beta^0_B)/2. \tag{41}$$

The proportional relation (40), in contrast to the Wolfsberg–Helmholtz formula (30), does not disrupt the invariance of the equations with respect to transformations of the basis-set. Bearing in mind that φ_μ refers to atom A, and φ_ν to B, we find from (40) for the non-diagonal elements of the Fock matrix the expression

$$F_{\mu\nu} = \beta^0_{AB}S_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{AB}. \tag{42}$$

An expression for the total energy in the CNDO/1 approximation[31] can now be readily obtained:

$$E_{\text{total}} = \sum_A E_A + \sum_{A>B}\sum E_{AB}, \tag{43}$$

where

$$E_A = \sum_{\mu}^{A} P_{\mu\mu}U_{\mu\mu} + \frac{1}{2}\sum_{\mu}^{A}\sum_{\nu}^{A}\left(P_{\mu\mu}P_{\nu\nu} - \frac{1}{2}P^2_{\mu\nu}\right)\gamma_{AA} \tag{44}$$

and

$$E_{AB} = \sum_{\mu}^{A}\sum_{\nu}^{B}\left(2P_{\mu\nu}\beta_{\mu\nu} - \frac{1}{2}P_{\mu\nu}^2\gamma_{AB}\right) + \\ + (Z'_A Z'_B R_{AB}^{-1} - P_{AA}V_{AB} - P_{BB}V_{BA} + P_{AA}P_{AB}V_{AB}). \quad (45)$$

The energies of the atomic orbitals $U_{\mu\mu}$ are expressed in this approximation in terms of mean ionisation potentials I_μ:

$$U_{\mu\mu} = -I_\mu - (Z-1)\gamma_{AA}. \quad (46)$$

Calculations by the CNDO/1 method give bond lengths in diatomic molecules that are too short and bond energies that are too large. Polyatomic molecules, however, are, roughly speaking, "too compressed". Pople and Segal[32] therefore proposed a different parametrisation (CNDO/2), which subsequently became widely accepted. Firstly it is assumed that

$$V_{AB} = Z'_B\gamma_{AB}. \quad (47)$$

Application of this relation enables "the effect of 'penetration' of one atom into the electron shell of the other to be diminished" (however, the physical justification for this is weak). Further, the parameter $U_{\mu\mu}$ is estimated by averaging the ionisation potential I_μ and the electron affinity A_μ:

$$U_{\mu\mu} = -\frac{1}{2}(I_\mu + A_\mu) + \left(Z' - \frac{1}{2}\right)\gamma_{AA}. \quad (48)$$

For the matrix elements of the Fock operator we then obtain the formulae

$$F_{\mu\mu} = -\frac{1}{2}(I_\mu + A_\mu) + \left[(P_{AA} - Z'_A) - \frac{1}{2}(P_{\mu\mu} - 1)\right]\gamma_{AB} + \sum_{B(\neq A)}(P_{BB} - Z'_B)\gamma_{AB} \quad (49)$$

$$F_{\mu\nu} = \beta^0_{AB}S_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{AB}. \quad (50)$$

The Slater basis-set with exponents 1 and 2 for the hydrogen atoms is used in computing the overlap integrals $S\mu\nu$. In contrast to the extended Hückel method, complete neglect of differential overlap requires self-consistency procedures. The iteration procedure consists in making initial estimates of the coefficients of the linear combination of orbitals from theories of Hückel type

$$F^{(0)}_{\mu\mu} = -\frac{1}{2}(I_\mu + A_\mu), \quad (51)$$

$$F^{(0)}_{\mu\nu} = \beta^0_{AB}S_{\mu\nu}, \quad (52)$$

and computing the total energy and the matrix elements $F\mu\nu$ until self-consistency is attained.

The success of the CNDO/2 method depends substantially on the parametrisation, especially on the choice of proportionality constants β^0_{AB} in Eqn. (40) (more precisely on the choice of the atomic constants $\beta^0_A, \beta^0_B, \ldots$). Pople and Segal[32] selected these constants to give the best possible reproduction of the results of non-empirical calculations of corresponding diatomic molecules made with the same set of atomic orbitals. Use of their parametrisation yields reasonable geometric parameters, conformational energies, and barriers to internal rotation. In any case, it becomes possible to make a serious search for a minimum total energy in order to obtain the geometry of the molecule and the energy characteristics of the conformers: in the extended Hückel method such a search leads in many cases to absurd results.

Table 3, based on Gordon's results[99], gives an idea of the extent of agreement between calculated and experimental values (bond lengths are given only to hundredths of an Ångström unit; extremal values reached during rotation are given for the calculated valency angles; and references to the experiments will be found in the original paper). Bond lengths are seen to be predicted with a mean accuracy of 0.1 Å, and valency angles to a few degrees. Nevertheless, the divergence between calculation and experiment is in some cases too large—e.g. the oxygen–oxygen bond length and the HOO valency angle in the hydrogen peroxide molecule, and the oxygen–fluorine bond length in the F_2O_2 molecule.

Table 3. Molecular geometry predicted by CNDO/2 method with Pople–Segal parameters.

Table 4, compiled from results in several papers (references to the experimental work will be found in a review[100]), gives calculated barriers to internal rotation. Comparison of the values calculated for methanol, methylamine, and ethane shows that the two variants of the method—CNDO/1 and CNDO/2—give closely similar results. It is evident that this method almost always underestimates the barriers, as a consequence of partial neglect of two-electron integrals and/or the parametrisation. Despite the discrepancy between calculated and

experimental values, however, the trend in the variation of the barriers is in the main correctly reproduced. Thus the proportions 3 : 2 : 1 for ethane, methylamine, and methanol are quite well satisfied[100], and the assignment of minima and maxima of the total energy during internal rotation is correct in all cases other than for hydrogen peroxide. With fluorinated derivatives calculation gives the right assignment of stable forms, but poor agreement with experiment both in the numerical values of the barriers and in the trend of their variation on passing from one molecule to another.

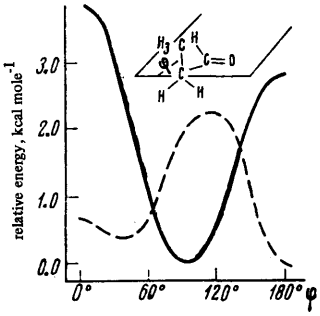

Figure 1. Variation in energy of propionaldehyde molecule during rotation of the methyl group about the C–C bond calculated by different methods: CNDO; extended Hückel method.

Nevertheless, calculations by the CNDO method by no means always give even qualitative agreement with experiment. Fig. 1 illustrates the variation in the total energy of the propionaldehyde molecule with the dihedral angle φ. Microwave[103] and nuclear magnetic resonance[104] spectra have shown the presence of two stable conformers differing in energy by 0.9 kcal mole^{-1}. The more stable conformer corresponds to $\varphi = 49°$, and the barrier separating them is 2.28 kcal mole^{-1}. The CNDO/2 method with Pople and Segal's parameters does not predict the existence of two conformers at all, quite apart from the position of the minimum[102]. In this case the extended Hückel method—which is considerably cruder than CNDO—yields better agreement with experiment.

In all the above examples the energy of internal rotation was calculated with bonds and valency angles fixed at values taken from experiment. This raises the question whether agreement with experiment could not be improved by basing the calculations on the optimum geometry, i.e. by requiring that the energy should be optimised with respect to bond lengths and valency angles for each angle of rotation. This question has been too little investigated for an unambiguous answer to be possible. We note merely that calculation with optimisation of the geometry for the hydrogen peroxide molecule gives two barriers—*cis* and *trans*—with energies of 5.0 and 2.85 kcal mole^{-1} respectively (in non-empirical calculations the *trans*-barrier can be predicted only with large basis-sets). Minimum energy corresponds to an angle of rotation of 87° read from the *cis*-form (the experimental angle is 111.5°).

The CNDO method makes it possible to understand which interactions are responsible for the appearance of barriers. The energy of interaction of the atoms E_{AB} (Eqn. 45) can be written as the sum of three components:

$$E_{AB} = E^{(1)}_{AB} + E^{(2)}_{AB} + E^{(3)}_{AB}, \tag{53}$$

where

$$E^{(1)}_{AB} = 2\sum_{\mu}^{A}\sum_{\nu}^{B} P_{\mu\nu}S_{\mu\nu}\beta^{0}_{AB} \tag{54}$$

$$E^{(2)}_{AB} = -\frac{1}{2}\sum_{\mu}^{A}\sum_{\nu}^{B} P^{2}_{\mu\nu}\gamma_{AB} \tag{55}$$

$$E^{(3)}_{AB} = P_{AA}P_{BB}\gamma_{AB} - P_{AA}Z'_{B}\gamma_{AB} - P_{BB}Z'_{A}\gamma_{AB} + Z'_{A}Z'_{B}/R_{AB} \tag{56}$$

and V_{AB} in (45) has been replaced by formula (47) in conformity with the CNDO/2 approximation.

The component $E^{(1)}_{AB}$ represents the main contribution to the energy of bonding made by the atomic orbitals $\varphi\mu$ and $\varphi\nu$ belonging to atoms A and B respectively. Since $\beta^{0}_{AB} < 0$, the inequality $E^{(1)}_{AB} < 0$ implies that this type of interaction between atoms A and B strengthens the bonding; the inequality $E^{(1)}_{AB} > 0$ corresponds to a weakening of bonding.

The component $E^{(2)}_{AB}$ represents stabilisation by exchange interactions.

Finally, $E^{(3)}_{AB}$ is the electrostatic interaction of atoms A and B, since

$$P_{AA} = \sum_{\mu}^{A} P_{\mu\mu}$$

is the total electron density on A. If at large distances $\gamma_{AB} \simeq 1/R_{AB}$, we actually have

$$E^{(3)}_{AB} = (P_{AA} - Z'_{A})(P_{BB} - Z'_{B})/R_{AB} = q_{A}q_{B}/R_{AB} \tag{57}$$

where q_A and q_B are the net charges of atoms A and B: i.e. Eqn. (57) corresponds to purely Coulombic interaction.

The energy E_A introduced by the orbitals of atom A (Eqn. 44) makes a very small contribution to the relative conformational energy. Thus for ethane, methylamine, and methanol $\Sigma_A \Delta E_A$ is respectively 0.08, 0.12, and 0.16 kcal mole^{-1}, and stabilises the eclipsed conformations[99].

Analysis shows[99] that in most cases the term $\Delta E^{(1)}_{AB}$ plays by far the major part in determining the barrier to internal rotation. In ethane, its fluorinated derivatives, methylamine, and methanol the barrier is due to H...H interaction (characterised by the parameter $E^{(1)}_{HH}$) in the eclipsed conformations. The electron density in the space between the hydrogen atoms is small, which leads to their repulsion. In the hydrazine molecule interaction of the lone pairs of the nitrogen atoms prevails over H...H repulsion. In molecules having large excess charges, such as hydroxylamine, the electrostatic contribution $\Delta E^{(3)}_{AB}$ plays an important part as well as $\Delta E^{(1)}_{AB}$.

The nature of the barriers in the hydrogen peroxide molecule is interesting. It is not surprising that H...H interaction, characterised by the parameter $\Delta E^{(1)}_{HH}$, is responsible for the *cis*-barrier. The *trans*-barrier is due mainly to interaction of π-electrons in the non-planar conformations, and is determined by the parameter ΔE_{OO} of the oxygen atoms. These characteristics of interatomic interaction appear only in calculations with optimisation of the geometry: if the experimental bond lengths and HOO valency angle are used, however, the minimum total energy will correspond to the *trans*-form.

Nevertheless, a more reliable assignment of the "nature" of the barriers to internal rotation in molecules can be obtained only on the basis of non-empirical calculations. Indeed, the neglect of many integrals and the replacement of a further series of integrals by empirical

parameters lead firstly to considerable errors in the calculated barriers and secondly to incorrect assessment of the effects of particular factors. Yet even an extremely rough non-empirical calculation (with a small basis-set) yields in most cases a correct idea of the relative importance of various contributions to the barrier. And still, independently of the method of calculation used, a fundamental difficulty arises in interpreting the "nature" of the barriers, because quantum-mechanical integrals can be combined in various groups in quite a number of ways, so that the interpretation will depend on the grouping adopted in a specific calculation.

The resolution of E_{AB} into components—$E_{AB}^{(1)}$, $E_{AB}^{(2)}$, and $E_{AB}^{(3)}$—enables us to understand why the extended Hückel method often gives reasonable conformational energies and barriers to internal rotation, while being completely unsuitable for calculating the geometry and the force constants of polyatomic molecules. Since the effective Hamiltonian of this method contains only terms proportional to $S_{\mu\nu}$, while ionisation potentials are used as diagonal elements, only the components E_A and $E_{AB}^{(1)}$ are taken into consideration, the remaining components being absorbed in empirical parameters. But the equilibrium geometry of the molecule is determined from the condition that the derivatives $\partial E/\partial x_i$ should vanish, where the x_i are independent geometric parameters, while the force constants $K_{ij} = \partial^2 E/\partial x_i \partial x_j$ are second derivatives. The contribution of electrostatic interaction $E_{AB}^{(3)}$ to these derivatives is, however, quite large, as estimates by Fisher and Kollmar[105] have shown. In many cases, therefore, calculation of molecular geometry and force constants by the extended Hückel method does not lead to the end in view.

The CNDO method, because of the presence of a large number of empirical parameters, is extremely flexible, and with appropriate choice of parameters may give good agreement with experiment. In fact, several successful attempts have been made to vary the parametrisation[106-117], especially in calculations of the geometry and the atomisation energies of hydrocarbons.

Table 5. Pople–Segal and Wiberg parameters for CNDO method.

Orbital	Core charge	Slater exponent	Ionisation potential, eV		β^0	
			P-S	W	P-S	W
1s H	1	1.2	7.1761	7.176	9	10.0
2s C	4	1.625	14.051	10.3	21	17.5
2p C		1.625	5.572	6.3		

Too profound significance should not be attached to calculations of energies of atomisation, of course, since correlation corrections amount numerically to an average 20% of the total energy. The LCAO-MO method in Roothaan's approximation does not predict the existence of the F_2 molecule at all[118], contrary to experimental results; in most cases, however, the existence of the equilibrium conformation is correctly predicted, but the calculated bond energies differ greatly from the true values. The same must be expected for the CNDO method, since it is a simplification of the Hartree–Fock model.

For certain homologous series, in particular for hydrocarbons, however, effective parameters can be so chosen that the calculated atomisation energies agree quite well with the experimental values.

Wiberg showed[117] that results calculated by the CNDO method are very sensitive to the proportionality constants β^0 and the mean ionisation potentials of the orbitals. Table 5 compares Pople and Segal's parameters with those of Wiberg. The slight difference in the constants β^0 for carbon atoms (17.5 instead of 21) permits considerable improvement in predicting molecular geometry. In fact, Table 6 shows that the calculations give bond lengths accurate to about 0.02–0.03 Å, and valency angles to 1–2°.

*Allowing for zero-point vibrations.

Varying the mean ionisation potentials of the orbitals (Table 5) enables quite satisfactory agreement to be attained between calculated and experimental atomisation energies. It is noteworthy that comparison with experiment is based not on the enthalpies (as is mostly done) but on the atomisation energies: i.e. the zero-point vibrational energies of the atoms (Table 7, column 3) are added to the experimental enthalpies with their sign reversed. In order to obtain agreement with experiment (column 5), however, the calculated atomisation energies ΔE_{at} were treated by the method of least squares, to give the relation

$$-\Delta E_{at}(\text{kcal mole}^{-1}) = 218.01[-\Delta E_{at}(\text{a.u.})] + 35.28. \quad (58)$$

The right-hand side of this equation contains atomisation energies found by the CNDO method in atomic units, and the left-hand side the atomisation energies that are to be compared with the experimental values. Equation (58) is clearly not simply a conversion from one type of unit to another. It is a purely empirical relation, which governs the predictive value of the CNDO method with appropriate parametrisation.

As in any semi-empirical method, successful choice of parameters in the CNDO method permits the prediction of many—but by no means all—properties of molecules. Thus Wiberg's parametrisation gives strongly underestimated barriers to internal rotation: the calculated barrier in ethane is only 0.7 kcal mole^{-1}. While yielding good agreement with experiment for atomisation energies, this parametrisation does not give reliable values for the energies of individual bonds, and therefore has recently been re-examined by Ehrenson and Seltzer[119].

As already mentioned, Pople and Segal's original parametrisation, while not leading to agreement with experiment for molecular geometry and atomisation energies, nevertheless indicates the changes in barriers to internal rotation occurring on passing from one molecule to another, although the calculated numerical values are usually considerably lower than the experimental values. In cases in which the barriers in π-electron systems are due mainly to repulsion of non-bonded atoms, however, the CNDO method does not give results agreeing with experiment. Thus a calculation for biphenyl showed[120] that the total energy does not pass through a minimum as a function of the dihedral angle between the phenyl rings, although such a curve should have a minimum at $\sim 40°$. The CNDO method also gives incorrect relations between total energy and equilibrium angle of deflection of the phenyl rings[121] for *cis*- and *trans*-stilbenes: they do not agree with the curves obtained from empirical potential functions and do not lead to equilibrium structures comparable with the results of X-ray diffraction; the calculated barrier to the *cis–trans* isomerisation of stilbene is too high—129 instead of the experimental 43 kcal mole^{-1}.

The above examples of the application of the CNDO method force us to treat the calculated results with caution, especially in the case of energy differences. An attempt to predict the mechanism of the *cis–trans* isomerisation of the difluorodi-imide molecule[122] is interesting in this connection. Both forms (Fig. 2) are stable at room temperature, and their structures have been established by detailed investigations[123,124]. Calculations by the CNDO method showed that they actually corresponded to energy minima, with the *cis*- more stable than the *trans*-form by 4.5 kcal mole^{-1} (the experimental energy difference is 3.0 kcal mole^{-1}). The geometry corresponding to the energy minima is not entirely consistent with experiment: the N=N bond length coincides with the experimental value, but the N–F bond is 0.15 Å shorter (calculated and experimental values 1.26 and 1.41 Å); the calculated valency angles differ from the experimental by 2–3°.

Two routes are obviously possible for *cis–trans* isomerisation in this compound: (i) an N–F bond may "bend back", when the transition state will correspond to a configuration in which the two nitrogen atoms and one fluorine atom lie on a straight line (Fig. 2); (ii) rotation about the N=N bond will give a transition state in which the two F–N=N planes are mutually perpendicular. Calculation gives saddle-point energies respectively of 75 and $\sim$ 80 kcal mole^{-1} for the two paths. However, the experimental kinetic equation[125] is $k = 10^{14} \exp[-32.2\ (\text{kcal})/RT]\ \text{s}^{-1}$. Thus the CNDO method gives an activation energy that is inconsistent with experiment. Since the calculated energies of the transition states were almost identical, however, no preference could be made for either mechanism in this example.

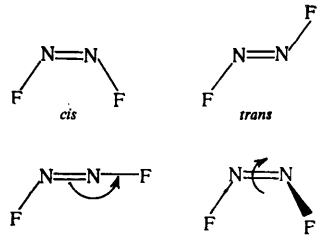

Figure 2. Stable and transitional forms of the difluorodiimide molecule.

The CNDO method bred a whole family of conceptually closely similar semi-empirical methods. Among them may be mentioned the neglect of diatomic differential overlap (NDDO) and partial (intermediate) neglect of differential overlap (INDO). The NDDO method, suggested long ago by Pople et al.,[31] neglects diatomic differential overlap while retaining integrals with the products $\varphi_\mu\varphi_\nu$ for different orbitals on the same atom. The INDO method[33] retains all one-centrel exchange integrals, while neglecting the remaining two-electron integrals. Finally, mention must be made of a few methods "terminating in differential overlap" and occupying a position intermediate between CNDO, NDDO, and INDO[97,98,126–136].

Among all the methods of zero differential overlap, NDDO is the closest approximation to the Roothaan equations[31,137]. The serious defects of NDDO must include the difficulty of parametrisation and the long computer time required. In a detailed examination of the possibilities of this method[101] the parameters β^0 were chosen to give agreement between calculated and experimental bond lengths and valency angles in hydrocarbons. This yielded a geometry agreeing satisfactorily with experiment: deviations in carbon–carbon bond lengths were on the average 0.01 Å and in carbon–hydrogen bond lengths 0.04 Å. But the barriers to internal rotation calculated with the same parameters were unsatisfactory: whereas the CNDO method underestimated all barriers, but gave the correct trend for variations from molecule to molecule, even the trend becomes blurred in the NDDO method. Energies of isomerisation (isobutene → *trans*-but-2-ene → *cis*-but-2-ene; isobutane → n-butane) disagree with experiment even in sign. Thus the introduction of additional integrals into the CNDO method not only does not improve but rather impairs the agreement with experiment. However, such a situation is typical of many semi-empirical methods, and was encountered repeatedly during the period of flowering of π-electron approximations.

The INDO method also does not improve (but does not worsen) the agreement with experiment. Table 8 gives bond lengths and valency angles calculated by this method[138] for several molecules. Comparison with Table 3 shows that, for ethane, methanol, hydrogen peroxide, and dioxygen difluoride, use of a more rigorous approximation has

hardly any effect on the molecular geometry. The impression is produced that optimisation of the parameters of a method is more effective for predicting geometry than are further complications of the theory.

Table 8. Geometry of molecules calculated by INDO method.

Table 9. Comparison between experiment and energies of formation ΔHform (at 298°K) of cyclic hydrocarbons calculated by MINDO/1 method[129].

Molecule	Heat of formation		Molecule	Heat of formation	
	MINDO/1	expt.		MINDO/1	expt.
Cyclopropane	16.36	12.72	Bicyclo-butane	52.29	51.9
Cyclobutane	11.34	6.35	Cyclopentene	8.11	7.73
Cyclopentane	−19.23	−18.46	Cyclopentadiene	30.16	32.44
Cubane	116.88	148.70			

Special consideration must be given to the MINDO (modified INDO) method proposed by Dewar and his coworkers[129-131]. The main idea of MINDO/1 consisted in selecting empirical parameters designed to reproduce experimental heats of formation of organic molecules from the atoms. This involved the parametrisation of many integrals. Since, however, computer time is mainly devoted to evaluating quantum-mechanical integrals, the MINDO method enabled the duration of the calculation to be shortened by more than 90% in comparison with CNDO. In the MINDO/2 variant[131] the parameters were chosen to obtain agreement with experiment not only for energies of formation but also for the molecular geometry. As a result, the accuracy with which heats of formation could be predicted for most organic molecules became about ±2–3 kcal mole^{-1}, and the accuracy of calculating bond lengths and valency angles ±0.01 Å and ±2–3° respectively. Because of its great accuracy the MINDO method is widely employed[139-144] for calculating geometry, barriers to rotation around bonds, and thermochemical properties of organic molecules, as well as for investigating the paths of organic reactions.

Table 9 lists heats of formation calculated for several cyclic and polycyclic hydrocarbons (by the MINDO/1 variant, which for thermochemical properties gives better agreement with experiment than does MINDO/2). These results show about the same agreement with experiment as in calculations using the interatomic potential model[13,145,146]. This is not surprising, however, for in the MINDO method quantum mechanics has already been brought down almost to the level of empirical models: the parameters of the method are very far from reproducing non-empirical calculations (and this was the idea of parametrisation in the CNDO method); on the other hand, they are very valuable for the chemist who wishes to predict with great accuracy the structures and the properties of complicated organic systems.

VI. APPLICATION OF LOCALISED ORBITALS IN SEMI-EMPIRICAL CALCULATIONS

Hitherto we have been examining methods based on delocalised molecular orbitals, each of which is a linear combination of atomic orbitals. It was precisely from them that the Slater determinant (6) was constructed. However, such a determinant can be constructed also on the basis of localised molecular orbitals, in particular those of valency bonds, representing the stereochemical character of the molecule. If functions set up from hybrid atomic orbitals (of types sp^3, sp^2, and sp) are chosen as these localised molecular orbitals, and the coefficients representing the hybrid state are fixed, there is no need to use the Hartree–Fock equations and hence a self-consistency procedure. Such a mode of action is not very good with a non-empirical approach, of course, for the resulting accuracy is too low. In calculations *ab initio*, therefore, the coefficients of hybrid orbitals are optimised by a variational method. Molecular orbitals of methane, for example, can be sought in the form[147]

$$i = A(i_1 + \lambda i_2) \qquad (59)$$

where i_1 is the hybrid tetrahedral orbital of carbon directed towards one of the hydrogen atoms, i_2 is a 1*s* orbital centred on the same hydrogen atom, and A is a normalising factor. The parameter λ can be optimised with respect either to the length of the carbon–hydrogen bond (to make the calculation coincide with experiment) or to some other property.

In semi-empirical methods, however, whose accuracy depends significantly on the parametrisation, it hardly makes sense to proceed in this way: the use of pure hybrid orbitals seems more promising, and then the total energy can be calculated without the need for variational procedures, resulting in a considerable saving of time in comparison with self-consistent methods of the zero differential overlap type.

The principal disadvantage of localised orbitals is that the wave function based on them differs significantly from that of the self-consistent field, while the total energy is far from the Hartree–Fock limit. However, by the use of localised orbitals together with a method of "interaction" of configurations, we can go far beyond the scope of the Hartree–Fock approximation and obtain a considerable proportion of the correlation energy due to "instantaneous" interactions of the electrons[148,149]. This represents a considerable advantage of localised molecular orbitals over delocalised LCAO-MO orbitals.

French workers[150] have used perturbation theory to develop a technique for computing the total energy of a molecule. The Slater determinant, constructed from bonding orbitals completely localised on the bonds, is regarded as a wave function of zero order. Antibonding

orbitals are used to construct wave functions of excited states, and a matrix of configurational "interactions" is based on such functions (configurations). The theory of perturbations is then used to find the energy and the eigenfunction of the ground state.

We shall consider in greater detail the above procedure for systems having closed electron shells (even number N of electrons). Let i and i^* be the bonding and the antibonding orbital corresponding to the ith bond, which can be represented by a linear combination of the hybrid orbitals i_1 and i_2:

$$i = \alpha i_1 + \beta i_2, \tag{60}$$

$$i^* = \beta' i_1 - \alpha' i_2. \tag{61}$$

We assume the localised molecular orbitals (60) and (61) to be known (they can be found, for example, from Hartree–Fock calculations of small molecules). The zero-order wave function can then be written as a Slater determinant:

$$\Psi_0 = (1/2n!)^{1/2} |1\bar{1} \ldots i\bar{i} \ldots n\bar{n}|, \tag{62}$$

which coincides with (6) as $n = \frac{1}{2}N$. The energy of this wave function is calculated as the average value of the Hamiltonian H.

We now consider singly excited configurations, by promoting one electron from the orbital i to the antibonding orbital j^*, and also doubly excited configurations, by promoting electrons from orbitals i and k to antibonding orbitals j^* and l^*:

$$\Psi(\bar{j}_i^*) = (1/\sqrt{2n!})^{1/2} |1\bar{1} \ldots i\bar{j}^* \ldots n\bar{n}|, \tag{63}$$

$$\Psi\left(\frac{\bar{j}^*\bar{l}^*}{ik}\right) = (1/\sqrt{2n!})^{1/2} |1\bar{1} \ldots i\bar{j}^* \ldots k\bar{l}^* \ldots n\bar{n}|. \tag{64}$$

Using the methods of perturbation theory, it was shown[150] that the approximate wave function Ψ and the energy E are given by the formulae

$$\Psi \cong \Psi_0 + \sum_{i,j^*} \frac{\left\langle \Psi_0 | H | \Psi_0 \left(\frac{j^*}{i}\right) \right\rangle}{E_0 - E(j_i^*)} \Psi(j_i^*) + \sum_{i,k,j^*,l^*} \frac{\left\langle \Psi_0 | H | \Psi \left(\frac{j^*l^*}{ik}\right) \right\rangle}{E_0 - E\left(\frac{j^*l^*}{ik}\right)} \Psi\left(\frac{j^*l^*}{ik}\right) \tag{65}$$

$$E \cong \langle \Psi_0 | H | \Psi_0 \rangle + \sum_{i,j^*} \frac{\left\langle \Psi_0 | H | \Psi_0 \left(\frac{j^*}{i}\right) \right\rangle^2}{E_0 - E\left(\frac{j^*}{i}\right)} + \sum_{i,k,j^*,l^*} \frac{\left\langle \Psi_0 | H | \Psi \left(\frac{j^*l^*}{ik}\right) \right\rangle}{E_0 - E\left(\frac{j^*l^*}{ik}\right)}, \tag{66}$$

where it is a simple matter to calculate $E(j^*/i)$ and $E(j^*l^*/ik)$. If the approximation of zero differential overlap is now applied, i.e. if n^4 integrals of type $(ij|j^*i^*)$ present in formulae (65) and (66) are equated to zero, it only remains to evaluate n^2 integrals of type $(ij|i^*j^*)$. But the main gain in time of calculation is due to the absence of a self-consistency procedure.

The above method has been termed perturbative configuration interaction using localised orbitals (PCILO). In practical application, this method is usually confined to a minimal basis-set of localised bond orbitals. Thus four bonding and four antibonding carbon–hydrogen orbitals are considered for ethylene, together with σ- and π-orbitals of the C=C bond. Not only valency orbitals but also 1s orbitals of the inner shells are included. Since the number of integrals is large, although considerably smaller than in methods of configurational interactions based on Hartree–Fock LCAO-MO, the method is usually restricted to zero differential overlap by the use of CNDO/2 parametrisation.

The great merit of the PCILO method with CNDO parametrisation is the comparatively short time of computation: the total energy of a molecule, allowing for a considerable proportion of correlation energy, is calculated on an electronic computer in roughly the time required to calculate empirical potential functions or total energy in the extended Hückel method. This makes PCILO suitable for solving relatively complicated conformational problems. Pullman and his coworkers have employed the PCILO method to construct conformational maps of dipeptides[151–156], to investigate the conformations of conjugated systems playing an important part in the mechanism of visual stimulation[157,158], to calculate the relative energies of steroid systems[159], and to make conformational analyses of disaccharides[160].

Although the PCILO method is in principle more accurate than the Hartree–Fock LCAO-MO method, it is still difficult to state whether it yields more reliable calculated geometric parameters and conformational energies. Even with restricted basis-sets Hartree–Fock calculations *ab initio* lead to an entirely reasonable geometry and reasonable barriers to internal rotation[161,162]. Hence correlation need not in general be taken into account. But it is not excluded that the introduction of correlation corrections into CNDO/2 may lead to an improvement of this semi-empirical method.

Certain results of calculations of simple molecules may give an idea of the possibilities of the PCILO method. Barriers to internal rotation calculated[151] for formamide, acetamide, *N*-methylformamide, and *N*-methylacetamide, respectively 20.8, 14.3, 13.1, and 12.8 kcal mole^{-1}, were close to the experimental values: for formamide, in particular, the experimental values lay in the range 16.8–21.9 kcal mole^{-1}[163–165], and those calculated *ab initio* in the range 19.4–24.7 kcal mole^{-1}[166,167]. In this case the PCILO method based on CNDO/2 parametrisation will give the correct height of the barrier (20.8 kcal mole^{-1}), whereas use of the CNDO/2 method in its original form usually underestimates the barriers.

Calculation of conformational energies for such classical systems as cyclohexane, cyclopentane, and decalin has given interesting results[159] (all values in kcal mole^{-1}): in cyclohexane the boat is less stable than the chair by 5.8 (the experimental energy difference is ~ 6); in cyclopentane the half-chair is more stable than the envelope by 0.7 (this result is not entirely satisfactory, as pseudorotation occurs in cyclopentane almost without hindrance[81]); and *trans*-decalin is more stable than the *cis*-isomer by 2.0 (experimental energy of isomerisation 2.7[168]). Further, calculated values[169] of the barrier to internal rotation in propene are 1.31 with second-order perturbation and 1.22 with third-order perturbation (experimental value 1.98[100]). In methylketen $CH_3.CH:C:O$ the calculated barrier to rotation of the methyl group is 1.54 and 1.31 with second- and third-order perturbation respectively (experiment gives 1.18[100]).

Langlet and van der Meer compared the results obtained by calculating the geometry of ethylene, propene, keten, and methylketen by the extended Hückel[170] and PCILO[169] methods. All calculations were made with fixed bond lengths taken from experiment; the ultimate aim was to find valency angles satisfying minimum total energy (such a procedure is not entirely systematic, of course: in principle a minimum should properly be sought with respect to all parameters). Neither method gave satisfactory results. For the H–C=C angle in methylketen, in particular, the extended Hückel method gives a value of 121.4°, and PCILO yields 119.2° and 117.3° with second- and

third-order perturbation respectively. These three values exceed considerably the experimental angle of 113.7°.[171]

Althqugh the PCILO method has been tested only on a small number of simple molecules, it has become clear that, like any semi-empirical method, it may suffer from the imperfections of parametrisation. The rôle of correlation corrections in the PCILO–CNDO/2 scheme has not yet been finally elucidated, and therefore it is at present difficult to know whether the PCILO method is to be preferred to the classical form of CNDO/2. Nevertheless, in contrast to the latter, the PCILO method makes it possible to calculate in a comparatively short time the relative energies of a multitude of conformations of extremely complicated molecules such as dipeptides and disaccharides. This is the chief merit of the new method.

---o0o---

Summing up, we can state that the semi-empirical methods examined in this Review—extended Hückel method, CNDO, MINDO, PCILO, and certain others—are undoubtedly useful for comparative estimates of the properties of polyatomic molecules. However, the results obtainable by semi-empirical methods depend on the parametrisation adopted, and therefore are not always reliable. In this sense calculations *ab initio* have an undoubted advantage.

But it must not be thought that non-empirical calculations will be able in the forseeable future to replace semi-empirical methods of quantum chemistry completely. Organic molecules of interest to chemists are usually too large for their geometry and conformational energies to be estimated by evaluating all the quantum-mechanical integrals. It is also difficult to envisage the possibility of minimising the Hartree–Fock functional with respect to independent geometric parameters: for molecules of moderate size such a procedure would require an unreasonably long computer time. Yet problems of seeking the equilibrium geometry and calculating conformational energies are easily solved by empirical and semi-empirical methods. This is why such methods, it must be assumed, will acquire still greater popularity among wide circles of chemists.

Separation of Liquid Organic Mixtures by Diffusional Permeation Through Non-porous Polymer Membranes

A.A.El'bert

The physicochemical aspects of a new method of separation of organic liquids by diffusional permeation through non-porous polymer membranes are discussed. The process is assumed to consist of 5 successive steps: transport of material from the liquid to the membrane surface, sorption by the surface layer of the membrane, diffusion through the membrane, desorption from the opposite side of the membrane, and evaporation of the desorbed molecules into the gas (or vapour) phase. The influence of the polymer structure (polyethylene, polypropylene) on the separation process is discussed, and possible modifications of the membrane by solvent treatment, unidirectional mechanical stress, cross-linking by radiation-chemical and photochemical methods, and grafting of other polymers are considered. The effects of the composition of the initial mixture, of the nature of the compounds to be separated, and of temperature are also discussed.

I. INTRODUCTION

Separation processes are extremely important in the chemical industry. New and increasingly complex problems concerning the separation of mixtures are often encountered, which traditional methods (fractional distillation, adsorption, absorption, fractional freezing, extraction) are powerless to solve. New methods of separation have therefore been proposed and developed, such as counter-current crystallisation, preparative chromatography, separation by ion-exchange resins and molecular sieves, and gel chromatography.

Separation by permeation through membranes is one of these newer methods. All variants of this technique rely on the selective transfer of materials through a semipermeable partition. The driving force of the process can be a temperature gradient, a concentration gradient, or a pressure gradient. Some processes use polymer membranes (reverse osmosis, ultrafiltration, diffusional permeation), others use porous glass or metal membranes, or metal foils. The nature of the processes within the membrane can vary quite considerably. For example, the separation of hydrogen by palladium alloy membranes relies on the unique properties of the palladium crystal lattice; ultrafiltration processes rely on the properties and on the molecular size of substances dissolved in water; separation by means of porous glasses depends almost entirely on the size of the solute molecules.

It is clear, from recent review articles dealing with various separation methods based on membranes[1-11], that diffusional permeation through non-porous polymer membranes is the method most widely used for separating mixtures of liquid organic compounds. The separation of organic liquids by ultrafiltration under high pressure (up to 100 kg cm^{-2}) through porous polymer membranes is unacceptably slow, and is complicated by irreversible changes in the membrane during operation[12,13].

We shall therefore confine our discussion to the separation of organic mixtures by diffusional permeation through non-porous polymer membranes. In the Western literature this method of separation is usually termed "permeation" or (less frequently) "pervaporation". The principle of the method, the essential differences from other methods of separation, and possible applications on an industrial scale were first discussed between the late 1950's and the early 1960's[14-18].

This review aims to explain (on the basis of published data) the main features of this method of separation and to assess the influence of various factors on the rate of permeation of materials through a membrane and on the selectivity of the separation process.

II. FIVE-STAGE MECHANISM FOR THE PERMEATION OF SUBSTANCES THROUGH THE MEMBRANE

The separation of substances by permeation through polymer membranes is carried out as follows: the liquid mixture, heated to the required temperature, is placed in contact with a thin polymer membrane (usually 50 to 100 μm thick). The material which passes through the membrane is removed by pumping or in a stream of inert gas. The permeation of a liquid through a membrane consists of the following 5 steps: 1) transfer of material from the centre of the liquid flow to the surface of the membrane, 2) sorption by the surface layer of the membrane, 3) diffusion through the membrane, 4) desorption from the opposite surface of the membrane, 5) transfer from the desorption layer of the membrane surface to the gas (or vapour) phase.

It is not always possible to resolve all 5 stages: for example, stages 1 and 2, and also 4 and 5, are sometimes combined by adding their resistances[19,20].

In order to simplify the terminology we shall assume that the membrane is located horizontally, and that its upper surface is in contact with the liquid and its lower surface with the vapour. We begin with a discussion of the 5 individual stages, and of the way in which each stage affects the overall process.

1. Transfer of Material from the Centre of the Liquid Flow to the Surface of the Membrane

This stage consists essentially in the transport of matter and heat to the surface of the membrane. It has fundamental significance both in the permeation of pure substances, when concentration polarisation cannot arise†, and in the separation of multicomponent mixtures. Hence, vigorous stirring of the liquid is advisable, as was suggested in some of the early papers[21-23]. A more recent paper[24] shows that the rate of permeation can be raised very considerably by increasing the speed of the stirrer.

It is stated[21-23] that a Reynolds number in the liquid of 2300 is sufficient to bring the resistance of stage 1 to a minimum. However, this conclusion may be true only for rates of permeation below 10 kg m^{-2} h^{-1}, and should be tested experimentally at the higher mass flows currently of interest (up to 50–60 kg m^{-2} h^{-1}).

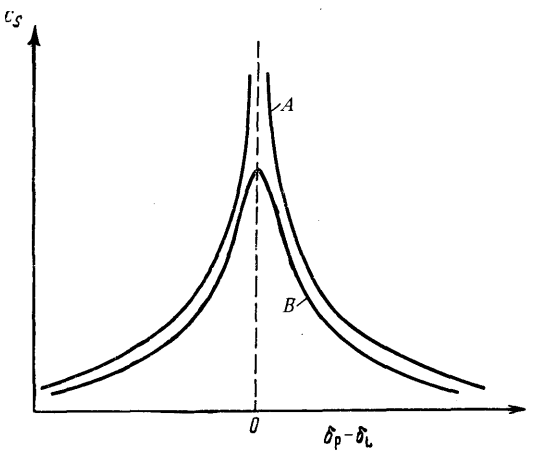

Figure 1. Influence of the Hildebrand solubility parameter on the solubility of liquids in a polymer: δ_p is the solubility parameter of the polymer, δ_L is the solubility parameter of the liquid, *A* is the curve for a linear amorphous polymer, *B* is the curve for a cross-linked or crystalline polymer.

2. Sorption by the Surface Layer of the Membrane

Sorption of the liquid by the polymer membrane is an essential step in the process, because substances which are not sorbed by the membrane (i.e. which are insoluble in it) are incapable of permeation. The dissolution of a liquid in a polymer is described by the Hildebrand solubility parameter. The smaller the difference between the solubility parameters of the liquid and of the polymer, the greater is the solubility (see Fig. 1).[10,25-28] For example, the solubility parameter δ for polyethylene is 7.7–8.4 $(cal\,cm^{-3})^{1/2}$, and for benzene and n-hexane, which are readily soluble in polyethylene, the parameter is 9.2 and 7.3 respectively (all values for 25°).[27]

Long[29] suggested that an equilibrium is rapidly set up at the liquid–polymer interface during the permeation of toluene, methylcyclohexane, and n-heptane through polypropylene membranes. He writes $c_1 = c_S$, where c_1 is the concentration of the permeating substance in the upper layer of the membrane and c_S is the solubility of the permeating substance in the polymer. According to Long, the solubility of hydrocarbons increases with temperature, reaching values of 0.17, 0.23, and 0.34 g per g of dry polymer for n-heptane, toluene, and methylcyclohexane respectively at 60°. Kim and Kammermeyer[30] have measured the concentration profiles during permeation of organic liquids through membranes, and have compared their results with experimentally measured equilibrium concentrations of dioxan in Nylon and dioxan, n-hexane, and benzene in polyethylene. They report that the true concentration of the permeating substance in the upper layer of the membrane is close to (but slightly lower than) the equilibrium value.

Michaels and coworkers[31] measured the solubility of xylene isomers in high-pressure and low-pressure polyethylene: at 25° the solubility of *o*-, *m*-, and *p*-xylene in high-pressure polyethylene is 0.169, 0.136, and 0.118 g per g of dry polymer respectively.

An unsuccessful attempt to measure directly the sorption of liquid benzene by polyethylene membranes has been reported[32]: the results were erratic, and in some cases the membrane lost weight as a result of the extraction of some of its material by the benzene.

The difficulties attending direct experimental measurements of sorption equilibrium have been stressed by Paul[33], who proposed an indirect method of measuring c_S based on the "time-lag" method[34]. In this method, two separate experiments are made on the permeation of the same substance through the membrane: in one experiment, the permeation is monitored from the time when the dry membrane first makes contact with the liquid to the time when equilibrium is established, in the other experiment the permeation is monitored under steady-state conditions. Fick's second law equation had been previously solved for the special case of a concentration-independent diffusion coefficient[35], and also for the general case when the diffusion coefficient is a function of the concentration of the permeating substance in the membrane[33]. A mathematical analysis of the experimental results, using these equations, yields the required value of c_S.

Fels[36] has described an interesting method of measuring equilibrium sorption: by using an electro-balance, he determined c_S for n-heptane and cyclohexane vapours at different activities, and hence he calculated c_S for the liquids by extrapolation. The only drawback of this method is the very laborious experimentation involved.

As we have already pointed out, substances which are not sorbed by the membrane cannot be transmitted through it. However, an exception to this rule is possible, at least in principle: substances which in the pure form are very slowly transmitted through a given membrane may acquire a higher solubility in the membrane, and be readily transmitted, when mixed with other substances which can diffuse rapidly through the same membrane[37]. Effectively, the substance which is readily soluble in the polymer retains the ability to dissolve the substance which in the pure form is insoluble in the polymer, and is thus able to "entrain" it. Furthermore, a very soluble material can expand the structure of the polymer and plasticise

†Concentration polarisation is the increase in concentration of the less rapidly diffusing component, in the boundary layer of liquid adjacent to the surface of the membrane, observed with inadequate stirring.

it[3,10,25,26,37-41], thus assisting the migration of other substances through the membrane. The plasticising effect can be detected also when all the components of a mixture are readily sorbed by the polymer: the rate of permeation of the mixture is usually greater than the "additive" value, calculated from the composition of the mixture and the rates of permeation of the individual components[36,41-43]. The abnormally high rate of permeation of mixtures (benzene–n-hexane, benzene–cyclohexane, n-hexane–cyclohexane) through a polyethylene membrane is also explained[42] by assuming an increased activity of the components, resulting from intermolecular interaction, which enables the molecules to penetrate more readily into the polymer structure, thus raising the concentration of each component in the outermost layer of the membrane beyond the level corresponding to the permeation of an ideal mixture. A decrease in the activity of the components (and therefore in the rate of permeation) as compared with ideal behaviour is another possibility.

Thermodynamic calculation of the sorption isotherm is not possible at the present time, and therefore the isotherms must be determined experimentally.

The sorption of one liquid component is complicated to such an extent by the presence of another component that it is impossible, as a rule, to predict the sorption behaviour of a mixture from a knowledge of the data relating to the individual components. Values of c_1 applicable to the separation of binary and more complex mixtures by permeation through a membrane are not available in the literature.

3. Diffusion Through the Membrane

The third stage of permeation through a membrane is diffusion under the influence of the concentration difference between the upper and the lower surface layer or, more precisely, under the influence of the activity difference. The activity in the polymer can be calculated by the Flory–Huggins equation

$$\ln a_p = \ln V_p + (1 - V_p) + \chi(1 - V_p)^2 \qquad (1)$$

where a_p is the activity of the material dissolved in the polymer, V_p is its volume fraction in the polymer, and χ is the interaction parameter. According to existing data, χ is a function of temperature and concentration, but in most systems it varies over a narrow range (from 0.3 to 0.8). For example, for benzene and an ethylene–propylene copolymer $\chi = 0.65$, and for n-hexane and the same polymer $\chi = 0.3$;[44] for the benzene–polyethylene system $\chi = 0.68$–0.90;[45] for xylene and polyethylene $\chi = (-0.48 + 318/T) \pm 0.2$ where T is temperature in °K.[46]

If the swelling of the membrane in the permeating liquid is appreciable (over 1%) the diffusion coefficient D_c increases exponentially with the concentration of the liquid in the polymer, and the activation energy for diffusion E_{D_c} decreases linearly[10,25,26,28-30,36,47]:

$$D_c = D_0 \exp(\gamma c), \qquad (2)$$

$$E_{D_c} = E_{D_0} - \gamma' c. \qquad (3)$$

In these equations c is the concentration of the permeating substance in the membrane and γ and γ' are constants. As the concentration is increased, E_{D_c} can decrease by 10 kcal mole^{-1},[10] and D_c (in the case of hydrocarbon diffusion through polyethylene membranes) can increase from 10^{-11} to 10^{-7} cm^2 s^{-1}.[25,26,41]

Long[29] has determined experimentally the values of D_0 and γ in the equation

$$G = \frac{D_0}{\alpha l}(e^{\gamma c_s} - 1) \qquad (4)$$

for the permeation of toluene, methylcyclohexane, and n-heptane through polypropylene membranes. In this equation α is a constant and l is the thickness of the membrane. Eqn. (4) was derived on the assumption that Eqn. (2) applies, that $c_1 = c_S$, and that the concentration at the lower surface of the membrane is $c_2 = 0$. From his experimental results Long was able to calculate the concentration profile across the membrane.

Kim and Kammermeyer[30], starting from Fick's second law and assuming an exponential dependence of the diffusion coefficient on concentration (Eqn. (2)), obtained the following equations for calculating the concentration profile in the membrane and the diffusion coefficient applicable to the permeation of a liquid through a membrane (assuming $c_2 = 0$):

$$\frac{dc}{dl} = \left(\frac{1}{l}\right)^2 \frac{1 - e^{\gamma c_1}}{(1 - e^{\gamma c_1})\, l + e^{\gamma c_1}}, \qquad (5)$$

$$\frac{dD}{dl} = D_0(1 - e^{\gamma c_1}). \qquad (6)$$

In these equations $0 \leqslant l \leqslant 1$. The authors concluded that the diffusion coefficient decreases linearly across the thickness of the membrane, as required by Eqn. (6). The mean (effective) diffusion coefficient $\bar{D}$ is defined as

$$\bar{D} = \frac{D_0}{c_1} \int_0^{c_1} e^{\gamma c}\, dc. \qquad (7)$$

The assumption that $c_2 = 0$ is usually admissible when the space below the membrane is continuously evacuated.

Kim and Kammermeyer[30] measured the concentration profile across the membrane and the permeation of water and dioxan through Nylon membranes and n-hexane, benzene, and dioxan through polyethylene membranes (see Fig. 2). The experimental technique consisted in using a pack of 15–25 tightly pressed thin layers as the membrane; after the experiment the pack was dismantled and the concentration of the permeating substance in each layer was determined.

Experimental determinations of the diffusion coefficient followed by graphical analysis of the results by the "time-lag" method have been reported. The method relies on measurements of the penetration of liquid through the membrane from the instant when the liquid is brought into contact with the dry membrane[48,49]. The main shortcoming of this method, according to the authors themselves, is that the error in the calculated diffusion coefficient is always several times greater than the error in the experimentally measured rate of permeation.

Fels and Huang[50] measured the diffusion coefficient by observing desorption from previously swelled membranes. They modified Fick's second law for the assumption of "volume-additive" swelling, i.e. that the increase in volume of the polymer is uniquely determined by the dissolution of liquid in it (as had been previously confirmed experimentally for the dissolution of benzene and n-hexane in polyethylene[51]), and they arrived at the equation

$$\frac{dc}{dt} = \frac{\partial}{\partial l}\left[\frac{D_c}{(1 - V_p)} \frac{\partial c}{\partial l}\right]. \qquad (8)$$

They used this equation in their next paper, devoted to a theoretical interpretation of the effect of the initial composition of the mixture on the separation of benzene and

n-hexane by permeation through a polyethylene membrane[26]. We shall summarise their arguments below.

