The p.m.r. spectra of these compounds show complicated temperature relations, from which it is difficult to calculate rate constants. These difficulties are due primarily to overlapping between the signals from protons of aromatic and five-membered rings. At low temperatures (−30°C with M = $Sn(CH_3)_3$) the spectrum of the protons divides into two parts—ABCD (aromatic protons 4–7) and ABX (protons 3–1). Heating produces a gradual broadening of the signals due to the exchangeable protons H_1 and H_3 in the ^1H spectrum: the spectrum of the aromatic protons passes into that of the AA′BB′ system, while the spectrum of protons 1–3 is transformed into the A_2B system. Because migration is intramolecular the multiplet character of the spectra does not disappear but is averaged out: e.g. the constant J_{AB} for the mean spectrum of type A_2B (protons 1–3) is $\frac{1}{2}(J_{12} + J_{23})$, where J_{12} and J_{23} are coupling constants for the instantaneous structure (XIVa).

The difficulties of calculating rate constants in strongly coupled spin systems with overlapping signals in the p.m.r. spectra can be avoided by using carbon-13 spectra. Under conditions of uncoupling from protons, splitting due to spin coupling with protons is absent from these spectra. It thus becomes possible to apply the Bloch–McConnell equations (Section II).

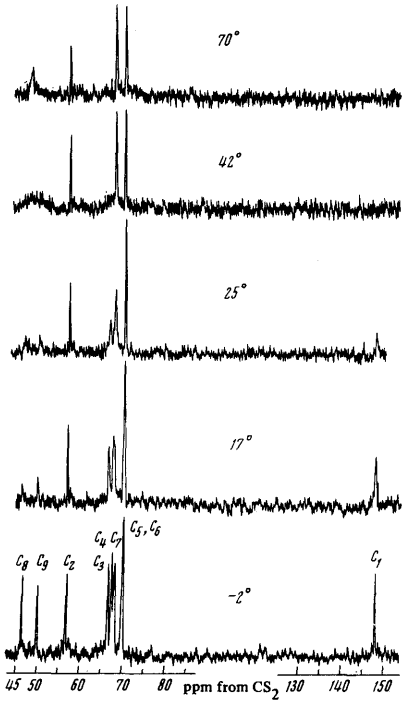

Figure 20. Carbon-13 n.m.r. spectra of trimethylstannylindene with uncoupling from protons at various temperatures[81].

Fig. 20 shows $^{13}C-\{^1H\}$ spectra (25.1 MHz) for trimethylstannylindene $C_9H_7Sn(CH_3)_3$ measured over a range of temperatures[81]. At room temperature (and below) the ^{13}C spectrum corresponds to the stereochemically rigid structure (XIVa). The assignment of the signals to individual carbon atoms is indicated on the spectrum (Fig. 20). Thanks to the absence of spin–spin interaction the exchange can at once be investigated for several pairs of

merging signals, viz. $C_{(1)}$–$C_{(3)}$, $C_{(4)}$–$C_{(7)}$, and $C_{(8)}$–$C_{(9)}$ (the signals from atoms $C_{(5)}$ and $C_{(6)}$ coincide in the limit of slow exchange). Comparison of experimental and theoretical spectral curves by line-shape analysis gives estimates of the activation functions for this process of $E_a = 13.8$ and $\Delta G^{\neq}_{300} = 15.3$ kcal mole^{-1}.

Fluctuating behaviour is of considerable theoretical interest, since it enables structural and kinetic features of certain molecular systems to be described from a single point of view. It may be supposed that d.n.m.r. spectroscopy will lead to the discovery of new classes of molecules of this type, and will enable quantitative aspects to be introduced into the construction of a theory of fluctuating behaviour.

Problems of the Kinetics and the Topochemistry of Heterophase Copolymerisation

V.A.Myagchenkov and S.Ya.Frenkel'

The kinetics and the mechanism of binary heterophase copolymerisation are discussed by analogy with the differences in the kinetics and the statistics of homophase and heterophase polymerisation. The appearance of an interface, even in the absence of interphase interactions, leads to changes in the composition of the copolymer macromolecules and to departures in the overall process from the Mayo-Lewis canonical scheme even when r_A and r_B are constant. In order to record heterophase effects it is hence impossible to use the standard treatment of equilibrium diagrams or to estimate the mean compositions of the copolymers: the composition distribution functions must be analysed. Work is therefore discussed in which copolymerisation was conducted (wittingly or unwittingly) under heterophase conditions, practical criteria of heterophase character are examined, and its possible effects on the kinetics and the mechanism of the reaction are determined qualitatively. Possible methods for the quantitative analysis of copolymerising systems diverging from the general Mayo-Lewis scheme are also discussed. A list of 88 references is included.

I. INTRODUCTION

The chief difficulties in the investigation of multicomponent systems arise from the need to allow for the contributions by individual components to the property or process studied. These difficulties can in principle be overcome if the contributions are additive. Then the calculated resultant functions describing the property or process (e.g. electrical conductivity, dielectric constant, heat capacity, entropy, optical density, etc.) usually agree well with the corresponding experimental quantities[1]. However, simple additivity is not satisfied by most multicomponent systems, which can be explained most generally by various types of interactions between the components influencing the magnitude and sometimes even the sign of the overall effect. In order to obtain the correct form or value of the resultant function it is necessary to introduce into the appropriate relations special parameters to allow for selective interactions between components, and these parameters should, of course, differ for different static or dynamic properties of the same multicomponent system. As a consequence, exact and detailed theories for specific resultant properties or processes have a limited sphere of application. In rare cases the unjustified extension of the limits of this sphere leads to fortuitous agreement between calculated and experimental values, but most often it yields erroneous results.

Special consideration will be given later to certain incorrect approaches in investigations of multicomponent copolymerising systems. Here we remark that, in the analysis of any polymeric systems, numerous additional complications arise connected with the nature of chain macromolecules, the special character of selective interactions, the presence together of different forms of polydispersity, etc.[2,3]. It is sufficient to recall that merely a change in molecular weight of a polymer component may cause a sharp change in the whole set of physicochemical properties of polymeric compositions and goods made from them[2]. Variation in composition of copolymers (inhomogeneity of composition) and the consequent spread of stable macromolecular conformations may lead to still greater uncertainty in the resultant physicochemical properties[4-6].

A typical example of complicated and ambiguous correlations between individual parameters in polymer systems is provided by the kinetics and the statistics of heterophase polymerisation[7,8]. Any specific and detailed theories (e.g. Stewart's theory of emulsion polymerisation) apply only to quite definite model system: outside the scope of such models, in application to workable processes of heterophase polymerisation, even qualitative use of the theories requires as a minimum careful preliminary investigation of the peculiarities of polymerisation in each specific system.

The situation is still more complicated with heterophase copolymerisation. The present stage of experimental work is hardly adequate for development of a general theory. Even use of the most general model of heterophase copolymerisation can yield only semi-quantitative agreement with experiment. And yet such a model is useful, since it will provide information on topochemical features of heterophase copolymerisation, on which the molecular-weight distribution and the inhomogeneity of composition largely depend. Furthermore, examples of the analysis of this model can show how aspects of heterophase processes *should not* be studied. It will later be shown in particular that application of the Mayo—Lewis scheme to the kinetics and the statistics of heterophase copolymerisation—and still more that of the Alfrey—Price "*Q—e*" scheme—may lead to errors even when the relative reactivities of the copolymers are independent of the reaction conditions.

II. GENERAL PROBLEMS OF THE ANALYSIS OF POLYMERISATION IN HETEROPHASE SYSTEMS

The interest of research workers in various forms of heterophase polymerisation is due primarily to the fact that they are usually easier and more convenient than homophase processes to conduct technically. Control of external (reactor) parameters is also easier with a heterophase than with a homophase process, and this at first glance widens the possibilities also of direct intervention in the kinetics, i.e. ultimately of controlling the physicochemical properties of the resulting polymer. It would be equally incorrect to underestimate or to overestimate these possibilities. Very much depends on the purpose of the polymer.

Let us consider a single example, in which the possibilities have perhaps been overrated. The emulsion polymerisation of vinyl acetate (a typical heterophase polymerisation[8]) is economically and technically more efficient than the so called "lacquer process", i.e. polymerisation in methanolic solution. If, however, the purpose of the process is to obtain *fibre-forming* poly(vinyl alcohol), all these advantages are completely levelled by the poor fibre-forming properties of the poly(vinyl alcohol) obtained in this way. As a result, the "lacquer" process exhibits greater overall efficiency. Nevertheless, the emulsion polymerisation of vinyl acetate must not be underrated if poly(vinyl acetate) itself is to be used as material in later stages, e.g. in emulsions employed in constructional engineering.

The principles of the statistical theory of heterophase homopolymerisation were set out by one of us elsewhere (Ref. 8, Chapter VI), and even brief mention of them is hardly required here. Therefore we shall merely consider those aspects of the theory and those approaches which are directly relevant to heterophase copolymerisation.

Let us first agree on terminology. The concepts of heterophase and heterogeneous polymerisation are by no means identical: heterogeneous polymerisation may be a homophase process, although the converse cannot apply. A heterogeneous system may in fact consist of two phases (e.g. a solid catalyst phase and a liquid monomer phase), but if chain growth and termination take place in only one phase, the process as a whole will be homophase. If, however, the elementary reactions of chain initiation, growth, termination, and transfer take place simultaneously at different rates in several coexisting phases, while interphase macromolecular reactions are possible (start of growth in one phase and continuation or completion in another phase, or bimolecular termination of chains growing in different phase, etc.), the process is heterophase[7,8]. The most characteristic indicator of a heterophase process is a multimodal molecular-weight distribution, in which the number of maxima shows a definite correlation with the number of intraphase and interphase mechanisms of termination of the kinetic chains. Henceforward we shall discuss only two-phase systems—not only because the difficulties of specific calculations increase disproportionately with increase in the number of phases but also because two-phase polymerising systems are most frequently met in practice.

Let us consider such a system consisting of phases I and II with any arbitrary distribution of components between these phases. Let the volumes of the phases be v_t^{I} and v_t^{II}, and the corresponding concentrations (in g cm^{-3} or g litre^{-1}) of monomer, initiator, and growing active centres (macroradicals in the case of radical polymerisation) M_t^{I} and M_t^{II}, I_t^{I} and I_t^{II}, and $\cdot R_t^{I}$ and $\cdot R_t^{II}$ respectively. We denote the concentrations of other components that may influence the kinetics and the mechanism of polymerisation by

$$\lambda_{1t}^{I}, \lambda_{1t}^{II}, \lambda_{2t}^{I}, \lambda_{2t}^{II} \ldots \lambda_{it}^{I}, \lambda_{it}^{II} \ldots \lambda_{kt}^{I}, \lambda_{kt}^{II}.$$

These components may be inhibitors, sensitisers, modifiers, chain-transfer agents, etc. The concentration ratios of individual components in phases I and II can in principle be varied over the ranges

$$0 \leqslant I_t^{I}/I_t^{II} \leqslant \infty,\ 0 \leqslant M_t^{I}/M_t^{II} < \infty,\ 0 \leqslant \frac{R_t^{I}}{R_t^{II}} < \infty,\ 0 \leqslant \frac{\lambda_{it}^{I}}{\lambda_{it}^{II}} < \infty \quad (i = 1, 2, 3 \ldots k).$$

In this notation the condition of "homophasicity" is formulated as the simultaneous approach by the ratios for M and R· to 0 or ∞; the condition of "diphasicity", on the other hand, requires that these ratios should be finite. The ratios of other concentrations have no decisive significance for the "phasicity" of the process. These conditions reflect the quite trivial fact that a heterogeneous system is not a sufficient criterion that polymerisation shall be a heterophase process.

All types of two-phase polymerisation (whether emulsion, suspension, or gas-phase polymerisation, in a precipitant, or the block polymerisation of monomers that are not solvents for their polymers) are characterised by the presence of an interface of area S_t. In the simplest form of steady-state process polymerisation occurs independently in phases I and II. This means that at time t the laws of polymerisation in phase I are determined unambiguously by the values of M_t^{I}, I_t^{I}, $\cdot R_t^{I}$, and λ_{it}^{I} ($i = 1, 2, \ldots, k$) and are independent of M_t^{II}, I_t^{II}, $\cdot R_t^{II}$, and λ_{it}^{II}. With "I" and "II" interchanged the same applies to phase II. The ratios

$$\frac{M_t^{I}}{M_t^{II}},\ \frac{R_t^{I}}{R_t^{II}},\ \frac{I_t^{I}}{I_t^{II}},\ \frac{\lambda_{it}^{I}}{\lambda_{it}^{II}},$$

depend indirectly on S_t, being determined in the simplest case by Langmuir's law. It is assumed that the contraction in each phase can be neglected, and also that the dimensions l of individual units (aggregates, drops, etc.) constituting the phases are large in comparison with those of the individual macromolecules.

Under these conditions it is reasonable to expect, at least for not too large degrees of conversion Ψ, that the chief laws of homophase polymerisation will be obeyed within phases I and II, e.g. that the overall rate of the process will be proportional to $(I_t^{I})^{\frac{1}{2}}M_t^{I}$ and $(I_t^{II})^{\frac{1}{2}}M_t^{II}$ in the respective phases. Resultant kinetic curves or molecular-weight distributions for such a heterophase system can be calculated simply by superposing corresponding curves for phases I and II.[8]

In order to obtain information on the parameters of interaction between the phases it is necessary to obtain data on the kinetics and the molecular-weight distribution in each phase for various degrees of conversion. This alone requires a large number of delicate experiments involving the separate study of polymerisation each phase. Amongst such important parameters controlling the process are firstly the time relations $M^{I}/M^{II} = f_1(t)$, $I^{I}/I^{II} = f_2(t)$, $\cdot R^{I}/\cdot R^{II} = f_3(t)$, and $\lambda_i^{I}/\lambda_i^{II} = f_{4,\,i}(t)$, secondly the physicochemical characteristics of the interfacial layers, and thirdly the kinetic parameters of all types of chemical reactions and mass exchange in the boundary layers.

Separate observation of the processes in phases I and II is possible only by use of the most recent methods, in particular optical (e.g. luminescent) or radioactive "labels"; in some systems the phases can be separated artificially by means of a preparative ultracentrifuge[9]; and in principle more standard optical methods can be used to determine M_t^I (or M_t^{II}), at least in one of the phases. Promising experiments have also been made on the principle of "intervention", when polymerisation in one phase is artificially suppressed (e.g. by introducing into the system an inhibitor soluble only in this phase).

On the other hand, use of certain favourite routine methods (e.g. dilatometry) for these purposes is by no means always possible, for the coefficients of contraction K^I and K^{II} in the two phases are not equal in many systems with interacting phases. (We recall that $\Delta v^I = K^I(M^I_{t=0} - M^I_t)$ and $\Delta v^{II} = K^{II}(M^{II}_{t=0} - M^{II}_t)$, where Δv^I and Δv^{II} are the changes in volume of the phases at degrees of conversion of Ψ^I and Ψ^{II}.) Hence the overall change in volume of the system is not proportional to $\Psi^I + \Psi^{II}$, and dilatometry does not give a quantitative measure even of the overall process.

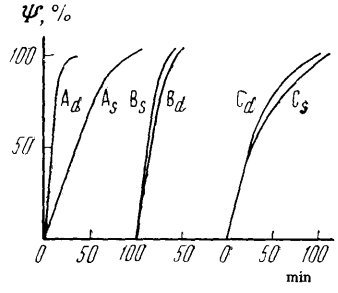

Figure 1. Dependence of degree of conversion Ψ on time in the heterophase (*d*) and homophase (*S*) polymerisation[13] of: A) acrylonitrile; B) vinyl chloride; C) vinylidene chloride—acrylonitrile system.

It appeared at one time that the main features of the most thoroughly investigated type of heterophase polymerisation—emulsion polymerisation—would be explained by Smith and Ewart's theory[10,11], which postulated that the emulsified particles were constant in number and merely underwent an increase in volume with increase in degree of conversion. However, later work by Medvedev and his collaborators showed that this theory paid insufficient attention to the role of the interface in the general reaction scheme. They showed in particular that the overall rate of polymerisation may be proportional either to the square root or to the first power of the concentration of the emulsifier according to whether the latter is soluble or insoluble in water. However, even Medvedev's theory gives quantitative agreement with experiment in by no means all cases. Only semi-quantitative agreement is obtained when calculated and experimental kinetic curves are compared[12]. As Kargin correctly remarked in his plenary report to a conference on emulsion polymerisation in Odessa in 1969, the theoretical problems of emulsion polymerisation are far from being exhausted, and more specialised experimental work must be undertaken with the development of new, improved theories.

A few specific examples will demonstrate the complications, in interpreting kinetic or statistical features of polymerisation, that arise from the two-phase character of the process. Fig. 1 compares kinetic curves for the homophase and heterophase polymerisation and copolymerisation of certain vinyl monomers. With vinyl chloride or in the copolymerisation of vinylidene chloride with acrylonitrile the change from a homophase to a heterophase process is not accompanied by significant change in the rate of polymerisation. With vinyl chloride the appearance of a new phase leads to some slowing down of the process, but in copolymerisation the appearance of a second phase results, on the contrary, in some acceleration. Nevertheless, the polymerisation of acrylonitrile is far more rapid in a two-phase system. Such relations between reaction velocity and nature of reaction medium can be explained only on the basis of the effective concentrations of monomers and initiator in phases I and II. The presence of several components often has the effect (especially in emulsion polymerisation) that slight changes in external conditions or small additions may change substantially the situation in the boundary layers and hence cause a shift in equilibrium in the system. This is clearly evident in Fig. 2, illustrating the effect of additions of various amines on the degree of conversion in the emulsion polymerisation of butadiene[14].

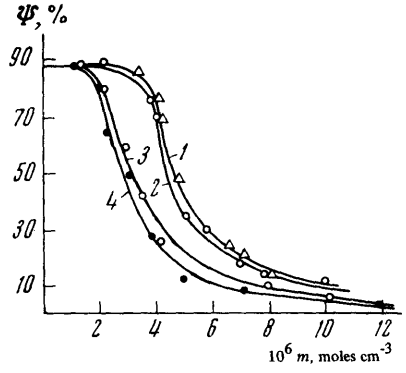

Figure 2. Dependence of degree of conversion Ψ in the emulsion polymerisation of butadiene[14] at pH 3.4 and 70°C for 24 h on the concentration *m* of amines: 1) propylamine; 2) butylamine; 3) hexylamine; 4) octylamine.

In this connection interesting results have been obtained[15,16] on the effect on the rate of emulsion polymerisation of which phase the surface-active agent is introduced into. The thickness of the surface layer in the emulsion polymerisation of vinyl acetate limits diffusion of the monomer[16]. In several cases a surface-active agent affects the rate of breakdown of the initiator, and hence the rate of polymerisation[17-19]. In such systems a definite sequence in the arrangement of monomer units may be expected in the surface layer. Under certain favourable conditions this in turn will enable us to influence not only the overall rate of the process but also the

fine structure of the chain by varying the emulsifier concentration.

When an emulsifier—activator is used, the rate of the process, the particle size of the disperse phase, the fine structure, and the molecular-weight distribution are greatly affected by the pH. Significantly different rates of emulsion polymerisation are obtained by the use of oligomeric or polymeric emulsifiers of fixed molecular weight but with different contents of ionogenic groups[20]. These differences were attributed to the size and shape of the chain molecules forming the boundary layer; these characteristics depend in turn on the concentration of ionogenic units in the chain[21].

Overenthusiasm for polymeric emulsifiers or emulsion stabilisers is dangerous. When poly(vinyl alcohol) of low molecular weight is used in the emulsion polymerisation of vinyl acetate, for example, the resulting polymer is almost completely unsuitable for the production of poly(vinyl alcohol), both because of the wide multimodal molecular-weight distribution and because of the enhanced degree of branching: the polymeric component of the emulsifier has an unfavourable effect on the balance of secondary reactions (Ref. 8, Chapter III).

On the whole, work published recently (that cited here can be supplemented by two papers by Enikolopyan and his coworkers[22,23]) confirms the fundamental principles that follow from the statistical consideration of heterophase processes. Significant progress in the corresponding experimental investigations will require more intense development of specific methods of the type mentioned in this Section.

III. TWO-PHASE COPOLYMERISATION AND LIMITS OF APPLICABILITY OF MAYO—LEWIS SCHEME

The kinetics of the binary radical copolymerisation of monomers A and B are determined by the four elementary reactions of chain growth

$$\begin{aligned} &A_{n-k-1}B_k\dot{A} + A \xrightarrow{k_{AA}} A_{n-k}B_k\dot{A} \\ &A_{n-k-1}B_k\dot{A} + B \xrightarrow{k_{AB}} A_{n-k}B_k\dot{B} \\ &A_{n-k-1}B_k\dot{B} + B \xrightarrow{k_{BB}} A_{n-k-1}B_{k+1}\dot{B} \\ &A_{n-k-1}B_k\dot{B} + A \xrightarrow{k_{BA}} A_{n-k-1}B_{k+1}\dot{A} \end{aligned} \qquad (1)$$

where $A_{n-k-1}B_kA\cdot$ and $A_{n-k-1}B_kB\cdot$ are macroradicals consisting of n repeating units with A and B terminal units respectively. It is supposed that $1 \leqslant k < n-1$, while the symbols B_0 and A_0 simply denote the absence of these units in the macroradical chains. The elementary reactions have the rate constants k_{AA}, k_{AB}, k_{BB}, and k_{BA} respectively. We shall further assume that the usual quasi-stationary conditions are satisfied, i.e. that the rates of initiation comprising the elementary reactions

$$I \longrightarrow 2\dot{R},\ \dot{R}+A \xrightarrow{k_u} R\dot{A};\ \dot{R}+B \xrightarrow{k_u'} R\dot{B},$$

in which the notation is self-evident, and of termination of the kinetic chain by recombination or disproportionation

$$A_{n-k}B_k\dot{A} + A_{n'-k'}B_{k'}\dot{B} \begin{cases} \xrightarrow{k_0} A_{n+n'+1-k-k'}B_{k+k'+1} \\ \xrightarrow{k_0'} A_{n-k+1}B_k + A_{n'-k'}B_{k'+1} \end{cases}$$

are far smaller than the rate of chain growth:

$$k_u + k_u' + k_0 + k_0' \ll k_{AB} + k_{AA} + k_{BB} + k_{BA}. \qquad (2)$$

Proceeding from these hypotheses Mayo and Lewis[24]—almost simultaneously with Wall[25] and also Alfrey and Goldfinger[26]—deduced a relation between the four growth rate constants, the composition of the initial monomer mixture (substrate), and the composition of the macromolecules formed. If m_A and m_B are the molar concentrations of monomers A and B in the substrate, while M_A and M_B are the molar concentrations of the components in the copolymer ($m_A + m_B = 1$ and $M_A + M_B = 1$), we have

$$\frac{M_A}{M_B} = \frac{m_A}{m_B}\,\frac{r_A m_A + m_B}{r_B m_B + m_A} \qquad (3)$$

in which $r_A = k_{AA}/k_{AB}$ and $r_B = k_{BB}/k_{BA}$. On passing to concentrations by weight we have

$$g\,\frac{\alpha_A(1-\beta_A)^2}{(1-\alpha_A)\beta_A^2}\,r_B - r_A = \frac{1-\beta_A}{\beta_A}\left(g - \frac{\alpha_A}{1-\alpha_A}\right) \qquad (4)$$

where β_A and α_A are the weights of component A in the substrate and in the copolymer respectively, and g is the ratio of the molecular weights of A and B.

The deduction of Eqns. (3) and (4) was based on five assumptions: (i) the ensemble of copolymer molecules contained no oligomers (in the true meaning of this word); (ii) both r_A and r_B were constant, so that the relative reactivities did not depend on the nature of the penultimate and more remote units; (iii) the degree of conversion was so small ($\leqslant 0.03$) that both β_A and m_A/m_B could be regarded as constant; (iv) growth reactions were completely reversible; and (v) the reaction system was homogeneous at all degrees of conversion.

Integrating (3) and passing to the relations $M_A/M_B = F(m_A/m_B, r_A, r_B)$ for $\Psi > 0.1$, we then obtain[27,28]

$$\lg\frac{(m_A)_t}{(m_A)_{t=0}} = \frac{r_A}{1-r_A}\lg\left(\frac{m_A}{m_B}\right)_{t=0}\cdot\left(\frac{m_B}{m_A}\right)_t - \frac{1-r_Ar_B}{(1-r_A)(1-r_B)}\lg\frac{(r_B-1)\left(\frac{m_B}{m_A}\right)_t - r_A + 1}{(r_B-1)\left(\frac{m_B}{m_A}\right)_{t=0} - r_A + 1}. \qquad (5)$$

All this work is quite well known. Equations (3)—(5) enable "copolymerisation constants" r_A and r_B to be found from known relations between the composition of the copolymer and that of the substrate. However, what is today called the "Mayo—Lewis scheme" and is used, often thoughtlessly, for the quantitative description of binary copolymerisation is quite different from the original theses[24]. Exaggerating somewhat, we can divide the "scheme" (all in today's interpretation) into the fundamental postulate and the actual scheme. The postulate states that r_A and r_B are actually copolymerisation *constants*, depending neither on the degree of conversion nor on the fine structure of the growing chain end. The actual scheme includes, besides the fundamental postulate, the above five principles, with the automatically satisfied quasi-stationary condition.

However, Mayo and Lewis emphasised the arbitrariness of this scheme. With regard to the fundamental postulate, they spoke in general not of copolymerisation "constants" but of activity ratios, which is far more to the point. It is necessary in principle to take into account the possible effect on these ratios of the fine structure of the chain end, i.e. the influence of the nature of penultimate and more remote units (this aspect has since been examined in detail in a series of papers by Ham and his coworkers). Nor can special modes of copolymerisation be excluded, in which the activity ratios change during the process

(these questions have already been reviewed in detail[31], so that here we shall be only incidentally concerned with them).

A roughly similar situation is found with the actual scheme. Even when the fundamental postulate is satisfied, the scheme as a whole may diverge sharply from the "canonical conditions" with non-observance of principle (v). Again, as early as the 1940s papers by Mayo[24], Ham[29], and Smith[30] specially stipulated that the appearance of phase heterogeneity in a system may cause strong departures from the laws of a homophase process, when it becomes problematical whether Eqns. (3)—(5) are satisfied. These papers were developed in later publications by Mayo and Ham (see monograph[27]). Even the observance of quasi-stationary conditions is complicated in two-phase systems (Ref. 8, Chapter VI).

Nevertheless, the number of publications in which the authors use the "Mayo—Lewis scheme", without settling the question of its applicability to the specific process, is continually increasing. We have already noted[31] that this is explained to some extent by the fact that the processing of experimental data in the form $M_A/M_B = F(m_A/m_B)$ by means of Eqns. (3)—(5) is not "self-checking", for it is relatively insensitive to the appearance of any anomalies in the copolymerisation.

It was shown experimentally[32] that the presence of polytetrafluoroethylene affects the composition of the macromolecules formed by the copolymerisation of styrene (A) with acrylonitrile (B) even at $\Psi < 0.03$, which was explained by selective solvation of the monomers on the polytetrafluoroethylene surface. On addition of a precipitant the transition to heterophase conditions of copolymerisation was accompanied by the appearance of macromolecules differing in composition from that calculated by means of formula (3) with values of r_A and r_B for the homophase process. Ryabov et al.[33,34] obtained products differing in composition by the block and by the suspension copolymerisation of methyl methacrylate (A) with methacrylic acid (B): in the block $r_A = 0.35 \pm 0.01$ and $r_B = 1.63 \pm 0.12$, but in suspension copolymerisation $r_A^* = 0.63 \pm 0.02$ and $r_B^* = 1.07 \pm 0.13$ (here and subsequently an asterisk (*) will mean that the quantity has been obtained by the formal application to a heterophase process of relations valid for the homophase process). These workers established that during suspension copolymerisation the copolymer is enriched in component A, the effect increasing with dilution of the suspension, which may be explained by preferential dissolution of component B in water, and thus be decrease in the effective concentration of methacrylic acid in the reaction zone.

Plate and Uzhinova[35] found that, in the copolymerisation of styrene (A) with methyl methacrylate (B) initiated by an activated sodium chloride surface, the values of $r_A^* = 1.40$ and $r_B^* = 0.30$ obtained did not correspond to the values $r_A = 0.46$ and $r_B = 0.52$ for the homogeneous process. This difference is especially significant because, in contrast to homogeneous copolymerisation, the system with the first pair of values has no azeotropic point. These results were explained by preferential adsorption of styrene on the sodium chloride surface, which they relate to features of the electronic interaction between the styrene radical and the surface. A transition from a system with an azeotropic point to one without it has been shown for the copolymerisation of methyl methacrylate (A) and methacrylic acid (B): in dioxan $r_A = 0.96 \pm 0.50$ and $r_B = 0.19 \pm 0.06$; in water (heterophase process) $r_A^* = 5.80 \pm 0.50$ and $r_B^* = 0.15 \pm 0.06$.

If, however, calculations are based on true monomer concentrations in the reaction zone, the heterophase copolymerisation conforms to the "classical" scheme in cases in which the fundamental postulate holds. This has been shown e.g. in the radiation gas-phase copolymerisation of acrylic acid and styrene on a polypropylene fibre[36], when r_A and r_B were calculated from the true concentrations of the monomers in the reaction zone. The necessity of allowing for the redistribution of monomer concentrations in two-phase copolymerisation has been pointed out also by one of us (Ref. 8, Chapter VI) in a discussion of certain features of the polymerisation of acrylonitrile in aqueous dispersion and the block copolymerisation of methyl methacrylate and methacrylic acid.

Herma[37] notes a change in the (apparent) relative reactivity on passing from homophase to heterophase systems in the case of the copolymerisation of acrylonitrile with acrylic and methacrylic acids in the mass, in dimethyl sulphoxide, and in other solvents. Roskin et al.[38] find relative reactivities to be unchanged on passing from a homophase to a two-phase system in the copolymerisation of methylallyl chloride with acrylonitrile. They reach the same conclusion in an investigation of the copolymerisation of acrylonitrile (A) with allylic amines (B) in a block, in benzene (heterophase process), and in dimethyl sulphoxide (homophase process)[39]. The constants Q and e in the Alfrey—Price equation were calculated from the values obtained for r_A^* (with r_B^* equated to zero). In a slightly later paper[40] on the copolymerisation of acrylonitrile (A) with bicyclo[2,2,1]heptenedicarboxylic acid and its anhydride in various media these workers give values for r_A^* (always on the assumption that $r_B = r_B^* = 0$): in benzene 3.36 ± 0.37 from analytical data for nitrogen and 3.51 ± 0.35 in radioactive tracer experiments; in dimethylformamide $r_A = 3.63 \pm 0.31$; in the mass $r_A^* = 3.41 \pm 0.41$; in water $r_A^* = 2.02 \pm 0.38$; and in aqueous sodium thiocyanate $r_A = 3.81 \pm 0.31$. For certain points the formal application of the Mayo—Lewis equations gave the definitely absurd results (as pointed out by the authors themselves) of $r_A^* < 0$.

In the copolymerisation of acrylonitrile with salts of allylamines and methylallylamines[40,41] r_A^* and r_B^* are independent of the degree of conversion, but on the other hand depend on the dielectric constant of the medium (copolymerisation was conducted in the mass, in benzene, and in water). It was also found that $r_A^* \neq r_A$ and $r_B^* \neq r_B$, where r_A and r_B were determined for the homogeneous process (in dimethylformamide and in dimethyl sulphoxide)[42].

The pH dependence of the composition of vinyl acetate—acrylonitrile copolymers is attributed[43] to redistribution of the concentrations of the two monomers on particles of the resulting copolymer.

Bender[44] studied the copolymerisation of butadiene (I) with vinyl (II), isopropenyl (III), and α-phenylvinyl (IV) acetates in an emulsion. Copolymerisation in the I—II and I—III systems gives low yields, and the copolymer macromolecules contain small quantities of components II and III. Copolymerisation in the I—IV system goes to considerably higher degrees of conversion, which was explained by enhanced resonance stabilisation of α-phenylvinyl acetate (in comparison with the monomers II and III) due to the α-phenyl group.

Korshak et al.[45] have investigated the copolymerisation of butadiene with isopropenylcarborane at high temperatures. They find differences in the kinetics of the process

and in the compositions of the macromolecules formed compared with the heterophase emulsion copolymerisation of the same monomers.

Brandrup[46] finds that the copolymerisation of acrylonitrile with acrylates in solution and in emulsion yields macromolecules differing significantly in composition.

Japanese workers[47] investigated the heterophase copolymerisation of vinyl chloride with ethylene with and without the addition of 30% aqueous silver nitrate solution. Enrichment of the copolymer with ethylene in the former case was explained by formation of a complex of ethylene with silver nitrate.

Investigation of the copolymerisation of methyl methacrylate with acrylonitrile, acrylic acid, and vinylidene chloride and of vinylidene chloride with acrylonitrile in a precipitant medium (cyclohexane) showed[48] that the kinetics of the process and the composition of the resulting macromolecules were influenced by the nature of the interface.

A study[49] of the copolymerisation of vinyl acetate (A) with diallylcyanamide (B) in an emulsion gave $r_A^* = 0.6$ and $r_B^* = 1.62$. During copolymerisation the monomer B underwent internal cyclisation to form piperidine rings in the framework of the macromolecular chain of the copolymer.

The copolymerisation of acrylonitrile with vinyl sulphone dyes in various solvents is a heterophase process[50], and the composition of the copolymer depends on the physicochemical properties of the solvent.

Ivanov et al.[51] investigated the kinetics of the copolymerisation of 2,3-bisdiethylphosphinobuta-1,3-diene with butadiene and isoprene in the presence of water as catalyst. They give data on the effect on the kinetics of the concentration of water, the composition of the substrate, the pH, and the degree of conversion. Although the separate monomers are incapable of homopolymerisation under the same conditions, copolymerisation is quite rapid, and the composition of the copolymers depends on that of the substrate. The composition data for this heterophase copolymerisation were processed on the basis of the "classical" Mayo—Lewis scheme.

A comparison of the kinetics and the chemical composition of the macromolecules in the homophase and heterophase copolymerisation of acrylonitrile with sodium ethylenesulphonate in aqueous medium at various pH values and in dimethyl sulphoxide achieved the transition from homophase to heterophase process by varying the composition of the initial monomer mixture[52,53]. Later Izumi[54] assessed the effect of the reaction medium on the copolymerisation of acrylonitrile (A) with methyl acrylate in solution (with dimethyl sulphoxide as solvent), in emulsion, and in suspension. The composition of the copolymer for $\Psi < 0.08$ was determined by infrared spectroscopy, by high-resolution nuclear magnetic resonance, and also by analysis for nitrogen. For homophase copolymerisation in dimethyl sulphoxide $r_A = 1.02 \pm 0.02$ and $r_B = 0.70 \pm 0.02$, with heterophase copolymerisation in an emulsion $r_A^* = 0.78 \pm 0.02$ and $r_B^* = 1.04 \pm 0.02$, and in suspension $r_A^* = 0.75 \pm 0.02$ and $r_B^* = 1.54 \pm 0.02$. Tacitly assuming that the "canonical" Mayo—Lewis scheme applied to all the processes investigated, these workers explained the differences in the values of r_A, r_A^* and r_B, r_B^* in terms of the *effective* concentrations of monomers A and B near the macroradical. In the case of suspension copolymerisation it was supposed that the concentration of the sparingly water-soluble methyl acrylate was higher in the dispersed particles than in the substrate. In the case of emulsion copolymerisation the process occurred both in the micelles and in the aqueous phase, which was regarded as explaining the intermediate values of r_A^* and r_B^* in the emulsion, between r_A and r_B in solution and r_A^* and r_B^* in suspension. The Alfrey—Price parameters were calculated from the values found for r_A and r_B as $Q_1 = 0.60$ and $e_1 = 1.2$ for acrylonitrile, and $Q_2 = 0.29$ and $e_2 = 0.62$ for methyl acrylate.

Rafikov et al.[55] found that the copolymerisation of aryldichlorophosphines with butadiene may be either homophase or heterophase depending on the composition of the substrate. Table 1 gives copolymer compositions for various substrate compositions. Careful analysis of these results indicates that formulae (3)—(5) cannot be used to describe the dependence of m_2/m_1 on M_2/M_1. The kinetics of copolymerisation in this system will be discussed later.

Table 1. Composition data for copolymers of aryldichlorophosphines (A) with butadiene (B).

Composition of initial mixture of monomers		Ψ, %	Composition of copolymer	
M_A	M_B		m_A	m_B

0.40	0.60	6.20	0.56	0.44
0.50	0.50	5.05	0.53	0.47
0.60	0.40	4.68	0.55	0.45

Fig. 3 shows composition diagrams[56] for the copolymerisation of methacrylic acid (A) with phenyl methacrylate (B) in benzene alone and mixed with dimethylformamide, the latter at a constant ratio to component A of 3:1. It was found that in benzene $r_A^* = 0.40 \pm 0.14$ and $r_B^* = 0.59 \pm 0.17$, but in its mixture with dimethylformamide the corresponding ratios were 0.21 ± 0.02 and 1.52 ± 0.13. Although r_A^* and r_B^* were assumed to describe the process quite unambiguously, it seems to the Reviewers that the results do not fit the Mayo—Lewis scheme, and this difference in opinion is not merely a matter of taste. In the former case (benzene) departures from the scheme would be due to the heterophase character of the process, but in the latter the relative reactivities of the monomers may actually depend on the benzene : dimethylformamide ratio.

A very interesting study was made by Kargin et al.[57] of the copolymerisation of potassium acrylate (A) with acrylamide as a homophase process initiated by ultraviolet

radiation and hydrogen peroxide and as a heterophase process initiated by hydrogen peroxide in the presence of magnesium oxide or of lead chromate and sodium thiosulphate. In the heterophase copolymerisation enrichment of the copolymer with component A was observed, and was explained by preferential adsorption of potassium acrylate at the solid interface (Fig. 4). Potentiometric titration of the copolymers gave especially interesting results (salt groups in the copolymer had first been converted into acid groups by treatment with hydrochloric acid). With the same mean composition $pK_1 = 4.4597$ in the case of heterophase copolymerisation, but $pK_2 = 4.2760$ in the homophase process. The incontrovertible conclusion was reached that the high value of $\Delta pK = 0.1837$ indicates a significant difference in fine structure between the copolymers obtained under different conditions. Evidence of this is provided also by the pH dependence of the specific viscosity and also directly by the potentiometric titration curves themselves (Fig. 5). A difference in fine structure at the same mean composition implies, of course, a difference in magnitude and character of the inhomogeneity of composition, which is greater in the heterophase than in the homophase process.

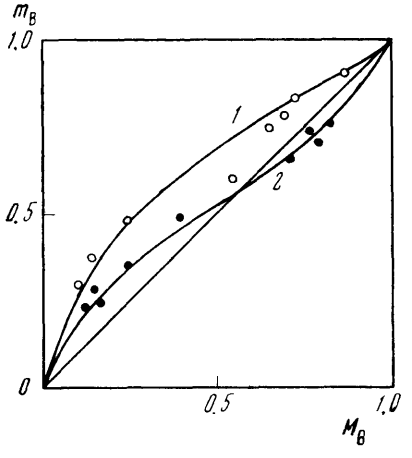

Figure 3. Composition diagrams for the copolymerisation of methacrylic acid (A) with phenyl methacrylate (B) in: 1) benzene–dimethylformamide mixture; 2) benzene.

Here it is opportune to recall certain characteristic differences between the statistical distribution of composition in a copolymer and the molecular-weight distribution in a homopolymer. The molecular-weight distribution is defined unambiguously by a *single* function. One function is, strictly speaking, insufficient for the heterogeneity of composition. The analogue of the molecular-weight distribution is the composition distribution discussed in a previous review[31]. In this case a set of linear chains of the same degree of polymerisation is characterised by their *composition*, not by their fine structure. The fine structure is the second characteristic of heterogeneity of composition. To make clear what we are talking about, we now imagine a set of linear chains having the *same composition* (and also degree of polymerisation, of course). Two limiting fine structures are possible: the alternant copolymer ABABABABABAB... can be regarded as a homopolymer with AB as the repeating unit; the other limiting structure is the block copolymer AAAAAAAA... BBBBBB... . All intermediate forms, while having the same composition (not the mean but the true composition!), will differ in fine structure, i.e. in the distribution of units along the chain†. The fine structure will affect the physicochemical properties of the macromolecules not a whit less—and in many cases more—than will the mean composition.