The theoretical approach of Fels and Huang[25,26,50] is based on Fujita's suggestion[52] that free volume is present within the polymer. This term is analogous to the concept of "holes" during thermal fluctuations, and denotes the total fraction of free volume in the polymer. The free volume is a function of temperature and of the concentration of solutes in the polymer, and can be presented in the form

$$f(V_p, T) = f(0, T) + \beta(T)V_p \quad (9)$$

where $f(V_p, T)$ is the free volume at given values of T and V_p, $f(0, T)$ is the free volume of the dry polymer, and $\beta(T)$ is a proportionality coefficient. When $V_p = 0$ we obtain the intrinsic free volume of the polymer, and when $V_p = 1$ the free volume of the diffusing substance. According to Fujita

$$\ln \frac{D_T}{D_c} = \frac{V_p}{[f(0, T)]^2/[B_d \cdot \beta(T)] + [f(0, T)/B_d] \cdot V_p} \quad (10)$$

where B_d is an arbitrary parameter corresponding to the smallest "hole" needed for diffusional transport, and D_T is the thermodynamic diffusion coefficient

$$D_T = \frac{D_c}{(1 - V_p)} \frac{\partial \ln V_p}{\partial \ln a_p} . \quad (11)$$

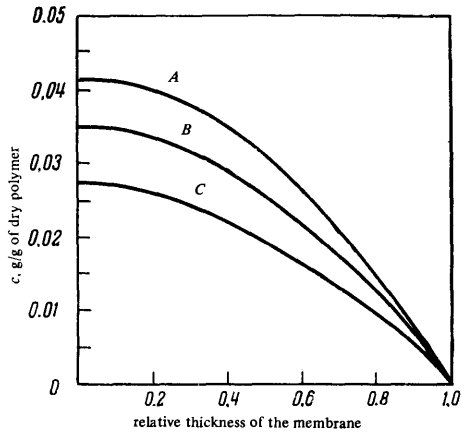

Figure 2. Concentration profiles during permeation of a liquid mixture through a membrane[30]. Membrane of high-pressure polyethylene, 0.0432 cm thick, separation temperature 35°, *A* is n-hexane, *B* is benzene, *C* is dioxan. c_S of the three components 0.043, 0.044, and 0.039 g/g of dry polymer respectively.

Michaels and coworkers[28] have measured, by two methods, the diffusion coefficient in polypropylene before and after treatment in a solvent at high temperature. (The effect of solvent treatment is discussed below.) The first method depends on calculating the rate of permeation (G) through the membrane by Fick's second law:

$$Q = \bar{D}_Q c_1 \quad (12)$$

where $Q = Gl$. Since the thickness of the membrane is constant, we can calculate $\bar{D}_Q$ from the experimentally measured quantities G and c_1 (assuming that $c_2 = 0$). The second method is a calculation based on experimental observations of sorption and desorption of the same substances by the membrane:

$$\bar{D}_a = \frac{\bar{D}_{abs.} + \bar{D}_{des.}}{2} \quad (13)$$

where $\bar{D}_{abs.}$ is the mean diffusion coefficient determined from absorption experiments, and $\bar{D}_{des.}$ is determined from desorption experiments.

Table 1. Comparison of diffusion coefficients obtained from membrane permeation experiments (Eqn. (12)) and from sorption–desorption experiments (Eqn. (13))[28]. $T = 40°$.

Permeating substance	$10^7\bar{D}_Q$, cm^2 s^{-1}			$10^7\bar{D}_a$, cm^2 s^{-1}		
	polypropylene membrane, untreated	polypropylene membrane treated 24 h in *p*-xylene at		polypropylene membrane, untreated	polypropylene membrane treated 24 h in *p*-xylene at	
		80°	100°		80°	100°
Toluene	3.7	9.1	12.6	1.4	3.0	3.3
Methylcyclohexane	3.1	5.5	8.2	1.1	1.6	2.4
Iso-octane	0.5	2.7	5.9	0.6	1.0	1.6

Numerical values of diffusion coefficients are listed in Table 1. Michaels and coworkers[28] ascribe the discrepancy between diffusion coefficients determined by different methods to the fact that in absorption and desorption the diffusion coefficient depends on time as well as on concentration.

Fels[36] reported some measurements of the diffusion coefficient of hydrocarbons in polyethylene by experiments on the absorption of vapours at different activity.

During the diffusional permeation of a multicomponent mixture through a membrane, resulting in separation of the mixture, we cannot assume that the components of the mixture diffuse independently of each other (in parallel flows, as it were). Intermolecular interaction, which is present in the original solution, is undoubtedly complicated by the interaction between the components of the mixture and the membrane material (i.e. the polymer[25,26,42,43,36,53,54]). The diffusion coefficients will depend not only on the concentration of each substance diffusing through the membrane, but also on their physicochemical interactions with each other and with the polymer. This interaction will undoubtedly influence also the concentration profile of the various components across the membrane[37].

Fels and Huang[25,26] suggest two basic reasons for the deviation from additive (i.e. ideal) behaviour of the rate of permeation of a benzene–n-hexane mixture: liquid–liquid interaction, and the plasticising effect of the solutes on the polymer (the presence of a second liquid component in the polymer alters the activity and hence the plasticising effect of the first). A similar view is put forward by Krewinghaus[41], who studied the separation of a benzene–cyclohexane mixture by permeation through modified polyethylene membranes: he treats benzene as a "stronger plasticiser" than cyclohexane.

No information on the diffusion coefficients which apply to the permeation of binary or multicomponent mixtures through a membrane is available in the literature.

4. Desorption from the Lower Surface of the Membrane and Transport from the Desorption Layer to the Gas (or Vapour) Phase

These two stages of the permeation process cannot easily be separated on the basis of published work, and we shall consider them jointly.

Substances which have permeated through the membrane are desorbed from the lower surface, forming a layer of liquid. In principle, however, we could choose experimental conditions such that no liquid is formed on the lower surface of the membrane, and the permeating substances are immediately removed as vapours (for example, by suitably evacuating or heating the space below the membrane). These are exactly the conditions which are most often chosen in practice. Permeation through a membrane can take place at a useful rate also if evaporation from the lower surface is hindered, e.g. if the lower space is maintained at atmospheric pressure or at low temperature: in this case the desorbed liquid simply drains off the lower surface of the membrane [53, 37, 55, 56].

In order to clarify the role of stages 4 and 5 in the separation process, we shall write Fick's second law equation in the form

$$G = -D_c \frac{c_2 - c_1}{l} . \qquad (14)$$

We shall assume that the absorption and desorption processes are fast, and $c_1 = c_S$, but $c_2 = c_g$, where c_g is the equilibrium concentration of the permeating species in the lowest layer of the membrane, corresponding to the concentration of the same species in the vapour. Eqn. (14) becomes

$$G = D_c \frac{c_s - c_g}{l} . \qquad (15)$$

In Eqn. (15) c_S and c_g depend essentially on the temperature, on the composition of the mixture, and on the physicochemical properties of the permeating substances. Furthermore, $c_g = f(p)$, and $p = f(P, t_V)$, where P is the total pressure below the membrane, t_V is the temperature of the vapour, and p is the partial pressure of the permeating substance below the membrane. Hence, $c_g = f(P, t_V)$, and changes in P or in t_V influence p and therefore also c_g. An increase in p produces an increase in c_g, a decrease in the concentration gradient across the membrane, and hence a decrease in the rate of permeation through the membrane, as has been observed experimentally [37, 53, 55, 56]. A change in P or in t_V affects not only the rate, but also the selectivity of the separation. For example, the separation coefficient of a mixture, defined as

$$\alpha = \frac{Y_A}{Y_B} \Big/ \frac{X_A}{X_B} \qquad (16)$$

(where $Y_A(Y_B)$ is the concentration of component A(B) in the mixture permeating through the membrane, $X_A(X_B)$ is the concentration of the same component in the original mixture), can be varied from 1.68 to 1.17 simply by varying P and t_V at constant liquid temperature [53, 56] in the case of the two close-boiling hydrocarbons n-heptane and iso-octane (50 : 50% mixture). Similar results were reported by other workers [57].

The effect of vapour pressure on the rate of permeation and on the selectivity of the separation of toluene–isobutanol mixtures [37] is illustrated in Fig. 3. (the special features of the separation of hydrocarbon–alcohol mixtures are discussed below.)

At P = 760 mmHg it is possible to increase p (by heating the space below the membrane) to such an extent that the rate of permeation almost vanishes. Conversely, by cooling the space below the membrane (still keeping P = 760 mmHg) we can lower p and therefore also c_g, and in this way the rate of permeation can be made comparable to the rate obtained in a fairly good vacuum (of the order of 10 mmHg) [37, 53, 55]. Unambiguous experimental confirmation of the sensitive dependence of the rate of permeation on vapour pressure [57] and on total pressure and vapour temperature [55, 56, 58] has been given in the literature.

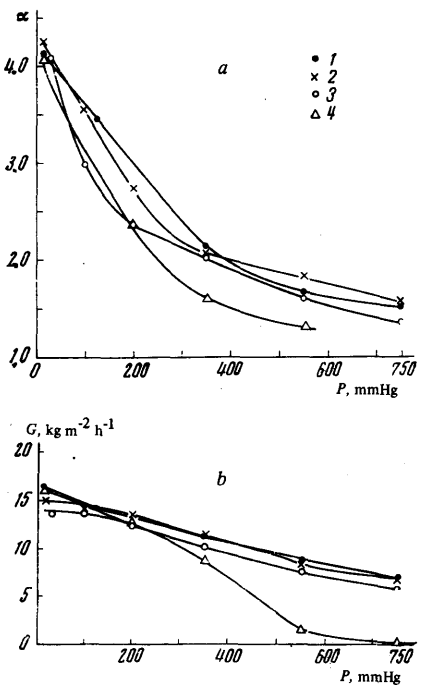

Figure 3. (*a*) Rate of permeation of a 50 : 50% toluene–isobutanol mixture against vapour pressure [37]. Temperature t_T of the heater jacket for the vapour space below the membrane: *1*) 15, *2*) 30, *3*) 50, *4*) 80°; temperature of the liquid 79°. (*b*) Separation coefficient of a 50 : 50% toluene–isobutanol mixture against vapour pressure [37]. Conditions as for Fig. 3*a*.

Ghosh and Rawat [57] have shown that an increase in vapour pressure from 20 to 160 mmHg results in a sharp fall in selectivity of the separation of n-heptane–iso-octane, benzene–cyclohexane, toluene–iso-octane, toluene–methylcyclohexane, and toluene–n-heptane mixtures. In the last three of these mixtures they observed an inversion of the separation: under different conditions the mixture permeating through the membrane may be

enriched in one or the other component. Inversion of the separation of benzene and n-hexane has also been reported [55,58].

Generalising our consideration of the five-stage mechanism of permeation of liquids through polymer membranes, we must stress the need to make proper allowance for each of the stages. Failure to do so may result in serious errors, lack of reproducibility, and incorrect design of apparatus for large-scale operation.

III. INFLUENCE OF POLYMER STRUCTURE AND POSSIBLE MODIFICATIONS OF THE MEMBRANE

Since polyethylene and polypropylene membranes are used almost exclusively at present for the separation of organic liquids by diffusional permeation, we shall not consider other types of membrane in this review.

Several workers have shown [59-63] that in crystalline polymers (such as polyethylene and polypropylene) diffusion is confined almost entirely to the amorphous regions. The permeability of crystalline regions towards gases (He, CH_4) is 2–3 orders of magnitude lower than the permeability of amorphous regions.

Increasing the degree of crystallinity leads to a drastic lowering of the rate of permeation of liquids through the membrane [31,53,64,65], since the permeation of liquids also takes place in the amorphous regions to a large extent. Since dissolution also is largely confined to the amorphous regions, and the diffusion coefficient varies exponentially with the concentration of the liquid in the polymer, decreasing the proportion of amorphous material causes a sharp decrease in the diffusion coefficient.

In a crystalline polymer the amorphous regions are separated by crystalline regions, which thus limit the volume fraction of the polymer available for diffusional permeation. Diffusion takes place along irregular, tortuous channels. Some of the amorphous regions may be close-ended, and not available for continuous permeation. There may also be very narrow channels, which are blocked by the diffusing material.

Not only does the presence of crystalline regions create geometric barriers and lower the rate of permeation, but (even more important) these barriers affect different substances to different extents, as shown by the different rates of permeation of chemically similar but structurally different substances. For example, the rate of permeation of normal alkanes decreases with increasing chain length [1,43,53,55]; iso-alkanes permeate more slowly than normal alkanes [1,43,53]; the xylene isomers [28,31], and benzene and cyclohexane [41,53,54,56], permeate at different rates.

In their paper on the separation of the xylene isomers [31] Michaels and coworkers treat polyethylene as a special type of molecular sieve, in which the intercrystalline pores are filled with amorphous material. On this basis they were able to explain the effect of a "conditioning" treatment on the polymer (lengthy immersion of the membrane in one of the xylene isomers at 50–60° (low-pressure polyethylene) or 90–100° (high pressure polyethylene)). They suggest that during the heat treatment of the membrane the crystals are rearranged without significant change in the degree of crystallinity (for temperatures up to 100°). A more ordered structure, with larger crystals, is formed, the molecules of the xylene isomer acting as "templates" for the reconstruction of the crystalline regions. After this conditioning treatment, the rate of permeation and the selectivity of the separation of the xylene isomer used as a template are significantly increased.

Michaels and Hausslein [46] explain the difference in the sorption capacity for *p*-xylene of polyethylene membranes prepared in different ways by distinguishing between elastically effective and elastically ineffective parts of the amorphous regions. In this model the activity coefficient of the compound dissolved in the polymer is given by the Flory–Renner equation

$$\ln a_p = \ln V_p + (1 - V_p) + \chi(1 - V_p)^2 + \frac{\langle\alpha\rangle_0^2 f \rho V_p (1 - V_p)^{1/3}}{M_c} \qquad (17)$$

rather than by the Flory–Huggins equation (1). In Eqn. (17) $\langle\alpha\rangle_0$ is a geometric factor, taken [46] to be unity, f is the weight fraction of elastically effective polymer, ρ is the density of the unswelled polymer, and M_C is the average molecular weight of the elastically effective regions.

The term elastically effective refers to polymer chains firmly attached to both ends to a cross-linked or to a crystalline region. Polymer chains fixed at one end only, short molecules, and tangles of loose polymer chains are non-elastic. The authors prepared polyethylene membranes with different degrees of crystallinity and different amounts of elastically effective polymer by cooling the membranes from 160° at different rates to 50° (in a dry ice–acetone mixture, in a few minutes, or over a period of 4 hours). Some membranes were mechanically stretched at 40°. The higher cooling rates gave larger amounts of elastically effective polymer. Heat treatment at 130° of samples previously cooled in dry ice–acetone mixture lowered the proportion of elastically effective polymer. Stretching at 40° gave the highest proportion ($f = 0.88$ g g^{-1}) of elastically effective amorphous polymer.

Elastically effective and elastically ineffective regions behave quite differently during dissolution and diffusion. The diffusing molecule can easily draw apart the ineffective, loose regions of the polymer, but it experiences considerable resistance to migration in the regions where the polymer molecules are anchored and elastically effective. As a result, the solubility of the permeating substance in the membrane and its diffusion coefficient are both lowered, but the effect on the diffusion coefficient is much greater than the solubility effect. This is because the diffusion coefficient is an exponential function of the concentration of diffusant in the polymer. For example, the solubility of hydrocarbon vapours in membranes which have been stretched at low temperatures is decreased 2–3 fold, whereas the diffusion coefficient is decreased by a factor of 10–1000.

In a more recent paper, Michaels and coworkers [28] apply the concept of an elastically effective polymer to the conditioning effect on polypropylene membranes of different solvents (methylcyclohexane, *p*-xylene, *o*-xylene, iso-octane, toluene) at temperatures between 60 and 100°. They re-examine their earlier model of the conditioning effect, in which the solvent molecules act as "templates" for the reorganisation of the crystalline regions [31,66], and they show experimentally, for example, that the rate of permeation of iso-octane is substantially increased (4-fold) after treating the membrane in a solvent composed of much smaller molecules (toluene). They also show that the smaller the difference between the Hildebrand solubility parameters of the polymer (polypropylene) and the solute, the lower is the temperature at which the polymer will dissolve. Solvent treatment is thought to involve 2 processes: 1) partial melting of the crystalline regions in the polypropylene and 2) recrystallisation to

give larger crystals. In the resulting structure the amorphous regions are less intimately constrained, less crowded by the crystalline regions, and therefore the proportion of elastically effective polymer is decreased and the diffusion coefficient and rate of permeation are increased. However, the selectivity of the separation is found to vary in inverse proportion to the rate of permeation‡, in contrast to earlier findings [31,66].

A preliminary comparison of polyethylene and polypropylene membranes [28,67] indicates that the diffusion coefficient and the rate of permeation are somewhat higher in the latter. Since the solubility in the two polymers is practically the same, it is concluded that more direct "paths" are available for molecular migration in polypropylene. The greater selectivity of polypropylene towards the separation of xylene isomers is ascribed to greater stiffness of the chains, lower mobility of polymer segments, and greater sensitivity to the size and shape of the permeating molecules in polypropylene.

We must stress that comparisons between polyethylene and polypropylene membranes are arbitrary to a large extent, because both the rate of permeation and the selectivity of the separation are extremely sensitive to the degree of crystallinity and other parameters of the polymer.

Michaels and coworkers [68] have discussed the possible advantages of thermal modification of the membranes; they have also considered modification by mechanical treatment (including unidirectional stretching at low temperatures) [41,69-71] and by solvent treatment [72,73].

They have shown that unidirectional cold stretching (at a temperature well below the melting point) produces drastic changes in the properties of the membrane [41,70,71]. The degree of crystallinity hardly changes at all, but the solubility of the permeating compounds is significantly decreased, the diffusion coefficient falls sharply, so does the rate of permeation through the membrane, and the selectivity of the process is increased. An annealing treatment after unidirectional cold stretching practically restores the original rate of permeation, but at some cost in selectivity (which remains, nevertheless, higher than the selectivity of the original, non-oriented membrane).

These observations are explained as follows. Low-temperature unidirectional stress extends the polymer chains, producing narrow, compressed amorphous channels. The "mobility" of the polymer decreases, and additional barriers to molecular migration in the polymer are produced, leading to a sharp decrease in the rate of permeation. At the same time, the significance of the size and shape of the migrating molecules becomes even more important, and therefore the selectivity of the separation is improved. For example, unidirectional cold stretching of polyethylene membranes at 35° increases the separation coefficient (see Eqn. (16)) of a 50 : 50% mixture of benzene and cyclohexane from ~2 to 4, but the rate of permeation is reduced approximately 30-fold [41].

Krewinghaus [41] therefore confirms the previous suggestion, based on experimental observations [46], that unidirectional cold stretching produces a marked increase in the proportion of elastically effective polymer, and hence a very marked decrease in the diffusion coefficient.

One way of increasing the throughput of this method of separation is to work at higher temperatures: this raises the problem of the thermal stability of the membranes. The thermal stability can be increased, for example, by inducing cross-linking in polyethylene with various forms of ionising radiation [74]. High-pressure polyethylene membranes modified by u.v. irradiation in the presence of PCl_3 have been examined: the rate of permeation of toluene through membranes cross-linked by this technique was found to have risen to 40–60 kg m^{-2} h^{-1}, and the rate of permeation of toluene mixed with ~50% of alcohols had risen to 20–30 kg m^{-2} h^{-1}, without serious loss of selectivity [81]. Cross-linked polyethylene membranes can be used at 80–100°, and in some cases up to 120°, whereas the original membranes were rapidly degraded at 60–65°.

Siegel and Coughlin [75,76] subjected to γ-ray irradiation polyethylene membranes which had been previously immersed in a solvent (benzene, toluene, cyclohexane) for 48 h. The rate of permeation through a membrane modified in this way is increased by about a factor of 2. The authors consider that solvent treatment assists the growth of large crystals at the expense of the smaller crystals, giving rise to a more "open" structure and increasing the number of "amorphous holes". During the subsequent irradiation, the interaction of free radicals in the amorphous regions of the polyethylene results in cementation (or fixation) of a modified structure at the boundaries of the crystalline regions. It is suggested that this method of membrane modification should increase the selectivity of the membrane towards the solvent used for the initial swelling, but the suggestion has not yet been tested experimentally.

Rogers [77] was among the first to study the permeation of gases and vapours (N_2, CO_2, CH_3Br, n-hexane, benzene, methanol) through membranes modified by radiation-induced cross-linking of acrylonitrile, styrene, and vinyl acetate previously sorbed from a solution onto polyethylene.

Huang and Fels [78,79] used γ-radiation to graft styrene from methanol solution onto polyethylene membranes at 35°. The extent of grafting obtained was 5.16 and 26%. They found that as the amount of graft copolymer is increased from 0 to 26%, the coefficient D_0 (see Eqn. (2)) at 45° decreases from 4.49 to 0.90×10^{-8} cm^2 s^{-1} (for the permeation of n-hexane) and from 6.90 to 1.00×10^{-8} (for the permeation of benzene). The solubility of n-hexane is almost unaffected (from 0.228 to 0.245 cm^3 cm^{-3}), but the solubility of benzene is significantly increased (from 0.234 to 0.340 cm^3 cm^{-3} of dry polymer). The authors also studied the changes in free volume $f(V_p, T)$ (see Eqn. (9)), and found that in the polymer–n-hexane system this parameter decreases from 55 to 8% at 45° as the degree of copolymerisation is increased from 0 to 26%. Under similar condition, $f(V_p, T)$ for the benzene–polymer system decreases from 36 to 21%. The activation energies for the permeation of benzene–n-hexane and toluene–n-heptane mixtures through grafted membranes were calculated from the $G-T$ relationships. Increasing the amount of graft copolymerisation lowers the activation energy, and hence increases the rate of permeation (by a factor of 2–3). The observed increase in the separation coefficient α for benzene–n-hexane and toluene–n-heptane mixtures is explained by the lower mobility of the polymer chains after grafting, and by the increased importance of the geometrical parameters of the permeating molecules. The separation coefficient was increased, depending on the extent of graft copolymerisation, by 10–25%.

‡The selectivity of the separation of *p*- and *o*-xylene was defined [28] in terms of the ratio of the rates of permeation of the two isomers.

IV. DEPENDENCE OF THE RATE AND SELECTIVITY OF THE SEPARATION ON THE COMPOSITION OF THE MIXTURE

The rate of permeation through a membrane can be unequivocally calculated from the known rates of permeation and the composition of the mixture to be separated only in a few special ("ideal") cases, such as the separation of mixtures of alkane hydrocarbons[42,53]. In mixtures of hydrocarbons of different classes the rate of permeation is greater than the value expected from the rates of permeation of the individual components and the composition of the mixture. It is given by the equation

$$G_{AB} = G_A X_A \gamma_A + G_B X_B \gamma_B. \qquad (18)$$

where G_{AB} is the rate of permeation of the mixture, γ_A and γ_B are coefficients describing the deviations from additivity (or ideality) for the components A and B, defined as

$$\gamma_A = G_A^v / G_A X_A; \quad \gamma_B = G_B^v / G_B X_B$$

where G_A^p is the partial rate of permeation of the component A for the composition of the mixture and G_B^p is the same quantity for component B.

For an "ideal" mixture of alkane hydrocarbons $\gamma = 1$; for a benzene–n-hexane mixture the value of γ for benzene can be as high as 2.3 [48] or 1.8.[42,53]

As already pointed out, we cannot treat the permeation of the components as a case of parallel flows. The solubility in the membrane of the substances to be separated is affected by the intermolecular interactions of the liquids with each other and with the membrane material. The diffusion coefficients depend not only on the concentrations of all the species present in the membrane, but also on their physicochemical interactions within the polymer structure. The desorption process also is complicated by intermolecular forces. For these reasons, the mathematical description of the permeation of a complex mixture through a membrane is a very difficult problem, which can only be solved at present for a few of the simplest and most fully characterised systems.

Fels and Huang[25,26] attempted a theoretical interpretation of the effect of composition on the rate of permeation of a mixture, allowing for liquid–liquid interactions and for the plasticising effect of the solute molecules on the polymer structure. Starting from the exponential dependence of the diffusion coefficient on concentration, and from Fujita's free volume theory[52], they obtained equations for the rate of permeation of mixtures with different compositions. The required numerical values of $Dc = 0$, $f(0, T)$, $\beta(T)$, and Bd (see Eqn. (10)) were obtained experimentally for the benzene–n-hexane–polyethylene system by desorption experiments described in another paper[50]. The ratio between experimentally observed and calculated rates of permeation is 0.68–2.69 at 25° and 0.93–1.35 at 45°, depending on the initial composition. Fels and Huang ascribe the fairly large discrepancy between experiment and theory to the following effects: 1) inadequacy of the "free volume" concept, 2) the assumption that the concentration c_1 in the upper layer of the membrane has the equilibrium value c_S, 3) the unsupported assumption of a constant concentration ratio of benzene and n-hexane at any point in the membrane, 4) liquid–liquid interaction and liquid–polymer interaction.

Fels[36] points out that his earlier calculations[25,26] involved an elaborate mathematic programme and extravagant use of computer time. He developed a simpler method of calculating rates of permeation of mixtures from the composition of the mixture, the rate of permeation of the individual components, the diffusion coefficient, and the calculated free volume. The diffusion coefficient is determined from the absorption of vapours at different activities, using an equation proposed by Crank[35]:

$$1 - \frac{Q_t}{Q_\infty} = \frac{8}{\pi^2} \exp \frac{D\pi^2 t}{l^2} \qquad (19)$$

where Q_t is the amount of vapour absorbed in time t, and Q_∞ is the total amount of vapour absorbed when equilibrium has been established.

Table 2. Calculated and experimental rates of permeation of cyclohexane and n-heptane through a polyethylene membrane[36].

Temp., °C	Ratio of experimental to calculated rate of permeation for different amounts of cyclohexane in the mixture, wt.%							
	80		60		40		25	
	cyclo-hexane	n-heptane	cyclo-hexane	n-heptane	cyclo-hexane	n-heptane	cyclo-hexane	n-heptane
25	1.27	1.62	1.15	1.36	0.88	1.32	0.86	0.85
30	1.07	1.65	0.99	1.33	0.80	1.27	0.75	0.80

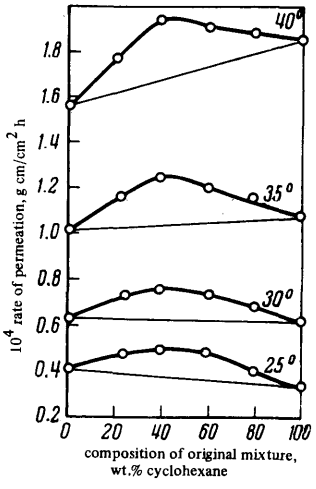

Figure 4. Rate of permeation of a cyclohexane–n-heptane mixture against composition of original mixture[36].

The ratios of experimental to calculated partial rates of permeation for cyclohexane–n-heptane mixtures of different composition are shown in Table 2. Fig. 4 shows experimental plots of the rate of permeation of a cyclohexane–n-heptane mixture as a function of composition.

This mixture does not deviate very strongly from "ideal" behaviour (indicated by the straight line joining the rates of permeation of the pure components). Hence, the results given in Table 2 are unacceptable. Nevertheless, the combined experimental and computational method proposed by Fels[36] has a great deal of merit, because it retains the strictly scientific and logical approach of the earlier attempt[25,26] to describe mathematically the separation of liquids by diffusional permeation through a membrane.

Krewinghaus[41] has tried to evaluate the combined plasticising effect of benzene and cyclohexane on polyethylene. He concludes that benzene is the "stronger" plasticiser, and he gives an empirical equation for the rate of permeation of a mixture with allowance for composition and for the plasticising effects of benzene and cyclohexane.

Several workers have reported (without comment) composition effects on the rate of permeation and selectivity during the separation of toluene–n-butanol mixtures (polypropylene membrane)[21,23] and benzene–isopropanol and benzene–methanol mixtures (polyethylene membrane)[32]. We should point out that whereas the separation coefficient α is usually less than 2 for mixtures of hydrocarbons (for example, benzene–n-hexane, n-heptane–iso-octane, benzene–cyclohexane, mixtures of xylene isomers, etc.), in mixtures of hydrocarbons and polar compounds (alcohols, acetic acid[23]) the separation coefficient is much higher (10–25, or even higher).

V. INFLUENCE OF THE NATURE OF THE COMPOUNDS TO BE SEPARATED

Although the influence of the nature of the compounds to be separated has been implicit in the whole of the preceding discussion, the subject is so important that we think it right to devote a special Section to it. It is the most complicated and the least clearly understood of all the problems which arise in the study of permeation. The difficulty stems from the fact that the permeation process takes place in several stages, and we must therefore consider a wide range of properties of the permeating liquids and of the polymer: boiling point, solubility in the other components of the liquid mixture and in the polymer, polarity, structure and size of the molecules, heat of evaporation, etc.

By analysing published data obtained under conditions such that $c_2 = 0$ and the resistance of steps 4 and 5 can be ignored, we can draw a number of general conclusions on the expected order of separation: 1) the lower members of a homologous series permeate faster than the higher members, 2) if two molecules have the same molecular weight and similar chemical nature, the one with the smaller cross-sectional area permeates faster, 3) if the only difference between the components is the degree of unsaturation, the more unsaturated species permeate faster, 4) the molecules which permeate fastest are those least likely to form hydrogen bonds with the material of the membrane.

The fourth conclusion is illustrated by the following example. The separation of chloroform–acetone mixtures with Teflon membranes is ascribed[80] to the fact that chloroform has an active hydrogen atom, and the fluorine atoms in Teflon have donor properties: as a result, hydrogen bonds are formed and the chloroform is held relatively firmly by the Teflon. In practice only acetone permeates through the membrane, and the chloroform is completely retained.

Most of the work on the separation of organic liquids by diffusional permeation through membranes has been done with hydrocarbons, whose rates of permeation through a given membrane are not very different. However, the separation of hydrocarbons from polar compounds (in particular, alcohols) is also a problem of great practical importance. Using the conventional polyethylene and polypropylene membranes, we would expect the rates of permeation of the hydrocarbon to be 2 orders of magnitude greater than the rate of permeation of the alcohol, leading to a very efficient separation of these mixtures. This expectation is not always borne out by experiment.

El'bert and coworkers[37] have suggested that the properties of the slowly permeating component are not the only factor (or even the main factor) determining the partial rate of permeation of the slow component (alcohol) when mixed with a fast permeating component (hydrocarbon) Hence, the properties of the slow component are not the only factor determining the selectivity of the separation. The solubility and the diffusion coefficient of the slow component are determined not only by the properties of this component and those of the polymer, but first and foremost by the concentration of the faster component at each point in the membrane and by its plasticising effect on the membrane. The fast diffusing substance, being dissolved in the membrane, appears to retain its power to dissolve the slowly diffusing substance, and is able to "drag" it across the membrane.

The same paper[37] describes an experimental study of the separation of a toluene–isobutanol mixture by permeation through polyethylene membranes modified by photochemical cross-linking. On cooling the space below the membrane, and raising the pressure from 20 to 760 mmHg, the selectivity of the separation is found to decrease very substantially. The following explanation is proposed: toluene is readily soluble in the polymer (according to Long, the solubility of toluene in polypropylene is 0.23 g g^{-1} of dry polymer at 60° [29]). Hence, the upper layer of the membrane, where the concentration is close to the equilibrium value, becomes essentially a gel with a high percentage of toluene, and the alcohol is dissolved by this gel rather than by the membrane material. On evacuating the space below the membrane (to a pressure of 10 to 20 mmHg) the concentration of toluene decreases sharply over the entire thickness of the membrane, and practically vanishes in the lower layer of the membrane[38]. In such a membrane (with a "damp" top layer and a "dry" bottom layer) the slowly migrating component has to pass from a region of extensively plasticised polymer, with a high concentration of fast diffusing solute, to a region where practically no plasticising has taken place. Thus, the geometrical barriers opposing migration of the alcohol increase throughout the thickness of the membrane. As a result, the partial rate of permeation of the alcohol is small, and the separation coefficients is acceptably high.

It is also pointed out[37] that on increasing the pressure below the membrane to 760 mmHg and cooling the space below the membrane the concentration profile across the membrane is greatly altered, and the concentration of the fast diffusing substance (toluene) is so high over the entire thickness of the membrane that the slowly diffusing substance (alcohol) is able to migrate across the membrane, which is now a gel (with a high concentration of plasticiser) over its entire thickness. In a "damp" membrane of this kind the geometrical barriers to migration of the alcohol are much lower than in a "dry" membrane.

As a result the separation coefficient of the toluene–isobutanol (50 : 50 wt.%) mixture decreases from 4.5 (at 15 mmHg) to 1.6 (at 760 mmHg).

The plasticising effect of hydrocarbons can be so marked that a hydrocarbon–alcohol mixture permeating through the membrane becomes enriched in the alcohol, although its individual rate of permeation through the membrane is 2 orders of magnitude lower [82].

Thus, a knowledge of the physicochemical properties of the compounds to be separated is far from sufficient to identify the order of the separation. We must also consider the way in which liquid–liquid and liquid–polymer interactions respond to changes in the experimental conditions, and first and foremost we must consider the temperature of the liquid and the temperature and pressure of the vapour.

VI. INFLUENCE OF TEMPERATURE OF THE LIQUID

As a rule, the rate of permeation through a membrane increases exponentially with the temperature of the liquid [17,21,23,28,53,56]. Michaels and coworkers [28] suggest 3 main reasons for the steep increase in rate of permeation: 1) activation of the molecules by the increase in temperature, 2) increased activity of the diffusing species in the polymer resulting from the lower compression, extension, etc. of the polymer chains in the amorphous phase (some decrease in the content of elastically effective polymer is also possible—this point is also stressed by Hausslein [83]), 3) the solubility of the permeating species in the polymer increases with temperature, and the diffusion coefficient is an exponential function of concentration.

The activation energy of the process of permeation through a membrane is usually in the range 7 to 10 kcal mole^{-1}.

Increase in the temperature of the liquid usually produces, in addition to a large increase in the rate of permeation, also a significant decrease in selectivity [17,21,31,28,37,42,56,69]. Michaels and coworkers [28] ascribe this effect to a decrease in the stiffness of the amorphous phase resulting from the combined solvent and temperature effects on the polymer: the polymer is plasticised, and the influence of geometrical barriers on the migration of molecules through the membrane becomes less marked.

Dytnerskii and Golovin [21] have shown, in the special case of the separation of an azeotropic mixture of toluene and n-butanol (containing 72 vol.% of toluene), that a reversible dependence of permeation rate on temperature is observed only if the polypropylene membrane is previously heated to the highest temperature in the experimental range.

Similar results were later reported by Michaels and coworkers [28], who consider that experiments at high temperature have an irreversible effect on the structure of the polymer by lowering the proportion of elastically effective polymer and partly releasing the internal stresses in the amorphous phase. It is pointed out that an increased rate of permeation of a given substance through a membrane can be obtained by previously subjecting the membrane to a high-temperature treatment in a solvent which does not need to be the same as the experimental liquid. For example, treatment of a polypropylene membrane at 60° in iso-octane, toluene, n-hexane, *p*-xylene, and methylcyclohexane increases the rate of permeation of iso-octane at 40° by factors of 2.07, 4.1, 3.58, 2.28, and 5.78 respectively. The selectivity of the separation is found to be somewhat lower after this treatment, in contrast to an earlier report [21] that the selectivity is unaffected.

Li and Long [84] measured the temperature dependence of the rate of permeation of a series of aromatic and non-aromatic hydrocarbons, acetic acid, methanol, water, ethyl methyl ketone, carbon tetrachloride, pyridine, and ethanol through polypropylene membranes. They also measured the effect of temperature on the permeation through Teflon membranes of n-heptane, toluene, ethanol, water, and on the permeation through Saran membranes of toluene, n-heptane, and ethanol. They found that when the permeation of non-aromatic hydrocarbons through polypropylene membranes at temperature in the range 10–70° is plotted as $1/T$ against $\ln G$ the curve shows a break at temperatures between 20 and 45°, corresponding to a sudden change in slope, and therefore also to a change in the activation energy of the permeation process. The break is not found in plots of the permeation of aromatic hydrocarbons through polypropylene membranes.

Chartov and coworkers [81] have shown that the rate of permeation of *o*-xylene and of a toluene–isobutanol (50 : 50%) mixture through photochemically modified polyethylene membranes is not an exponential function of temperature. The rate of permeation was measured at temperatures between 60 and 100° (for the toluene–isobutanol mixture) and between 60 and 120° (for *o*-xylene). The deviation from exponential behaviour is explained as follows: during photochemical cross-linking the new bonds are formed preferentially in the amorphous regions [85]. However, under the influence of a solvent and of elevated temperature we can expect partial dissolution of the crystalline regions, with formation of amorphous regions which are not cross-linked. Since the molecules diffuse through the amorphous regions of polyethylene, this process widens the permeation front, and furthermore the rate of permeation is different in the amorphous regions with and without cross-linking.

As already pointed out, an increase in temperature leads to an increased rate of permeation through the membrane, and at the same time it lowers the selectivity of the separation process. Hence, an optimum choice of temperature is most important since it allows the total area of the membrane to be decreased in industrial processes. It is stated [28] that the number of separation stages required to achieve a given degree of enrichment of one of the components is approximately inversely proportional to the logarithm of the separation coefficient (i.e. $\lg \alpha$), and the separation surface at each stage is inversely proportional to the rate of permeation (by raising the temperature), though accompanied by some loss of selectivity, could result in a decrease of the total working surface of the membrane required for an industrial apparatus. However, if $\alpha \simeq 1$ a small loss of selectivity, even if accompanied by a large increase in the rate of permeation, could greatly increase the number of separation stages required, and thus increase the total membrane area.

---o0o---

The selectivity of separation methods based on diffusional permeation through polymer membranes is determined by a set of properties entirely different from those relevant to other methods of separation currently used in industry (fractionation, absorption, adsorption, crystallisation). Hence this method of separation could successfully be adopted industrially for the following operations:

1) separating mixtures of compounds of similar chemical nature and having similar boiling points (e.g. benzene and cyclohexane); 2) separating mixtures of isomers (for example, xylene isomers, normal and iso-alkanes); 3) separating various azeotropic mixtures (for example, mixtures of toluene and isobutanol, which form an azeotrope and boil at 110.6 and 108° respectively under atmospheric pressure).

Many different practical designs, and technological variants of the process, have been described. For example, "evaporation through a membrane" and "extraction through a membrane"[10], in which the substances migrating across the membranes are removed in a stream of air (or water vapour) or in a flow of inert solvent. Michaels and Bixler[10] point out that membranes suitable for use in the chemical and petrochemicals industry already exist. The main obstacle to the penetration of this method of separation into industrial practice is the unconventional design and operating mode of the necessary plant, which is radically different from traditional separation plant and therefore needs to be specially developed for the purpose.

Vibration Spectra and Structures of the Simplest Aromatic Derivatives of Group I-VI Elements

A.N.Rodionov

The review gives a general and systematic account of experimental and calculated data on the vibration spectra and structures of the simplest aromatic derivatives of non-transition Group I-VI elements. Particular attention has been devoted to "M-sensitive" vibrations, i.e. vibrations involving the element M, the frequencies of the corresponding bands, their activites, and the splittings of the components as a function of molecular structure. The monosubstituted benzene approximation is shown to have poor suitability for the interpretation of the spectra of derivatives of polyvalent elements. The bibliography includes 145 references

I. INTRODUCTION

The extremely common occurrence of aromatic compounds in natural and synthetic materials is generally known. The specific features of aromatic molecules associated with the delocalisation of π electrons and the transmission of electronic effects from one part of the molecule to the entire conjugated system have found extremely wide applications in science and engineering. The creation of new materials with specified properties requires a profound study of the various factors which affect the structure and physicochemical characteristics of aromatic molecules. One of the physical methods most widely employed is that of vibration spectroscopy with which it is often possible to determine the structure of the compound, the type and nature of the substituent, the stability and structure of the complexes, etc.

Therefore this method has been widely used in the last 10–20 years in analytical and structural studies on numerous aromatic compounds, particularly in view of its availability to a wide circle of not only spectroscopists but also chemists working on synthesis. Monographs devoted fully or partly to the vibration spectra of aromatic derivatives have been published in recent years both in the USSR and abroad[1-3]. However, the vibration spectra of purely aromatic molecules of different structures are as a rule discussed in these general texts. In those cases where a substituent is introduced into the aromatic system it usually consists of hydrocarbon groups (aliphatic, unsaturated, etc.) or halogen atoms.

There has now been an appreciable growth of interest in heteroaromatic molecules containing heteroatoms of different types. Studies have been made in recent years on the vibration spectra of compounds of this type but so far these have been non-systematic and sometimes contradictory.

The present review attempts to compile and arrange systematically the original studies on the vibration spectra and structures of the simplest aromatic derivatives of Group I–VI elements and to demonstrate the possibility of employing these spectra for the identification of the individual Ar–M bonds, to determine their strength, and to investigate the molecular structure.

A single system of notation for vibrations is at present lacking in the literature on the vibration spectra of the simplest aromatic compounds (monosubstituted benzenes). In the discussion of the vibration spectra of aromatic compounds with hydrocarbon substituents, one usually employs the notation proposed by Herzberg[2] or Wilson[4]. However, in most studies on the vibration spectra of aromatic derivatives of the elements, Whiffen's notation has been used[5]. Since the present review deals with the spectra of compounds of the second type, we shall continue to employ Whiffen's notation for the vibrations of monosubstituted benzenes in order to simplify comparison with the original studies.

The conversion from one system of notation for monosubstituted benzene vibrations to the other is illustrated in Table 1 which includes in addition the vibration symmetries and approximate absorption regions.

Analysis of the experimental and theoretical data on the vibration spectra of many phenyl derivatives of various elements shows the complexity of the majority of vibration modes. Thus, in contrast to aliphatic derivatives of the elements where stretching and deformation vibrations of the C–M bond can be more or less clearly distinguished, in aromatic derivatives there are as a rule several vibrations in which the Ph–M group is involved to different extents.

According to Whiffen's suggestion[5], these vibrations are called "M-sensitive". These vibrations are in fact of greatest interest in the study of the nature of the substituent and molecular structure and therefore they will be henceforth discussed in greatest detail. On the other hand, the vibrations of the benzene ring, which do not involve the heteroatom, will be considered only where they throw light on the structure of molecules or their complexes.

It is noteworthy that, in contrast to phenyl derivatives of univalent Group VII elements, the spectra of which were studied by Whiffen[5], for polyvalent heteroatoms (with several substituents linked to a single heteroatom), one

must take into account the overall molecular symmetry; this may lead to the splitting of the bands owing to the interaction of the vibrations of adjacent groups via the central atom.

Ph_4M	S_4	A+E	A(p)+B(d)+E(d)

Notation. p = polarised; d = depolarised.

This effect should probably be shown most markedly in vibrations involving the heteroatom, i.e. in M-sensitive vibrations. Depending on molecular symmetry, the components of the split band can appear in different ways in the infrared and Raman spectra. Table 2 gives the selection rules for the infrared and Raman spectra of M-sensitive vibrations corresponding to different molecular symmetries.

II. VIBRATION SPECTRA AND STRUCTURES OF PHENYL DERIVATIVES OF GROUP I ELEMENTS

The structures of aromatic derivatives of Group I elements have been hardly investigated at all. The formation of stable dimers has been demonstrated for the lithium derivatives [6,7]. There is no unanimous view as to the nature and structures of these association complexes. Wittig suggests that the structure of the phenyl-lithium dimer be regarded as that of the autocomplex $(Ph_2Li)^-Li^+$, [6] while in other studies it is believed that a cyclic dimer may exist as a result of "electron-deficient" bonds [7]. An increase of the C–M bond polarity in the series Li → Na → K → Rb, Cs is known to occur in alkali metal compounds and therefore, starting with sodium, the C–M bond is usually regarded as mainly ionic.

Lanpher [8] measured the infrared spectra of phenyl derivatives of lithium, sodium, and potassium and found an intense band in the range 1160–1260 cm^{-1} which he assigned to the C–M bond vibration on the basis of its shift when one metal is replaced by another. However, it has been shown [7,9,10] that the band near 1250 cm^{-1} in the spectra of PhLi does not undergo an isotopic shift on replacement of lithium-7 by lithium-6 and therefore cannot be assigned to the C–Li stretching vibration. The use of compounds containing different proportions of the lithium-7 and lithium-6 isotopes made it possible to isolate in the spectra bands associated with the Ar–Li vibration in the dimers (Table 3).

Table 3. C–Li... absorption bands in the infrared spectra of dimeric lithium aryls (cm^{-1}). [7]

Compound	Medium	
	in liquid paraffin	in butyl ether
[^{7}Li]-Phenyl-lithium	280,320,350,427	352,390,440
[^{6}Li]-Phenyl-lithium	290,326,357,430	no data available

[^{6}Li]-*o*-Tolyl-lithium	338,400,420	278,354,387,440
[^{7}Li]-*p*-Tolyl-lithium	275,310,353	357,395
[^{6}Li]-*p*-Tolyl-lithium	297,318,362	365,416
[^{7}Li]Mesityl-lithium	278,314,342	—
[^{6}Li]Mesityl-lithium	290,326,357	—
[^{7}Li]-α-Naphthyl-lithium	335,383,407	352,390
[^{6}Li]-α-Naphthyl-lithium	350,390,410	360,410

Comparison of the infrared spectra of the PhLi and monosubstituted benzenes with a substituent of similar mass revealed the absence from the spectra of the former of bands sensitive to the substituent in the region above 700 cm^{-1} [for example the 1220 cm^{-1} (*q*-vibration) and 806 cm^{-1} (*r*-vibration) bands in the infrared spectrum of PhF]. [11] This effect is observed in the spectra of all the aromatic lithium derivatives investigated and can probably be accounted for by a weakening of the C–Li bonds owing to stable association of the electron-deficient type. Calculations on in-plane vibrations for the monomeric model of PhLi indeed showed that, even without taking into account the change in molecular configuration on dimerisation, when the force constant K_{Ph-Li} decreases to 1.5×10^6 cm^{-2} the bands in the regions expected for *q*- and *r*-vibrations cease to shift on isotopic substitution of lithium-7 by lithium-6 [12] and, in agreement with experimental data, the isotopic shift occurs only in the long-wavelength part of the spectrum (374 and 259 cm^{-1} for lithium-7 and 400 and 270 cm^{-1} for lithium-6). Moreover, it is noteworthy that the infrared spectra of all the lithium aryls investigated show additional bands in the C–H stretching region displaced towards longer wavelengths by 50–100 cm^{-1}

together with bands in the normal ν_{C-H} region (3030 to 3100 cm^{-1}). The decrease of the ν_{C-H} band intensity in the infrared spectra of lithium aryls is probably associated with a weakening of the C–H bonds in the *ortho*-position relative to the C–Li group, which is satisfactorily correlated with the effect observed in the ^1H NMR spectra of PhLi (Ladd [13]) and is consistent with the decrease in the frequency of the α-C–H bonds in the infrared spectra of aliphatic organolithium compounds [14,15].

III. VIBRATION SPECTRA AND STRUCTURES OF PHENYL DERIVATIVES OF GROUP II ELEMENTS

The presence of vacant p-orbitals and the relatively low electronegativity of beryllium and magnesium result in a fairly stable association of organic derivatives of these elements. The structures of the association complexes of $(CH_3)_2Be$ and $(CH_3)_2Mg$ have been investigated and an appreciable departure of the molecular framework from linearity has been noted ($\angle CBeC \simeq 114°$; $\angle CMgC \simeq 105°$). [16]

Table 4. Experimental and calculated frequencies (wave-numbers, cm^{-1}) of the M-sensitive vibrations in the spectra of Ph_2Be and Ph_2Mg (Rodionov et al. [18]).

Designation of vibration according to Whiffen (Ref.5)	Symmetry (C_2)	Ph_2Be		Ph_2Mg	
		i.r. spectra	calc. for $\alpha = 120°$	i.r. spectra	calc. for $\alpha = 120°$
q	B	1250 m.	1265	1045 m.s.	1060
	A	1200 m.	1198		1075
r	B	902 s.	900	670 m.	675
	A	780 m.	800		685
t	B	570 m.	582	425 s.	415
	A	545 m.	540	310 s.	358
		250 w.	236	200 w.	200
u	B	410 m.	380	255 m.	257
		225 m.	202		185
y	B	475 m.		425 s.	

Note. The following designation of band intensities has been adopted in Tables 4–15: s = strong (intense), m = medium, w = weak, p = polarised, d = depolarised.

We were unable to find direct data concerning the structure of compounds of the type Ph_2M but the fairly large dipole moment of Ph_2Be in benzene [17] and X-ray diffraction data for the crystalline ether adduct of PhMgBr suggest that aromatic derivatives of beryllium and magnesium also have a bent structure with $\angle CMC$ smaller than 180° but probably somewhat larger than for methyl derivatives. In this case structures with C_{2v} or C_2 symmetries are possible. For C_{2v} symmetry, class A_2 vibrations are inactive in the infrared. The decrease of molecular symmetry to C_2 results in all the vibrations becoming active in the infrared and Raman spectra.

We investigated the infrared spectra of Ph_2Be and Ph_2Mg in the range 200–3500 cm^{-1} [18] and assigned the principal bands and confirmed the bent structure of the molecules by comparison of experimental data with the frequencies and vibration modes calculated for different conformations of the Ph_2M molecules.

Table 4 presents bands assigned to the components of the M-sensitive vibrations in the above investigation. In accordance with the selection rules for the proposed molecular symmetry, both components of the M-sensitive vibrations are fairly intense in the infrared spectra, the splitting between them depending significantly on the C–M–C angle. It is noteworthy that, as for PhLi, the association of aromatic derivatives of beryllium and particularly of magnesium leads to a decrease of the force constant K_{C-M} and the appearance in the C–H stretching region in the infrared of C–H bands displaced towards longer wavelengths, in agreement with the ^1H NMR data for PhMgX solutions [13].

The band near 365–383 cm^{-1} in the infrared spectra of ethereal solutions of Ph_2Mg and PhMgBr, assigned by Salinger and Mosher [19] to the stretching PhMg vibration, is probably the B component of the t-vibration with its frequency reduced owing to the formation of an ether adduct.

IV. VIBRATION SPECTRA AND STRUCTURES OF PHENYL DERIVATIVES OF GROUP IIB ELEMENTS

1. Compounds of the Type Ph_2M

Aromatic derivatives of zinc, cadmium, and mercury are monomeric [20–22]. There are X-ray diffraction data demonstrating the linearity of the C–M–C framework of aliphatic derivatives of these elements [23] and also of Ph_2Hg. [24,25] On this basis a planar structure with D_{2h} symmetry has been adopted for Ph_2Zn, Ph_2Cd, and Ph_2Hg, but, as a result of the presence of a centre of symmetry, it should lead to an alternative prohibition: B_u vibrations are active only in the infrared and class Ag and B_g vibrations are active only in the Raman spectra. Unfortunately only the infrared spectra of these compounds have been studied sufficiently fully and the spectra have been interpreted by analogy with monosubstituted benzenes without taking into account the overall molecular symmetry. Therefore the infrared bands assigned [21,26,27] to M-sensitive vibrations should probably be regarded as B_u components of these vibrations active in the infrared spectra. Although the Raman spectra of Ph_2Zn (Kubas and Shriver [28]) and Ph_2Hg (Rodionov et al. [12]) published recently are in fact very incomplete, when combined with calculations on the in-plane vibrations of these molecules [12] they make it possible to detect certain symmetrical components of the M-sensitive vibrations. Table 5 lists the experimental and calculated wave-numbers of the M-sensitive vibrations of diphenyl compounds of zinc, cadmium, and mercury. The results show that the t-vibration, which appears in the range from 200 to 330 cm^{-1} with all the components, shows the maximum splitting of the B_{3u} and Ag components and the greatest sensitivity to the replacement of one metal by another. The 462 and 496 cm^{-1} bands, assigned [29] to the C–Hg–C stretching vibrations in the infrared spectra of $(C_6H_5)_2Hg$ and $(C_6F_5)_2Hg$ respectively, are probably associated with an out-of-plane y-vibration.

The effect of the deuteriation of the benzene rings on the position of the M-sensitive bands in the infrared spectra of $(C_6D_5)_2Zn$ and $(C_6D_5)_2Hg$ has been investigated [21,26]. It has been shown that the B_{3u} components of the t-vibration hardly change on deuteriation, while the r- and q-vibrations shift towards longer wavelengths by 30–40 cm^{-1}; on the other hand, according to Mink et al. [26] the wave-number of the q-vibration of $(C_6D_5)_2Hg$ decreases by approximately 100 cm^{-1}.

2. Compounds of the Type PhMX

X-Ray diffraction data demonstrated the linearity of the C–Hg–Cl and PhHgCl frameworks [30]. The structures of the analogous zinc and cadmium compounds are unknown. If it is assumed that all the compounds discussed in this section have a monomeric linear structure with C_{2v} symmetry, then, in contrast to compounds of the type Ph_2M, only class A_2 vibrations are inactive in the infrared.

The infrared spectra of a large number of compounds with the general formula PhHgX, where X = Cl, Br, I, S, OH, O, CO, NO_3, etc. have been described in a review [27]. However, an adequate interpretation of the infrared spectra has been made only for the simplest derivatives PhHgCl, [21,26,27] PhHgBr, PhHgI, [26,27] PhZnI, and PhCdI. [21] The M-sensitive vibrations listed in Table 6 were isolated by analysing the experimental infrared spectra and by calculations on in-plane vibrations.

V. VIBRATION SPECTRA AND STRUCTURES OF PHENYL DERIVATIVES OF GROUP IIIB ELEMENTS

1. Compounds of the Type Ph_3M

It has been established experimentally that Ph_3B, Ph_3Ga, PhIn, and Ph_3Tl are monomeric in solutions and that only Ph_3Al is appreciably associated [20,31]. X-Ray [32] and electron [33] diffraction data indicate a planar trigonal structure of the central MC_3 unit in Ph_3B, Ph_3Ga, and Ph_3In molecules with D_{3h} symmetry and with the symmetry reduced to D_3 for the molecule as a whole owing to the relative positions of the phenyl groups. Ph_3Al crystals contain molecular dimers with symmetrical bridging phenyl groups [34]. These dimers are at least partially retained in solutions [35]. Therefore Ph_3Al presumably has a distorted planar molecular framework and there is probably a transition to C_{3v} or C_3 symmetry. Table 2 shows that the selection rules for the vibration spectra of molecules with D_{3h} and D_3 symmetries indicate that the M-sensitive vibrations (A_1' or A_1) are forbidden in the infrared and are active with marked polarisation in the Raman spectra. Degenerate vibrations (E′ or E) are active both in the infrared and Raman spectra and are depolarised. When the planar skeleton is distorted, i.e. on passing to C_{3v} symmetry, the symmetrical vibrations are no longer forbidden and the class A_1 vibrations should appear in the infrared spectra.

The infrared spectrum of Ph_3B was reported for the first time by Sharp and Sheppard [36] and that of Ph_3Al by Costa and coworkers [37,38], but without a detailed interpretation of the observed frequencies and their assignment. The infrared spectra of crystalline specimens of Ph_3B (Shurvell and Faniran [39,40]) and Ph_3Al (Shurvell [41]) have been measured and the observed bands have been assigned in terms of monosubstituted benzenes (local C_{2v} symmetry).

The present author and his coworkers [31,42,43] investigated the infrared spectra of triphenyl derivatives of boron, aluminium, gallium, and indium from 200 to 3200 cm^{-1} in different states of aggregation. In order to interpret the spectra, specimens enriched in boron-10, boron-11, and deuterium were obtained and calculations were made on the normal vibrations for the Ph–M and C_6D_5–M models. Subsequently the same investigators obtained the Raman spectrum [44] of Ph_3B and carried out calculations for the in-plane molecular vibrations of the class E′, A_1', and A_2' discussed in this section [12,44]; this yielded a complete interpretation of the vibration spectrum and demonstrated unambiguously the planar structure of the BC_3 central unit. Table 7 lists the experimental and calculated wavenumbers of the M-sensitive vibrations of the Ph_3M molecules, where M = B, Al, Ga, or In.

2. Compounds of the Type Ph_2MX

We were unable to find in the literature any direct measurements designed to elucidate structures of this type. Ph_2BCl and Ph_2BBr are known to be monomeric and they have been assigned the C_{2v} or C_2 symmetry with a planar central unit and rings displaced to some extent from this plane. All the vibrations of the C_2 structure are active in the infrared. The analogous aluminium and gallium compounds are dimerised and have M–X...M bridges [45], which leads to a distortion of the plane of the C_2MX central unit. The infrared spectra of compounds of the type Ph_2MX have been by no means fully investigated.

Bellamy and coworkers measured the infrared spectra of a number of compounds containing the Ph_2B group and assigned the intense absorption in the range 1250–1280 cm^{-1} to νPh–B.[46,47] However, fairly complete spectra and their interpretation have been published very recently. Nahm et al.[48] measured the infrared spectra of a series of compounds Ph_2BX, where X = F, Cl, Br, or I, and assigned the principal bands by comparing these spectra with one another and with the literature data[49]. Measurements have been made[12] of the infrared spectra of a number of compounds Ph_2MX (M = B, Al, or Ga; X = Cl or Br) in the range 200–2000 cm^{-1} and they have been interpreted with the aid of calculations of the frequencies and modes of the in-plane vibrations for a model with C_{2v} symmetry. Analysis of the experimental and calculated data indicates a strong interaction between the vibrations of the Ph–M and M–X groups. There is particularly strong mixing of the r and ν_{B-X} vibrations in the Ph_2BX spectrum, t and ν_{Al-X} in the Ph_2AlX spectrum, and t, u, and ν_{Ga-X} vibrations in the Ph_2GaX spectrum. Additional difficulties arise in the interpretation of the spectra of the gallium and aluminium compounds as a result of their dimerisation[45].

Deacon and Green[50] investigated the infrared spectra of Ph_2TlBr in the range 200–3650 cm^{-1} and Srivastava et al.[51] extended this study to a series of compounds Ph_2TlX (X = Cl, CN, CNO, NCS, N_3, NO_2, etc.). The differences in the assignments by these two groups of investigators concern mainly two infrared bands. Deacon and Green[50] assigned a weak band near 1063 cm^{-1} to the q-vibration and a band near 230 cm^{-1} to the u-vibrations, while Srivastava assigned an intense band at 1020 cm^{-1} to the q-vibration and interpreted the 230 cm^{-1} band as a second component of the u-vibration.

The experimental and calculated wave-numbers of the M-sensitive vibrations of compounds with the general formula Ph_2MX are compiled in Table 8.

3. Compounds of the Type $PhMX_2$

The planar structure of the $PhBCl_2$ molecule was demonstrated by electron diffraction[52] and this is probably also true of the Br and I derivatives. If this is so, they have the C_{2v} symmetry and their infrared spectra should show all the vibrations except A_2.

The compounds $PhAlX_2$ and $PhGaX_2$ are associated into cyclic dimers with bridging M–X–M bonds, which should lead to a distortion of the geometry of an individual molecule and to changes in the vibration spectra[45].

The vibration spectra of boron derivatives have been investigated in greatest detail. Thus Butcher and Gerrard[53] measured the infrared spectra of $PhBCl_2$ and $PhBBr_2$ in the range 400–4000 cm^{-1} and assigned the principal bands. An intense 1215–1236 cm^{-1} band was assigned to Ph–B stretching vibrations and bands in the range 850–960 cm^{-1} were assigned to the symmetric and antisymmetric vibrations of the group BX_2.

Greenwood and Wright[54] supplemented these investigations by a study of the infrared spectra of $PhBF_2$. They noted an appreciable increase of the wave-number of the Ph–B stretching vibrations (1292, 1300 cm^{-1}) and detected the vibrations of the BF_2 group in the range 1340–1380 cm^{-1}. The increase of νPh–B was explained by the partial double bond character of Ph–B owing to the delocalisation of the ring π electrons and the P_π non-bonding electron of fluorine via the vacant p orbital of the boron atom. Lockhart[55,56] measured the infrared and Raman spectra of the $PhB^{35}Cl_2$, $PhB^{35}Cl^{37}Cl$, $PhBBr_2$, and PhBBrCl over a wide range (20–1650 cm^{-1}) and carried

out a complete assignment of the observed bands. The differences between the band assignments in the $PhBCl_2$ and $PhBr_2$ spectra by the two groups of investigators[53,55] concern mainly the position of the νS band of BX_2.

Nahm et al.[48] studied the infrared spectra (250–4000 cm^{-1}) of a series of compounds $PhBX_2$, where X = F, Cl, Br, or I, and Lee[57] described the infrared spectrum of $PhTlX_2$.

The present author and his coworkers[58] investigated experimentally (infrared spectra) and theoretically (calculation of the frequencies and modes of the normal vibrations) a series of compounds of the type $PhMX_2$ (where M = B, Al, or Ga; X = Cl or Br). Analysis of the results enabled the authors to refine the band assignments in the spectra of boron derivatives and to follow the variation of the frequencies and modes of the M-sensitive vibrations on replacement of M and X.

Stephenson and Coburu[98] discussed certain questions of the structure of the compounds and their dimers on the basis of calculations for planar and tetrahedral conformations of the gallium and aluminium derivatives and a comparison of the infrared spectra with the available[59–64] infrared and Raman spectra of the dimers $(AlX_3)_2$ and $(GaX_3)_2$.[59–64] Table 9 lists the experimental and calculated wave-numbers of the M-sensitive vibrations of a series of compounds of the type $PhMX_2$.

VI. VIBRATION SPECTRA AND STRUCTURES OF PHENYL DERIVATIVES OF GROUP IVB ELEMENTS

Numerous studies have been made on the vibration spectra of compounds of the type $PH_4 - nMX_n$ (where M = C, Si, Ge, Sn, or Pb; X = Cl, Br, or I; n = 0, 1, 2, 3, or 4), but here too there are contradictions in the interpretation and many of the investigations do not include the long-wavelength part of the spectrum, which is particularly important for heavy elements.

1. Compounds of the type Ph_4M

X-Ray diffraction studies showed that crystalline Ph_4C,[65] Ph_4Si,[66] Ph_4Ge,[67] and Ph_4Sn[68] have a central C_4M unit with a tetrahedral structure (T_d symmetry) with the overall molecular symmetry reduced to S_4 when the disposition of the phenyl groups is taken into account. Such decrease of symmetry from T_d to S_4 should be reflected in the infrared spectra primarily by a lifting of the prohibition of symmetrical class A_1 vibrations in the infrared. However, the majority of studies on the vibration spectra of the compounds Ph_4M dealt with individual parts of the spectrum[69–74] and the bands observed in the infrared and Raman spectra were interpreted by comparison with the spectra of aliphatic compounds of the same elements[75] or of halogenobenzenes, i.e. in terms of the monosubstituted benzene approximation with C_{2v} symmetry without taking into account the vibrations of the central unit of the molecule and the interaction of different phenyl groups[76].

In later studies by Smith[77,78], Poller and coworkers[79,80], and other investigators[81–83] the vibration spectra of Ph_4M were considered from the standpoint of the overall molecular symmetry and the possible splitting of the M-sensitive vibrations. The present author and his coworkers[84] calculated the wave-numbers and modes of the in-plane vibrations of the Ph_2M fragment with a CMC angle of 109° and M = C, Si, Ge, Sn, or Pb, which largely confirmed the assignments of the M-sensitive vibrations in the above investigations[78–83] and showed the necessity to take into account the overall molecular symmetry.

Table 10 presents the experimental wave-numbers of the M-sensitive vibrations for Ph_4M molecules and the values calculated for the Ph_2M fragment.

2. Compounds of the Type Ph_3MX

We were unable to find in the literature any direct data concerning the compounds of the type Ph_3MX. The central unit most probably has a tetrahedral structure with C_{3v} or C_3 molecular symmetry. In this case both components of the M-sensitive vibrations (A and E) should be active in the infrared and Raman spectra. The differences in the spectra on passing from C_{3v} to C_3 symmetry are probably small.

A number of workers investigated the vibration spectra of Ph_3MX, where M = C, Si, Ge, Sn, or Pb; X = H, D, Cl, Br, etc., but, as for Ph_4M molecules, most of the investigations dealt only with individual sections of the spectrum and the assignments were made by analogy with monosubstituted benzenes (C_{2v} symmetry).

The infrared spectra of a number of compounds containing the Ph_3C group have been measured[69,85-87] and two bands, at 1185 and 1280 cm^{-1}, have been assigned to the C_6H_5-C stretching vibrations; these vibrations were found to depend little on the substituent X. On the basis of the $^{12}C \rightarrow {}^{13}C$ isotopic shift, Weston et al.[88] assigned only one infrared band to the stretching vibration, this is near 1192, 1202, and 1211 cm^{-1} for Ph_3CH, Ph_3COH, and Ph_3CCl respectively.

Table 10. Experimental and calculated frequencies (wave-numbers, cm^{-1}) of the M-sensitive vibrations in the spectra of Ph_4M (M = C, Si, Ge, Sn, or Pb).

*The calculation was performed for the Ph_2M model with the angle $\alpha = 109°$.

Kriegsmann and Schowtka[71] assigned the 490–515 cm^{-1} bands in the spectra of Ph_3SiX (where X = H, F, Cl, or OH) to $\nu Ph-Si$ (ν_{as}) and Smith assigned the 420–445 cm^{-1} and 330 cm^{-1} bands to t_E- and t_A-vibrations respectively[72].

Later Smith[77] made a detailed study of the infrared and Raman spectra of Ph_3SiX and the Si-sensitive vibrations listed in Table 11 were taken from his communication. The infrared spectra of compounds of the type PhGeX in the range 200–2500 cm^{-1} were reported by Cross and Glockling[89] and by Mackay et al.[90], while Durig et al.[91] extended the infrared range to 33 cm^{-1} and investigated the Raman spectrum; on this basis, they assigned the Ge-sensitive bands (the A and E components).

The vibration spectra of Ph_3SnX were studied by a number of workers[70,73-75,79-83,85-92]. Kriegsmann measured the infrared and Raman spectra of Ph_3SnX (where X = OH, Cl, Br, or I).[75,93,94]. Harrah and Ryan[95] interpreted the spectra of a number of aromatic organotin compounds and extended the measurements to 200 cm^{-1}.

Poller made a detailed study of the $Ph_{4-n}SnX_n$ (where X = Cl or Br; n = 1, 2, 3, or 4) spectra[79] and his assignments have been confirmed by other workers[80,92,96].

Clark et al.[83] investigated the infrared and Raman spectra of Ph_3PbX (where X = F, Cl, Br, or I) and assigned the observed bands. From the shift of certain Pb-sensitive bands in different states of aggregation, the authors deduced that the compounds are monomeric in benzene solutions and associated in crystals.

3. Compounds of the Type Ph_2MX_2

There are almost no experimental data concerning the structure of compounds of this type. Keidel and Bauer[85] suggest that Ph_2SiCl_2 has C_2 symmetry. The M-sensitive vibrations should then be split into A and B components active in the infrared and Raman spectra. A more complex crystalline structure, consisting of planar Cl_2PbCl_2 cells containing equivalent Pb–Cl bonds with the phenyl groups at right angles to the axis of the ring and bonds approximately perpendicular to the plane of the ring, has been described for Ph_2PbCl_2.[87]

The vibration spectra of Ph_2CH_2, Ph_2SiX_2 (X = H, CH_3, F, Cl, or OH,[71,72,77,78,90] Ph_2GeX_2 (X = Cl or Br),[90] Ph_2SnX_2 (X = Cl, Br, or I),[73,80,90] and Ph_2PbX_2 (X = Cl, Br, or I)[84] have been investigated experimentally[78,97]. The M-sensitive vibrations of these compounds are listed in Table 11.

4. Compounds of the Type $PhMX_3$

It has been shown by electron diffraction that $PhMX_3$ molecules have a CMX_3 tetrahedral framework and the C_{3v} symmetry has been assigned to them[23]. Calculation of the normal vibration modes for molecules of the type $PhMX_2$, where M is a Group IIIB element, showed that the M-sensitive vibrations do not have the character of individual group vibration and include to a greater or lesser extent the vibrations of all the atoms of the central unit[58]. However, in analysing the vibration spectra of $PhMX_3$, most workers consider separately the vibrations of the Ph–M (C_{2v} symmetry) and MX_3 (C_{3v} symmetry) groups and observe the non-split q-, r-, t-, u- and x-vibrations of monosubstituted benzene and the symmetrical and degenerate vibrations of the MX_3 groups.

The vibration spectra of $PhCH_3$, its deuteriated analogues, and $PhCCl_3$ have been investigated in detail by a number of workers[98-100] and have been fully interpreted from an analysis using experimental infrared, Raman spectroscopic, and calculated data.

The infrared and Raman spectra of $PhSiX_3$, where X = F, Cl, or H, have been studied[71]. Smith extended the investigation of the infrared spectra of these compounds initially to 250 cm^{-1} [72,77] and later to 50 cm^{-1}.[73]

Durig et al.[101] supplemented these studies by investigating the Raman spectra of $PhSiCl_3$. The same

workers[78,101] and also Jakoubkova and Hetflejs[102] made a detailed study of the vibration spectra of $PhGeCl_3$; Durig and Sink[103] obtained and analysed in detail the infrared and Raman spectra of $PhGeCl_3$. The infrared spectra of $PhSnCl_3$ have been investigated up to 400 cm^{-1} [70,73] and subsequently the range was extended to 50 cm^{-1} (Smith[78]) and the Raman spectra were also studied[101].

VII. VIBRATION SPECTRA AND STRUCTURES OF PHENYL DERIVATIVES OF GROUP VB ELEMENTS

A pyramidal structure is characteristic of Group VB elements in the tervalent state. The angle between the bonds at the vertices of the pyramid depends on the nature of the group joined to the element. In aromatic derivatives the CMC angle is reduced from 116° ± 2° in Ph_3N (Sasaki et al.[104]) to 103° in Ph_3P (Daly[105]) and 96° in Ph_3As (Gullen and Hochstrasser[106]), which has been attributed to different degrees of conjugation. The overall symmetry of molecules of this type depends on the structure of the groups combined with the elements.

1. Compounds of the Type Ph_3M

As stated above molecules of this type are pyramidal and, for the same phenyl substituents, the central MC_3 unit should have C_{3v} symmetry. However, it has been shown[104,105] that the overall symmetry of such molecules is reduced to C_3 owing to the rotation of the planes of the rings. Such molecular symmetry should lead to the activity of the class A and E vibrations to which all M-sensitive vibrations belong, both in the infrared and Raman spectrum, and in the latter the class A vibrations should be polarised.

Despite the large-scale employment of aromatic nitrogen derivatives in the chemistry of dyes and in photochemical research, the vibration spectra or even the simplest derivative Ph_3N have been studied very incompletely. As a rule, only the positions of individual bands have been determined in the spectra of tertiary aromatic amines.

Thus, having analysed the infrared spectra of a large number of tertiary aromatic amines, Bellamy[107], Ritschl[108], and Katritzky and Jones[109] assigned the intense bands in the range 1210–1340 cm^{-1} to νPh–N stretching vibrations and noted that the positions of the bands depend on the electron-accepting properties of the ring substituents.

Colthup[110] assigned the medium-intensity band near 1275 cm^{-1} in the infrared spectrum of Ph_3N to νPh–N. Since account must be taken of the possibility of the splitting of the M-sensitive vibrations of the Ph_3N molecule, the infrared band discovered by Colthup should probably be assigned to the E component of the q-vibration. However, the q_A-component has never been observed, although it should be active in the infrared for C_{3v} or C_3 symmetry. Colthup's studies on the infrared and Raman spectra with polarisation and also calculations on the A and E class vibrations of Ph_3N made it possible to assign to the q_E- and q_A-vibrations an intense infrared and depolarised Raman band near 1280 cm^{-1} and a weak infrared band and intense and highly polarised Raman line near 1175 cm^{-1}.[44] These data indicate a small deviation of the central Ph–N bonds from the plane and suggest the possibility of D_3 symmetry for the Ph_3N molecule.

In recent years a number of studies have been made on the vibration spectra of triphenyl compounds of phosphorus[76,95,105,111–123], arsenic[76,95,111,117,119,123–127], antimony[76,95,111,123,128], and bismuth[76,95,111]. However, despite a fairly large number of investigations and the availability of data not only for infrared but also for Raman spectra with polarisation, the observed bands were as a rule assigned to specific vibrations in terms of the monosubstituted benzene approximation. The possible splittings of the M-sensitive vibrations were discussed only in later studies by Green and coworkers[118,125,126]. Table 13 lists the M-sensitive bands.

It is noteworthy that, in contrast to Ph_3N, in the infrared spectrum of which the A components of the M-sensitive vibrations are inactive (approximate D_3 symmetry), both components are as a rule observed in the infrared spectra

of the compounds Ph_3M, where M = P, As, or Sb. This can be traced particularly clearly for the components of the *t*-vibrations.

2. Compounds of the Type Ph_2MX

It has been shown by electron diffraction that aliphatic derivatives of Group VB elements of the type $(CH_3)_2MX$ have C_S symmetry [23]. Similar conclusions have been reached concerning the structure of aromatic derivatives on the basis of polarisation data for Raman spectra. In the case of C_s symmetry all the vibrations should be observed in the infrared and Raman spectra and therefore the infrared spectra should show both components of the M-sensitive vibrations.

Bellamy [107] and Katritzky and Jones [109] assigned to the Ph–N vibrations the intense infrared bands of Ph_2NH and Ph_2NCH_3 in the range 1280–1350 cm^{-1}, increasing to 1370 cm^{-1} in Ph_2ND as a result of interaction with N–D deformation vibrations [129].

Bearing in mind the smallness of the deviation from planarity of the C_3N central unit in Ph_3N, we calculated the wave-numbers and modes of the vibrations of the planar Ph_2NCH_3 model (C_{2v} symmetry). [130] The principal bands were assigned by comparison of the infrared spectra of Ph_3N and Ph_2NCH_3 and calculations on the vibrations of these molecules.

The vibration spectra of Ph_2PH, [115,131] Ph_2AsH, [131] Ph_2PCl, [122,132] Ph_2AsCl, Ph_2AsBr, [127] and Ph_2AsCH_3 [125,126] were investigated in a number of studies. Analysis of the infrared and Raman spectra of most of these compounds made it possible to separate the M-sensitive vibrations, which are listed in Table 14.

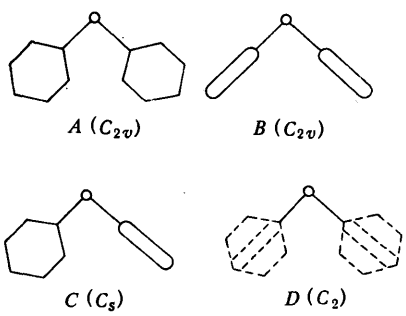
3. Compounds of the Type $PhMX_2$

It has been shown by electron diffraction that in the vapour phase $PhNH_2$ has the C_S symmetry and therefore the N-sensitive vibrations are active in both infrared and Raman spectra. Bellamy [107] and Katritzky and Jones [109] assigned to νPh–N a band in the range 1250–1340 cm^{-1} in the infrared spectra of a large series of primary aromatic amines. Ritschl and Kunkel [133] studied the infrared spectra of 18 *para*- and *meta*-substituted dimethylanilines and assigned the 1340 cm^{-1} band to the Ph–N vibrations and the 1057 and 943 cm^{-1} bands to the ν_{as} and ν_s vibrations of the CH_3–N group. On the basis of the $^{14}N \rightarrow {}^{15}N$ isotopic shift, Tsuboi assigned the 1276 cm^{-1} infrared band of $Ph^{15}NH_2$ to the stretching vibration of the Ph–N group. [134]

According to Evans's data [135], this band should be regarded as due to the *q*-vibration. The remaining N-sensitive vibrations have been much less studied. The infrared and Raman spectra of $PhPH_2$, [121,131] $PhAsH_2$, [131] $PhPCl_2$, [122,132] $PhAsCl_2$, [127,132] $PhAsBr_2$, [127] and $PhAs(CH_3)_2$, [125,126] have been studied in a number of investigations. Table 14 lists the vibrations assigned to the PhM and MX_2 groups.



Analysis of the vibration spectra has confirmed the C_S symmetry of the molecules investigated [121,131,132,135]. The barrier to rotation of the C–N bond in the $PhNH_2$ molecule (3.54 kcal $mole^{-1}$) and the barrier to inversion at the nitrogen atom (4.5 kcal $mole^{-1}$) have been estimated [135].

VIII. VIBRATION SPECTRA AND STRUCTURES OF PHENYL DERIVATIVES OF GROUP VIB ELEMENTS

Aromatic derivatives of Group VIB elements in the crystalline state have an R–M–R central unit with a bent structure ($\alpha < 180°$) and the planes of the benzene rings are rotated relative to one another by an angle φ. The angles depend on the central atom M and are $\alpha = 123° \pm 2°$ for $(p\text{-Br–}C_6H_4)_2O$, [23] $\alpha = 109°$ and $\varphi = 56°$ for $(p\text{-}CH_3C_6H_4)_2S$, [138] $\alpha = 106°$ and $\varphi = 55°$ for $(p\text{-}CH_3C_6H_4)_2Se$, [139] and $\alpha = 101°$ and $\varphi = 62°$ for $(p\text{-}CH_3C_6H_4)_2Te$. [140]

Compounds of the Type Ph_2M

When discussing the vibration spectra of molecules of this type, one considers several configurations differing in the disposition of the benzene rings relative to one another and referring to different symmetry species:

As for the phenyl derivatives of the elements of other Groups, some investigators interpret the vibration spectra of the compounds examined in this section in terms of the monosubstituted benzene approximation without taking into account the interactions of two phenyl groups via the M atom [137]. Katon and Feairheller [141] and Green [142] believe that the asymmetric configuration C (C_S symmetry) is the most probable and interpret the vibration

spectra of Ph_2O and Ph_2S from the standpoint of the presence of two non-equivalent weakly interacting rings: the π orbitals of one ring overlap with those of the O or S atoms, while the second ring is not involved in such overlapping. On this basis, different M-sensitive vibrations are assigned to each benzene ring. However, other investigators concluded from a comparison of the polarisabilities and dipole moments [143] and also an analysis of the infrared, Raman, and NMR spectra [147] that the rings in these molecules are fairly mobile and therefore the B and D configurations with equivalent rings are probable for Ph_2M. The present author's calculation on class A_1 and B_1 vibrations of the A and B models of the Ph_2O and Ph_2S molecules [136] permits an interpretation of the bands which have been assigned [142,143] to the M-sensitive vibrations of two non-equivalent rings, being the symmetric and antisymmetric components of these vibrations. However, it has been shown that the contributions of the first and second rings of model C to the M-sensitive vibrations are in fact non-equivalent.

The vibration spectra of the phenyl derivatives of selenium and tellurium have been hardly investigated. Fritz and Keller [137] measured the infrared spectra of a number of O, S, Se, and Te derivatives in the range 250 to 3500 cm^{-1}, but the spectra are quoted almost without interpretation. The authors assigned bands near 455 to 487 cm^{-1} to Ph–Te vibrations.

McWhinnie and coworkers [145] assigned the 255 and 202 cm^{-1} bands in the infrared and Raman spectra of Ph_2Te_2 to the asymmetric and symmetrical Ph–Te vibrations respectively. The present authors' calculations of the wave-numbers and modes of the in-plane normal vibrations of the Ph_2Se and Ph_2Te molecules [18], using experimental spectra [137] and structural data [139,140], make it possible to assign the bands in Table 15 to the Se- and Te-sensitive vibrations.

Analysis of the experimental and calculated data for the vibration spectra of aromatic derivatives of the elements permits certain general conclusions.

1. For the vibration spectra to yield sufficiently complete information concerning the structure of aromatic derivatives of the elements, the influence of the nature of the element, and of the degree of complex formation, it is necessary to take into account the overall molecular symmetry and the possible interaction of the substituents via the atom of the element. The monosubstituted benzene approximation employed in the majority of investigations is inadequate for polyvalent elements.

2. Calculations on the vibrations of the phenyl derivatives of Group I–VI elements have established a general relation governing the dependence of the force constants K_{Ph-M} on the position of the element in the Periodic System (Table 16).

Table 16. The force constants K_{Ph-M} for Ph_nM (in units of 10^6 cm^{-1}).

Li 1.2	Be 6.7	B 6.5	C 6.5	N 7.5	O 7.5	F 9.0
	Mg 3.2	Al 3.7	Si 4.3	P 4.12	S 4.1	Cl 5.8
	Zn 3.7	Ga 3.82	Ge 3.8	As	Se 3.7	Br 4.8
	Cd 3.5	In 3.6	Sn 3.65	Sb	Te 3.55	I 3.9
	Hg 3.7	Tl	Pb 3.5	Bi		

Note. The K_{Ph-M} were obtained for derivatives of Group I, III, and V elements [12,44], Group II and VI elements [18], Group IV elements (Ph_2M model with $\angle CMC = 109°$), [84] and Group VII elements [3] using a conversion factor of 1.56.

The principal, most significant change in K_{Ph-M} is its decrease within each Group on passing from elements of the Second Period to those of the Third, Fourth, etc. Periods, K_{Ph-M} decreasing most markedly on passing from elements of the Second Period to those of the Third Period.

Analysis of the published data on the force constants K_{C-M} for methyl derivatives of the same elements reveals a qualitatively similar behaviour [137]. This leads to the conclusion that the main factor influencing the value of K_{C-M} is probably the efficiency of the overlapping of the orbitals forming the C–M σ bond which depends significantly on the relative dimensions (principal quantum number) and geometry (hybridisation) of the orbitals of the valence electrons linking the atoms.

3. The Ph–M stretching vibration of the compounds considered here is not characteristic only of the C–M bond and involves to a greater or lesser extent several complex vibrations of the entire molecule (the q-, r-, and t-vibrations according to Whiffen [5]). When several phenyl groups are attached to a polyvalent atom M, each such vibration is split into components, whose number, activity, and the degree of splitting depend on the nature of the element and molecular structure.

4. Analysis of the calculated modes of the q-, r-, and t-vibrations shows that the contribution of ν_{Ph-M} to each of the three vibrations is non-equivalent and depends

mainly on the force constant K_{Ph-M}. When the C–M bond is very rigid ($K_{Ph-M} > 5 \times 10^6$ cm^{-2}), the q- and r-vibrations are most sensitive to the stretching of this bond and to structural changes in the molecule. Under these conditions, the t-vibration hardly includes ν_{Ph-M} and therefore carries little information about the central framework of the molecule. Table 16 shows that derivatives of elements in the Second Period should be regarded as of the same type and that in this case ν_{Ph-M} contributes most to the q- and r-vibrations.

When $K_{Ph-M} < 5 \times 10^6$ cm^{-2}, which is characteristic of derivatives of elements in the Third, Fourth, Fifth, etc. Periods, the contribution of ν_{Ph-M} to the q- and r-vibrations diminishes significantly and these vibrations, having been displaced towards longer wavelengths to 1050–1070 cm^{-1} and 670–700 cm^{-1} respectively, become relatively insensitive to the nature of the element and the rigidity of the C–M bond. On the other hand, ν_{Ph-M} contributes most to the t-vibration in the spectra of such molecules, and for large masses of M (Hg, Tl, Pb, Te, etc.) and low force constants K_{Ph-M} [around $(3.5-3.6) \times 10^6$ cm^{-2}] the t-vibration becomes a virtually pure ν_{Ph-M} vibration.

5. Within each Group of the Periodic System, the force constant K_{Ph-M} varies in the opposite sense to the mass of the element, i.e. K_{Ph-M} as a rule decreases appreciably with increase of the mass of M. Hence follows the rule, discovered by Whiffen, of the dominant contribution of ν_{Ph-M} to the q-vibration of "light" elements and to the t-vibration of "heavy" elements. However, calculation of the vibration modes shows that, when for any reason K_{Ph-M} decreases appreciably in derivatives of a "light" element or increases in derivatives of a "heavy" element, Whiffen's rule ceases to hold. Thus, for the "lightest" of the elements discussed in this review (lithium), as a result of the sharp decrease of K_{Ph-Li} (1.2×10^6 cm^{-2}) due to the polarisation of the C–Li bond and "electron-deficient" binding the experimental and calculated data fail to show an isotopic shift on replacement of lithium-7 by lithium-6 and there is a decreased contribution of ν_{Ph-Li} to the q- and r-vibrations, an appreciable isotopic shift, and a significant contribution of ν_{Ph-Li} to the t-vibration.

6. It is noteworthy that within each Period K_{Ph-M} varies slightly as a function of the electronic nature of the elements belonging to different Groups of the Periodic System, but these changes are comparatively small (with the exception of lithium in the Second Period) and do not lead to the breakdown of Whiffen's rule. If in addition account is taken of the relatively small change of the mass of the elements within the same Period, the possibility of finding the absorption regions of the q-, r-, and t-vibrations for derivatives of any element from the known spectra of the derivatives of another element in the same Period becomes understandable. However, this interpretation fails to take into account molecular structure and is therefore rough and qualitative.

Advances in the Chemistry of Stable Hydrocarbon Radicals

V.D.Sholle and E.G.Rozantsev

The current data on the structure of tervalent carbon radicals are examined and their principal spectroscopic characteristics are presented. The latest studies on the synthesis of stable hydrocarbon radicals, including ultrastable perchlorotriarylmethyl radicals, are considered together with classical investigations. In the discussion of chemical properties, much attention has been devoted to the dimerisation of triarylmethyls, since this problem has altered drastically the traditional concept of tervalent carbon radicals. Modern ideas concerning certain hydrocarbon biradicals are presented. The bibliography includes 150 references.

CONTENTS

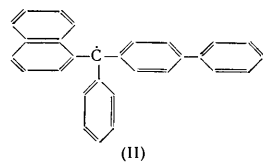
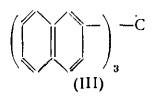
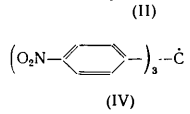
I. INTRODUCTION



After Gomber's discovery[1] of the triphenylmethyl radical, an enormous number of studies have been published on the chemistry and physics of stable hydrocarbon radicals. Many of them have been analysed in familiar reviews by Soviet and foreign workers[2-4]. However, progress in this field of knowledge has been so great in recent years that many postulates which were believed to be firmly established have become obsolete. Together with classical investigations, the present review deals in detail with the latest studies which have greatly modified the traditional ideas about tervalent carbon radicals.

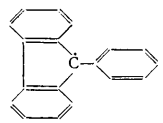


In the literature all stable hydrocarbon radicals are as a rule included under one name — triarylmethyls — which is not altogether correct. It is therefore useful to consider the principal types of stable hydrocarbon radicals before discussing their properties and methods of synthesis.

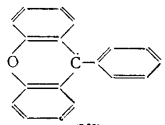


II. PRINCIPAL TYPES OF STABLE HYDROCARBON RADICALS

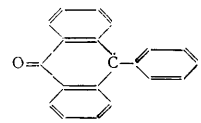
Gomberg did not synthesise the triphenylmethyl radical but its dimer and it was not until 1909 that Wieland[5] showed that this dimer is in equilibrium with its radical in solution. After establishing the nature of triphenylmethyl, many of its derivatives were synthesised, some of which, namely tri-*p*-biphenylylmethyl (I)[6], *p*-biphenylyl-α-naphthylphenylmethyl (II)[7], tri-β-naphthylmethyl (III)[8], and tri-*p*-nitrophenylmethyl (IV)[9], have been isolated in a crystalline form:



(I)

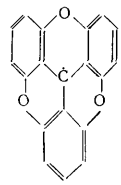


(II)



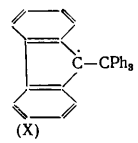
(III)

(IV)



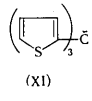
The 9-phenylfluorenyl (V)[6], phenylxanthyl (VI)[10], phenanthronyl (VII)[11], di-*p*-biphenylyl-t-butylmethyl (VIII)[12], and sesquixanthydryl (IX)[13-14] radicals exist in equilibrium with their dimers:

(V)

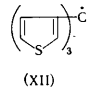


(VI)

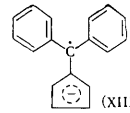
(VII)



(VIII)

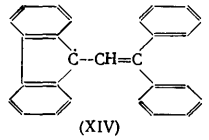


(IX)

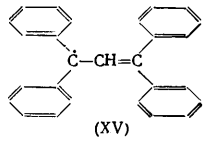


As early as 1922, Schlenk and Mark obtained a higher homologue of triphenylmethyl (pentaphenylmethyl) and its biphenylene analogue (X)[15]:

(X)

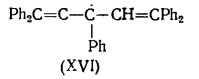


Very stable fluorinated[16-18] and chlorinated[19] derivatives of triphenylmethyl were synthesised recently; analogues of triphenylmethyl radicals were also obtained – trithienylmethyls (XI) and (XII)[20] and the radical-anion of diphenylfulvene (XIII)[21]:



(XI)

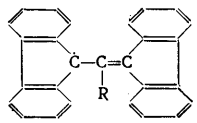
(XII)



(XIII)

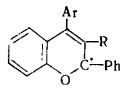
In 1922 Ziegler[22, 23] achieved the synthesis of the allyl radicals (XIV) and (XV), which are examples of a new series of tervalent carbon radicals:

(XIV)

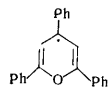


(XV)

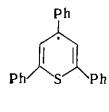
Wittig extended this series having synthesised the diallyl and triallyl radicals [(XVI) and (XVII) respectively][24]:



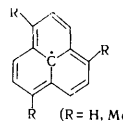
(XVI)



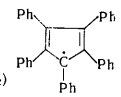
(XVII)



Later Koelsch[25], Solar[26], and Kuhn and coworkers[27, 28] investigated a series of bisbiphenyleneallyl radicals of type (XVIII):



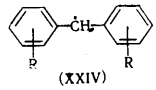
(XVIII) (R=H, Me, Ar)



Chromenyl (XIX)[29, 30], pyryl (XX)[31], thiapyryl (XXI)[32], and perinaphthyl (XXII)[33] radicals as well as the highly symmetrical pentaphenylcyclopentadienyl radical (XXIII), which has been isolated in a crystalline form[34], can also be included among radicals of the allyl type:

(XIX) (R = H, Alk, Ar)

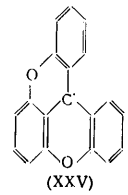
(XX)



(XXI)

(XXII) (R = H, Me)

(XXIII)



The heterochain radicals $(C_6H_5S)_3C\cdot$ and $CH_3S(C_6H_5S)_2C\cdot$ obtained recently proved to be relatively unstable[35].

Diarylmethyl radicals (XXIV), which have been investigated in detail by Nauta[36, 37] and Theilacker[38], are much less stable than triarylmethyls. Only perchlorodiphenylmethyl has now been isolated in a pure form[39]:

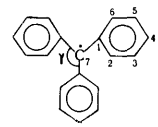
(XXIV)

III. STRUCTURE AND SPECTRA

The electronic spectra of triarylmethyls have two characteristic regions; a region with a very intense absorption at 200 – 400 nm ($\epsilon \simeq 10^4$) and a region of less intense absorption at 500 – 650 nm ($\epsilon \simeq 10^2 - 10^3$)[40]. Triphenylmethyl itself absorbs in the visible region at 484 and 515 nm.[41] Substituents in the *para*-position cause a bathochromic shift of this band, while *ortho*-substituents give rise to a hypsochromic shift owing to the decrease of the coplanarity of the phenyl rings. However, the radical (XXV) absorbs at 490 and 500 nm[42]:

(XXV)

since oxgen bridges prevent the breakdown of coplanarity. The spectrum of 9-phenylfluorenyl (V) is close to that of triphenylmethyl, but the bands are displaced by 800 cm^{-1} towards higher wave-numbers[43]. The electronic spectrum of diphenylmethyl has been interpreted theoretically[44].



The luminescence spectra of di- and triphenylmethyl radicals were also recorded[45] and showed that diphenylmethyl is more coplanar than triphenylmethyl.

The infrared spectra of tervalent carbon radicals are not characteristic[19, 46].

As expected on symmetry grounds, the dipole moment of triphenylmethyl is close to zero[47].

The earlier quantum-mechanical calculations[48] were based on the hypothesis that the triphenylmethyl molecule is planar. However, it was noted subsequently[49] that account must be taken of the mutual repulsion of the *ortho*-hydrogen atoms. Calculation, taking into account such repulsion, shows that the benzene rings must be rotated relative to the plane of the bonds of the central carbon atom by 30° (the θ angle), i.e. the triphenylmethyl molecule should have the shape of a propeller. In this case the conjugation energy decreases only slightly, while the repulsion energy falls very markedly.

The θ angle in tri-*p*-nitrophenylmethyl, which was determined by X-ray diffraction, proved to be 30°.[50] The value for triphenylmethyl in the gas phase is somethat greater (40 – 45°)[51].

The $C_{(7)} - C_{(1)}$ bond length is 1.48 Å for triphenylmethyl, which is less than in triphenylmethane (1.53 Å). On passing from triphenylmethane to the radical, the angle γ increases from 112° to 118°, which corresponds to a change in the hybridisation of the central atom from sp^3 to sp^2.

The X-ray diffraction patterns of perchlorodiphenylmethyl show that the benzene rings are displaced from the trigonal plane of the central atom[52].

Since di- and triarylmethyls are typical π-electron radicals, their unpaired electron is delocalised over the entire π-bond system, which is clearly reflected in the ESR spectra. The constants for the hyperfine coupling (HFC) with protons, determined from the ESR spectra, are $a_{H(ortho)} = 2.55$ G, $a_{H(meta)} = 1.11$ G, and $a_{H(para)} = 2.78$ G for triphenylmethyl[53]. Similar values were obtained from electron nuclear double resonance (ENOR) spectra[54]. The constant for hyperfine coupling with ^{13}C in the central position is 26 G and the *g*-factor is 2.0026.[55]

More than 50% of the spin density of the unpaired electron is concentrated at the central carbon atom. The spin density is positive in the *ortho*- and *para*-positions of the benzene rings and negative in the *meta*-positions.

para- and *meta*-Substituents have only an insignificant influence on the distribution of spin density, while on introduction of *ortho*-substituents the spin density of the central carbon atom increases and that in the benzene rings decreases[13]. This is due to an increase of the deviation of the benzene rings from coplanarity. An increase of the coplanarity of the rings, as for example in sesquixanthydryl (IX), leads to an increase of $a_{H(para)}$ to 3.17 G.[14]

Table 1. The HFC constants (in gauss) for certain triarylmethyls

Radical	$a_{H(ortho)}$	$a_{H(meta)}$	$a_{H(para)}$	References
$Ph_3\dot{C}$	2.55	1.11	2.78	53
$(p\text{-}FC_6H_4)_3\dot{C}$	2.70	1.13	6.5 (F)	55
$(m\text{-}FC_6H_4)_3\dot{C}$	2.64	1.09 (F)	2.85	55
$(2,6\text{-}F_2C_6H_3)_3\dot{C}$	2.11 (F)	1.06	2.61	57
$(3,5\text{-}F_2C_6H_3)_3\dot{C}$	2.14	1.67 (F)	2.52	57
$(p\text{-}NO_2C_6H_4)_3\dot{C}$	2.50	1.14	0.66 (N)	58
$(p\text{-}MeOC_6H_4)_3\dot{C}$	2.89	1.05	0.34 (Me)	59
$(2,6\text{-}(MeO)_2C_6H_3)_3\dot{C}$	0.14 (Me)	1.06	2.26	13
Sesquixanthydryl(IX)	—	0.39	3.17	14

The unusual ratio $a_{H(ortho)} : a_{H(para)} = 2$ in the 9-phenylthiaxanthyl radical is evidence of the hindered rotation of the phenyl group, the angle of its displacement from the plane of the heterocycle amounting to 72°.[56] Table 1 lists the HFC constants for certain triarylmethyls.

Table 2. The proton HFC constants a_i and spin densities in symmetrical diarylmethyls

Substituent	a_2	a_3	a_4	a_7	ρ_C^π	References
H	3.05	1.22	3.05	8.36		62
2,6-Me_2	2.15	1.43	3.25	16.27	0.71	63
2,6-Et_2	1.47	1.7	3.17	16.22	0.70	63
2,6-(i-Pr)$_2$	2.22	0.74	2.22	16.69	0.73	63
2-(t-Bu)	3.42	1.37	3.42	15.92	0.69	63
2,5-(t-Bu)$_2$	3.15	1.20	3.50	15.15	0.66	64

The ESR spectrum of perchlorotriphenylmethyl radicals consists of a singlet with satellites due to the ^{13}C nuclei, the *g*-factor amounting to 2.0025. In these radicals, 70% of the spin density is at the central carbon atom, which corresponds to an angle rotation of the benzene rings $\theta \simeq 60°$.[60]

It has been shown[61] that in the radicals (XXVI) and (XXVII) approximately 10% of the spin density is delocalised over remote benzene rings:

$Ph_2\dot{C}-C_6H_4-C\equiv CPh$ (XXVI) $\quad (Ph-C\equiv C-C_6H_4)_3\dot{C}$ (XXVII) .

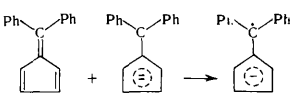
In broad outline, the distribution of spin density in diarylmethyls differs little from the distribution in triarylmethyls. Table 2 presents the HFC constants and spin densities (ρ_C^π) at the central carbon atom:

The constant for hyperfine coupling with the ^{13}C atom in the central position in the $(C_6Cl_5)\dot{C}Cl$ radical is 39 G, which corresponds to $\rho_C^\pi = 0.9$, and the *g*-factor is 2.0055. The angle of rotation θ is 60°.[60]

Comparison of the ESR spectra of various diarylmethyls led Buchanchenko and Vasserman[65] to the conclusion that, in contrast to its substituted derivatives, the hybridisation of the central carbon atom in the diphenylmethyl radical is not sp^2.

IV. METHODS OF SYNTHESIS

The method of synthesising triarylmethyls by the reduction of halogenotriarylmethanes with metals which Gomberg[1] developed still remains important:



$$Ar_3CX \xrightarrow{M} Ar_3\dot{C} + MX .$$

Silver, mercury, zinc, and various amalgams are most frequently used as reducing agents. Triarylmethyl perchlorates are also employed in place of the halides. The reaction is carried out in an inert medium free from moisture in solvents such as benzene, acetone, ether, petroleum ether, ethyl acetate, and others. In general, triarylmethyl halides and perchlorates are such powerful electron acceptors that they are very readily reduced by a wide range of nucleophilic agents, such as organomagnesium compounds[22, 66], alkoxides and phenoxides[67], sodium diethylphosphite[68], sodium iodide[16], inorganic anions[69], triphenylphosphine and diphenylamine[70], organo-mercury compounds[70], the cyclo-octatetraene dianion[71], and metal ketyls[72].