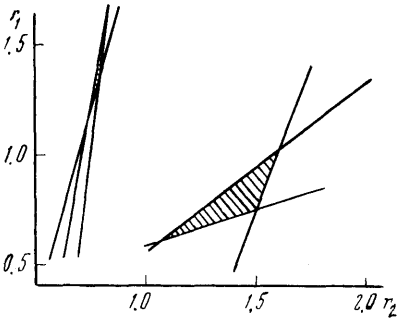

Figure 4. Relative reactivities of potassium acrylate (r_1) and acrylamide (r_2) in homophase and heterophase copolymerisations[57].

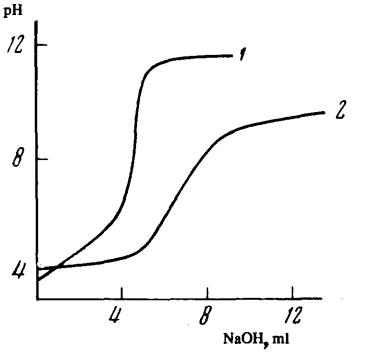

Figure 5. Potentiometric titration curves for saponified copolymers of potassium acrylate and acrylamide having the same composition but obtained by: 1) heterophase copolymerisation; 2) homophase copolymerisation[57].

Supplementing the work cited above[57] we may mention the difference in properties between copolymers of methyl methacrylate and methacrylic acid of the same mean composition obtained by the usual random copolymerisation and by saponification of poly(methyl methacrylate) respectively. In the former case reactivity ratios "work", and

† In conformity with the terminology adopted the distribution of macromolecules having the same composition but differing in fine structure is characterised by the *configurational heterogeneity* function.

the fine structure can be identified by the distribution in the chain of dyads, triads, tetrads, etc. of one of the components, which, of course, depends on the true values r_A and r_B (or their mean values, if they vary with the degree of conversion). In the latter case the fine structure can be characterised in the same way, but the distribution will be purely accidental. In "neutral" solvents like ethyl acetate or dichloroethane such copolymers form "vulcanised" (by hydrogen bonds) molecular loops. A single methacrylic-acid group, a dyad, and a triad are obviously equally effective in forming a "vulcanisation" bond with some distant unit along the chain. But this implies that the efficiency of "ultilisation" of the carboxyls is considerably higher with an absolutely random distribution of units: in a triad, for example, two units are "unemployed". This is shown in the average number of intrachain hydrogen bonds and hence in the tightness of the coil, which can easily be determined e.g. viscometrically.

One of the first qualitative predictions of differences in fine structure between homophase and heterophase copolymerisation based on the "Langmuir" approximation was made in an analysis of the copolymerisation of acrylonitrile with vinyl monomers in aqueous dispersion (Refs.39, 38, and 8, Chapter VI). Because of the redistribution of monomer concentrations in solution and on the surface of the growing polymer particles, with interphase recombinations occurring, the fine structure of the "heterophase" copolymer should contain blocks varying in mean composition.

Quite recently Japanese workers[58] have obtained a similar result directly in the heterophase copolymerisation of acrylonitrile with methyl methacrylate in hexane. The composition of the copolymer inside the deposited particles differed appreciably from that of the macromolecules obtained in homogeneous systems. Since the degree of conversion in this work was sufficiently large (>0.05), the variation with Ψ was allowed for in calculating the theoretical mean composition α.

In a paper mentioned already[51] and also in the more detailed account of this work[59] values of r_A^* and r_B^* were calculated, and the composition of the resulting copolymers was found to depend on the accessibility of the polymerising system to atmospheric oxygen.

IV. SIMPLIFIED MODELS OF HETEROPHASE COPOLYMERISATION

In this Section we try to use model systems, free from additional complications, firstly to establish experimental criteria of the applicability of the canonical Mayo—Lewis scheme to the description of heterophase copolymerisations, and secondly to compare the level of information obtained by determining the mean composition of copolymers and analysing composition distribution curves.

We consider an idealised system[60] in which a transition can occur from homophase to heterophase copolymerisation or conversely. Such a system comprises a pair of monomers having upper and lower consolute temperatures T_{1c} and T_{2c} within a relatively narrow temperature range. Copolymerisation is assumed to be possible both in regions of complete miscibility and between T_{1c} and T_{2c} (Fig. 6). We quite deliberately ignore one of the chief complications that always arise in reality—the appearance of the copolymer, which itself may affect the "phasicity" of the process, as well as the variation in concentration of the comonomers—and assume that the copolymer leaves the reaction zone. The position of the copolymerising system on the phase diagram (Fig. 6) will then be determined solely by the concentrations of unconsumed monomers and by the temperature. With this reservation, the following modes of copolymerisation are possible.

1. Isothermal copolymerisation at constant temperature T_3. We assume the volume of phases I and II to be fixed; $\beta = \beta_3'$ and β_3'' in phases I and II; and both r_A and r_B are constant.

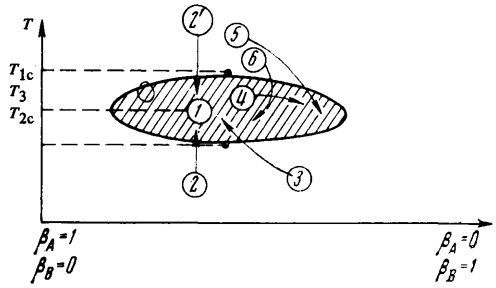

Figure 6. Equilibrium diagram of simplified schemes for the heterophase copolymerisation of partly miscible monomers. The hatched area represents separation of the system into two phases. The numbering corresponds to the models in the text. Models 1, 2, and 2′ are azeotropic processes, with the composition of the substrate remaining unchanged. In the more complicated models 3—6 the arrows indicate the variation in composition of the substrate during copolymerisation. The main explanations will be found in the text.

2. Non-isothermal copolymerisation beginning either below T_{2c} or above T_{1c}, then continuing with rise or fall in temperature respectively, and emerging into the region of phase separation, which occurs at a critical degree of conversion Ψ_c. When $\Psi < \Psi_c$ the process is homophase; when $\Psi \geq \Psi_c$ it is heterophase. We ignore interaction between the phases, and assume as before that both r_A and r_B are constant.

3. A variant of models *1* and *2* complicated by dependence of r_A and r_B on temperature or (alternatively) substrate composition. Interaction between the phases is neglected.

4. A two-phase process from the start, with both r_A and r_B constant. Interaction does occur between the phases, and in the simplest form can be reduced to variation in the volumes v^I and v^{II} and in the compositions β_A^I and β_A^{II} (as a result of mass exchange).

5. Model similar to *4*, but the two-phase process begins at $\Psi = \Psi_c$.

6. Additional complications in comparison with models *4* and *5*, caused by the dependence of the reactivity ratios on temperature and substrate composition: $r_A = r_A(T, \beta)$ and $r_B = r_B(T, \beta)$.

Quantitative treatment of models *4*—*6* requires that definite parameters should be specified for the interaction between phases I and II, which involves fundamental difficulties in attempts to allow for the specific limits of separation on variation of components A and B in the phases. Thus even with the above oversimplifications

(neglect of the effect of the copolymer formed) actual calculations can easily be completed only for the most primitive models *1* and *2*. The analytical expression[61]

$$1-\Psi=\left(\frac{\beta_A}{\beta_A^0}\right)^{\frac{r_B}{1-r_B}}\left(\frac{1-\beta_A}{1-\beta_A^0}\right)^{\frac{r_A}{1-r_A}}\left\{\frac{\beta_A-\dfrac{g(1-r_B)}{1+g-r_A-r_Bg}}{\beta_A^0-\dfrac{g(1-r_B)}{1+g-r_A-r_Bg}}\right\}^{\frac{1-r_Ar_B}{(1-r_B)(r_A-1)}} \quad (6)$$

($\beta_A^0 = \beta_A$ when $\Psi = 0$) will be used to plot composition distribution curves. When $g = 1$, Eqn. (6) passes into Meyer and Lowry's formula[62] for molar composition distribution functions. The instantaneous composition of the macromolecules α_A is connected with the composition of the initial monomer mixture by the relation

$$\alpha_A=\frac{\beta_A^2(r_A-g)+\beta_Ag}{\beta_A^2(r_Bg+r_A-1-g)+\beta_A(1+g-2r_Bg)+r_Bg}. \quad (7)$$

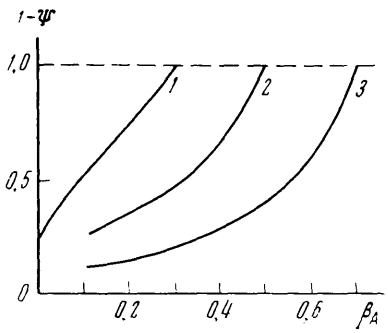

Figure 7. Monomer consumption curves for a model having $r_A = 3$, $r_B = 0.2$, and $g = 1.5$ with different values of β_A^0: 1) 0.3; 2) 0.5; 3) 0.7.[60]

Assuming now for concreteness $r_A = 3.0$, $r_B = 0.2$, and $g = 1.5$,[60] we plot the dependence of $1 - \Psi$ on β_A for several values of β_A^0 (Fig. 7). The integral composition distribution curve can easily be obtained from the composition diagram or by calculating α_A by means of Eqn. (7). (We again emphasise that the formalism involved in reproducing the integral curve takes into account only that "part" of the heterogeneity of composition which is unconnected with the fine structure of the chains.) From the integral curves for various values of β_A^0 it is easy to pass to the superposed integral curves for the heterophase process.

Fig. 8 shows integral composition distribution curves for models *1* and *2*. The substantial difference in corresponding curves is immediately apparent. In conformity with the second of the starting principles of this Section, however, we would like to lay special stress on the negligible difference between these models in the mean composition of the copolymers produced even despite the difference in form of the integral curves—unimodal distribution for the homophase process (curve *1*), and bi- and termodal distributions for the heterophase process (curves *2* and *3*)—and in the degree of heterogeneity of composition.

This is illustrated by Table 2, in which the parameter

$$f=(\bar{\alpha}_z-\bar{\alpha}_w)\bar{\alpha}_w=\left(\frac{\sum_{i=1}^{k}\alpha_i^2w_i}{k}-\sum_{i=1}^{k}\alpha_iw_i\right)\sum_{i=1}^{k}\alpha_iw_i \quad (8)$$

(k is the number of fractions, w_i is the proportion by weight of the ith fraction, and α_i is its weight-average composition) is a statistical measure of the heterogeneity of composition[63].

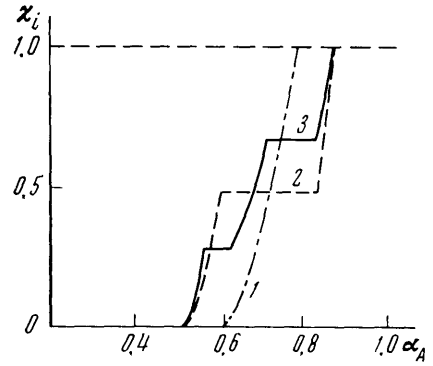

Figure 8. Integral composition distribution curves for copolymerisation: 1) homophase with $\beta_A^0 = 0.5$; 2) heterophase with $\Psi_{cr} = 0$ and $\Psi_I = \Psi_{II} = 0.25$; 3) heterophase with $\Psi_{cr} = 0.2$ and $\Psi_I = \Psi_{II} = 0.15$.

Comparison of the integral curves (Fig. 8) with the data in Table 2 leads to the conclusion[60] that use of the weight-average parameter $(\overline{\alpha_A})_w$ to describe the laws of heterophase copolymerisation may in individual cases produce gross errors. In other words, it is still more inappropriate to examine the heterophase process by means of the formalism developed to describe homophase copolymerisation than formally to process kinetic and statistical data for heterophase polymerisation by means of laws and equations for homophase polymerisation[8].

Table 2. Values of parameter f for certain models of copolymerisation ($r_A = 3$, $r_B = 0.2$, $g = 1.5$, $\Psi = 0.5$).

Process	Wt.-average composition of copolymer α_A	$10^3 f$	Process	Wt.-average composition of copolymer α_A	$10^3 f$
Homophase	0.71	2.4	Homophase for $0 \leqslant \Psi \leqslant 0.2$		
Heterophase $\Psi_{cr} = 0$ $\Psi_I = \Psi_{II} = 0.25$	0.70	19.4	Heterophase $0.2 < \Psi \leqslant 0.5$ $\Psi_I = \Psi_{II} = 0.15$	0.69	13.7

We can illustrate this by analysing the composition diagrams for homogeneous and heterogeneous copolymerisation (Fig. 9). In the heterophase process the position of a point on the composition diagram clearly depends not only on the substrate composition β_A^0 and the initial values of r_A and r_B but also on how and when (Ψ_c) the system separated into phases and on the ratio of the gross rates in each phase V^I/V^{II}. Thus the composition diagram itself is already arbitrary in character. In the simplest

two-phase systems the relation between β_A^I, β_A^{II}, and β_A can be described by the Langmuir adsorption law (see end of Section III).

The need for special caution in interpreting data on composition, kinetics, and molecular-weight distribution for heterophase systems is indicated also be results[64] (Fig. 10) for the effect of additions of zinc chloride complexing agents on the heterophase copolymerisation of acrylonitrile with vinylidene chloride, allyl alcohol, and vinyl acetate. This work is also interesting in that the experimental composition data are formally consistent with the Mayo—Lewis scheme (which applied also to individual points in Fig. 9). The insensitivity to phase separation of the canonical scheme of treating data is further evidence of the limited character of this scheme.

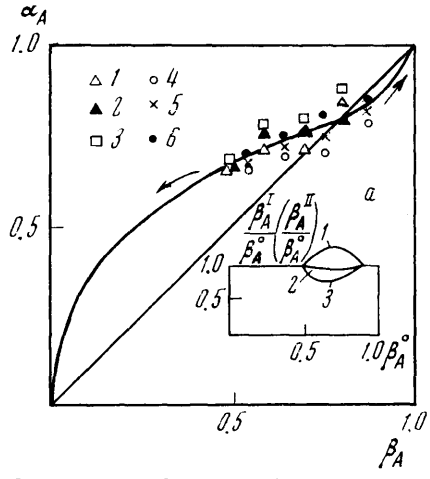

Figure 9. Composition diagrams for homophase (full curve) and heterophase (*a*) models of copolymerisation with $r_A = 0.1$, $r_B = 0.7$, $g = 0.8$, and $\Psi \leq 0.02$: models 1 and 2 with different ratios $(V^I/V^{II})_{\Psi \to 0}$: 1) 0.2; 2) 1.0; 3) 5.0; 4)—6) models 1—3 with the same ratios respectively [sic].

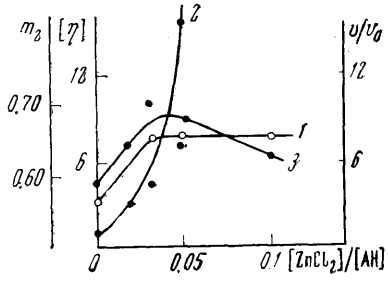

Figure 10. Effect of zinc chloride on heterophase process at 55°C: 1) composition m_2 of copolymer obtained from equimolecular mixture of vinylidene chloride and acrylonitrile (AH); 2) initial rate of copolymerisation; 3) intrinsic viscosity in dimethylformamide[64].

Heterophase copolymerisation is especially interesting at an azeotropic point ($\alpha'_A = \beta'_A$, $r_A < 1$, $r_B < 1$). For a classic homogeneous process the parameter $f = 0$ for $0 \leq \Psi \leq 1$ at an azeotropic point, but in a heterophase process the parameter $f \neq 0$ and should increase with Ψ even when both r_A and r_B are constant. In this case the very shape of the integral composition distribution curve should be unusual, with one branch convex and the other concave. Unfortunately, no work has yet been done which would enable these arguments to be tested.

Finally we note that heterophase copolymerisation would not exhibit a one-to-one correspondence between the individual integral curves, as occurs in classical cases of homophase copolymerisation[65]. This can be seen simply by comparing the composition distribution curves for homophase and heterophase copolymerisation[60].

V. ASPECTS OF THE KINETICS OF HETEROPHASE COPOLYMERISATION

The rates of consumption of monomers A and B in copolymerisations conforming to the complete Mayo—Lewis scheme are given by

$$\left.\begin{aligned} -\frac{dm_A}{dt} &= \frac{I^{1/2}}{\lambda}(r_A m_A^2 + m_A m_B) \\ -\frac{dm_B}{dt} &= \frac{I^{1/2}}{\lambda}(r_B m_B^2 + m_A m_B) \\ -\frac{d(m_A + m_B)}{dt} &= \frac{I^{1/2}}{\lambda}(r_A m_A^2 + 2m_A m_B + r_B m_B^2) \end{aligned}\right\}, \quad (9)$$

$$\lambda = (r_A^2 \delta_A^2 m_A^2 + 2\varphi r_A r_B \delta_A \delta_B m_A m_B + r_B^2 \delta_B^2 m_B^2)^{1/2}, \quad (10)$$

$$\delta_A = \frac{k_{tAA}^{1/2}}{k_{pAA}}; \quad \delta_B = \frac{k_{tBB}^{1/2}}{k_{pBB}}; \quad \varphi = \frac{k_{tAB}}{(k_{tAA} k_{tBB})^{1/2}}.$$

The rate constants for chain growth and termination are defined in terms of the reactions

$$\sim\!\dot{A} + \sim\!\dot{A} - (k_{tAA}) \to P; \quad \sim\!\dot{B} + \dot{B}\sim - (k_{tBB}) \to P;$$

$$\sim\!\dot{A} + \sim\!\dot{B} - (k_{tAB}) \to P; \quad \sim\!\dot{A} + A - (k_{pAA}) \to \sim\!A\dot{A};$$

$$\sim\!\dot{A} + B - (k_{pAB}) \to \sim\!A\dot{B}; \quad \sim\!\dot{B} + A - (k_{pBA}) \to \sim\!B\dot{A};$$

$$\sim\!\dot{B} + B - (k_{pBB}) \to \sim\!B\dot{B},$$

where P denotes a macromolecule. It is immediately apparent from formulae (9)—(10) that knowledge of the parameter λ—and hence also of δ_A, δ_B, and φ—is necessary in order to find the absolute reaction velocities dm_A/dt, dm_B/dt, and $d(m_A + m_B)/dt$. Great difficulty attends the experimental determination of all these quantities[7,8]. Furthermore, it has been shown for several systems that the parameters δ_A, δ_B, and φ themselves—and thus also λ—do not remain constant but are functions of β and Ψ.[66] The latter aspect greatly hinders the processing of kinetic data on random copolymerisation[67].

These difficulties can in considerable measure be eliminated by changing to relative parameters $dM_A/(dM_A + dM_B)$ or $dC_A/(dC_A + dC_B) = \alpha_A$. In fact α_A can be found by separate determination of the rates of consumption of the monomers A and B, while the degree of conversion

$$[(C_A)_{t=0} + (C_B)_{t=0} - (C_A)_t - (C_B)_t]/[(C_A)_{t=0} + (C_B)_{t=0}] = \Psi_t$$

is determined from the kinetic curves without special difficulty. (We recall that all calculations and arguments relate to quasi-stationary processes, when the lifetime τ of the macroradical is far shorter than the time $t_{\Delta\Psi_i}$ during which an increment of polymerisation $\Delta\Psi_i$ is produced[8].) In most real systems the condition $\tau \ll t_{\Delta\Psi_i}$ is satisfied automatically even for very rapid processes[7,67].

Taking this into consideration, we suggested[68,69] bypassing the difficulties of determining absolute rates of polymerisation of monomers A and B by analysing composition distribution curves. This is all the more useful in that the integral curves are themselves most important statistical characteristics of a copolymerisation. Replacement of kinetic by statistical analysis is only possible, of course, in those systems in which the consumption of each monomer can be followed separately.

We shall examine the kinetics of heterophase copolymerisation with such systems as example, and assume that model *2* in Section IV is valid. Unfortunately, no reliable experimental data are available, even for the primitive models *1* and *2*, which would enable specific numerical calculations to be made, so that our discussion must be most general in form. We shall suppose as before that at $\Psi \geqslant \Psi_c$ the consumption of the monomers can be determined separately in both phases. It can then readily be shown that the composition distribution function will be termodal for model *2* and bimodal for model *1*. In fact we use Eqns. (9) to describe the model, and choose the time t_q such that

$$\int_0^{t_q} \frac{I^{1/2}\{r_A[A]^2 + 2[A][B] + r_B[B]^2\}}{\lambda}\,dt = \frac{\{[A]+[B]\}_{t=0} - \{[A]+[B]\}_{t=t_q}}{\{[A]+[B]\}_{t=0}} \leqslant \Psi_c .$$

For $\Psi \leqslant \Psi_c$ we then have

$$-\frac{dA}{dt} = \frac{I^{1/2}\{r_A[A]^2 + [A][B]\}}{\lambda}; \quad -\frac{dB}{dt} = \frac{I^{1/2}\{r_B[B]^2 + [A][B]\}}{\lambda}, \quad (11a)$$

and for $\Psi > \Psi_c$, with copolymerisation occurring independently in phases I and II,

$$-\frac{dA^I}{dt} = \frac{(I^I)^{1/2}}{\lambda^I}\{r_A[A^I]^2 + [A^I][B^I]\}\ ,$$

$$-\frac{dB^I}{dt} = \frac{(I^I)^{1/2}}{\lambda^I}\{r_B[B^I]^2 + [A^I][B^I]\}\ , \quad (11b)$$

$$-\frac{dA^{II}}{dt} = \frac{(I^{II})^{1/2}}{\lambda^{II}}\{r_A[A^{II}]^2 + [A^{II}][B^{II}]\}\ ,$$

$$-\frac{dB^{II}}{dt} = \frac{(I^{II})^{1/2}}{\lambda^{II}}\{r_B[B^{II}]^2 + [A^{II}][B^{II}]\}\ , \quad (11c)$$

and in general $\lambda^I \neq \lambda^{II}$, as was shown experimentally for several systems[67]. If Ψ_c and v_k^I/v_k^{II} are known, and the above conditions (independent of the reactions in the two phases) are satisfied, formulae (11) can be used to obtain the integral composition distribution curves while omitting determination of the difficultly calculable λ, λ^I, λ^{II}, I^I, and I^{II}.

It can reasonably be expected that in real systems the shape of the integral curves will be influenced, in both models *1* and *2*, by monomeric mass exchange between the phases. This may lead to some smoothing of the integral curves. On the other hand, comparison of the integral curves at the same substrate composition but with different values of V, S, V_c, and v^I/v^{II} can give important information on the character of the mass exchange of monomers A and B and also on the properties of the interface. Unfortunately, no reports have been published of the simultaneous determination of rates of consumption of monomers in two phases, simply owing to the experimental difficulties. Furthermore, while the need for such investigations is obvious, little controlled work has been done in this field.

Data are usually available on the total rates of consumption of the monomers, i.e. $d(A^I + A^{II})/dt$ and $d(B^I + B^{II})/dt$. In this case even the change from rate curves to integral composition distribution curves becomes in some measure arbitrary[70,71]. If the volumes of phases I and II are comparable, and the overall rates of copolymerisation do not differ too greatly (roughly $0.2 < V^I/V^{II} < 5$), the integral curves obtained by processing the kinetic curves (for consumption of the monomers) are smoother than the real curves[72]. The main reason is that the instantaneous heterogeneity of composition depends considerably on the ratios

$$\left(\frac{dA^I}{dA^I + dB^I}\right)_{t=t_a}, \qquad \left(\frac{dA^{II}}{dA^{II} + dB^{II}}\right)_{t=t_a},$$

(or the corresponding ratios for the concentrations by weight of the monomers in the two phases, C_A and C_B). This alone suggests that the integral curves obtained from the consumption curves will underestimate the compositional heterogeneity. However, if the difference in the total rates of copolymerisation in the two phases is so large that we can reckon $V^I/V^{II} \gg 1$ or $V^I/V^{II} \ll 1$, good agreement must be expected between the real integral curves and those obtained from the consumption curves.

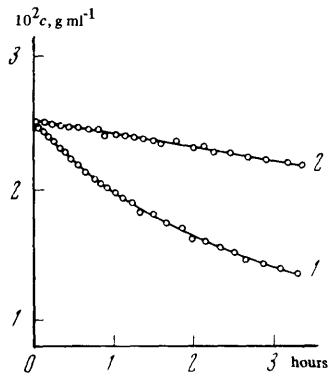

Figure 11. Rate curves for copolymerisation in dioxan with [I] = 0.2 wt.% at 70°C: 1) acrylamide; 2) maleic acid.

Nevertheless, even in the unfavourable range $0.2 < V^I/V^{II} < 5$ the consumption curves—$d(C_A^I + C_A^{II})/dt$ and $d(C_B^I + C_B^{II})dt$—show "anomalies" in heterophase copolymerisation (though not completely, in view of the above). "Anomalies" of this type were recorded[70] for the acrylamide—maleic acid system when the rate curves for copolymerisation in dioxan were analysed (Figs. 11 and 12). The integral curves obtained in this way cannot be defined[70,72] by two fixed copolymerisation constants in the range $1.0 \leqslant r_A < 3.0$ and $0 \leqslant r_B \leqslant 0.2$, which is additional evidence of the "special"[31] character of the copolymerisation of this system. Unfortunately, it was not possible in this work to estimate the time variation in the phase volumes and the overall reaction velocities in them, which limited the "degree of quantitativity" in the assessment of the "anomaly" and the contribution of the two-phase character of the system to it.

Work in which the "phasicity" was changed by varying the composition of a binary solvent is of interest in connection with overcoming (or bypassing) such difficulties. If copolymerisation is a homophase process at certain ratios χ of the components, but a heterophase process at others (beginning with a certain value χ_c), it can reasonably be expected that suitable control of the process variables in the vicinity of χ_c will enable us to judge the effect of adjustable parameters of the heterophase character on the appearance and the development of the "anomaly" in the integral curves. However, even here agreement can be obtained only in single researches.

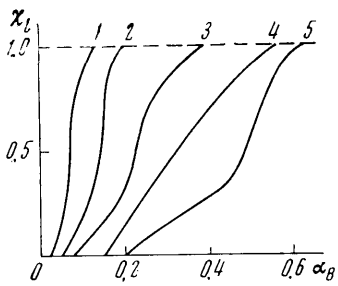

Figure 12. Integral composition distribution curves for copolymers of acrylamide (A) and maleic acid (B) in dioxan for different values of β_A (and Ψ_A): 1) 9 (0.69); 2) 4 (0.37); 3) 1 (0.39); 4) 0.67 (0.37); 5) 0.43 (0.34).

Thus studies[73,74] of the copolymerisation of 5% solutions of acrylamide with maleic acid in aqueous dioxan showed a variation in the relative reactivities of the monomers with change in the composition of the solvent mixtures and the same substrate composition, but apart from this the integral curves, after reaching χ_c, become more diffuse than those for homophase copolymerisation. The appearance of an "anomaly" originating from the heterophase character of the copolymerisation was illustrated[73,74] by analysing the position and shape of the integral curves for the same substrate composition but different values of χ. The parameters f for homophase and heterophase copolymerisation were also compared.

Kinetic anomalies were observed also on passing from a homophase to a heterophase process in work already referred to[55] (we recall that the "phasicity" of the process was determined here by the composition of the substrate). The overall kinetics of copolymerisation was determined dilatometrically, i.e. simultaneously in the two phases. Inversion of the rate was recorded for different substrate compositions (Fig. 13). With all the drawbacks of dilatometry applied to the investigation of multiphase processes, the results are nevertheless extremely significant. As was to be expected, the transition from homophase to heterophase copolymerisation is accompanied by "anomalous" kinetic relations. Similar conclusions can be reached from a careful examination of data in Ref. 75, also obtained in a dilatometric investigation of the copolymerisation of acrylonitrile with styrene.

An unusual form of kinetics was obtained for different substrate compositions (Fig. 14) in work already cited[53,54] on the copolymerisation of acrylonitrile (A) with sodium styrenesulphonate (B) in aqueous medium and in dimethyl sulphoxide. The most probable reason was the occurrence of a heterophase process in aqueous medium at substrate compositions [A] $\gg$ [B] and in dimethyl sulphoxide at [B] ≥ 10[A].

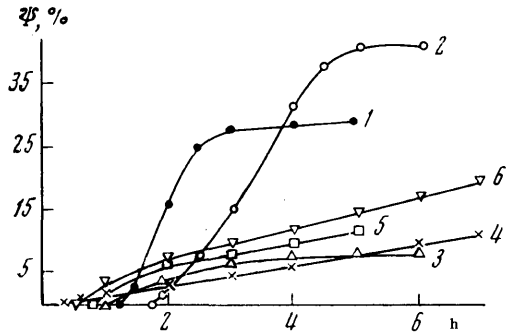

Figure 13. Kinetics of the copolymerisation of butadiene in mixtures with different initial contents (mole %) of phenyldichlorophosphine: 1) 5; 2) 10; 3) 20; 4) 30; 5) 40; 6) 50.

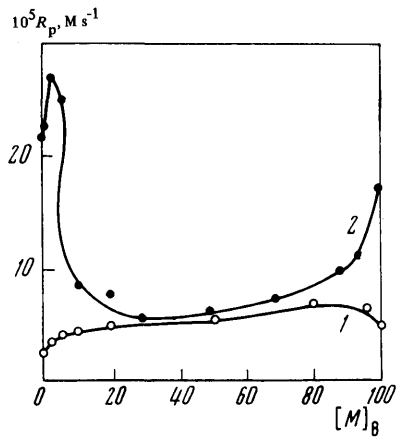

Figure 14. Dependence of initial rate of copolymerisation on composition of initial mixture of acrylonitrile (A) and sodium styrenesulphonate (B) in: 1) dimethyl sulphoxide; 2) aqueous medium at pH 7.

Kabankin et al.[76], in a kinetic investigation of the heterogeneous gas-phase copolymerisation of tetrafluoroethylene with ethylene and hexafluoropropene, were able to monitor the consumption of each monomer during the reaction by a previously developed technique[77,78]. The copolymerisation of ethylene with tetrafluoroethylene was studied also in a solvent, perfluorotriethylamine, when a heterophase process occurred. These workers emphasise that their values of r_A^* and r_B^* are arbitrary, since the true compositions of the initial mixture of monomers would differ from the mean values found from the composition of

the gaseous mixture at certain degrees of conversion. Figs. 15 and 16 illustrate the most typical results of this work. With certain reservations these workers conclude that the Mayo—Lewis scheme can be used to a first approximation for describing the heterogeneous and heterophase copolymerisations examined. In our opinion, however, Fig. 16 indicates rather the converse, i.e. that the "classical" or "canonical" scheme is not applicable to these systems.

---o0o---

We are very far from intending to acknowledge any kind of "blind alley" in the theory of copolymerisation, but nevertheless must remark that the complexity of the determination of heterogeneity—especially of the separate determination of heterogeneity of composition itself and of differences in fine structure—greatly retards the development of theoretical work and to some extent engenders a tendency for calculations to be so approximate that *chemical* features of the process are neglected. With the limited number of examples available to us we have attempted to show that, even when the fundamental postulate (the ratio of reactivities—actually the copolymerisation constants) is satisfied, the Mayo—Lewis scheme may not work for thermodynamic and hence topochemical reasons.

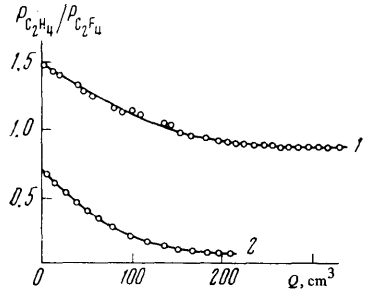

Figure 15. Dependence of relative partial pressures of ethylene and tetrafluoroethylene over perfluorotriethylamine solution on the consumption Q.[76]

On the other hand, both the previous[31] and the present reviews have shown the existence of entirely practicable and quite simple methods for converting "special" copolymerisation into the usual process or for controlling its "phasicity". The problem thus reduces to developing rational methods for analysing compositional heterogeneity and the fine structure. In this respect the position has improved in comparison with that reported previously[31]. For the first time compositional heterogeneity has been determined by rapid sedimentation with the use of two optical systems[79]. Inagaki[80] and Belen'kii et al.[81] have demonstrated quite convincingly the possibility of determining the *continuous* composition distribution function for copolymers by thin-layer chromatography. This method combined with gel chromatography and hydrodynamic experiments of the type described in Section IV may prove extremely sensitive also to the fine structure.

If the problem of the quantitative determination of heterogeneity of composition is solved—and there is every ground for hoping that this will occur in the near future—the statistical theory of copolymerisation may be expected to undergo the same improvements as occurred in the theory of homopolymerisation after reliable methods were developed for the analysis of molecular-weight distributions.

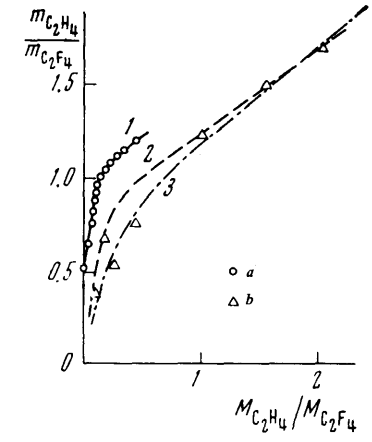

Figure 16. Composition diagrams for copolymers of ethylene and tetrafluoroethylene formed in: *a*) perfluorotriethylamine; *b*) gas phase. Theoretical composition curves for various values of $r_{C_2H_4}$ (and $r_{C_2F_4}$): 1) 0.61 (0.024); 2) 0.38 (0.10); 3) 0.46 (0.25).[76]

Certain polycondensation processes, especially interphase copolycondensation, are of interest in connection with "intervention" in the process and the simulation of copolymerisation. In this case problems of "phasicity" are solved relatively easily[82,83], and actual simulation can be achieved by suitable choice of difunctional reactants. Systems of this type are convenient also for the special investigation of processes developing in thin layers on one or other side of the interface[84].

Irrespective of how and when all these experimental problems will be solved, full responsibility can now be taken for stating that it is impossible to reach any quantitative conclusions from an analysis of the mean compositions of copolymers: this parameter is completely insensitive (cf. Table 2) to detailed kinetics and to any departures from the canonical scheme. Only analysis of heterogeneity of composition can give a complete idea of the mechanism of the process.

Consequently the attempts to reduce the reactivity of monomers to Alfrey—Price parameters determined from the equilibrium diagrams, still appearing in the literature, must be treated with great caution, and the use of copolymerisation as a *method* of analysing the activity of monomers in homopolymerisation must be approached with still greater caution and circumspection (the analysis of heterophase copolymerisation is, of course, implied).

At the same time we would like to direct the attention of investigators to interesting studies of the heterophase copolymerisation of styrene with acrylonitrile by Mino[85]

and with vinylidene cyanide by Gilbert, Miller, et al.[86] From an analysis of the composition distribution curves obtained by preparative fractionation the extremely significant conclusion was reached that copolymers obtained in a heterophase system show greater non-uniformity of composition than do those prepared under homogeneous conditions. The use of specially selected solvent–precipitant systems sensitive to the composition of the copolymer macromolecules[87,88] enables us to hope that information will be obtained on interphase interactions during synthesis. It would be especially interesting to isolate the copolymer separately from phases I and II, and to fractionate the two specimens. Such experiments are entirely practicable, at least for certain models of heterophase copolymerisation.

We would also like to emphasise that the conditions under which copolymerisation occurs need to be specified in works of reference, and in particular that it should be mandatory to indicate the "phasicity" of the process.

Electrochemical Initiation of Polymerisation

G.S.Shapoval and A.V.Gorodyskii

Publications on the electrochemical initiation of polymerisation are surveyed, and methods are classified on the basis of the mechanism of the electrode reaction in which active centres are formed and the mechanism of growth of the polymer chain. The laws of the electrochemical initiation of radical and ionic polymerisation are analysed, and the advantages and prospects of the latter are shown. The features and possibilities of electrochemical initiation, leading to the formation of linear and network polymers, are examined on specific examples. A list of 138 references is included.

I. INTRODUCTION

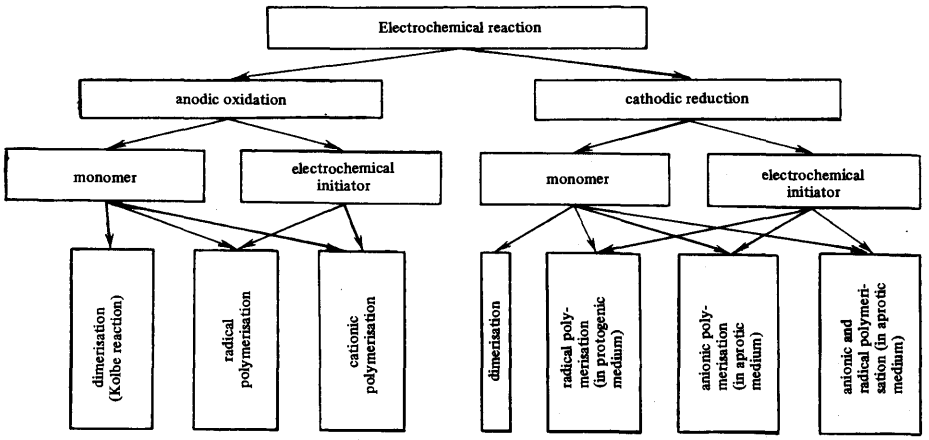
It was established long ago[1] that organic radicals could be formed during electrochemical oxidation or reduction. However, the use of such radicals to initiate polymerisation came only during recent years.

In 1939 Wilson[2] pointed out that reduction by alkali metals occurs in the same way as reduction at a cathode surface, and he suggested that electrochemical initiation of polymerisation was possible. Ten years later Dineen, Schwan, and Wilson[3,4] observed that, at a mercury cathode in acid medium, unsaturated compounds undergo hydrogenation with great difficulty, whereas they are rapidly polymerised. The advantages of such a process are obvious: the species responsible for initiating polymerisation are formed by an electrode reaction, so that the rate of initiation can be controlled very simply by varying the current density. It can be maintained constant or varied in pulses, which may yield a polymer having a narrow molecular-weight distribution.

Published information[5-8] indicates that electrochemical initiation may play a significant part in the solution of such important problems of polymer chemistry as the orientation of molecules during chain growth (stereoregulation), the creation of mild conditions of polymerisation, and the absence from the polymer of initiator fragments, which might in time cause degradation of the latter[9].

By no means all the potentialities of electrochemical initiation have been studied. Obviously for this reason it has not yet become so widespread as other, less controllable methods of initiation. However, the progress which has been achieved in replacing chemical initiation of the polymerisation of certain monomers, in particular halogenated alkenes[6,7], and the possibility of obtaining crystalline polymers during electrolysis[5,10], provide grounds for believing in the prospects for electrochemical initiation. This is perhaps the only electrochemical process in which considerably more than one mole of substance is transformed per faraday of electricity. The efficiency of the electrochemical reaction can be measured by the mean molecular weight of the resulting polymer.

A considerable number of publications have now appeared on the electrochemical initiation of polymerisation, but, apart from brief surveys mainly of the radical polymerisation of certain monomers[11-13], of dimerisation[14], and of a very narrow field[15], no papers of a review character have been published. Nevertheless, Breitenbach[16-18], Funt[19-23], Yamazaki[24], Parravano[25], and Soviet workers[26,27] have recently reported investigations of the electrochemical initiation of ionic polymerisation, in particular the preparation of "living" polymers[22-27]. Careful analysis of work on electrochemical initiation is urgently necessary in order to discuss the possibilities, merits, and defects of this method.



The polymer chain grows by a radical or an ionic mechanism depending on the conditions, and is little affected by whether initiation is electrochemical or chemical. The character of electrochemically initiated polymerisation is primarily determined by the mechanism and the rate of the electrode reaction. In the present Review, therefore, attention will be paid mainly to investigations of the mechanism and the kinetics of the electrode process and of the accompanying chemical reactions. From these data we can predict the yield of initiating species and of byproducts (resulting from dimerisation or complete reduction of the double bond), the accumulation of which prevents polymerisation.