Diarylmethyls are mainly obtained by Gomberg's method involving the reduction of the corresponding chlorides with metals[64, 73]. Perchlorodiphenylmethyl was obtained for the first time by the reduction of the corresponding chloride with t in (II) chloride[39]:

$$(C_6Cl_5)_2CCl_2 \xrightarrow{SnCl_2} (C_6Cl_5)_2\dot{C}Cl .$$

The diphenylfulvene radical-anion (XIII) was obtained by the reduction of diphenylfulvene by its dianion[21]:

(XIII)

Another general method of synthesising triarylmethyls, involving the reduction of triarylmethyl carbonium ions, was proposed by Conant[74]. Vanadium(II) chloride and sulphate have been used as reducing agents. The carbonium ion was obtained by the dissolution of chlorotriphenylmethane or triphenylmethanol in sulphuric or hydrochloric acid:

$$Ar_3COH \xrightarrow{H^+} Ar_3\overset{+}{C} \xrightarrow{V^{2+}} Ar_3\dot{C} .$$

Chromium[42, 57] and titanium[18] salts have been proposed as reducing agents and trifluoroacetic acid[57] and a mixture of acetic and hydrochloric acids[42] have been suggested as ionising solvents.

The triarylmethyl carbanions formed on dissolution of triarylmethanes in alkalis are readily oxidised to triarylmethyls. The reaction proceeds in an aqueous medium

from which the radical is readily extracted[17]. $KMnO_4$,[17] $K_3Fe(CN)_6$,[28] $AgNO_3$,[8] mercury salts, and bromotriphenylmethane[70] have been used as oxidants:

$$Ar_3CH \xrightarrow{OH^-} Ar_3C^- \xrightarrow{[O]} Ar_3C^{\cdot}$$

Perchlorodiphenylmethyls and perchlorotriphenylmethyls have been obtained by the oxidation of the corresponding carbanions with iodine and oxygen[19].

Zieglar[75, 76] developed a convenient method of synthesising arylalkyl radicals using dibromotetramethylethylene as the electron acceptor:

$$Ar_2RCK + Me_2CBrCBrMe_2 \rightarrow Ar_2RC^{\cdot} + Me_2C{=}CMe_2 + 2KBr$$

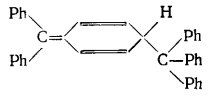
Ar_2RCK was obtained by treating the substituted methyl ether with the metal:

$$Ar_2RCOMe + 2K \rightarrow Ar_2RCK + MeOK$$

A modification of Gomberg's method has been proposed by Schmidlin[77], who obtained triphenylmethyl by treating triphenylacetyl chloride with silver:

$$Ph_3CCOCl \xrightarrow{Ag} Ph_3C^{\cdot} + CO$$

Mention may be made of several other methods of synthesising triarylmethyls but these have no preparative value.



Triphenylmethyl is formed in the decomposition of azo-compounds containing the triphenylmethyl residue[5, 78], t-butyltriphenyl peracetate[79], and *N*-diphenylmethyl-$\alpha\alpha$-diphenylnitrones[80], in the pyrolysis of trityl ethers[81, 82], and in photochemical[83] and certain other reactions[84-87].

The principal method of synthesising the unstable diphenylmethyl radical is photolysis and thermolysis of various diphenylmethane derivatives[45, 62, 88].

V. CHEMICAL PROPERTIES

1. Dimerisation

Tervalent carbon radicals are in thermodynamic equilibrium with their dimers. Since triphenylmethyl was obtained for the first time in an attempt to synthesise hexaphenylethane, the latter was in fact believed to be a dimer of the radical. However, as early as 1905 Jacobson[89] proposed the cyclohexadiene (XXVIII) structure for the dimer:

(XXVIII)

Gomberg[90] also postulated the possibility of several triphenylmethyl dimerisation pathways. The lack of reliable physical methods for the determination of the structure precluded at the time a final solution of this problem and the controversy concerning the structure of triphenylmethyl dimers led to the belief that the only possible structure is that of hexaphenylethane. However, the finding that the dimerisation of tri-(p-*t*-butylphenyl)methyl[91], di-(2,5-di-t-butylphenyl)methyl[92], and di-*p*-substituted diarylmethyls proceeds with extreme difficulty led to the revision by Lankamp et al. of the hypothesis concerning the structure of triarylmethyl and diarylmethyl dimers[93]. The NMR spectra of the diarylmethyl and triarylmethyl dimers which they investigated are consistent with the cyclohexadiene structure and contradict the polyarylethane structure.

The same workers synthesised true tetra-arylethanes by treating diarylmethanols with an excess of vanadium(II) or chromium(II) ions in an acetone solution of hydrochloric acid. True tetra-arylethanes dissociate to diarylmethyl radicals with difficulty and only at a high temperature and the radicals dimerise to cyclohexadienes and not tetra-arylethanes. The melting points of true tetra-arylethanes are much higher than those of the radical dimers. Subsequently the cyclohexadiene structure of the triphenylmethyl dimers was confirmed yet again by ^1H NMR[94] and ^{13}C NMR[95] spectra.

As frequently happens, the fact established not only failed to put an end to the old problems but actually gave rise to new ones. Firstly, not all the radicals dimerised in the "new" way; for example, 9-phenylfluorenyl (V) associates to an ethane derivative[95] and it is probably necessary to determine the structure of the dimer for each radical †. Secondly, it is not clear, for example, why di-(2-t-butylphenyl)methyl dimerises to a cyclohexadiene, while the 2,4- and 2,5-t-butyl derivatives form ethanes[96]. Thirdly, the entire chemistry of polyarylethanes, on which research has been continued for more than 70 years, was suddenly found to be completely unknown.

Other conditions being equal, two main factors influenced the thermodynamic radical – dimer equilibrium: (1) mesomeric stabilisation of the radical and (2) steric interactions in the dimer which promote dissociation.

Estimates of the relative importance of these factors, based on thermochemical data[97], show that the mesomeric effect is approximately twice as effective in promoting dissociation (50 – 55 kcal mole^{-1}) as the steric effect (17 – 22 kcal mole^{-1}).

The heat of dissociation of the triphenylmethyl dimer determined by ESR is 11 kcal mole^{-1}.[98] The activation energy for dissociation, determined by the reaction of this radical with oxygen, is 19 kcal mole^{-1}.[37, 99] A comparison of the thermodynamic data for the recombination and dissociation of diarylmethyls and triarylmethyls has been carried out[37]. While the heats of dissociation of the dimers are almost independent of the solvent, the dissociation constants vary extremely markedly (Table 3).

Table 3. The constants and heats of dissociation of the triphenylmethyl dimer[100]

Solvent	Dissociation constant 10^4K at 20°C	Heat of dissociation, kcal mole^{-1}	Solvent	Dissociation constant 10^4K at 20°C	Heat of dissociation, kcal mole^{-1}
			Ethylene dibromide	3.9	11.4
Propiononitrile	1.2	11.4	Benzene	4.1	11.3
Ethyl benzoate	1.67	12.0	Chloroform	6.9	10.5
Acetophenone	1.70	11.5	Carbon disulphide	19.2	11.0
Dioxan	2.5	11.6			
Bromobenzene	3.7	11.5			

According to Walter's classification[101], triarylmethyl radicals belong to class S, i.e. the degree of dissociation of their dimers increases following the introduction of both electron-donating and electron-accepting substituents.

† A communication was published recently where the literature data on the thermodynamic radical – dimer equilibrium were re-examined in connection with a revision of the structure of the dimers and a correlation equation was successfully applied to the dissociation of the dimers using Taff's steric constants[150].

p-Nitro- and *p*-phenyl substituents have a very marked influence on the dissociation of the dimers (Table 4).

It has been noted that *p*-alkyl-substituted triarylmethyls do not dimerise even at a low temperature. This confirms the cyclohexadiene structure of the dimer. Alkyl substituents in the *meta*- and *para*-positions increase the degree of dissociation but *ortho*-substituents have a particularly marked influence[104]. Thus tri-(2,6-dimethoxyphenyl)-methyl does not dimerise even in the solid state[13]. Coeranthryl (XXV) is also completely dissociated[42]. In contrast, sesquixanthydryl (IX) exists almost entirely as the dimer[13]. This is probably related to the absence of steric hindrance to dimerisation.

Table 4. Dissociation of triarylmethyl dimers[102]

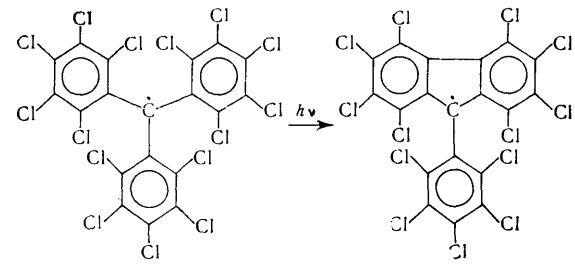
Radical formed	Percentage dissociation in benzene at 5°C	Radical formed	Percentage dissociation in benzene at 5°C
$(C_6H_5)_3\dot{C}$	2—3	$(C_6H_5)_2C{=}CH(C_6H_5)_2\dot{C}$	80
$p\text{-}C_6H_5C_6H_4(C_6H_5)_2\dot{C}$	15	$(CH_3)_3C\,(p\text{-}C_6H_5C_6H_4)_2\dot{C}$	74
$(p\text{-}C_6H_5C_6H_4)_2(C_6H_5)\dot{C}$	79	$\alpha\text{-}C_{10}H_7(C_6H_5)_2\dot{C}$	60
$(p\text{-}C_6H_5C_6H_4)_3\dot{C}$	100	$\beta\text{-}C_{10}H_7(C_6H_5)_2\dot{C}$	33
$(C_6H_5)_3C(C_6H_5)_2\dot{C}$	100	$(\beta\text{-}C_{10}H_7)_3\dot{C}$	24
$(p\text{-}NO_2C_6H_4)_3\dot{C}$	100		

Bisbiphenyleneallyl radicals (XVII) are highly dissociated in solution, although in the solid state they exist mainly as the dimers[27].

Fluorinated triarylmethyls are dissociated in the solid state to the extent of 80 – 90%.[16] Perchlorotriarylmethyls are entirely monomeric both in solution and in the solid state[19].

Table 5. Heats and degrees of dissociation of diarylmethyl dimers[105]

Diarylmethyl dimer	Degree of dissociation, %	Heat of dissociation, kcal mole^{-1}
Di-(2,6-dimethylphenyl) methyl	0.35	22
Di(2-t-butylphenyl)-methyl	0.61	19.7
Di-(2,6-Diethylphenyl)-methyl	1.97	12.0
Triphenylmethyl	12.0	10.9
Di-(2,6-di-isopropyl-phenyl)methyl	100	*



* Not determined owing to the superposition of the disproportionation process

Diarylmethyl radicals dimerise like triarylmethyls, but their dimers are dissociated to a much smaller extent. Diphenylmethyl itself cannot be obtained by the homolytic decomposition of the dimer. Table 5 lists the heats and degrees of dissociation of diarylmethyl dimers in *m*-xylene at 25 °C determined by ESR.

The introduction of alkyl substituents in the *meta*- and *para*-positions does not lead to the dissociation of the dimer. Only the presence of two *ortho*-substituents such as methyl, ethyl, and isopropyl or a single *ortho*-substituent such as t-butyl leads to the dissociation of the dimer. The bis-(2,5-di-t-butylphenyl)methyl dimer dissociates almost completely in solution[64, 96]. Perchlorodiphenylmethyl is the only example of a radical of this type which is fully monomeric even in the crystalline state[39].

2. Disproportionation

Triphenylmethyl solutions in non-polar solvents are decolorised rapidly on standing in the light with formation of triphenylmethane[106] and 1,2-diphenylbisbiphenylenethane[107], i.e. 9-phenylfluorenyl, which is associated more than triphenylmethyl, is formed as an intermediate. Solutions of triphenylmethyl in an ionising solvent such as sulphur dioxide are photochemically stable[108]. The photochemical reaction of perchlorotriphenylmethyl takes place similarly[109]:

p-Alkyl substituents increase the tendency of triarylmethyls towards disproportionation to such an extent that the radical decomposes spontaneously, immediately after formation, into the corresponding triarylmethane and a quinonoid compound which polymerises rapidly[104]:

Di-*p*-t-butyldiphenylmethyl constitutes an exception. It cannot form the quinonoid species by loss of hydrogen. Alkyl substituents in the *meta*- and *ortho*-positions increase the stability of triarylmethyls. Radicals of the allyl type are stable even on heating[27].

In the series of diarylmethyls, 2,4,6,-trialkyl- and 2,5-di-t-butyl-substituted derivatives disproportionate rapidly[36, 91]. The reaction products have not been investigated.

Diarylalkylmethyls disproportionate spontaneously[10] via the reaction

$$2Ar_2\dot{C}Me \rightarrow Ar_2C{=}CH_2 + Ar_2CH{-}Me\,.$$

3. Oxidation and Reduction

Diarylmethyls and triarylmethyls are readily reduced to the corresponding hydrocarbon by sodium amalgam[27], zinc in hydrochloric acid[28], phenylhydrazine[64], and catalytically by activated hydrogen[16]. Bisbiphenyleneallyls are not reduced by reductants such as hydroquinone, sulphite, and ascorbic acid[28].

Alkali metals add reversibly to triphenylmethyl with formation of brick-red salts[111]. Bent et al.[112] used this reaction to determine the electron affinity of triphenylmethyl and found it to be 17.9 kcal mole^{-1}.

Inert perchloro-radicals are reduced by potassium in ether to the corresponding carbanions[19]. Triphenylmethyl can also be reduced by a mixture of magnesium and magnesium bromide with formation of an organomagnesium compound[113].

Iron(III), mercury(II), silver(I), and gold(III) salts readily oxidised triphenylmethyl. In the $SO_2 - O_2$ system triphenylmethyl is oxidised to the carbonium ion[114], while at a rotating platinum electrode perchlorotriphenylmethyl can be reversibly reduced and oxidised to the corresponding ion[115].

4. Reaction with Radicals

Almost all tervalent carbon radicals interact with oxygen forming the colourless peroxide $Ar_3COOCAr_3$. The qualitative detection of triarylmethyls, the so called Schmidlin test[116], depends on this reaction. The coloured solution of the radicals is decolourised on shaking in air but subsequently the colour returns as a result of the dissociation of the dimer. The Schmidlin test can be repeated several times until the quantitative formation of the peroxide takes place. Janzen et al.[117] showed by ESR that the first stage in this reaction is the reversible formation of the peroxy-radical:

$$Ph_3\dot{C} + O_2 \rightleftarrows Ph_3C\dot{O}O \ .$$

Bisbiphenyleneallyls (XVIII, R = Ar) are stable in relation to oxygen[25]. Triarylmethyls combine with nitric oxide[118] forming hyponitrites; it has been suggested that this reaction proceeds via a stage involving the formation of nitrones[119].

The peroxide formed when oxygen acts on diarylmethyls is unstable and decomposes with formation of Ar_2CO, Ar_2CHOH, and $Ar_2CHOCHAr_2$.[120] The same products are formed when diarylmethyls react with NO.

The reactions of diaryl- and triarylmethyls with O_2 and NO have been frequently used to obtain thermodynamic data for the dissociation of radical dimers.

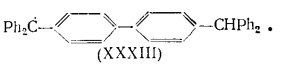
Nitrogen dioxide reacts with triphenylmethyl both via the nitrogen and via the oxygen with formation of two products – nitrotriphenylmethane and triphenylmethyl nitrite[118]:

$$Ph_3\dot{C} + O{=}N{-}\dot{O} \leftrightarrow O{=}\overset{+}{N}{-}O^- \rightarrow Ph_3C{-}N\begin{matrix}O\\ \diagup\!\diagdown\\ O\end{matrix} + Ph_3C{-}O{-}N{=}O \ .$$

On heating, triarylmethyls can abstract hydrogen from certain hydrocarbons, for example from toluene with formation of triarylmethane and triarylbenzylmethane via the mechanism[121]:

$$Ar_3\dot{C} + PhCH_3 \rightarrow Ar_3CH + Ph\dot{C}H_2 \ ,$$

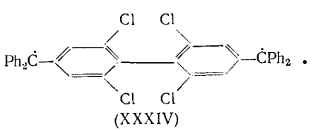
$$Ar_3\dot{C} + Ph\dot{C}H_2 \rightarrow Ar_3CCH_2Ph \ .$$



Active radicals interact with triarylmethyls, adding to the *p*-position of the benzene ring[83]:

$$Ph_3\dot{C} + \dot{P}h \rightarrow \begin{matrix}Ph\\ \diagup\\ H\end{matrix}\!\!\!

Compounds of this type can exist both in the triplet biradical form (a) and in the singlet quinonoid form (b). The amount of the biradical form depends on the energy difference between the singlet and triplet levels. For Thiele's hydrocarbon[134] (XXXII, $n = 1$), this energy difference is high (5.3 kcal)[135], as a result of which the compound is diamagnetic[136].

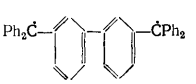


The situation is more complicated with Chichibabin's hydrocarbon[137] (XXXII, $n = 2$). The excitation energy for this compound is 2.5 kcal, i.e. even at room temperature there is a possibility of a thermodynamic equilibrium involving a small amount (1 – 3%) of paramagnetic species. Such a small admixture of paramagnetic species cannot be detected by magnetic methods[138], but has been detected by ESR.[136] However, a new problem arises, which enabled McConnell to formulate the so-called "biradical paradox"[139]. The point is that theory predicts $J = 15 \times 10^6$ MHz for electron – electron interaction in biradicals of the type of Chichibabin's hydrocarbon, while the experimental value is only 70 MHz. The problem was solved by analysing the ENDOR spectra[140].

It was found that the ESR spectra of solutions of Chichibabin's hydrocarbon are due to the presence of the monoradical (XXXIII), which is formed from (XXXII, $n = 2$) following the abstraction of a hydrogen atom from the solvent:

(XXXIII)

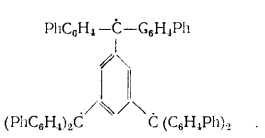
The breakdown of the coplanarity of the benzene rings due to the presence of *ortho*-substituents can stabilise the biradical form[141, 142]. Although (XXXIV) does give an ESR spectrum in the solid state, it too is not a biradical[143]:



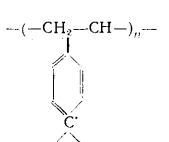
(XXXIV)

The introduction of non-conducting bridges such as O and CH_2 makes it possible to obtain stable hydrocarbon biradicals (XXXV)[136]:

X=O, $(CH_2)_n$



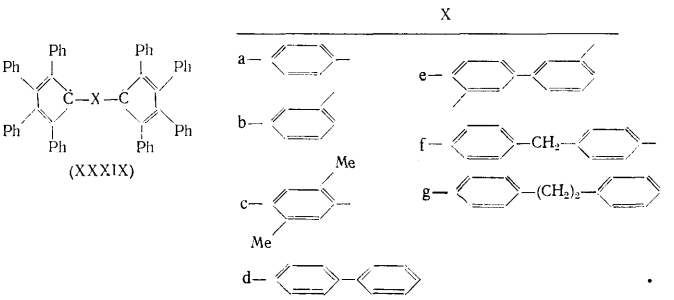
(XXXV)



(XXXVI)

Schlenk's hydrocarbon (XXXVI), which is incapable of giving rise to quinonoid forms, also has a triplet ground state[144]. In solution (XXXVI) is largely associated[145] and its ESR spectrum is additionally complicated by the presence of monoradicals[146].

Triradicals (XXXVII)[147] and polyradicals (XXXVIII)[148] of the triarylmethyl series were obtained. In solution these radicals are probably associated:



(XXXVII)

(XXXVIII)

In contrast to the compounds described above, the biradicals (XXXIX, $a-g$ are not associated[149]. All these, with the exception of (XXXIXa), have a triplet ground state; although (XXXIXa) is in fact paramagnetic, it is not a biradical:

(XXXIX)

The chemical properties of biradicals and polyradicals differ little from those of the monoradicals.

Non-equilibrium Copolycondensation in Homogeneous Systems

V.A.Vasnev and S.I.Kuchanov

Theoretical and experimental data for the composition and structure (microheterogeneity) of copolymers obtained by non-equilibrium copolycondensation in homogeneous systems are considered. The effect of the relative reactivities of the comonomers, the reactivities of the first and second groups of the intermonomer, the order and duration of addition of the initial compounds to the reaction zone, and other factors on the composition and microheterogeneity of the copolymers has been demonstrated in relation to interbipolycondensation. The available experimental literature data have been compared with the results of calculations based on a quantitative theory of homogeneous copolycondensation.
The bibliography includes 57 references.

I. INTRODUCTION

Copolycondensation embraces the polycondensation of three and more monomers when none can condense independently under the conditions of the given process. When such condensation is possible, for example, when hydroxy- or amino-acids are employed as the monomers, copolycondensation includes also processes involving two monomers. Since the chains of polycondensation copolymers contain two or more types of units, they will differ from one another by their composition and structure (microheterogeneity) as well as the degree of polymerisation. An important task in the study of copolycondensation (and incidentally in copolymerisation in general) is the determination of quantitative relations between the reactivities of the monomers and the process conditions on the one hand and the characteristics of the polymer obtained as the product on the other. However, whereas for radical polymerisation this has been largely achieved as early as 20 years ago[1,2], systematic studies on copolycondensation on these lines were begun only in the very recent years.

Possibly this is because in the early stages of the investigation of polycondensation mainly equilibrium processes were studied. The synthesis of high-molecular-weight products by this method is known[3,4] to require, firstly, an equimolar mixture of monomers and, secondly, the reaction must be continued up to conversions close to 100%. In this method of copolycondensation the entire initial monomer is present in the polymer chains at the end of the reaction and hence the problem of composition does not arise. The inhomogeneity of the composition of the copolymer should not be unduly great, because the distribution of the equilibrium copolycondensation products with respect to composition should be very narrow. This factor, which makes it possible to assume with a high degree of accuracy that all the macromolecules have the same chemical composition, is specific to equilibrium copolycondensation and generally speaking does not apply to copolymerisation. In the latter process the possibility of appreciable inhomogeneity in composition arises because a copolymer appreciably enriched in one of the monomers can be formed in the early stages, while in subsequent stages it may be enriched in the other monomer. In equilibrium copolycondensation the vigorous occurrence of exchange reactions "mixes" the compositions of the individual macromolecules, eliminating thereby the above cause of inhomogeneity of the composition and leading to a random (statistical) distribution of units in the copolymer chains. Consequently, equilibrium copolycondensation results in the formation of macromolecules with a statistical distribution of units which have virtually identical compositions corresponding to that of the initial monomeric mixture. Hence it is clear that in equilibrium copolycondensation there is no need to determine the dependence of the statistical characteristics of the copolymer on the process conditions. This problem does however become very urgent for non-equilibrium copolycondensation, which is characterised by the absence of exchange and degradative reactions[5]. In this case the difference between the homophase and heterophase methods of carrying out the process, the chemical reactions of which may be complicated by the effects of diffusion and adsorption of the reactants on the interface, is shown particularly clearly. In conformity with the title of the review, we shall consider only processes involved in homogeneous copolycondensation; these are the simplest and most systematically investigated both theoretically and experimentally. Naturally any quantitative description of the macrokinetics of heterophase copolycondensation is impossible without a preliminary determination of the general characteristics of homogeneous processes.

The review does not deal with processes associated with the molecular weight distribution and with the molecular weights of polycondensation copolymers. This is because, on the one hand, there are at present no reliable experimental data whereby an unambiguous quantitative relation can be established between the above parameters and the reactivities of the initial compounds and conditions under

which they are injected. On the other hand, since the chain termination rate constants are unknown, it is impossible to compare the theoretical molecular-weight distributions and molecular weights with the observed values. The range of problems considered in the present review (chemical composition and structure of the chains in the copolymer macromolecules) is independent of side reaction leading to chain termination and the above characteristics of copolymers are determined only by the relations between the chain propagation rate constants.

In connection with the development of new methods for the investigation of high-molecular-weight compounds and in particular the considerable progress achieved in the application of high-resolution nuclear magnetic resonance (NMR), it has become possible to obtain reliable quantitative data for the compositions and structures of copolycondensation products.

The high accuracy of this method makes it possible, when the appropriate theory is available, to discover detailed features of the kinetics of the formation of copolymer chains. The fruitful application of high-resolution NMR to the study of products of homogeneous copolycondensation made it possible, despite the relatively small number of studies in this field, to establish the general characteristics of the process and has greatly stimulated the development of its quantitative theory.

II. CLASSIFICATION OF PROCESSES IN HOMOGENEOUS NON-EQUILIBRIUM COPOLYCONDENSATION AND METHODS OF QUANTITATIVE DESCRIPTION OF THE COPOLYMERS

Linear copolycondensation of compounds containing not more than two functional groups has been investigated theoretically and experimentally to the greatest extent. The simplest instances of linear copolycondensation, which at the same time exhibit all the characteristic features, are bipolycondensation and interbipolycondensation. The first case, where at least one of the two initial compounds employed in the reaction is capable of self-condensation under the conditions of the given processes, can be achieved, for example, with monomers of the amino- or hydroxy-acid type. The second case, where three monomers A–R–A, B–S–B, and C–I–C are involved in the reaction, is more common. The first two, called the comonomers, do not react directly with one another, but each condenses with the third component (the intermonomer).

The interbipolycondensation products can be divided into copolymers belonging to one or different classes. The former are formed from comonomers with identical functional groups. An example of such copolymers is provided by mixed polyamides synthesised from two diamines and one dicarboxylic acid chloride or from one diamine and two dicarboxylic acid chlorides. In order to synthesise copolymers of the second group, it is necessary to employ comonomers with different functional groups. Polyamidoesters obtained by the copolycondensation of a diamine and a glycol with a dicarboxylic acid, may serve as an example of such copolymers.

The chains formed in the course of interbipolycondensation have the structure...–IRIRISIRI–..., in which the comonomer units alternate with the intermonomer units. In order to characterise the composition of the copolymer, it is sufficient to indicate the fraction of units of one of the comonomers, P_R or P_S, while the fraction of the second is determined from the self-evident equality $P_R + P_S = 1$.

In order to describe the inhomogeneity of the composition of the copolycondensation products, one can introduce a distribution function for the macromolecules with respect to size (the number of polymer units) and composition. By analogy with the molecular weight distributions (MWD), this function is known as the size–composition distribution (SCD).

The simplest unit suitable for the description of the chain structure (microheterogeneity) of copolymers is a triad. Homotriads (RIR and SIS) and heterotriads (RIS) are distinguished. In the simplest description of the nature of the distribution of the units R and S in the copolymer chain, one can specify the fractions of the P_{RR}, P_{SS}, and P_{RS} triads of various types. The inhomogeneity of the interbipolycondensation products is estimated quantitatively in terms of the microheterogeneity coefficient K_M, which is expressed in terms of the fractions of various triads by means of the relation

$$K_M = \frac{P_{RS}}{P_{RS} + 2P_{RR}} + \frac{P_{RS}}{P_{RS} + 2P_{SS}} . \qquad (1)$$

For a mixture of two homopolymers, $P_{RS} = 0$ and correspondingly $K_M = 0$, while for a copolymer with a regular alternation $P_{RR} = P_{RS} = 0$, which corresponds to $K_M = 2$. Between these two extreme cases, corresponding to fully ordered arrangement of units in macromolecules, there are all possible values of the microheterogeneity coefficient, $K_M = 1$ corresponding to a statistical (i.e. the most disordered) distribution. Consequently the absolute deviations of K_M from unity can be used for a quantitative assessment of the degree of order in the distribution of units in the copolymer and from the latter one can infer the direction of the deviation—the tendency of the monomer residues towards a regular alternation in the chains ($K_M > 1$) or (when $K_M < 1$) towards the formation of long blocks of both comonomers. It has been shown [6] that the composition and the average block lengths L_R and L_S of a copolymer with a fairly high molecular weight most molecules of which consist of numerous blocks, can be determined with the aid of the relations

$$P_R = P_{RR} + \frac{P_{RS}}{2}, \; P_S = P_{SS} + \frac{P_{RS}}{2}, \; L_R = \frac{2P_R}{P_{RS}}, \; L_S = \frac{2P_S}{P_{RS}} \qquad (2)$$

in terms of the fractions of various triads. In this case Eqn. (1) assumes a particularly clear form:

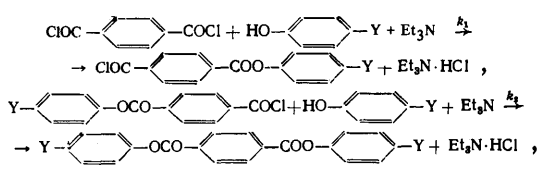
$$K_M = \frac{1}{L_R} + \frac{1}{L_S} . \qquad (3)$$

Another more detailed method of describing the microheterogeneity of copolycondensation products, which however is more difficult to test experimentally, consists in finding the distribution functions for blocks of various comonomer units with respect to their lengths.

III. INITIAL COMPOUNDS

1. Reactivity of Bifunctional Monomers

The view according to which one of the main factors influencing the composition and structure of copolymers obtained by non-equilibrium polycondensation is the relative reactivity of the comonomers is widely held at present [7,8]. Evidently, this question is closely related to the problem of the constancy of the reactivity of the functional groups of polyfunctional monomers. This type of constancy is as a rule postulated in a theoretical examination of various aspects of polycondensation processes [9].



However, there is at present no doubt that the reactivity of the functional groups of many monomers changes in the course of the process[4,5].

Comparatively recently a number of studies were published in which the reactivity of certain initial aromatic compounds widely used in non-equilibrium polycondensation was estimated from the p-electron density at the corresponding atom of the functional group: the nitrogen atom of the NH_2 group in diamines and tetramines[10,11], at the oxygen atom of the OH group in bisphenols[12], and at the carbon atom of the COCl group in dicarboxylic acid chlorides[13].

A preliminary conclusion concerning the reactivity of dicarboxylic acid chlorides was reached with the aid of nuclear quadrupole resonance (NQR) spectra. It has been established that the frequency of the chlorine atom in COCl depends on the electron density in the carbonyl group[14]. A convenient criterion of the capacity of the bisphenol and diamines components for involvement in the polycondensation process is provided by the acid–base properties of their functional groups: phenolic[15,16] or amino-groups[17,18]. Sokolova and Sokolov[19] suggest that the thermochemical method be employed for rapid estimation of the reactivity of the dicarboxylic acid chloride, the principle of which consists in the determination of the heats of reaction of the given monomer with solvents.

Special evidence is not required to show that the methods discussed above can yield only a preliminary fairly qualitative idea about the reactivity of the monomer. Thus, on the one hand, the change in any one characteristic, for example the pK for the acid dissociation of bisphenols, can in some cases entail an increase of the reactivity of the monomers and a decrease in others[15]. On the other hand, it is known that the variable influence of polar effects on the reactivity of a particular functional group depends significantly on various factors: the type of reaction, its mechanism, the nature of the solvent, temperature, etc.[20]

A more effective method for the solution of the above problems is based on kinetic studies of the reactions of bifunctional monomers with monofunctional compounds, which are carried out under conditions close to those in polycondensation. An example of such a reaction is provided by the acylation of phenols by terephthaloyl chloride in the presence of triethylamine (Table 1):

which simulates acceptor–catalytic polyesterification:

$$ClOC-Y'-COCl+HO-Y''-OH+2Et_3N \rightarrow \cdots-CO-Y'-COO-Y''-O-\cdots+2Et_3N\cdot HCl.$$

The data presented in Table 1 show that the rate constant ratio for the first and second COCl groups is not constant and depends on the structure of the phenol. As shown recently,[21] it is important to note that the reactivity of the second group of the bifunctional monomer relative to the first may not only decrease (Table 1, Nos. 1–3) but also increase (Table 1, No. 4).

Kuritsyn and Kuritsyna[22], Sokolov and Kuritsyn[23], and Vorob'ev et al.[24] reported the results of kinetic studies on the reaction of carboxylic acid chlorides with aniline and its derivatives (Table 2). They observed that the ratio of the reactivities of the first and second acid chloride groups depends significantly on the nature of the aromatic amine.

The reactivity of the first COCl group of terephthaloyl chloride (Table 2) in the reaction with aniline (in benzene at 25°C) is higher than that of the first COCl group in isophthalic and carborane-m-dicarboxylic acid chlorides by factors of 1.6 and 2.7 respectively.

The problem of the effect of the length of the macromolecule on the reactivity of its terminal groups is undoubtedly of independent interest. Until recently, studies on these lines have hardly been made. Recently, Turska and coworkers[26] established that the rate constant for non-equilibrium polyesterification in solution is influenced by the solvent power of the organic medium. The explanation is that the reactivity of the terminal groups of the macromolecule depends on chain length.

A number of studies have been published lately in which the relative reactivities of the comonomers (diols) in the interaction with the intermonomer (terephthaloyl chloride) were estimated from the contents of the comonomer residues in the polymeric product (Table 4).[27-29]

2. The Order of Introduction of the Initial Compounds into the Reaction Zone

In the synthesis of copolymers by non-equilibrium copolycondensation several methods for the introduction of the initial compounds into the reaction zone are employed. Single-stage copolycondensation is frequently carried out in such a way that all the initial compounds are present in the reaction zone from the very beginning of the process. This order of introduction of the monomers is most frequently employed in the synthesis of copolymers by both non-equilibrium and equilibrium copolycondensation[3-5]. In two-stage copolycondensation the initial compounds (these are usually the comonomers) are introduced into the reaction zone in succession at specified time intervals.

One of the ways of carrying out the process involves three-stage copolycondensation which some investigators employ for the synthesis of block copolymers[30,31]. In this procedure each comonomer is subjected initially to polycondensation with the intermonomer in different reaction vessels. In one system the intermonomer is present in an excess and in the other in a deficiency, but the overall molar amounts of the interacting functional groups are as a rule equal in both vessels. At the end of the polycondensation the systems are combined, which results in copolycondensation between the intermediates formed.

In the synthesis of copolymers by non-equilibrium polycondensation a gradual introduction of one of the initial compounds, usually the intermonomer, into the reaction zone has begun to be used recently[29,32]. This order of addition of the initial compounds frequently leads to the formation of block copolymers.

IV. THEORY OF NON-EQUILIBRIUM COPOLYCONDENSATION IN HOMOGENEOUS SYSTEMS

1. Composition of the Copolymers and Its Inhomogeneity

The task of the theory of copolycondensation is to establish quantitative relations between the average composition of the copolymer, the inhomogeneity of its composition, and the structure of its chains on the one hand and the proportions and reactivities of the initial compounds and the method of their introduction into the reaction zone on the other. As stated above, for equilibrium copolycondensation this task is trivial but for the non-equilibrium processes discussed in this review it becomes important.

It is noteworthy that a similar problem arises also in radical copolymerisation and considerable advances have been made in its solution[1,2]. However, the processes discussed in this review have many important characteristics which distinguish them from copolymerisation and therefore require separate analysis. The first of these differences is a qualitatively different mechanism of polymer chain propagation, which generally speaking makes it impossible to regard chain propagation in copolycondensation as the usual Markov process[1,2]. Another important difference is in the time scales of the formation of polymer chains in the two processes. In radical copolymerisation the chain-formation time, which is comparable to the lifetime of the radical, usually constitutes a negligible proportion of the duration of the process itself. The latter factor, which makes it possible to regard the conditions governing the formation of each individual chain as unaltered, does not hold in copolycondensation where the time required for the formation of high-molecular-weight products is comparable to the duration of the process. The third characteristic feature of copolycondensation kinetics is the possibility of the interdependence of the reactivities of the functional groups of the initial monomers. As will be shown below, this phenomenon plays the leading role in the formation of the copolymer chain microstructure.

At present the number of computational theoretical studies described in the literature and dealing with homogeneous copolycondensation is extremely small. The first classification of these processes was made by Shtraikhman[33], who also derived an equation for the composition of the interbipolycondensation products when all the initial compounds are introduced simultaneously into the reaction zone. The composition of the copolymer is then defined thus:

$$P_R = \frac{[A]_0 - [A]}{[A]_0 - [A] + [B]_0 - [B]}; \quad P_S = \frac{[B]_0 - [B]}{[A]_0 - [A] + [B]_0 - [B]}, \qquad (4)$$

where the variation of the concentrations of the functional groups of the comonomers [A] and [B] with their initial values $[A]_0$ and $[B]_0$, the reactivities, and the degree of reaction is found by solving differential equations describing the process kinetics. From these equations for the case of the unaltered reactivities of all the functional groups A, B and C, Shtraikhman[33] and, independently, Beste[34] obtained the relations

$$\frac{[A]}{[A]_0} = \left(\frac{[B]}{[B]_0}\right)^r, \quad [A] + [B] = [A]_0 + [B]_0 - [C]_0 p, \qquad (5)$$

where $p = \{[C]_0[C]\}/[C]_0$ is the conversion, [C] and $[C]_0$ are the current and initial concentrations of the functional groups of the intermonomer C–I–C, and r is its relative reactivity in condensation reactions with the comonomers A–R–A and B–S–B. The variation of the composition of the products with conversion has been investigated[35] on the basis of Eqns. (4) and (5) for different values of the parameter r and different proportions of the monomers. For initial compounds with interdependent functional groups, it is impossible to obtain mathematical formulae analogous to Eqn. (5) and the composition of the copolymer was calculated for individual specific instances on a computer[36]. However, it is noteworthy that the problem of the determination of the composition of the non-equilibrium homogeneous interbipolycondensation products with simultaneous introduction of all the initial compounds arises only when they are present in non-equimolar proportions whereupon the final reaction products are oligomers with a small number of units. In order to obtain high-molecular-weight products in this process, it is necessary (as in equilibrium copolycondensation) to carry out the reaction between rigorously equimolar amounts of the monomers until a high conversion approaching 100% is reached. With this method of simultaneous introduction of the starting materials, the composition of the copolymer is always the same as that of the initial monomer mixture and the problem of its calculation does not arise.

Another situation obtains when any one of the initial compounds is gradually introduced into the reaction zone, which may lead to the formation of high-molecular-weight products even when the initial molar ratios of the monomers deviate appreciably from unity[37,38]. For this purpose, it has been necessary to introduce the monomer in excess into the reaction zone at a rate many times less than the rate of its chemical interaction. A typical example of a process of this kind is provided by interbipolycondensation with gradual introduction of the intermonomer into the reaction zone. When all the functional groups of the monomers are independent, the Shtraikhman–Beste equation [Eqn. (5)] is again valid for this process. However, when the intermonomer is introduced fairly slowly, high-molecular-weight products can be formed long before the reaction of the two monomers. This happens when the reactivity of one of the comonomers greatly exceeds that of the other. The process can then be arbitrarily divided into two stages. At the end of the first stage, which is analogous to the polycondensation of the more reactive comonomer with an excess of the intermonomer, high-molecular-weight products are already formed, although the second comonomer has still hardly reacted. Consequently, in this method of carrying out the process it is possible to obtain a high-molecular-weight polymer the composition of which differs from those of the initial compounds. At the beginning the polymer is enriched in the more reactive comonomer and then, as conversion increases and this monomer is exhausted, the copolymer composition begins to approach that of the monomer mixture. The smaller the difference between the reactivities of the comonomers the less distinct are the two stages of the process and the smaller the molecular weight of the products at intermediate conversions. In the limiting case of equal reactivities of the comonomers high-molecular-weight products are formed only after the complete conversion of both comonomers.

It is noteworthy that theoretically only one case is possible in the synthesis of high-molecular-weight products in homogeneous irreversible polycondensation with simultaneous introduction of a non-stoichiometric mixture of the initial compounds[39]. For this, it is necessary that, following the reaction of the first functional group of the monomer taken in excess, the reactivity of the second group should increase sharply. If it were possible to select such an intermonomer, then, in the course of its homogeneous irreversible interbipolycondensation with a mixture of two comonomers having markedly different reactivities, the composition of the resulting copolymer would differ from those of the initial compounds even when the latter are introduced simultaneously. However, the above case is hypothetical, since so far monomers in which the reactivity of the second group greatly exceed that of the first have not been found.

For the same average composition of the polymerisation copolymers, their properties may[40] differ considerably depending on the type of distribution of the compositions of the individual macromolecules, i.e. on the inhomogeneity of the composition of the products. Despite its great practical importance, until recently the problem of this type of inhomogeneity of polycondensation copolymers was not investigated. The method of calculations on the kinetics of homogeneous irreversible polycondensation developed by Kuchanov and Pis'men[41,42] makes it possible to calculate the distribution of the macromolecules with respect to size and composition (DSC) in copolycondensation[6]. It is noteworthy that this method is very general, since the calculation based on it does not impose any limitations either on the number of the initial compounds, or on the relative reactivities of their functional groups (they can be interdependent), or on the number of these groups in the monomer molecules. The latter factor permits the calculation of DSC not only of linear but also of branched products. Another general approach to the calculation of DSC, based on methods of the theory of random processes, has been proposed[43]. However, the relations obtained by the authors cannot be used to describe the copolycondensation of monomers with interdependent functional groups. Their results[43] include as a special case the formulae derived by Cito[44] for the products of the interbipolycondensation of a stoichiometric mixture of monomers with the same reactivities.

On the basis of Kuchanov's results[6], it is possible to show that the kinetic calculation of the distribution of the homogeneous irreversible copolycondensation products

with respect to size and composition leads to the important conclusion that there is a virtual absence of inhomogeneity in the composition of polycondensation copolymers. This is valid provided that their average degree of polymerisation is fairly high. This conclusion does not apply to oligomeric products, the length of which is comparable to that of an individual block. On the other hand, if most of the macromolecules consist of many blocks, then calculation shows that all these molecules may be regarded as having identical compositions to a high degree of accuracy. The latter conclusion is diametrically opposed to Turska's view[7], according to which the composition of the above copolymers should not be inhomogeneous. A conclusion of this kind can be reached when the relations governing the formation of chains in radical copolymerisation are extended to copolycondensation processes. However, one then fails to take into account the fact that the time required for the formation of each individual chain constitutes in the first instance a negligible proportion of the duration of the process itself, while in the second instance, is comparable to this duration.

2. Calculation of the Chain Structure of the Copolymers

In devising a quantitative theory of homogeneous copolycondensation, the most complex problem is that of the calculation of quantities characterising the microheterogeneity of the products. An attempt at a quantitative description of the chain structure of polycondensation copolymers was made by Sawada[45,46], who related by a statistical method the microheterogeneity of the copolymer to the changes in the thermodynamic potentials in the course of the chemical reaction. Since his relations[45,46] do not contain kinetic constants explicitly, they do not make it possible to discover the effect of the reactivities of the monomers on the chain structure.

The coefficient of microheterogeneity K_M defined by Eqn. (1) is a simple characteristic of the copolymer chain structure which can be conveniently determined both theoretically and experimentally. Kuchanov's calculation[6] of K_M for interbipolycondensation products with simultaneous introduction of all the monomers shows that the nature of the distribution of units in the chains is determined mainly by the interdependence of the reactivities of the functional groups in the intermonomer. If these groups are independent, then according to theory $K_M = 1$ and the distribution of units is always statistical for any conversion, proportions of the monomers, and their reactivities. This conclusion disproves the view put forward by some investigators[7,35] that the products of non-equilibrium homogeneous copolycondensation have a block structure. In contrast to copolymerisation, a statistical distribution of the chain units of polycondensation copolymers can occur however large the difference between the reactivities of the comonomers. A general correspondence has been established between the functional group reactivity difference in the intermonomer and the distribution of chain units in the copolymer[6]. If following the reaction of the first group of the intermonomer the reactivity of the second group increases, a tendency of the monomer units towards alternation should be observed ($K_M > 1$); in the opposite case an increase of the reactivity of the second group should entail the appearance of a tendency towards the formation of blocks ($K_M < 1$). For the same intermonomer with interdependent reaction centres, the order in the distribution of chain units in the copolymer increases with the difference between the reactivities of the comonomers.

Theoretical study of the dependence of K_M on the method of introduction of the monomer[47] has shown that there is a possibility of obtaining block copolymers in homogeneous non-equilibrium copolycondensation even when an intermonomer with independent functional groups is involved. This case occurs when the intermonomer is introduced fairly slowly into the reaction zone. When the intermonomer is introduced at a rate much lower than that of the condensation reaction, the following expressions are obtained for the average block lengths and K_M:

$$\frac{1}{L_R} = \alpha_S \mathcal{J}, \frac{1}{L_S} = \alpha_R \mathcal{J}, K_M = (\alpha_R + \alpha_S)\mathcal{J} , \quad (6)$$

$$\mathcal{J} = \int_0^1 \frac{r x^{r-1}\, dx}{\alpha_S + \alpha_R x^{r-1}} , \quad (7)$$

which depend only on the mole fractions α_R and α_S of the comonomers and their relative reactivity parameter r, but are independent of the rate of supply of the intermonomer to the reaction zone. The variation of K_M with r for $\alpha_R = \alpha_S$ (Fig. 1) shows that an increase of the difference between the reactivities of the comonomers leads in the present instance to the formation of longer blocks.

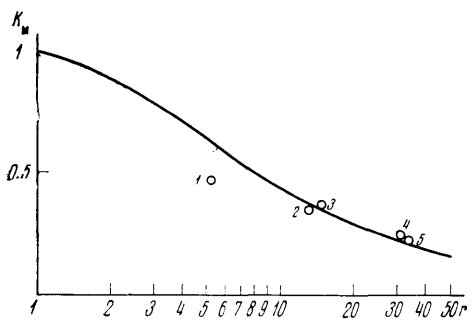

Figure 1. Theoretical variation of the microheterogeneity coefficient with the relative reactivity parameter of the comonomers on slow introduction of the intercomponent (see Table 9 for the significance of the experimental points).

The results obtained by Kuchanov[47] can be used to calculate the K_M for the products of two-stage interbipolycondensation. In this case, apart from its variation with α_R and α_S, K_M depends only on the parameter κ which is equal to the ratio of the reactivities of the first and second groups of the intermonomer in its reaction with the monomer which is introduced first. A plot of K_M against κ for an equimolar ratio of comonomers with independent functional groups is presented in Fig. 2. The same plot evidently describes single-stage copolycondensation with simultaneous introduction of all the initial compounds in the limiting case where the reactivities of the comonomers differ markedly. κ then refers to the reaction of the intermonomer with the more reactive comonomer.

The second method of describing the microheterogeneity of copolymers consists in specifying a distribution function with respect to the block lengths of different monomeric units. A distribution function of this kind was calculated

for the first time by Beste[34] for the products of the interbipolycondensation of a stoichiometric mixture of monomers with independent functional groups. Using a statistical method, he obtained the following expression for the fractions of the comonomer units entering into a block with a length n:

$$W_R(n) = (1 - \nu_{RR})^2 n \nu_{RR}^{n-1}, \; W_S(n) = (1 - \nu_{SS})^2 n \nu_{SS}^{n-1} . \quad (8)$$

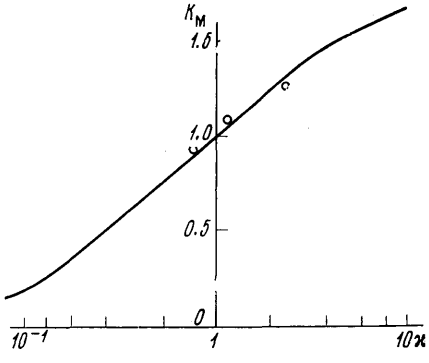

Figure 2. Theoretical variation of the microheterogeneity coefficient with the reactivity ratio of the functional groups of the intermonomer in stage-by-stage interbipolycondensation (see Table 6 for the significance of the experimental points).

The parameters of the distributions defined by Eqn. (8) are expressed in terms of the initial mole fraction σ_R and σ_S of the comonomers and their conversions p_A and p_B:

$$\nu_{RR} = \alpha_R p_A^2, \; \nu_{SS} = \alpha_S p_B^2 . \quad (9)$$

As stated above, only the statistical copolymer is formed in the case considered by Beste. Calculation of the distribution of blocks with respect to length in the chains of arbitrary copolymers based directly on kinetic process equations leads to Eqns. (8) precisely[47]. However, it is significant that the parameters of distributions (8) are not determined in the general case by relations (9) but are expressed in terms of the concentrations of the triads T_{RR} and T_{SS} and the initial concentrations of the comonomers:

$$\nu_{RR} = \frac{2T_{RR}}{[A]_0}, \; \nu_{SS} = \frac{2T_{SS}}{[B]_0} . \quad (10)$$

When the functional groups of the initial compounds are independent, Eqns. (10) become identical with Eqns. (9).

For long macrochains, the microheterogeneity coefficient may be related to the parameters of distributions (8):

$$K_M = 2 - \nu_{RR} - \nu_{SS} . \quad (11)$$

Since for a statistical copolymer $K_M = 1$, according to Eqn. (11) the relation $\nu_{RR} + \nu_{SS} = 1$ should hold. In the general case of chains of arbitrary length, K_M cannot be expressed in terms of the parameters ν_{RR} and ν_{SS}.