II. CLASSIFICATION OF METHODS FOR THE ELECTROCHEMICAL INITIATION OF POLYMERISATION

Methods of electrochemical initiation can conveniently be classified according to the type of electrode process producing the initiating centres and according to the mechanism of growth of the polymer chain. Thus, depending on the type of electrode process, initiation is either anodic or cathodic; and according to the electrochemical reaction used initiation can occur either by (*a*) direct reduction or oxidation of the monomer or (*b*) oxidation or reduction of the electrochemical initiator, i.e. the compound whose anodic oxidation or cathodic reduction forms radicals or radical-ions capable of initiating polymerisation[10]. Radical and ionic (cationic or anionic) polymerisation processes are distinguished by the mechanism of chain growth. On the basis of this classification, Scheme I represents the types of electrochemical processes that have now been used for the initiation of polymerisation.

Thus the electrochemical reaction is usually a one-electron transition involving either the monomer or the electrochemical initiator. As a result active centres are formed on the electrode surface, and these are capable of

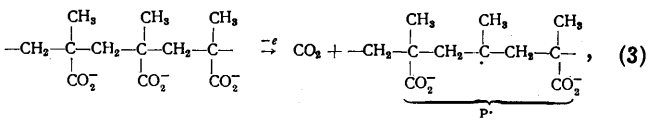
Scheme I

initiating either ionic or radical polymerisation depending on the conditions.

1. Anodic Oxidation

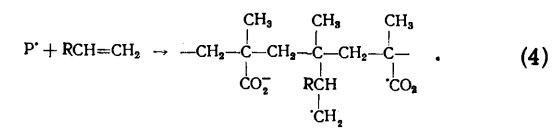
The direct electrochemical oxidation of organic compounds, in particular of carboxylate anions

$$C_nH_{2n+1}C(=O)O^- \rightarrow e \rightarrow C_nH_{2n+1}C(=O)O^{\cdot}\ , \qquad (1)$$



$$C_nH_{2n+1}C(=O)O^{\cdot} \rightarrow C_nH_{2n+1}^{\cdot} + CO_2\ , \qquad (2)$$

forms alkyl or alkanoxyl radicals, which then dimerise[1]. This is a particular case of electrochemical initiation—the Kolbe reaction, which has long served as a method for lengthening aliphatic hydrocarbon chains[28,29].



If the anodic oxidation of carboxylic acids or their salts is conducted in the presence of monomers, under appropriate conditions the radicals formed can initiate the radical polymerisation of such monomers as styrene, butadiene, isoprene, vinyl acetate, methyl methacrylate, and vinyl chloride[30-38]. Here the aliphatic acids and their salts undergoing oxidation at the anode are the electrochemical initiators.

Salts of metals of variable valency, in particular nickel(II) and manganese(II), can also be used as electrochemical initiators during anodic oxidation; Koval'chuk suggests[39,40] that during their electrolysis polymerisation is initiated by π-complexes with the monomer (e.g. acrylamide) of the metal in a higher valency state. Formation of such complexes is most probable on the adsorption at the electrode surface of a monomer whose double bond is polarised. Polymerisation can be initiated also by electrochemical oxidation of the sulphate anion, which may yield the radical-anion $SO_4^{\cdot-}$, capable of initiating polymerisation[41].

The use of macromolecular acids as electrochemical initiators is of undoubted interest. Thus the macroradicals of polymethacrylic acid obtained by anodic oxidation are able to interact with monomers[42]:

(3)

(4)

Such a reaction opens up great opportunities for modifying polymers[42,43].

In 1955 a method for the electrochemical initiation of the polymerisation of aliphatic halogenoalkenes was patented in Federal Germany[6,7].

The polymerisation of tri- and tetra-fluoroethylene initiated by peroxides takes place at high pressures (up to 100 atm) and temperatures (up to 100°C). Electrochemical initiation enables the process to be conducted at normal pressure and temperatures below 0°C. This eliminates the possibility of an explosive reaction, which at high temperatures may be caused by hot spots. Polymerisation is initiated by radicals formed at the anode during electrolysis, by $F^{\cdot}$ in hydrogen fluoride and by $CF_3^{\cdot}$ in trifluoroacetic acid. Low current densities enable the radicals to react with the monomer:

$$CF_3^{\cdot} + CF_2{=}CF_2 \rightarrow CF_3{-}CF_2{-}CF_2^{\cdot}\ . \qquad (5)$$

At low temperatures and high monomer concentrations chain growth can then occur with formation of a product of relatively high molecular weight[7].

If the radical formed by oxidation of the electrochemical initiator possesses high electron affinity, it may oxidise the monomer, which will lead to the initiation of cationic polymerisation[17].

2. Cathodic Reduction

A cathodic process results in formation of the initiating species both by direct reduction of the monomer and by reduction of the electrochemical initiator. The mechanism of growth of the polymer chain depends on the conditions. Thus direct electrochemical reduction of a monomer in a protogenic medium leads to formation of a radical (a protonated radical-anion) that initiates radical polymerisation[44-49], whereas in an aprotic medium anionic polymerisation takes place[5,17-22,50-53]†. Furthermore, simultaneous growth of the polymer chain by anionic and radical mechanisms is also possible during the early stages in an aprotic medium[8,20]. In several cases either an anionic or a mixed mechanism can be realised by conducting polymerisation in an aprotic medium and using cathodic reduction of an electrochemical initiator, in particular an alkali-metal ion[20].

The first electrochemical initiator of radical polymerisation to be used was the hydrogen ion[3,4,54,55], which on cathodic reduction causes the polymerisation of such monomers as methyl methacrylate, acrylic acid, vinyl acetate, etc.[56,57] According to the recombination theory of hydrogen overpotential[58] the efficiency of initiation depends on the electrode material and is a function of the overpotential[54]. Parravano[54,56] suggested that the initiating action of hydrogen atoms obtained electrolytically was analogous to their behaviour when adsorbed on a metal surface:

$$MH + R \rightarrow {}^{\cdot}RH + M \quad (6)$$

Mairanovskii[59] showed that a more probable mechanism in acid media is reduction of an already protonated monomer molecule, which as a result of the electrochemical process becomes the initiating agent[60,61]:

$$RH^+ + e \rightarrow {}^{\cdot}RH \quad (7)$$

This mechanism is supported by a phenomenon observed in the polarographic investigation of acrylamide[62]. This compound facilitates the electrochemical reduction of hydrogen, whose half-wave potential becomes more positive in the presence of this monomer, whereas that of acrylamide itself is independent of pH.[63] Thus, in the formation of a radical capable of initiating polymerisation, it is not the proton but the complex RH^+ that is reduced:

$$H^+ + R + e \rightarrow {}^{\cdot}RH \quad (8)$$

On the basis of views developed by Antropov[64] it can be concluded that the potential-determining stage is reaction (8), whose rate, according to the slow discharge theory[58], is given by

$$i = kC^S_{H^+}C^S_R \exp\left(-\frac{\alpha nFE}{RT}\right) \quad (9)$$

where i is the current, k is the rate constant of reaction (8), $C^S_{H^+}$ and C^S_R are the surface concentrations of protons and of acrylamide, α is the transfer coefficient of the electron (~ 0.5), F is Faraday's constant, and $n = 1$ is the number of electrons. Since the hydrogen diffusion current i_d remains unchanged in the presence of acrylamide, a definite concentration of the monomer, proportional to its concentration C_R in the solution, can be assumed to be present on the electrode surface:

$$C^S_R = k'C_R . \quad (10)$$

Then

$$E = E_0 + \frac{2RT}{F}\ln\frac{C_{H^+}}{i_d} + \frac{2RT}{F}\ln k'C_R - \frac{2RT}{F}\ln\frac{i}{i_d - i}, \quad (11)$$

whence

$$E = E_{1/2} + 0.118\lg\frac{i}{i_d - i}, \quad (12)$$

where

$$E_{1/2} = \text{const} + 0.118\lg C_R. \quad (13)$$

The experimental slope of this relation is close to the theoretical value (0.125 and 0.118 respectively).

The electrochemical reduction of oxygen can be used to initiate radical polymerisation[65]. Fedorova et al.[65] showed that the first stage involves the formation of hydrogen peroxide:

$$O_2 + e + H^+ \rightarrow HO_2^{\cdot}, \quad (14)$$

$$HO_2^{\cdot} + e + H^+ \rightarrow H_2O_2 . \quad (15)$$

This is then reduced to water:

$$H_2O_2 + e \rightarrow {}^{\cdot}OH + HO^-, \quad (16)$$

$$HO^- + H^+ \rightarrow H_2O, \quad (17)$$

$${}^{\cdot}OH + e + H^+ \rightarrow H_2O . \quad (18)$$

The radical $HO^{\cdot}$ formed as intermediate is able to initiate the polymerisation of methyl methacrylate and other derivatives of acrylic acid[66].

Radical polymerisation in aqueous medium can be initiated by a redox system in which the product of the cathodic reduction of one component reacts with the second component to form the initiating radicals[66]. An example is the cathodic reduction of tervalent iron in the presence of a peroxide:

$$Fe^{3+} + e \rightleftarrows Fe^{2+}, \quad (19)$$

$$Fe^{2+} + H_2O_2 \rightleftarrows Fe^{3+} + OH^- + {}^{\cdot}OH, \quad (20)$$

or

$$Fe^{2+} + S_2O_8^{2-} \rightleftarrows Fe^{3+} + SO_4^{2-} + SO_4^{\cdot-}, \quad (21)$$

The radical $HO^{\cdot}$ and the radical-ion $SO_4^{\cdot-}$ are able, as Kolthoff showed[66], to initiate the polymerisation of acrylic monomers:

$${}^{\cdot}OH + R \rightarrow HOR^{\cdot}, \quad (22)$$

$$SO_4^{\cdot-} + R \rightarrow {}^{-}SO_4 - R^{\cdot} . \quad (23)$$

Furthermore, a redox system can be established in which a cathode acts as reductant, while the oxidant is converted during reduction into an active polymerisation initiator[67,68]. The advantage of such a system in comparison with the preceding system is the possibility of controlling the rate of formation of initiating centres by eliminating intermediate stages.

Thus quite a wide range of reactions can now be used for the electrochemical initiation of polymerisation.

Since one of the main advantages of electrochemical initiation is the possibility of controlling the rate of polymerisation by varying the current density, we must

† The radical mechanism suggested originally[52,53] for the polymerisation of acrylonitrile in an aprotic medium with electrochemical initiation was subsequently revised. The absence of an inhibiting effect by diphenylpicrylhydrazyl and also experiments on the copolymerisation of acrylonitrile (study of the composition of the copolymers) established that polymerisation takes place by an ionic mechanism under these conditions[16,17].

examine in greater detail how this possibility is realised, starting not only from the mechanism of the electrode process but also from that of polymerisation as a whole.

III. RADICAL POLYMERISATION

1. Direct Electrochemical Reduction (Oxidation) of the Monomer

The simplest case of the electrochemical initiation of radical polymerisation in a protogenic solvent is direct cathodic reduction of the monomer. The first stage in this process is the actual electrochemical formation of the radicals capable of initiating polymerisation:

$$R + e + H^+ \underset{k_2}{\overset{k_1}{\rightleftarrows}} HR^{\cdot} . \qquad (24)$$

The rate of reaction (24) can be expressed[69] in terms of the current:

$$v = \gamma i = k_1 [R][H^+] \exp\left(-\frac{\alpha\varphi F}{RT}\right) - k_2 [{}^{\cdot}RH] \exp\frac{\beta\varphi F}{RT} , \qquad (25)$$

where φ is the electrode potential, α the transfer coefficient of the electron for the cathodic process, $\beta = 1 - \alpha$ the transfer coefficient for the anodic process, and γ (moles amp^{-1} cm^{-1} s^{-1}) a coefficient of proportionality. Formation of ·RH radicals is immediately followed by three parallel reactions, whose rates are limited by the rate of generation of these radicals—(i) recombination of the radicals on the electrode surface

$$ {}^{\cdot}RH + {}^{\cdot}RH \underset{k_4}{\overset{k_3}{\rightleftarrows}} HR{-}RH , \qquad (26)$$

at a rate

$$v_1 = k_3 [{}^{\cdot}RH]^2 - k_4 [H{-}R{-}R{-}H] ; \qquad (27)$$

(ii) further electrochemical reduction of ·RH at the same potential (an organic radical undergoes electrochemical reduction more readily than does the molecule from which it has been formed[70])

$$ {}^{\cdot}RH + e + H^+ \underset{k_6}{\overset{k_5}{\rightleftarrows}} RH_2 , \qquad (28)$$

at the rate

$$v_2 = \gamma i_2 = k_5 [{}^{\cdot}RH][H^+] \exp\left(\frac{-\alpha\varphi F}{RT}\right) - k_6 [RH_2] \exp\frac{\beta\varphi F}{RT} ; \qquad (29)$$

(iii) actual initiation of polymerisation—reaction of HR· with the monomer

$$HR^{\cdot} + R \underset{k_8}{\overset{k_7}{\rightleftarrows}} HR{-}R^{\cdot} , \qquad (30)$$

at the rate

$$v_3 = k_7 [{}^{\cdot}RH][R] - k_8 [{}^{\cdot}R{-}RH] . \qquad (31)$$

Since reactions (24), (26), (28), and (30) are irreversible[71,72], so that $k_2 = k_4 = k_6 = k_8 \to 0$, the second term on the right-hand side of Eqns. (25), (27), (29) and (31) can be neglected.

Thus, under otherwise similar conditions, both the actual rate of initiation and the yield of polymer depend on the rates of reactions (24) and (30), which in turn are determined by the electrode potential φ, the concentration of active centres HR·, and the concentration of the monomer R. However, increasing the rate of reaction (24) by raising the electrode potential (increasing the current density) leads to the accumulation of radicals HR· on the electrode surface, i.e. to an increase in the rates of reactions (26) and (28), which result in deactivation of the initiating species and hence decrease the rate of initiation and the polymer yield (after a certain time of electrolysis).

Radicals formed by cathodic reduction tend to be adsorbed, as a consequence of the presence of the unpaired electron[73]. The monomer can be assumed to react with the radical on the electrode surface, occupying unfilled sites on the latter. We express the surface concentration of radicals HR· in terms of the surface coverage θ, and that of the monomer [RS] in terms of its bulk concentration [R] and surface coverage:

$$[{}^{\cdot}RH] = f\theta , \qquad (32)$$

$$[R_S] = \varkappa [R](1-\theta) , \qquad (33)$$

where f and κ are proportionality coefficients. Equating to zero the second terms in Eqns. (25), (27), (29), and (31), and substituting for [·RH] and [RS], we obtain

$$v = k_1^* [R](1-\theta)[H^+] \exp\left(-\frac{\alpha\varphi F}{RT}\right) ,$$

$$v_1 = k_3^* \theta^2 , \qquad (35)$$

$$v_2 = k_5^* \theta [H^+] \exp\left(-\frac{\alpha\varphi F}{RT}\right) , \qquad (36)$$

$$v_3 = k_7^* \theta (1-\theta)[R] , \qquad (37)$$

where the k^* are rate constants allowing for f and κ.

The yield η of the polymer can be written provisionally as the ratio of the rate of reaction (30) to the sum of the rates of the parallel reactions (26), (28), and (30):

$$\eta = \frac{v_3}{v_1 + v_2 + v_3} . \qquad (38)$$

Then

$$\eta = \frac{k_7^* (\theta)(1-\theta)[R]}{k_3^* \theta^2 + k_5^* \theta [H^+] \exp\left(-\frac{\alpha\varphi F}{RT}\right) + k_7^* \theta (1-\theta)[R]} = \frac{k_7^* (1-\theta)[R]}{k_3^* \theta + k_5^* [H^+] \exp\left(-\frac{\alpha\varphi F}{RT}\right) + k_7^* (1-\theta)[R]} . \qquad (39)$$

Or, starting from formulae (25), (27), (29), and (31) with the assumptions adopted, we have

$$\eta = \frac{k_7 [{}^{\cdot}RH][R]}{k_3 [{}^{\cdot}RH]^2 + k_5 [{}^{\cdot}RH][H^+] \exp\left(-\frac{\alpha\varphi F}{RT}\right) + k_7 [{}^{\cdot}RH][R]} = \frac{k_7 [R]}{k_3 [{}^{\cdot}RH] + k_5 [H^+] \exp\left(-\frac{\alpha\varphi F}{RT}\right) + k_7 [R]} . \qquad (40)$$

Equations (39) and (40) show that the yield of polymer decreases with increase in electrode potential, the hydrogen-ion concentration, the free-radical concentration, and hence the surface coverage of the electrode. In fact the dependence of polymer yield on current density obtained by Funt[74] for the electrochemical initiation of the polymerisation of *N*-vinylpyrrolidone approaches zero asymptotically (Fig. 1). The dependence of polymer yield on monomer concentration established in this work (Fig. 2) also agrees well with Eqn. (40).

It is easy to show that, since the rate constant of the recombination of radicals k_3 is usually $\sim 10^7$–10^8 M^{-1} s^{-1},[72] the yield of polymer is insignificant even at low current densities. This is confirmed also by experimental results obtained by Dineen et al.,[3] Palit and Das[56], and Parravano[54] for the cathodic initiation of the polymerisation of various derivatives of acrylic acid, and also by Funt for the electrochemical initiation of the polymerisation of *N*-vinylpyrrolidone[74].

The radical polymerisation of acrylamide also proceeds similarly during its direct electrochemical reduction[45]. Two schemes were suggested to describe the mechanism, and explained satisfactorily the observed reactions of acrylamide (R). According to the first scheme (II) the interaction of two radical-anions leads to anionic polymerisation, which can develop only in an anhydrous medium. According to the second scheme (III) addition of a proton leads to formation of the radical HR$^{\cdot}$, which is capable either of initiating polymerisation or of recombining with formation of a dimer. Experiment showed[46] that the yield of polymer was negligible. Minute quantities (around 2–3 mg) of polyacrylamide were formed as a thin, water-insoluble film on the cathode surface.

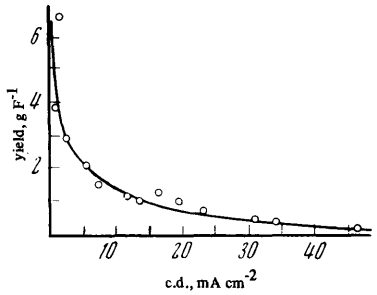


Figure 1. Effect of current density on current efficiency of polyvinylpyrrolidone formation[74].

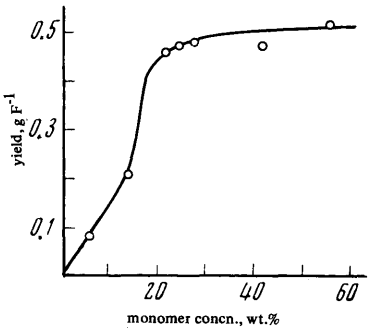

Figure 2. Dependence of yield of polyvinylpyrrolidone on monomer concentration with electrochemical initiation[74].

Another reason for such a low yield of polymer may be that the acrylamide dimers, trimers, or tetramers formed by recombination of the radicals or their interaction with the monomer diffuse slowly into the bulk of the solution, screening the electrode surface and thereby preventing transport of the monomer. Possible experimental support for this may be the unusually rapid fall in the cathodic peak for acrylamide when examined by oscillographic polarography at a stationary electrode with rapid polarisation by specified alternating current[63,75]. Yet the peaks representing reduction of simple ions under the same conditions do not vary with time[76]. Stable peaks for the reduction of acrylamide can be observed only with rapid rotation of the electrode[63].

The rate of initiation of radical polymerisation can be increased by rapid rotation of the electrode, which increases the rate of supply of monomer to its surface and somewhat diminishes coverage of the surface by $^{\cdot}$RH radicals. However, adsorption of radicals cannot thereby be completely eliminated or their recombination rate constant influenced. Because of adsorption of radicals, their recombination, and adsorption of the recombination products[59], the reaction is in effect localised on the electrode surface, and the most probable process is then formation of simple or additive dimerisation products, the yield of which was shown by Tomilov and Fioshin to be proportional to the current density[13,14].

	Scheme II	Scheme III
Electrochemical stage		$R+e \rightleftarrows R^{\cdot-}$
Chemical stage (*a*) in aqueous medium	$R^{\cdot-}+R^{\cdot-} \rightarrow {}^{-}R-R^{-}$	$R^{\cdot-}+H_2O \rightarrow HR^{\cdot}+OH^{-}$ $HR^{\cdot}+R \rightarrow HR-R^{\cdot}$ . . . . .
(*b*) in non-aqueous medium	${}^{-}R-R^{-}+2H_2O \rightarrow HR-RH+2OH^{-}$	$HR^{\cdot}+HR^{\cdot} \rightarrow HR-RH$
	${}^{-}R-R^{-}+nR \rightarrow {}^{-}R-(R)_n-R^{-}$	

Since the formation of initiating radicals occurs similarly during electrochemical oxidation and reduction, the above arguments apply both to the direct cathodic reduction and to the anodic oxidation of organic compounds, the radicals of which, as a consequence of the presence of the unpaired electron, tend to be adsorbed both on positively and on negatively charged surfaces[40]. High surface coverage and large recombination rate constants k_3 are the main conditions ensuring relatively high current efficiences for the formation of dimers[77], and this has served as a basis for their industrial production[13].

Thus one of the chief advantages of electrochemical initiation—the possibility of controlling the rate of the process by varying the current density—can be exploited, in radical polymerisation effected by direct reduction of the monomer, only over a narrow range of current densities at low surface coverage of the electrode.

2. Reduction (Oxidation) of the Electrochemical Initiator

If radicals are formed as a result of cathodic reduction or anodic oxidation of an electrochemical initiator, they are adsorbed on the electrode surface, as are the monomer radicals[40]. This is followed by preferential recombination either of the primary radicals or of products formed by them with the monomer. The probability of polymer formation is very small. This is confirmed by experimental results obtained by using the reduction of hydrogen[54–57] and oxygen[65] (hydrogen peroxide) in a protogenic medium for electrochemical initiation. The rate of initiation can be described, on certain assumptions, by equations analogous to those obtained for direct reduction of the monomer. As the processes are localised in a thin layer at the electrode surface, some increase in efficiency of initiation can be achieved by rapid rotation of the electrode and the use of very highly concentrated solutions of the monomer.

In order that initiation should be accomplished in the bulk of the solution, the species formed by the electrochemical reaction must be similarly charged to the electrode. This enables the charged species to leave the

electrode surface (the surface coverage to be reduced to a minimum). On the other hand, Coulombic repulsion prevents interaction between the charged species itself and lower polymerisation products. Chain growth—reaction between charged species and the monomer—predominates, which favours formation of a polymer of high molecular weight. In the choice of initiator satisfying these requirements it is necessary that the product of its electrochemical reaction should be able to initiate polymerisation of the chosen monomer under the given conditions.

3. Initiation of Polymerisation by Electrochemical Reduction of the Persulphate Ion

Persulphates are used to initiate polymerisation of vinyl monomers in water or in aqueous–organic emulsions. Their thermal decomposition produces $SO_4^{\cdot-}$ radical-anions, which are responsible for initiation[28,72,78,79]. According to Antropov[69] and Kryukova[80] this radical-anion is formed as intermediate also in the electrochemical reduction of the persulphate ion. On the basis of this hypothesis and the above requirements for an electrochemical initiator[81] potassium persulphate was used[67,68] for the electrochemical initiation of the polymerisation of acrylamide.

In this case initiation can be represented as consisting in (i) electrochemical reduction of the persulphate ion with formation of the radical-anion

$$S_2O_8^{2-} + e \underset{k_2}{\overset{k_1}{\rightleftarrows}} SO_4^{2-} + SO_4^{\cdot-} \qquad (41)$$

and (ii) chemical reaction between the radical-anion and the monomer

$$SO_4^{\cdot-} + R \underset{k_4}{\overset{k_3}{\rightleftarrows}} {}^{-}SO_4{-}R^{\cdot} . \qquad (42)$$

Since reactions (41) and (42) are almost irreversible[79,80], it can be assumed that $k_2 \ll k_1$ and $k_4 \ll k_3$. The rate of reaction (41) can then be written

$$v_1 = \gamma \cdot i_1 = k_1 [S_2O_8^{2-}] \exp\left(-\frac{\alpha\varphi F}{RT}\right) \qquad (43)$$

and the rate of reaction (42) as

$$v_2 = k_3 [SO_4^{\cdot-}] [R] . \qquad (44)$$

With a sufficiently high monomer concentration under steady-state conditions it can be postulated that

$$v_1 = v_2 = \text{const} \qquad (45)$$

i.e. the rate of initiation is equal to the rate of electrochemical formation of the radical-ions, and hence depends on the concentration of persulphate ions and the electrode potential. However, the rate of initiation can increase with rise in potential only until the latter permits further electrochemical reduction of the persulphate radical-ion

$$SO_4^{\cdot-} + e \underset{k_6}{\overset{k_5}{\rightleftarrows}} SO_4^{2-} . \qquad (46)$$

The rate of this process (allowing for the irreversible character of the reaction) is

$$v_3 = k_5 [SO_4^{\cdot-}] \exp\left(-\frac{\alpha_1\varphi F}{RT}\right) \qquad (47)$$

where α_1 is the transfer coefficient of the second electron.

Thus the rate of formation of the polymer, and hence its yield after a certain time of electrolysis, should be proportional to the electrode potential (current density) only until the latter reaches a certain value. Further rise in potential diminishes the yield.

The experimental dependence of the yield of polyacrylamide on the cathodic current density when potassium persulphate is used as electrochemical initiator in fact passes through a maximum at a certain current density (0.04 mA cm^{-2}). The shape of the curve is almost independent of the material of the electrode[45]. Fig. 3 shows that the rate of the electrochemical polymerisation of acrylamide can be controlled by varying the current density only in the range up to 0.04 mA cm^{-2}.

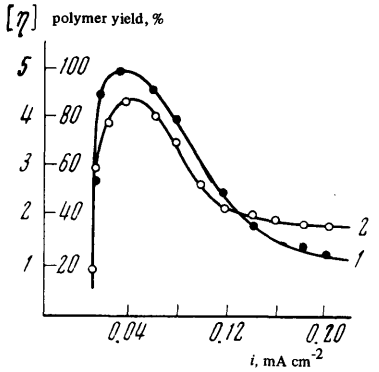

Figure 3. Effect of cathodic current density on formation of polyacrylamide: 1) yield; 2) intrinsic viscosity[45].

The dependence of the intrinsic viscosity of polyacrylamide on current density also shows a maximum. High values of the intrinsic viscosity may indicate a product of high molecular weight. The decrease in viscosity at a low current density is evidently an effect of dissolved oxygen, whose inhibiting action is apparent only at a low concentration of radicals, becoming insignificant when the concentration is considerable. One reason for the appearance of a descending section on the $[\eta]$–i curve at $i > 0.04$ mA cm^{-2} is the evolution of oxygen, which is able to interact with persulphate, acrylamide, and a growing polymer radical.

In the present case the yield of polyacrylamide at 0.03 mA cm^{-2} is proportional to the first power of the monomer concentration[45], in good agreement with Eqn. (44). A similar dependence of polymer yield on monomer concentration in solution was obtained by Funt in the electrochemical initiation of the polymerisation of vinylpyrrolidone[74] by its direct reduction (Fig. 2) (cf. also Eqn. 40).

With chemical initiation $SO_4^{\cdot-}$ radical-anions are formed not only in the thermal decomposition of persulphate ions[78] but also when the latter react with iron(II) compounds (reaction 21).[82,83] The persulphate ion then acts as oxidant in the redox process, which can be regarded as analogous to electrochemical reduction of the persulphate ion[84]. The rôle of reductant is played by the cathode, whose potential can be varied to shift the equilibrium in a required direction. When bivalent iron is used as reductant with the electrochemical initiation[66], an electrode process is necessary to maintain a certain concentration of reductant in the solution.

Thus the rate of initiation is determined by the rate of formation of active centres and the concentration of monomer with both direct and indirect (involving Fe^{2+} ions) electrochemical reduction of persulphate ions. Systems of the latter type have been successfully used by Kolthoff[66]. However, they are inferior to systems with direct electrochemical reduction of persulphate ions with respect to the possibility of controlling the rate of formation of initiating species[68].

IV. IONIC POLYMERISATION

Experience of the initiation of polymerisation by the electrochemical reduction of persulphate shows that formation of charged species by an electrode process considerably broadens the possibilities of electrochemical initiation, since it tends to spread the reaction into the bulk of the solution. However, this path provides only a partial solution of the problem of controlling the rate of the electrochemical initiation of polymerisation.

The most effective way of diminishing surface coverage of the electrode with active species is evidently to create in the polymerisable system conditions such that initiating anions would be generated on cathodic reduction, and cations by anodic oxidation, i.e. so that the initiation of ionic polymerisation would result from the electrochemical reaction. Systematic investigations in the field of ionic polymerisation have been made only during the past fifteen years[85-88], and the electrochemical initiation of such a process has been studied for barely ten years[19-25]. A few publications have appeared on the electrochemical initiation of ionic polymerisation[17-27,50-53], but the possibilities of the method and recent advances[5,23,24,26] suggest that such initiation is the most promising.

1. Cationic Polymerisation

Carbonium ions, capable of carrying the polymer chain, are formed as a result of the electrode reaction in the electrochemical initiation of cationic polymerisation[16-18]. They can be obtained by reaction of an oxidation product of the electrochemical initiator with the monomer[16] or by direct anodic oxidation of the latter[18]. Thus Breitenbach showed[16] that, when tetrabutylammonium or silver perchlorate is electrolysed in a monomer medium to which nitrobenzene has been added, polyacrylonitrile or poly-α-methylstyrene can be obtained in the anolyte by a cationic mechanism.

The suggested mechanism of initiation involves anodic oxidation of the perchlorate ion with formation of the radical $ClO_4^{\cdot}$

$$ClO_4^- \xrightarrow{k_1} ClO_4^{\cdot} + e \qquad (48)$$

and interaction between the radical and the monomer on the electrode surface to form a carbonium ion

$$ClO_4^{\cdot} + R \xrightarrow{k_2} ClO_4^- + R^+ \ . \qquad (49)$$

The carbonium ion, having like charge to the anode, passes into solution, carrying with it the polymer chain. Carbonium ions are formed similarly when the tetrafluoroborate anion is used as electrochemical initiator[53].

The rate of initiation due to oxidation of the electrochemical initiator is given by the equations

$$v_1 = k_1[ClO_4^-]\exp\frac{\beta\varphi F}{RT}\ , \qquad (50)$$

$$v_2 = k_2[ClO_4^{\cdot}][R]\ . \qquad (51)$$

In a steady state $v_1 = v_2$, and the overall rate of polymerisation is evidently determined by the rate v_1 of the electrode reaction, which varies exponentially with the electrode potential and very little with the concentration of perchlorate ions, which are regenerated by reaction (49). However, the rate of polymerisation depends strongly on the concentration of the monomer, which can be adsorbed on the electrode only until it reacts with the electrochemical initiator[40]. The cation, of like charge to the electrode, then diffuses into the bulk of the solution, where it initiates cationic polymerisation.

The second possible mode of electrochemical initiation of cationic polymerisation—direct anodic oxidation of the monomer

$$R \xrightarrow{k_1} R^+ + e \qquad (52)$$

was accomplished by Breitenbach with styrene, isobutyl vinyl ether, and *N*-vinylcarbazole[17,18].

Breitenbach compared the polarographic oxidation half-wave potentials $E_{\frac{1}{2}}$ for several monomers with the Q–e scheme of copolymerisation parameters‡.[18] The Table shows that the value of $E_{\frac{1}{2}}$ gives an idea of the mechanism of the formation of active centres during the electrochemical initiation of cationic polymerisation and copolymerisation, and also indicates the activity of monomers in this process.

Anodic oxidation potentials of some monomers in acetonitrile (rotating platinum electrode in tetraethylammonium perchlorate as supporting electrolyte; reference electrode Ag/AgCl in acetonitrile) and values of the parameter e in the Q–e scheme.

Depolariser	Oxidation potential $E_{\frac{1}{2}}$, V	e
N-Vinylcarbazole	1.14	—1.40
N-Vinylpyrrolidone	1.67	—1.14

Vinyl acetate	—	—0.22

The rate of initiation with direct oxidation of the monomer

$$v = k_1[R]\exp\frac{\beta\varphi F}{RT} \qquad (53)$$

depends on the monomer concentration and the electrode potential. An analogous relation should be observed for the yield of polymer after a certain period of electrolysis.

Although the possibility of the electrochemical initiation of cationic polymerisation has been demonstrated and

‡ Q and e are parameters in the Alfrey–Price equation, representing respectively the reactivity of the radical towards the monomer and the polarisation of the monomer molecule[89].

explained theoretically, it has been accomplished in only a few cases by Breitenbach and his coworkers[16,17,52,53] and also by Strobel and Schulz[90].

2. Anionic Polymerisation

The cathodic reduction of an electrochemical initiator in an aprotic medium—in the absence of electron-accepting impurities, in particular moisture and oxygen—followed by interaction with a monomer or the direct electrochemical reduction of the monomer to form a radical-anion leads to the initiation of anionic polymerisation[5,19-25]. Radical-anions, bearing a like charge to the cathode, are not adsorbed on its surface, but diffuse into the interior of the solution. They interact to form dianions; chain growth then takes place from the two ends by an anionic mechanism, as with chemical initiation[86,87].

(*a*) Initiation by reduction of electrochemical initiator

Electrochemically initiated polymerisation is usually accomplished in the presence of an electrically conducting additive (a tetra-alkylammonium or an alkali-metal salt). If the electron affinity of the metal ion of the additive is greater than that of the monomer, an amalgam of the metal may be obtained on the cathode during electrolysis, which will react with the monomer to form species capable of initiating anionic polymerisation:

$$M^+ + e \underset{k_2}{\overset{k_1}{\rightleftarrows}} M, \tag{54}$$

$$M + R \underset{k_4}{\overset{k_3}{\rightleftarrows}} M^+ + R^{\cdot-}, \tag{55}$$

$$R^{\cdot-} + R^{\cdot-} \xrightarrow{k_5} {}^-R{-}R^-, \tag{56}$$

$${}^-R{-}R^- + R \xrightarrow{k_6} {}^-R{-}R{-}R^-. \tag{57}$$

The rates of each stage in the process are

$$v_1 = k_1[M^+]\exp\left(-\frac{\alpha q F}{RT}\right) - k_2[M]\exp\frac{\beta q F}{RT}, \tag{58}$$

$$v_2 = k_3[M][R] - k_4[M^+][R^{\cdot-}], \tag{59}$$

$$v_3 = k_5[R^{\cdot-}]^2. \tag{60}$$

The rate of the electrode reaction depends on the cathode potential and very little on the concentration of the electrochemical initiator, since metal ions are regenerated by interaction with the monomer (reaction 55).

The efficiency of initiation, which may be measured by the constant k_3 of the forward reaction (55), is determined by the difference in electron affinity between the metal M and the monomer[86-88,91]. This quantity is constant for each metal–monomer pair. Thus as a result of the electrochemical reaction we arrive in effect at chemical initiation by an amalgam of the alkali metal. However, the electrode is always negatively charged, so that anions are repelled from its surface, whereas in chemical initiation the metal amalgam may acquire a positive charge during interaction with the monomer, which will tend to attract radical-anions[92].

Control of the rate of the process, with electrochemical reduction of the metal ion, is somewhat restricted by the fixed value of k_3. In order to increase this constant it is necessary to select a metal–monomer pair such that the metal possesses a low ionisation potential, while the monomer has a high electron affinity[88,91]. Nevertheless, if the electron affinity of the monomer exceeds that of the metal ion of the electrochemical initiator, radical-anions are formed by direct cathodic reduction of the monomer[20].

(*b*) Initiation by direct reduction of monomer

The electron affinity of various compounds (in particular aromatics) varies in parallel with the half-wave potential for their polarographic reduction[93]. Thus the mechanism of formation of the active centres responsible for initiation of anionic polymerisation can be assessed in each specific system from polarographic data. If the half-wave potential for the cation of the supporting electrolyte is more negative than the half-wave potential of the monomer, electrochemical initiation of polymerisation will occur by direct reduction of the monomer[21,23,24,94] to the radical-anion

$$R + e \underset{k_2}{\overset{k_1}{\rightleftarrows}} R^{\cdot-} \tag{61}$$

whose dimerisation yields a dianion carrying the polymer chain[85,95] (reactions 57 and 61). The rate of the electrochemical stage

$$v_1 = k_1[R]\exp\left(-\frac{\alpha\varphi F}{RT}\right) - k_2[R^{\cdot-}]\exp\frac{\beta\varphi F}{RT} \tag{62}$$

is proportional to the concentration of the monomer and depends on the electrode potential φ ($k_2 \to 0$). The rate of chemical reaction of the radical-anions (Eqn. 60) is limited by their rate of formation and by Coulombic repulsion. The rate of growth of the polymer chain (reaction 57)

$$v_2^* = k_6[{}^-R - R^-][R] \tag{63}$$

is determined by the concentration of initiating dianions and the monomer. The rate of formation of the polymer (its yield after a definite time)

$$\eta = f(v_2^*) = f(v_1 + v_3) \tag{64}$$

(v_3 from Eqn. 60) is directly dependent on the electrode potential (current density), as is observed in practice (Fig. 4).

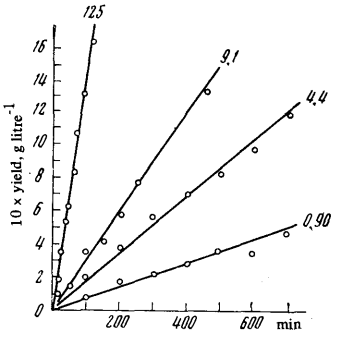

Figure 4. Dependence of yield of polyacrylonitrile on duration of reaction for various currents (mA).[21] The area of the electrode was the same (1 in^2) in all experiments.

Feoktistov and Tomilov[96,97], with acrylonitrile as example, showed that the dianion $R^=$ may be formed by direct two-electron reduction of the monomer. This mechanism is atypical of other monomers. Nevertheless, the rate of initiation and hence the yield of polymer are

determined even in this case by the electrode potential and the monomer concentration.

Thus there exist various types of electrode reactions, as a result of which either radical or ionic polymerisation occurs depending on the conditions. The above survey shows that one of the most attractive features of electrochemical initiation—the possibility of controlling the rate of polymer formation—can be successfully realised only in the initiation of ionic polymerisation. In the case of radical polymerisation ways must be sought of diminishing the surface coverage of the electrode by active species.

3. Possibilities of Simultaneous Radical and Ionic Mechanisms of Chain Growth with Electrochemical Initiation

A radical-anion formed by reaction (55) or (61) has an unpaired electron in the lowest vacant π-orbital[85] of the monomer. This electron is usually delocalised, so that the recombination of monomeric radical-anions (reaction 56) is, according to Szwarc[85,86] and to Bagdasar'yan[98], the slowest stage in the initiation of anionic polymerisation and limits the overall rate of polymerisation. Funt reaches a similar conclusion from an investigation of the electrochemical initiation of the anionic polymerisation of acrylonitrile[21].

At a sufficiently high monomer concentration (at the electrode surface) reactions (61) and

$$R^{\cdot-} + R \xrightarrow{k_5} {}^{\cdot}R{-}R^{-} \qquad (65)$$

can evidently occur consecutively. This involves stabilisation of anionic and radical ends, after which the dimeric radical-anions may undergo recombination

$${}^{\cdot}R{-}R^{-} + {}^{\cdot}R{-}R^{-} \xrightarrow{k_6} {}^{-}R{-}R{-}R{-}R^{-} \qquad (66)$$

and chain growth by an anionic mechanism; in the limiting case the chain may grow at the two ends simultaneously by radical and anionic mechanisms

$${}^{\cdot}R{-}R^{-} + R \xrightarrow{k_7} {}^{\cdot}R{-}R{-}R^{-}. \qquad (67)$$

The possibility of such a process was postulated by Tobolsky et al. in the polymerisation of styrene initiated by metallic sodium[99] and by Funt et al.[21] under conditions of electrochemical initiation. The latter workers discovered that the composition of a copolymer of acrylonitrile with methyl methacrylate or styrene indicates that a radical mechanism of polymerisation predominates at the start of electrolysis (polymerisation), and an anionic mechanism as time elapses.

The possibility of the simultaneous addition of monomer molecules to anionic and radical ends of a radical-ion has been confirmed by experiments on the inhibition of the electrochemically initiated polymerisation of acrylonitrile in dimethylformamide[8,95]. Such chain-transfer agents for radical polymerisation as benzene, toluene, and chlorobenzene, which can be adsorbed on the electrode[100], partly inhibit the cathodic polymerisation of acrylonitrile, diminishing the yield of polymer by ~ 20%, whereas they completely inhibit anodic polymerisation (a purely radical process).

It is difficult to determine the rate of reactions (65) and (66). Since, however, k_5 evidently exceeds k_6, and the rate of chain growth by anionic polymerisation at low temperatures and in the absence of impurities considerably exceeds the rate of growth by radical polymerisation, the total rate of polymerisation can be assumed to be determined by the electrode potential and the monomer concentration, as in anionic polymerisation.

4. Electrochemical Initiation of the Anionic Polymerisation of Isocyanates

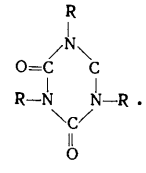
The electrochemical initiation of anionic polymerisation can be most conveniently studied on monomers that cannot be polymerised by any other mechanism. A classic example of this is phenyl isocyanate, which can be polymerised only by an anionic mechanism[101-103]. The possibility of the electrochemical reduction of phenyl isocyanate has been shown polarographically[104]. On reduction at a dropping mercury electrode in dimethylformamide this compound gives a single polarographic wave representing the addition of two electrons by the reactions

$$R + e \rightarrow R^{\cdot-}, \qquad (68)$$

$$R^{\cdot-} \xrightarrow{PD} {}^{\cdot}RH, \qquad (69)$$

$${}^{\cdot}RH + e \rightarrow {}^{-}RH, \qquad (70)$$

$${}^{-}RH \xrightarrow{PD} RH_2, \qquad (71)$$



(where PD represents a proton donor).

This mechanism is possible at low concentrations of phenyl isocyanate, when sufficient hydrogen ions are present at the electrode surface to protonate the reduced molecule§. At considerable concentrations of the isocyanate ([R] ≫ [H_2O]) its wave divides into two. The second wave corresponds to addition of an electron to the radical-anion at a more negative potential:

$$R^{\cdot-} + e \rightarrow R^{=} \qquad (72)$$

With increase in the isocyanate concentration, however, the second wave does not grow but diminishes: the total height of the waves approaches the height of a one-electron wave, so that the number of added electrons n changes from 2 to ~ 1. The reason is that the radical-ions of phenyl isocyanate recombine to form a bianion (reaction 56), which is able to initiate polymerisation.

These results suggest that electrochemical initiation of the anionic polymerisation of phenyl isocyanate can occur at a monomer concentration of 0.02 M and an electrode potential (current density) corresponding to the potential of its first wave. Electrolysis of a solution of phenyl isocyanate in an aprotic medium in fact yields a polymer[5] corresponding in properties to the poly(phenyl isocyanate) obtained by the action of anionic catalysts[101,103]. The suggested mechanism of electrochemical initiation by direct reduction of the monomer with cleavage of the N=C bond is confirmed by the elementary composition and the infrared spectra of the resulting poly(phenyl isocyanate) and by the formation, under the same conditions at room temperature, of the trimer[105,106]

The yield of polymer increases with fall in temperature, increase in monomer concentration, and decrease in

§ Karl Fischer's method indicates that well dehydrated dimethylformamide contains 0.01% of moisture, corresponding to a concentration of ~ 0.005 M: i.e. the quantity of water is comparable with the concentration of depolariser.

current density[10,107], which agrees well with the general laws of anionic polymerisation with chemical initiation. The increase in polymer yield with decrease in current density observed in this work appears at first glance to be inconsistent with Eqn. (62) for the rate of electrochemical formation of the active centres responsible for the initiation of anionic polymerisation. The explanation is that at a high current density the rate of formation of the cyclic trimer of phenyl isocyanate by an anionic mechanism increases, which lowers the rate of initiation of actual polymerisation. Isocyanates are known to tend to form trimers[101,102].

Special stress must be laid on the crystallinity of the poly(phenyl isocyanate) obtained by electrochemical initiation: i.e. it has a regular structure, as indicated by the coincidence of its X-ray patterns with those of the polymer obtained by Natta[101] using stereospecific catalysts. With chemical initiation the crystallinity of the polymer is strongly dependent on the solvent, gegenion, and temperature[108]. With electrochemical initiation crystalline poly(phenyl isocyanate) was obtained in such solvents as dimethylformamide, oxolan, and acetone in the presence and in the absence of tetrabutylammonium iodide.

All this is evidence that, with electrochemical initiation, stereoregularity is largely achieved by orientation of monomer molecules on the electrode surface in the initial stages of growth of the polymer chain. Thus with phenyl isocyanate as example it has been shown for the first time that stereospecific polymerisation is fundamentally possible with electrochemical initiation.

5. Preparation of "Living" Polymers by Electrochemical Initiation

During the 1960s so called "living" polymers aroused the special interest of scientists in the field of anionic polymerisation. Such polymers were first obtained by Szwarc[91] by polymerising α-methylstyrene in a non-polar medium under the influence of metallic sodium or an alkali-metal alkyl[85,86]. Great advances in the field of anionic polymerisation were made by Soviet investigators—Medvedev's school[109-112], Bagdasar'yan[98], Erusalimskii[113,114], Enikolopyan[115,116], and Lipatova[117]. A "living" polymer is brightly coloured owing to the presence of the ion-pairs $\sim CH_2CHAr^-M^+$ at the ends of the macromolecules (M = Na, Li). Fresh portions of a monomer undergo polymerisation when added to a solution of a "living" polymer. Polymers obtained in this way have a narrow molecular-weight distribution.

Electrochemical initiation of polymerisation, as a result of which "living" polymers are obtained, allows either the number of active centres to be changed during polymerisation or their rate of formation to be maintained constant, in addition to the general opportunities available with chemical initiation.

Furthermore, increasing attention has been paid during recent years to polymers (oligomers) having definite functional terminal groups. They are usually obtained by adding to a solution of a "living" polymer compound which react with the "living" carbanion to form new functional groups at the ends of the macromolecule[91]. Thus the addition of proton donors results in the appearance of hydrogen at the ends of a polymer chain, carbon dioxide yields a carboxy-group, oxiran produces a hydroxyl, etc.

A virtue of electrochemical polymerisation is the possibility of deactivating "living" polymers by changing the polarity of the electrodes, i.e. the possibility of obtaining terminal groups of a polymer by interaction of the products of anodic and cathodic reactions[23]:

$$^-R—R_n—R^- + 2R_1^+ \rightarrow R_1—R_{n+2}—R_1 \quad (73)$$

This feature of electrochemical initiation opens up new routes for the synthesis of macromolecules having specified terminal groups.

Yet another important advantage is that electrochemical initiation enables "living" radical-anions to be obtained by direct cathodic reduction of the monomer, eliminating the stage of preparation of a catalyst, which is especially sensitive to contamination by moisture and oxygen[91].

(*a*) Preparation of linear "living" polymers

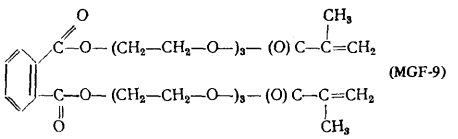
Especially clean conditions—absence of contamination and of impurities of proton-donating and electron-accepting character—are required to obtain "living" polymers by an anionic mechanism. Electrochemical "living" poly-α-methylstyrene was first obtained in 1965 by Yamazaki et al.,[24] who electrolysed a solution of the monomer in oxolan in the presence of lithium tetrahydroaluminate and a sodium tetra-alkylaluminate. This polymer had a bright cherry-red colour and a quite high molecular weight. Values found for the molecular weight were close to those calculated by means of the formula[23]

$$M_n = \frac{[M]}{0.5I} \quad (74)$$

(I is the number of faradays of electricity and [M] the concentration of the monomer), which was deduced on the assumption that polymerisation was initiated by dianions formed by recombination of radical-anions produced initially (i.e. it was assumed that two electrons were consumed in the formation of one macromolecule).

The bright colour of the styrene carbanions formed by electrolysis enables the rate of formation of active centres to be followed from the variation in the absorption maximum (λ_{max} = 340 nm) in the electronic spectrum, and their rate of disappearance from the change in polarisation of the electrodes.

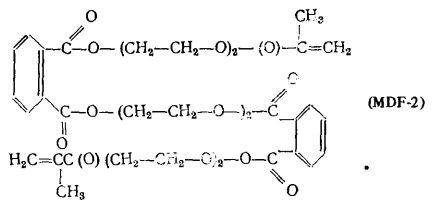
The possibility of obtaining "living" polymers in liquid ammonia by the electrochemical initiation of anionic polymerisation is especially noteworthy. Thus Parravano et al.[25] electrolysed 4-vinylpyridine in liquid ammonia, and obtained in quantitative yield at the cathode a polymer of molecular weight $(6-10) \times 10^4$ and a quite narrow molecular-weight distribution (M_W/M_n = 1.5). In this case initiation takes place in the bulk of the solution, by addition of a so called "solvated" electron to the monomer, which involves formation of radical-anions and their recombination products—bianions. Current efficiencies of 0.5 mole F^{-1} are cited as evidence of the suggested mechanism.



Experiments in which polymerisation occurred after addition of a second portion of the monomer, without further electrolysis, confirm that the polymer obtained is "living".

(*b*) Preparation of network "living" polymers

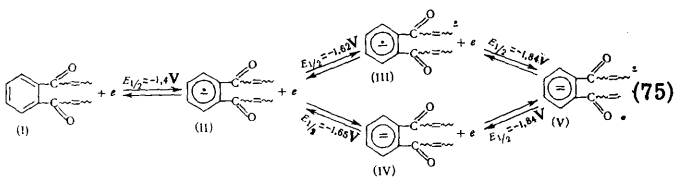
If a monomer contains two or more double bonds, a three-dimensional network polymer is formed, which under certain conditions may be "living". Lipatova and Siderko obtained such "living" network polymers by anionic polymerisation with chemical initiation from oligo(ether-acrylates).[117] These compounds contain reducible groups



(phthalate and methyl methacrylate[118]) differing in electron affinity and separated by a system of σ-bonds. All this makes them interesting both with regard to the laws of anionic polymerisation itself and with regard to the mechanism of their electrochemical reduction and the formation, during the electrochemical reaction, of the active centres responsible for the initiation of polymerisation.

The possibility of obtaining "living" network polymers from oligo(ether–acrylates) by electrochemical initiation was established in the cases of bismethacryloyloxyethoxyethyl phthalate (MGF-9)

(MGF-9)



and oxadiethylene bis(methacryloyloxyethoxyethyl phthalate) (MDF-2)¶

(MDF-2)

It is especially noteworthy that a "living" polymer can be obtained by electrochemical initiation from an oligo(ether–acrylate) not only under a high vacuum (with oxolan as medium), as in the electrochemical polymerisation of styrene[23,24], but also in such a highly polar solvent as dimethylformamide (with addition of tetrabutylammonium iodide and a current of argon)[25,119,120].

Investigation of the mechanism of the electrochemical reduction of oligo(ether–acrylates) by polarography and oscillographic polarography with a specified alternating current and the use of model compounds (methyl methacrylate and dimethyl phthalate) shows that the transfer of electrons to the oligomer molecule is a stepwise process, characterised by three diffusion waves[121], and each electrochemically active group is reduced independently of the others[27]. From the half-wave potentials of the functional groups in the oligomer the electrochemical reduction of MGF-9 can thus be represented[27]

(75)

Products (III) and (V) are able to initiate anionic polymerisation, whereas the products of the one- and two-electron reduction of the phthalate group in the oligomer (II and IV respectively) do not cause polymerisation, although the solution on electrolysis has the bright colour characteristic of the radical-ion or the dianion of dimethyl phthalate.

Thus the electrochemically reduced oligo(ether–acrylate) molecules carry 1–3 negative charges. On the one hand this causes repulsion from the cathode of similarly charged species, i.e. the occurrence of polymerisation in the bulk of the solution; on the other hand, it promotes formation of a polymer network from previously uncoiled oligomeric blocks, which in turn produces a certain (fibrillar) supermolecular structure in the polymer, as is confirmed by electron microscopy[122].

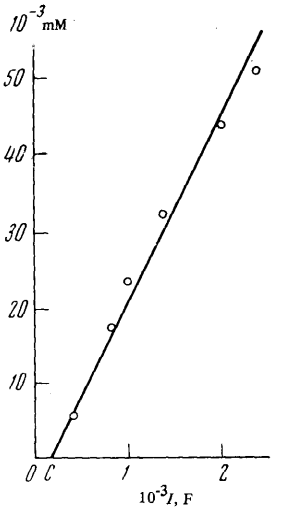


Figure 5. Dependence of yield of network poly(ether–acrylate) on quantity of electricity that has passed through 0.5 M solution of MGF-9 oligo(ether–acrylate) in dimethylformamide[120].

Features of the mechanism of the electrochemical initiation of polymerisation associated with the specific structure of oligo(ether–acrylates) affect the dependence of polymer yield on the quantity of electricity that has passed through the oligomer solution. According to Eqn. (64) the yield of polymer with electrochemical initiation of anionic polymerisation is proportional to the monomer concentration and to the quantity of initiating particles formed by the electrode reaction (to the electrode potential). In the present case the yield is actually proportional to the concentration of oligo(ether–acrylate). Nevertheless, the dependence of the yield of poly(ether–acrylate) on the quantity of electricity that has flowed through the solution is a straight line not passing through the origin (Fig. 5). The reason is that part of the electricity is consumed in charging the oligomer molecules (formation of products II and IV in reaction 75), which confirms the suggested scheme of electrochemical reduction of these compounds. The straight line is represented by the equation

$$\eta = K(I - I_{thr}), \qquad (76)$$

where η (expressed as molarity of oligomer that has reacted) is the yield of polymer, I (F) the quantity of electricity that has passed through during electrolysis, I_{thr} the minimum quantity of electricity necessary for polymerisation of the oligomer to begin under the given conditions (the intercept O–C made by the straight line in Fig. 5), which is termed a "threshold" by analogy with Lipatova and Siderko's "threshold" catalyst concentration[117], below which the anionic polymerisation of oligo(ether–acrylates) under the influence of sodium naphthalene does not take place, although the solution is

¶ Notation of oligo(ether–acrylates) taken from Ref. 118.

coloured, and K a constant representing the efficiency of the electrochemical reaction—the number of moles of the oligomer converted under the given conditions by one faraday of electricity. The value of K determined in the electrochemical initiation of the polymerisation of MGF-9 is 23.5 moles F^{-1}, indicating that the electrochemical reaction is highly efficient.

---o0o---

With electrochemical initiation the electrode process is thus the source of the active centres responsible for initiating polymerisation. This allows their rate of generation to be controlled, the mechanism to be determined, and aspects of initiation to be examined in the formation of both linear and network polymers. On the other hand, the field of the electrode affects the growth of the polymer chain. The carbanion or carbonium cation carrying the chain interacts with monomer molecules already oriented in the field of the electrode. This determines the structure and the physicochemical properties of the polymers. Several publications have appeared on electrochemical initiation[122-138] while the manuscript was being prepared for the press.

Homolytic Substitution at the Metal Atom in Organometallic Compounds

E.B.Milovskaya

Homolytic substitution at the metal atom involves a wide range of organic derivatives of non-transition metals and takes place in reactions with free radicals where the reaction centre is located at an oxygen, nitrogen, or sulphur atom. The qualitative and quantitative aspects of these reactions have been examined. The applicability of the relations established both in the treatment of a series of reactions involving organometallic compounds and for synthetic purposes has been demonstrated. The bibliography includes 75 references.

I. INTRODUCTION

Oxidation reactions of organic derivatives of non-transition metals have been attracting attention for a long time. These reactions are not only of theoretical but also of practical interest. In particular, the oxidation of metal alkyls leads to a convenient method of synthesising oxygen-containing compounds which are difficult to obtain otherwise; combinations of the metal alkyl-oxygen type are sometimes capable of initiating the radical polymerisation of vinyl monomers at a low temperature, etc.

The oxidation of metal alkyls takes place very rapidly, in a fraction of a minute, and since the process is heterogeneous the use of kinetic criteria to infer its mechanism proved to be difficult. Moreover, it has been established that inhibitors of free-radical reactions (hydroquinone, diphenylamine, etc.) do not affect this process. Therefore it has been suggested that the oxidation has a polar and not a homolytic mechanism. However, some authors admit the possibility of homolytic stages in the oxidation process†.

In connection with the discovery of powerful inhibitors of free-radical processes, methods for the synthesis of pure stereoisomeric forms of metal alkyls, and the application of ESR spectroscopy, in recent years it was possible to discover stages in the oxidation process which had been unknown hitherto. It was shown that the oxidation of organic derivative of boron, zinc, cadmium, aluminium, magnesium, antimony, and bismuth constitutes a bimolecular homolytic substitution at the metal atom via a mechanism of the type which obtains in S_H2 reactions‡.

In the case of polyvalent organometallic compounds, reactions of the S_H2 type proceed not only with peroxy- but also with alkoxy- and acyl radicals and with radicals in which the reaction centre is located at a nitrogen or sulphur atom.

This review deals with qualitative and quantitative aspects of the homolytic substitution reactions. Certain processes involving organometallic compounds have been analysed and it has been shown that the relations discovered may be used for preparative purposes in organic chemistry.

†The oxidation reactions and subsequent reactions of organometallic peroxides have been considered in reviews [1–3].

‡The term S_H2 reactions was introduced by Pryor [4] and was used by Davies in relation to bimolecular reactions of free radicals with the metal atom in organometallic compounds.

II. HOMOLYTIC SUBSTITUTION AT THE METAL ATOM

1. Oxidation of Organic Derivatives of the Elements

The beginning of a fundamental and systematic revision of earlier views concerning the nature of the oxidation of organic derivatives of the elements must be attributed to a study of the oxidation of 1-phenylethylboronic acid (1967), where a complete loss of stereospecificity was observed in the hydroperoxide obtained as a result of the reaction [5]. It was established that the kinetics of the oxidation of organic derivatives of boron, zinc, cadmium, aluminium, antimony, and bismuth are influenced by inhibitors of free-radical processes: galvinoxyl, nitroxide phenothiazine. An induction period, the duration of which depends on the inhibitor concentration and the nature of the metallic compound, is observed in their presence; free-radical sensitising agents (copper salts and hyponitrite) initiate the process [6–9]. The existence of a radical stage in the oxidation of organomagnesium compounds is indicated by the loss of stereospecificity and the formation of a mixture of the *exo*- and *endo*-forms of norbornylmagnesium halides having a unique composition [10].

On the basis of literature data [5,6,8–10], Davies and coworkers formulated the hypothesis that the oxidation of organometallic compounds, like the oxidation of hydrocarbons, is a radical chain process the stages of which are presented below:

$$\text{sensitisation} \xrightarrow{\text{slow}} \text{radicals}, \quad (1)$$

$$R^{\cdot} + O_2 \xrightarrow{\text{very rapid}} RO_2^{\cdot}, \quad (2)$$

$$RO_2^{\cdot} + R_nM \xrightarrow[k_p]{\text{slow}} RO_2MR_{n-1} + R^{\cdot}, \text{ chain propagation}, \quad (3)$$

$$2RO_2^{\cdot} \xrightarrow[k_{обр.}]{} \text{inactive products, chain termination}. \quad (4)$$

The mechanism shows that the stage determining the rate of propagation is the interaction between peroxy-radicals and the organometallic component [reaction (3)], alkyl radicals behaving as reaction chain transferring agents. Chain termination involves bimolecular interaction

between two peroxy-radicals leading to inactive products. The sensitisation stage will be considered below§.

Organoboron compounds are very useful for the investigation of such reactions. The bond between boron and carbon is purely covalent [14], which favours homolytic processes. In contrast to organic derivatives of aluminium or zinc, there is a wider set of stable boron alkyls available, which gives rise to a greater scope for the investigation of the oxidation reaction in this class of compounds.

A detailed kinetic study of the oxidation of a wide range of organoboron compounds yielded the quantitative characteristics of the chain propagation stage and made it possible to establish a relation between this stage and the structure of the initial boron alkyl [15,16]. It has been shown for oxydiboron derivatives, boroxins, and mono- and di-alkoxy-derivatives of boron, which are oxidised at a moderate rate, that the process is described by the relation

$$-\frac{d[O_2]}{dt} = k[BR_3]R_i^{1/2},$$

where $k = k_p/(2k_t)^{1/2}$ and R_i is the rate of sensitisation. The relation follows from Eqns. (1)–(4).

Table 1. Rate constant ratios $k_p/(2k_t)^{1/2}$ in the autoxidation of organoboron compounds [15,16] (iso-octane, 30°C).

Compound	$k_p/(2k_t)^{1/2}$, litre$^{1/2}$ mole$^{-1/2}$ s$^{-1/2}$				
	R=*n*-Bu	s-Bu	t-Bu	1-phenylethyl	benzyl
$(RBO)_3$	0.21	40	870	850	64
R_3BOR	4.4	11	—	—	—
R_3BOBR_2	43	56	—	—	—
R_3B[a]	300[b]	70[c]	—	—	300[d]

[a] In pyridine–octane mixture.
[b] $K_{eq} = 2.2 \times 10^2$ litre mole^{-1}.
[c] $K_{eq} = 0.16$ litre mole^{-1}.
[d] $K_{eq} = 8.7 \times 10^3$ litre mole^{-1}.

In a kinetic study of the oxidation of n-butyl-, s-butyl, benzyl-, and phenyl-boron derivatives, which react very rapidly, pyridine (Py), which is a powerful complex-forming agent, was introduced into the mixture. The relation established in this case is of the form

$$-\frac{d[O_2]}{dt} = k\frac{[BR_3]}{[Py]}\left(\frac{R_i}{2k_t}\right)^{1/2},$$

where $k = k_p/K_{eq}$ and reflects the following complex formation reaction:

$$BR_3 + Py \overset{K_{eq}}{\rightleftharpoons} BR_3 \cdot Py.$$

§This view has been expressed also in studies by other investigators [7,11,12]. Davies and coworkers previously held different views on the oxidation mechanism; at present this school has made the greatest experimental contribution and has obtained most of the quantitative characteristics of the mechanism described by Eqns. (1)–(4); see also Davies and Roberts [13].

This reaction results in a decrease of the initial concentration of the boron alkyl; only the non-complexed form of the alkyl is involved in the oxidation reaction. The ratios $k_p/(2k_t)^{1/2}$, i.e. the quantities corresponding to the "oxidisability" of the organoboron compounds, and the propagation rate constants are listed in Tables 1 and 2.

Table 2. Rate constants for chain propagation in the autoxidation of boron alkyls [15,16] (iso-octane), 30°C.

Compound	k_p, litre mole^{-1} s^{-1}				
	R=*n*-Bu	s-Bu	t-Bu	1-phenylethyl	benzyl
$(RBO)_3$	$1 \cdot 10^3$	$5 \cdot 10^4$	$3 \cdot 10^4$	$4 \cdot 10^6$	$1 \cdot 10^6$
R_3BOR	$3 \cdot 10^4$	$1 \cdot 10^4$	—	—	—
R_3BOBR_2	$3 \cdot 10^5$	$7 \cdot 10^4$	—	—	—
R_3B	$2 \cdot 10^6$	$8 \cdot 10^4$	—	—	$5 \cdot 10^6$
$2k_t$(ROO)	$4 \cdot 10^7$	$1.5 \cdot 10^8$	$1 \cdot 10^8$	$2.5 \cdot 10^7$	$3 \cdot 10^8$

Evidently the "oxidisability" is determined by the nature of the substituting groups; groups containing oxygen retard the oxidation, which has been attributed to an increase of electron density at boron due to oxygen: $B-OR \leftrightarrow \bar{B}=\dot{O}R$. The chain propagation rate constant does not depend quite so explicitly on the nature of the R groups.

Table 3. Rate constants for the abstraction of a hydrogen atom from organic compounds by peroxy-radicals [15].

Compound	k, litre mole^{-1} s^{-1}	°C	Compound	k, litre mole^{-1} s^{-1}	°C
Toluene	0.24	30	Phenol	$4.3 \cdot 10^3$	65
Cumene	0.18	30	2,6-di-t-butyl-4-methoxyphenol	$8 \cdot 10^4$	65
Tetralin	6.4	30	Diphenylamine	$4 \cdot 10^4$	65
Cyclohexa-1,4-diene	$1.5 \cdot 10^3$	30	*NN'*-Diphenyl-*p*-phenyldiamine	$1.9 \cdot 10^6$	65

While the ratio $k_p/(2k_t)^{1/2}$ decreases in the series n-butylboron < s-butylboron < t-butylboron, this type of relation is not observed for the chain propagation rate constant. Hence it follows that the differences between the oxidisabilities of the compounds are related mainly to changes in the chain termination rate constant¶. The relation between k_p and the nature of R is fairly complicated and reflects a number of effects which frequently act in opposition (the stability of the radical removed, the steric accessibility of the boron atom, the reactivity of the attacking radical, etc.). Table 2 shows that the rate constant for homolytic substitution at the boron atom is extremely high, particularly when compared with the abstraction of a hydrogen atom by a peroxy-radical (Table 3). Thus dealkylation of the polyvalent boron atom

¶The kinetic relations show that the chain termination is in all cases a consequence of the interaction between peroxy-radicals.

by peroxy-radicals is one of the most rapid organic reactions of the S_H2 type. The sensitisation stage is particularly complicated in self-sensitised reactions. Davies and coworkers suggest that there are three processes responsible for the formation of radicals, namely direct oxidation, which is important at the very beginning of the process, monomolecular decomposition of the peroxide formed, and finally bimolecular interaction between the oxidised and non-oxidised forms of the boron alkyl [Eqns. (5) to (7)].

$$R_3B + O_2 \xrightarrow{k_5} R_2BO_2^{\cdot} + R^{\cdot}, \quad (5)$$

$$R_3B + O_2 \rightarrow [R_2BOOR] \rightarrow [R_2BO^{\cdot} + {}^{\cdot}OR] \begin{cases} \xrightarrow[k_6]{\text{liberation from cage}} \\ \xrightarrow{\text{reaction in cage}} [R(RO)BO^{\cdot} + R^{\cdot}] \rightarrow \end{cases} \quad (6)$$

$$\xrightarrow{\text{recombination}} R(RO)_2B, \cdot$$

$$R_2BOOR \rightarrow \begin{bmatrix} R_2BO \ldots OR \\ R_3B \quad \uparrow \quad \downarrow \\ R \ldots BR_2 \end{bmatrix} \begin{cases} \xrightarrow{\text{liberation from cage}} R^{\cdot} + R_2BO^{\cdot} + R_2BOR \\ \xrightarrow{\text{recombination in cage}} 2R_2BOR. \end{cases} \quad (7)$$

The numerical values of the rate constants for the primary sensitisation steps (k_5) and for the monomolecular decomposition of certain peroxyboron compounds (k_6) are listed in Table 4.

Table 4. Rate constants for the primary sensitisation (k_5) and monomolecular decomposition of the peroxide (k_6).

Compound	10^3k_5, litre mole^{-1} s^{-1} (benzene, 25°C) (Ref.17)
R_3B	R = iso-Bu, s-Bu, cyclohexyl 0.9 1.9 21.9
R_2BOOR	10^4k_6, s^{-1} (octane, 30°C) (Ref.15)
	R = n-Bu, s-Bu 0.11 3.8

Apart from Davies, investigators who studied the polarisation of methyl methacrylate (MMA) under the influence of systems based on $BR_3 + O_2$ also pointed to reaction (7) as a source of free radicals [3,18,19]. This view is confirmed by kinetic results obtained under model conditions [11,12,15,20]. At the same time, it has been noted [15] that the experimental data at present available concerning the pathways involved in the formation of free radicals are still inadequate for final conclusions.

2. Reaction of RO· Radicals with the Metal Atom in Organometallic Compounds

The interaction of alkoxy-radicals with the central metal atom is an example of a non-chain radical substitution process. The existence of such reactions was demonstrated for the first time and then investigated by Krusic and Kochi [21] and by Davies and coworkers [22–24] using a low-temperature ESR technique (from −100°C onwards). The experiments were performed directly in the spectrometer tube containing the organometallic compound; the free alkoxy-radicals were obtained by the photolysis (P) or thermolysis (T) of t-butyl peroxide or di-t-butyl hyponitrile.

Although one might have expected under these conditions signals corresponding to the formation of products resulting from the abstraction of a hydrogen atom by RO· radicals from the solvent or from the alkyl group of the organometallic compound, analysis of the spectra showed that radicals of only one type are generated, mainly those which were incorporated previously in the metal alkyl molecule (Table 5). The results indicate the occurrence of a quite unique reaction of the RO· radical with the C–metal bond [Eqn. (8)], which had not been observed hitherto:

$$RO^{\cdot} + R_xM \rightarrow (ROMR_x)^{\cdot} \rightarrow ROMR_{x-1} + R^{\cdot}. \quad (8)$$

Table 5. The nature of the radicals formed in the interaction between RO· and MR [22,24].

MR	Method of decomposition of peroxide	Solvent	Radical detected by ESR
$ZnEt_2$	P	Tetrahydrofuran	Et
$CdMe_2$	T	Iso-octane	Me
B-n-Bu_3	P, T	"	n-Bu
B-s-Bu_3	P	t-Butyl peroxide	s-Bu
$AlMe_3$	P	Iso-octane	Me
$AlEt_3$	P	"	Et
Et_2AlOBu	P	"	Et
$SbEt_3$	P	"	Et
$BiEt_3$	T	t-Butyl peroxide	Et

It is not clear whether reaction (8) is a stepwise or synchronous S_H2 process, i.e. whether $(ROMR_X)^{\cdot}$ is a true intermediate complex or a transition stage [24]. The postulate that the reaction pathway (8) is preferable to the abstraction of hydrogen atoms is based on the greater energy gain. This follows from a comparison of the stabilities of the corresponding dissociated and formed bonds; some of the available literature data are presented in Table 6.

Table 6. Comparison of the heats of reaction ΔH between RO· and MR and between RO· and $-\overset{|}{\underset{|}{C}}-H$.

Type of bond in M–R	Bond strength, kcal mole^{-1}		ΔH	References
	M–C	M–O		
B–C	85	125	20	25,24
	70	110	40	26
Al–C	65	138	70	25,27
H–C	99	H–O 111	12	28

The energy gain in this pathway for aluminium alkyls is so great that there is actually no need for an initial decomposition of the peroxide into free radicals [22]†; we shall consider later the mechanism of this interaction.

†After this fact had been established, Davies employed in a later study a monoalkoxyaluminium derivative.

The importance of the energy parameter has been demonstrated for trialkoxyboron; in this case, the only pathway is one involving the abstraction of a hydrogen atom from the alkoxy-group with formation of the $(RO)_2BO\dot{C}HCH_3$ radical[21]. The absolute values of the homolytic substitution rate constants and the activation energies for this process have been established for a series of boron alkyls[24]. The required parameters were obtained by the method of competitive reactions in which t-BuO· radicals were able to react with BR_3 and with cyclopentane (C_5H_{10}):

$$(R'O)_2 \xrightarrow{P} 2R'O\cdot \begin{cases} \xrightarrow[k_9]{BR_3} R'OBR_2 + R\cdot & (9) \\ \xrightarrow[k_{10}]{C_5H_{10}} R'OH + C_5H_9\cdot . & (10) \end{cases}$$

(R'=t-Bu)

The concentrations of alkyl and cyclopentyl radicals were determined by ESR and k_9 was evaluated from the expression

$$\frac{k_9}{k_{10}} = \frac{[C_5H_{10}][R\cdot]}{[BR_3][C_5H_9\cdot]}$$

using the literature value of k_{10}. The relevant data (the rate constants k_9 and the activation energies E_9) are presented in Table 7.

The excited triplet form of a carbonyl compound frequently behaves like a free radical in the hydrogen abstraction reaction[4]. It has been shown[29,30] that the excited form of a carbonyl compound, like an alkoxy-radical, gives rise to homolytic substitution of the boron alkyl:

$$Me_2CO \xrightarrow{P} Me_2CO^*,$$
$$Me_2CO^* + BR_3 \xrightarrow{k_{11}} Me_2\dot{C}OBR_2 + R\cdot . \qquad (11)$$

Table 7. Absolute rate constants and activation energies for the S_H2 reaction between $(CH_3)_3CO\cdot$ radicals and boron alkyls[24] (iso-octane, 30°C).

Compound	k_9, litre mole^{-1} s^{-1}	E_9, kcal mole^{-1}
n-Bu_3B	$3\cdot10^7$	0
iso-Bu_3B	$1\cdot10^6$	1.1
s-Bu_3B	$3\cdot10^5$	4.5
$(n\text{-BuBO})_3$	$6\cdot10^5$	2.2
$(iso\text{-BuBO})_3$	$1\cdot10^6$	2.3
$(s\text{-BuBO})_3$	$6\cdot10^5$	—
$(t\text{-BuBO})_3$	$3\cdot10^6$	2.6
C_5H_{10}	k_{10} $2\cdot10^5$	E_{10} 5.2

In conformity with Eqn. (11), two signals were detected in the ESR spectra[30]. The data for the rate of the S_H2 reaction of acetone in the triplet state (Table 8) show that its reactivity in relation to boron alkyls is comparable to that of t-BuO· radicals and varies in the same sequence (cf. Table 7).

3. Interaction of Organometallic Compounds with Acyl Radicals

The interactions of organic derivatives of tin, lead, and mercury, with a number of acyl peroxides and perbenzoates, which have been investigated by Razuvaev and coworkers[31-34], are logically closely related to the reactions discussed in the preceding sections. It has been established that the interaction occurs only at the decomposition temperature of the peroxide; the products indicate the simultaneous occurrence of several processes. One of these is homolytic substitution at the metal atom by free acyl radicals formed as a result of the decomposition of the peroxide.

Table 8. Rate constants for the S_H2 reaction between acetone in the triplet state and boron alkyls at 20°C.[30]

Compound	k_{11}, litre mole^{-1} s^{-1}
Pr_3B	$1.4\cdot10^7$
$(C_6H_{13})_3B$	$8\cdot10^6$
n-Bu_3B	$7\cdot10^6$
iso-Bu_3B	$8\cdot10^4$
s-Bu_3B	$<10^4$

Organic derivatives of aluminium, thallium, and cadmium constitute a special group[35-41]. Their interaction with acyl peroxides is so vigorous that there is no necessity for a preliminary decomposition of the peroxide into free acyl radicals for homolytic substitution‡.

The interaction of AlR_3 (R = ethyl or isobutyl) with benzoyl peroxide (BP), which has been investigated in detail[35-37] both in the absence and presence of a free-radical acceptor, established a number of characteristic features of the process. The reaction is of the donor–acceptor type and is almost instantaneous down to −70°C; the stoichiometric ratio is Al:BP = 2:1. The final products are compounds corresponding to the reactions of free alkyl radicals and dialkylaluminium benzoate; only one Al–C is involved in the reaction and the yield of free radicals is about 10%. For the associated and non-associated forms of the aluminium alkyl, the reaction proceeds identically and is not accompanied by the formation of free benzoate radicals:

$$2AlR_3 + (PhCOO)_2 \rightarrow \left[\begin{array}{cc} R_3Al & AlR_3 \\ \vdots & \vdots \\ O & O \\ | & | \\ PhC \cdots O{-}O \cdots CPh \end{array} \right] \rightarrow \qquad (12)$$

$$\rightarrow 2R_2AlOCOPh + 2R\cdot \rightarrow RH,\ R_{-H},\ R{-}R.$$

The $AlEt_3$–BP interaction takes place virtually with zero activation energy and the rate constant k for the decomposition of the peroxide exceeds by many powers of 10 the rate constant for its thermal decomposition ($k \simeq 10^{-2}$ at 0°C)[42,43].

A kinetic study of the interaction between $AlEt_3$ and BP in the presence of an electron donor–ethyl acetate (EA)—showed that the rate of formation of free radicals follows the relation

$$V = k\frac{[Al]}{[EA]}[BP]^{0.5}, \text{ where } k = \frac{k_{in}}{K_{eq}},$$

‡Strictly speaking, these are trimolecular and not bimolecular reactions.

where $k = k_{in}/K_{eq}$, which corresponds to the reactions formulated below:

$$\begin{gathered} AlEt_3 + EA \overset{K_{eq}}{\rightleftharpoons} AlEt_3 \cdot EA, \\ 2AlEt_3 + BP \overset{k_1}{\rightleftharpoons} [(AlEt_3)_2 \cdot BP] \overset{k_2}{\rightleftharpoons} 2\,(Et_3AlOCOPh)^{\cdot} \rightarrow \\ \xrightarrow[\text{slow}]{k'_{in.}} 2Et_2AlOCOPh + 2Et; \quad k_{in} = k'_{in.}(k_1k_2)^{0.5}. \end{gathered} \tag{13}$$

Thus the results show that only the non-complexed form of the metal alkyl takes part in the reaction with benzoyl peroxide and the role of the electron donor reduces to the decrease of its initial concentration. As shown above, similar relations have been established also for the interaction of peroxy-radicals with R_3B in the presence of an electron donor [15,16]§.

The results obtained for triethylthallium [38,41] and diethylcadmium [40] suggest that mechanism (12) is general for this group of organometallic compounds. The driving force of the interaction is due to the enormous energy gain resulting from a number of causes: the formation of the complex leads to a weakening of the pre-existing bonds, which facilitates their dissociation, while, on the other hand, the final result of the reaction is related to the conversion of the covalent M–C bond into the ionic M–O–C–R linkage. Using $AlEt_3$–BP as an example, one may attempt to calculate the thermal balance for this interaction. By analogy with the heat of formation of a complex of $AlEt_3$ with an ester [42–44], in the formation of the complex via the two carbonyl groups of the peroxide approximately 20 kcal mole^{-1} is presumably evolved. The decomposition of the peroxide is known to require 30 kcal mole^{-1}, i.e. in the complex this process takes place almost without the consumption of heat. The stability of the AlOCOR linkage has been calculated from the formula $E = e^2/R$. If one assumes that the charge $e = 4.8 \times 10^{-10}$ e.s.u. and the distance between the charges $R = 2$ Å, [47,48] then $E \simeq 160$ kcal mole^{-1}¶. The dissociation energy of the Al–C bond (65 kcal mole^{-1}) [25] yields an overall energy gain of about 100 kcal mole^{-1}.

As already mentioned, when t-butyl peroxide interacts with $AlEt_3$, an extremely vigorous reaction also takes place [22]. The mechanism of this process is analogous to that discussed for benzoyl peroxide [Eqn. (12)]. In this case, the final product is an alkoxy-derivative of aluminium [39].

Thus homolytic substitution at the metal atom is determined by the energy gain in the conversion of M – C into M–O or M–OCOR bonds, the Lewis acidity of the metal alkyl, and the ease of dissociation of the peroxide bond. The first condition is to some extent correlated with the position of the metal in the electronegativity series, being reflected in the amount of ionic character of the bond formed. For example, boron alkyls, which contain the least "metallic" of the elements of the series considered, altogether fail to react with benzoyl peroxide [49].

§The conclusion that only the non-complexed form of $AlEt_3$ is involved in the reaction with benzoyl peroxide follows from the data obtained in a study of the kinetics of the polymerisation of vinyl chloride under the influence of the $AlEt_3$–BP system in the presence of electron donors: butyl ether, pyridine, and allyl acetate [44]. However, it has been suggested [45] that the interaction between triethylaluminium-ether and peroxides involves the displacement of one ligand by another.

¶Infrared spectra show that the Al–OCOR bond formed is ionic according to its vibration frequency [35].