In order to describe the structure of the copolymers obtained as a result of interbipolycondensation, it is necessary to specify with the aid of functions (8) two parameters ν_{RR} and ν_{SS}. By virtue of the condition $\nu_{RR} + \nu_{SS} = 1$, it is sufficient to specify only one independent parameter for a statistical copolymer. Eqns. (1), (2), (8), (11), and (10) show that, in order they characterise quantitatively the microheterogeneity of polycondensation copolymers, it is sufficient to determine the proportions of triads of various types. Calculation of the triad concentrations directly on the basis of the kinetic process mechanism[6,47] makes it possible to relate the nature of the distribution of units in the chains to the process conditions and the reactivities of the monomers. On the other hand, the proportions of triads of various types in the copolymer can be determined experimentally with a high degree of accuracy by ^{1}H NMR.

Copolycondensation processes involving initial compounds of the ARC type capable of self-condensation have characteristics qualitatively different from those discussed above. It has been noted[6] that, in the bipolycondensation of monomers the functional groups of which are independent, a statistical copolymer is not formed. This last factor constitutes a significant difference between the above process and interbipolycondensation where the condition of the independence of the functional groups of the intermonomer was itself sufficient for the formation of products with a statistical distribution of units. Only a simplified case of comonomers of the A–R–C and B–S–C types, when both contain the same functional group C and all the groups are independent, has been considered in quantitative terms. For this special case, Lavalou[48] derived equations describing the composition and subsequently the microheterogeneity coefficient of the copolymer was calculated[6]:

$$K_M = \frac{2(\alpha_R p_B + \alpha_S p_A)(p_A + p_B)}{[p_A + \alpha_R (p_A + p_B)][p_B + \alpha_S (p_A + p_B)]} . \quad (12)$$

The value of K_M defined by Eqn. (8) is always greater than unity and tends to it with increase of the degree of reaction. Consequently, despite the fact that intermediates in the above bipolycondensation process exhibit a tendency towards an alternation of units, the distribution of the latter in the high-molecular-weight copolymer is statistical. When the reactivities of all four functional groups of the comonomers are different, statistical copolymers are not formed at all.

V. APPLICATION OF HIGH-RESOLUTION NMR SPECTROSCOPY IN THE ANALYSIS OF POLYCONDENSATION COPOLYMERS

NMR spectroscopy is at present the principal physical research technique whereby it is possible to characterise quantitatively the distribution of the units in the macromolecules of copolymers. The essential feature of this method, which allows the determination of the contents of homo- and hetero-triads in copolymers, is that the chemical shifts of the protons of the intermonomer residue depend in some cases on which comonomer residues adjoin the given compound in the polymer chain. Fig. 3 shows that the chemical shifts of the signals corresponding to the phenylene proton of the terephthalic acid residue in the NMR spectra of polyesters vary with its environment. The integrated signal intensities are proportional to the relative contents of triads in the copolymer.

Only a few studies in which high-resolution NMR was used to determine the structures of polycondensation copolymers have now been published and these refer exclusively to polyesters.

The first time when high-resolution NMR was used to investigate the structures of polycondensation copolymers was published in 1965 when Harada and Veda[49] investigated the compositions and structures of ethylene glycol,

diethylene glycol, and terephthalic acid copolyesters (Table 5, No. 4).

NMR spectroscopy was also used by Yamadero and Murano[50] and Slonim and coworkers[51] to determine the structures of a number of polyesters synthesised by equilibrium polycondensation in the melt (Table 5). Hamb[52] used this method to investigate the structures of polyesters synthesised by the reaction of poly(ethylene terephthalate) with terephthalic acid and the diacetate of di-2,2-(4-hydroxyphenyl)propane (Table 5, No. 3). In 1972 it proved possible to employ NMR for the elucidation of the structures of copolyesters based on ethylene glycol and terephthalic and isophthalic acids[53]. The introduction of chelate complexes of europium into the test solution enabled the author to increase the difference between the chemical shifts of the signals due to the ethylene glycol residues entering into different triads.

In 1972 Korshak et al.[54] published for the first time data on the structures of copolymers obtained by non-equilibrium polycondensation. They employed terephthalic acid chloride as the intermonomer and various bisphenols and hexamethylene glycol as the comonomers. This choice of initial compounds enabled the authors to determine quantitatively by NMR spectroscopy to within 5% the contents of homo- and hetero-triads in copolyesters (Table 5, No. 1).

Table 5 shows that copolyesters based on intermonomers such as ethylene glycol or terephthalic acid are suitable for the quantitative determination of triads by high-resolution NMR.

Despite certain limitations of the applicability of the NMR method in the study of polycondensation copolymers, its importance in such applications is very great. The method opens up wide prospects for the elucidation of the overall dependence of the compositions and structures of polycondensation copolymers on the reactivities of the initial compounds and reaction conditions.

VI. EXPERIMENTAL DATA FOR THE COMPOSITIONS AND STRUCTURES OF COPOLYMERS OBTAINED BY NON-EQUILIBRIUM COPOLYCONDENSATION IN HOMOGENEOUS SYSTEMS

The experimental data for the effect of various factors, including reaction time, for the compositions and structures of copolymers obtained by non-equilibrium copolycondensation in homogeneous systems were not available in 1972. However, it was postulated that under the conditions of non-equilibrium condensation it is difficult to obtain copolymers with a statistical distribution of fundamental units[7,8,30,35].

In her report at the Third Microsymposium on Polycondensation Processes, Turska[7] emphasised that "when there is a difference between the reactivities of the initial comonomers, there are altogether no grounds for the expectation of a statistical distribution of monomer residues" in copolycondensation products obtained under non-equilibrium conditions.

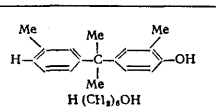
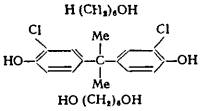
In 1972 Korshak and coworkers[29,54] were the first to report experimental data for the compositions and structures of copolymers obtained by non-equilibrium polycondensation in solution. They chose for investigation polyesters obtained by acceptor-catalytic copolycondensation in the presence of tertiary amines:

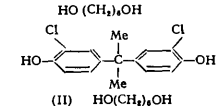
(13)

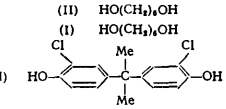
Acceptor-catalytic polyesterification is known to be a typical non-equilibrium process in which exchange reactions hardly occur[55].

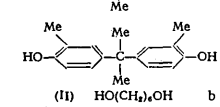
The relative contents of the RIR, SIS, and RIS triads in the copolyesters obtained were determined by NMR spectroscopy (Table 6, No. 1 and Fig. 3). The degree of disorder in the copolymer (B) calculated in accordance with Yamadero and Murano's scheme[50] is identical in its significance to the microheterogeneity coefficient K_M.

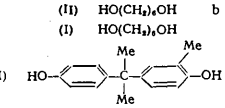












1. Single-stage Copolycondensation

The study of the dependence of the composition of the copolymers obtained by single-stage non-equilibrium polycondensation in homogeneous systems yielded results, which agreed fully with the earlier hypotheses (see, for example, Turska[7]). It was found that the composition of the linear copolymers formed by non-equilibrium copolycondensation in solution for low degrees of reaction with respect to the intermonomer is enriched in the more reactive comonomer[32]. Subsequently the fraction of the less reactive comonomer in the copolymer increases and, when the reaction reaches completion, the composition of the resulting high-molecular-weight compound is the same as that of the mixture of initial compounds. An example of such a process is provided by the acceptor-catalytic copolycondensation of terephthaloyl chloride with 2,2-bis-(3-chloro-4-hydroxyphenyl)propane and hexamethylene glycol in the presence of triethylamine (under these conditions, the reactivity of the bisphenol is more than 30 times greater than that of the glycol[27]). Fig. 4 shows that, as the reaction proceeds, the contents of the comonomers (bisphenol and glycol) in the copolyester become equal to their initial values, i.e. $P_R = P_S = 0.5$.

Turska[7] reported the results of the fractionation of two copolymers synthesised by single-stage non-equilibrium copolycondensation, which indicate the inhomogeneity of the compositions of the products.

Interesting experimental data were obtained in a study of the structures of the copolymers formed by non-equilibrium copolycondensation in solution using the single-

b. Triethylamine (0.01 mole) added to dichloroethane solution (25 ml) of terephthaloyl chloride (0.005 mole) and bisphenol (0.0025 mole) at 40°C. Hexamethylene glycol (0.0025 mole) introduced after 30 min and the reaction continued for a further 1 h.
c. m.f. = mole fraction.

stage method[29,32]. Thus it was established that the structure of the macromolecules formed in single-stage non-equilibrium copolycondensation (see Scheme 13) in homogeneous systems depends little on the differences between the reactivities of the comonomers (Table 6, Nos. 1 and 2). Moreover, it was shown that the distribution of units in the polymer chains of the copolyesters obtained under the above conditions is close to the statistical distribution. The microheterogeneity coefficient is approximately unity and is independent of the molar ratio of the comonomers in the initial mixture.

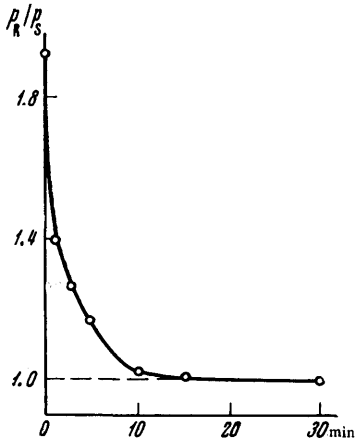

Figure 4. Variation of the composition of the copoly-terephthalate of 2,2-bis-(3-chloro-4-hydroxyphenyl)propane dichlorodian and hexamethylene glycol with reaction time (see footnotes in Table 6).

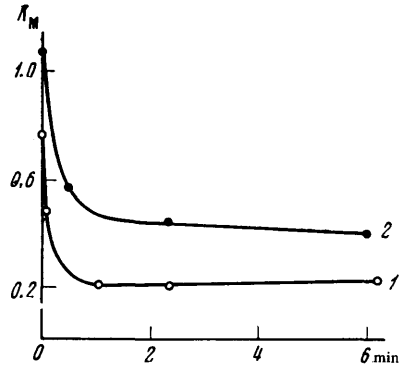

Figure 5. Variation of the microheterogeneity coefficient of the copolyester with the time taken to introduce the solution of terephthalic acid chloride into the solutions of the other components: 1) 2,2-bis-(3-chloro-4-hydroxyphenyl)propane dichlorodian, hexamethylene glycol, and triethylamine; 2) 2,2-bis-(3-methyl-4-hydroxyphenyl)propane dimethyldian, hexamethylene glycol, and triethylamine (dichloroethane, 30°C).

The study of the influence of the duration of the copolycondensation on the structure of the copolymers obtained by the reaction of terephthaloyl chloride with certain pairs of comonomers having different copolycondensation constants showed[32] that at the beginning of the reaction the copolymer is enriched in the RI units containing the more reactive comonomer, but subsequently the relative contents of the units formed by different comonomers become equalised (Table 7). It is important to emphasise that the coefficient of microheterogeneity of copolyesters remains constant throughout the reaction, the value of K_M showing that the distribution of fundamental units in the macromolecules is nearly statistical.

Table 7. Dependence of the composition and structure of the copolyesters of 2,2-bis-(3-chloro-4-hydroxyphenyl)propane, hexamethylene glycol and terephthalic acid on the duration of copolyesterification*.

Reaction time, min	Yield of copolyester, %	η_{int} (0.5% soln. in *sym*-tetrachloroethane at 25°C), dl g^{-1}	Content of fundamental units, m.f.**		Microheterogeneity coefficient K_M

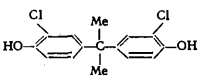
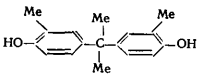
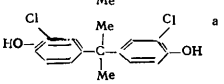
60	93	0.52	0.50	0.50	1.12

*See footnote a to Table 6.
**m.f. = mole fraction.

Thus, as a result of the difference (r = 5.3–33) between the reactivities of the comonomers, the composition of the copolymer changes as non-equilibrium polycondensation proceeds, while the distribution of fundamental units remains constant and nearly statistical.







2. Two-stage Copolycondensation

One of the methods of synthesising block-copolymers proposed previously by a number of workers involves the introduction of the comonomers into the reaction sphere stage by stage[8,30]. However, until recently there were no experimental data confirming the block structure of the copolymers prepared by this procedure.

It is interesting to note that the stage-by-stage method of introduction of the initial comonomers into the reaction zone as it were simulates the case of simultaneous copolycondensation when the copolycondensation constant for the comonomers is high ($r \to \infty$). Initially fragments comprising the intermonomer and the more reactive comonomer are formed and the less reactive comonomer only then begins to react with these fragments, which leads to the formation of the copolymer.

The first study of the copolyester obtained by two-stage non-equilibrium copolycondensation in solution was published in 1972.[29] Certain results of these investigations are presented in Table 6 (Nos. 3–6). It was found that the distribution of units in the chains of the copolyesters obtained by stage-by-stage polycondensation is nearly statistical. Thus, even the simulation of an infinite difference between the reactivities of the comonomers did not lead to the formation of block-copolymers. When the stage-by-stage polycondensation of terephthaloyl dichloride with 2,2-bis-(3-chloro-4-hydroxyphenyl)propane and hexamethylene glycol was carried out for different molar ratios of the latter, block-copolymers were not obtained either.

Table 8. The structures of the copolyesters obtained by two-stage non-equilibrium acceptor-catalytic polyesterification in the presence of triethylamine with gradual introduction of the intermonomer in stage I (dichloroethane, 40°C)[29,32,56].

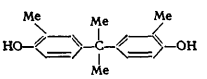
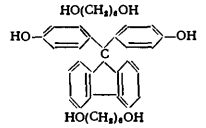
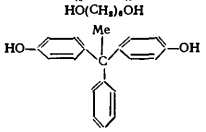
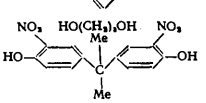
c. m.f. = mole fraction.

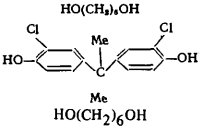
3. Gradual Introduction of the Intermonomer into the Reaction Zone











Block-copolyesters were synthesised with a gradual introduction of the intermonomer (terephthaloyl chloride) into the reaction zone[29,32,56], both in the solid state and as a solution. In the first case the rate of introduction of the intermonomer into the reaction zone was determined by the rate of its dissolution and in the second case by the rate of injection.

In the stage-by-stage synthesis of comonomers in the presence of triethylamine when terephthaloyl chloride was introduced in the first stage in the solid state, a statistical or a block sequence of fundamental units in the macromolecules was obtained depending on the reactivity of the diol (Table 8, Nos. 1, 3, and 4). The use of the relatively unreactive hexamethylene glycol in the first stage leads to a statistical distribution of the fundamental units in the copolyester. An increase of the reactivity of the comonomer used in the first stage causes a decrease of the microheterogeneity coefficient of the copolyester and a corresponding increase in block length. Thus the smallest microheterogeneity coefficient of the copolymers was obtained when dichlorodian ($r \simeq 33$), i.e. the most reactive of the comonomers investigated, was employed in the first stage.

The addition of solid terephthaloyl chloride to a solution of diols with $r \neq 1$ in the presence of triethylamine also leads to the formation of block-copolymers (Table 9). It was established that the size of the blocks in the copolyesters[54] depends significantly on the particular difference between the reactivities of the comonomers or, what amounts to the same thing, on their copolycondensation constant. An increase of the copolycondensation constant promotes an increase in block size and a decrease in the coefficient of microheterogeneity of the copolymers (Table 9).

The formation of block-copolymers with $K_M = 0.2-0.4$ when the intermonomer is introduced in the solid state into a solution of the comonomers with $r \gg 1$ was noted for different molar ratios of the initial diols[32]. However, the formation of block-copolymers on introduction of solid terephthalic acid did not occur when the acceptor-catalyst employed was pyridine[32], which is much less effective than

Table 9. The structures of the copolyesters obtained by single-stage non-equilibrium acceptor-catalytic polyesterification in the presence of triethylamine with the introduction of solid terephthaloyl chloride into the reaction zone (dichloroethane, 40°C).[54]

*m.f. = mole fraction.

triethylamine. Indeed, it has been shown for the benzoylation of *p*-nitrophenol in dioxan at 30°C that the reaction rate constant decreases from 6.48×10^{-2} to 5.92×10^{-2} litre^2 mole^{-2} s^{-1} on passing from triethylamine to pyridine[57]. Since acylation in the presence of pyridine is much slower, there is sufficient time for the complete dissolution of the solid intermonomer introduced into the reaction space, which leads to its greater involvement in the reaction and hence to the conditions of single-stage non-equilibrium copolycondensation in solution. Consequently, regardless

of the difference between the reactivities of the comonomers, in the presence of pyridine copolymers with a statistical distribution of units were obtained under these conditions[32]. In the presence of pyridine block-copolymers were obtained only after a slow introduction of the intermonomer solution into a solution of the comonomers and the acceptor-catalyst. This method of introduction of the intermonomer was investigated in detail in relation to the reaction of terephthaloyl chloride with two pairs of comonomers in the presence of triethylamine in dichloroethane solution at 40°C (Table 8, Nos. 2 and 5 and Fig. 5)[29,32,56]. It was observed that, when the entire solution of terephthalic acid chloride is added at once to the solution of the bisphenol, hexamethylene glycol, and triethylamine, the microheterogeneity coefficient of the resulting copolymers approaches the value corresponding to a statistical distribution of units. When the intermonomer is introduced into the reaction zone over a fairly long period, the microheterogeneity coefficient of the copolyester decreases, tending to a limiting value, which depends on the copolycondensation constant of the comonomers (Fig. 5).

4. Three-stage Copolycondensation

As already mentioned above, in three-stage copolycondensation each comonomer undergoes polycondensation with the intermonomer in different reaction zones. In one case the intermonomer is introduced in excess relative to the comonomer and in the other in a deficient amount such that the overall molar amounts of the functional groups of the intermonomer and the comonomers are the same in both reaction spaces. At the end of the polycondensation in the two systems, the latter are combined, and the reaction begins to proceed between the intermediates formed in the first stages.

Table 10. The structures of the copolyesters obtained by three-stage non-equilibrium acceptor-catalytic polycondensation in the presence of triethylamine (dichloroethane, 40°C).

3	0.9:1	1.1:1	0.44	0.56	5.9	7.7	0.30

*m.f. = mole fraction.

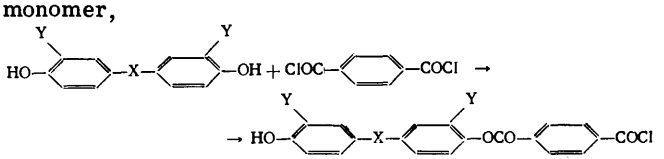
Many workers[30,31] use three-stage copolycondensation as a method of synthesising block-copolymers, although until recently there was no experimental evidence for the structures of the resulting copolymers. One could only presume that the block length in such copolymers depends on the molecular weight of the products obtained in the first stages. Thus, it was reasonable to conclude that, with increase or decrease of the excess of the intermonomer, relative to the comonomers, the block length in the copolymers will change.

It was established quite recently that the degree of disorder and length of the blocks in the copolymer are determined to a considerable extent by the deviation from equivalent amounts of the functional groups (Table 10).[32] Thus the smallest microheterogeneity coefficient of the copolymer was obtained for the closest approach to the equivalent amounts of the groups of the intermonomer and comonomer at each of the first stages (Table 10, No. 3).

Thus, experimental study of the structures of the copolymers obtained by non-equilibrium copolycondensation in a homogeneous system yielded the following relations. 1. The introduction of the entire intermonomer into the reaction zone at the beginning of non-equilibrium copolycondensation leads to the formation of copolymers with a nearly statistical distribution of polymer chain units regardless of the differences between the reactivities of the comonomers employed. 2. The stage-by-stage introduction of the comonomers into the reaction zone is not a sufficient condition for the formation of block-copolymers. 3. For the synthesis of copolymers with a block structure by single-stage non-equilibrium polycondensation in solution, it is necessary that the reactivities of the initial comonomers should be different and that the rate of introduction of the intermonomer is lower than the rate of its reaction with the more reactive monomer. By varying the above factors, it is possible to obtain block-copolymers with different lengths of the block fragments.

VII. COMPARISON OF THEORY WITH EXPERIMENT

The above experimental data are not only in qualitative agreement with the theory of homogeneous non-equilibrium copolycondensation developed by Kuchanov[6,47] but also provide a quantitative confirmation of the calculated relations. The microheterogeneity coefficients of copolyesters determined by ^{1}H NMR can be conveniently compared with the theoretical K_M, which are determined, in particular, by the relative reactivities of the functional groups of the initial compounds. Since the comonomers employed in the investigations[29,32,54,56] contained independent functional groups, and those in the intermonomer were interdependent, the interbipolycondensation processes involving them are generally characterised by four kinetic chain propagation constants. The microheterogeneity coefficients of the copolymers obtained in such processes are determined by three independent parameters κ_A, κ_B, and r_1. The first two of these are equal to the ratio of the reactivities of the first and second groups of the intermonomer in its reactions with each of the comonomers and the parameter r_1 characterises the relative reactivities of the comonomers in their reactions with the first groups of the intercomponent. The reactivities of the comonomers in relation to the second groups of the intercomponents (parameter r_2) can be simply expressed in terms of the above parameters: $r_2 = 2_1\kappa_A/\kappa_B$. When the condition $\kappa_A = \kappa_B = \kappa_1$ holds, it is evident that $r_1 = r_2 = r$ and therefore K_M is determined by the two parameters x and r. When $\kappa_A \neq \kappa_B$, the concept of the relative reactivity parameter of the comonomers r becomes purely qualitative, since only r_1 and r_2 have a definite quantitative significance.



It is simplest to compare theory with experiment in two-stage interbipolycondensation where the second comonomer is introduced into the reaction zone after the first has already reacted. For a specified ratio of the comonomers, K_M is determined according to theory only by the value of κ for the comonomer introduced first and is independent of the parameters r_1 and r_2. The theoretical curve relating K_M to κ for different amounts of the

comonomers is presented in Fig. 2. The Figure also compares the experimental K_M taken from Table 6 taking into account the κ from Table 1. Clearly there is a good quantitative agreement between the theoretical and experimental data, the difference between them being within the limits of experimental error. It follows from Fig. 2, that the parameters κ found, on the one hand, by analysing the structures of the copolymers and, on the other, from kinetic measurements virtually agree. In the first case the synthesis of copolyesters is carried out in dichloroethane solution and in the second the acylation rate constants are determined in dioxan. The small differences between the values of κ obtained by the two independent methods permit the conclusion that the solvent has only a weak influence on the ratio of the rate constants for the first and second groups of the intermonomer. One must emphasise that the solvent does have a very marked influence on the absolute values of the acylation rate constants. For example, the rate constant for the reaction of *p*-nitrophenol with benzoyl chloride in the presence of triethylamine increases almost by four powers of ten on passing from dioxan to dichloroethane [28].

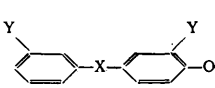


Fig. 1 illustrates the influence of the relative reactivity parameter of the comonomers r on the structure of the copolymers obtained on slow introduction of the intermonomer. It shows that all the experimental points taken from Table 9, with the exception of one, fit satisfactorily on the theoretical $K_M - r$ curve defined by Eqns. (6)–(7) for $\alpha_R = \alpha_S = 0.5$. This agreement should be regarded as satisfactory bearing in mind that, both in the derivation of Eqns. (6) and (7) and in the experimental determination of r in accordance with Eqn. (5), no account was taken of the difference between κ_A and κ_B. The latter factor implies that the values of r quoted in Table 4 yield in general only a preliminary estimate of the relative reactivities of the comonomers. Since r is intermediate between r_1 and $r_2 = r_1\kappa_A/\kappa_B$, the estimate will be more accurate the smaller the difference between κ_A and κ_B and hence between r_1 and r_2. It is therefore clear that the r quoted in Table 4 for 2,2-bis-(3-methyl-4-hydroxyphenyl)propane and 2,2-bis-(3-chloro-4-hydroxyphenyl)propane, which differ appreciably in the values of the parameter κ, constitute only a conventional quantitative characteristic of the relative reactivities of the above comonomers. This explains why the experimental K_M for 2,2-bis-(3-methyl-4-hydroxyphenyl)propane does not fit on the theoretical curve in Fig. 1.

Comparison of r for the bisphenol–glycol comonomer pair and the values of κ for terephthaloyl chloride (in relation to the phenolic component) found by any procedure shows a definite relation between these parameters. By comparing the results presented in Tables 1 and 4, it is seen that κ diminishes with increase of r. The reactivity of the bisphenol increases, i.e. r increases, in the case of non-equilibrium polycondensation under consideration when substituents Y with more pronounced electron-accepting properties are introduced into its molecule [15].

When a bisphenol of this kind interacts with the intermonomer,

a new group

the electron-accepting properties of which are to a large extent determined by the nature of Y, is formed in place of the COCl group. As the electron-accepting properties of Y become more marked, the reactivity of the second acid chloride group of the intermonomer may become not only comparable to that of the first group but may actually exceed it, which is in fact observed in the reaction of many substituted phenols with terephthaloyl chloride. The experimental microheterogeneity coefficients of the products obtained when all the initial compounds are introduced at once, are presented in Table 6. It is noteworthy that these values are close to the K_M for the copolymers formed in two-stage interbipolycondensation (Table 6). This result, which also follows from theory, is quite reasonable for comonomer pairs with a large value of the parameter r. As a result of the appreciable difference between reactivities, mainly the more reactive comonomer (bisphenol) reacts at the beginning of the process and hexamethylene glycol reacts only after some time when the bisphenol has been exhausted. Thus the distribution of units in the copolymer is close to that obtained in the two-stage process, when the bisphenol is added first. Since the above rule holds better the greater the difference between the reactivities of the comonomers, the maximum departure from it is to be expected for the bisphenol with the smallest value of r in relation to hexamethylene glycol. This conclusion is confirmed by the experimental data in Table 6.

---o0o---

Thus, the results presented in the review show that a quantitative theory of non-equilibrium copolycondensation in homogeneous systems has now been established. The conclusions of this theory have been quite convincingly confirmed by experimental results. Further study on copolycondensation should probably have the following two aims. Firstly, a similar theoretical and experimental treatment of non-equilibrium copolycondensation processes in heterophase systems is needed. Secondly, systematic studies are required on the influence of the compositions and structures of the polycondensation copolymers on their properties. The solution of this problem will make it possible to employ successfully the data quoted in this review for the synthesis of copolymers with specified properties.

System of Retention Indices and Its Physicochemical Application

R.V.Golovnya and Yu.N.Arsen'ev

The system of retention indices widely used in gas chromatography is reviewed. Methods of calculating indices are examined, their accuracy and reproducibility, and the effect on the index of parameters of the gas-chromatographic experiment (temperature, pressure, velocity of carrier gas, and quantity of stationary phase in the column). Systems resembling retention indices are described, problems of polarity, selectivity, and effectiveness of separation are discussed, and the physicochemical application of indices to calculate various thermodynamic functions is considered. A list of 252 references is included.

I. INTRODUCTION

Choice of the best mode of expressing retention data has hitherto been one of the highly debated problems of gas chromatography[1-5].

The use of retention parameters in the form of absolute units, e.g. as the specific volume retained, is not generally accepted, since change in the sorbent during prolonged use, inadequate accuracy in measuring the speed of the carrier gas and the pressure at the inlet to the column, and also unsatisfactory reproducibility of the column temperature lead to uncompensated errors[2-4]. Furthermore, this determination is very laborious[6]. Relative retention volumes, which are less dependent on the conditions of analysis, can be determined more simply and with sufficient accuracy[1,7,8]. However, this method requires a multiplicity of standards, which in fact makes correlation between different publications impossible[2,3].

These difficulties in determining universal gas-chromatographic characteristics led Kováts[9,10] to introduce retention indices. In the opinion of many investigators this system is the most systematic and convenient for generalising retention data. Several reviews have been published[2,3,11-14], and a large number of original papers, mainly concerned with the use of retention indices for identification purposes. The aim of the present Review is to give a comprehensive survey of indices as retention parameters and to reveal the main fields of and prospects for application of this system in physicochemical calculations. This permits an approach both to certain analytical problems (identification of substances, choice of selective stationary phases, selection of conditions of separation) and to several physicochemical problems (study of structure, determination of physicochemical properties from chromatographic data, and investigation of interactions in solution).

II. METHODS OF CALCULATION OF RETENTION INDICES

The elution maxima of individual members of the homologous series of n-alkanes form the fixed points of the system of indices. In the original definition of retention indices[9] Kováts proposed to use only n-alkanes with an even number of carbon atoms. He assumed that an appreciable difference in chromatographic behaviour would be observed in the successive identification of all the members of a homologous series. However, this limitation was subsequently removed[15], and the retention index came to be determined by means of the equation

$$I = 100\frac{\lg V_X - \lg V_n}{\lg V_{n+1} - \lg V_n} + 100n \qquad (1)$$

provided that $V_n \leqslant V_X \leqslant V_{n+1}$, where V_X, V_n, and V_{n+1} are the corrected retention volumes of the test substance and of the standard n-alkanes containing n and $n + 1$ carbon atoms respectively. It follows from Eqn. (1) that any absolute or relative (reduced to the same standard) retention parameters[2,3,8,15], corrected for the dead space, or the corresponding distances on the chromatogram, can be used as initial parameters for calculating retention indices.

The linear dependence of the logarithm of the retention volume of an n-alkane on the number n of carbon atoms[2,3,16-18]

$$\lg V_n = a + bn \qquad (2)$$

where b depends solely on temperature and on the properties of the stationary phase[19-21], will yield the simpler equation

$$I = 100\frac{\lg V_X - \lg V_n}{b} + 100n \qquad (3)$$

for calculating retention indices[2]. Calculation of retention indices by means of Eqn. (3) is based on a "theoretical" series constructed from 3 or 4 experimental retention times for normal hydrocarbons having $n \geqslant 6$.

In work with capillary columns the gas-dynamic pulse at the start of an experiment produces an appreciable scatter in the values of I calculated by means of Eqn. (3).[22] It was suggested that the reproducibility could be improved by calculating initially the relative retention $V_{X,\,st}$ and then converting it into the retention index by means of the equation

$$I = 100\frac{\lg (V_{X,\,st} \cdot V_{st,\,n})}{b} + 100n\,. \qquad (4)$$

Preliminary determinations had been made of b and of the relative retention of the standard with respect to n-alkanes $V_{st,n}$.

Graphical methods [23-25], nomograms [26-28], and a special slide-rule [15] have been suggested to simplify calculations of retention indices. Computer programmes have also been written for calculating indices [29-31].

Not only n-alkanes but any other components whose indices under the given conditions are known (I_1 and I_2) can be used to determine the retention indices of unknown components. The Kováts formula then becomes [25]

$$I_X = (I_2 - I_1)\frac{\lg V_X - \lg V_1}{\lg V_2 - \lg V_1} + I_1 . \quad (5)$$

Equation (5) is advantageous for prolonged analyses, e.g. when a capillary column is used, since it is unnecessary to reuse the standard n-alkanes. Furthermore, formula (5) may find application for calculating retention indices on polar stationary phases if Eqn. (2) does not apply.

Theoretical Calculation

Cases quite often arise in analytical practice when it is necessary to calculate retention indices theoretically. Linear equations are very often used for this purpose, relating retention indices with the number of carbon atoms in the molecule or with the boiling point, or else the calculation is based on the difference in retention indices on columns differing in polarity [32-54]. Such an approach underlies the standard-free identification of substances. In several cases relations of this type give only a first approximation to the index, owing to departures from linearity.

Retention indices can be determined additively from structural increments [11,14,32-40,44,47,55-68]. According to Tatevskii's theory [69] additivity calculations are based on the general relation [70]

$$\lg L = \sum_{i,j}^{k} n_{i,j}\Gamma_{i,j} \quad (6)$$

where L is the elution characteristic, $\Gamma_{i,j}$ the contribution of the structural unit, and $n_{i,j}$ the number of structural units in the molecule. Temperature coefficients of retention indices are sometimes used in calculating the latter from structural increments [71-74]. The validity and practical application of additivity calculations have been shown by many workers [10,32-42,45,75-84], but there is no doubt about their approximate character.

Retention indices for solutions that are nearly ideal can be calculated from the vapour pressures of the components at the temperature of the column [85]:

$$I_{p^0} = 100\frac{\lg p^0_X - \lg p^0_n}{\lg p^0_{n+1} - \lg p^0_n} + 100n \quad (7)$$

where p^0_X, p^0_n, and p^0_{n+1} are the vapour pressures of the test substance X and the standard hydrocarbons containing n and $n+1$ carbon atoms respectively. Tourres [86] showed that in non-polar systems I_{p^0} and the experimental I have almost the same temperature dependence, since the variation of the activity coefficients with temperature can be neglected in this case [87]. With the vapour pressure at various temperatures (and hence I_{p^0}) known, therefore, it is possible to predict both the behaviour of substances and their degree of separation. The so called standard retention index I_{st} [88], calculated from the boiling points by means of the formula

$$I_{st} = 100\frac{\lg T_{bp(X)} - \lg T_{bp(n)}}{\lg T_{bp(n+1)} - \lg T_{bp(n)}} + 100n \quad (8)$$

must be regarded as a particular case of I_{p^0}.

A more exact equation for calculating retention indices of hydrocarbons on non-polar stationary phases, proposed by Dimov and Shopov [89,90], involved the molar volumes:

$$I_{p^0,v^0} = 100\frac{\ln\left(\frac{p^0_X v^0_X}{p^0_n v^0_n}\right) - \left(\frac{v^0_X - v^0_n}{v^0_1}\right)}{\ln\left(\frac{p^0_{n+1} v^0_{n+1}}{p^0_n v^0_n}\right) - \left(\frac{v^0_{n+1} - v^0_n}{v^0_1}\right)} + 100n \quad (9)$$

where v^0_X, v^0_n, v^0_{n+1}, and v^0_1 are the molar volumes of the substance X, the normal hydrocarbons containing n and $n+1$ carbon atoms, and the stationary phase respectively. A thermodynamic proof of Eqn. (9) has been given by Hammers and de Ligny [91]. However, the "physicochemical indices" obtained in this way differ to some extent from the experimental values I. Conversion from I_{p^0,v^0} to I requires the introduction of corrections equal to the mean difference between I and I_{p^0,v^0} for hydrocarbons of the same class [92].

Unfortunately, theoretical calculation of retention indices by means of Eqns. (7)-(9) is possibly only for hydrocarbons and non-polar stationary phases, which considerably diminishes the significance of these relations.

Thus the foundation of the gas-chromatographic study of real systems remains as before the experimental determination of the retention index by means of Eqns. (1) and (3).

III. PARAMETERS RESEMBLING RETENTION INDICES

The indices I_{p^0}, I_{st}, and $I_{p^0v^0}$ discussed in Section II (Eqns. 7-9) are completely analogous to the Kováts index. Retentions are replaced by physicochemical constants.

The Kováts indices were followed by several similar scales, but these found limited application in gas chromatography. Examples are the "methylene unit" [93-95], which is identical with the retention index divided by 100, the "effective molecular weight" [79,96-98], where the molecular weights of n-alkanes are used as fixed points on the scale, and the "carbon numbers" [99,100] ("equivalent chain length" [101]), which are convenient for the analysis of aliphatic acids and their methyl esters. All these systems, being particular cases of the general Kováts system, possess closely similar properties. The mathematical equivalence of the above systems was shown by Guerin and Banks [102].

In several cases, e.g. in high-temperature gas-chromatographic analyses or with the use of strongly polar phases, n-alkanes are not always convenient as standard substances [103]. Swoboda [104], without changing the general construction of the Kováts system, proposed that the standards should be chemically similar to the test compounds. Thus "steroid numbers" [93-95] proved convenient in the gas-chromatographic analysis of steroids, the "phenyl number" [105] in the chromatography of linear polyphenyls, and the "siloxane index" [106-108] for the identification of organosilicon derivatives. An analogous system was proposed for the characterisation of high-boiling (up to 500 °C and above) fused aromatic and heteroaromatic compounds, where comparisons are based on polyacene hydrocarbons—benzene, naphthalene, anthracene, tetracene, etc. [109]

A rational generalisation of these systems is the dimensionless parameter φ[110]. Standard compounds belonging to the same homologous series as the test substance are used in calculating φ:

$$\frac{\lg V_{g\,X} - \lg V_{g1}}{\lg V_{g2} - \lg V_{g1}} = \varphi = \frac{T_{bp(X)} - T_{bp(1)}}{T_{bp(2)} - T_{bp(1)}} \qquad (10)$$

where V_gX, V_{g1}, V_{g2}, $T_{bp(X)}$, $T_{bp(1)}$, and $T_{bp(2)}$ are the retention volumes and the boiling points of the related compounds (X unknown, and *1* and *2* known). The parameter φ was shown to be constant, independent of the temperature of the analysis and the composition of the stationary phase. However, it cannot be recommended for the identification of complicated mixtures, comprising substances belonging to different homologous series, owing to ambiguity in the choice of standards and the absence of a natural "zero point". Retention indices have an undoubted advantage in this respect.

In order to avoid comparatively laborious stages in determining the "dead space" and taking logarithms in calculating Kováts indices, it was suggested that an "arithmetic index"[111-113] should be calculated by means of the equation

$$I_A = 100\,\frac{t_X - t_n}{t_{n+1} - t_n} + 100n \qquad (11)$$

where t_X, t_n, and t_{n+1} are uncorrected retention times for the test substance X and the standard n-alkanes. Equation (11) is sometimes written without the coefficients 100.[111,112,114] The arithmetic index has been used to estimate partition and activity coefficients[114]. However, the usefulness of the arithmetic index as a retention parameter is debatable[113,115,116], since no thermodynamic interpretation has yet been found. The theoretical possibility of the graphical conversion of I_A into I has been established[114]. An equation has recently been deduced[117] linking the arithmetic index with the retention index:

$$\frac{I - 100n}{100} = \frac{\lg\left[1 + \frac{I_A - 100n}{100}(D-1)\right]}{\lg D} \qquad (12)$$

where

$$D = \frac{t_{n+1} - t_n}{t_n - t_{n-1}}$$

t_{n-1}, t_n, and t_{n+1} being uncorrected retention times of successive n-alkanes. Furthermore, D = antilog b, where b is the coefficient in Eqn. (2). A thermodynamic basis for I_A may, perhaps, be found by the application of Eqn. (12).

IV. ACCURACY AND REPRODUCIBILITY OF RETENTION INDICES

For a long time the accuracy and the reproducibility of retention indices remained an open question. In connection with the increasing importance of gas chromatography in qualitative analysis and physicochemical research, interest has arisen during recent years in the precise measurement of retention parameters[23,118-124]. These aspects of retention indices calculated by means of Eqn. (1) can be extended equally to the simpler equation (3), since the two equations give values of comparable accuracy[17].

Tests of the reproducibility of indices determined on standard instruments in different laboratories[125] gave a standard deviation of ±1 on squalane and dinonyl phthalate and ±3 on [polyethylene glycol] PEG-400; the divergence in the indices on a polar stationary phase depends on the size of the sample of n-alkanes introduced into the chromatograph. It was shown later[126] that reproducible retention indices can be obtained even on such a polar phase as oxy-$\beta\beta'$-dipropionitrile if the samples of n-alkanes used in solution are 0.002–0.007 μl, when the linear portion of the partition isotherm is reached.

Loewenguth[127] gave a similar statistical assessment of the reproducibility of retention indices. Reproducibility is influenced mainly by the accuracy with which retention times and column temperatures are measured. The latter factor is especially significant in the analysis of compounds with a large temperature coefficient of the index dI/dT. Kaiser[23] reaches the same conclusion.

The first precision measurements of retention indices were made on ordinary and deuteriated squalane, with a maximum discrepancy of 0.06.[16,128] Schomburg et al.[129] used an on-line computer to measure retention indices with a reproducibility of ±0.03–0.05. Cramers et al.[130] achieved the same reproducibility (±0.03) without using an electronic computer. Analysis of these results showed that, in order to obtain reproducible retention indices, careful attention should be paid to measuring and stabilising the temperature of the thermostat; an inert material of uniform grain size should be used as solid support; the length and diameter of the column, the effectiveness of separation of the mixture, the rate of flow of the carrier gas, and the inlet and outlet pressures to and from the column must be taken into account; and the retention times of test substances and standard n-alkanes must be measured accurately[119].

Whereas the reproducibility of retention indices can be judged from how well the calculated values of I converge in a series of experiments, it is a more complicated task to determine the accuracy of the calculation of indices. A rigorous approach to this problem based on the principles of mathematical statistics was first made by Takács and Králik[131,132]. A solution of the problem was obtained independently by Uhdeova[118], but only in general form.

Analysis of the extended error formula deduced by Takács and Králik (called the Erdey equation) showed that the accuracy with which retention indices are determined depends on the absolute retention times of the test substance t_X, the n-alkanes t_n and t_{n+1}, and the unsorbed gas t_M, as well as the arithmetic mean errors of their determination. With a favourable choice of chromatographic conditions, when t_n, t_X, $t_{n+1} \gg t_M$, errors in the determination of the "dead space" can be neglected. From this the important conclusion can be drawn that, in the determination of retention indices, direct measurement of t_M can be replaced by indirect calculation, e.g. by use of the equation of Peterson and Hirsch[133]. For squalane the determination of t_M with respect to methane and hydrogen and by the Peterson–Hirsch method[133] was shown by Cramers et al.[130] to give identical results, with a reproducibility of the index of ±0.03.

Thus indices can be obtained with a minimum error. It is also noteworthy that the precision measurement of other retention parameters has not been studied so thoroughly, and this constitutes an indubitable advantage of the Kováts system of indices.

V. TEMPERATURE DEPENDENCE OF RETENTION INDICES AND ITS USE IN GAS CHROMATOGRAPHY WITH TEMPERATURE PROGRAMMING

In the early gas-chromatographic investigations Kováts and Wehrli [9,10] established a linear correlation between the index and the temperature of the analysis. They proposed that three parameters—(*a*) the index at the given temperature, (*b*) the temperature coefficient $10dI/dT$ for a 10 deg change in temperature, and (*c*) the temperature limits within which the indices were measured—should be stated to express the temperature dependence of retention indices. The temperature dependence was subsequently studied by many investigators [3,15,71,76,78,85,87,134-141]. The relation was found to be hyperbolic over a wide temperature range [78,134].

Allowing for the temperature dependence of the corrected retention volume [142], Takács et al. [12,142-144] showed by rigorous mathematics that the temperature dependence of retention indices obeys a hyperbolic equation with three constants, resembling Antoine's equation

$$I_{(T)} = A + \frac{B}{T + C} \qquad (13)$$

where A, B, and C depend on the properties of the test substance and the stationary phase. Experimental verification of Eqn. (13) is accomplished by means of an electronic computer [145,146]. The hyperbola (13) is usually essentially linear in the gas-chromatographic temperature range [143]. Fig. 1 shows the general form of the temperature dependence of the retention index of propan-1-ol on PEG-400.

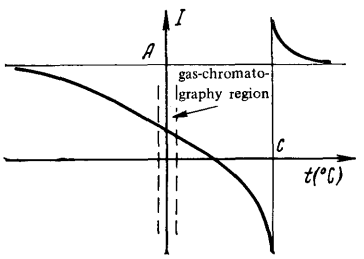

Figure 1. General form of temperature dependence of retention index of propan-1-ol for the phase PEG-400. [143]

The temperature coefficient dI/dT is an important characteristic of the substance and the stationary phase, and can be used for identification purposes [72,140,147]. In several investigations [73,87] the coefficient $dI/d(1/T)$ has been used to establish structure. The differential dI/dT was employed [148,149] to calculate the equivalent isothermal index in the case of linear temperature programming. If at least one component in a solute–stationary phase system is polar, the sign of the differential will depend on the properties of the system for the individual case [91,150-153].

Study of the temperature dependence of the retention indices of various hydrocarbons [71,86,87,91,154] showed that the coefficient is affected by the number and the steric arrangement of the side-chains in the molecule. Hammers and de Ligny [91] gave a rigorous thermodynamic basis to the coefficient dI/dT, and established that its magnitude is determined by the free energy and the entropy of vaporisation of the substance undergoing analysis.

The temperature dependence of retention indices has been examined thermodynamically for ideal solutions [155]. The general dependence of the index on the temperature and the enthalpies and entropies of vaporisation was shown for three simple hypotheses—(i) that the enthalpy of evaporation of n-alkanes is constant, (ii) that the enthalpy decreases linearly with rise in temperature, and (iii) that the enthalpy varies in conformity with the Thiesen (Watson) equation [156]—among which the third assumption gives the best agreement between calculated and experimental indices.

The Kováts index has proved a convenient retention parameter not only in isothermal but also in temperature-programmed gas chromatography. An equation has been proposed for calculations [105,135,136,157-159], based on a nearly linear dependence of the elution temperature of n-alkanes on the number of carbon atoms:

$$I_{tpr} = 100\frac{T_{r_X} - T_{r_n}}{T_{r_{n+1}} - T_{r_n}} + 100n \qquad (14)$$

where I_{tpr} is the retention index of the test substance with temperature programming, and T_{rX}, T_{rn}, and $T_{r,n+1}$ are the retention temperatures of the test substance and of n-alkanes containing n and $n + 1$ carbon atoms respectively. A theoretical deduction of Eqn. (14) has recently been achieved by Takemura [160] on the basis of his previously established [161,162] linear relation between the isothermal relative retention and the relative retention with temperature programming.

The index calculated by means of formula (14) usually differs from, but is quite close to, the isothermal index at some equivalent temperature T_{eq}. Thus Guiochon [135,136] found that programmed indices agree best with the isothermal value at 20 deg below the retention temperature. Habgood and Harris showed [157] that, with cyclic hydrocarbons, the indices with temperature programming correspond to the isothermal values at a temperature 30–50 deg below T_r. Giddings [163] proposed the correlation equation $T_{eq} = 0.92T_r$.

The opinion has become established among specialists in this field that, with temperature programming, the retention index varies little with quite a wide choice of analysis conditions—initial temperature, rate of programming, and speed of carrier gas [135,136,157,158,163].

The experimental conditions have an appreciable effect on the index with programming, especially when substances showing a large temperature coefficient are analysed on polar phases [148,149]. An equation was deduced to allow for the experimental parameters—rate of linear programming β, temperature coefficient of index dI/dT, and retention temperature of substance T_r:

$$I_{T_0/\beta} = I_{T_0} + \frac{\beta T_r}{2} \cdot \frac{dI}{dT} . \qquad (15)$$

Comparison of the calculated equivalent isothermal indices I_{T_r-20}, $I_{0.92T_r}$ and $I_{T_0/\beta}$ showed that $I_{T_0/\beta}$ will give the best agreement with the experimental value I_{tpr} [148,149]. This is because $I_{T_0/\beta}$ takes into account not only T_r but also the conditions of the programmed experiment (T_0, β, t). The equivalent isothermal index $I_{T_0/\beta}$ has been used with linear temperature programming for the qualitative analysis of monocarbonyl compounds in the volatile components of certain foodstuffs [164,165]. Robinson and Odell [88] extended

the mathematical approach[148,149] to non-linear temperature programming (with the temperature raised in steps), and suggested that the mean temperature of the elution and the temperature coefficient of the index should be taken into account in calculating retention indices.

Erdey et al.[12,166,167] integrated Eqn. (13) from the initial temperature T_0 to the retention temperature T_r, and obtained a general equation for the equivalent isothermal index in temperature-programmed gas chromatography:

$$I_{eq} = A + \frac{2.3B \cdot \lg\left(\frac{T_r + C}{T_0 + C}\right)}{T_r - T_0} \qquad (16)$$

where A, B, and C are the constants in Eqn. (13) determined from the isothermal indices measured at three different temperatures[143]. If these constants are known, I_{eq} can be calculated by means of (16) without the need to chromatograph n-alkanes. Because the computation of A, B, and C is laborious, the determination of I_{eq} by means of Eqn. (16) is extremely complicated.

Formulae (15) and (16) are essentially similar, although the former was deduced on the hypothesis of a linear temperature dependence of retention indices, and the latter from a hyperbolic dependence. Because the hyperbola usually has a linear section in the gas-chromatographic temperature range[143], Eqns. (15) and (16) should give the same calculated result. Erdey et al.[167] found that equivalent isothermal indices calculated by means of the two equations for benzene and PEG-1500 as stationary phase differed at most by ±1. From a practical point of view, therefore, use of the simpler equation (15) is to be preferred, despite its less general character.

Thus the temperature dependence of retention indices obeys in general a hyperbolic law, although the hyperbola usually has a linear section in the gas-chromatographic temperature range. This enables retention indices at different temperatures to be handled very simply, and validates the use of the temperature coefficient dI/dT. It also presents greater opportunities for the widespread use of Eqn. (15) in gas chromatography with linear programming of temperature.

VI. EFFECT OF THE INDEX OF PARAMETERS OF GAS-CHROMATOGRAPHIC EXPERIMENT

The principles of classical equilibrium chromatography, when the temperature of analysis T, the speed of the carrier gas w, the input pressure to the column p_i, and the pressure drop factor j_2^3 are constant, are generally used in calculating retention indices, as with other retention parameters[131]. Under these conditions the fall in pressure in the column and the speed of the carrier gas in numerator and denominator of Eqns. (1) and (3) cancel out, with small variations in T, w, and p_i partly or completely balanced out. This forms the basis for the conclusion that the system of indices is stable with respect to experimental conditions[2,3,15,168]. Nevertheless, it is useful to examine the effect of various experimental variables on the retention index.