4. Interaction of Metal Alkyls with Radicals having the Reaction Centre at the Nitrogen Atom

The reactions of free radicals with the reaction centre at the nitrogen atom have been investigated for the interaction of organic derivatives of boron and antimony with the dimethylnitrogen radical generated photolytically or thermally from tetramethyltetrazene [50]. Data indicating the occurrence of the following reactions have been obtained by ESR and ^{1}H NMR spectroscopy:

$$\begin{gathered} [(CH_3)_2N{-}N{=}]_2 \xrightarrow{P} \underset{(I)}{2\,(CH_3)_2N^{\cdot}} + N_2, \\ (I) + MR_x \rightarrow (CH_3)_2N{-}MR_{x-1} + R^{\cdot}. \end{gathered} \tag{14}$$

The rate constant for reaction (14) involving Bu_3B is 8×10^3 litre mole^{-1} s^{-1} at 35 °C. A similar reaction takes place with aluminium alkyls, giving a high yield of the final product, which is of preparative value for the synthesis of aluminium amides [51]. The ESR spectra for the reaction of aluminium alkyls with $(CH_3)_2N^{\cdot}$ are less definite than for alkoxy-radicals [50]. The reactions of succinimidyl radicals with organic derivatives of tin have been investigated; in the case of alkyl derivatives, the process proceeds via a radical mechanism [52]. It has been shown [53] that the interaction of R_3SnH with triazenes $Ar\underset{1}{-}N\underset{2}{=}N\underset{3}{-}N{-}R'{-}R''$ can proceed via different pathways depending on the nature of R′ and R″: either via an $S_H2(\alpha)$ reaction with formation of $R_3SnNR'R''$ or via an $S_H2(\gamma)$ 1–3 displacement reaction leading to $Ar{-}\underset{\displaystyle SnR_3}{\underset{|}{N}}{-}N{=}NR''$ and R′.

The reactions discussed in Section II, subsections 2, 3, and 4 are radical non-chain processes, i.e. a significant concentration of free radicals could be achieved in this way. For this reason, they may serve as a very convenient secondary source of free alkyl radicals with a wide variety of structures.

5. Reactions of Metal Alkyls with Radicals having the Reaction Centre at the Metal Atom

Reactions equivalent to those discussed for oxygen- and nitrogen-containing radicals obtain also with radicals where the reaction centre is at the sulphur atom. The interaction between thiophen and organic derivatives of antimony and bismuth has been investigated; thiyl radicals were generated with the aid of hyponitrile and the process was followed by NMR spectroscopy [54]. The possibility of sensitising this reaction with the aid of free radicals and of inhibiting it with phenothiazine or galvinoxyl suggested [54] that a free-radical chain process takes place, the stages of which are presented below:

$$R^{\cdot} + C_6H_5SH \rightarrow \underset{(II)}{RH} + C_6H_5S^{\cdot}, \tag{15}$$

$$(II) + MR_3 \rightarrow C_6H_5S{-}MR_2 + R^{\cdot}. \tag{16}$$

The formation of alkyl radicals following attack by sulphur-containing radicals has been demonstrated under the conditions of the photolysis of diaryl or dialkyl sulphides in the presence of boron alkyls in the tube of the ESR spectrometer [55]. The relative rates of the S_H2 reaction with participation of the organoboron compound and the reaction involving the addition of butane-1-thiol to an olefin [55] have been investigated by the method of competing reactions. The following reactivity series has been established for boron alkyls: n-Bu_3B > iso-Bu_3B > > s-Bu_3B. According to the authors, the rate of the

dealkylation reaction is determined by the steric characteristics of the butyl group. The rate constants have the same order of magnitude as for the reaction of alkoxy- or peroxy-radicals with BR_3 (10^5–10^7 litre mole^{-1} s^{-1}). The energy gain in this process is due to the difference between the stabilities of the B–S and B–C bonds, amounting to approximately 10 kcal mole^{-1}.

6. Homolytic Substitution at the Metal Atom in the Reaction with Alkyl Radicals

Homolytic substitution at the metal atom is not limited to reactions with radicals having the reaction centre at the heteroatom. Thus the kinetic parameters of the interaction of methyl radicals (produced by the photolysis of azomethane in the gas phase) with BEt_3 have been estimated [56]. The relations obtained for the two possible pathways of the process [Eqns. (17) and (18)] suggest that in this case the homolytic substitution reaction is slightly preferable to the abstraction of hydrogen:

$$CH_3^{\cdot} + BEt_3 \begin{cases} \xrightarrow{k_{17}} Et^{\cdot} + CH_3BEt_2; & k_{17}=10.6-\frac{5200}{4.58T}, \quad (17) \\ \xrightarrow{k_{18}} CH_4 + CH_3\dot{C}HBEt_2; & k_{18}=12.6-\frac{7780}{4.58T}. \quad (18) \end{cases}$$

Probably the reaction of $AlEt_3$ (or $AlEt_2Cl$ with azobisisobutyronitrile (under the conditions of the decomposition of the latter) can be classified as homolytic substitution at the metal atom by an alkyl radical; signals due to two radicals–the ethyl and dimethylcyanomethyl radicals—were detected in the ESR spectra [57].

The data presented show that reactions involving homolytic substitution at the metal atom are characteristic of a wide range of organometallic compounds. The energy gain in these reactions ensures the formation of significantly more stable bonds than those existing previously; the reactions take place with a low activation energy at a high rate, which is in many cases close to the rate determined by diffusion. Consequently, such reactions can successfully compete with other free-radical processes.

III. ANALYSIS OF CERTAIN REACTIONS INVOLVING ORGANOMETALLIC COMPOUNDS

1. Radical Polymerisation

We shall consider certain examples the interpretation of which has become possible (or more definite) on the basis of the relations discussed above. Mixtures of metal alkyls with oxygen are used as low-temperature sensitising systems, but the mechanism of the formation of free radicals under these conditions has hitherto remained fairly tentative. The reactions discussed in the first part of the review [Eqns. (5)–(7)], responsible for the formation of free radicals on oxidation, take place during the sensitisation of polymerisation under the influence of such systems. The relative contribution of reactions (5)–(7) to sensitisation is related to the nature of the metal alkyl, the relative concentrations of oxygen and the metal alkyl, temperature, etc. [2,3]

In a study of the polymerisation of methyl methacrylate in the presence of boron alkyl, it was noted that inhibitors do not affect the process. This suggested an unusual mechanism of chain propagation, involving a complex of the growing radical with the boron alkyl, which is not acted upon by the inhibitor [58,59]. It has been shown that this idea [60–62] is erroneous and the causes of the above effect have been discussed. Firstly, Arimoto [58] employed inhibitors which are in general ineffective in the polymerisation of methyl methacrylate (hydroquinone, *N*-phenyl-α-naphthylamine, etc.). The second reason is related to the specific features of the action of the usual inhibitors on boron alkyls. This phenomenon must be considered in detail, since it reflects features which are fundamentally different from those usually adopted in the chemistry of radical reactions. The interaction of inhibitors with free alkyl radicals generated in the sensitisation stage leads to the appearance of radicals with the reaction centre at oxygen or nitrogen atoms. As stated above (Section II, subsections 2 and 4), in model conditions, the reaction of radicals having such a structure with boron alkyls involves an extremely high energy gain. This leads to the formation of a new highly active alkyl radical and not a stable radical from the inhibitor. For polymerisation (M = monomer) using an inhibitor, for example quinone $C_6H_4O_2$, this is illustrated by the following mechanism [61,62]:

$$M_xM^{\cdot} + C_6H_4O_2 \rightarrow \underset{(III)}{M_xMOC_6H_4O^{\cdot}}, \quad (19)$$

$$(III) + BEt_3 \rightarrow M_xMOC_6H_4OBEt_2 + Et^{\cdot}, \quad (20)$$

$$Et^{\cdot} + M \rightarrow EtM^{\cdot}, \quad (21)$$

$$\text{etc}\dagger.$$

Thus, in a radical process involving boron alkyls (oxidation or sensitisation of polymerisation), the usual inhibitors behave at best as chain transfer agents.

All the data quoted demonstrate that only stable free radicals such as galvinoxyl or compounds generating such radicals as a result of the primary reaction (phenothiazine, nitroxide) can serve as effective inhibitors of processes involving organometallic compounds.

One may quote further examples concerning polymerisation and demonstrating that homolytic substitution at the metal atom alters the primary pattern of radical reactions. It has been established that aluminium alkyls are involved in the thermal polymerisation of styrene (St), behaving as highly active chain-transfer agents ($C_{transf} \simeq 20$) [64]. This process does not occur as a result of the abstraction of a hydrogen atom from the alkyl group but as a homolytic substitution of the entire group which had been previously linked to aluminium:

$$\text{poly-St}^{\cdot} + AlR_3 \rightarrow \text{poly-StAl}R_2 + R^{\cdot}. \quad (22)$$

Thus, instead of the relatively inactive benzyl radical, reaction (22) generates a highly active alkyl radical. Presumably the energy gain in such a reaction is associated with the stabilisation of the Al–benzyl bond relative to the Al–alkyl bond as a result of electron transfer from the benzene ring.

In the polymerisation of methyl methacrylate under the influence of systems of the type AlR_3–BP, the organoaluminium component is an extremely active chain-transfer agent [65]. Probably in this case the energetically favourable reaction between the oxygen form of the growing PMMA$^{\cdot}$ radical,

$$\sim CH_2-\underset{\underset{H_3C}{|}}{\overset{\overset{\cdot}{|}}{C}}-\underset{\underset{OR}{|}}{C}=O \leftrightarrow \sim CH_2-\underset{\underset{H_3C}{|}}{C}=\underset{\underset{OR}{|}}{C}-\dot{O},$$

†The possibility of employing a metal alkyl–hydroquinone (or quinone) mixture for the sensitisation of radical polymerisation, is also related to reactions of type (19)–(21). [63]

and the aluminium alkyl, leading to the termination of the material chain, is responsible for the observed effect.

It is well known that aluminium alkyls are themselves incapable of sensitising the polymerisation of vinyl monomers. However, when a very high concentration of $AlEt_3$ and illumination are employed, the radical polymerisation of methyl methacrylate proceeds very effectively[66]. The mechanism of the formation of free radicals is in this case probably very similar to that of reactions between the excited form of the carbonyl compound and the boron alkyl [Eqn. (11)].

2. The Applications of Reactions involving Homolytic Substitution of Groups Linked to the Metal in Synthetic Organic Chemistry

In this subsection we shall confine ourselves to a small number of examples in order to demonstrate the possibilities inherent in the process involving homolytic substitution of groups linked to the metal in preparative organic chemistry. Controlled oxidation of organoboron compounds has been used by Brown and coworkers to synthesise a wide variety of compounds. The process has a free-radical mechanism and includes a series of consecutive reactions at the boron atom with participation of $R_2^{\cdot}$, $RO^{\cdot}$, and $RS^{\cdot}$ radicals [67-73,75].

Conditions for the quantitative oxidation of organoboron compounds to the corresponding alcohols have been found[67]. It has been stated that the reaction is appreciably inhibited by a small amount of iodine[68]. The oxidation of Bu_3B in the presence of organic iodides R'I' (R' = benzyl, allyl, *p*-nitrobenzyl, etc.) leads to the formation of butyl iodide in an amount equivalent to that of the initial iodide and of the recombination products of the R'' radicals[69]. Reactions responsible for the observed course of the process have been suggested:

$$R_3B + O_2 \rightarrow R_2BO_2^{\cdot} + R^{\cdot}, \quad (23)$$

$$R^{\cdot} + R'I \rightarrow RI + R''^{\cdot}, \quad (24)$$

$$2R''^{\cdot} \rightarrow R'—R', \quad (25)$$

$$R''^{\cdot} + O_2 \rightarrow R'O_2^{\cdot}, \quad (26)$$

$$R'O_2^{\cdot} + R_3B \rightarrow R'O_2BR_2 + R^{\cdot}. \quad (27)$$

$\alpha\beta$-Unsaturated aldehydes or ketones with an external double bond are known to undergo a 1,4-addition reaction with boron alkyls, giving rise to saturated carbonyl derivatives[70]. The process is inhibited by galvinoxyl radicals. This led to the assertion that it has a homolytic mechanism; earlier it was believed that the reaction has a polar mechanism with a six-membered transition state[71]. In the absence of specially introduced sensitisers, unsaturated β-substituted carbonyl compounds are incapable of this type of reaction with boron alkyls. The presence of a measurable amount of oxygen (or of other free-radical sensitisers) ensures the development of the process in the required direction and the yield of the desired product is close to theoretical. The intermediate stages of this reaction (for methyl propenyl ketone) are quoted below[72]:

$$BR_3 + O_2 \rightarrow R^{\cdot}, \quad (28)$$

$$R^{\cdot} + CH_3CH{=}CH{-}CO{-}CH_3 \rightarrow \underset{\displaystyle CH_3CH{-}CH{=}CO{-}CH_3}{\overset{\displaystyle R}{\overset{|}{CH_3CH{-}\dot{C}H{-}CO{-}CH_3}}}, \quad (29)$$

(IV)

$$(IV) + BR_3 \rightarrow \overset{\displaystyle R}{\overset{|}{CH_3CH}}{-}\overset{\displaystyle CH_3}{\overset{|}{CH}}{=}CO{-}BR_2 + R^{\cdot}, \quad (30)$$

$$\xrightarrow{\text{hydrolysis}} CH_3\overset{\displaystyle R}{\overset{|}{C}}H{-}CH_2{-}\overset{\displaystyle CH_3}{\overset{|}{C}}{=}O. \quad (31)$$

The synthesis of homologues of the tetra-atomic carbon chain, achieved by the interaction of the monoepoxy-derivative of buta-1,3-diene with the boron alkyl, is closely related to these reactions [reactions (28)–(31)].[73]

It has been established that the reaction of organic derivatives of boron with mercaptans hardly occurs in the absence of oxygen or peroxy-compounds. In the presence of free-radical sensitising agents, the process proceeds at a high rate and leads to the formation of dialkylthioboronic acids and saturated hydrocarbons[74]. A convenient synthesis of organic sulphides from disulphides and boron alkyls has been proposed by Brown and Midland[75].

---o0o---

The review can be aptly concluded by Davies' words[13]: "Reactions of the bimolecular homolytic substitution type take place readily at a metallic centre, particularly where the displaced group is an alkyl radical. This provides a new context for investigating the behaviour of free radicals, and is the key to the understanding of many organometallic reactions".

The Properties of Orthoesters and Their Applications in Organic Synthesis

V.V.Mezheritskii, E.P.Olekhnovich, and G.N.Dorofeenko

A systematic and general account is given of data on the properties of orthoesters and their applications in organic synthesis. The mechanisms of certain reactions involving orthoesters have been considered or revised.
The bibliography includes 278 references.

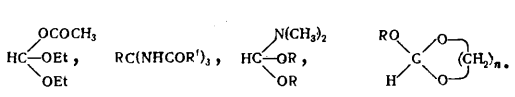
I. INTRODUCTION

Despite the fact that the esters of orthocarboxylic acids cannot always be compared as regards the number of known examples with certain widely familiar classes of organic compounds, their importance in many synthetic methods is very great. It is sufficient to say that the application of orthoesters made it possible to develop extremely simple methods for the introduction of the formyl or acyl residue into an aromatic ring, at a double bond, and in the α-methyl and methylene groups of carbonyl and heterocyclic compounds. Acylation and also alkylation of oxygen, sulphur, nitrogen, phosphorus, and silicon atoms of a wide variety of organic and inorganic substances has been achieved with the aid of orthoesters.

It is noteworthy that hitherto orthoformates (in particular ethyl orthoformate) have found the greatest number of applications, which is due to their high reactivity in many reactions and greater availability compared with other orthoesters.

The advances achieved in the chemistry of aliphatic orthoesters were described in Post's review[1] published in 1943. In 1953, the properties of ethyl orthoformate were briefly reviewed[2]. Certain examples of the applications of orthoesters have been compared in familiar monographs on organic chemistry[3-5]. However, there are no reviews in the Soviet literature dealing with this problem.

The vigorous development of the chemistry of orthoesters in recent years led to the accumulation of extensive factual data, a systematic and general account of which is required. Moreover, the mechanisms of certain reactions have been re-examined and revised in the light of recent studies.



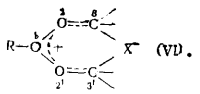
In the present review, we attempted to cover the known types of reactions of orthoesters without endeavouring to give an exhaustive description of data for individual reactions.

II. THE STRUCTURE AND REACTIVITY OF ORTHOESTERS

Organic orthoesters have the general formula (I) and are the esters of orthoacids which do not exist in a free state:

$$RC(XR')_3.$$
(I)

Oxygen or sulphur function as the heteroatom X. The group R can be an alkyl, aryl, or aralkyl residue or a functional group (COOR, OR, etc.). The group R′ is as a rule aliphatic, although aryl orthoformates are known[6]. There exist mixed orthoesters containing groups R′ of different types. These include, for example, diethoxymethyl acetate (II)[7]. Certain amino-derivatives of orthoacids [orthoamides(III)][8], acetals of dimethylformamide (IV)[9], cyclic orthoesters (V)[10], etc. resemble orthoesters as regards the nature of the reactions in which they are involved.

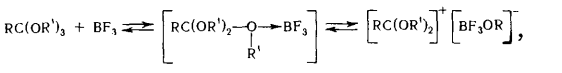


(II) (III) (IV) (V)

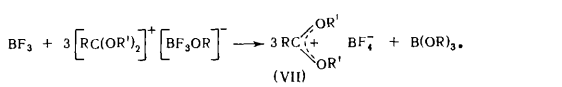
Orthoesters are highly reactive owing to the electron deficient central carbon atom caused by the $-I$ effect of the electronegative groups XR. The presence of a positive charge on the central atom results in their affinity for nucleophilic agents and the transition state is stabilised fairly readily by the elimination of HXR (an alcohol or mercaptan).

Orthoesters can be activated by protic and aprotic acids. The catalytic effect of acids is due to their interaction with orthoesters, which gives rise to the formation

under the reaction conditions of an extremely reactive carboxonium ion (VI), which has been isolated as a salt [10]:



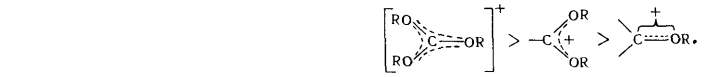
(VI).



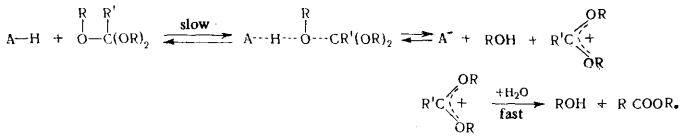
As a result of [electron] delocalisation, the dialkoxycarboxonium cation carries a partial positive charge both on the oxygen atoms and on the carbon atoms linked to them (1,3,3′). As a result of such charge distribution, the carboxonium ion exhibits a dual reactivity. In those cases where the nucleophilic centre of the reacting species is attacked by the central carbon atom of the carboxonium ion, insertion into the molecule of the acetal fragment $RC(OR')_2$, i.e. acylation, takes place. On the other hand, when the attack is by the 3- or 3′-carbon atom of the alkyl group, alkylation takes place. Acylation can occur both at a carbon atom in organic compounds (the formation of a C–C bond) and at a heteroatom (O, S, N, P, etc.). Alkylation is as a rule directed only to a heteroatom which is involved in a multiple bond (=O, ≡N, =S, etc.). However, cases of alkylation at S–H or O–H bonds are known [11,12], as well as cases where an alkyl group combines with a halide ion [13,14]. Under certain conditions acylation and alkylation reactions can occur simultaneously and behave therefore as competing or parallel processes [15]. Under conditions of acid catalysis, the orthoesters of alkanecarboxylic acids give a lower yield of condensation products with amines [16] and ketones [7] than orthoformates. This can be accounted for by the compensation of the positive charge of the carboxonium ion produced by the $+I$ effect of the alkyl group.

The specific effect of the structure of the orthoester on its reactivity is discussed in the individual sections of the review.

III. REACTIONS OF ORTHOESTERS WITH INORGANIC ACIDS

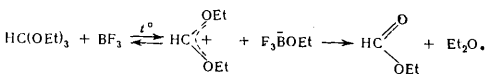


Orthoesters react with protic and aprotic acids, metal halides, and certain oxides. Acids and metal halides (calcium, magnesium, platinum, antimony, etc. halides) tend to form complexes which are sometimes fairly stable and can be isolated. Meerwein [10] showed that orthoesters form complexes with BF_3 and $SbCl_5$, which in certain cases can ionise at the C–O bond with formation of a carbonium ion and the complex anions $(ROBF_3)^-$ or $(ROSbCl_5)^-$, disproportionating to the stable anions BF_4^- and $SbCl_6^-$:



(VII)

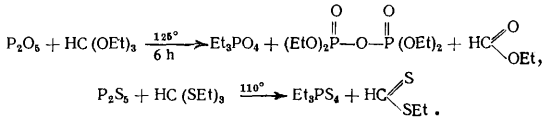
The anion disproportionation stage is rate-limiting. The capacity of the complexes for ionisation increases with electron density at the central atom and with increase of the stability of the carboxonium ion (VII) formed. In the general case, the stability of carboxonium ions decreases with the number of oxygen atoms bound to the charged carbon atom, owing to the decrease of the contribution of the oxonium forms to the corresponding carboxonium structure:



The hydrolysis of orthoesters is one of the most thoroughly investigated reactions. Many studies have been made on the elucidation of its mechanism. In the light of recent data [18–20], the hydrolysis of orthoesters is an example of general acid catalysis reaction and may be regarded as an example of bimolecular electrophilic S_E2 substitution at the oxygen atom:

The reaction of ethyl orthoformate with hydrogen sulphide takes place similarly to hydrolysis [21]:

When ethyl orthoformate is heated in the presence of very small amounts of BF_3, it undergoes catalytic decomposition into ethyl formate and ethyl ether [22]:



Acidic oxides are alkylated by orthoesters at the oxygen atom. Evidently this process also involves the formation of a carboxonium ion, since the reaction products include ethers and esters. When a 1 : 3 mixture of boron trioxide and an alkyl orthoformate is heated, trialkyl borates are formed [23] in yields of about 50%:

Under more severe conditions, boron trisulphide also reacts with orthoesters:

Reactions of ethyl orthoformate and ethyl thio-orthoformate with phosphorus pentoxide and pentasulphide have been described [25]:

The reactions of orthoesters with metal and non-metal halides have been investigated. These reactions usually result in the substitution of halogen atoms by alkoxy-groups. The reaction products may include alkyl halides, ethers, and carboxylic acid esters. Thus Arbuzov and Bogonostseva [26], who investigated the reaction of phosphorus trichloride with ethyl orthopropionate, observed that, by altering the proportions of the reactants, it is possible to replace in succession all three halogen atoms in the PCl_3 molecule by ethoxy-groups.

In the presence of $AlCl_3$, germanium tetrachloride reacts with orthoformates [27] to form substances having the general formula $Cl_nGe(OR)_{4-n}$, where $n = 0-3$.

The capacity of orthoesters to give rise to alkyl halides in the presence of halide ions has been used in the synthesis of ethyl fluoride [14], which is formed in 90% yield.

A novel method of synthesising alkyl iodides, proposed by Dangiyan [13], is based on the interaction of alkyl orthoformates with elemental iodine in the presence of various metals (Mn, Zn, Mg, Fe, Al).

The reactions of orthoesters with halogen-containing organic derivatives of the elements have been investigated. A method of preparing alkoxysilanes by the reaction of halogenosilanes with alkyl orthoformates in the presence of $AlCl_3$ has been described [28]:

$$R_mH_nSiX_{4-(m+n)} + HC(OR')_3 \xrightarrow{AlCl_3} R_mH_nSi(OR')_{4-(m+n)}$$

($m = 0, 1, 2, 3$; $n = 0, 1, 2, 3$; $m + n \leqslant 3$, X = halogen). Chlorocyanoalkylsilanes [29], boron-containing chloroalkylsilanes [30], and 1,1,1-trihalogenophospholens [31] are alkoxylated similarly.

A convenient method for the alkylation of phosphorodithioic acid ester consists in heating in with the orthoesters of alkanecarboxylic acids:

$$(EtO)_2P(S)SH + RC(OR')_3 \rightarrow (EtO)_2P(S)SR' + R'OH + RC(O)OR'.$$

The alkylation reaction also constitutes the basis of the synthesis of alkyl hypophosphites from hypophosphoric acid [12]:

$$H_2P(O)OH + RC(OR')_3 \xrightarrow{N_2} H_2P(O)OR' + R'OH + RC(O)OR'.$$

An interesting method of formylation at a phosphorus atom consists in heating a mixture of orthoformate and dialkyl metaphosphate [32]:

$$(RO)_2P(O)H + HC(OR')_3 \rightarrow (RO)_2P(O)CH(OR')_2 + R'OH.$$

IV. EXCHANGE OF ALKOXY-GROUPS AND ALKYLATION REACTIONS

1. Exchange of Alkoxy-groups of Orthoesters

Transesterification reactions leading to partial or complete replacement of alkoxy- or alkylthio-groups of the orthoesters by new RO or RS groups may be regarded as the simplest reactions of orthoesters. These reactions take place when orthoesters are treated with alcohols, phenols, carboxylic acids, carboxylic acid anhydrides, and mercaptans and are typical examples of nucleophilic substitution at a saturated carbon atom.

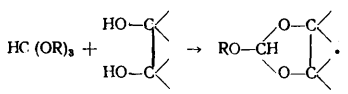
Transesterifications with alcohols, phenols, and mercaptans as a rule requires an active catalyst, while in the case of carboxylic acids the latter probably are sufficiently acidic to catalyse the reaction. The reactions involve a carboxonium ion:

$$RC(XR')_3 + H^+ \rightleftharpoons RC^+(XR')_2 + R'XH,$$

$$RC^+(XR')_2 + R''YH \rightleftharpoons R''\overset{+}{Y}(H)-C(XR')_2R \rightleftharpoons RC(XR')(YR''),$$

$$RC(XR')_2(YR'') \overset{+R''YH}{\rightleftharpoons} RC(XR')(YR'')_2 \overset{+R''YH}{\rightleftharpoons} RC(YR'')_3.$$

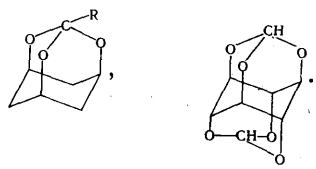
The exchange of alkoxy-groups constitutes the basis of the synthesis of higher alkyl orthoformates, which are obtained in yields of 75–95%. [33,34]



The corresponding orthoformates are also produced when a mixture of ethyl orthoformate is refluxed with ethyl or butyl alcohol in the presence of $ZnCl_2$. [35] If zinc chloride is replaced by sulphuric acid, another reaction takes place:

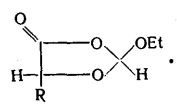
$$HC(SEt)_3 + 3BuOH \xrightarrow{H_2SO_4} 3EtSH + HC(O)OBu + (Bu)_2O.$$

β-Chloroalkanols react with orthoformates, giving rise to a 54–88% yield of β-chloroalkyl orthoesters [36]. Aryl orthoformates have been obtained similarly [6,37].



Mercaptans can react with orthoesters even at room temperature. The products are thio-orthoesters produced in nearly quantitative yields [38].

Compounds containing two or three hydroxy-groups also react with orthoesters, giving rise to the corresponding cyclic derivatives. Ethylene glycol and its derivatives [methylethylene glycol, glycerol α-chlorohydrin, pinacol, cyclohexane-1,2-diol, (+)-tartaric and mesotartaric acids, etc.] give rise to 2-alkoxy-1,3-dioxolanes on heating with methyl or ethyl orthoformates [39,40]:



Glycerol and polyhydric alcohols behave similarly.

In the presence of BF_3, *cis*-phloroglucitol reacts with ethyl orthoformate and ethoxycarbonyltriethoxymethane [41,42], the oxa-analogues of adamantane being formed in yields in excess of 70%:

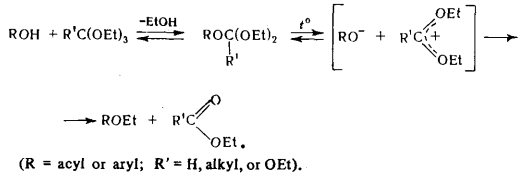
The syntheses of cyclic orthoesters of sugars [43], steroids [44], and other complex compounds have been described. On heating in benzene in the absence of a catalyst, ethyl orthoformate reacts with hydroxyacids [45]. 2-Ethoxy-1,3-dioxolan-4-ones (VIII) were obtained in high yields by this procedure:

(VIII)

In the presence of BF_3, oxiran or methyloxiran adds to methyl or ethyl orthoformate with formation of adducts differing in the proportion of alkoxy-groups [46]:

$$HC(OR)_3 + CH_2(O)CH_2 \xrightarrow{BF_3} HC(OR)_n[(OCH_2CH_2)_mOR]_{3-n}.$$

(n=0, 1, 2; m=1, 2, 3)



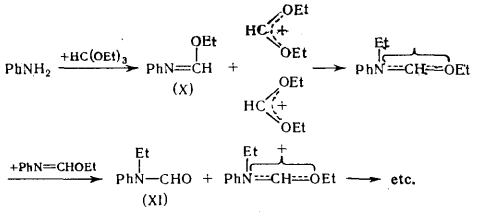
Post and Erickson [47] observed that, when carboxylic acid anhydrides are allowed to react with orthoesters, an alkoxy-group is replaced by an acyloxy-group:

$$RC(OEt)_3 + (R'CO)_2O \rightarrow RC(OEt)_2OCOR' + R'C(O)OEt.$$

This reaction takes place only at elevated temperatures and is irreversible.

2. Alkylation Reactions

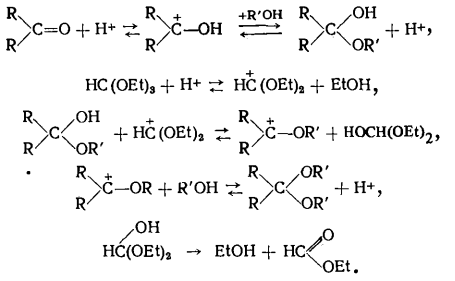
Orthoesters are used to alkylate carboxylic acids, phenols, and certain amines. When acids and phenols are alkylated, the usual transesterification of the orthoesters probably takes place initially. This is followed by the thermal dissociation of the newly formed RO–C linkage and alkylation of the RO^- anion by a carboxonium ion (see Section II):



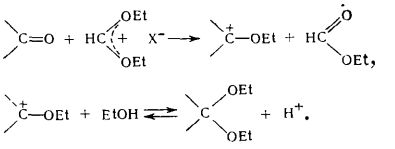
(R = acyl or aryl; R' = H, alkyl, or OEt).

The esterification of carboxylic acids by orthoesters is very promising for preparative purposes [49]. The method is applicable to the esterification of aliphatic, aromatic, and sterically hindered acids as well as certain acids which are difficult to esterify.

Smith [37] obtained alkyl ethers of phenols by refluxing mixtures of the corresponding phenol with a small excess of orthocarbonate:



An interesting reaction was discovered by Roberts and Vogt [50], who showed that, when aniline is heated with ethyl orthoformate in the presence of sulphuric acid above 140°C, the aniline is *N*-alkylated. The ethyl ether of *N*-phenylformamide (X) is formed initially and then *N*-ethylformanilide (XI):



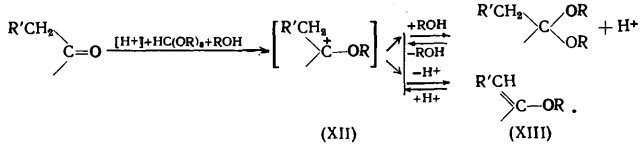
Compound (X) can be converted into (XI) also in the absence of orthoesters but the presence of the latter increases the yield of (XI). When compound (X) is treated with sulphuric acid and isopentyl orthoformate, a mixture of *N*-ethyl- and *N*-isopentyl-formanilides is formed. Toluene-*p*-sulphonic acid also catalyses this reaction but the yield of compound (XI) is low, while the reaction with HCl does not occur at all. These findings are consistent with the sequence of reactions expressed by the above mechanism, which takes into account the intermolecular nature of the conversion of compound (X) into (XI). The method of Roberts and Vogt can be recommended for the synthesis of *N*-monoalkylanilines via the corresponding formanilides in high yields [51,52].

V. SYNTHESIS OF ACETALS AND ENOL ETHERS

The method of synthesising acetals and ketals from the corresponding carbonyl compounds, orthoformates, and alcohols was developed by Claisen [53] and was subsequently widely adopted. The formation of acetals and ketals is an acid-catalysed reaction; it is assumed that the alcohol and not the orthoester behaves as a donor of alkoxy-groups [54]:

Kabuss [55] and Dimroth and Heinrich [56] observed that diethoxycarbonium salts obtained by Meerwein's method [10] from ethyl orthoformate are highly active alkylating agents. In particular, when these salts are mixed with aldehydes or ketones, the latter are *O*-ethylated with formation of ethoxycarbonium salts in nearly quantitative yields. This means that direct interaction between dialkoxycarbonium ions and the carbonyl compound is possible:

Naturally it is probable that the reaction proceeds simultaneously via the two mechanisms indicated with formation of the same final products.



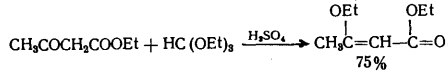
Hydrochloric, sulphuric, phosphoric, and toluene-*p*-sulphonic acids, ammonium chloride, sulphate, or nitrate, iron chloride, and other reagents are used as catalysts for the synthesis of acetals and ketals. Catalysts such as ammonium sulphate and nitrate and the hydrochlorides of mono-, di-, and tri-ethylamines are more effective than ammonium chloride. Magnesium and zinc chlorides give satisfactory results. Alkali metal chlorides are ineffective. Organic acids also exhibit catalytic activities but much weaker than inorganic acids. Their catalytic activity decreases in the sequence oxalic acid > formic acid > > acetic acid.

Ethyl orthoformate is usually employed to synthesise acetals. Other alkyl orthoformates give lower yields and ethyl orthoacetate does not react at all [57]. Benzaldehyde and its substituted derivatives form acetals in nearly quantitative yields regardless of the nature of the substituent [53,58]. Ketals of aliphatic-aromatic ketones such as acetophenone are obtained in yields up to 90% [54,59]. Acetals of aliphatic [58] and $\alpha\beta$-unsaturated aldehydes and ketones are formed in lower yields (which do, however, reach 80%) [60,61].

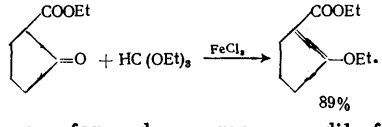
The rate of formation of ketals decreases with increase of the molecular weight of the ketone. Ketones with a branched hydrocarbon chain react more slowly than those with straight-chain alkyl groups and t-butyl methyl ketone does not react at all with orthoformate ester [3,62].

The questions concerning the synthesis of acetals and ketals have been described in detail in monographs by Post [1] and Houben [3] and partly in other publications [2,4,5].

The formation of enol ethers via an elimination reaction probably competes with the formation of acetals:

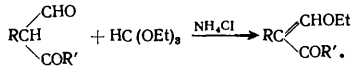


(XII) (XIII)

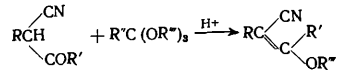


The mechanism shows that the synthesis of acetals and enol ethers invariably involves the intermediate formation of a carboxonium ion (XII). Since acetals and vinyl ethers are products of competing reactions, they are as a rule present together, their relative amounts depending on the process conditions and the structure of the carbonyl component.

The presence of an electronegative group at the α-carbon atom of the carbonyl compound increases the mobility of the α-methylene hydrogen atoms and thereby facilitates the conversion of the carbonium ion (XII) into the vinyl ether (XIII). The ease of formation of enol ethers is satisfactorily correlated with the tendency of the carbonyl compound to enolise. Favourable conditions for the formation of vinyl ethers are created when a mixture of orthoester and the carbonyl compound is heated for a long time in the presence of acids. In this instance, the action of toluene-*p*-sulphonic acid is most specific.

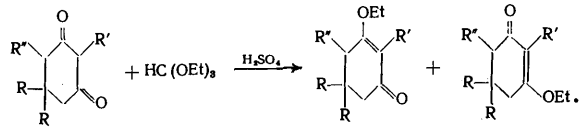


Enol ethers are formed extremely readily from β-dicarbonyl compounds, which is caused not only by the greater acidity of the α-methylene hydrogen atoms but also by the appearance of the group $O{=}C{-}C{=}C{-}OR$, which contains conjugated double bonds. Thus β-ethoxycrotonate is obtained from acetoacetic ester in the presence of several drops of sulphuric acid [63]:

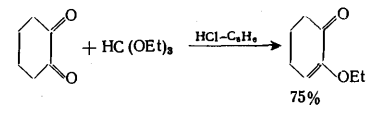


Esters of cyclic β-ketoacids react similarly [64]:

Enol ethers are formed even more readily from β-ketoaldehydes [65,66]:

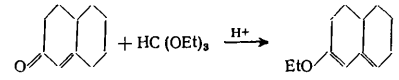


The highly electronegative cyano-group can activate the methylene group [67]:



(R and R′ = H, alkyl, or aryl; R″ = H or alkyl; R‴ = alkyl).

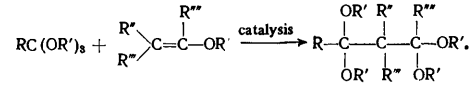
Cyclic ketones show a greater tendency towards the formation of enol ethers than open-chain compounds. A general method for synthesising monoenol ethers of substituted cyclohexane-1,3-diones has been described [68]:



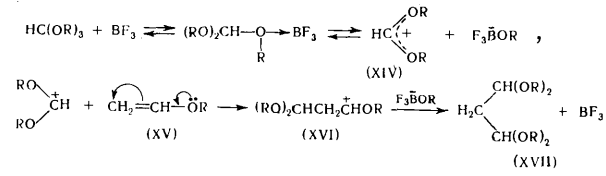
The monoenol ether of cyclohexane-1,2-dione can be obtained in solution in benzene saturated with hydrogen chloride [69]:

The conjugation of the keto-group with a benzene ring facilitates the formation of cyclic enol ethers. Thus an enol ether is formed from α-tetralone even at room temperature [70].

When enol ethers are produced from non-aromatic polycyclic compounds, the new double bond is formed in such a way that a conjugation chain is created (or preserved). This usually involves the migration of the existing double bond. As an example, one may quote the reaction of ethyl orthoformate with $\Delta^{1,9}$-2-octalone [71]:



The formation of enol ethers with simultaneous migration of the double bond is very typical of steroids [72,73].



VI. REACTIONS WITH VINYL ETHERS AND THEIR ANALOGUES

The reaction of orthoesters with vinyl ethers has been described in detail in a highly informative review by Povarov [74]. This section gives a brief description of the general properties of this reaction, attention being concentrated on the reaction of orthoesters with analogues of vinyl ethers involving a similar mechanism.

The overall reaction of orthoesters with vinyl ethers can be represented schematically as follows:

This process, which takes place in the presence of acid catalysts (BF_3, $ZnCl_2$, $FeCl_3$, etc.), can have an ionic mechanism similar to that proposed for the analogous reaction of acetals [75]:

In the course of this reaction, as in many of the cases discussed above, a reactive dialkoxycarbonium ion (XIV) is formed and attacks the β-carbon atom of the vinyl ether (XV), the double bond of which is activated owing to the $+M$ effect of the alkoxy-group. As a result, the acetal fragment ($-HC(OR)_2$) is inserted into the molecule of the vinyl ether with subsequent addition of the alkoxy-group to the carbonium ion (XVI). The final products (XVII) are tetra-acetals of β-dicarbonyl compounds.