1. Retention Index and Speed of Carrier Gas

Guerin and Banks[102] found that the constant b in Eqn. (3) is unaffected by changing the speed of the carrier gas from 40 to 200 ml min^{-1}.

Equation (1) was transformed[169,170] to contain rates of flow of the carrier gas w (instead of specific retention volumes) and the constants in the equation for the dependence of retention time on w. Changing the speed of the carrier gas from 1 to 500 ml min^{-1} left the indices almost unchanged. This enables retention indices to be used to identify components in gas chromatography with programming of the gas flow.

2. Retention Index and Pressure in System

Two main factors—considerable non-ideality of the gas phase and solubility of the carrier gas in the stationary phase—complicate the interpretation of retention indices and the calculation of thermodynamic functions from chromatographic data obtained at high pressures[54]. Vigdergauz and Semkin[171-173] demonstrated the effect of non-ideality of the gas at high pressures on the retention indices of hydrocarbons. They showed that changing from helium to carbon dioxide and raising the pressure in the column to 15 atm are accompanied by changes in the retention indices, and in some cases even the sequence in which substances are eluted may change. Retention indices at high pressures have been used for the calculation of second virial coefficients[54,171-173].

Unfortunately, the effect of increased pressure on retention characteristics, including Kováts indices, has still been comparatively little studied.

3. Retention Index and Quantity of Stationary Phase in Column

The relative retention volumes of polar substances (in relation to non-polar substances) are strongly dependent on the proportions of highly polar stationary phases when these are below 5%.[174] This makes it difficult to identify components of a mixture by means either of relative retention volumes or of retention indices. Kováts[15] recommended working at high proportions of the stationary phase in order to obtain good reproducibility of the retention indices. However, this diminishes the efficiency of the column, the height of a theoretical plate is considerably more strongly dependent on the speed of the carrier gas, and the duration of the analysis increases[175]. In order to achieve maximum separating power with a chromatographic column, therefore, the optimum quantity of stationary phase must be taken. With diatomites this varies within 5–10% of the total weight of sorbent[176].

In the analysis of unsaturated and substituted methyl esters of C_{16}–C_{18} acids on the non-polar stationary phases Apiezon L and SE-30 the retention indices are almost independent of the quantity of the stationary phase on the solid support, whereas a very considerable variation is found on the polar polyethylene glycol succinate[177]. The chromatography of polar substances shows that the nature of the adsorbent has an appreciable effect on the index. Thus the retention indices of alcohols on squalane columns become smaller when Chromosorb V is replaced by Chromosorb G[179].

Bonastre et al.[178] obtained an equation for calculating retention indices that took into account adsorption phenomena in the column:

$$I = 100\,\frac{\lg\dfrac{\left|V_g^\infty + \frac{h}{\Pi} + \hbar\left(\frac{1}{\Pi} - \frac{1}{10}\right)\right|_x}{\left|V_g^\infty + \frac{h}{\Pi} + \hbar\left(\frac{1}{\Pi} - \frac{1}{10}\right)\right|_n}}{\lg\dfrac{\left|V_g^\infty + \frac{h}{\Pi} + \hbar\left(\frac{1}{\Pi} - \frac{1}{10}\right)\right|_{n+1}}{\left|V_g^\infty + \frac{h}{\Pi} + \hbar\left(\frac{1}{\Pi} - \frac{1}{10}\right)\right|_n}} + 100n \qquad (17)$$

where V_g^∞ is the specific retention volume with maximum possible percentage impregnation Π, and the coefficient h and $\hbar$ represent adsorption on the film of stationary phase and on the solid support respectively. With the standard n-alkanes $\hbar \simeq 0$. With PEG-20 000 and thio-ββ-dipropionitrile as the stationary phases, polytetrafluoroethylene and Chromosorb P as solid supports, and a large number of substances belonging to various classes these workers showed that the retention indices increase with increase in the degree of impregnation Π, in conformity with Eqn. (17), and approach their limiting values I^∞. It was found also that the constant $\hbar$ can be substantially diminished by the use of inert supports. A generalised equation for the retention volume in gas-liquid chromatography which in addition to solution in the stationary phase takes into account adsorption at its interfaces with the carrier gas and adsorbent has also been proposed [180,181].

On the whole it can be accepted that retention indices are extremely stable over a wide range of rates of flow of the carrier gas at column pressures that are usual in analytical gas chromatography. However, the quantity of stationary phase in the column (especially one of high polarity) has an appreciable effect on the index. In order to obtain reproducible indices, therefore, inert solid supports must be used, the same quantity of stationary phase (not less than 5–10 wt.%), and with highly polar phases minimum samples of the standard n-alkanes in order to reach the linear portion of the partition isotherm.

VII. CHARACTERISATION OF STATIONARY PHASES AND COLUMNS BASED ON RETENTION INDICES (POLARITY, DONOR AND ACCEPTOR POWER, SELECTIVITY, EFFECTIVENESS OF SEPARATION)

Problems of forecasting the chromatographic value of stationary phases and columns from the theory of dissolution and the physicochemical properties of solute and solvent have been solved during recent years [4,176,182,183]. In order to make a preliminary estimate of retention parameters, many attempts were undertaken to relate them to the thermodynamic, electrical, and geometric properties of stationary phases. Many groups of substances exhibit a certain dependence of the relative retention parameters on the electrical characteristics (dipole moment, dielectric constant, polarisability, refraction) of the stationary phase or of the separable components) [184–189].

Polarity

The terms "polar", "weakly polar", "non-polar", etc. are too inexact to characterise stationary phases. As Kováts showed [15], the concept of "polarity" is convenient, and in some cases sufficient, to describe many effects, but it cannot be expressed by a single parameter.

The polarity of stationary phases determined from retention characteristics is ultimately a function of the cohesion potential: i.e. it depends on the contribution by orientation, induction, and dispersion forces. Together with these, donor–acceptor interactions are especially important in gas chromatography [190]. The energy of van der Waals interaction, except for the dispersion component, depends on the temperature, so that polarity is also a function of temperature [188,191].

Rohrschneider [192] originally proposed a graphical method, in which the stationary phases were arranged along the horizontal axis with the polarities 0 and 100 assigned to squalane and oxy-ββ′-dipropionitrile respectively, which enabled stationary phases to be characterised by appropriate polarity indices. Almost the same approach to classifying phases was being followed by several other workers [191,193–205], except that the standard substances used were not butadiene and butane, but methanol and butane, acetylene and ethane, benzene and hexane, two n-alkanes, etc. Sakharov has shown [185,206] that all these methods derive from the general relation

$$\lg V = B_1 \lg V_{st} + B_2 \qquad (18)$$

where V and V_{st} are the retention volumes of the substance and the standard respectively, B_1 is a constant representing the polarity of the substance undergoing analysis, B_2 is another constant, and $\lg V_{st}$ measures the polarity of the stationary phase. However, the considerable uncertainty in the choice of standard substances imposes considerable limitations on this method.

The system of retention indices provides a more convenient form for expressing differences in the character of stationary phases. This assignment is based on the difference between the interaction of the substance with the test phase and with a phase which is by definition regarded as non-polar (squalane, Apiezon).

Wehrli and Kováts [10,15] suggested measuring the difference ΔI between the retention indices for compounds of general formula RX, where R is a hydrocarbon radical containing six or more carbon atoms, and X a functional group. Since $\Delta I = 0$ when X = H, the proposed scale begins at zero. It is termed the "dispersion of retention" of the stationary phase.

Developing this idea, Rohrschneider [207–210] suggested that the polarity of the column depends not only on the nature of the stationary phase but also on the type of substance analysed. The polarity of a stationary phase must therefore be assessed simultaneously with respect to a whole group of compounds possessing diverse donor–acceptor properties. This is a more rigorous approach to solving the problem. Rohrschneider originally proposed one- and three-term equations, but these did not find wide application. Later he worked out a general five-term polarity system, which has been recommended for the widest use in gas chromatography [211–213]. The general equation is

$$\Delta I = ax + by + cz + du + es \qquad (19)$$

where a, b, c, d, and e are polarity factors of the stationary phase, and x, y, z, u, and s are polarity factors of the substances undergoing analysis. Having determined the polarity factors of 22 stationary phases with respect to the compounds adopted as standards (benzene, ethanol, butan-2-one, nitromethane, and pyridine) and those of 30 substances, Rohrschneider calculated 660 indices with errors not exceeding 4–6. Accurate measurements have shown that the values of the Rohrschneider constants depend on the size of sample introduced [214], so that this size must be indicated when such constants are published.

Without changing Rohrschneider's general concept, McReynolds [215] suggested a different list of standards—including benzene, butanol, pentan-2-one, nitropropane, pyridine, and five other substances for solving particular problems—which are more convenient experimentally. McReynolds compiled a table of differences in retention indices of ten test substances for various stationary phases. The list of stationary phases comprises approximately 200 items.

Takács et al. [212,213] has recently shown, by rearranging Eqn. (19), that the interaction between test substances and

stationary phases can be characterised not only by the difference between but also by the ratio of the indices. They obtained the equation

$$I_X^P = I_X^S \sum_{i=1}^{5} f_i s_i \qquad (20)$$

where I_X is the isothermal retention index of the substance X, the letters P and S represent a polar stationary phase and squalane respectively, $f_i = I^P/I^S$ is the ith polar factor, i is the serial number of Rohrschneider's or McReynolds' standard substance, and

$$\frac{a}{100}\cdot\frac{I_1^S}{I_X^S} = s_1;\ \frac{b}{100}\cdot\frac{I_2^S}{I_X^S} = s_2;\ \cdots\ \frac{e}{100}\cdot\frac{I_5^S}{I_X^S} = s_5$$

are specific factors for the substance, characterising the molecular structure and the interaction potential. Equation (20) represents more accurately the effect of the specific factors s_i for substances and gives better agreement between calculated and experimental values of the index than does Eqn. (19).

Another proposed method for determining the polarity of a stationary phase is based on the equation [85,178,216]

$$P = (k^0 - k)\cdot 10^5 = 10^3 \lg(\gamma_{n+1}^{\infty}/\gamma_n^{\infty}) \qquad (21)$$

in which γ_n^{∞} and γ_{n+1}^{∞} are the activity coefficients of the n-alkanes containing n and $n+1$ carbon atoms. The quantities k^0 and k are related to the retention indices I_1 and I_2 of two substances by indices $I_{p_{(1)}^0}$ and $I_{p_{(2)}^0}$, computed from the vapour pressures (Eqn. 7) and by the relative activity coefficient $\gamma_{1,2}^{\infty}$:

$$\lg\gamma_{1,2}^{\infty} = k^0(I_{p_{(1)}^0} - I_{p_{(2)}^0}) - k(I_1 - I_2). \qquad (22)$$

Bonastre et al. [178] then suggested that, to allow for adsorption phenomena on the surface of the adsorbent and the stationary phase, indices should be calculated by means of Eqn. (17) and k replaced by k^{∞}, corresponding to the largest proportion of stationary phase. In this case the polarity computed by means of formula (21) will then be determined almost entirely by the dissolution of the substance in the stationary phase, which is more accurate.

Comparison of the Chovin–Lebbe [193-195,201,202] and the Bonastre–Grenier [85,178,216] methods for determining the polarity of stationary phases shows that physically the former consists in measuring the constant b (Eqn. 2), which is equal to the increment of the partial molar free energy of sorption per methylene group $\Delta G_{s,CH_2}$ in an n-alkane [19]. Thus in this method the polarity is estimated solely from the dispersion component of the total interaction potential, and increase in polarity correlates with a decrease in b. In contrast Bonastre and Grenier assess polarity not on the basis of the above increment but on $\Delta G^E_{CH_2}$, which measures the departure of the system from Raoult's law. The more the ratio $\gamma_{n+1}^{\infty}/\gamma_n^{\infty}$ in Eqn. (21) differs from unity, and hence $\Delta G^E_{CH_2}$ from zero, the more polar is the stationary phase. Strictly speaking, however, Eqn. (21) defines not the polarity but the selectivity of the stationary phase with respect to the n-alkanes, since, apart from a constant (2.3 RT), the logarithm of the relative activity coefficient is the "empirical" selectivity—the difference between the partial molar excess (free) energies of sorption [17,183].

Kováts and Weisz [217] also used retention indices to examine the polarity of stationary phases. If the total free energy of dissolution is determined by the work of separation (the energy of a hole), by a dispersion term, by a polar term, and by the energy of donor–acceptor interaction, the sum of the last two terms is proportional to the difference between the retention indices of the test substance on the column with a given solvent and a standard non-polar phase.

Thus a survey of published information shows that Rohrschneider's method, with the standard compounds proposed by McReynolds, is the most widely used at the present time for assessing the polarity of stationary phases.

Donor and Acceptor Power

Using Brown's triangular method [218], Guiochon et al. [61,219] showed that retention indices could be employed to assess such important properties of a phase as its donor and acceptor power. The method involves constructing a triangular diagram, on which are plotted the normalised retention indices of an electron acceptor (1,4-dioxan), an electron donor (1,1,2-trichloroethane), and a neutral compound (n-decane). Use of a triangular diagram provides a simple and graphic procedure for assessing the donor and acceptor power of a stationary phase, but the method has no significant advantages over Rohrschneider's system.

Selectivity

The selectivity of a stationary phase in gas–liquid chromatography is a static characteristic independent of kinetic factors, e.g. plate height [220]. It is measured [4,182,183,220] by the relative activity coefficient or by the difference in the free energies of mixing $\Delta\Delta G^E_{i,j}$. In this connection retention indices provide the most rational system, since they represent the relative retention with n-alkanes as a scale of standards of the same type. Several equations have been suggested [17,20,21,221] for estimating the selectivity of a stationary phase from retention indices:

$$\lg\alpha_{i,j} = \frac{b\,\delta I_{i,j}}{100} = -\lg(\gamma_{i,j}^{\infty} p_{i,j}^0) \qquad (23)$$

$$\Delta\Delta G_{i,j}^E = -2.3RT\left(\frac{b\,\delta I_{i,j}}{100} + \lg p_{i,j}^0\right) \qquad (24)$$

$$\Delta\Delta H_{i,j}^E = -2.3RT\left[\frac{\delta I_{i,j}}{100}\cdot\frac{\partial b}{\partial 1/T} + \frac{b}{100}\cdot\frac{\partial(\delta I_{i,j})}{\partial 1/T} + \cdot\frac{1}{2.3p_{i,j}^0}\frac{\partial p_{i,j}^0}{\partial 1/T}\right] \qquad (25)$$

$$\Delta\Delta S_{i,j}^E = \frac{\Delta\Delta H_{i,j}^E - \Delta\Delta G_{i,j}^E}{T} \qquad (26)$$

where $\alpha_{i,j}$ is the separation factor, $\Delta\Delta G^E_{i,j}$, $\Delta\Delta H^E_{i,j}$, and $\Delta\Delta S^E_{i,j}$ are the differences between the free energies, enthalpies, and entropies of mixing, b is a constant in Eqn. (2), $\delta I_{i,j} = I_i - I_j$ is the difference between the retention indices of two substances, $p^0_{i,j}$ is the relative vapour pressure with the column at temperature T°K, and i and j are the compounds under examination.

Equations (23)–(26) have enabled a successful choice to be made of selective columns for the analysis of carbonyl [222] and sulphur-containing compounds [17,20,21,221,223]. In the latter case eleven stationary phases were examined, for which values of $\Delta\Delta G^E_{i,j}$ were calculated by means of Eqn. (24) using n-hexanethiol, dipropyl sulphide, and diethyl disulphide as examples (results in Table). The maximum values of this difference were obtained for columns containing oxy-$\beta\beta'$-dipropionitrile, polyethylene glycols (PEG), and Triton X-305. It was found that oxy-$\beta\beta'$-dipropionitrile, previously regarded as the most

selective column for all sulphur-containing compounds[224], was not selective in the separation of thiols and sulphides (as $\Delta\Delta G^{E}_{2,1} \simeq \Delta\Delta G^{E}_{3,1}$—see Table), but was convenient in the separation of thiols and disulphides, and also of sulphides and disulphides.

Values $\Delta\Delta H^{E}_{i,j}$ and $\Delta\Delta S^{E}_{i,j}$ have been calculated by means of Eqns. (25) and (26) in order to reveal the nature of the selectivity of phases. It is found, for example, that the enthalpy factor predominates in the separation of dipropyl sulphide from diethyl disulphide on PEG-1000, but the entropy factor with hexanethiol and diethyl disulphide[17, 20, 21, 221].

Differences in partial molar free energies of mixing, calculated by means of Eqn. (24), of certain organosulphur compounds on various stationary phases[17, 40].

Stationary phase (at 60°C)	$\Delta\Delta G^{E}_{2,1}$	$\Delta\Delta G^{E}_{3,1}$	Stationary phase (at 60°C)	$\Delta\Delta G^{E}_{2,1}$	$\Delta\Delta G^{E}_{3,1}$	Stationary phase (at 130°C)	$\Delta\Delta G^{E}_{2,1}$	$\Delta\Delta G^{E}_{3,1}$
SE-30	—60	—100	Tritolyl phosphate	140	220	Apiezon M	10	20
Apiezon M	—70	—100	Triton X-305	200	330	Silicone DS-550	70	60
Silicone DS-200	—70	—120	PEG-1000	250	390	Triton X-305	220	290
Dinonyl phthalate + 5% diphenylamine	5	60	Oxy-ββ′-dipropionitrile	390	380	PEG-20000	260	370
Dinonyl phthalate	10	60						

Note. $\Delta\Delta G^{E}_{2,1}$ = difference between free energies of mixing of hexanethiol and diethyl disulphide.
$\Delta\Delta G^{E}_{3,1}$ = difference between free energies of mixing of dipropyl sulphide and diethyl disulphide.
Values of $\Delta\Delta G^{E}_{i,j}$ given in cal mole^{-1}.

Thus it has been shown experimentally that Eqns. (23)–(26) are extremely convenient for estimating the selectivity of stationary phases.

Effectiveness of Separation

The practical value of a chromatographic column is always determined by the fundamental possibility of separation and the time required for this separation. The effectiveness of separation is usually understood to refer to the blurring of the peak during the analysis[225].

Kováts[9] deduced the relation

$$\delta I \simeq 5\delta T_{bp} \qquad (27)$$

for the difference between the indices of two substances, from which can be estimated the minimum difference in boiling points necessary for the separation of isomers on non-polar stationary phases. However, Eqn. (27) is apparently not general in character, for it has recently been shown[51] with branched C_9 and C_{10} alkenes that the proportionality constant may differ considerably from 5, and assume values from 1.8 to 13.9.

A suggested criterion of separation R was determined by the ratio of the distance between the peak maxima to the sum of their half-widths at the base[226].

Instead of R Strickler and Kováts[19] used the $N\sigma$ criterion —the distance between the two separable substances expressed in σ-units (where σ is the half-width at the level of the point of inflection): separation does not occur if the distance between the peaks is equal to or less than 2σ. The 4σ criterion corresponds to adequate separation, and the 6σ criterion to almost complete separation. These workers compared the $N\sigma$ criterion with the difference between the retention indices of the separable substances δI, with the free energy of evaporation of the substances from the stationary phase per methylene group $\Delta G_{e(CH_2)} = b$—see Eqn. 2), and with the number of theoretical plates N_t:

$$\delta I = \frac{N\sigma\Phi}{\sqrt{N_t}}\left(1 + \frac{1}{k_i}\right) \qquad (28)$$

where k_i is the reduced retention time relative to the dead time, and

$$\Phi = \frac{100RT}{\Delta G_{e\,(CH_2)}}.$$

Struppe[227] proposed the use of a quantity Z which allowed for the progressive broadening of the peak on the chromatogram. In general, however, the calculation of this parameter is extremely complicated. From an analysis of values of Z this author concluded that, when highly efficient capillary columns are used, identification is possible only from the retention indices.

Ettre and Billeb[228] deduced an equation linking the difference in retention indices with the number of effective plates N_{eff} and the separation criterion R:

$$\delta I = \text{const} \cdot \lg \frac{\sqrt{N_{eff}}}{\sqrt{N_{eff}} - 4R} \qquad (29)$$

where the constant is $100/\lg(t_{R(n+1)}/t_{R(n)})$.

Rohrschneider showed[229] that R can be calculated from the difference between the retention indices by means of the equation

$$R = \frac{\delta I}{1.6998_I} \qquad (30)$$

where θ_I is the width of the peak at mid-height (in index units). He used an equation relating the logarithm of the relative retention to the difference in molar free energies of sorption to assign a rigorous thermodynamic meaning to the criterion R. He demonstrated also[230] that the effectiveness of separation depends on the polarity of the stationary phase expressed as in Eqn. (19).

In conclusion we note that the separation criterion R is used in gas chromatography far more often than are $N\sigma$ and Z, because R is most simply related to data obtained directly from a chromatogram. In order to estimate effectiveness of separation from retention indices, therefore, Eqn. (30) must evidently be used.

VIII. APPLICATION OF RETENTION INDICES IN THE CALCULATION OF PHYSICOCHEMICAL PARAMETERS

Tourres[86], as well as Bonastre and Grenier[85, 216], established the relation

$$I = 100\frac{\lg p^0_n - \lg p^0_X + \lg(\gamma^{\infty}_n/\gamma^{\infty}_X)}{\lg p^0_n - \lg p^0_{n+1} + \lg(\gamma^{\infty}_n/\gamma^{\infty}_{n+1})} + 100n \qquad (31)$$

between the relative activity coefficient, the vapour pressure, and the retention index, and used it to predict retention indices and to assess the polarity of stationary phases.

Vigdergauz and Semkin have recently suggested[54, 171–173] that retention indices at two elevated pressures P_1 and P_2 should be used to determine the mixed second virial coefficient B_{12}:

$$\frac{\Delta I}{\Delta P} = \frac{(I_1 - 100n)(\beta_{n+1} - \beta_n) - 100(\beta_X - \beta_n)}{-b_2} \qquad (32)$$

where $\Delta P = P_2 - P_1$, $\Delta I = I_2 - I_1$ measured at pressures

P_2 and P_1 in the column, $\beta_i = (2B_{12i} - v_i^\infty)/2.303RT$ ($i = x$, n, $n+1$), v_i^∞ is the molar volume of the liquid sorbate, and $b_2 = \lg(V_{g(n+1)_2}/V_{g(n)_2})$ is the logarithm of the relative retention volume of adjacent n-alkanes at pressure P_2. Calculation of B_{12} by means of Eqn. (32) is assumed to give more accurate results than its determination from the retention volumes.

Martynov and Vigdergauz [54] suggested a method for determining the density of alkanes at 20°C from the retention indices on squalane.

The most obvious though approximate method for determining the properties of substances is based on the relation, widely used in practical analysis, between the index or the logarithm of the relative retention and the boiling point, the number of carbon atoms in the molecule, or the logarithm of the vapour pressure [32-54, 59, 231-238].

Martin showed [239] that the free energy of sorption can be estimated by summing the structural increments for the molecule. Additivity of the retention index follows as a particular case [10, 56, 182, 240, 241]. The possibility thus appears of determining chromatographically the properties of compounds differing e.g. in quantity of substituents, number of multiple bonds, skeletal structure, etc.

Thermodynamic Nature of Index

Kováts [9] made the first attempt to find a thermodynamic basis for the retention index. Using the relation between the relative retention and the difference between the molar free energies of evaporation of the test substance and of the standard n-alkane $\Delta G_{e,X}$ and $\Delta G_{e,n}$, he established that

$$I = 100\frac{\Delta G_{e_X} - \Delta G_{e_n}}{\Delta G_{e\,(CH_2)}} + 100n\,. \qquad (33)$$

Comparison with Eqn. (3) shows that the constant b has a quite definite thermodynamic significance: it is the increment of the free energy of evaporation (dissolution) per methylene group [9, 17, 19, 91, 155, 242]. Kováts [9] obtained values of approximately 500 and 460 cal mole^{-1} for $\Delta G_{e(CH_2)}$ for Apiezon L and the Emulphor O respectively. He pointed out that, in the thermodynamic interpretation of retention indices, the free energies not only result from dissolution but also contain a contribution due to adsorption on the solid support and on the surface of the stationary phase.

Kováts and Weisz [217] showed later that the index measures the retention of a component on the scale of the standard chemical potentials of the n-alkanes:

$$I = 100\frac{\Delta\mu_X - \Delta\mu_n}{\Delta\mu_{n+1} - \Delta\mu_n} + 100n \qquad (34)$$

where $\Delta\mu_X$, $\Delta\mu_n$, and $\Delta\mu_{n+1}$ are the differences, between an ideal dilute solution and the ideal gas state, in the standard chemical potentials of the compound and of the n-alkanes. Formula (34) is most often written in terms of the Gibbs function [17, 20, 21, 91, 155, 242] or the free energy [54, 243].

Bach et al. [244] have recently used relations connecting the logarithm of the relative retention time with the thermodynamic functions of dissolution, Trouton's rule† and Klages' equation; these establish that the square of the boiling point is an additive function for homologues, to give an original thermodynamic proof of the system of retention indices.

†According to this rule the molar heat of evaporation of a non-associated liquid at its boiling point and atmospheric pressure is directly proportional to the absolute boiling point.

Thermodynamic Functions of Sorption

For a long time retention indices, because of their quite complicated thermodynamic interpretation (Eqn. 34), were not used in calculating the thermodynamic functions of the fundamental process in gas–liquid chromatography. It was found experimentally that the index varies linearly with the change in the molar free energy of sorption, and can serve as a measure of the latter when different substances are being compared [242].

The first systematic investigation of the thermodynamic application of retention indices [17, 20, 21, 221, 245, 246] led to deduction of the equations

$$\lg K_X = \frac{(I-100n)\lg\left(\frac{t_{R_{n+1}}}{t_{R_n}}\right)}{100} + \lg\frac{V_{g_n}^0 T\rho}{273}\,, \qquad (35)$$

$$\Delta G_{s_X} = -2.3RT\lg K_X\,, \qquad (36)$$

$$\Delta\Delta G_{s_X,\,n} = -0.023RT(I-100n)\lg\frac{t_{R_{n+1}}}{t_{R_n}}\,, \qquad (37)$$

$$\Delta H_{s_X} = \Delta H_{s_n} - 0.023R\left[\lg\left(\frac{t_{R_{n+1}}}{t_{R_n}}\right)\cdot\frac{\partial I}{\partial 1/T} + (I-100n)\frac{\partial}{\partial 1/T}\lg\left(\frac{t_{R_{n+1}}}{t_{R_n}}\right)\right], \qquad (38)$$

$$\frac{(I-100n)}{100}\lg\left(\frac{t_{R_{n+1}}}{t_{R_n}}\right) = \frac{-\Delta H_{s_X} + \Delta H_{s_n}}{2.3RT} + \frac{\Delta S_{s_X} - \Delta S_{s_n}}{2.3R}\,, \qquad (39)$$

enabling determinations to be made of partition coefficients K and partial molar enthalpies ΔH_s, entropies ΔS_s, and free energies ΔG_s of sorption (it is advisable to calculate excess thermodynamic functions and estimate the selectivity of chromatographic columns by means of Eqns. 23–26). In the above equations t_{R_n} and $t_{R_{n+1}}$ are the corrected retention times of the n-alkanes, and ρ is the density of the stationary phase. If $n \geqslant 6$, we can replace $\lg(t_{R_{n+1}}/t_{R_n})$ by the constant b of Eqn. (2). [17, 18] An equation analogous to (38) has since been published by other workers [91, 247, 248].

Since the dependence of $(I - 100n)b/100$ on $1/T$ (°K^{-1}) conforms closely to a linear law (Fig. 2), the calculation of enthalpies and entropies of sorption, as well as of separation factors, is considerably simplified by the graphical interpretation of Eqn. (39). [17, 20, 221]

The proposed method of calculating thermodynamic functions is simple and makes rather smaller demands on the experimental apparatus than does the classical method, based on the measurement of specific retention volumes. Thus it becomes unnecessary to measure the quantity of "active" phase in the column, the space velocity of the carrier gas, and the drop in pressure. Provided that $\Delta H_{s,n}$ and $\Delta S_{s,n}$ are known, neither the density nor the molecular mass of the stationary phase need be known in order to calculate $\Delta H_{s,X}$ and $\Delta S_{s,X}$ by means of Eqns. (38) and (39). With stationary phases that form athermal solutions with alkanes (hydrocarbons, phthalic esters, etc.), moreover, the tabulated value of the latent heat of evaporation can be used [243] instead of the standard function $\Delta H_{s,n}$.

With substances having retention indices exceeding 600, as mentioned above, $\lg(t_{R_{n+1}}/t_{R_n})$ can be replaced by the constant b in Eqn. (2), which expresses the linear dependence of the logarithm of the corrected retention volume of n-alkanes on the number of carbon atoms in the molecule. However, the legitimacy of using a linear equation has

hitherto been a controversial matter in gas–liquid chromatography. Several workers proposed non-linear equations to describe the gas-chromatographic behaviour of straight-chain hydrocarbons[203, 249, 250]. The accuracy of known equations has been assessed statistically by the use of regression analysis[17,18]. Experimental data on the retention of n-alkanes have been taken from McReynolds' tables[152] for thirteen stationary phases of varying polarity. The calculations were made on an electronic computer. The best of the non-linear equations, suggested by Sakharov and Voskov[250], has an accuracy of around 0.2% in $\lg V_g^0$, while that of the linear equation (2) is 0.8%. Thus the linear approximation provides quite satisfactory accuracy, and can be used in gas–liquid chromatography for various calculations and correlations, including the calculation of thermodynamic functions from retention indices.

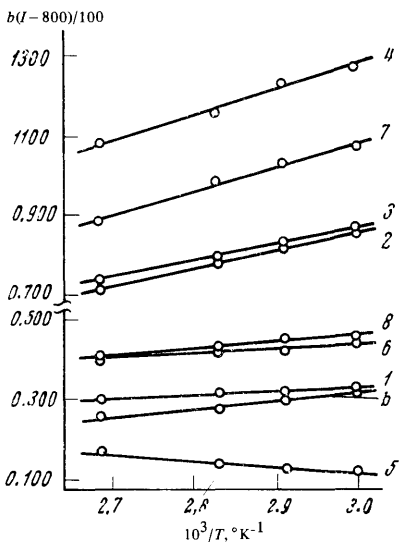

Figure 2. Dependence of $b(I - 800)/100$ on reciprocal of the temperature for the phase PEG-1000 [20] and the compounds: 1) $(C_2H_5)_2S$; 2) $(n\text{-}C_3H_7)_2S$; 3) $(CH_3S)_2$; 4) $(C_2H_5S)_2$; 5) $n\text{-}C_3H_7SH$; 6) $n\text{-}C_4H_9SH$; 7) $n\text{-}C_6H_{13}SH$; 8) C_6H_6.

The accuracy with which thermodynamic characteristics can be calculated from retention indices has been estimated[17,251]. Mathematical statistics have been used to deduce formulae for the standard deviation of the determination of thermodynamic functions by means of Eqns. (23)–(26) and (35–39). The accuracy of the calculation is comparable with that for the calculation of the same functions from specific retention volumes. Other work[243,252] has shown the fundamental possibility of determining thermodynamic functions from retention indices by extrapolation and interpolation.

Thus both experimental and theoretical results indicate that, among the gas-chromatographic retention parameters that are currently available, the system of indices is most generally applicable, is highly accurate and reproducible, and provides adequate information on stationary phases and chromatographic columns. The system of retention indices has a great advantage in analyses with programming of the temperature or the velocity of the carrier gas, as well as when high pressures are used. It is convenient also for the calculation of physicochemical quantities characterising the process of sorption in gas chromatography.

Group Identification of Hydrocarbons by Reaction Gas-chromatography

E.E.Kugucheva and A.V.Alekseeva

Methods for the group identification of hydrocarbons of the following classes have been examined: paraffins, olefins, conjugated dienes, acetylenes, naphthenes, and aromatic hydrocarbons. Methods of consecutive group analysis of complex industrial mixtures have been specially considered.
The bibliography includes 118 references.

CONTENTS

I. Classification of chemical-chromatographic methods of analysis 1048
II. "Elimination" or "subtraction" methods 1048
III. "Transformation" or "peak shift" methods 1052
IV. Schemes for the consecutive group analysis of hydrocarbon mixtures 1057

I. CLASSIFICATION OF CHEMICAL-CHROMATOGRAPHIC METHODS OF ANALYSIS

The use of chemical reactions specific to substances with a particular functional group greatly simplifies the identification of the components of mixtures analysed by gas-chromatography. Therefore, soon after the publication of substances, studies were made where chemical reactions were employed for identification in gas-chromatography. Up to 1960 there were only a few studies of this kind: bromination was employed to determine multiple bonds[2], alcohols were determined with the aid of 3,5-dinitrobenzoyl chloride or acetic anhydride, and carbonyl compounds were determined by treatment with semicarbazide or 2,4-dinitrophenylhydrazine[3]. The structures of involatile organic compounds were established by preliminary pyrolytic[4] or oxidative decomposition[5].

Since 1960 the combination of the two methods of analysis has greatly developed and more than a thousand original studies and a number of reviews and monographs[6-13] dealing with methods of identification based on the results of chemical and chromatographic analyses have now been published.

Drawert et al.[14] were the first to combine in a separate group the methods of chromatographic analysis in which a reactor is placed in the carrier gas system of the chromatograph and which they called "reaction gas-chromatography".

Despite the recognition of Drawert's term by other authors of original studies and reviews[7-10], there is no complete unanimity concerning terminology. Thus methods in which a transformation of the specimen is combined with chromatographic separation have been included in reaction gas-chromatography in some reviews[6,11,12] regardless of the analytical procedure.

"Elimination" or "subtraction" methods, "transformation" or "peak shift" methods, as well as analytical methods which do not give rise to changes in the chromatogram can be distinguished on the basis of the changes in the chromatogram after chemical or physical modification of the specimen.

"Subtraction" or "elimination" consist in the conversion of compounds of a particular chemical type into involatile or undetectable products. The peaks corresponding to these transformed substances disappear (are "subtracted") in the chromatogram beyond the reactor. This method of identification was employed for the first time by Martin[15], who absorbed olefins in a reactor with sulphuric acid.

"Transformation" or "peak shift" are distinguished by the fact that the disappearance of the peaks from the chromatogram after treatment with the reagent is accompanied by the appearance of new peaks due to volatile reaction products. The term "peak shift" was employed for the first time by Langer and Pantages[16], who described the conversion of alcohols into trimethylsilyl ethers in the presence of hydrocarbons.

When the reactions are carried out after chromatographic analysis, there are no changes in the initial chromatograms. An example of this kind is provided by the qualitative group tests carried out at the instant of isolation of the substance from the chromatograph[17,18].

This review deals with methods for the analysis of hydrocarbons combining chromatographic separation with chemical and physicochemical processes, which lead to a change in the composition of the sample. Special identification procedures, such as pyrolysis and elemental analysis, have been excluded from consideration. Regardless of the experimental technique employed (using a divided or continuous scheme), the analytical methods have been grouped on the basis of the changes induced in the chromatogram after the transformation of the specimen. "Elimination" or "subtraction" methods are considered first and then the "transformation" or "peak shift" methods. Apart from the analytical methods applicable exclusively to hydrocarbons, methods of identification developed for mixtures of different classes of compounds, including hydrocarbons, are also quoted. Consecutive group analysis is treated separately, since this has become particularly important recently in the petrochemical industry.

II. "SUBTRACTION" OR "ELIMINATION" METHODS

"Subtraction" methods are most suitable for the group identification of complex mixtures, since in the assessment of the changes in the chromatograms after the transformation of a specimen the interpretation of the results is not complicated by the appearance of new peaks due to reaction products. A general disadvantage of the "subtraction" methods consists in the low accuracy of the

analysis at low concentrations of the components constituting the unresolved peaks.

1. Overall Determination of Unsaturated Hydrocarbons

Martin[15] was the first to employ an absorber with sulphuric acid in a single system with chromatographic separation and tested the effect of the reagent on model C_3–C_6 hydrocarbon mixtures. Sulphuric acid (98%) was deposited on silica gel in proportions of 3 : 2 by weight. The height of the reagent layer (2 cm) was sufficient for the quantitative absorption of unsaturated hydrocarbons of all classes, except ethylene, acetylene, and benzene. In order to remove ethylene and acetylene, it was necessary to add silver sulphate to sulphuric acid. A mixture of hydrocarbons could be analysed in two ways: either by comparing the chromatograms recorded before and after the reactor or by single-stage chromatography on apparatus with two katharometers and a reactor with sulphuric acid placed between them. The first detector recorded all the components of the initial mixture and the second only paraffins and naphthenes. The error of the method in the group determination of olefins amounted to 2–9%.

The reagent (98% sulphuric acid) has been used most widely in the gas-chromatographic analysis of petroleum fractions and of pyrolytic petrol[19–22].

Hines and Smith[19] employed sulphonation and dehydrogenation in a divided system with chromatographic separation for the group analysis of a petroleum fraction containing aromatic hydrocarbons, naphthenes, and paraffins. After the first sulphonation in order to remove aromatic hydrocarbons, the residue was subjected to dehydrocyclisation and the dehydrogenated product was again sulphonated. At each stage of the treatment the reaction product was chromatographed on a capillary column with squalane and the changes which had occurred in the mixture composition were inferred from the chromatograms.

Sulphuric acid at different concentrations was employed for the successive removal of unsaturated hydrocarbons of different classes[22]. Initially olefins were adsorbed with 80% sulphuric acid and then aromatic hydrocarbons with 98% sulphuric acid. The fraction of unsaturated hydrocarbons of each class was determined by comparing chromatograms obtained on a column with Apiezon L without complete separation of the components.

In the group analysis of petrols described below, Rowan[23] employed a reactor with sulphuric acid deposited on glass fibres. He noted that the absorption of olefins is accompanied by the evolution from the acid of hydrocarbons, which he did not identify.

Similar observations were made in another study[24]. In the absorption of olefinic admixtures in ethylene , an increase of the height of the isobutane peaks was observed together with the appearance of peaks due to new substances, which had been absent from the initial mixtures. The above investigators[23,24] did not consider the mechanism of the formation of new substances as a result of reaction.

Ipat'ev[25], who carried out a special investigation of the action of sulphuric acid on olefins, made the following important remark: "The determination of olefins with the aid of sulphuric acid in the presence of paraffins and naphthenes must be performed with caution using an excess of the acid and over a short period, since, on standing, olefin polymers which are sparingly soluble in sulphuric acid with the $d = 1.86$ are separated from it".

It is noteworthy that, in contact with sulphuric acid under optimal conditions (10–50°C), paraffins containing a tertiary carbon atom can also isomerise[26].

A novel location for the reactor with sulphuric acid in the chromatograph detector was proposed by Berezkin et al.[27] They placed the absorber between two katharometer chambers. A mixture of hydrogen and paraffins was not recorded by the detector, since the signals of the sensor elements cancelled out and the overall signal was proportional to the concentration of the olefin. Thus the concentration of olefins in a mixture with paraffins was established from a single chromatogram and not by comparing two chromatograms.

In the identification of atmospheric impurities, Williams[28] employed an absorber with sulphuric acid, deposited on Chromosorb in proportions of 1 : 4, designed for the absorption of unsaturated hydrocarbons. The impurities concentrated from air were either passed directly through the analytical column or through the absorber.

A separate investigation of the absorption properties of sulphuric acid at different concentrations was undertaken by Innes et al.[29], who found that, when the acid is diluted to 80%, the absorption of olefins became incomplete and at a concentration of 60% ceased completely.

Table 1. Absorption of hydrocarbons by chemical absorbents[29].

Hydrocarbon	Degree of absorption, %					
	20% $HgSO_4$ in 20% H_2SO_4	$Hg(CH_3COO)_2$	4% Ag_2SO_4 in 95% H_2SO_4	H_2SO_4		
				95%	80%	60%
Methane	0	0	0	0	0	0
Ethane	0	0	0	0	0	0
Propane	0	0	0	0	0	0

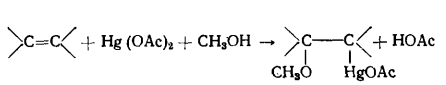
Apart from sulphuric acid, Innes et al.[29] investigated the absorption properties of a number of other reagents. They noted that liquid absorbers are less active than those deposited on a solid carrier. They prepared absorbers 10 cm long containing diatomaceous earth impregnated with liquid reagents and compared the degrees of absorption of hydrocarbons of different classes present in air at a concentration of 0.5% and contained in a sample having a volume of 5 ml (Table 1). Table 1 shows that mercury sulphate removed olefins quantitatively, while sulphuric acid with added silver sulphate eliminated in addition aromatic hydrocarbons. However, the latter reagent suffered from the disadvantage that ethylene was evolved for a long time after its absorption. The authors also established that nitric and hydrochloric acids and bromine water are ineffective. On the basis of their

investigation, they recommended that mercury sulphate be employed for the removal of olefins in gas-chromatographic analysis[30,31]. They developed a model of an industrial exhaust gas analyser[30], which consists of a chromatograph with two parallel columns and two flame-ionisation detectors with a reactor containing mercury sulphate placed in front of one of the columns.

It has been found[24] that the rate of reaction of olefins with mercury sulphate depends on the steric configuration of the olefins. The reaction is greatly retarded for the *trans*-isomers of β-olefins and fails to reach completion under the conditions of the stream of carrier gas.

In the chromatographic analysis of petrols[23,32,33] and exhaust gases[34], mercury perchlorate deposited on a solid carrier was also employed. This reagent absorbed olefins and partly aromatic hydrocarbons. For a quantitative elimination of aromatic hydrocarbons, it was necessary to add perchloric acid to mercury perchlorate. However, this led to the retention of branched paraffins in the absorber. The use of this reagent required special precautions. At room temperature high-boiling components were strongly absorbed, while on heating above 65°C the olefins were incompletely absorbed and side reactions with unsaturated hydrocarbons took place to a greater extent.



Albert[33] placed the absorber in the thermostat of the chromatogram in front of the analytical column and recommended that the absorber be back-flushed after each analysis in order to avoid the access of side products into the column in subsequent analyses.

Soulages and Briewa[35] investigated the interaction of olefins and aromatic hydrocarbons with mercury perchlorate. They found that the degree of reaction in the absence of side processes depends on the extent to which the optimal conditions are maintained: the amount of absorbent, the contact time, temperature, and the moisture content of the carrier gas. The last factor is particularly important. The moisture content in the gas must be equivalent to the vapour pressure of the absorbent; only then does the concentration of perchloric acid remain constant. Since in previous investigations the moisture content of the gas was not taken into account, dilution or increase of the acid concentration might have been a likely source of secondary phenomena.

It has been suggested that an absorber with mercury perchlorate be employed for the type analysis of liquid industrial mixtures. Analytical schemes[35-37] are discussed below.

Kerr and Trotman-Dickenson[38] suggested that a paste of mercury acetate and nitrate in ethylene glycol deposited on a refractory brick be used to absorb olefins under flow conditions.

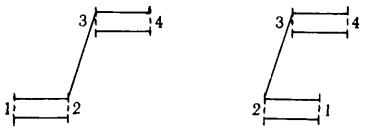
Doring and Hauthal[39] investigated the kinetics of the competing reaction of olefins with mercury acetate in methanol:

They established that the rate of esterification with mercury acetate decreases in a series of olefins with different structures in the following proportions: α-olefins: β-olefins: γ-olefins = 100 : 10 : 1, *cis*-isomers reacting faster than their *trans*-analogues. In order to identify C_6–C_8 olefins, the authors removed samples from the reaction mixture at different times after the start of the reaction and subjected them to chromatographic analysis. The degree of conversion of the unknown component was calculated from the decrease of its peak height and its structure was established.

As already noted earlier, Innes et al.[29] found that bromine water is ineffective for the absorption of olefins under flow conditions. However, bromination in a stream has been carried out with bromine deposited on activated charcoal, which was capable of the stable retention of up to 40 wt.% of bromine. Wirth[40] achieved a quantitative separation of a mixture of ethylene, acetylene, and ethane. At −78°C only ethylene reacted with the bromine and at 0°C acetylene reacted as well. The gases which failed to react were desorbed with evacuation, and were collected in a measuring burette. Ray[41] used this method to establish the content of light impurities in ethylene. Ethylene was brominated at room temperature. Non-olefinic impurities were removed from the charcoal column in a stream of carbon dioxide and were collected in a nitrometer over aqueous alkali.

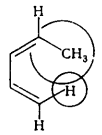
Bromination under flow conditions was carried out separately from the subsequent chromatographic analysis in some investigations[24,42]. In order to reduce the volatility of bromine, its solution in aqueous sodium bromide was employed. The reagent, deposited on Chromosorb in proportions of 1 : 1 by weight, eliminated quantitatively olefins and C_2–C_8 dienes from vapour–gas mixtures.

Hoff and Feit[43] used a saturated solution of bromine water under static conditions to absorb the vapours of olefins and certain oxygen-containing compounds.



In this section of the review, it is useful to consider the analytical method described by James and Martin[2] and Hoff and Feit[43]. Although aliphatic acids and not hydrocarbons were the object of investigation, this procedure may be of wider applicability. The authors brominated the methyl esters of saturated and unsaturated aliphatic acids in the liquid phase and compared the chromatograms of the initial mixture and the reaction products. James and Martin[2] carried out the chromatographic separation of such products on Apiezon L as the stationary phase. By subtracting the peaks of the bromides of the unsaturated components, they were able to distinguish the esters of acids of two types—saturated and unsaturated. Landown and Lipski[44] improved this method by using for the separation a more polar phase—diethylene glycol glutarate. After bromination, the peaks due to the dibromides (which the authors identified component by component) were seen on the chromatograms obtained with the aid of this phase, in addition to the peaks due to the saturated acid esters. Thus they established that the esters belonged to three groups of compounds: (1) saturated compounds whose peaks remained unchanged under bromination; (2) mono-olefins the disappearance of whose peaks was accompanied by the appearance of those of the dibromides; (3) polyolefins the removal of which after bromination did not entail the appearance of the peaks of the corresponding tetra- and hexa-bromides owing to the low vapour pressures of the latter.

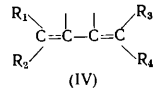
2. Identification of Conjugated Dienes and Acetylenes



Janak and Novak[45,46] used maleic anhydride to retain the main mixture component (butadiene) and to determine in the latter the admixtures of light hydrocarbons. Maleic anhydride deposited on Kieselguhr was placed in the reactor in front of the analytical column. The authors noted the following disadvantages of the method: solubility

of light hydrocarbons in maleic anhydride and the catalytic effect of traces of maleic acid on the polymerisation of isobutene. The degree of absorption of butadiene increased with catalyst temperature and it was difficult to maintain the optimal temperature because the anhydride sublimed readily and blocked the gas channels in the apparatus.

The reactivity of dienes in Diels–Alder reactions depends on the structure, configuration, and the nature of substituents in the conjugation chain [47]. In the two possible coplanar systems [(I) and (II)], the reacting 1,4-carbon atoms approach one another sufficiently closely for diene condensation only in dienes with a cisoid disposition of the carbon bonds [system (II)]:



The transoid conformation (I) is characteristic of the *cis*-piperylene molecule. In the cisoid form (III) the distance between CH_3 and H would be less than the sum of the van der Waals radii of these groups. This would lead to a considerable internal strain, as a result of which the cisoid conformation is hindered.

(III)

Dienes with fully substituted terminal C atoms of the conjugated system (IV) are likewise incapable of undergoing the Diels–Alder reaction.

(IV)

Gil-Av and Herzberg-Minzly [48,49] investigated by gas chromatography the kinetics of the reaction of dienes with chloromaleic anhydride. They employed chloromaleic anhydride as the stationary phase and chromatographed the mixture of dienes at different flow rates of the carrier gas. Since in the presence of an excess of anhydride the reaction became pseudomonomolecular, its rate was directly proportional to the contact time. Therefore the decrease of the peak areas for dienes with the cisoid conformation, reacting with the anhydride [47], depended on the flow rate of the carrier gas, while for other dienes the peak areas remained constant. The authors employed these findings for the identification of dienes [48]. *cis*- and *trans*-Piperylenes and 2,4-hexadienes were identified in this way.

Berezkin and coworkers [50–52] also made a chromatographic study of the kinetics of the reactions of dienes with maleic anhydride. In order to increase the temperature and the contact time, the reagent (maleic anhydride) was introduced in solution in tricresyl phosphate. The reactor with the anhydride was placed between two detectors. In each analysis the concentrations of the diene before and after absorption were obtained. The authors suggested that this method be used to calculate the rate constants for bimolecular reactions at variable concentrations of the anhydride. In addition, the method may be useful in the determination of the initial concentrations of unstable compounds [52]. It has been shown for butadiene that the error of the method is 3–4 rel.%.

Kugucheva and Alekseeva [24,53] used the reaction with maleic anhydride to identify the dienes present in vapour–gas mixtures in microconcentrations. The analytical scheme with separate steps made it possible to raise the reactor temperature to 135°C and to increase sharply the absorption of dienes (Table 2).

Table 2. Absorption of hydrocarbons by maleic anhydride [53].

Hydrocarbon	Degree of absorption, mole %	Hydrocarbon	Degree of absorption, mole %
Butadiene	73	*cis*-Penta-1,3-diene	26
Isoprene	100	Cyclopentadiene	100
trans-Penta-1,3-diene	90	2,3-Dimethylbuta-1,3-diene	100

Together with a high degree of absorption of dienes, an enhanced solubility of compounds, non-specific in relation to the reagents, was noted [24].

An aqueous solution of silver nitrate deposited on Chromosorb has been used [53] to absorb monosubstituted acetylenes. The reaction was quantitative and was not complicated by secondary phenomena.

3. Adsorption of n-Alkanes on a 5 Å Molecular Sieve

Molecular-sieve analysis in gas chromatography was achieved for the first time by Brenner and Coates [55]. They placed the reactor with the 5 Å molecular sieve in front of the analytical column and showed that n-alkanes in a mixture of C_3–C_{11} straight-chains and branched-chain alkanes, cycloalkanes, and aromatic hydrocarbons were retained in the reactor at 60–180°C.

Adlard and Whitham [56] compared the results of liquid-phase and vapour-phase adsorption of n-alkanes on a 5 Å molecular sieve and the results of extraction by urea and obtained similar results. They extended the molecular sieve analysis in chromatography to hydrocarbons with up to 44 carbon atoms [56–58]. In order to prevent the spreading of the chromatographic peaks when the specimen passes through the reactor, the zeolite was impregnated with a small amount of the stationary phase.

Barrall and Baumann [59] investigated the effect of water remaining in the zeolite pores on the accuracy of the molecular-sieve analysis in chromatography. They found that traces of water cause degradation of the zeolite pores, which leads to the breakthrough of the straight-chain hydrocarbons during analysis and a rapid decrease of the adsorption capacity of the sorbent. High-temperature dehydration procedures under various conditions have been proposed for the activation of zeolites: by evacuation [60], in a stream of nitrogen or helium [61], and in an open system [62]. Dehydration by heating to 350–400°C in a stream of dry nitrogen is most frequently employed.

Molecular-sieve analysis in gas chromatography is widely employed in group determination of n-alkanes in petrols, kerosenes, and waxes [23,33,63].

In the determination of small amounts of n-alkanes in a mixture with branched-chain alkanes, Eggertsen and Groennings [63] placed two reactors in the anlytical circuit.

The first analytical cycle included separation on the chromatographic column, absorption of n-alkanes in the reactor with the zeolite placed beyond the analytical column, and the recording of the residual branched-chain alkanes by the katharometer. In the second cycle the n-alkanes retained in the reactor were desorbed and were redirected with the aid of the back-flushing apparatus to the analytical column. In the course of their elution from the column, the n-alkanes entered the second reactor where they were combusted to carbon dioxide and were recorded by the katharometer with a higher sensitivity than the initial alkanes. The method permitted the determination of n-alkanes at concentrations down to 0.01% and branched-chain alkanes present in large amounts did not interfere.

In the first study involving the application of a 5 Å molecular sieve in gas-chromatographic analysis, Brenner and Coates [55] already mentioned the possibility of extending their analytical procedure to compounds of other homologous series. Subsequently they demonstrated for artificial mixtures of hydrocarbons and oxygen- and halogen-containing compounds that straight-chain olefins, alcohols, acids, and aldehydes are also retained in the zeolite pores [69].

However, molecular sieve analysis has not been widely used in the study of compounds belonging to classes other than the paraffins owing to the aluminosilicate catalytic activity of the zeolite [54, 70].

Table 3. Isomerisation of olefins on contact with a Linde molecular sieve at 200°C. [75]

Initial substance	Reaction products		Degree of reduction*
	hydrocarbons	content, %	
2-Methylbut-1-ene	2-Methylbut-1-ene	29	71

2,3,3-Trimethylbut-1-ene	2,3,3,-Trimethylbut-1-ene	100	0

*Calculated relative to the isomerisation products.

There are only isolated reports on the molecular sieve analysis of olefins in gas chromatography [59, 67, 69]. This is due to the isomerisation of straight-chain olefins during their desorption [56, 71, 72]. There are also data indicating the isomerisation of iso-olefins on contact with the zeolite [73].

However, there exist contradictory views concerning the nature of the isomerisation of olefins. Norton [74], who characterised the isomerising properties of zeolites of various types, concluded that a 5 Å molecular sieve is inactive in relation to olefins. On the other hand, Baas and Vlugter [73] not only observed the migration of the double bond in the molecular under these conditions but also skeletal isomerisation.

Kugucheva and Aleksseva [75] investigated the behaviour of individual isomeric olefins on contact with a zeolite under flow conditions. Branched-chain olefins did indeed change: instead of a single peak on the initial chromatogram, two or three peaks appeared beyond the reactor. For the olefins listed in Table 3, the transformations consisted in the migration of the double bond and in a change of the steric configuration. There was no skeletal isomerisation, which was specially confirmed in relation to 2,3,3-trimethylbut-1-ene. The migration of the double bond in the molecule of this isomer is impossible due to the presence of the quaternary carbon atom. The results of chromatographic analysis beyond the catalyst with the zeolite confirmed the absence of isomerisation.

Investigators [64, 66, 75] who used low concentrations of various substances noted that a certain amount of compounds having a critical molecular diameter greater than the pore size of the molecular sieve (5 Å) undergoes irreversible absorption on contact with the zeolite, namely cycloalkanes, branched-chain alkanes or aromatic hydrocarbons. This adsorption is not eliminated when the zeolite is impregnated with a small amount of the stationary phase [66]. The reason for the absorption may be adsorption on the outer surface of the zeolite crystals and, in the case of zeolite granulated with a binder, on the surface of the secondary pores formed by the gaps between the zeolite crystals and the coarse-grained binder [76, 77]. The possibility of methyl-substituted alkanes being able to pass into the molecular sieve pores as a result of a change in the pore size and in the critical diameter of the hydrocarbon molecules at a high temperature has been examined [78].

III. "TRANSFORMATION" OR "PEAK SHIFT" METHODS

1. Exhaustive Hydrogenation of Unsaturated Hydrocarbons

The elimination method, a great advantage of which is simplicity of the interpretation of the chromatograms, are of limited applicability because it is possible to make only a group identification of the components of the mixture analysed, involving their assignment to groups of substances which react in the same way with the reagent employed. In the case of hydrogenation, on the other hand, which is one of the transformation methods where the chromatogram shows, instead of the peaks of the initial unsaturated hydrocarbons, those of the saturated analogues, there is a possibility of "skeletal" identification, i.e. one can determine the hydrocarbon skeleton of the initial molecule. However, the positions of the multiple bonds and the *cis–trans* configuration of the olefins remain unknown.

Moreover, in contrast to the elimination method, the reduction method can yield information about the composition of the unresolved peaks corresponding to several unsaturated hydrocarbons. In this case "elimination" makes it possible to infer the presence of multiple bonds in the molecules and hydrogenation can achieve the separate identification of the components in terms of their saturated analogues.

Reduction usually leads to a simplification of the composition of mixtures and to a more complete chromatographic separation. The method has been widely used in the gas-chromatographic analysis of petroleum fractions.

In one of the first studies on the chemical-chromatographic analysis of petroleum, Nelson et al. [79] used a

multistep analytical scheme in which each step was carried out separately. In the first step saturated hydrocarbons were separated by liquid-phase chromatography on silica gel. Paraffins and naphthenes in the isolated fraction were identified component by component. The identification was carried out with the mixture separated on columns with two stationary phases of different polarity—squalane and silicone oil, using a standard mixture of isomers. The corresponding paraffin and naphthene peaks were found on the chromatogram of the initial mixture before the separation on silica gel. After the liquid-phase reduction of the initial mixture in the presence of palladium on charcoal (10% Pd) at 100°C, the content of olefins and their hydrocarbon skeletons were determined from the increments in the peak areas of the known paraffins and naphthenes. The authors estimate the error of the method as ±6%.

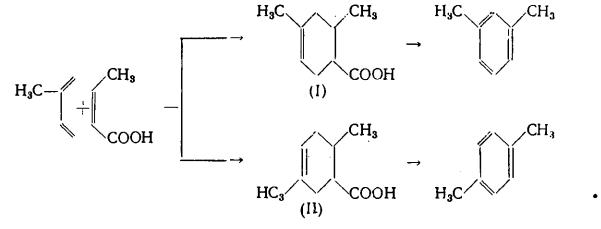
Hydrogenation in a microreactor in a stream of hydrogen, which serves at the same time as the carrier gas in the apparatus, has been widely used. The reactor is placed in front of the sample inlet or in front of the analytical column. The advantage of the process carried out in this way consists in a very rapid reaction and a very low consumption of the catalyst, the activity of which hardly changes owing to the small sample volume. Group VIII metals on various carriers have been used as catalysts.

Klesment et al.[80] investigated the properties of catalyst carriers employed for reduction in chromatographic analysis. They found that alumina gives rise to side reactions involving cracking, isomerisation, and cyclisation and activated charcoal and silica gel adsorb organic compounds too strongly. The authors employed platinised diatomaceous earth (2–10% Pt) saturated with hydrogen as the catalyst. The petrol specimens from shale oil which they employed were reduced in a microreactor at 200°C in a stream of hydrogen or helium and were then transferred to the analytical column.

Rowan[23] suggested that olefinic and aromatic hydrocarbons be hydrogenated on a platinum catalyst (Pt/Al_2O_3) at 299°C and that the selective reduction of olefins alone be performed on a palladium catalyst (5% Pd on asbestos) at room temperature.

Nickel, platinum, and palladium catalysts have been used for the vapour-phase hydrogenation and investigation of the composition of shale petrols[81–83] and other petroleum products[21,84,85], including procedures where hydrogenation was combined with pyrolysis[86,87].

An interesting combination of reduction reactions with separation of the products on a capillary column was proposed by Struppe[88]. An aluminium capillary 6 m long with an internal diameter of 0.3 mm was filled with chloroplatinic acid, which was reduced in a stream of hydrogen at 150°C. Platinum black was then deposited on the inner walls of the capillary. The capillary reactor thus obtained was placed between the sample inlet and the separating column. Mono-olefins, dienes, and cyclo-olefins were reduced in the reactor at 125°C. Aromatic hydrocarbons and naphthenes did not react. Individual identification could be achieved by combining the reactor with capillary columns filled with different stationary phases. The author determined the time required by the sample to pass through the capillary reactor and took it into account in the calculation of the retention volumes.



The method involving the reduction of individual compounds of different classes, including unsaturated hydrocarbons, has been investigated systematically by Beroza and coworkers[10,89,90]. The authors developed a model of a standard apparatus for hydrogenation[90], which can be connected to any chromatograph with a katharometer or a flame-ionisation detector. The gas channel scheme was such that the reaction products were transferred by the carrier gas directly to the analytical column. The reduction was carried out on a palladium catalyst (1% Pd on Gas Chrom P) at different temperatures and hydrogen flow rates. Table 4 summarises the results of hydrogenation under conditions leading to the formation of the hydrocarbon with the same number of carbon atoms as in the initial compounds or to a lower homologue.

Table 4. Determination of the carbon skeleton by hydrogenation using Beroza's method[10] (catalyst—1% Pd on Gas Chrom P, temperature 300°C, hydrogen flow rate 20 ml min^{-1}).

Classes of substances yielding a hydrocarbon analogue	Reaction
Paraffins	None
Unsaturated hydrocarbons	Hydrogenation of double bond
Halogeno-derivatives	Dissociation of C–X bond
Secondary and tertiary alcohols	Dissociation of C–O bond
Secondary and tertiary ethers	Dissociation of C–O bond
Ketones	Dissociation of C=O bond
Secondary and tertiary amines	Dissociation of C–N bond
Amides (amine component with a secondary or tertiary carbon atom)	Dissociation of C–N bond
Classes of substances yielding a hydrocarbon analogue and (or) the next lower hydrocarbon homologue	**Reaction**
Aldehydes	$RCHO \rightarrow RH,\ RCH_3^{\alpha}$
Acids	$RCOOH \rightarrow RH,\ RCH_3^{\alpha}$
Anhydrides	$(RCO)_2O \rightarrow RH,\ RCH_3^{\alpha}$
Primary alcohols	$RCH_2OH \rightarrow RH,\ RCH_3^{\alpha}$
Esters, alcoholic component with a primary carbon atom (OCH_2R) and R'CO acid component	$R'COOCH_2R \rightarrow RH,\ RCH_3$; $R'H,\ RCH_3^{\alpha}$
Primary ethers	$RCH_2OCH_2R \rightarrow RH, RCH_3$
Amides, amine component ($NHCH_2R$) at a primary carbon atom, R'CO acid component	$R'CONHCH_2R \rightarrow RH,\ RCH_3$; $R'H,\ R'CH_3^{\alpha}$

*α—slight or none.

The practical application of the method can be clearly demonstrated using as an example the reaction of isoprene with crotonic acid[10]:

In order to identify the product formed in the reaction [(I) or (II)], it was reduced at 330°C. Apart from decarboxylation, the aromatic ring underwent aromatisation at this temperature. *m*-Xylene, corresponding to reaction product (I), was identified on the basis of the retention time. The identification was confirmed by the ultraviolet spectrum. The usual methods for the determination of structure by an oxidation procedure would have been more laborious.

In reduction by Beroza's method, it is necessary to maintain the hydrogenation conditions exactly, since at temperatures intermediate between the optimal values (200°C for hydrogenation and 300°C for dehydrogenation), alicyclic and aromatic derivatives are formed in different proportions.

The reduction is usually accompanied by the formation of intermediates or side products. Beroza [91] suggested, for example, that ketones be identified not only on the basis of the main product of the hydrogenation reaction (the hydrocarbon analogue) but also on the basis of the small amounts of compounds appearing as a result of the dissociation of the bond between the carbon atom and the adjacent carbonyl group. Thus ethane and butane were detected in the reduction of 3-heptanone in addition to n-heptane.

It is difficult to carry out the hydrogenation reaction in a single cycle with chromatographic separation because of the spreading of the chromatographic peaks and the change in the retention times of the components on passing through the reactor. This is caused by adsorption on the catalyst layer and occurs to a particularly marked extent in the analysis of polar or high-boiling substances.

Beroza [10] suggested that, in order to establish the structure of the hydrocarbon skeleton of strongly adsorbed compounds, one should collect initially the reduction products in a cooled trap and then introduce them into the chromatograph.

Langner [92] investigated the influence of various methods of packing of the catalyst in the reactor on the retention times of substances reduced by Beroza's method. He found that the retention times change after filling the reactor with a fresh portion of the catalyst. In order to obtain reproducible relative retention times, it is necessary to carry out a calibration with standard substances directly before or after the analysis.

Even in the reduction of pure substances, the nature of the test substance must be known for a correct interpretation of the results. For example, different chemical compounds such as toluene, benzyl alcohol, benzaldehyde, and benzonitrile give rise to the same product on reduction–methylcyclohexane.

An interesting method for determining the chemical nature of the test substance in the reduction process was proposed by Franc and Kolouskova [93], who investigated the relation between the number of reduced double bonds or the functional group and the ratio of the retention times of the initial and reduced compounds. They found that the logarithm of the ratio of the retention volumes of the corresponding analogues is determined solely by the type of functional group. On the basis of their relation, they identified hydrocarbons and other compounds. They designed a special device for analysis whereby it is possible to record in a single chromatographic cycle both the initial and the reduced compounds. An empty glass capillary was inserted through the reactor containing a platinum catalyst (10% Pt on pumice). The sample introduced was divided in the reactor into two parts. One part passed through the capillary to the analytical column in an unchanged form and the other was reduced on contact with the catalyst.

2. Selective Hydrogenation of Conjugated Dienes and Acetylenes

Beroza and Sarmiento [90], who investigated the reduction of unsaturated acids esters with different numbers of double bonds in different positions, attempted to relate the change in the retention time of the reduced compound to the position of the double bond. By reducing the contact time with the catalyst, they identified the incomplete reduction products on the chromatogram. However, according to their data, the interpretation of the chromatograms did not always lead to unambiguous results and was not developed further in subsequent investigations.

A more successful attempt to employ partial reduction for identification was made by Smith and Ohlson [94]. The pure substances or narrow fractions were isolated on a preparative scale, collected in a U-shaped reactor, and hydrogenated on the Adams catalyst (PtO_2 with added iron) or sodamide. After raising the temperature, hydrogen was passed into the reactor at a pressure of 3 atm and the system was maintained at 80–90°C for 1 min in order to complete the reduction process. After connecting the chromatograph to the device for the introduction of the sample, the volatile reaction product entered the analytical column.

Table 5. Hydrogenation of dienes on the Adams catalyst [94].

Initial hydrocarbon	Unchanged fraction	Composition of catalytic reaction mixture			
		partly reduced products	wt.%	fully reduced products	wt.%
Buta-1,3-diene	82	But-1-ene	6		
		cis-But-2-ene	1	n-Butane	9
		trans-But-2-ene	2		
Penta-1,4-diene	75	Pent-1-ene	9	n-Pentane	16
cis-Penta-1,3-diene	21	Pent-1-ene	4		
		cis-Pent-2-ene	10	n-Pentane	58
		trans-Pent-2-ene	7		
trans-Penta-1,3-diene	9	Pent-1-ene	4		
		cis-Pent-2-ene	3	n-Pentane	78
		trans-Pent-2-ene	6		
Penta-1,2-diene	98	Pent-1-ene	0.3		
		cis-Pent-2-ene	0.6	n-Pentane	1
		trans-Pent-2-ene	0.7		
Hexa-1,5-diene	68	Hex-1-ene	11	n-Hexane	21
cis, trans-Hexa-2,4-diene	22	*cis*-Hex-2-ene	8		
		trans-Hex-2-ene	14	n-Hexane	47
		cis-Hex-3-ene	3		
		trans-Hex-3-ene	6		
trans, trans-Hexa-2,4-diene	15	*cis*-Hex-2-ene	2		
		trans-Hex-2-ene	14	n-Hexane	60
		cis-Hex-3-ene	3		
		trans-Hex-3-ene	6		
trans-Hexa-1,3-diene	60	*cis*-Hex-2-ene	2	n-Hexane	20
		trans-Hex-2-ene	15		
		trnas-Hex-3-ene	3		
Cyclopenta-1,3-diene	79	Cyclopentene	8	Cyclopentane	13

On shortening the reaction time, the dienes and acetylenes were not reduced completely. The authors investigated the partial reduction products of certain dienes (Table 5) and acetylenes (Table 6) and suggested that the method be employed for their identification. Tables 5 and 6 show that the catalysts chosen by the authors are not very selective. The reduction either takes place to a very low degree or leads to completely hydrogenated products. The method requires a relatively high content of the components to be separated, which are detected by a katharometer, and is applicable only to pure compounds.

Kugucheva and Alekseeva [60,95] proposed a method for the identification of conjugated dienes and acetylenes mixed with hydrocarbons of other classes. The method consists in the selective reduction of dienes and acetylenes, olefins being involved in the reaction to only a slight extent.

Palladium prepared by Lindlar's method [96] was chosen as the catalyst. The hydrogenation was carried out under flow conditions at room temperature. The conjugated dienes and acetylenes with different structures and steric configurations were reduced to a high degree and selectively to olefins (Table 7). The olefins reacted (reduction and isomerisation) to an extent not greater than 20% (Table 8). The method, which was developed on artificial mixtures, was applied to real products of petrochemical synthesis [85].

Table 6. Hydrogenation of acetylenes [94].

Initial hydrocarbon	Catalyst	Unchanged fraction, %	Composition of catalytic reaction mixture			
			partly reduced products	wt.%	fully reduced products	wt.%
Hex-3-yne	PtO_2	50	*cis*-Hex-3-ene	15	n-Hexane	32

3. Dehydrogenation of Naphthenes

Keulemans and Voge [97] were the first to suggest the dehydrogenation of naphthenes in gas-chromatographic analysis. They were aromatised on a reforming catalyst (platinum on Al_2O_3 containing a halogen) at 350°C in a stream of hydrogen. The reaction products were transferred by the stream of hydrogen to the analytical column. The authors found that cyclohexane derivatives were aromatised to the extent of 96–100% except for the 1,1-dimethyl derivative (66%). Cyclopentanes were converted into benzene derivatives to the extent of only 1.4 to 25%.

Table 8. Reactions of olefins on a palladium catalyst [53].

Hydrocarbon	Degree of reaction, mole %		Hydrocarbon	Degree of reaction, mole %	
	hydrogenation	isomerisation		hydrogenation	isomerisation
Pent-1-ene	12.9	6.9	2-Methylbut-2-ene	0.0	0.0
Hex-1-ene	10.5	7.2	*trans*-Hex-2-ene	0.0	4.7
3-Methylbut-1-ene	0.0	0.0	Cyclopentene	5.3	—
2-Methylbut-1-ene	0.0	0.0			

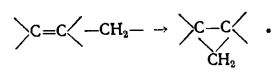
In order to suppress the aromatisation of cyclopentane hydrocarbons, Rowan [23] carried out the dehydrogenation at 299°C in a stream of helium with a small amount of added hydrogen. Dehydrogenation, which takes place to the extent of 100% for six-membered naphthenes, was used as a method for their group identification in complex hydrocarbon mixtures.

Klesment et al. [80] dehydrogenated petrols in a stream of helium at 325°C on platinum black deposited on diatomaceous earth. The yield of aromatic hydrocarbons from six-membered naphthenes was 87% and above, while five-membered cycloalkanes did not react. The process was complicated by cracking. The catalytic aromatisation of naphthenes and heterocyclic compounds on platinium catalysts was also carried out by Nigam [98].

Ivanova et al. [99] aromatised by the Zelinskii method the fraction of paraffins and naphthenes isolated by liquid–liquid chromatography and deduced the results on the basis of subsequent gas-chromatographic analysis.

The dehydrogenation and sulphonation of the aromatisation products in a system with separate steps involving subsequent chromatographic separation [19] have already been described.

4. The Introduction of the Methylene Group



Dvoretzky et al. [100] treated alkanes, cycloalkanes, and olefins with diazomethane and then separated the reaction products on a capillary column with squalane. The treatment with diazomethane was accompanied by short-wavelength irradiation. In order to avoid side reactions between the methylated products and diazomethane, the reaction was carried out with a 50-fold excess of the hydrocarbon.

The methylene group is introduced according to the following scheme:

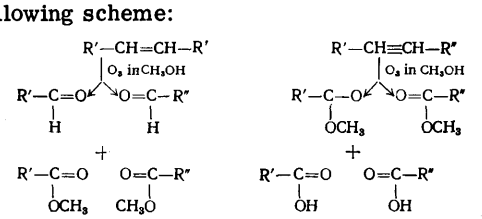
$$\rangle C{-}H + {-}CH_2{-} \rightarrow \left[\rangle C{-}CH_2{-}H\right] \rightarrow \rangle C{-}CH_3 .$$

This method of introduction is independent of the type of C–H bond: aliphatic vinyl, or allyl. The yield of isomers is directly proportional to the number of primary, secondary, and tertiary C–H bonds in the initial hydrocarbon molecule and can be calculated beforehand.

The reaction with olefins is complicated by the formation of cyclopropane:

The ratio of the contributions of the C=C/C–H reactions varies in the range from 6 to 8 and therefore the corresponding substituted cyclopropane is the main reaction product.

The method has been applied mainly to alkanes. The structure of the unknown component was established on the basis of the number and relative amounts of the methylenation reaction products. Moreover, data for the contents of the isomers obtained may be used to identify unknown mixtures. The retention times of 19 nonanes synthesised from 6 initial octanes have been obtained [101]. By comparing the retention times of the nonanes and the components of a real mixture—the products of the alkylation of isobutane with olefins—the authors determined the mixture composition.



It has been shown for a large number of examples involving alkanes [100] that the ratio of the yields of the isomers coincides with theoretical predictions within the limits of the error of the chromatographic analysis.

5. Ozonolysis

Blumer and Thomas [102] isolated on a preparative scale the olefin fraction from a plankton extract and subjected it to ozonolysis. The ozonides were cleaved in the chromatograph injector and the presence of methylene and vinyl groups as well as conjugated double bonds in the molecule of the initial olefin was inferred on the basis of the identified carbonyl compounds.

Davison and Dutton [103] placed a reactor with zinc oxide beyond the chromatograph injector. Acidic compounds formed on decomposition of the ozonides were retained in the reactor, while aldehydes passed to the analytical column without hindrance.

Spencer et al. [104] used the ozonolysis method for the identification of double and triple bonds. They ozonised hydrocarbons in methanol solution. After subsequent cleavage of the ozonides (also carried out in the chromatograph injector), only olefins gave rise to aldehydes, while esters and acids were obtained from acetylenic hydrocarbons. The reaction was carried out according to the following scheme:

Thus 83% of methyl valerate and 17% of valeric acids were obtained from dec-2-yne, which was completely ozonised after 7 min.

Smith et al. [105] ozonised unsaturated compounds isolated by preparative chromatography. The carbonyl compounds obtained on decomposition of the ozonides were treated with dinitrophenylhydrazine. The dinitrophenylhydrazones isolated were identified by paper chromatography. The ozonolysis method has been used successfully to identify C_6–C_{11} α-olefins, C_5–C_6 dienes, styrene, pentynes, etc. Ozonolysis combined with gas chromatography has also been used in other investigations [106,107].

6. Other Identification Methods

Frank et al. [108] used reductive catalytic cleavage for the identification of alkyl substituents in the aromatic ring. The reaction was carried out at 620°C in a quartz tube filled with the Leuna WK 9063 catalyst (silicon and aluminium oxides in proportions of 60:40, impregnated with 4.5% WO_3 and MoO_3) in a stream of hydrogen, which served as the carrier gas in the apparatus. The reaction tube was connected to the sample injection device, so that the volatile cleavage products entered the analytical column directly. At the above temperature carbon–carbon bonds in the alkyl group were ruptured in all positions and the relative amounts of the hydrocarbons formed remained constant (to within ±3 rel.%). On the basis of the ratios of the reaction products obtained, it was possible to infer whether one or several alkyl groups are split off from the initial alkylbenzene. The authors also established that there are optimal temperatures for the scission of various alkyl groups and suggested that this phenomenon be employed for identification. 5-Isopropyl-1,2,4-trimethylbenzene gives rise to only propane at 200°C, to propane and propene at 300°C, to propane, propene, ethane, and ethylene at 500°C, and to methane as well as the compounds enumerated above at 600°C.

Walsh and Merrit [17] treated the elutate with reagents for qualitative analysis directly at the outlet from the column. A device for dividing the stream into five parts was connected to the outlet tube of the katharometer. This made it possible to carry out five calorimetric reactions for each substance. Reagents were proposed for oxygen-, sulphur-, nitrogen-, and halogen-containing compounds and also for aromatic hydrocarbons and olefins. Having determined the homologues series to which the compound belongs, it was identified with the aid of plots of the logarithm of the retention volume against the number of carbon atoms in the molecule.

Casu and Cavalotti [18] improved the method by suggesting an attachment to the pen recorder of the chromatograph. A glass strip on which a layer of silica gel impregnated with the appropriate reagents has been deposited, moves at the same speed as the paper strip of the pen recorder. A coloured spot appears on the silica gel synchronously with the appearance of a peak on the chromatogram.

The methods described above [17,18] require the application of relatively large samples and the use of detectors which do not decompose the substance, since the lower limit of the sensitivity of the reagent varies from 20 to 100 μg.

Janak [109] employed a similar attachment to the pen recorder for the crystal-chemical identification of substances isolated on a preparative scale. High-boiling compounds, separated in a capillary column at 280°C, were condensed on a thin glass sheet moving at a distance of 1–2 mm from the chromatograph outlet and cooled from inside. These compounds formed bands 3–4 mm wide with characteristic microcrystals. The author investigated the crystals under the microscope and described a method for the preparation of coloured complexes by carrying out the reaction with samples of the substances isolated weighing 10^{-2} μg and having a volume of 10^{-5} ml. Janak [109] investigated the crystals of 15 aromatic hydrocarbons (naphthalene, anthracene, phenanthrene, fluorene, benzopyrene, and other polycyclic hydrocarbon derivatives) as well as certain oxygen-, nitrogen-, and sulphur-containing compounds. Sublimatograms and a colour table of the complexes of the test compounds with tricyanoethylene are quoted.

IV. SCHEMES FOR THE CONSECUTIVE GROUP ANALYSIS OF HYDROCARBON MIXTURES

This section deals with examples of group analysis of hydrocarbon mixtures in which elimination and transformation methods are combined in a single scheme with chromatographic separation at each stage of the treatment.

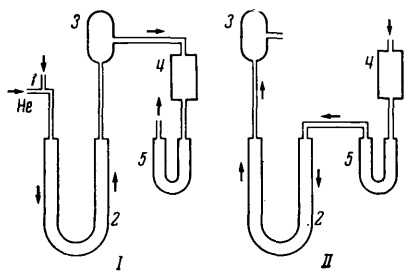


Figure 1. Schematic illustration of Martin's gas-chromatographic apparatus[32]: 1) injector; 2) analytical column; 3) katharometer; 4) absorber with $HgClO_4$; 5) trap.

Martin[32] developed a combined method for the analysis of petrol based on the elimination of substances of certain classes. The gas stream scheme is illustrated in Fig. 1. A column with $\beta\beta'$-oxydipropionitrile retained aromatic hydrocarbons. Naphthenes, paraffins, and olefins were recorded by the detector in the form of a single peak (*A* in Fig. 2). Beyond the katharometer, the sample passed through an absorber with mercury) perchlorate (Fig. 1, position I). Olefins were absorbed in the absorber and paraffins and naphthenes were collected in a cooled trap. By altering the direction of the carrier gas stream (Fig. 1, position II), aromatic hydrocarbons were initially eluted from the column in the form of a single peak *B* and then the trap was warmed and saturated hydrocarbons (peak *C* in Fig. 2) were recorded.

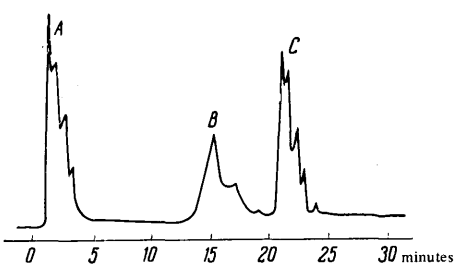

Figure 2. Chromatogram of a hydrocarbon mixture[32]: *A*) naphthenes + paraffins + olefins; *B*) aromatic hydrocarbons; *C*) paraffins + naphthenes.

Albert[33] employed a similar scheme for the analysis of petrol having supplemented it by the elimination of straight-chain paraffins and the interpretation of each peak. Aromatic hydrocarbons were initially retained on a column with *NN'*-bis-(2-cyanoethyl)formamide as the stationary phase and the remaining hydrocarbons were eluted from the column, detected by the katharometer, passed through an absorber with mercury perchlorate and a molecular sieve, and were collected in a trap. After heating the trap, the stream of gas was directed to the column and branched-chain paraffins were separated and detected. Finally the absorber with the molecular sieve was heated for 15 min at 400°C and the gas stream was again switched to the column, whereupon the desorbed straight-chain paraffins were identified component by component.

The most complete method of group analysis of hydrocarbon mixtures by a continuous procedure was proposed by Rowan[23]. The apparatus is illustrated schematically in Fig. 3. As in the examples described previously, its principle involves the switching of the gas stream and chromatography of the sample collected in the trap after preliminary separation. Steps of the following types were employed: retention of straight-chain hydrocarbons on a 5 Å molecular sieve, absorption of olefins by mercury perchlorate, hydrogenation of aromatic hydrocarbons and olefins, hydrogenation of olefins alone, and dehydrogenation of six-membered naphthenes. The analytical scheme illustrated in Fig. 4 combines the operations enumerated above and makes it possible to select the required sequence of steps.

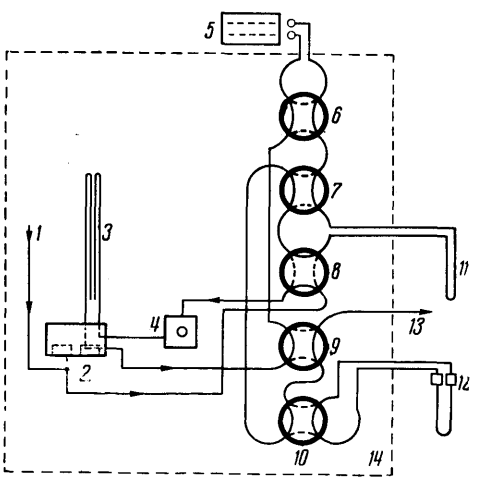

Figure 3. Schematic illustration of Rowan's gas-chromatographic apparatus[23]: 1) carrier gas supply line; 2) katharometer; 3) analytical column; 4) injector; 5) furnace; 6)–10) four-way taps; 11) cooled trap; 12) absorber with sulphuric acid or 5 Å molecular sieve; 13) outlet; 14) chromatograph thermostat.

Reactors with sulphuric acid, mercury perchlorate, and a molecular sieve can be replaced and interchanged. Sulphuric acid was deposited on glass fibre and the absorber temperature was maintained at 54°C. The reactor with mercury perchlorate was constructed by Coulson's method[110]. The water evolved in the reaction with olefins was absorbed by a layer of a 4 Å molecular sieve. Adsorption was carried out with the aid of a 5 Å

molecular sieve at 93° and 165°C, depending on the boiling point range of the fraction analysed. Palladium on asbestos (5% Pt) was employed as the catalyst for the hydrogenation of olefins at room temperature, while the hydrogenation of aromatic hydrocarbons and the dehydrogenation of naphthenes at 299°C were carried out on the platinum–alumina catalyst proposed by Keulemans and Voge[97].

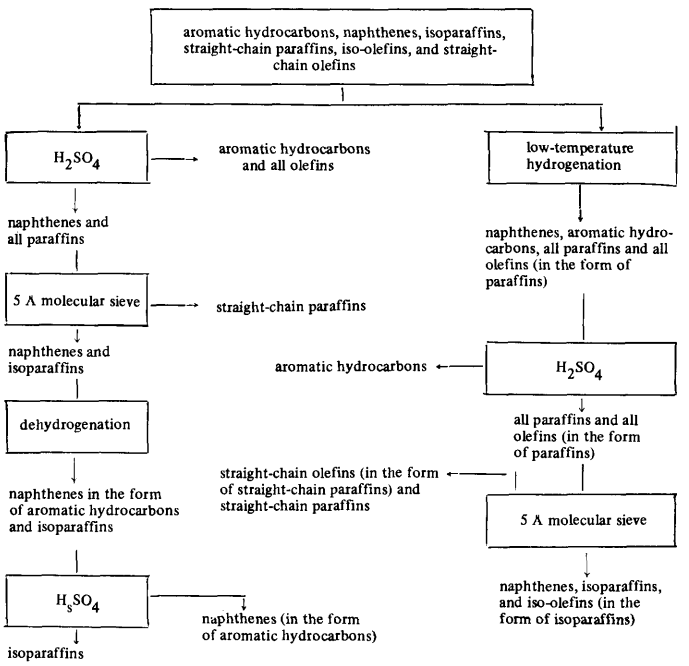

Figure 4. Analytical scheme for the assignment of gas-chromatographic peaks to different classes of hydrocarbons[23].

Fig. 3 shows the taps in the position where the sample, having passed column *3*, proceeds via taps *9* and *6* into the catalytic furnace *5* and is then collected in trap *11* after passing through taps *6* and *7*. After trap *11* has been heated and tap *8* switched over, the concentrated hydrocarbons are again directed to column *3*. The changes which have occurred are recorded by the katharometer and the specimen is returned to the trap via an absorber with the appropriate reagent.

The method was tested on artificial mixtures of hydrocarbons of different classes but without cyclopentane derivatives, acetylenes, and conjugated dienes and also on technical petrol in which the fraction of aromatic components predominated.

Methods for continuous group analysis of hydrocarbons were developed also for exhaust gases[31] and atmospheric contaminants[28].

A scheme of group analysis[24], involving the identification of olefins, conjugated dienes, acetylenes, and straight-chain paraffins, has been developed for hydrocarbons present in gases in microconcentrations.

Hoff and Feit[111,112] described a consecutive functional analysis of a vapour–gas mixture of hydrocarbons and oxygen-containing compounds by the method of "syringe reactions".

Several schemes for the type analysis of liquid hydrocarbon mixtures have been proposed recently. They require an apparatus modified by the introduction of additional valves, by-pass systems, and chambers with various heating devices. In their practical application these schemes differ from those already described by the fact that provision is made for the heating of the taps, in order to prevent adsorption, and cooled traps for the collection of samples for repeated analysis are eliminated. This made the new methods more accurate and faster.

Robinson et al.[37] described a system comprising the two capillary columns and a device which divides the sample into two equal portions. One portion passes through the empty column into the detector, giving rise to a signal corresponding to the size of the entire sample, while the other passes in succession through a column with *NN'*-bis-(2-cyanoethyl)formamide, where aromatic hydrocarbons are retained reversibly, and a reactor with mercury perchlorate for the irreversible retention of olefins. Thus the second chromatogram shows only paraffins and naphthenes. The back-flushing device makes it possible to switch the direction of the stream and to transfer aromatic hydrocarbons from the *NN'*-bis-(2-cyanoethyl)-formamide column to the detector. The third chromatogram shows aromatic hydrocarbons. The olefin content is calculated from the difference between the peak areas on the three chromatograms.

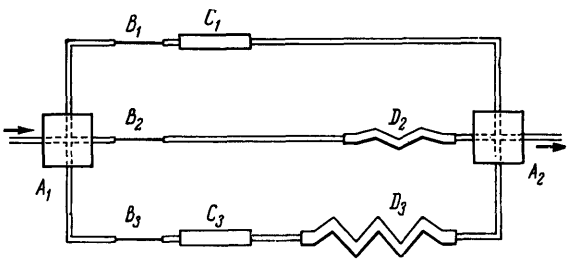

Figure 5. Schematic illustration of the analyser[35]: A_1 and A_2—four-way connecting sleeves; E_1, E_2, and B_3—capillary connections; C_1—absorber with $HgClO_4$.$HClO_4$; C_3—absorber with $HgSO_4.H_2SO_4$; D_2 and D_3 flow retarding devices.

A scheme for analysis in which the sample is divided into three streams (Fig. 5) was proposed by Soulages and Briewa[35]. One part of the sample passes to the detector without hindrance, olefins are subtracted from another in a reactor with H_2SO_4, and olefins and aromatic hydrocarbons in the third are retained in a reactor with $HgClO_4$. In order to avoid the superposition of peaks, capillary sections were fitted in the path of each sample in order to regulate the flow rates. The subdivision of the sample into three [equal] parts was adjusted by introducing pure heptane and comparing the areas of the three peaks. The time required to apply the methods described[35,37] is 5–15 min.

McTaggart and Luke[36] introduced an improvement into type analysis by introducing an additional stage involving the separation of paraffins, naphthenes, and olefins on the

basis of the number of carbon atoms. The method provides for the introduction of two liquid samples of equal size. In the first cycle of the analysis aromatic hydrocarbons are retained on a packed column with *NN'*-bis-(2-cyanoethyl)formamide. The remaining hydrocarbons pass through a reactor with a platinum catalyst (Pt/Al_2O_3), where olefins are reduced quantitatively to the corresponding paraffins and naphthenes. Together with the paraffins and naphthenes present in the initial mixture, they pass to a column with a 13X molecular sieve treated with alkali and are separated on the basis of the number of carbon atoms according to the method of Brunnock and Luke[113]. In the same analytical cycle the aromatic hydrocarbons retained on the column are flushed out with the aid of the back-flushing device and recorded by the detector in the form of a single peak. In the second analytical cycle aromatic hydrocarbons and olefins are retained irreversibly in a reactor with mercury perchlorate and paraffins and naphthenes are separated on the basis of the number of carbon atoms.

By subtracting the areas of the corresponding peaks obtained on the first and second chromatograms after separation on the molecular sieve, the content of olefins is calculated and the results of analysis are produced in the following form:

Paraffins	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}	C_{11}
Naphthenes	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}	C_{11}
Olefins	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}	C_{11}
Cyclo-olefins	C_1	C_5	C_6	C_7	C_8	C_9	C_{10}	C_{11}
Aromatic hydrocarbons	Sum							

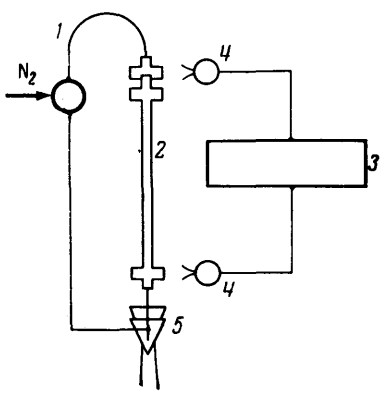

Figure 6. Trap and device for the reintroduction of sample[116]: 1) flexible tube; 2) trap; 3) heater; 4) clamp; 5) injector.

Comparison of reaction chromatographic methods[35-37] with the FIA type method[114] (adsorption separation on a silica gel column in the presence of an indicator, which dyes the boundaries between the following bands: paraffins and naphthenes–olefins–aromatic hydrocarbons), which is widely used for hydrocarbon mixtures, demonstrated a satisfactory agreement between the results. Reaction chromatographic methods require much less time and are applicable to highly coloured specimens.

The analytical methods described have been applied to hydrocarbon fractions boiling up to 180–220°C. An analytical scheme incorporating hydrogenation, molecular sieve analysis, partition and displacement chromatography, and spectroscopic research techniques has been proposed[115] for hydrocarbons boiling in the range 160 to 250°C.

In the present section of the review it is useful to consider the very promising method of "multidimensional chromatography"[116]. In contrast to the methods described earlier, in this case type analysis is not based on the application of chemical reactions but on a consecutive separation on columns with stationary phases of different polarity. While the components are eluted from the nonpolar phase in order of increasing boiling points, the order of their appearance after separation on the polar phase depends mainly on their polarity. The following series in terms of increasing polarity holds for hydrocarbons: paraffins < aliphatic olefins + naphthenes < < aliphatic dienes + cyclo-olefins < acetylenes < cyclodienes < aromatic hydrocarbons.

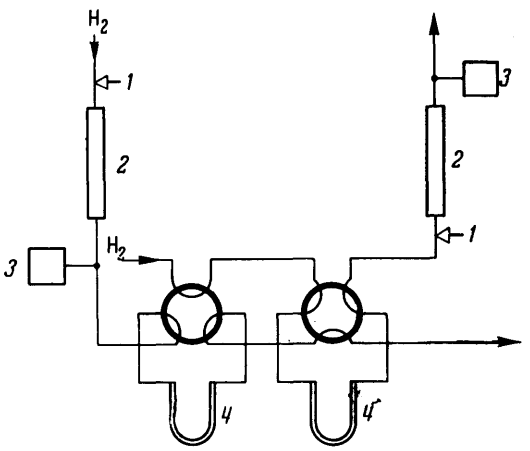

Figure 7. Schematic illustration of the universal two-dimensional chromatograph[116]: 1) injector; 2) analytical column; 3) detector; 4) trap.

Boer[116], who employed successfully the method of multidimensional chromatography for the analysis of complex hydrocarbon mixtures, regards it as "quantitative trapping of the required fraction after separation on the first column and its introduction into the second column". The method can be applied in continuous and discontinuous schemes. The first case has the advantage of the possibility of employing any standard chromatograph. It is only necessary to connect to it via a three-wave tap a heated trap (duration of heating to 250°C 10–15 s) and a device for the reintroduction of the sample (Fig. 6). A universal apparatus for continuous analysis is illustrated in Fig. 7. It consists of two chromatographs connected by a system comprising two traps and several devices, which can be switched in different directions, for the reintroduction of the sample and for back-flushing. Stream dividers are placed before flame-ionisation detectors. One part of the fraction is detected, while the other is directed to further analysis.

Boer[116] describes also more complex schemes with four columns and three traps and a specific example of the analysis of a petroleum fraction. The petroleum fraction was introduced into the first column with a polar phase (cyanoethylsucrose). Saturated hydrocarbons together with benzene and toluene were detected, the results integrated, and the substances collected in trap *1*. The residual aromatic hydrocarbons were flushed out in the opposite direction, detected, the signals integrated, and the substances collected in trap *2*. The contents of trap *1* were introduced into a second column with a non-polar phase (SF-96) and divided, under the conditions of a programmed temperature, into 24 fractions, which were collected alternately in trap *3* and directed one at a time into a third column with a polar phase (picryl chloride). The contents of trap *2* were then introduced into a fourth column (SF-96) and chromatographed under isothermal conditions. The analysis yielded 86 peaks and the weight and molar percentages of isoparaffins, naphthenes, and aromatic hydrocarbons were determined for each group with identical numbers of carbon atoms.

The principles of multidimensional chromatography constitute the basis of a standard apparatus for the analysis of petroleum fractions[117,118]. During an analytical cycle lasting 2–3 h, it is possible to obtain the following data: the individual compounds present in the aromatic hydrocarbons and the distribution of straight-chain paraffins, isoparaffins, and naphthenes among groups corresponding to numbers of carbon atoms ranging from 5 to 12.

Analysis of pyrolytic petrol is more difficult owing to the presence of olefins and dienes. Boer[116] suggests that the specimen be separated on a non-polar phase into very narrow fractions, which are chromatographed in succession on a polar phase.

Attempts are now being made to develop a scheme for the standard analysis of industrial mixtures containing olefins[117].

Gas Chromatography of Organometallic Compounds of Groups I-IV of the Periodic System

V.A.Chernoplekova, V.M.Sakharov, and K.I.Sakodynskii

The development of the gas-chromatographic analysis of organometallic compounds of groups I-IV of the periodic system in the period 1960-1972 has been reviewed. The characteristic features of the gas-chromatographic analysis of organometallic compounds have been discussed. The use of reaction chromatography for the analysis of the organic compounds of the metals of groups I-IV has been examined. The bibliography contains 238 references.

I. INTRODUCTION

The present review deals with the gas chromatography of organic compounds of the non-transition metals of groups I–IV. It should be noted that published data on the gas chromatography of the organic compounds of non-transition metals are not evenly distributed. There are almost no papers on the analysis of organic compounds of rubidium, caesium, barium, indium, or thallium, and few papers on the gas chromatography of organometallic compounds of groups I–III, apart from organomercury compounds[1,2]. The problems of the gas-chromatographic analysis of organometallic compounds of group IV have been examined in most detail[3,4].

As far as the analysis of the organic compounds of transition metals is concerned, the gas-chromatographic analysis of the organic compounds of most transition metals is still in the stage of initial development.

II. CHARACTERISTIC FEATURES OF THE GAS-CHROMATOGRAPHIC METHOD FOR THE ANALYSIS OF ORGANOMETALLIC COMPOUNDS

Organometallic compounds are generally highly reactive, many tending to undergo spontaneous ignition or oxidation by oxygen and hydrolysis by water. With the exception of some lower alkyl derivatives, these compounds are solids or liquids with boiling points in the range 200–450°; they are most frequently thermally unstable at temperatures close to the boiling point.

As a consequence of these characteristic features of the physicochemical properties and structure of organometallic compounds, the gas-chromatographic analysis exhibits various specific features.

Stationary phases and carriers. The gas chromatography of organometallic compounds most frequently involves gas-liquid chromatography. Gas-adsorption chromatography has found only limited application[5-7].

The high boiling point of most organometallic compounds makes it necessary to use high-temperature stationary phases, and the increased reactivity of organometallic compounds restricts the choice of materials considerably. Thus of the hundred or so sorbents used for the analysis of organometallic compounds, more than half have silicone stationary phases (the methylsilicones PMS, Se-30, E-301, MS-200, and Gi-7100; the phenylsilicones PFMS, FS, DC-550, DC-702, and OE-4011; the fluorosilicones SKTFT, QF-1, and SF-96, and the nitrylsilicone XF-1112). Much less extensive use is made of strongly polar stationary phases (nitrobenzene and 1,2,3-tris(2-cyanoethoxy)propane), phases of medium polarity (dibutyl phthalate, dinonyl phthalate, diethylene glycol succinate, and butane-1,4-diol succinate), or hydrocarbon phases (Apiezon). In the selection of the stationary phase it is necessary to take account of the possibility of decomposition of the organometallic compounds. In particular, alkyltin hydrides decompose on squalane, chlorosilanes on polyethylene glycol[8], and alkylmercury halides on tricresyl phosphate[9].

As a rule, the separation of organometallic compounds is carried out using sorbents with a low percentage of stationary phase (5–10%); this makes it possible to lower the working temperature and to prevent the thermal decomposition of the compounds being analysed, to decrease the time taken for the analysis, to increase the length of time for which the stationary phase can be used, and to extend the choice of stationary phases.

Organometallic compounds are polar or weakly polar compounds, and the most inert diatomite carriers are used for their analysis (celite 545, Chromosorb W, Silo-cel S-22, modified Inzer brick, and quartz sand (flusine) [sic][9]). The carriers have been modified by treatment with silanes[8] or alkali[10] to decrease their catalytic activity. The use of Fluoroplast carriers is of considerable interest.

Characteristic features of the operation of detectors, and quantitative measurements. The thermal conductivity detector has found the most extensive application in the analysis of organometallic compounds. At high filament temperatures, or when high concentrations of the organometallic compounds are used, however, partial decomposition of the compounds on the incandescent filaments of the catharometer takes place[8]. The metal, which is deposited in a highly dispersed state, and the tarry residues bring about a decrease in sensitivity and an increase in the noise level. In these cases it

is best to use a catharometer with glazed filaments, and to dry the carrier gas thoroughly, in order to avoid the deposition of hydrolysis products in the detector.

A density meter has been used successfully by a number of authors[8,11,12] in the analysis of organometallic compounds. The calibration of a detector of this type is simple.