The cationic polymerisation of vinyl ethers is an undesirable competing process. Moreover, the carbonium

ion (XVI) can react further with the vinyl ether, which results in the formation of high-molecular-weight adducts. However, since the reactivity of the cation (XIV) is usually higher than that of the cation (XVI), the reaction proceeds preferentially with formation of the tetra-acetal (XVII) even when the molar ratio of the components is 1 : 1 and does not depend very markedly on the amount of the orthoester [76]. Nevertheless, in order to ensure higher yields of the monoadducts (XVII), it is better to employ an excess of the orthoester. In the presence of an excess of the vinyl ether, adducts with higher molecular weights can also be isolated, for example 1,1,3,5,5-pentaethoxypentane [76]:

$$HC(OEt)_3 + 2CH_2{=}CHOEt \xrightarrow{BF_3} EtOCH[CH_2CH(OEt)_2]_2.$$

Povarov [74] showed on the basis of the literature data that orthoesters are intermediate between saturated and $\alpha\beta$-unsaturated acetals as regards reactivity in the above reactions and resemble aromatic acetals. Therefore orthoesters form readily and in high yields monoadducts with unsubstituted and β-substituted vinyl ethers. In the reaction with the more reactive α-alkyl-substituted vinyl ethers, the yield of monoadducts falls approximately by a factor of two and the yield of polymeric products increases. Finally, in the reaction with the highly reactive alkoxydienes, cationic polymerisation predominates and adducts of orthoesters are not formed at all. As was to be expected, in the reactions with vinyl ethers (see Section II) orthoformates are more reactive than orthoacetates [77].

Among the wide variety of tetra-acetals obtained by the reaction of orthoesters with vinyl ethers, one should distinguish the tetra-acetals of malonic dialdehyde, which are difficult to obtain by other methods and which are important intermediates in many syntheses of heterocyclic systems. A simple method of preparation of the tetra-acetals of malonic dialdehyde from readily available compounds consists in the condensation of vinyl acetate with ethyl orthoformate, which involves the exchange of the acetoxy-group for an ethoxy-group [78]:

$$HC(OEt)_3 + CH_2{=}CHOCOCH_3 \xrightarrow{FeCl_3} H_2C\begin{matrix}CH(OEt)_2\\CH(OEt)_2\end{matrix}\ (60\%).$$

Thio-orthoesters react similarly with vinyl ethers [79] and vinyl sulphides [80]:

$$HC(SEt)_3 \xrightarrow{CH_2{=}CHOR} (EtS)_2CHCH_2CH\begin{matrix}OR\\SEt\end{matrix}$$

$$HC(SEt)_3 \xrightarrow{CH_2{=}CHSR} (EtS)_2CHCH_2CH\begin{matrix}SR\\SEt\end{matrix}.$$

Nitrogen analogues of orthoesters and enamides undergo a similar reaction [81]:

$$HC(NHCOOEt)_3 + R'CH{=}CHNHCOOEt \rightarrow R'CH[CH(NHCOOEt)_2]_2.$$

The reaction of orthoesters with ketones in the presence of Friedel–Krafts catalysts leads to the formation of dialkylacetals of β-keto-aldehydes [15, 82]. The enolic form of the ketone (XVIII) plays the role of the vinyl ether in this reaction. The essential features of the reactions can be traced using as an example the interaction between ethyl orthoformate and acetophenone, which gives rise to the diethylacetal of benzoylacetaldehyde (XX):

$$HC(OEt)_3 + HClO_4 \rightleftarrows \overset{+}{H}C(OEt)_2ClO_4^- + EtOH,$$

$$PhC(OH){=}CH_2\ (XVIII) + \overset{+}{H}C(OEt)_2 \rightleftarrows Ph{-}\overset{+}{C}H{-}CH_2CH(OEt)_2\ (XIX) \xrightleftharpoons{-H^+} PhCOCH_2CH(OEt)_2\ (XX,\ 30\%).$$

A characteristic feature of this reaction is that the intermediate cation (XIX) is not stabilised by the addition of an RO radical, as for vinyl ethers, but by the dissociation of a proton. This gives rise to a dimethylacetal of the β-dicarbonyl compound instead of the tetra-acetal. The formation of ketals is a competing reaction.

All the above reactions of orthoesters with ketones in an acidic medium can be described by an overall general mechanism. For simplicity, the reversibility of the reaction is not indicated:

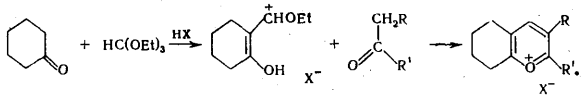
$$-H_2C{-}C(=O){-}H \xrightarrow[+H^+\downarrow\uparrow -H^+]{+\overset{+}{C}H(OR)_3} \left[-H_2C{-}\overset{+}{C}(OR){-}\right] \begin{matrix}\xrightarrow{+ROH} -H_2C{-}C(OR)_2{-}\\ \xrightarrow{-H^+} -HC{=}C(OR){-}\end{matrix}\ \text{pathway } A.$$

$$\left[-H_2C{-}\overset{+}{C}(OH){-}\right] \xrightarrow{+ROH} \left[-H_2C{-}C(OR)_2{-}OH\right], \quad (+\overset{+}{C}H(OR)_3)$$

$$-CH{=}C(OH){-} \xrightarrow[-H^+\downarrow\uparrow +H^+]{+\overset{+}{C}H(OR)_3} \left[(RO)_2CH{-}CH(OR){-}\overset{+}{C}(OH){-}\right] \xrightarrow{-H^+} -HC(CH(OR)_2){-}C(=O){-}\ \text{pathway } B.$$

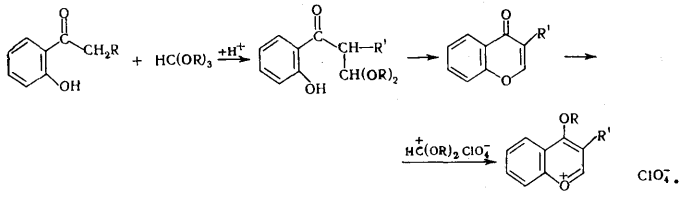
Thus the dual reactivity of dialkoxycarbonium ions is revealed by the fact that they are capable of *O*-alkylation (pathway *A*) with formation of ketals (or enol ethers) and of *C*-formylation, or more precisely of inserting the fragment $HC(OR)_2$ with formation of β-ketoacetals (pathway *B*).

The nature and relative amounts of the final products are greatly influenced by the amount of the acidic reagent. In the presence of catalytic amounts of acids, the reaction could be carried out with a limited number of ketones [17]. Apart from the diethylacetal of benzoylacetaldehyde (XX), low yields are obtained also of the diethylacetals of *p*-methoxy- and *p*-ethoxy-benzoylacetaldehydes.



The reaction with aliphatic and alicyclic ketones usually cannot be arrested at the stage of a monoadduct of type (XX), more far-reaching transformations taking place. Thus the condensation of two molecules of a ketone with an orthoester in the presence of molar amounts of acid results in the formation of a 1,5-diketone, which cyclises under the reaction conditions to a pyrylium cation:

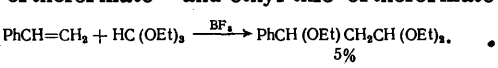
$$RCOCH_3 + HC(OR')_3 \xrightarrow{H^+} RCOCH_2CH(OR')_2 \xrightarrow{+RCOCH_3} \rightarrow \begin{matrix}OR'\\CH\\CH_2\ (RCO)\end{matrix}\ \begin{matrix}CH_2\ (OCR)\\\xrightarrow[-R'OH;\ -H_2O]{+HX}\end{matrix}\ \left[R{-}\overset{+}{O}{=}C(R){-}R\right]\ X^-.$$



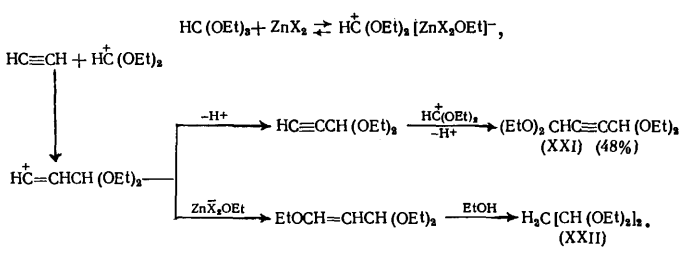
This reaction has served as a basis for a method of synthesising pyrylium salts, which is of general validity. The acid reagents employed are 70% perchloric and 98% sulphuric acids, boron trifluoride-ether, dry hydrogen chloride, aluminium chloride, iron(III) chloride, and others [83].

It has been shown [17] that orthoformates are the most reactive in this process. The yields of pyrylium salts decrease with increase in the chain length of the alkyl substituents in the orthoformate molecule. Orthoesters of alkanecarboxylic acids form [pyrylium] salts in low

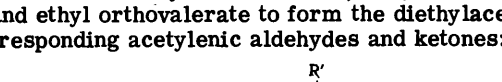
yields. Aliphatic-aromatic, alicyclic, and certain aliphatic ketones enter into the reaction. The yields of pyrylium salts are as a rule high. Cross-condensation was achieved with alicyclic ketones [84]:



When alkyl *o*-hydroxyaryl ketones are employed, the intermediate acetals of β-ketoaldehydes are probably initially cyclised to chromones, which are alkylated and converted into 4-alkoxychromylium salts. The latter are hydrolysed to give high yields of chromones and isoflavones (including natural products of this structure [17,85,86]:

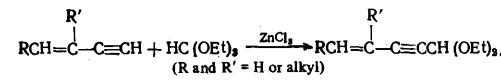


The mechanism of the reaction of vinyl ethers with orthoesters can be quite legitimately applied to the reaction of orthoesters with olefins. The only difference is that the addition to one of the carbon atoms at the double bond is not due to the activating and directing influence of the alkoxy-group, as in vinyl ethers, but is due to the polarisation of the double bond induced by the carbonium cation:

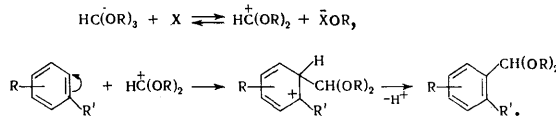


Orthoesters are known [87] to add to isobutene and cyclopentadiene. In the presence of BF_3, styrene condenses with ethyl orthoformate [77] and ethyl thio-orthoformate [87]:

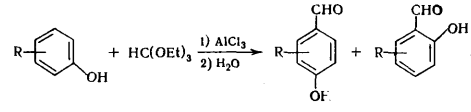
Acetylene reacts with ethyl orthoformate in the presence of zinc halides [88,89], the main reaction product being the tetraethylacetal of acetylenedialdehyde (XXI)—the tetraacetal of malonic dialdehyde (XXII) is formed as a side product:



The reaction is of general validity. Alkyl- and arylacetylenes react with ethyl orthoformate, ethyl orthoacetate, and ethyl orthovalerate to form the diethylacetals of the corresponding acetylenic aldehydes and ketones:

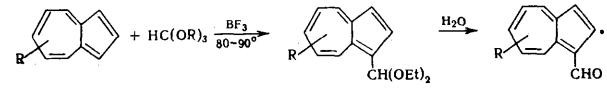


Highest yields (up to 80%) are achieved when ethyl formates are employed. In the reaction involving the orthoesters of alkanecarboxylic acids, the yields decrease approximately by a factor of two. Ethyl orthocarbonate gives rise to acetylenic orthoesters in low yields, for example:

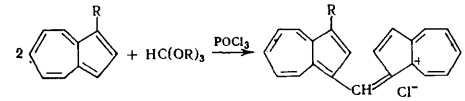


Substituted vinylacetylenes also enter into the reaction with ethyl orthoformate [90]:

The group of reactions including the interaction of dialkoxycarbonium ions with benzenoid of heterocyclic systems is of very great interest. They proceed via a general mechanism involving electrophilic substitution of an aromatic compound:



A new method of formylating phenols by orthoformic ester in the presence of aluminium chloride was proposed in 1963: [91]

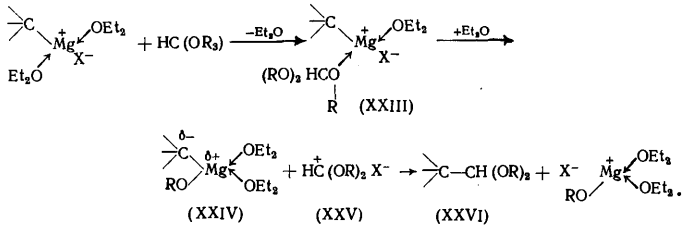


The method was tested on a large series of phenols, methylphenols, and naphthols [92]. Owing to its simplicity, it has substantial advantages over the methods of formylating the above compounds employed previously.

In the presence of acid catalysts (BF_3, $AlCl_3$, $SnCl_4$), azulene and its alkyl-substituted derivatives react with alkyl orthoformates to form the corresponding derivatives of azulene-3-aldehyde [93]:

In the presence of $POCl_3$, the interaction of ethyl orthoformate or ethyl thio-orthoformate with azulenes leads to azulenemonomethine dyes [94]:

When ferrocene is treated with an excess of orthoester in the presence of $AlCl_3$, the following reaction takes place [95]:



Alkyl-substituted pyrroles [96], 2-ethoxypyrroles [97], indoles [98], and 2-ethoxyindoles [99] react with ethyl orthoformate in the presence of acids (HCl, HBr, BF_3) to form monomethine derivatives.

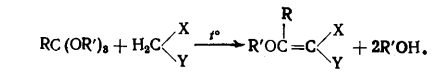
VII. REACTIONS WITH ORGANOMETALLIC COMPOUNDS

Orthoesters react with organometallic compounds as follows:

Orthoformates give rise to acetals and the esters of other orthocarboxylic acids form ketals. In the reaction with orthocarbonic esters, the reaction products are other orthocarbonic esters. Probably the first reaction stage involves the formation of a coordination complex (XXIII) of the organometallic compound with the orthoester as a result of the replacement of a solvent molecule [1,100]. Subsequently the complex decomposes into the alkoxylated organometallic compound (XXIV) and the dialkoxycarbonium salt (XXV). Interaction between these intermediates yields the acetal (XXVI):

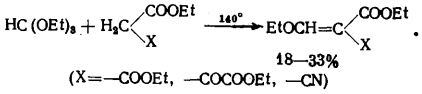
An organomagnesium compound plays the role of an acid activator of the orthoester in this reaction.

The method of acylation with orthoesters described above was proposed by Chichibabin [101]. The synthesis is carried out by refluxing a 1 : 1 mixture of components in ether or in higher-boiling solvents. For the reaction to be successful, it is sometimes necessary to evaporate the solvent after the addition of the orthoester to the solution of the organometallic compound. Frequently, instead of the acetals themselves, one isolates the corresponding aldehydes and ketones by hydrolysing the reaction mixture. The reaction may not stop at the acetal formation stage, since under certain conditions the latter are also capable of exchanging an alkoxy-group for an organic substituent of the organometallic compounds. Methyleneacetals and acetals of aliphatic aldehydes react with greater difficulty, aromatic aldehydes react more readily, and the reaction involving ketals is easiest [3]. In certain cases, all the alkoxy-groups of the orthoesters may be replaced, which results in the formation of a hydrocarbon [102].



The first alkoxy-group is replaced most readily, the reaction being exothermic. The replacement of the second and even more so the third alkoxy-group requires an elevated temperature.

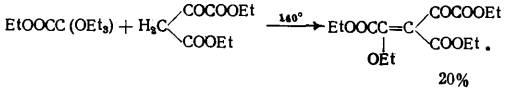
Aliphatic organometallic compounds form acetals in lower yields than aromatic derivatives. The yields of aliphatic acetals decrease with increase of the aliphatic chain length. Orthoformates are more reactive in this process than the orthoesters of alkenecarboxylic acid. In general, the method is convenient for the synthesis of aliphatic [1,103], aliphatic-aromatic [104], unsaturated [105], acetylenic [106], aromatic [107], and heterocyclic [108] aldehydes and ketones. More detailed information about this reaction and its conditions has been given in two monographs [1, 109].



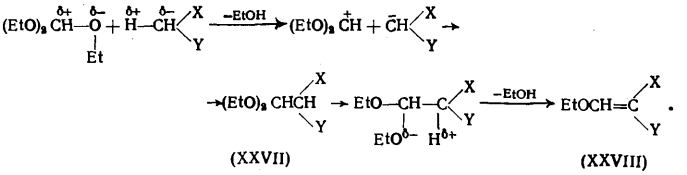
VIII. REACTIONS OF ORTHOESTERS WITH SUBSTANCES CONTAINING AN ACTIVE METHYLENE GROUP

1. Interaction of Orthoesters with Aliphatic Methylene Derivatives

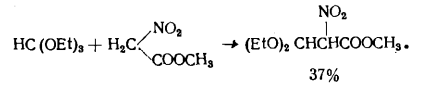
Orthoesters react with compounds containing an active methylene group via the mechanism



The substituents X and Y must be electronegative (COOR, COR, C≡N, and NO_2) and may be the same or of different types. The reaction proceeds on heating (140–150°C) the methylene derivatives with a small excess of the orthoester. The interactions of ethyl orthoformate with acetoacetic, oxaloacetic, and cyanocetic esters have been described [110]:

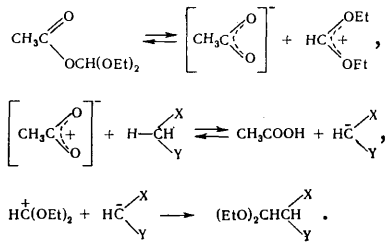


Ethyl orthoformate [110] and ethyl orthoacetate [111] show the greatest reactivity in this reaction (with malononitrile) forming the corresponding ethoxymethylene derivatives in high yields:



Triethoxyethyl acetate reacts with oxaloacetic ester [110]:

Post and Erickson [112] and also Jones [110] believe that the elimination of an alcohol from the orthoester must be preceded by additional polarisation of the C–O bond in the orthoester under the influence of the acidic hydrogen atoms of the methylene compound. One cannot rule out the possibility that at certain stages the reaction is ionic:



In certain cases, the intermediate acetal (XXVII) was isolated as the final reaction product. Thus, on heating ethyl nitroacetate with a small excess of ethyl orthoformate, the diethylacetal of methoxycarbonylnitroacetaldehyde is formed [113]:

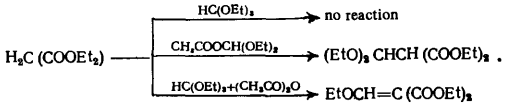
When the acetal is heated to 170°C, a second alcohol molecule is split off and an ethoxymethylene derivative (XXVIII) (X = NO_2; Y = COOEt) is formed.

The diethylacetal of 2,2-dinitropropionaldehyde was synthesised similarly in 18% yield. Owing to the low yields of alkoxymethylene compounds, this method has little preparative value. A version of the synthesis first proposed by Claisen [114] and giving excellent results is employed in laboratory practice for the synthesis of alkoxymethylene compounds. In this procedure, a mixture of the orthoester and the methylene compound is refluxed in the presence of an excess of acetic anhydride which behaves as an activator of the orthoester, forming the reactive diethoxymethyl acetate and, moreover, shifts the reaction in the required direction by combining with the alcohol split off from the orthoester.

The higher reactivity of diethoxymethyl acetate in this reaction compared with ethyl orthoformate is due to the fact that the acetate anion is more stable than the alkoxide anion. Therefore diethoxy methyl acetate should undergo thermal dissociation to a considerable degree and the resulting acetate anion can deprotonate the methylene group:

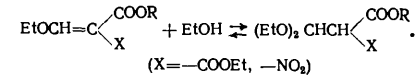
Jones [115], who carefully separated all the products of the reaction of ethyl orthoformate with oxaloacetic ester in acetic anhydride and who determined their amount, proposed a mechanism involving successive transformations which accounts for all the compounds isolated (ethyl acetate, ethyl formate, acetic acid, and exothymethyleneoxaloacetic ester). The quantitative proportions of products which he found are in good agreement with the proportions calculated according to the mechanism proposed:

$$HC(OEt)_3 + (CH_3CO)_2O \rightarrow CH_3COOCH(OEt)_2 + CH_3COOEt,$$



$$CH_3COOCH(OEt)_2 + H_2C(X)(Y) \rightarrow CH_3COOH + (EtO)_2CH-CH(X)(Y), \quad (XXIX)$$

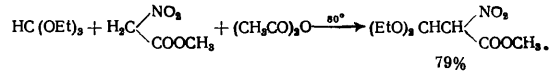
$$(XXIX) \rightarrow EtOCH=C(X)(Y) + EtOH,$$



$$EtOH + (CH_3CO)_2O \rightarrow CH_3COOH + CH_3COOEt,$$

$$CH_3COOCH(OEt)_2 \xrightarrow{t^\circ} CH_3COOEt + HCOOEt.$$

Jones's mechanism also reflects two important factors which were already mentioned above. Firstly, the activating effect of acetic anhydride is shown only in the stage where the acetal (XXIX) is formed. Secondly, in the succeeding stage where the alcohol is split off by compound (XXIX) acetic anhydride serves only to bind the alcohol, displacing the reaction thereby to the right. These postulates are confirmed by the fact that diethyl malonate, a relatively inactive methylene compound, does not react with orthoesters in the absence of acetic anhydride [110] but does react with diethoxymethyl acetate to form only the acetal of formylmalonate [116], and ethoxymethylenemalonate is formed only on heating in the presence of an excess of acetic anhydride [117]:

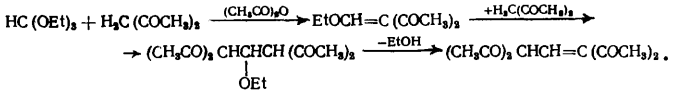


The assertion that acetic anhydride behaves as an alcohol-binding agent in the formation of the ethoxymethylene derivative from compound (XXIX) is consistent with the reversibility of this stage in the absence of acetic anhydride [116,118]:

(X=—COOEt, —NO_2)

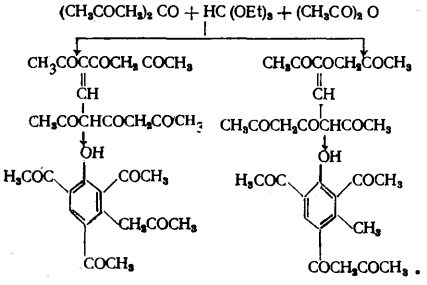
It is also noteworthy that the acetic acid formed in the course of the reaction naturally catalyses the elimination of the alcohol from compound (XXIX). Under mild conditions, compound (XXIX) can be isolated even in the presence of acetic anhydride [118]:

The syntheses of ethoxymethylene derivatives in acetic anhydride from oxaloacetic ester, trifluoroacetic ester, ethyl acetylpyruvate [115], nitroacetic ester [119], acetylacetone [113], ethoxyacetylacetone [120], acetoacetic ester [113,121], ethyl acetonedicarboxylate [122], cyanoacetic ester [123,124], substituted amides of cyanoacetic acid [125,126], malononitrile [127,128], and benzoylacetic ester [129,130] have been described.



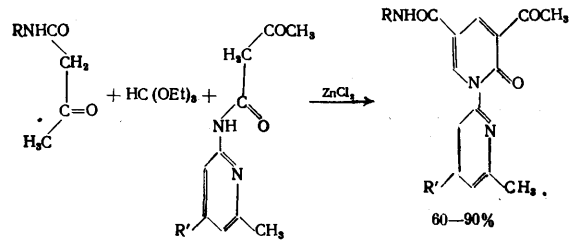
The reactivity of methylene compounds in reactions with orthoesters is higher the greater the electronegativity of the groups X and Y. The group C–N has the highest electronegativity, COR is less electronegative, and COOR is least electronegative.

The reaction with relatively unreactive methylene compounds requires catalysis. Thus prolonged refluxing in the presence of zinc chloride gives diethyl ethoxymethylenemalonate in high yield [131,132].

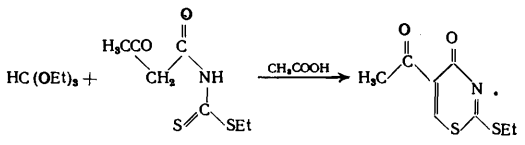


In view of the possibility of creating a system of conjugated bonds, it is possible to carry out the reaction of orthoformate esters with ethyl pyruvate [133]. The interaction of orthoesters with cyclopentene-1,3-dione [134] and indan-1,3-dione [135] has been described.

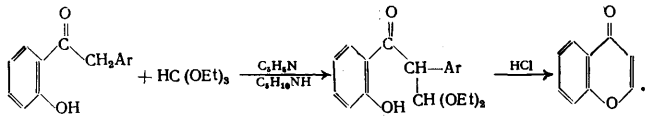
A patent has been taken out [136] for a method of synthesising alkoxymethylene compounds by the reaction of orthoesters with methylene derivatives in the presence of small amounts of glacial acetic acid as the catalyst with continuous distillation of the alcohol formed.



After prolonged heating of orthoesters with methylene compounds in acetic anhydride, one orthoester molecule condenses with two diketone or ketoester molecules [114]:

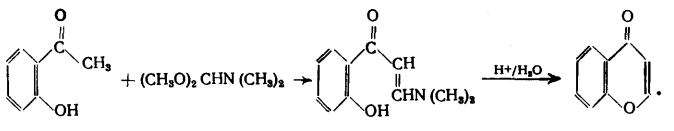


When diacetylacetone interacts with ethyl orthoformate in acetic anhydride, a mixture of isomers, cyclising under the reaction conditions into the corresponding phenols, is formed [137]:

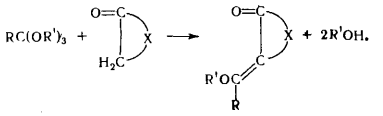


On refluxing in alcohol in the presence of $ZnCl_2$, cyclic products were obtained from substituted amides of acetoacetic acid [138]:

In the presence of a further reactive functional group in the molecule of the methylene derivative, internal cyclisation can occur [139]:

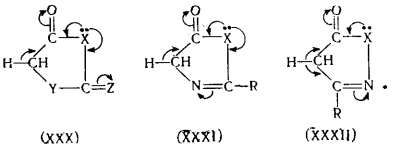


The methylene group in compounds containing a ketobenzyl group is also fairly reactive in the interaction with orthoesters in the presence of basic catalysts. A method of synthesising isoflavones by the condensation of orthoformate ester with benzyl *o*-hydroxyaryl ketones on heating in pyridine in the presence of piperidine was developed on this basis in 1949:[140]



Subsequently the method found extensive application in the synthesis of a wide variety of natural isoflavones and their analogues, which are obtained in high yields.

A modification of the method has been used to synthesise chromone, the orthoester being replaced by the dimethylacetal of dimethylformamide, which functions simultaneously as a reactant and a basic catalyst [9]:

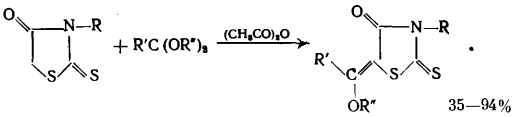


2. Condensation of Orthoesters with Heterocyclic Ketomethylene Compounds

Five- and six-membered ketomethylene compounds with one or two heteroatoms enter into the reaction with orthoesters. This results in the formation of heterocyclic alkoxyalkylidene derivatives:

A wide variety of five-membered heterocyclic systems, which enter into this reaction, correspond to one of the structures [135] presented below:

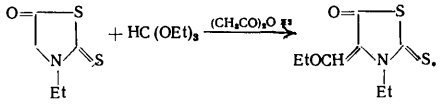
(XXX) (XXXI) (XXXII)



In the first two types [(XXX) and (XXXI)], the hydrogen atoms of the methylene group are activated mainly by the adjacent electronegative keto-group and to a considerable degree also by the fragment Y (XXX, Y = O, S, or NR) or $-N=C\langle$ (XXXI) owing to the $-I$ effect. The group X (O, S, or NR) lowers the electronegativity of the keto-group ($+M$ effect) and has a passivating influence on the methylene group. Passivation in structures (XXX) and (XXXI) is weakened by the influence of a second electronegative group (mesomeric with X) $-C=Z$ or $\rangle C=N-$.

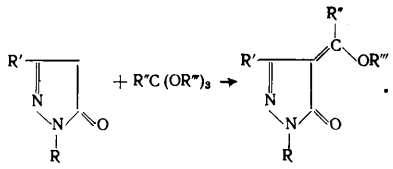
In heterocyclic compounds of type (XXXII), the methylene group is activated simultaneously by the two highly electronegative fragments $-C=O$ and $-C=N$, which leads to a much higher reactivity of compounds of this type compared with (XXX) and (XXXI). Therefore, pyrazolones and isoxazolones (XXXII, X = N or O), for example, react readily with orthoesters in the absence of acetic anhydride, while compounds described by formulae (XXX) and (XXXI) have to be refluxed in acetic anhydride [135].

Steric factors are also important in the reactions of orthoesters, other than orthoformates, with ketomethylene compounds in which the atom adjoining the methylene group has a substituent. This effect can be demonstrated for 3-ethyl-2-thiothiazolidin-5-one, which condenses with ethyl orthoformate to form a planar 4-ethoxymethylene derivative, but does not react with ethyl orthoacetate. An analogous phenomenon has been observed for 1,3-disubstituted 2-thiohydantoins (XXX, X and Y = NR, Z = S) and other compounds with structure (XXX) and a bulky group Y.

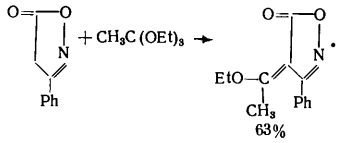


Pyrazolones (XXXII, X = NR) and isoxazolones (XXXII, X = O), which are more reactive, interact with ethyl orthoacetate and ethyl orthopropionate but the alkoxyalkylidene-derivatives formed are unstable for steric reasons. Ethyl thio-orthoformate cannot be made to react with the above types of ketomethylene compounds. Acetic anhydride plays the same role in this reaction as in the case of the acyclic methylene compounds discussed above.

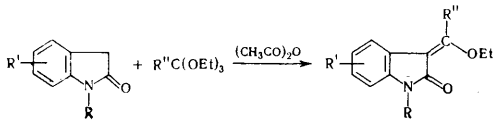
A general method has been developed for the synthesis of 3-substituted 5,1′-alkoxyalkylidene-2-thionothiazolidin-4-ones by refluxing 3-R-rhodanine (R = aryl, alkyl, benzyl, cyclohexyl, allyl, and ethoxycarbonylmethyl) in the presence of an excess of orthoester and acetic anhydride [135,141,142]:



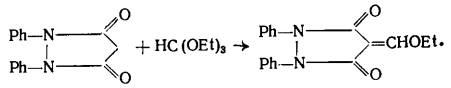
The highest yields of products are achieved with methyl and ethyl orthoacetates, while methyl and ethyl orthoformates and ethyl orthopropionate give somewhat less



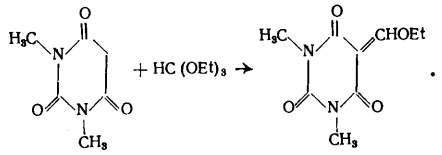
satisfactory results. When a mixture of 3-ethyl-2-thionothiazolidin-5-one is heated with ethyl orthoformate and acetic anhydride, the following reaction takes place [135]:



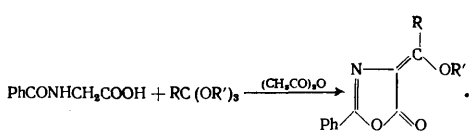
On refluxing with orthoesters in acetic anhydride [142] or in its absence [143], 1,3-disubstituted 5-pyrazolones readily form 4-alkoxyalkylidene derivatives:



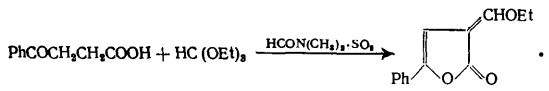
In the absence of acetic anhydride, 3-phenyloxazol-5-one reacts similarly with ethyl orthoacetate to form the unstable 4,1′-ethoxyethylidene-3-phenyloxazol-5-one [135]:



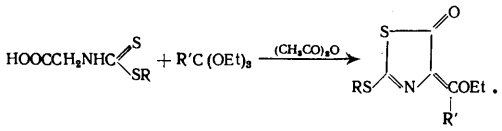
The condensation of orthoesters with oxindole [144] and its derivatives [145], in which the presence of a benzene ring causes additional activation of the methylene group, has been described:



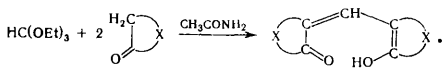
Diketomethylene heterocycles are also extremely reactive in the reaction with orthoesters. Ethyl orthoformate interacts with 1,2-diphenylpyrazole-3,5-dione [146]:



1,3-Dimethylbarbituric acid behaves similarly:

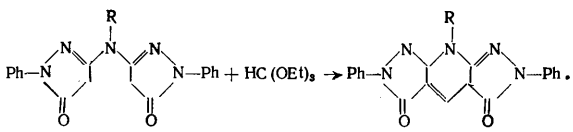


Frequently alkoxyalkylidene derivatives are synthesised in one stage from acyclic compounds. In such cases the condensation involving the methylene group is preceded by cyclisation with formation of a ketomethylene heterocycle. Thus, when hippuric acid was refluxed with orthoesters in acetic anhydride, 4,4′-alkoxyalkylidene-2-phenyloxazol-5-ones were obtained [147,148]:

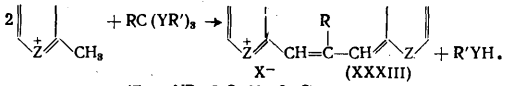


Benzoylpropionic acid reacts with ethyl orthoformate in the presence of a dimethylformamide–sulphur trioxide complex [149]:

N-(Ethylthiothionomethyl)glycine has been used [135] to synthesise 4,1′-alkoxyalkylidene-2-alkylthiothiazol-5-ones:

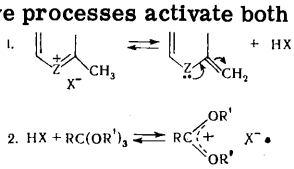


The reaction of orthoesters with ketomethylene heterocyclic compounds can lead to the so called oxonal dyes under certain conditions. Catalysis by a weak base (amides, pyridine) is sometimes used for such syntheses. Zenno [150] developed a method of synthesising oxonol dyes from ethyl orthoformate and certain ketomethylene heterocycles (3-methyl-1-phenylpyrazol-5-one, 3-ethylrhodanine, and barbituric, thiobarbituric, 1,3-diethylbarbituric, and 4-aminobarbituric acids) in the presence of acetamide:



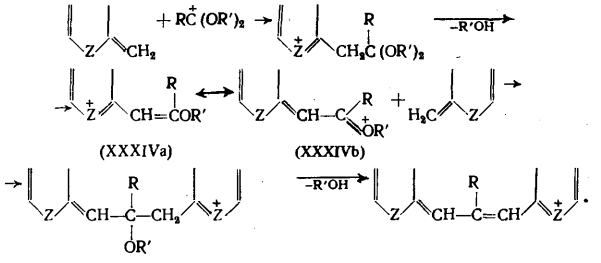
Oxonol dyes have also been obtained from 2-phenylthiazolidin-4-one [151] and certain 3-substituted 2-phenylpyrazolones [152].

The capacity of orthoesters to react with ketomethylene heterocycles can be used to cyclise certain compounds of suitable structure [153]:



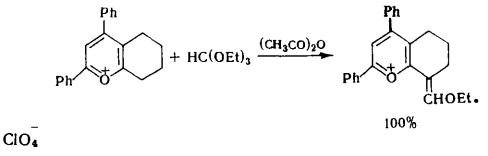
IX. SYNTHESES OF CYANINE DYES

Organic compounds containing a methyl group conjugated with a positively charged atom of a heterocyclic cation can react with orthoesters to form carbocyanine dyes (XXXIII):



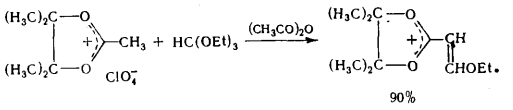
(Z=—NR, O,S; Y=O, S)

It is believed [154] that initially the charged system dissociates into a methylene base and an acid (HX), which reacts with the orthoesters to form a carboxonium salt. These consecutive processes activate both reactants:

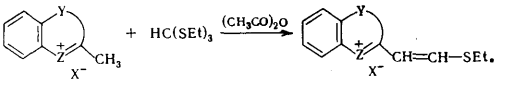


Dissociation is also promoted by solvents such as pyridine and acetic anhydride.

The aim of further reactions is clear from the following scheme:



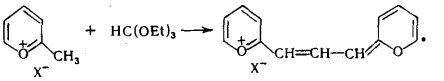
The scheme is valid also for thio-orthoesters.



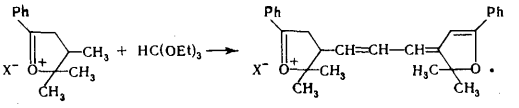
Mizuno and Tanabe [155] showed that the synthesis of cyanines does indeed proceed via an intermediate alkylidene derivative (XXXIV), which is also suggested by the sharp decrease of the yield of cyanine dyes in the presence of a large excess of orthoesters. In certain cases, alkoxyalkylidene compounds can be isolated as the main reaction product. Thus, when tetrahydrobenzopyrylium and tetrahydroxanthylium salts and their derivatives were heated briefly in acetic anhydride in the presence of ethyl orthoformate, the corresponding ethoxymethylene derivatives of these compounds were obtained [156,157]:

Ethoxymethylenedioxolanium salts are formed under similar conditions [158]:

This reaction is particularly characteristic of thio-orthoesters. For example, ethyl thio-orthoformate reacts with quaternary salts of 2-methylbenzothiazole, 2-methylbenzoxazole, and quinaldine on refluxing in acetic anhydride [159]:

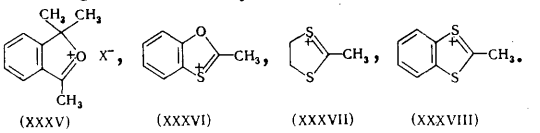


A wide variety of orthoesters are used in the synthesis of cyanine dyes. Orthoformates and thio-orthoformates form carbocyanines containing an unsubstituted trimethine chain (XXXIII, R = H) and orthoesters of higher acids give rise to dyes substituted at the central carbon atom of the chain. A wide variety of five-, six-, and seven-membered condensed systems condensed with other rings or charged monocyclic systems with one-, two-, or more heteroatoms can be involved in the reactions with orthoesters. Simple mononuclear heterocycles form cyanine dyes with greater difficulty than heterocycles condensed with aromatic rings.

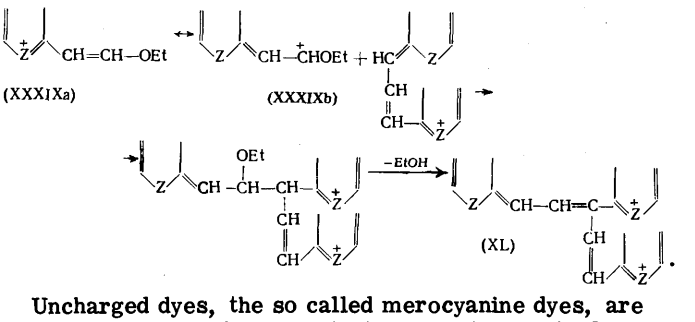


The greatest number of studies on the synthesis of cyanine dyes concern heterocycles of the thiazole series. Both monocyclic thiazolium salts [160] and salts condensed with benzene [161] and heterocyclic [162] rings have been used in the condensation reaction. The use of substituted imidazolium and benzimidazolium salts in this reaction has been described [163]. Pilyugin and coworkers synthesised cyanines from a wide variety of *N*-alkyl- and *N*-aryl-substituted quinaldinium [164] and benzoquinaldinium [165] quaternary salts. Lepidine derivatives [166] and other compounds containing the pyridine ring [167] enter into the reaction.

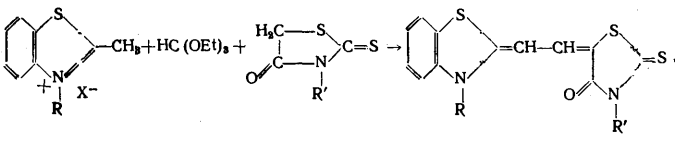
Trimethinecyanines are formed from benzoxazole [168], thienopyridine [169], 1,2,4-triazine [170], 1,4,7,9-tetra-azaindenes [171], 1,7-diazaindene [172], azepine [173], and tetrazole [174].



Oxonium heterocycles or their thio-analogues are used in the synthesis of cyanine dyes. Thus α- or γ-alkyl-substituted pyrylium [175] and benzopyrylium [176] salts and 9-methylxanthylium salts [177] readily form trimethine dyes on heating with ethyl orthoformate in pyridine or in a mixture of acetic anhydride and acetic acid:

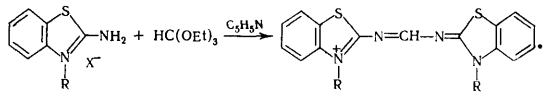


Non-aromatic furylium salts can also take part in the reaction [178]:



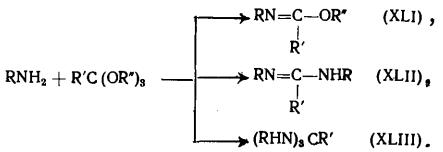
On heating in acetic acid or in a mixture of acetic anhydride and pyridine, ethyl orthoformate reacts with benzofurylium (XXXV) [179], benzoxanthylium (XXXVI) [180], dithiylium (XXXVII) [180] and benzodithiylium (XXXVIII) salts, forming trimethine dyes:

Trinuclear neocyanine dyes, for which Konig's formula (XL) [154] was recently shown to be correct [155], are almost invariably formed as side products in the synthesis of trimethinecyanines. The mechanism of the formation of neocyanines was investigated by Japanese workers [155], who observed that the yield of neocyanines is lower the higher the yield of trimethinecyanines. This indicates competition between two modes of binding of the alkoxymethylene cation (XXXIX):



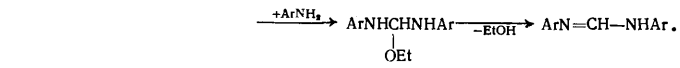
Uncharged dyes, the so called merocyanine dyes, are obtained when one of the reactants is a heterocyclic ketomethylene derivative and the other is a quaternary salt of a nitrogen-containing heterocycle [182]. For example:

Ethyl orthoformates react similarly with barbituric or thiobarbituric acid and quaternary salts of nitrogen-containing heterocycles (α-picoline, 2,6-lutidine, quinaldine, and 2-methylbenzothiazole)[183].



Orthoesters are suitable for the synthesis of azacyanines—compounds in which one or several methine groups are substituted by nitrogen atoms[184,185]:

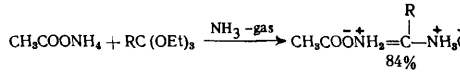
X. REACTIONS OF ORTHOESTERS WITH AMINO-DERIVATIVES



1. Synthesis of Acyclic Products

When orthoesters react with substances containing an amino-group (amines, amides, substituted ureas, and hydrazines, hydrazides, etc.) products of three types may be obtained depending on the reaction conditions and the structure and relative amounts of the components:

The first two reactions, which lead to imidoesters [imidates] (XLI) and amidines (XLII) respectively, are general, while the formation of nitrogenous analogues of orthoesters (XLIII) is possible only from certain compounds of suitable structure and constitutes a special case. Since the synthesis of imidoesters and amidines with the aid of orthoesters has been discussed in a number of reviews[186-188], we shall consider only the fundamental studies carried out recently.



Spectroscopic studies on the reaction of aniline with ethyl orthoformate showed[189] that imidoesters are intermediates in the synthesis of amidines:

The formation of *N*-arylformimidoesters[51] becomes possible under the conditions of acid catalysis when the activation of orthoformate by the acid causes the rate of formation of the formimidoester to predominate over the rate of its conversion into diarylformamidine.

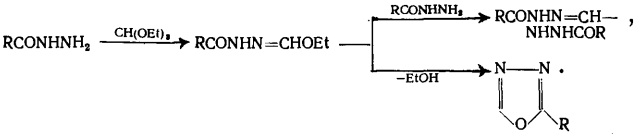
Roberts et al.[190] developed a general method for the synthesis of *N*-phenylformimidoesters by the reaction of alkyl orthoformate with aniline.

Ammonium acetate reacts with ethyl orthoformate and ethyl orthoacetate to form amidinium acetates[191]:

Dimethylformamidine is obtained by passing gaseous methylamine through ethyl orthoformate[192]. The synthesis of higher *NN*-dialkylformamidines in the presence of boron trifluoride-ether has also been described[193].

Heterocyclic bases react with orthoesters too. *N*-Heterocyclic derivatives of formimidoesters of the pyrazole[194], imidazole[194], isoxazole[195], isothiazole[196], and pyridine[197] series have been obtained.

Syntheses of formamidines from 5-aminopyrazole[198], 3-amino-2-pyrazoline[199], 2-aminopyrimidine[200], and 3-aminoisoxazole[201] have been described.



On heating with orthoesters, arylhydrazines[202] give high yields of ethoxyalkylidenehydrazines:

The reaction of benzaldehyde hydrazone with a fourfold excess of ethyl orthoformate in the presence of sulphuric acid yields ethoxymethylenephenylmethylenehydrazine, which contains conjugated double bonds[203]:

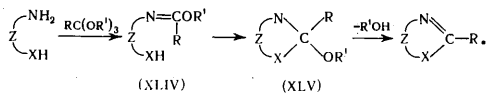
The reaction of carboxylic acid hydrazides with ethyl orthoformate, which can give rise to cyclic products in addition to ethoxymethylenehydrazides and hydrazidomethylenehydrazides takes place in a more complex manner[204,205]:

Owing to the reduced reactivity of the amino-group in acid amides, their reactivity in relation to orthoesters is much lower than that of amines, hydrazines, and hydrazides. Whereas ethyl orthoformate still reacts with acetamide and benzamide, giving low yields of diacylformamidines[206], ethyl orthoacetate can no longer be made to react in this way[207]:

The reactivity of urea and its derivatives is similar to that of acid amides. On refluxing with ethyl orthoformate, urea and its alkyl and arylalkyl derivatives yield high-melting sparingly soluble products—*NN*-dicarbamoylformamidines[208].

The condensation of ethyl orthoformate with urethanes in the presence of acids has been described[209].

The condensation of three moles of an amide with one mole of orthoester in boiling toluene yields triacylaminomethanes[210]:

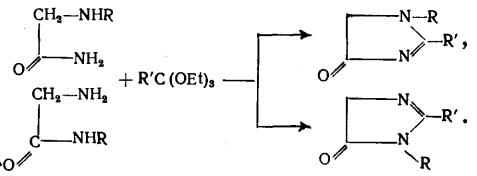


Electronegative substituents reduce the basicity of the amide and the yields of products are low.

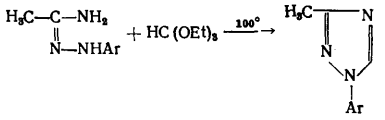
2. Synthesis of Cyclic Compounds

When the molecule contains two amino-groups, the reaction usually leads to the formation of cyclic amidines. Cyclic systems with different heteroatoms are obtained when other functional groups are introduced into the reaction apart from the amino-group. The cyclisation is achieved by heating the components with or without the distillation of the alcohol.

It was sometimes possible to isolate the intermediates (XLIV) and (XLV) in the cyclisation reaction. The elimination of the alcohol from the alkoxy-derivative

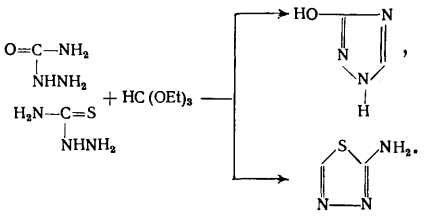


(XLV) is the rate-determining stage of the cyclisation process:

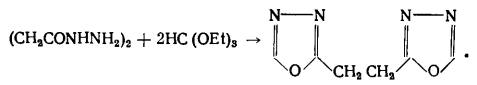


(XLIV) (XLV)

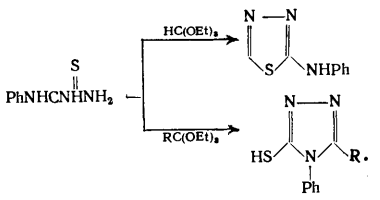
Usually X is a substituted or a free amino-group, oxygen, or sulphur. The group Z can be a carbochain or heterochain bridge and also constitutes part of a carbocyclic or heterocyclic system.



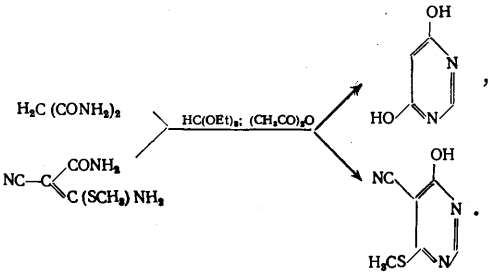
A general method of synthesising 4-imidazolones and 5-imidazalones is based on the cyclisation of *N*- or *N'*-substituted glycine amides [211]:



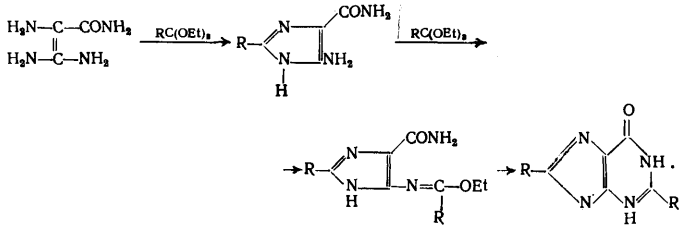
Acetamide arylhydrazones react with ethyl orthoformate to form 1-aryl-3-methyl-1,2,4-triazoles [212]:



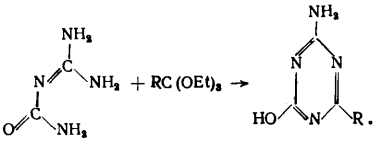
It is interesting that semicarbazide [213] and thiosemicarbazide [214] hydrochlorides form different types of heterocycles:



The synthesis [215] of heterodiazoles on refluxing hydrazides and thiohydrazides of alkyl- and aryl-substituted and heterocyclic carboxylic acids with orthoesters has been described. Succinic acid dihydrazide undergoes biscyclisation on treatment with ethyl orthoformate [204]:

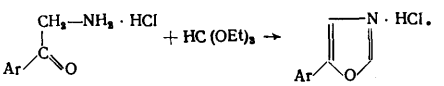


Owing to differences in the reactivities of orthoformates, the reaction of 4-phenylthiosemicarbazide with ethyl orthoformate or the orthoesters of alkanecarboxylic acids (ethyl orthoacetate and ethyl orthopropionate) gives two types of heterocycles[216]:

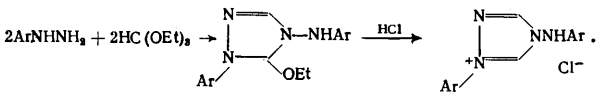


Malonodiamide [213] and 3-amino-2-cyano-3-methylthioacrylic acid cyclise in the presence of acetic anhydride [217]:

Hypoxanthine[218] and a number of its substituted derivatives [219] are obtained under similar conditions. The reaction proceeds via the formation of intermediates, which have been isolated:

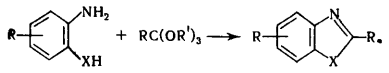


Guanylurea [220] can be condensed with orthoesters and the dimethylacetal of dimethylformamide with formation of substituted 1,3,5-triazines:

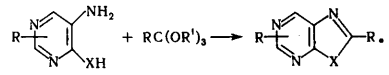


A convenient method for the synthesis of 3-aryl-1,2,4-oxadiazoles consists in heating the amidoximes of arylcarboxylic acids with ethyl orthoformate in the presence of boron trifluoride-ether [221]:

Oxazoles can be prepared from the hydrochlorides of substituted ω-aminoacetophenones and ethyl orthoformate [222]:

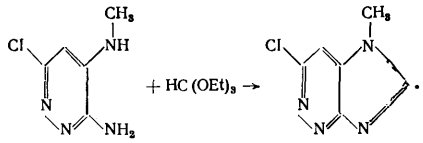


Arylhydrazines with electron-donating substituents in the benzene ring yield derivatives of 1,2,4-triazole on interaction with ethyl orthoformate [202]:

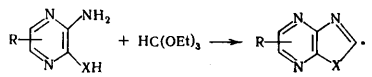


Condensed heterocyclic systems can be synthesised when the functional groups involved in cyclisation occupy the 1- and 2-positions in the benzene or heterocyclic ring.

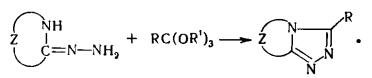
When ring-substituted *o*-phenylenediamines[223], *o*-aminophenols[224], and *o*-aminothiophenols[225] react with orthoesters, the products are derivatives of benzimidazole, benzoxazole, and benzothiazole respectively:



(X = NH; O; S; NR)

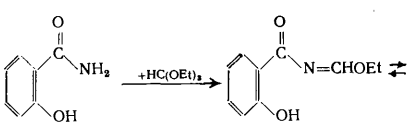


Heterocyclic compounds containing purine and thiazolopyrimidine groups were synthesised similarly from a wide variety of derivatives of 4,5-diamino,[226] 4-R-amino-5-amino-[227], and 5-amino-4-mercapto-pyrimidines[228]:

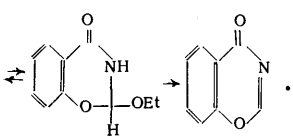


A substituted imidazopyridazine is obtained when 3-amino-6-chloro-4-methylaminopyridazine is heated with ethyl orthoformate[229]:

Syntheses of imidazopyrazines have been described[216,230]



Heterocyclic systems containing three nitrogen atoms in the ring are formed when the hydrazones of a wide variety of heterocyclic keto-derivatives react with orthoesters:

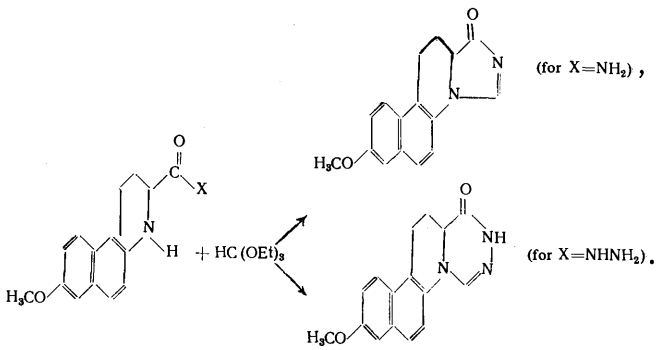


The hydrazones of 2-benzimidazolone, 2-benzoselenazolone[216], 2-quinolone[216], derivatives of 2-pyrimidinone[231], 4-quinazolone[232], 2-quinoxalinone[233], and imidazopyridazinone[234] can participate in this reaction.

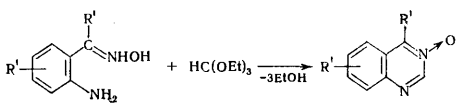
When the amides of aromatic or heterocyclic carboxylic acids containing an active functional group in the *ortho*-position are introduced into the reaction with orthoesters, the products are six-membered heterocyclic keto-derivatives with two heteroatoms in the ring.

When the amide of salicyclic acid was refluxed with ethyl orthoformate, an intermediate iminoether (XLVI), which is a tautomer of the cyclic product (XLVII), was isolated[213,235]:

(XLVI)

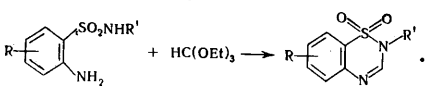


(XLVII)



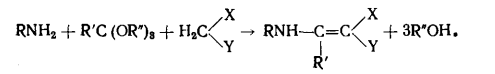
The reaction of the amide of anthranilic acid with ethyl orthoformate gives 4-quinazolone[213].

Apart from the amides of aromatic acid, a wide variety of heterocyclic *o*-substituted carbamides are used for similar cyclisations. The use of imidazole[236], isoxazole[237], 1,2,3-triazole[238], quinoline[239], pyrimidine[240], and pyrazine[241] derivatives has been described.

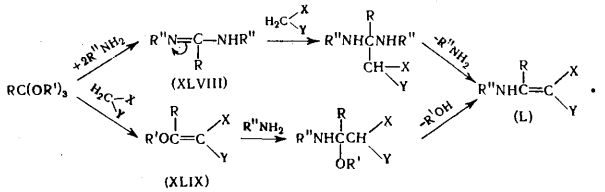


This principle has also been employed to synthesise di- and tri-azasteroid systems[242]:

On being refluxed with an excess of ethyl orthoformate, *o*-amino-derivatives of aldoximes and ketoximes give rise to quinazoline $N_{(3)}$-oxides[243]:

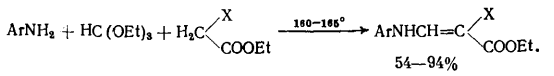


Aromatic sulphonamides with *o*-amino-substituents react with *o*-aminocarbamides, the difference being that in this case *SS*-dioxide rings are formed[244]:

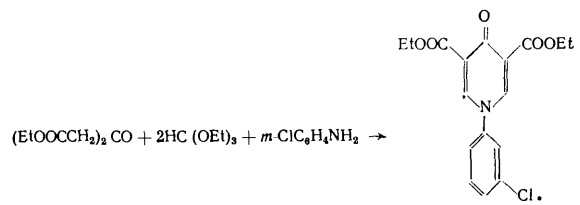


XI. THREE-COMPONENT CONDENSATIONS

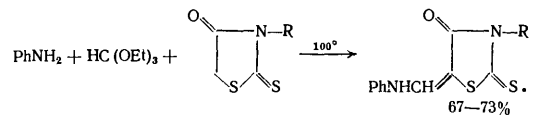
This group combines single-stage reactions of orthoesters with amino-compounds (arylamines, heterocyclic amines, urea, and substituted ureas) and substances which can react as CH acids. For example:



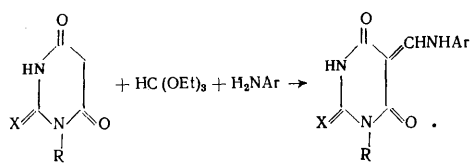
At first sight this reaction resembles the Mannich reaction. The difference is that the Mannich reaction gives rise to a monofunctional aminoalkyl group $\rangle N-\overset{|}{C}-\overset{|}{C}-$, while the use of orthoesters yields the bifunctional enamine unit $\rangle N-\overset{|}{C}=\overset{|}{C}-$. Probably the reaction proceeds simultaneously via two similar mechanisms:



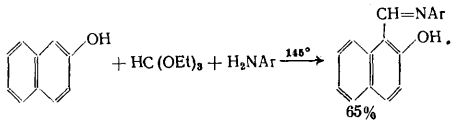
The yields of the intermediates (XLVIII) and (XLIX), where these are obtained specially by heating the components in pairs (the amine and the orthoester or the CH acid and the orthoester) are frequently much lower than the yield of the final product (L) obtained when all three starting materials are involved simultaneously in the reaction. Evidently the reason for this phenomenon may consist in a favourable mutual influence of the starting materials on one another. On the one hand, the formation of the alkoxyalkylidene compound (XLIX) should undoubtedly be facilitated by the catalytic action of the base (amine), while the acidity of the methylene component is a factor promoting the activation of the orthoester and therefore facilitating both reactions. Moreover, the products of the interaction of any pair of the starting compounds are removed from the sphere of the reversible reaction owing to the interaction with the third component.



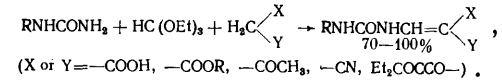
Three-component condensation was achieved for the first time by Snyder and Jones [244], who developed a method for synthesising β-arylamino-substituted acrylic esters by the reaction of compounds containing an active methylene group with aromatic amines and ethyl orthoformate:



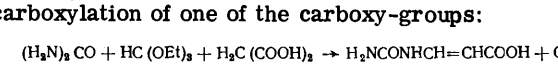
Later a general method was developed for the synthesis of a wide variety of enamines by the reaction of orthoesters with compounds containing an active methylene group and with arylamines [245]. The reaction of acetonedicarboxylic acid esters with ethyl orthoformate and *m*-chloroaniline gives a substituted pyridone [244]:



Ketomethylene heterocyclic derivatives may serve as the CH acid components in the reaction with aromatic amines and ethyl orthoformate [246]:

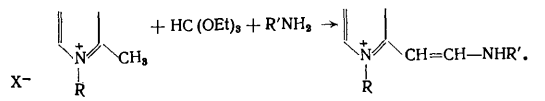


On heating with ethyl orthoformate and aromatic amines, barbituric [247], thiobarbituric [247], and 1,3-dimethylbarbituric [248] acids form arylaminomethylenebarbiturates:

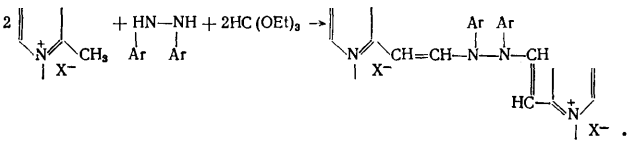


Aromatic phenolic systems can also behave as the CH acid components [249]. In this case the products are not enamines but Schiff bases:

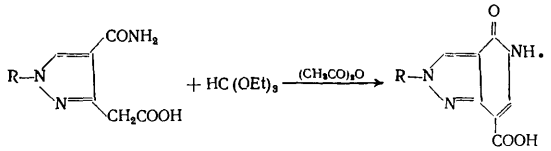
Apart from aromatic amines, substituted ureas participate in this reaction. Whitehead [250,251] developed a general method for synthesising ureidoethylenes by the reaction of ethyl orthoformate with urea, *N*-cyclohexylurea, *N*-alkylureas, and *N*-arylalkylureas and compounds containing an active methylene group:



It was shown that the activity of the methylene component in this reaction decreases in the sequence COOH > CN > > $COCH_3 \gg COOC_2H_5$. Malonic acid and oxaloacetic ester, which are the most reactive, react even at room temperature; the reactions with acetylacetone, cyanoacetamide, acetoacetic ester, and cyanoacetic ester require heating for 8–12 h, while in the case of malononitrile refluxing for 1–2 h is sufficient. When malonic acid is allowed to react with ethyl orthoformate and urea on heating, the condensation involves the simultaneous decarboxylation of one of the carboxy-groups:

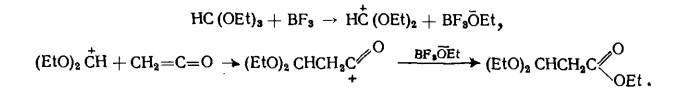


Other examples of the reaction of ethyl orthoformate with urea [252] or alkylureas [253–255] and cyanoacetic ester [256], malononitrile [255,257], nitroacetic ester [258], α-nitroacetonitrile [254], oxaloacetic ester [252], acetylpyruvate [252] and acetylacetothienone [259] have also been described.

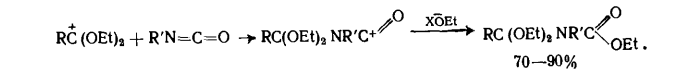


Knott [260] and Dzenno [261] showed that methyl-substituted quaternary salts of nitrogen-containing heterocycles (α-picoline, 2,6-lutidine, quinaldine, and 2-methylbenzothiazole) can take part in the reaction with ethyl orthoformate and aromatic amines (aniline, toluidine, *m*-aminophenol, *p*-aminoacetophenone):

Symmetrical disubstituted hydrazines, benzidine, and certain other diamines form bisdiaminodivinyl derivatives [262]:

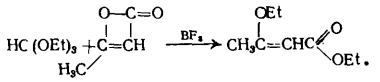


When the molecule contains an amino- and an active methylene group simultaneously, internal condensation with formation of a cyclic product takes place [263]:

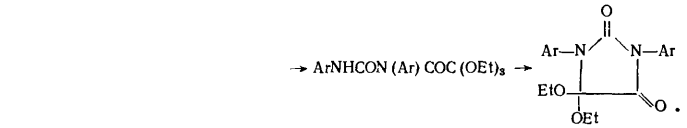


XII. OTHER REACTIONS OF ORTHOESTERS

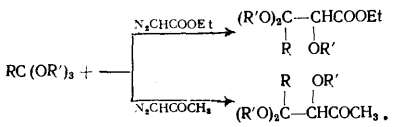
The reactions of orthoesters with individual compounds, which do not fit the classification adopted in the review, are considered in this section.



In the presence of zinc chloride or boron trifluoride, ethyl orthoformate reacts with keten [264,265] according to the following mechanism:



The interaction of orthoesters on heating with aliphatic, alicyclic, and aromatic isocyanates and also with polyisocyanates in the presence of acidic condensing agents (BF_3, $ZnCl_2$, $AlCl_3$) involves a similar mechanism [266,267]:

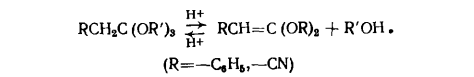


Acid catalysis is also essential for the reaction of ethyl orthoformate with diketen [77]:

In the absence of acids, the reaction of isocyanates with orthoesters proceeds via a different mechanism. Thus Whitehead and Traverso [268] found that, when aryl isocyanates are refluxed (for 12–24 h) in the presence of an excess of ethyl orthoformate, 1,3-diaryl-5,5-diethoxyhydantoins are formed:

In the presence of Lewis acids, diazoacetic ester and diazoacetone react with orthoesters to form addition products [269]:

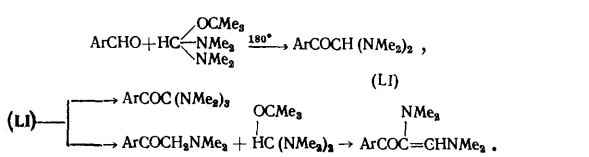
The reaction proceeds with evolution of nitrogen and the yields of products are 37–99%.



The α-methylene group of the orthoesters of alkanecarboxylic acids [270] and phenylacetic acid [271] is readily brominated, the other groups remaining unaffected:

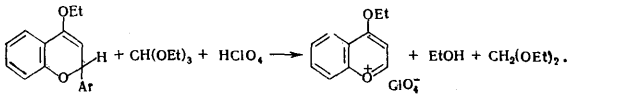
The bromo-derivatives of orthoesters can be used to prepare keten acetals [270]:

Orthoesters containing in the α-position an activating group, such as phenyl [271] or the cyano-group [272], are a convenient source from which keten acetals may be obtained. In this case the alcohol may be split off both as a result of pyrolysis at 220–230°C and under the conditions of acid catalysis, the reaction being reversible in the presence of acids:



In certain cases, catalysis by strong bases was employed in the synthesis of keten acetals from orthoesters [273].

The formation of carbenes on treatment of di(methylthio)- or dialkoxy-carbonium salts of ethyldi-isopropylamine in methylene chloride at −10°C was reported recently [274]. The carbene dimerises under the reaction conditions, forming tetrasubstituted ethylenes:



The interaction of aromatic aldehydes with nitrogenous analogues of orthoesters is unusual [275]. The aminal of arylglyoxal (LI) formed initially subsequently disproportionates via the Cannizzaro reaction:

The interaction of hydrocyanic acid [276] and acetonitrile [277] with orthoesters leads to the replacement of the alkoxy-group by a cyano-group:

In the presence of acidic agents, orthoesters can behave as hydride ion acceptors [278]:

The examples quoted in the present review by no means exhaust all the applications of orthoesters in organic synthesis.

Advances in the Synthesis of Purine Derivatives from Uric Acid

E.S.Golovchinskaya

The review deals mainly with the discussion of the synthesis of purine derivatives based on the interaction between uric acid and acetic anhydride. Problems of the structure, intermediates in the reaction, *N*-methylated derivatives of the compounds, and their conversion into 8-methylxanthines are discussed. Much attention has been devoted to the synthesis of 9-methylpurine derivatives from uric acid using 1,3,8,9-tetramethylxanthine as an intermediate. Various methods of synthesising *N*-methylated purines substituted in the 8-position have been described.
The bibliography includes 157 references.

III. Syntheses based on *N*-methylated 8-methylxanthines 417

I. INTRODUCTION

In the course of the last two decades, synthetic studies on purines have developed on an enormous scale throughout the world. The great interest in purine derivatives, which re-emerged in the 1950's after a fairly long slack period, has been to a great extent the result of the outstanding advances achieved in the study of various enzymes systems, cell biochemistry, and principally the structure and role of nucleic acids. This renewed interest is associated with one of the most urgent problems in modern medicine—the search for effective therapeutic agents for the treatment of diseases involving various types of impairment of nucleic acid metabolism, including those used in the fight against malignant diseases. Numerous studies in this field ultimately led to the synthesis of many hundreds of new derivatives of purine and its analogues, the aim being to investigate their biological activity.

All the syntheses in the purine series described in the literature may be divided into two groups. The first and largest group includes methods based on successive or simultaneous synthesis of the pyrimidine and imidazole rings of the purine molecule[1-3]. A fairly exhaustive systematic account of these methods has been given in a number of reviews (including Robins's detailed review[4]) and they will not be considered in this paper.

The syntheses of the second group, based on the so called semisynthetic methods, i.e. on the employment and reactions of natural compounds already containing a purine skeleton, have been much less satisfactorily described in the review literature.

More than 30 natural purines from various sources of plant and animal origin are known. These are primarily the aglucones of nucleosides constituting the structural elements of nucleic acids, the purine components of antibiotics (puromycin, nebularine, etc.), and also the normal metabolic products of the organisms of higher animals. Despite the comparatively great variety of the purine glucosides known at present, the fairly constant structure of their purine moiety is striking—with rare exceptions this is adenine and its derivatives substituted at the amino-group or at $C_{(2)}$ and also guanine and its derivatives methylated at the exocyclic nitrogen atom or at the $N_{(1)}$ atom.[5]

Recently a substance called herbipoline, characterised as a new type of purine derivatives, mainly purinium betaines with a zwitter-ionic structure hitherto unknown for purine, was recently isolated from the organisms of lower animals, in particular from the stroma of the sponge *Geodia gigas*[6,7]. Natural 1-methyladenine, identified by comparison with the synthetic specimen and called by the author spongopurine, was obtained from the same source[8].

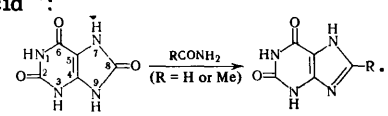
With the exception of the main examples of aglucones mentioned above—adenine and guanine—almost inexhaustible amounts of which are available in living organisms, the remaining aminopurines are present in the organs and tissues of animals in very small amounts and their isolation and characterisation constitute refined and laborious operations. From this standpoint, the most promising natural purines are uric acid and two purine alkaloids from the group of methylated xanthines—caffeine and theobromine. The amounts of these purine derivatives in nature are fairly large and methods for their extraction from natural sources on an industrial scale have been developed.

Uric acid is the final product of the protein metabolism of birds and reptiles and is present in large amounts in the excrement of these animals. The guano deposits, from which it is derived, have now become appreciably depleted. During the Second World War, industrial manufacture of uric acid, based on the extraction of chicken dung diluted with alkali, which contains 2–3% (relative to the dry material) of uric acid, was organised in the Soviet Union in state poultry farms. The uric acid obtained in this way served as the raw material for the synthesis of caffeine and theophylline as well as methylcaffeine; the last derivative was manufactured for several years as an independent preparation which successfully replaced caffeine in several cases[9].

This review deals with the syntheses of purines based on the reactions of uric acid. It includes also studies on the synthesis of purine derivatives from caffeine and theobromine, which are logically related to the synthesis of the same compounds from uric acids.

II. REACTIONS OF URIC ACID

Practically all known reactions of uric acid(I) which result in the derivatives of di- and monoxopurines (including xanthine and hypoxanthine), as well as oxygen-free purines can be classified into three types of reactions.



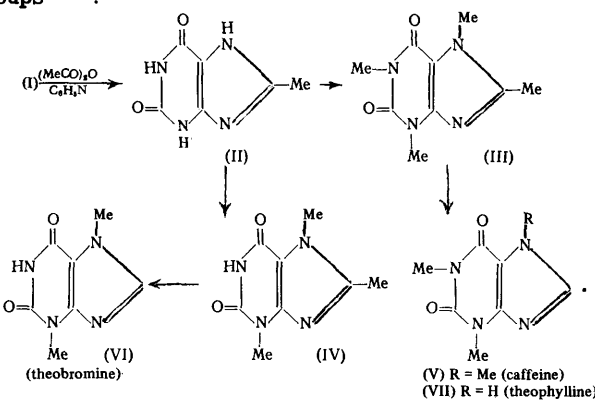
1. Interaction with Phosphoryl Chloride and Subsequent Reactions of the Resulting 2,6,8-Trichloropurine.

This series of reactions, already described by Fischer in the past century, permitted a reliable determination of the structure of uric acid and also the structures of natural purines already known at the time, such as adenine hypoxanthine, guanine, and others. The synthesis of trichloropurine and its reactions confirmed the structural relations between these natural purines and uric acid and with one another, culminated in the synthesis of the parent compound of this class (unsubstituted purine), and served as a firm foundation for a detailed elucidation of the chemistry of purines[10].

The scientific value of the brilliant studies by Fischer has persisted until the present day but the reaction between uric acid and phosphoryl chloride has been very rarely employed for preparative purposes.

2. Direct Conversion into Xanthines by Refluxing with Formamide (or Other Amides)

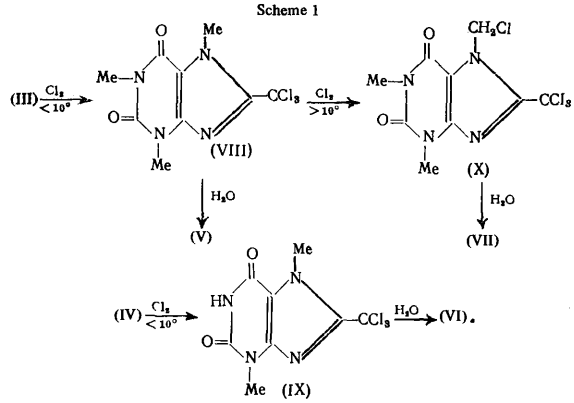
This completely new reaction, discovered by Bredereck and coworkers, can serve according to the authors as a quite realistic basis for a two-stage synthesis of caffeine from uric acid[11]:



(I)

The authors convincingly disproved the possibility that the essential feature of the process is reduction by formamide of the $>C_{(8)}=O$ ($>C_{(8)}$–OH) fragment of the imidazolone ring. On the basis of the formation of 8-methylxanthine in a similar reaction with acetamide and also of a number of experimental data, they believe that, on heating with formamide, the imidazolone ring of uric acid is cleaved; this is accompanied by a reaction of the resulting 5-formylamino-4-ureidouracil culminating in ring closure. The authors assert that the precursor of the $C_{(8)}$ atom of the imidazole ring in the resulting xanthine is not the $C_{(8)}$ atom of the initial uric acid but the carbon atom of formamide.

The observation that on heating with formamide in an autoclave uric acid can be converted not only into xanthine but also into hypoxanthine is likewise noteworthy. The importance of this reaction, which has no preparative value, is due to the fact that it clearly indicates the capacity of the ureide group of both the imidazole and pyrimidine ring to react with formamide[12].

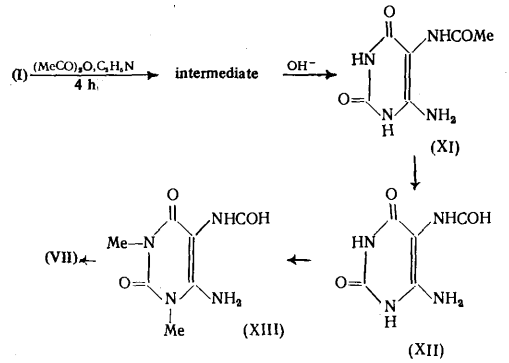


3. Interaction with Aliphatic Acid Anhydrides (Mainly Acetic Anhydride)

This reaction constitutes the basis of a whole group of patents taken out by the Boehringer Company which enabled a realistic synthesis of all three purine alkaloids (caffeine, theobromine, and theophylline) in a single common industrial scheme as early as the beginning of the present century. The first stage of this synthesis is the conversion of uric acid into 8-methylxanthine (II), which is formed in a nearly quantitative yield as a result of refluxing it for 80 h with an excess of acetic anhydride in the presence of pyridine or other pyridine bases[13]. Next, methylation of 8-methylxanthine leads to the formation of 8-methylcaffeine (III) or 8-methyltheobromine (IV) depending on the reaction conditions[14,15]. As a result of the removal of the methyl group from the $C_{(8)}$ atom in compounds (III) and (IV), caffeine (V) and theobromine (VI) are formed respectively[16,17]. In addition, methylcaffeine can be converted also into theophylline (VII) as a result of the simultaneous elimination of the $C_{(8)}$- and $N_{(7)}$-methyl groups[17,18]:

The removal of methyl groups from compounds (III) and (IV), i.e. their conversion into caffeine, theophylline, and theobromine, is achieved, in accordance with the above patents, by the substitution of hydrogen atoms in these groups by chlorine and subsequent hydrolytic removal of the chloromethyl groups from the resulting trichlorides (VIII) and (IX) and also from the tetrachloride (X)

Scheme 1

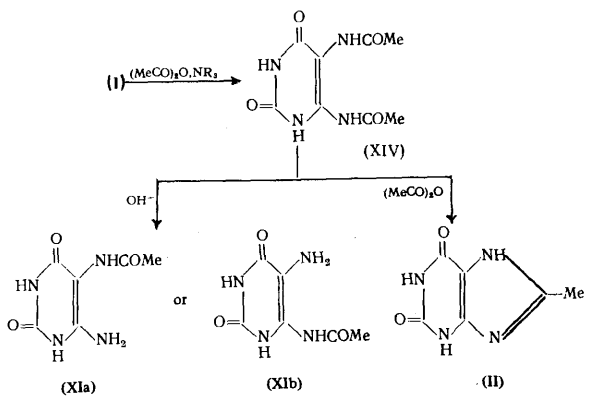


Scheme I has found wide-scale practical application and was used, in particular, in Soviet chemical-pharmaceutical industries in 1943–1953[19–29] for the synthesis of caffeine and theophylline.

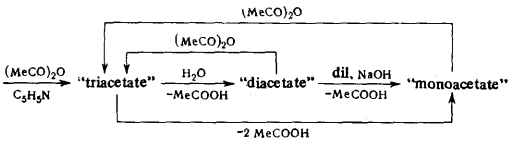
Scheme 2 for the synthesis of theophylline, whereby it is also manufactured in the USSR, is based on the reaction between uric acid and acetic anhydride interrupted after a period of 4 h, the conversion of the resulting intermediate by hydrolysis into 5-acetamido-4-aminouracil (XI), and the transacylation of the latter by treatment with formic acid. 4-Amino-5-formamidouracil (XII) was methylated and the resulting 4-amino-5-formamido-1,3-dimethyluracil (XIII) was converted by cyclisation into theophylline (VII)[30–33] (Scheme 2).

Nowadays the industrial synthesis of purine alkaloids from uric acid has been displaced in many countries (and possibly throughout the world by economically more effective synthetic methods. Nevertheless the interaction of uric acid with acetic anhydride and also the substitution of hydrogen atoms in the methyl groups of *N*-methylated 8-methylxanthines by chlorine and subsequent hydrolytic

Scheme 2

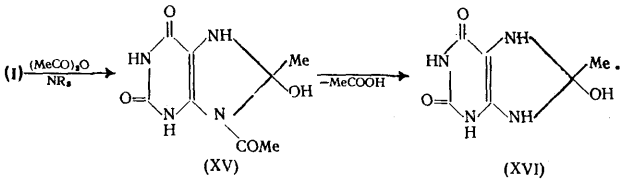


cleavage of the chloromethyl groups survived for a long time their "elimination" from industry. In particular, owing to earlier studies in connection with the needs of industry, convenient methods were found for the synthesis of a new group of derivatives of *N*-methylxanthines substituted in the 8-position (see Section III, subsection 1).



Moreover, these studies threw light on certain controversial problems concerning the structure of the compounds formed in the conversion of uric acid into 8-methylxanthine and permitted the use of the result for preparative purposes, namely for the synthesis of 9-methylpurine derivatives which had been hitherto unknown or difficult to obtain (see Section III, subsection 2).

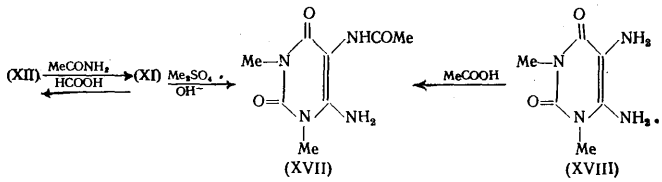
Since the initial publication of the methods of preparation of 8-methylxanthines from uric acid[13], it has been discovered that this complex process proceeds via two stages. The first, which terminates after only brief heating with acetic anhydride (4–5 h), requires the presence of tertiary amines and is accompanied by the evolution of CO_2. The reaction product is a mixture consisting of a substance readily soluble in boiling water and a comparatively small amount of compound (II) which is virtually insoluble in it. A crystalline compound $C_8H_{10}N_4O_4$, which was believed to be an intermediate in the above process for half a century, is precipitated from the cooled aqueous filtrate.