In early work on the gas chromatography of organic compounds of silicon and tin[13,14], the separated compounds were oxidised to water and carbon dioxide, with subsequent conversion of the water into hydrogen (detected by Green's method[15]).

When a flame-ionisation detector is used, the combustion of the organometallic compounds leads to the formation of the metal oxides, which accumulate on the electrodes; these oxides are insulators, and they alter the electrical characteristics of the detector[8]. A number of authors[8,16] have observed inversion of the peaks of organometallic compounds when a flame-ionisation detector is used. The detection of organosilicon compounds in the form of negative peaks by using a mixture of hydrogen and small quantities of methane as carrier gas has been proposed[16,17]. Organic compounds are then recorded as positive peaks, with a lower sensitivity.

The most reliable results have been obtained using a flame-ionisation detector with both electrodes in the vertical position and a hydrogen burner with a nozzle of small cross-section, since a decrease in the diameter of the nozzle of the burner increases the rate of flow of gas and decreases the proportion of oxidation products[18].

The sensitivity of the flame-ionisation detector towards organometallic compounds is less than its sensitivity towards organic compounds[8,18], and a sharp decrease in sensitivity takes place with increase in the relative proportion of metal in the molecule of the organometallic compound[19]. In spite of the above difficulties, the flame-ionisation detector has been used for the analysis of organic compounds of tin, silicon, lead, and mercury[8,10,18-23].

In the analysis of micro-quantities of organometallic compounds in various media it is possible to use highly-sensitive selective detectors—electron-capture, thermo-ionic, flame-emission, coulometric, and flame-photometric. The electron-capture detector has an increased sensitivity with respect to organomercury and organolead compounds and is often used for their analysis[24-31] including their determination in the biosphere (air[31], water[26,29], and soil[28]). The electron-capture detector has also been used in the analysis of alkyltin and alkylgermanium halides[32]. Traces of organometallic compounds containing halogen atoms have been identified by comparing the signals from thermo-ionic halogen and flame-ionisation detectors[33]. The sensitivity of electron-capture or thermo-ionic detectors is greater than that of flame-ionisation detectors by a factor of several hundreds or even thousands[24].

In the analysis of organosilicon compounds, use has been made of a specific "silicone" detector, based on a combination of flame-emission and atomic-absorption detectors[34].

Different methods of quantitative analysis are used in the analysis of organometallic compounds; the internal-standard method is most frequently employed, and the absolute-calibration method is used less frequently. Wurst[12] has analysed the errors in the quantitative determination of organosilicon compounds. The results are typical of the quantitative analysis of other types of organometallic compound. The mean relative error usually does not exceed 7% if the component is present in quantities of 1–2%. The error is appreciably smaller (3%) at higher concentrations of the component. At very low concentrations of the order of 0.1–0.001%, the mean error reaches 10–12%.[19] In quantitative calculations it is necessary to take account of the possibility of mutual transformations ['scrambling'] of the organometallic compounds being analysed[35].

Methods of introducing the specimens. In the case of reactive organometallic compounds which tend to ignite spontaneously, the specimens are introduced in an inert atmosphere. Fig. 1*A* gives a diagram of the so-called three-needle method for the introduction of specimens[36]. When the nitrogen outlet is closed, the specimen is forced into the syringe.

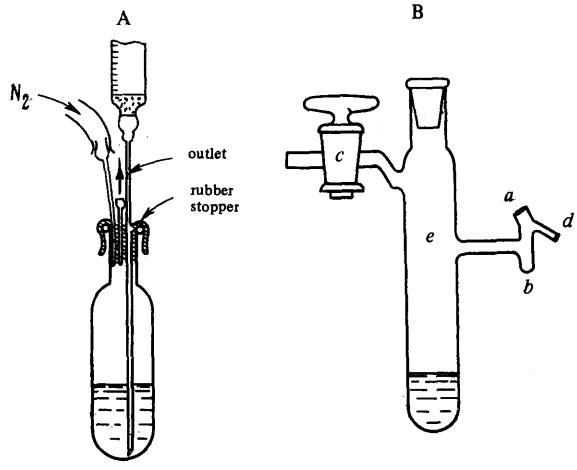

Figure 1. Apparatus for working with unstable liquids.

The specimen can be introduced into the chromatograph[37] directly from the sampler (*e*) (Fig. 1*B*). For this purpose, part of the specimen is poured into the cell (*b*). The needle of the micro-syringe is introduced through the stopper of the tube (*a*) and the syringe is flushed beforehand by passing a stream of dry nitrogen through the tap (*c*). The needle is then lowered into the liquid and the syringe is filled. For the introduction of the specimen into the chromatograph, the needle of the syringe is introduced into the tube (*d*), the end of which is closed by a stopper; when the latter is punctured, the specimen passes to the volatiliser of the chromatograph.

In some cases the introduction of specimens can be carried out by means of syringes previously flushed with an inert gas and carrying on the ends of their needles a self-sealing covering[38].

The drying of the carrier gas is most frequently carried out with phosphorus(V) oxide and molecular sieves. A method for the quantitative determination of the residual moisture in gases after drying has been published[39]. The sensitivity of the determination corresponded to 2×10^{-3} mg water in 1 litre of gas for a volume of specimen being analysed equal to 0.5 ml.

III. RELATIONSHIP BETWEEN THE STRUCTURE AND CHROMATOGRAPHIC BEHAVIOUR OF ORGANOMETALLIC COMPOUNDS

For the identification of organometallic compounds, use is made of the usual relationship between the retention and structure of organic compounds[40-42], but in a number of cases the behaviour of organometallic compounds is so unique that all the correlations must be rigorously verified. Sometimes it is more appropriate to relate the retentions of organometallic compounds not to the retention volumes of the normal paraffins, used as standards, but to the retentions of a series of organometallic homologues.

Wurst[43] put forward modified retention indices I_{Si}, in which the retentions are related to the dimethylsiloxane series

$$I_{Si} = y + m\frac{\lg V_{N(x)} - \lg V_{N(y)}}{\lg V_{N(y+m)} - \lg V_{N(\ )}}$$

where $V_{N(x)}$ is the retention volume of the substance being analysed, and $V_{N(y)}$ or $V_{N(y+m)}$ the retention volumes of the linear dimethylsiloxanes with y or $(y + m)$ silicon atoms.

An advantage of this system is that the substances belong to the same class, but a slight disadvantage is the difficulty of carrying out a comparison with the retentions obtained on the basis of other standards.

One of the most important correlations between retention and structure is the relationship between the retention and the number of groups or atoms of the same type (analogous to the relationship between the logarithm of the retention volume and the number of methylene groups in homologous series of organic compounds). These relationships have been used to identify the products of the synthesis of mixed hydrides of silicon and germanium, which were obtained in small quantities and were present as mixtures in the reaction product[44].

Some authors have reported deviations from the linear dependence of the logarithm of the retention volume on the number of carbon atoms in series of organometallic compounds[45,46], and this must be taken into account in correlation calculations. The extended additivity scheme for the calculation of the retention volume has not been used. A retention volume calculation scheme, developed for the calculation of thermochemical quantities[47], has proved useful.

The additivity of the logarithm of the retention volume and the retention index has led to the development of a method of calculation for asymmetric compounds from the retention values for symmetric compounds[48-50]. The retention volumes for compounds of the type $R_2MR'_2$ were calculated from those of symmetric organometallic compounds of the type R_4M formed by silicon, germanium[48,49], and tin[50].

Retention volumes for compounds in which the two parameters change simultaneously (for example cyclosiloxanes containing two different siloxane groups in the ring) can be represented by means of nomograms[51] (Fig. 2).

IV. GAS CHROMATOGRAPHY OF ORGANOMETALLIC COMPOUNDS OF GROUPS II AND III

The gas-chromatographic analysis of organometallic compounds of the first group by the direct method is apparently impossible, because of the low volatility of these compounds. The reaction chromatography of organometallic compounds of the first group is examined in section VI.

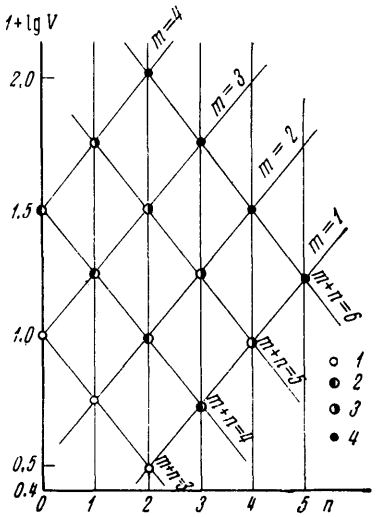

Figure 2. Dependence of the logarithm of the retention volumes of methylpropyldimethylcyclosiloxanes on n, where $n = 0-5$, $m = 0-5$, and $m + n = 3-6$. *1*) Cyclotrisiloxanes, *2*) cyclotetrasiloxanes, *3*) cyclopentasiloxanes; *4*) cyclohexasiloxanes.

Table 1.

Type of compound	Conditions of analysis	Detector	Notes	References
Et_nM, M—Be, B, Zn, Al, Sn, Pb	Glass column. 1 m x 4 mm, sorbent: Chromosorb W + paraffin and diphenylamine (85:15), 73°, 143°	Catharometer		38
RHgX	Steel column. 0.19 m x 3 mm, sorbent shimalite + 25% diethylene glycol succinate, butane-1,4-diol succinate, silicone DC-550, 170-200°	Flame-ionisation		23, 27, 60, 63,
RHgX	Steel column. 2 m x 3 mm, glass column, 2.75 m x 4 mm, carrier Chromosorb W + 5% polyethylene glycol succinate, flusine + 1.5% polyethylene glycol, 140-150°	Catharometer, electron-capture		25, 26, 64, 65
RHgX, X=Cl, Br, $OOCCH_3$, SO_4, OH	Column 1-3 m x 3 mm, sorbent Chromosorb W + 10% 13 stationary phases, 120-200°	Electron-capture	Decomposition of RHgX on tricresyl phosphate and butanediol succinate	9

Group II

The chief conditions for the analysis of the ethyl derivatives of beryllium, zinc, boron, and aluminium, and other organometallic compounds of groups II–IV are systematised in Tables 1–3, the data in which give a fairly clear picture of the characteristic features of the gas-chromatographic analysis of this group of compounds.

Organomagnesium and organocalcium compounds have been analysed by reaction chromatography (see section VI).

Organomercury compounds. The high toxicity of organomercury compounds makes it necessary to develop effective methods for the analysis of the biosphere for contamination by these compounds.

Table 2.

Type of compound	Conditions of analysis: stationary phase, temperature	Detector	References
Alkylsilanes	Polyphenylsilicone oil, polyethylene glycol M 1500, 100–175°; silicones SE-30, QF-1, XF-1112	Catharometer	50, 77, 98–100
Chlorosilanes, methylchlorosilanes	Nitrobenzene, 25°; mixture of diethyl phthalate and silicone oil, 104°; benzophenone, 52°; transformer oil, 106°; liquid paraffin and insulating oil, 50–60°; PFMS-4, DS-703, 40°; phthalates, phosphates, silicones	Catharometer, flame-ionisation	101–112
Ethylchlorosilanes	Silicone MS-0150, 90°. PFMS-4, FS-16, 50–100°	Ditto	113–116
Phenylchlorosilanes	Apiezon L + bentone-34 (1 : 1); E-302 120°; silicone MFSD-3, PFMS-4; silicone rubber; Lucopren G-1000, temperature programming; SKTFT-50, 120°; SE-30, temperature programming	»	12, 91, 92, 117–121
Alkylchlorosilanes	Dinonyl phthalate, 40°; nitrobenzene, 40°; PFMS-4, FS-16, 151°; fluorosilicone 169, 160°	»	122–126
Linear and cyclic siloxanes	Silicone DS-703, 125°; Lucopren M, 150–195°; copolymer of diphenylsiloxane and dimethylsiloxane, temperature programming; Apiezon L; PFMS-100, temperature programming; SKTFT-50°; PDMS 80 M, 160–190°; silicone OE-4011, 60°; SKTFT-50, 190–250°; dimethylsiloxane with carboranylene or diphenyl oxide groups, 235–260°	»	40, 127–146
Alkoxysilanes	Silicone G-7100, 175–180°; E-301, 150–180°; SKTFT-50, 175°, 235°		147–150

Methods have been developed for determining organomercury compounds in food[52–56], water and aqueous solutions[26–29], and soil[28,57], based on the extraction of the organomercury compounds from the natural materials, followed by gas-chromatographic analysis.

The selectivity of 16 stationary phases for the separation of alkyl and aryl compounds of mercury has been studied, and it has been established that the best separation is achieved on diethylene glycol succinate and butane-1,4-diol succinate at 160°.[25]

Methods have been developed for the analysis of methylmercury and phenylmercury compounds in various mixtures[28,58–62] (in phenylmercury acetate[28] and in specimens containing sulphides[58]).

For the identification of a number of organomercury compounds, Kitamura and coworkers[62] used a combination of thin-layer and gas chromatography. The conditions for the analysis of compounds of the type RHgX are given in Table 1.

Determination of the retention times of compounds of the type RHgX, with different substituents, on the stationary phases diethylene glycol succinate and butane-1,4-diol succinate established that the retention time is independent of the nature of the substituent X, and is determined by the length of the alkyl radical[24,25]. The fact that the measured retention times of different compounds of the type RHgX are identical is due to the decomposition of these compounds in the volatiliser with the formation of dimethylmercury[66]. The decomposition products were determined by means of flame-ionisation and electron-capture detectors (Fig. 3).

Highly-sensitive selective electron-capture and emission detectors[67] have been used for the determination of micro-quantities of organomercury compounds. A method has been developed for the determination of nanogram quantities of a dialkylmercury by means of a flame-ionisation detector and an MAS-50 detector; this has been proposed for the determination of organomercury compounds in river water[29].

Table 3.

Type of compound	Conditions of analysis	Detector	References
Alkylstannanes, alkyldistannanes, tin hydrides	Column 2 m × 6 mm, sorbent Chromosorb W + 20% polyethylene glycol 20 M, silicone E-301, 200	Catharometer	50
Alkyl- and arylhalogenostannanes	Column 1 m × 4 mm, sorbent celite 545 + 5% silicone oil MS-200, 180°, 200°	Flame-ionisation	185
Mono-, di-, and trihalogenostannanes	Column 2 m × 4 mm, sorbent Sterchamol + 15% silicone OE-4011, 160–180°	Catharometer	186
	Column 2 m × 3 mm, sorbent Sterchamol + 5% polyethylene glycol 20 M, silicone OE-4011, 160–170°	"	35, 187
Dibromodialkylstannanes	Capillary column 2.5 m × 0.3 mm, coated with polyethylene glycol 20 M, 200°	Flame-ionisation	188

The minimal measurable quantity of methylmercury chlorides for the optimal conditions on a column containing butane-1,4-diol succinate is 10^{-12} g when an electron-capture detector is used[24]. A method for the analysis of compounds of the type RHgX is given in section VI.

The chromatographic and biological aspects of the behaviour of organomercury compounds[2], and the analysis of organomercury compounds by photometric, spectroscopic, and chromatographic (paper, thin-layer, and gas chromatography) methods[1] have been reviewed.

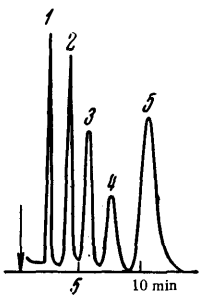

Figure 3. Chromatogram of alkylmercury chlorides. 25% diethylene glycol succinate (4 m × 4 mm), 160°, nitrogen flow rate 80 ml min^{-1}. *1*) Methylmercury chloride; *2*) ethylmercury chloride; *3*) n-butylmercury chloride; *4*) n-pentylmercury chloride; *5*) methylethylmercury chloride.

Group III

The gas chromatography of boron compounds has been carried out chiefly in the analysis of inorganic compounds, for example boron hydrides, borazoles, boranates, and derivatives of boric acid[68–77].

Organoaluminium and organogallium compounds have been analysed by gas chromatography as the ethyl derivatives[37,38]. It should be noted, however, that organoaluminium compounds are usually analysed by reaction chromatography (see section VI).

V. GAS CHROMATOGRAPHY OF ORGANOMETALLIC COMPOUNDS OF GROUP IV

1. Organosilicon Compounds

Study of reaction mechanisms and the composition of reaction products. The redistribution of radicals in a number of organometallic compounds often produces a wide range of components with similar structures, the study of which would be difficult by any method other than gas chromatography. Pollard[11,78] and Phillips[48] made extensive studies of the redistribution of tetra-alkyl derivatives of the group IV elements, including silicon (Fig. 4). These studies were subsequently continued[79,80].

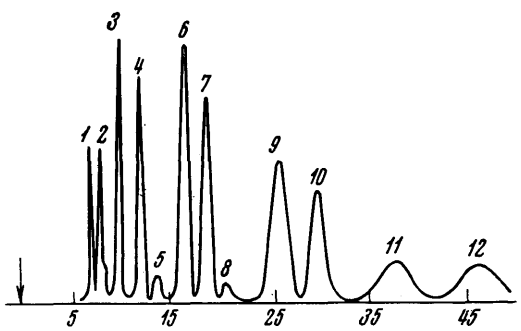

Figure 4. Chromatogram of the products of radical redistribution between $(n\text{-}C_3H_7)_4Si$ and Et_4Ge: *1*) Et_4Si, *2*) Et_4Ge + Et_3GeCl, *3*) $Et_3Si(n\text{-}Pr)$, *4*) $Et_3Ge(n\text{-}Pr)$, *5*) $Et_2(n\text{-}Pr)SiCl$, *6*) $Et_2Si(n\text{-}Pr)_2$, *7*) $Et_2Ge(n\text{-}Pr)$, *8*) $Et(n\text{-}Pr)_2GeCl$, *9*) $EtSi(n\text{-}Pr)_3$, *10*) $EtGe(n\text{-}Pr)_3$, *11*) $(n\text{-}Pr)_4Si$, *12*) $(n\text{-}Pr)_4Ge$.

The redistribution of alkoxy-groups or methyl groups with alkoxy-groups between silicon and phosphorus atoms or silicon and tin atoms takes place with difficulty[79]. Gas chromatography has been used in this case for the analysis of small quantities of products of the redistribution of the radicals, which would be extremely difficult to study by other methods. The analysis was carried out with 25% silicone oil on celite at 100–150°.

Redistribution in sterically hindered tetra-alkylsilanes containing isopropyl and isobutyl groups has been studied[80]. The deviation of the distribution of the reaction products from the statistical distribution is particularly marked for radicals with a long hydrocarbon chain. The specific retention volumes of the redistribution products were measured on E-301 methylsilicone (15% on Sil-o-cel) at 150–200°. A remarkable feature is the nonlinearity of the graphs giving the dependence of the logarithm of the retention on the number of carbon atoms (or number of radicals of the same type) for isopropylsilane, n-pentylsilane, and isobutylsilanes; this is apparently due to the steric influence of the atoms in the molecules of the substances being separated. Deviation from linearity has been observed in other analogous cases[81]. The exchange of alkyl radicals between heterocyclic organosilicon compounds has been studied[82,83]; in the first of the works cited, the reaction between hexamethylcyclotrisilathiane and nonamethylcyclotrisilazane was investigated, and two new cyclosilathiazanes were studied. The redistribution of methyl and ethyl radicals in alkylcyclotrisilazanes has been studied[84]. The reaction products were separated by gas chromatography with a detector sensitive towards nitrogen. The compounds were identified more accurately by NMR.

The products of various other reactions have been studied by gas chromatography[85-93]; the composition of the products of the reaction of methyl chloride with a copper–silicon alloy has been determined[86]; and the products of the reaction of hexamethyldisilazane and polymethylchlorosilane have been studied[87].

It has been proved by gas-liquid chromatography that in the presence of iron pentacarbonyl, ethers are split by triethylsilane with the formation of triethylalkoxysilane and hydrocarbon. The alkoxysilanes were analysed on a column containing 5% silicone elastomer on Chromosorb R at 134°.[88] The composition of acyl compounds of silicon has been studied by gas-chromatographic analysis of the reaction products[89].

The products of the catalysed formation of 1,1-dimethylcyclopentasilane were studied by Nametkin and coworkers[90] by gas chromatography. The electrophilic chlorination of phenylchlorosilanes and benzylchlorosilanes has been studied[91,92]. It has been established that the ratio of the quantities of meta- and para-isomers obtained depends on the type of catalyst.

Gas chromatography has been used to study the equilibrium constants of reactions of methylphenoxysilanes and phenylchlorosilanes[93]. Polymethylsiloxane was used as stationary phase, at 230°.

The products of the pyrolysis of phenyldimethylsilane[94,95], aryltrimethylsilanes[19], and tetramethylsilanes[96] have been studied, and the products of the thermal decomposition of tetra-ethoxysilanes have been analysed[97]. The conditions for the analysis of organosilicon compounds of various types are given in Table 2.

Organosilicon compounds containing hetero-atoms in the molecule. Bortnikov[5-7] used gas-liquid and gas-adsorption chromatography to separate organometallic compounds of group IV containing a bond between two silicon, germanium, or tin heteroatoms, and to separate heterocyclic compounds containing silicon and germanium atoms. Various thermodynamic parameters of *cis*- and *trans*-isomers of 1,2-bis(trimethylsilyl)-substituted ethylenes and their germanium analogues have been determined on graphitised carbon black and Apiezon L[5].

The processes of intermolecular sorbate–sorbent interaction in solution and on the surface of an adsorbent have been studied for organometallic compounds of the type $Et_3M\text{–}M'Et_3$ (M and M′ = Si, Ge, and Sn). The separation of these compounds on columns containing Apiezon L, 20 M polyethylene glycol, and graphitised carbon black has been studied. The absolute retention volumes and differential heats of adsorption and dissolution were measured, and the electronic polarisabilities of the compounds were determined[6].

It has been found that graphitised carbon black is a

promising sorbent for the separation of various organometallic compounds, containing two or three hetero-atoms, and sterically hindered silicon-containing ortho- and para-isomers of phenol derivatives[7].

The analysis of impurities is necessary in the study of the purity of monomeric materials in the production of highly pure substances for semiconductor technology (silicon dioxide, silicon carbide) and in the production of polymers.

A number of authors[151-155] have determined impurities in monomeric organosilicon compounds. Traces of dimethyl ether, ethanol, and benzene have been determined in triethoxysilane, trichlorosilane, and methyl chloride[152].

Impurities in methyltrichlorosilane—the starting material for the production of single crystals of silicon—have been identified as chlorides and oxide chlorides of boron and phosphorus on a column containing fluorosilicone oil 169 and DS-701 silicone oil[153]. Impurities in the form of derivatives of aluminium, iron, magnesium, and calcium were absorbed by the stationary phase, and the concentration of metals was reduced below 10^{-6}–10^{-7} wt.%.

Impurities in trichlorosilane were determined on a glass column containing silica gel modified with trimethylchlorosilane[33]. The carrier gas was dried thoroughly, and the concentration of moisture was 5×10^{-4} mole %. Methanol, ethanol, propane, 2-methylpropane, butane, ethyl chloride, silicon tetrachloride, and methylchlorosilane were identified by comparing the signals from thermo-ionic and flame-ionisation detectors. The sensitivity of the determination was $1 \times 10^{-4} - 5 \times 10^{-2}$ mole %.

The vat residues remaining after the fractional distillation of commercial dimethyldichlorosilane were found to contain traces of ethylchlorosilane, tetramethyldichlorosilane, and hexamethyldichlorotrisiloxane. The individual components were separated by preparative chromatography[154]. Traces of cross-linking agents in the raw material for the production of silicone rubbers have been determined[136]. Traces of bis(dialkylsilyl)arenes, arylsilanes, and halogenobenzenes in the products of the manufacture of monomers for silicone rubbers were identified on a column containing 5% of an arylene siloxane polymer with the formula $[-SiMe_2-Ar-SiMe_2-O-]_n$, where Ar = $-C_6H_4-$ and $-C_6H_4-O-C_6H_4-$, at 141–146°.[155] Traces of water have been determined in polyorganosiloxanes and the carrier gas in the analysis of readily hydrolysed organosilicon compounds[39,156].

Preparative chromatography of organosilicon compounds. Preparative chromatography has been used to separate the components of complex reaction mixtures[153,154,157,158]. The method has also been used to separate a number of deuteriated organosilicon compounds. Deuteriated methylethoxysilanes were separated on a column (7 m × 33 mm) containing 20% dinonyl phthalate on Inzenskii brick at 95°. 1,4-Bisdeuteriomethyltetrasiloxane was isolated on a column (4.8 m × 17 mm) containing 20% SKTFT-50 on S-22 celite at 154°.[157]

Chromatographically pure chlorosiloxanes have been isolated on a column (4.8 m × 17 mm) containing as sorbent 20% SKTFT-50 on S-22 celite at 150–190° in order to convert them into methylated and deuteriated derivatives for mass-spectrometric studies[158]. The purity of the products was 99.2%.

Isomeric high-boiling organosilicon compounds have been isolated by micro-preparative chromatography[159]. The use of a highly efficient trap packed with filter material increased the efficiency of recovery to 95%.

Turkel'taub[160,161] examined the possibility of the preparative isolation of high-boiling organosilicon compounds (b.p. 500–600°C) and proposed organosilicon stationary phases for preparative chromatography[162].

Determination of the physicochemical properties of organosilicon compounds. Gas-liquid chromatography can be used to solve such problems as the choice of separating agent for the extractive separation of mixtures of methylchlorosilanes[163], the determination of the solubility of nitrogen and oxygen in organosilicon liquids[164], and the study of the molecular weight distribution of polydimethylsiloxanes[132].

Gas chromatography has been used most widely for the determination of the saturated vapour pressures and boiling points of organosilicon compounds on the basis of their retention values on non-polar stationary phases[11,42].

2. Organogermanium Compounds

There are relatively few papers on the gas chromatography of organogermanium compounds[5,11,41,44,49,165-172]. Gas chromatography has been used for the first time for the analysis of silicon and germanium hydrides[44,165-167], for the separation of tetramethyl derivatives of germanium on a column containing Apiezon L at 60°,[99] and in the determination of the percentage composition of azeotropic mixtures of trimethylgermanium chloride and diethyl ether on a stationary phase of DS-550 methylsilicone at 70°.[168]

Gas chromatography has been used to study the redistribution of the radicals of tetra-alkyl derivatives of germanium[11], to determine the products of the alkylation of alkylchlorogermanes[170] and the electrophilic chlorination of alkylchlorogermanes[171], and to identify organogermanium compounds in the products of the exchange reaction of bis(triethyl)germylmercury with organotin halides[172].

The additivity method for the calculation of the retention times of unsymmetrical compounds from data on the retention of their symmetrical analogues has been applied for the first time for organogermanium and organosilicon compounds[48,49]. Organogermanium compounds were separated on a column containing squalane (2–13%) or a column containing a mixed phase consisting of 3% squalane and 3% phenylsilicone 702 at 100–150°.

Retention data have been published for a number of organogermanium compounds[41,48,49,125].

Gas-adsorption and gas-liquid chromatography have been used to separate the *cis*- and *trans*-isomers of 1,2-bis(trimethylgermyl)-substituted ethylenes and their silicon analogues[5] on graphitised carbon black and Apiezon L. The retention volumes and the heats of adsorption and dissolution have been measured for these compounds.

3. Organotin Compounds

The first papers on the gas-chromatographic analysis of organotin compounds appeared in 1960–1961[13,99,173-175].

Tetramethyl-derivatives of tin, germanium, silicon, and lead were analysed by Pollard[99] on a column containing Apiezon L at 60°. The preparation and chromatographic analysis of perfluorovinyltin derivatives have been described[173,174]. Matsuda[175] used gas chromatography for the analysis of tin derivatives of the type R_nSnX_{4-n}, where R represents radicals from methyl to pentyl, and X = chlorine, bromine, or iodine. The stationary phase was DS-550 silicone, the temperature 170°, and the column length 3 m.

Study of reaction mechanisms and the composition of reaction products. Gas chromatography has been used to identify the products of the reaction of tetra-alkyl compounds of tin with tin tetrachloride and tetrabromide[176] and the redistribution of the radicals of tetra-alkyl derivatives of group IV metals[11] (Fig. 5).

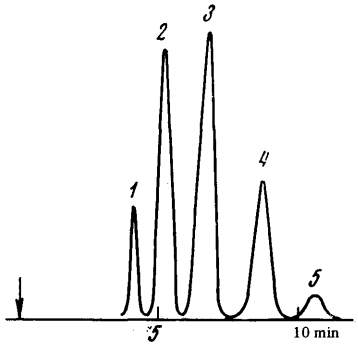

Figure 5. Chromatogram of the products of radical redistribution between $(n\text{-Pr})_4Sn$ and $(n\text{-Bu})_4Sn$: *1*) $(n\text{-Pr})_4Sn$, *2*) $(n\text{-Pr})_3Sn(n\text{-Bu})$, *3*) $(n\text{-Pr})_2Sn(n\text{-Bu})_2$, *4*) $n\text{-PrSn}(n\text{-Bu})_3$, *5*) $(n\text{-Bu})_4Sn$.

The products of the redistribution of the radicals were identified on the basis of the linear dependence of the logarithms of the retention volumes on the number of carbon atoms or the number of substituents of the same type.

Advantages of gas chromatography as a method for studying the redistribution of the radicals include not only the simple and reliable identification and effective separation of the reaction products but also the possibility of carrying out the reaction with extremely small quantities of material (0.002–0.01 mole).[11] The separation of the reaction products was carried out on a 2 m column containing 15% squalane E-301 on S-22 Sil-o-cel. The temperature of the analysis varied in the range 100–250°, depending on the composition of the reaction products.

The use of gas chromatography made it possible to study the exchange of methyl and alkoxy groups between tin and silicon atoms or between tin and phosphorus atoms[77], the hydrostannation of unsaturated compounds, and the reactions of trimethylstannane[75,177].

Gas chromatography has been used to identify the products of many reactions: the redistribution of radicals between alkyltin trichlorides and compounds of the type $RSnR'_3$,[178] the radiolysis of methyl and ethyl derivatives of tin[179], the reactions of tetra-alkyl derivatives of tin and germanium under the influence of ^{60}Co γ-radiation[32], the thermal degradation of tetrabutyltin[180], the reactions of tetra-alkyl-derivatives of tin with boron trichloride[181] and of metallic tin with alkyl halides[182], the reactions of bis(trifluoromethyl)diazomethane with organotin compounds[183], and the photolysis of tetramethylstannane[184].

The analysis of organotin compounds of different types is represented in Table 3.

Retention values have been published for various organotin compounds[11,41,45,50,189].

Putnam[45] measured the retention indices of 14 organotin compounds of the type R_4Sn on three stationary phases[45]. The retention indices of the organotin compounds are slightly larger for polar stationary phases, particularly in the case of unsaturated radicals. The ratio of the retention index to the molecular weight for a polar column shows a correlation with the refractive index of the organotin compound. The dependence of the retention indices on the number of carbon atoms, the molar refraction, and the boiling points has been given, and can be used for the approximate estimation of these quantities for organotin compounds.

With temperature programming, the indices of organotin compounds on a non-polar phase depend little on the rate of heating and change in the same sense as the molar refractions of these compounds[189].

Some deviations from the linear dependence of the logarithm of the retention volume on the number of carbon atoms in homologous series of organotin compounds have been noted[11,45,46]; these must be taken into account in the calculation of retention values by the additivity scheme. These deviations are apparently due to the mutual screening of the tin atom and the methyl groups from the interaction with the molecules of the stationary phase[46].

Preparative chromatography has not yet found extensive application for the separation of organotin compounds. Only the preparative purification of tetramethyltin and tetraethyltin on a column (13 m × 25 mm) containing 18% polyethylene glycol 400 has been described. A 10 ml specimen was purified in 40 min. The concentration of impurities in the product was 10^{-3}%.[190,191]

The determination of impurities in tetrabutyltin and the analysis of alkyltin halides by reaction chromatography are examined in section VI.

Some additional information on spectroscopic and chromatographic methods in the analytical chemistry of organotin compounds is given in two reviews[3,4].

4. Organolead Compounds

Organolead compounds are widely used as additives in motor fuel. Before the development and comprehensive application of chromatographic methods, the analysis of alkyl compounds of lead in petrol involved the determination of the total lead content. In the earliest work[99,192,193] on the gas-chromatographic analysis of organolead compounds, the components separated on the chromatographic column were detected by means of a spectrophotometer or catharometer.

Lovelock and Zlatkis[194] were the first to use for this purpose an electron-capture detector, the sensitivity of which towards organic compounds of lead is several times greater than its sensitivity towards hydrocarbons. The use of an electron-capture detector helped to solve the problems of the identification of complex mixtures.

In addition to organic compounds of lead, petrol always contains alkyl halides which prevent the successful separation of the mixture. An additional column containing as sorbent 20% polyethylene glycol, saturated with silver nitrate, on Chromosorb W treated with 8% potassium hydroxide, was proposed for the separation of alkyl halides[195]. This column was placed after a separating column containing 15% methylsilicone SE-30 on Chromosorb W. 1,2,3-Tris(2-cyanoethoxy)propane[196] and Apiezon L[197] have also been used for the separation of alkyl compounds of lead.

Soulages[10,198] developed a method for the simultaneous

determination of alkyl compounds of lead and alkyl halides in petrol. The analysis involved the separation of the alkyl compounds of lead and the alkyl halides from the hydrocarbons of the petrol on a sorbent consisting of 10% polyethylene glycol 400 on Chromosorb P and hydrogenolysis of the alkyl-lead compounds and alkyl halides at 140° on nickel deposited on Chromosorb P. The reduction products methane and ethane were separated on a column containing active carbon, modified with 3% vaseline at 70°. An electron-capture detector was used.

The above method was used in subsequent work by the same author for the determination of five methylethyl derivatives of lead and alkyl halides in petrol[10]. The separation was carried out on a stationary phase consisting of 1,2,3-tris(2-cyanoethoxy)propane on Chromosorb P, treated with 1% potassium hydroxide at 80°.

The identification of mixtures of organolead compounds is made difficult by the lack of pure specimens of the alkyl compounds of lead for the calibration of the detectors. Soulages[22] put forward a simple method of identification with thermal-conductivity and flame-ionisation detectors. The catharometer recorded the alkyl compounds of lead and the alkyl halides separated on the chromatographic column. Simultaneously, the flame-ionisation detector recorded, in the form of methane and ethane, the products after hydrogenolysis. This method was used to identify a mixture of tetramethyl-, tetraethyl-, trimethylethyl-, dimethylethyl-, and methyltriethyl-lead, dichloroethane, dibromoethane, and toluene, separated on a column containing 10% polyethylene glycol 400 and 1% tetrakis(2-hydroxypropyl)ethylenediamine on Chromosorb W.

In the determination of alkyl compounds of lead in aromatic petrols, an additional column containing Apiezon L was used for the separation of the aromatic hydrocarbons. The alkyl compounds of lead were separated on a sorbent consisting of 10% 1,2,3-tris(2-cyanoethoxy)propane on silanised Chromosorb W at 75° or 85°.[199] The chromatogram of the separated products is shown in Fig. 6.

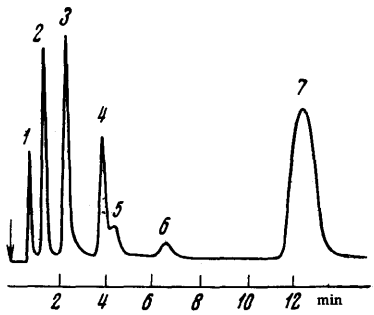

Figure 6. Chromatogram of alkyl compounds of lead, 10% 1,2,3-tris(2-cyanoethoxy)propane (4 m × 3 mm), 85°, nitrogen flow rate 30 ml min^{-1}. *1*) Me_4Pb, *2*) Me_3PbEt, *3*) Me_2PbEt_2, *4*) $MePbEt$, *5*) $C_2H_4Cl_2$, *6*) Et_4Pb, *7*) $C_2H_4Br_2$.

A combination of gas chromatography and atomic-absorption spectroscopy has been used for the quantitative determination of organolead compounds in petrols[200]. The quantitative analysis does not require the calculation of correction coefficients.

All lead compounds are highly toxic, and their concentration in the surrounding atmosphere must be strictly controlled. In the analysis of organolead compounds in air, the problems of concentration of the specimen immediately arise. The use of Yanak's method[201] of concentration, involving the passage of air through an absorbing column filled with the sorbent used in the separating column, has been proposed[31]. Air was forced by means of a pump through a column (8 cm × 1 mm) containing 10% silicone SE-52 on Chromosorb P for 10–15 min. After the concentration, the column was heated rapidly, and the lead compounds were introduced into the chromatographic column, on which the separation was carried out at 80°. An equation was put forward for calculating the concentration of alkyl compounds of lead in air.

VI. REACTION CHROMATOGRAPHY OF ORGANOMETALLIC COMPOUNDS OF GROUPS I–IV

Many organometallic compounds of groups I–IV have a low volatility and are unstable towards atmospheric moisture and oxygen. It is difficult to analyse these compounds by classical methods of gas chromatography, so that in most cases it is not the organometallic compounds themselves, but their transformation products, which are analysed. The version of gas-chromatographic analysis in which chemical reactions are used to convert the substances into forms more convenient for analysis is called reaction chromatography. We shall subsequently use this term in the description of this type of work.

GROUP I

Reaction chromatography has been used for the analysis of organic compounds of lithium, sodium, and potassium, which in most cases are solid, almost non-volatile compounds. These are converted into more volatile compounds by hydrolysis. A system of two chromatographs[202] has been used for the analysis of solutions of vinyl-lithium in tetrahydrofuran. The specimen was hydrolysed on the first chromatograph in an additional column containing hexane-1,2,6-triol on Chromosorb. The ethylene liberated on hydrolysis was identified and determined quantitatively on a column containing 20% dodecyl phthalate on Chromosorb W at 75°. A second chromatograph, connected to the first, was used to determine the trace components present in the ethylene, such as acetylene and buta-1,3-diene, on a sorbent consisting of 20% dimethylsulpholane on brick.

Reaction chromatography has been used to study a number of reactions: the metallation of organic compounds with organopotassium compounds[203–205], the kinetics of the polymerisation of butadiene, isoprene, and styrene in the presence of an alkyl-lithium[206], the reaction of epichlorohydrin with butyl-lithium[207], and the products of the reaction of methylcyclopentane in the presence of benzylsodium[208].

GROUP II

Organomagnesium and organocalcium compounds, like the organic compounds of the group I metals, have a low volatility and are unstable to hydrolysis.

1. Organomagnesium Compounds

The conversion of these compounds into more volatile compounds by hydrolysis or by exchange with alkyltin and alkylsilicon halides has been proposed[209–213].

Reaction chromatography has been used for the first time for the analysis of ethylmagnesium iodide solutions, which were hydrolysed with phosphoric acid in a micro-reaction vessel. The gaseous products were introduced into the chromatographic column through a by-pass line and separated on a column with activated silica gel.

The concentration of solutions of partly decomposed Grignard reagents (*p*-t-butylphenylmagnesium bromide) was determined by double chromatographic analysis[210]. The quantity of aromatic hydrocarbon formed by the decomposition of the Grignard reagent was first determined by direct gas chromatography on a column containing polyethylene glycol. The solution being analysed was then hydrolysed with methanol, and the quantity of t-butylbenzene liberated was determined. The results from the two analyses were used to calculate the true concentration of Grignard reagent in the solution. This method for the analysis of aryl Grignard reagents was subsequently used in a study of the kinetics of the reaction of alk-1-enes with phenylmagnesium bromide[211].

Tributyltin chloride has been used as reagent in the analysis of vinylmagnesium chloride[212]. This reaction gave vinyltributyltin, which was separated from the reaction products on a column containing 20% phenylsilicone DS-550 with temperature programming from 120° to 210° at a rate of 15 deg min^{-1}. This method of analysis appears more promising, since the reaction mixture contains a smaller number of components. The reaction with dimethylphenylchlorosilane has been used for the analysis of methyl Grignard reagents[213]. The trimethylphenylsilane obtained was determined quantitatively by the internal-standard method.

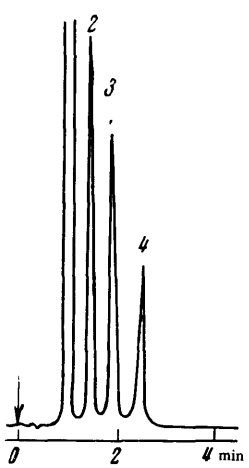

Figure 7. Chromatogram of the products of the hydrolysis of the complex of dioxan with phenylcalcium iodide: *1*) diethyl ether, *2*) benzene, *3*) toluene (standard), *4*) dioxan.

2. Organocalcium Compounds

Reaction chromatography has been used for the analysis of organocalcium compounds isolated for the first time in the individual state in the form of complexes with dioxan and amines[214]. The solution of the complex of dioxan and arylcalcium iodide in ether was decomposed with water. The CaI(OH) precipitate was separated by centrifuging. The aromatic hydrocarbon and dioxan obtained on hydrolysis were separated on a column containing 5% diethylene glycol succinate at 94° (Fig. 7). The quantitative determination of the aromatic hydrocarbon and dioxan was carried out by the internal-standard method. The method of analysis of organocalcium compounds by gas chromatography has made it possible to develop an optimal method for the preparation of diphenylcalcium.

3. Organomercury Compounds

There is only one published paper on the reaction chromatography of organomercury compounds; this describes the identification of a mixture of alkylmercury halides by means of the reactions with various sulphur-containing substances—sodium thiosulphate and metal sulphides—and metal powders[215]. The method involves double chromatography of the mixture being analysed; the separation is first carried out by the direct method, after which the solution being analysed is treated with various sulphur-containing compounds or passed through an additional column containing metal powder, and subjected to a second separation.

GROUP III

Reaction chromatography has been used chiefly for the analysis of organoaluminium compounds.

Organoaluminium Compounds

Organoaluminium compounds decompose readily under the influence of oxygen and water. The temperatures of the start of the thermal decomposition of these compounds are lower than the boiling points at atmospheric pressure.

Reaction chromatography has been used for the analysis of triethylaluminium, which is a catalyst for the preparation of polyethylene[216].

A solution of triethylaluminium in cyclohexane was evaporated in a stream of hydrogen and passed through a tube filled with 30% lauric acid on Sil-o-cel, connected to the chromatograph. The hydrolysis products were determined in two stages; ethane and butane were first determined on a column containing dibutyl phthalate, after which hydrogen and ethane were determined on a column containing silica gel.

In the analysis of triethylaluminium and tripropylaluminium, these compounds were hydrolysed with n-hexanol, diethylene glycol, and its mixture with aqueous sulphuric acid solution[217,218]. Hydrogen, methane, ethane propane, and butane were separated on dimethylsulpholane deposited on silica gel, and dinonyl phthalate on celite at 30°.

Palamarchuk[219] put forward a method for the analysis of triethylaluminium, in which the specimen was decomposed directly in the entry compartment of the reaction vessel. The specimen in an atmosphere of dry nitrogen was decomposed with diethylene glycol, and the hydrolysis products were transferred by the carrier gas into a separating column containing alumina. If the triethylaluminium contained impurities, for example diethylaluminium oxide, the alcohol and ethane liberated in its hydrolysis were separated on a column containing a mixed sorbent of 15% tricresyl phosphate on Polysorb and 10% squalane on Teflon.

Gas chromatography has been used for the analysis of the products of the reaction of α, ω-dienes with di-isobutyl-lithium hydride[220] and in the study of the kinetics of the reaction of alkyl compounds of metals with alkenes[221].

GROUP IV

Reaction chromatography has been used in the analysis of organosilicon and organotin compounds.

1. Organosilicon Compounds

Reaction chromatography has found extensive application in the structural analysis of organosilicon compounds. This method was developed by Franc and coworkers[222-227]. The method involves a number of reactions with BF_3, BCl_3, H_2SO_4, HNO_3, HI, Zn, NaOH, and KOH in a special reaction vessel (Fig. 8) to determine the structure of the organosilicon compounds and to detect functional groups. In the reaction with BF_3, the organosilicon compounds are split at the siloxane bonds, halogen and hydrogen are replaced by fluorine, and the phenyl radical is split off as benzene[225,227]. In hot concentrated sulphuric acid, alkyl-, aryl-, chloroalkyl-, and chloroaryl-silanes are split with the formation of hydrocarbons and alkyl halides[223,226,227]. Hydrogen iodide splits alkoxy-compounds with the formation of alkyl iodides[223,227]. Si–H and Si–Si bonds are split by potassium hydroxide solution with the formation of hydrogen. The reaction products are analysed by gas-liquid chromatography and paper chromatography[227].

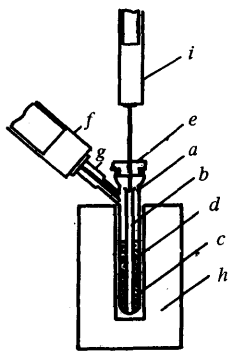

Figure 8. Glass reaction vessel for carrying out decompositions before application to the chromatographic column: *a*) glass vessel, *b*) glass tube, *c*) layer of calcium fluoride, *d*) layer of porous material (Risorb) [sic], *e*) silicone rubber stopper, *f*) 10 ml syringe, *g*) silicone rubber tube, *h*) copper block, *i*) 1 ml syringe.

A method of reaction thermal analysis has been developed, which makes it possible to determine the nature of a functional group and to establish the structure of a molecule on the basis of the reaction between the substance being studied and a suitable reagent, with temperature programming[225,226]. The method has been used to determine the structure of linear and cyclic polyorganosiloxanes by splitting these compounds with sulphuric acid. The relationship between the structure of the substance being studied and the temperature at which the separation of individual functional groups took place was examined. The thermograms of polyorganosiloxanes were given. A number of authors[228-230] have also used reaction chromatography for the analysis of organosilicon compounds. For the determination of Me_3Si-, $Me_2Si=$, and $MeSi\equiv$ groups in methylpolysiloxanes, it has been suggested that the polymer be depolymerised by the action of $2BF_3 .(C_2H_5)_2O$, with subsequent chromatographic analysis of the methylfluorosilanes produced[228]. The separation and quantitative analysis of a mixture of phenylmethyldichlorosilane, phenyltrichlorosilane, and silicon tetrachloride were carried out by converting them into the corresponding fluoro-derivatives on a column containing Na_2SiF_6.[229]

Gas chromatography has been used to study thermal processes taking place in polymers[231]. Pulse pyrolysis under chromatographic conditions has been used for the determination of vinyl groups in alkylcyclosiloxanes[232].

2. Organotin Compounds

Reaction chromatography has been used for the analysis of a mixture of alkyltin halides, which are thermally unstable and readily undergo radical redistribution[233,234].

Butyltin, octyltin, and phenyltin halides react with Grignard reagents with the formation of the more stable tetra-alkyl compounds, which have lower boiling points. For example, butyltin bromides are converted quantitatively into the butylmethyl analogues by the action of methylmagnesium bromide. The separation and quantitative determination of organotin compounds has been carried out on a column containing 20% methylsilicone SE-30 with temperature programming, from 50° to 270°.

Pyrolytic gas chromatography has been used for the determination of impurities in tetrabutyltin[235]. The substances separated on the chromatographic column were subjected to thermal decomposition, and the pyrolysis products in turn were separated on a column containing methylsilicone E-301 and recorded by means of a flame-ionisation detector. A number of impurities with general formula $(R_1)_nSn(R_2)_{4-n}$ (where R_1 and R_2 represent ethyl, methyl, butyl, or s-butyl) were identified.

VII. FUTURE DEVELOPMENTS IN THE GAS-CHROMATOGRAPHIC ANALYSIS OF ORGANOMETALLIC COMPOUNDS

The introduction of gas chromatography in the chemistry of organometallic compounds took place in the period 1960–1965. The gas chromatography of organometallic compounds can now be regarded as a sufficiently well-developed field of application of the method, but its possibilities have not yet been exhausted. We can expect an extension of the range of classes of organometallic compound analysed by gas chromatography, and also of the range of problems to be solved and versions of the chromatographic methods used.

Up to the present, almost no use has been made of capillary gas chromatography in the analysis of organometallic compounds; this is due to the adsorption of the organometallic compounds to be separated on the walls of the capillary, and the difficulty of detecting micro-quantities of organometallic compounds. When these difficulties have been eliminated, the use of capillary chromatography

for the separation of a large number of mixed isomeric compounds of several elements will appear particularly promising.

By analogy with the gas chromatography of organic compounds, we can expect the development of methods of combined chromatographic analysis (combination of gas and thin-layer, gas and liquid, and gas and paper chromatography).

Up to the present, only a few papers have been published on the use of highly sensitive selective detectors for organometallic compounds. An extension of the range of types of highly sensitive detector, and their more intensive use in the analysis of micro-components and the identification of organometallic compounds, appear probable.

The use of chromatography–mass spectrometry (for organomercury [63,236] and organosilicon [237] compounds) will apparently be extended after the elimination of a number of difficulties encountered at present, namely the non-availability of the mass spectra of many organometallic compounds, the complexity of the analysis of organometallic compounds under chromatography–mass spectrometric conditions, and the phenomena of instrument memory.

Gas chromatography is extensively used for the determination of the physicochemical characteristics of substances, the study of reaction mechanisms, and the study of catalytic processes [238].

We can expect the development of methods associated with the determination of physicochemical characteristics, and an extension of the types of reaction carried out under chromatographic conditions (catalytic reactions involving organometallic compounds).