Indeed, it can be converted into compound (II) on prolonged heating with acetic anhydride. The second stage no longer requires the presence of tertiary amines and proceeds with elimination of acetic acid[34]. The first views concerning the course of the process were expressed at the same time[35] and a process mechanism was put forward, according to which the structure of 4,5-diacetamidouracil (XIV) was attributed to the intermediate and the compound $C_6H_8N_4O_3$ obtained from it by the hydrolytic elimination of one acetyl group in an alkaline medium was assumed to be the monoacetyl derivative of 4,5-diaminouracil (XIa or XIb).

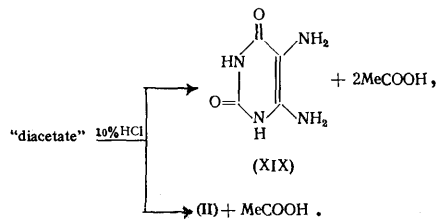
In the first place we must note that fifty years later Bredereck et al.[36] established that the intermediate in the conversion of uric acid into 8-methylxanthine is not the compound $C_8H_{10}N_4O_4$, as believed previously, but a compound containing a further acetyl group ($C_{10}H_{12}N_4O_5$). It was found that it hydrolyses with elimination of one mole of acetic acid after only brief heating with water. They isolated this substance directly from the mixture which was untreated with water and was formed in the interrupted synthesis of compound (II) and also by treating with acetic anhydride the "intermediate compound" crystallised from water or the compound $C_6H_8N_4O_3$ obtained from the latter by alkaline hydrolysis†.

In 1923 Biltz and Schmidt published their first detailed study of the structures of "diacetate" and "monoacetate".[37] They suggested that both "diacetate" and "monoacetate" are bicyclic carbinols, namely, 9-acetyl-8-hydroxy-8-methyl-8,9-dihydroxanthine (XV) and 8-hydroxy-8-methyl-8,9-dihydroxanthine (XVI):



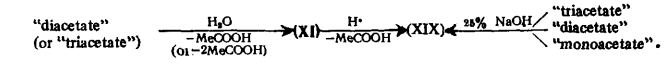
In 1953–1954, i.e. 30 years later, the structures of "triacetate", "diacetate", and "monoacetate" were revised in studies published almost simultaneously in the German Federal Republic[36,38,39] and in the Soviet Union[40–43].

It is remarkable that although their results were closely interrelated and many of their fundamental aspects were identical, their authors arrived at opposite conclusions concerning the "closed" (i.e. bicyclic) or "open" (i.e. uracil) structures of "diacetate" and "triacetate". "Monoacetate" was shown unanimously and by different methods to have the uracil structure (XI) and not the bicyclic carbinol structure (XVI).



Structure (XI) of "monoacetate" was confirmed by many reactions, including the quantitative isolation of one mole of acetic acid at low pH, its formation from 4-amino-5-formamidouracil (XII) known previously[44] on treatment with acetamide, and finally its conversion into compound (XII) by heating with an excess of formic acid[33,36]. In addition, two specimens of "1,3-dimethylmonoacetate" (XVII) were

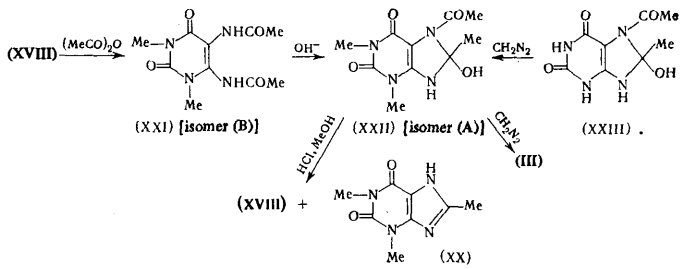
† For brevity, they suggested that the following names be given to the three compounds (these have been adopted in subsequent descriptions): "triacetate"—the true intermediate, "diacetate"—obtained by the crystallisation of "triacetate" from water, and "monoacetate"—obtained from "triacetate" or "diacetate" by the hydrolytic removal of two or one acetyl groups.



identified; one of them was obtained by heating 4,5-diamino-1,3-dimethyluracil (XVIII) with acetic acid and the other by methylating "monoacetate" (XI)[41]:

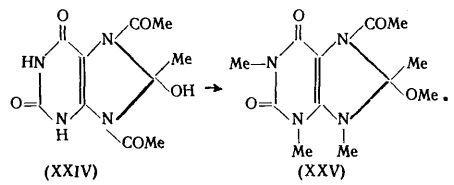
Both series of studies described demonstrated the error of Biltz and Schmidt's assertion[37] that "diacetate" is incapable of splitting off both acetyl groups on hydrolysis. The exact determination of the amounts of acetic acid distilled off during the hydrolysis of "diacetate" at low pH showed that it indeed never reaches two moles and is approximately one and a half moles. This was convincingly explained by the fact that, when "diacetate" is heated with inorganic acid, it can cyclise with formation of 8-methylxanthine[45]. The measured amounts of distilled acetic acid showed that in the acid hydrolysis of "diacetate", two parallel processes take place: (a) the hydrolysis of both acetyl groups and (b) the hydrolysis of one acetyl group accompanied by the formation of 8-methylxanthine via the second group. 8-Methylxanthine could be always isolated from the "diacetate" hydrolysis mixture[41]:

The quantitative isolation of two moles of acetic acid as a result of the hydrolysis of "diacetate" (and correspondingly three moles from "triacetate") can be achieved by their prolonged refluxing with water, which results in the formation of "monoacetate"[43], and subsequent hydrolysis of the latter in the presence of inorganic acids. On the other hand, 4,5-diaminouracil (XIX) was obtained in a yield exceeding 90% by treating "monoacetate", "diacetate", and "triacetate" with 25% sodium hydroxide solution[45]:

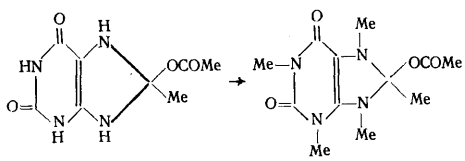


The preparation of the following methylated derivatives of "diacetate" was described in both studies: "tetramethyldiacetate" and two isomeric "dimethyldiacetates" (A) and (B), one of which was obtained by methylating "diacetate" with dimethyl sulphate in an alkaline medium [compound (A)]; its properties differed from those of the second dimethyl derivative obtained by heating 4,5-diamino-1,3-dimethyluracil (XVIII) with acetic anhydride [compound (B)].

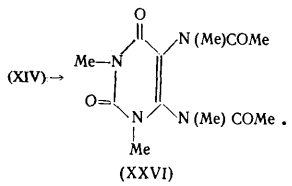
It was shown that this is not a consequence of the different positions of the *N*-methyl groups, because compound (B) is readily converted into compound (A) by dissolution in dilute alkali and subsequent precipitation with acid or by refluxing in butyl alcohol[38,40]:



Compound (B) does not react with diazomethane and is readily hydrolysed by HCl in methanol with evolution of two molecules of acetic acid and by 20% acetic acid with evolution of one molecule of CH_3COOH.

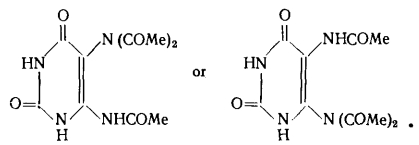


In contrast to (B), its isomer (A) readily reacts with diazomethane and is converted thereby into 1,3,7,8-tetramethylxanthine (III), but does not react at all with 20% acetic acid. The reaction with HCl in methanol results in the elimination of only 1.5 moles of acetic acid and the formation of a mixture consisting of a diamino-derivative (XVIII) and 1,3,8-trimethylxanthine (XX), i.e. behaves in the same way as the initial non-methylated "diacetate". The chemical behaviour of the isomer (B) led the German workers (Bredereck and coworkers) to the hypothesis that it is 4,5-diacetamido-1,3-dimethyluracil (XXI), which cyclises under the influence of alkali with formation of the dihydropurine isomer (A) (XXII). The fact that the latter can be obtained from "diacetate" by methylation of diazomethane suggested that the initial non-methylated "diacetate", obtained in the conversion of compound (I) into compound (II), has a bicyclic carbinol structure like "triacetate":



The German workers disagreed with Biltz and Schmidt[37] only as regards the position of the "hydrolysable" acetyl groups—at $N_{(7)}$ and not at $N_{(9)}$—and attributed structures (XXIII) and (XXIV) to "diacetate" and "triacetate" and structure (XXV) to "tetramethyldiacetate" obtained from them[38]:

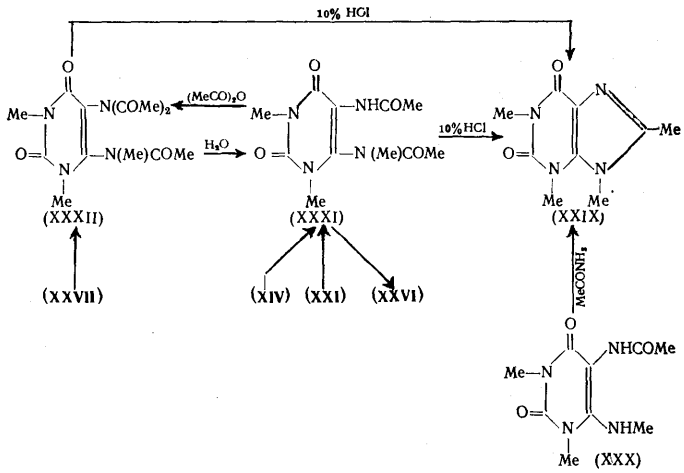
They did not notice that not even traces of a methoxy-group could be detected in "tetramethyldiacetate" by analytical methods, although this finding ruled out the validity of their hypothesis concerning the structure of (XXV). The possibility of another bicyclic structure of "tetramethyldiacetate", which they did not consider, where the "hydrolysable" acetyl group is joined to the dihydroimidazole ring by an ester and not an amide linkage and all four methyl groups are joined to the ring nitrogen atoms, was disproved by an infrared spectroscopic study of "diacetate" and all its methylated derivatives[40].



The absence of the methoxy-group from "tetramethyldiacetate" and the spectroscopic data thus disproved the possibility of any bicyclic structure of "tetramethyldiacetate" and suggested that it is 1,3-dimethyl-4,5-di(methylacetamido)uracil (XXVI), which in turn constituted important evidence in support of the validity of the structure (XIV) proposed initially for "diacetate"[40]:

(XXVI)

This structure of "diacetate" was confirmed by its capacity, mentioned above, to be hydrolysed comparatively readily with evolution of two moles of acetic acid when conditions ruling out the possibility of cyclisation are observed. The elimination of one acetyl group and the formation of "monoacetate", i.e. 5-acetamido-4-aminouracil (XXI) take place under such mild conditions (heating with water) that the opening of the imidazole ring in this reaction is unlikely[43]:



(XXVII) (XXVIII)

The choice between the two possible structures of "triacetate", (XXVII) and (XXVIII), was made by studying the reactions of "trimethyldiacetate", which was isolated for the first time from the reaction mixture obtained in the methylation of "diacetate". It was obtained also from "1,3-dimethyldiacetate" (XXI) and its methylation yielded "tetramethyldiacetate" (XXV).

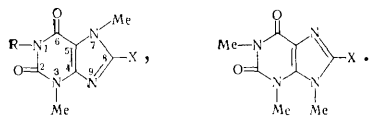
It was found that the third methyl group of "trimethyldiacetate" is at the amino-group joined to $C_{(4)}$ (the position of the two other methyl groups at $N_{(1)}$ and $N_{(3)}$ gave rise to no doubts), since on heating with 10% hydrochloric acid a single molecule of acetic acid is split off and cyclisation with formation of 1,3,8,9-tetramethylxanthine (XXIX) takes place[42]. The latter was identified with methylisocaffeine, synthesised from 1,3-dimethyluramil[46] and also by condensing 5-acetamido-4-methylamino-1,3-dimethyluracil (XXX) with acetamide[38].

On the basis of the uracil structure of "tetramethyldiacetate" and the formation of methylisocaffeine as a result of the cyclisation of "trimethyldiacetate", the latter is 5-acetamido-4-acetylmethylamino-1,3-dimethyluracil (XXXI). When it is treated with acetic anhydride, it is acetylated to "trimethyltriacetate", the only possible structure of which is 5-diacetamido-4-acetylmethylamino-1,3-dimethyluracil (XXXII). It was identified with "trimethyltriacetate" obtained by methylating "triacetate" isolated directly from the reaction mixture obtained when uric acid interacts with acetic anhydride. This showed that the acetyl groups in "triacetate" are located in the same positions as in compound (XXXII), which fully confirmed that their structure is (XXVII)[47,48] and not (XXVIII)[42].

The cyclisation of (XXXI) and (XXXII) on treatment with inorganic acids led to the possibility of employing this reaction as a convenient method of synthesising methylisocaffeine (XXIX) which was previously difficult to obtain. The solutions formed as a result of the methylation of "diacetate" or "triacetate" are heated with an acid for this purpose. The highly soluble "trimethyldiacetate" (XXI) contained in these solutions is then converted into the comparatively sparingly soluble compound (XXIX), which crystallises in its entirety on cooling[49]. Its yield is 60–65% with respect to two stages (methylation and cyclisation) or 40–45% relative to uric acid (i.e. with respect to all three stages).

Methylisocaffeine (XXIX) obtained in this way subsequently serves as the starting material for the synthesis of hitherto unknown derivatives of 9-methylpurine.

III. SYNTHESES BASED ON *N*-METHYLATED 8-METHYLXANTHINES



Both isomeric tetramethylxanthines synthesised from uric acid, i.e. 8-methylcaffeine (III) and 8-methylisocaffeine (XXIX), as well as 3,7,8-trimethylxanthine, i.e. 8-methyltheobromine (IV), were employed successfully to synthesise *N*-methylated purines: (1) xanthines (2,6-dioxopurines) substituted at $C_{(8)}$ and (2) 1,9-dimethylhypoxanthines (6-mono-oxopurines) and 9-methylpurines substituted at the carbon atoms of the pyrimidine ring‡.

1. Methylated Xanthines Substituted at $C_{(8)}$

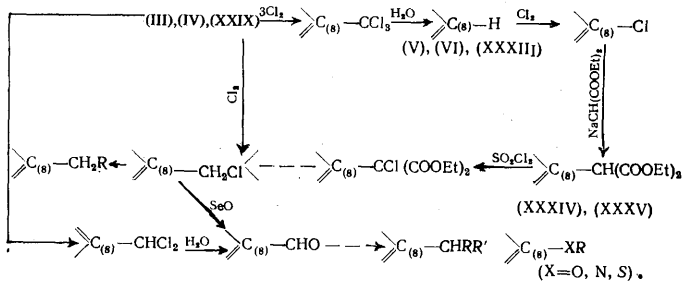
In accordance with the difference between the positions of the *N*-methyl group of the imidazole ring (7- or 9-) in the initial compounds (III) or (IV) and (XXIX), these are

‡ In accordance with the aim of this review, it does not include questions concerning the synthesis of the isomeric derivatives of 3,7-dimethylhypoxanthine and 7-methylpurine, since the starting material for their synthesis is theobromine, which is not as a rule obtained from uric acid.

the parent compounds of two isomeric α- and β-series of $C_{(8)}$-substituted xanthines with different positions of the double bond in the ring, which sometimes differ significantly in their properties. The results of methylation in an aqueous alkaline medium[50,51], the rate of hydrolytic cleavage of the pyrimidine ring under the influence of alkaline agents[52], ultraviolet spectra[53,54], and certain other chemical and physical properties can serve as examples of such differences for α- and β-xanthines, in particular for compounds (III)–(VI), (XXIX), and (XXXIII):

(III, R = X = Me) (V, R = Me, X = H) (XXIX, X = Me)
(IV, R = H, X = Me) (VI, R = X = H) (XXXIII, X = H)

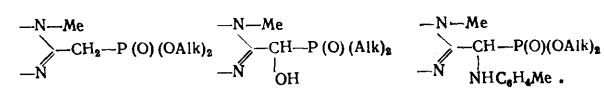
The first widely occurring stage in the reactions of all three 8-methyl derivatives of *N*-methylated xanthines (III), (IV), and (XXIX) is the substitution of the hydrogen atoms in the $C_{(8)}$-methyl group by chlorine. Such substitution is as a rule achieved by treatment with chlorine or sulphur chloride[15,18,24-28,55-60] and does not require vigorous heating[18,25,27]. The substitution of one or two hydrogen atoms in this methyl group by chlorine leads to the formation of mono- and di-chlorides[15,58-60,66] and the replacement of chlorine in such groups by other substituents leads to the synthesis of a wide variety of $C_{(8)}$ derivatives of caffeine (V)[56], theobromine (VI)[58,60-62], and isocaffeine (XXXIII)[59,63]. Compounds of this type may be obtained from 8-methylderivatives of *N*-methylxanthines also by another longer but more universal procedure based on the preliminary elimination of the $C_{(8)}$-methyl group by complete substitution with chlorine and subsequent hydrolysis[15,16,18,24-28,55-58].



The substitution of a hydrogen atom in the 8-position by halogen[55,64-68] in compounds (V), (VI), and (XXIII) formed§ and condensation of 8-halogeno-*N*-methylxanthines with sodiomalonic and sodioalkylmalonic esters also makes it possible to prepare various $C_{(8)}$-derivatives. Caffeine-8-malonic ester (XXXIV) and isocaffeine-8-malonic ester (XXXV) exhibit a fairly high acidity[65,69], exceeding that of other monosubstituted malonic esters and of malonic ester itself and are produced in the condensation reaction as crystalline sodium derivatives, which are formed from the unreacted part of the sodiomalonic ester. Therefore the normal termination of the reactions always requires the use of two moles of sodiomalonic ester per mole of the chloride:

$$\rangle C_{(8)}-Cl + 2NaCH(COOEt)_2 \xrightarrow{-NaCl} \rangle C_{(8)}-CH(COOEt)_2 + NaCH(COOEt)_2 \rightarrow \rangle C_{(8)}-C(Na)(COOEt)_2 + CH_2(COOEt)_2.$$

The electron-accepting properties of the purine molecule lead to an enhancement of the polarity of the C–H bond of the malonic acid group in compounds (XXIV) and (XXXV).

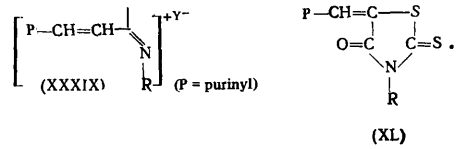


This influence is general and is observed for other *C*-malonic acid derivatives of various purine systems, regardless of the position of the malonic acid residue in the purine molecule—at $C_{(8)}$,[70-73] at $C_{(6)}$,[74,75] or at $C_{(2)}$.[76-78] This influence is shown also by the fact that the halogen atom in the malonic acid residue in purinylhalogenomalonic esters reacts as a halogen cation[79] and also by the capacity of purinylmalonic, alkylmalonic, and acylaminomalonic esters to split off, on heating with alkoxides in an alcoholic medium, one of the two ethoxycarbonyl groups with formation of esters of the corresponding purinylmonocarboxylic acids and of the carbonic ester[80-82].

Subsequent reactions of the malonic acid residue in the diesters (XXXIV) and (XXXV) as well as the conversion of 8-monochloro- and dichloro-methyl derivatives obtained by direct chlorination of compounds (III), (IV), and (XXIX), permitted a fairly wide variation of the nature of the substituent linked to $C_{(8)}$ in *N*-methylated xanthines and the synthesis via the two schemes discussed above of compounds with a wide variety of substituents R—derivatives of alkanoic acids with straight or branched chains[63,65,69,71-73,83-90], aldehydes, alcohols[59,60,61,72,85,87-90], amines[52,63,85,88-92], derivatives of α-alanine substituted with a xanthine molecule at the β-carbon atom[58,59,88,92] (cf. Refs. 74–78), and certain others (see, for example, Refs. 93–95):

Lugovkin synthesised a group of purinylphosphonic acid esters from 8-monochloro and dichloromethyl-*N*-methylxanthines (1,3,7-, 1,3,9-, and 3,7-derivatives) via the Arbuzov reaction. Diesters of the corresponding purinylmethylphosphonic acids (XXXVI) were obtained by the condensation of 8-monochloromethylcaffeine[96] (and later also 2-chloro-6-monochloromethyl-9-methylpurine[74,97]) with trialkyl phosphites and diesters of α-hydroxy-8-purinylmethylphosphonic acids (XXXVII) were obtained by the reaction of dialkylphosphorous acids with caffeine-8-aldehyde and theobromine-8-aldehyde[98,99].

A series of dimethyl esters of 8-purinyl-(*p*- and *m*-tolylamino)methylphosphonic acids (XXXVIII) were synthesised by treating with dialkylphosphorous acids 8-xanthinylazomethines obtained by the condensation of the above aldehydes with *m*- or *p*-toluidine[100]:



(XXXVI) (XXXVII) (XXXVIII)

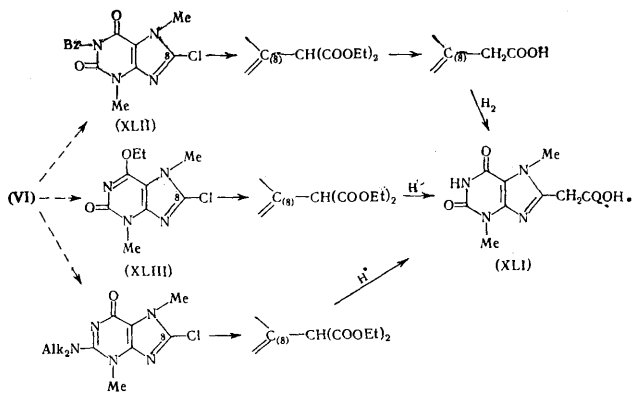
Lugovkin investigated the condensation of *N*-methylated xanthine-8-aldehydes with the active methylene groups of the alkiodides of α- and β-picolines, quinaldine, lepidine, and 2-methylbenzothiazole and its derivatives[101-103] and also with 3-alkyl- and 3-phenylrhodanines[104], which yielded the quarternary salts of various heterocyclic systems with *N*-methylated xanthine-8-ylidene substituents

§ It is self-evident that the synthesis of uric acid is not obligatory for the synthesis of caffeine which is nowadays manufactured by another synthetic procedure or isolated from natural materials. However, this scheme may be regarded as entirely reliable for the preparation of derivatives of 9-methylpurines, and it has many advantages over other versions of their synthesis.

(XXXIX) and also purine rhodanines with the general formula (XL):

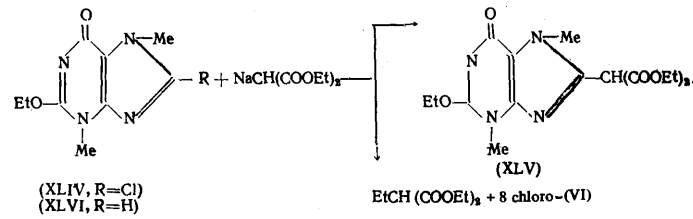
(XXXIX) (P = purinyl)

(XL)



The interaction of *N*-methylated 8-chloroxanthines with amines, alkoxides, and other nucleophilic agents leads readily to the formation of the corresponding xanthines with C–N, C–O, and C–S bonds at the $C_{(8)}$ carbon atom.

Such reactions and also the direct substitution of the hydrogen atoms of the $C_{(8)}$-methyl group by chlorine discussed above and the subsequent conversion of the mono-, di-, and tri-chlorides takes place in more or less the same manner for *NNN*-trimethylxanthines and those *N*-methylated xanthines where one or two ring hydrogen atoms are unsubstituted (see, for example, Golovchinskaya et al.[52]).

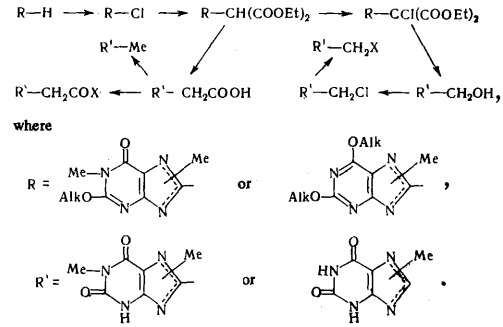


In contrast to these reactions, the condensation of 8-chloro-derivatives of *NN*-dimethylxanthines and *N*-monomethylxanthines with sodiomalonic ester is much more complicated than the analogous condensation of *NNN*-trimethylxanthines, i.e. of 8-chlorocaffeine and 8-chloroisocaffeine, since it requires a preliminary introduction of protecting groups. *N*-Benzylation or the introduction of *C*-alkoxy groups are usually employed for this purpose. Catalytic reduction is used to remove the benzyl group[62,72,89,105,106] and the alkoxy-group is eliminated hydrolytically[71–73,88].

Both methods of protection can be clearly illustrated by the synthesis of theobromine-8-acetic acid (XLI) and its derivatives from 1-benzyl-8-chlorotheobromine (XLII) and from 8-chloro-6-ethoxy-3,7-dimethylhypoxanthine (XLIII)[72,107].

Recently yet another method of synthesising theobromine-8-acetic acid from theobromine (VI) has been discovered; it is based on the fact that the alkylamino-groups linked to the $C_{(2)}$ atom of 3,7-dimethylhypoxanthine are readily split off on heating with inorganic acids[108]. Therefore such groups can be successfully employed at $C_{(2)}$ instead of alkoxy-groups at $C_{(6)}$ for protection in the condensation of 8-chlorotheobromine with sodiomalonic ester. They are eliminated with regeneration of the xanthine structure and simultaneous hydrolytic cleavage of the malonic acid residue[109]:

An interesting fact was observed in an attempt to synthesise the acid (XLI) from 8-chloro-2-ethoxytheobromine or 8-chloro-2-ethoxy-3,7-dimethylhypoxanthine[110–111] (XLIV), i.e. from an isomer of compound (XLIII). The yield of the condensation product, 2-ethoxytheobromine-8-malonic ester (XLV), was found to be appreciably lower than the yield of the condensation product obtained from the 6-ethoxy-derivative (50% instead of 80%), because the condensation of (XLIV) was accompanied by a parallel reaction involving the ethylation of the malonic ester owing to the cleavage of the ethoxy-group at $C_{(2)}$. In this case, the final reaction products were, apart from (XLV), ethylmalonic ester (yield 42%) and 8-chlorotheobromine:



(XLIV, R=Cl) (XLVI, R=H)

(XLV)

$EtCH(COOEt)_2$ + 8 chloro-(VI)

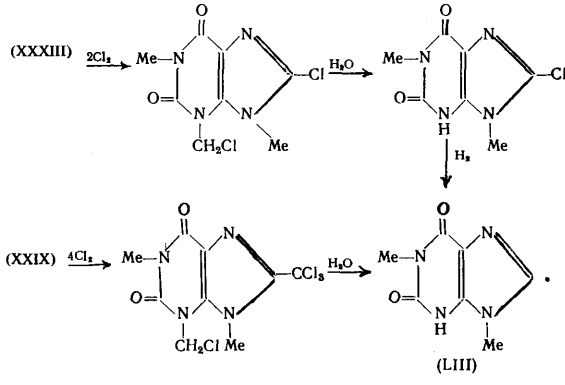
The yield of ethylmalonic ester increases and reaches 92% when the possibility of the competing condensation reaction is excluded, i.e. when 2-ethoxy-theobromine (XLVI), which does not contain a chlorine atom at $C_{(8)}$, is allowed to react with sodiomalonic ester. The capacity of compounds (XLIV) and (XLVI) to behave as ethylating agents has been confirmed also in other reactions[112].

The isomeric 2-ethoxy-1,9-dimethylhypoxanthine (XLVII) and 2-ethoxy-1,7-dimethylhypoxanthine (XLVIII) and their 8-chloroderivatives (XLIX) and (L)[113–116] also alkylate malonic ester, but the main reaction products formed are the corresponding 2-ethoxypurinyl-8-malonic esters[112]. As a result, both 2-alkoxydimethylhypoxanthines [(XLVII and XLVIII) and also 2,6-dialkoxy-7-methylpurine (LI) and 2,6-dialkoxy-9-methylpurine (LII); see below] were used as the starting materials for the synthesis in satisfactory yields of a series of derivatives of 1,7- and 1,9-dimethylxanthines and also 7- and 9-monomethylxanthines substituted by various groups in the 8-position[72,113]:

It was suggested that the reason why 2-ethoxytheobromine (XLVI) and its 8-chloro-derivative (XLIV) are more active ethylating agents than compounds (XLVII)–(L) is associated with the *p*-quinonoid structure of the pyrimidine part of the molecule, which entails an additional decrease of electron density at $C_{(2)}$ and a consequent loosening of the bond between the oxygen in the ethoxy-group and the carbon atom of the alkyl group.

The real reason for the inability of 8-chloro-6-ethoxy-theobromine (XLIII), mentioned above, to alkylate malonic ester is probably the steric effect of the $N_{(7)}$-methyl group, which is in the *peri*-position relative to the $C_{(8)}$ reaction centre[112].

LCAO-MO calculations using the parameters of Pullman's system for the compounds (XLVI), (XLIV), (XLVII)–(L), 1,7-, 1,9-, and 3,7-dimethylhypoxanthines, 3,7-dimethyl-2-oxo-2,3-dihydropurine[67–69] and the study of their ^{1}H NMR spectra yielded a satisfactory qualitative correlation between the experimental and calculated data characterising the reactivity of the substituents (the ethoxy-group at C$_{(2)}$ and the chlorine atom at C$_{(8)}$) in the reactions discussed above[117].



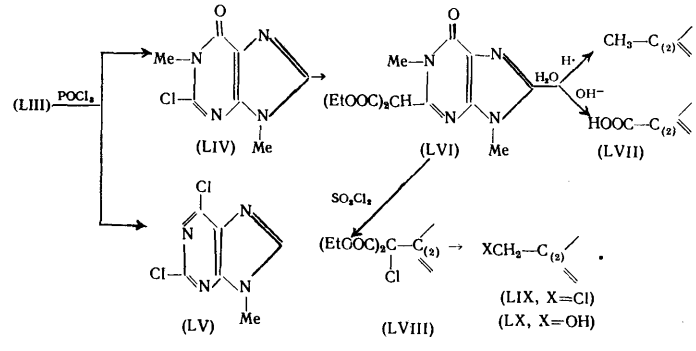
In conclusion of this section, it should be noted that the difference between α- and β-xanthines is shown to only a slight degree in the reactions enumerated above.

2. 9-Methylpurine Derivatives Substituted in the Pyrimidine Ring

a. Preparation of 1,9-dimethylxanthine from 8-methylisocaffeine. Substitution of tetramethylxanthines with chlorine in the C$_{(8)}$-methyl group and directly at C$_{(8)}$ in *NNN*-tri- and *NN*-di-methylxanthines takes place in the α- and β-series without significant differences, while in the substitution with chlorine in the *N*-methyl groups (reactions requiring higher temperatures[18,25,118–121] and the use of an excess of the chlorinating agent) certain differences are observed.

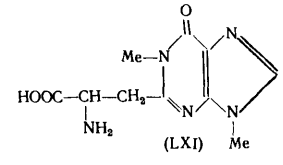
The replacement by chlorine of some of the hydrogen atoms in the *N*-methyl group of 8-chlorocaffeine[118–120] and 8-trichloromethylcaffeine[18,24,25] with subsequent hydrolytic elimination of the *N*-monochloromethyl group constitutes the basis of the methods of industrial synthesis of theophylline (VII) from caffeine[122] or uric acid, which have been known for a long time.

The chlorination of isocaffeine (XXXIII) and its 8-methyl derivative (XXIX) and subsequent hydrolysis yielded 8-chlorodimethylxanthine and dimethylxanthine containing *N*-methyl groups in the 9-position; on the other hand, the chloromethyl groups at N$_{(3)}$ in the pyrimidine ring were eliminated[53,123–129]:



The observed difference in the order of substitution by chlorine of the hydrogen atoms in the *N*-methyl groups of *NNN*-trimethylxanthines of the α- and β-series led to a comparatively simple and short method for the conversion of compound (XXIX) into 1,9-dimethylxanthine (LIII)[130], which had been synthesised hitherto by more time-consuming procedures[127,128,131]. Owing to the ease of the new method of synthesising (LIII), it has become the starting material for the synthesis of many derivatives of 1,9-dimethylhypoxanthine substituted at C$_{(2)}$ and also of 9-methylpurine substituted at C$_{(2)}$ and at C$_{(6)}$.

b. Synthesis of derivatives of 1,9-dimethylhypoxanthine substituted at C$_{(2)}$. When 1,9-dimethylxanthine is heated with phosphoryl chloride, 2-chloro-1,9-dimethylhypoxanthine (LIV) is formed in 55% yield with an admixture of about 10% of 2,6-dichloro-9-methylpurine (LV).[128] When the monochloro-derivative (LIV) is heated with aqueous solutions of ammonia and primary and secondary amines and also with alcoholic solutions of thiourea and sodium alkoxides at temperatures below 100°C, derivatives of 1,9-dimethylhypoxanthine substituted at C$_{(2)}$ by various groups via the N, S, and O heteroatoms are formed comparatively readily[113]. 2-Amino-1,9-dimethylhypoxanthine had been obtained previously by the methylation of methylguanine[51].

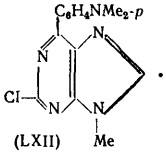


The high reactivity of chlorine in 2-chloro-1,9-dimethylhypoxanthine (LIV) was employed for malonic ester synthesis[76].

Like *NNN*-trimethylxanthine-8-malonic ester and *NN*-dimethyl- and *N*-monoethyl-hypoxanthine-8-malonic esters mentioned above, the diester (LVI), obtained in this process has a relatively high acidity constant and therefore two moles of sodiomalonic ester are employed per mole of (LIV) to obtain a high yield of the diester. Hydrolysis of compound (LVI) in an alkaline medium yielded 1,9-dimethylhypoxanthine-2-acetic acid (LVII), its esters, and amides. In contrast to xanthine-8-acetic acids, this acid readily splits off CO_2 at a low pH and therefore hydrolysis of the diester in the presence of inorganic acids leads to the formation of 1,2,9-trimethylhypoxanthine.

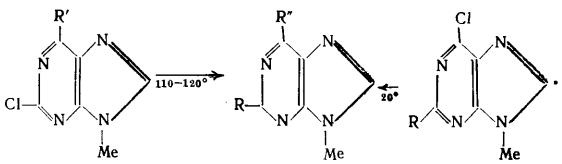
When the diester (LVI) is treated with sulphuryl chloride, 1,9-dimethylhypoxanthine-2-chloromalonic ester (LVIII) is obtained; depending on the conditions, the latter can be hydrolysed to the chloromethyl derivative (LIX) or the hydroxymethyl derivative (LX):

A group of derivatives of 1,9-dimethylhypoxanthine substituted at C$_{(2)}$ via a C–C bond, including β-(1,9-dimethylhypoxanthin-2-yl)-α-alanine (LXI), an analogue of β-(8-purinyl)-α-alanine mentioned above, was obtained by treating the chloro-derivative (LIX) with various nucleophilic agents[76]:



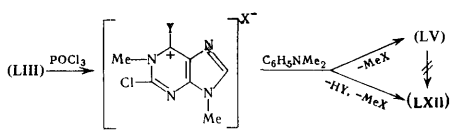
c. Synthesis of 9-methylpurine derivatives substituted at C$_{(2)}$ and at C$_{(6)}$. 9-Methylpurine derivatives substituted at C$_{(2)}$(R) and at C$_{(6)}$(R′) were obtained from 1,9-methylxanthine via two procedures:

with intermediate formation of 2,6-dichloro-9-methylpurine (LV) or from compound (LIV) by substituting the chlorine at $C_{(2)}$ with subsequent conversion of 2-R-1,9-dimethylhypoxanthine into 2-R-6-chloro-9-methylpurine and the subsequent replacement of chlorine by the required substituent R'.[114]



The formation of 2,6-dichloro-9-methylpurine (LV)[128] as the main product from compound (LIII) is a complicated process requiring heating with phosphoryl chloride at a high temperature (about 160°C)[132] or the addition of agents such as tertiary amines or phosphorus pentachloride.

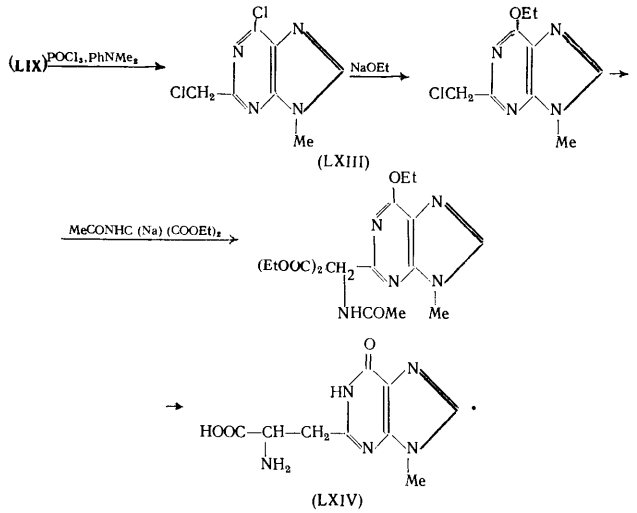
Dimethylxanthine (LIII) can be converted into dichloropurine (LV) by heating with phosphoryl chloride in the presence of dimethylaniline, by analogy with the synthesis of 2,6-dichloro-7-methylpurine from theobromine[133], but the yield of the dichloro-derivative does not exceed 30–32%. The product is a bright-yellow substance (LXII), which was identified by ^{1}H NMR spectroscopy with a substance which had been obtained by the interaction of 2-chloro-1,9-dimethylhypoxanthine (LIV) with $POCl_3$ and dimethylaniline[134–136]:



(LXII)

The structure of compound (LXII) is confirmed by its similarity to 2-chloro-6-R'-9-methylpurines in which R' is a dimethylamino- or a benzylamino-group (the substitution of chlorine by amines requires prolonged heating at 110–120°C). The reactivity of compound (LXII) is very much lower than that of the highly reactive 2-R-6-chloro-9-methylpurines, which undergo nucleophilic exchange reactions even at room temperature[137]:

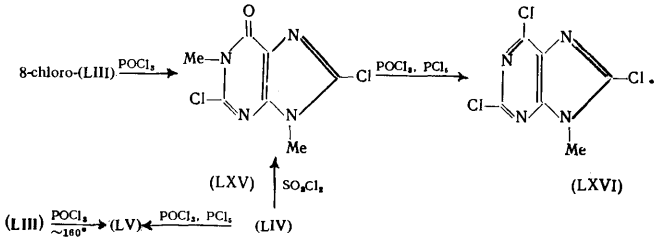
Condensation with dimethylaniline was found to be a side reaction taking place simultaneously and not a secondary process involving the final dichloro-derivative (LV) after its formation. Its comparatively high reactivity of the chlorine atom at $C_{(6)}$ in this dichloro-derivative was still found to be inadequate to ensure para-condensation with dimethylaniline, as shown by experiments in which compound (LV) was heated with dimethylaniline in phosphoryl chloride.



Evidently a purine compound in which the $C_{(6)}$ atom is more electrophilic takes part in the para-condensation reaction. It was suggested that an intermediate of the amidochloride type[138–140], which is partly cleaved with formation of a dichloro-derivative and partly condenses with dimethylaniline and only then splits off the $N_{(1)}$-methyl group, should be regarded as responsible for the formation of the para-condensation product. The primary product of such para-condensation is a precursor of compound (LXII), which was isolated[138]:

(X, Y = Cl, Cl or Cl, $OPOCl_2$)

The validity of this interpretation of the process is partly confirmed by the analogy with the isomeric dimethylxanthine of the α-series, namely theobromine: its reaction with dimethylaniline and phosphoryl chloride led to the isolation, apart from 2,6-dichloro-7-methylpurine, of the primary para-condensation products retaining the $N_{(3)}$-methyl group in the pyrimidine ring[141].



Certain derivatives of 1,9-dimethylhypoxanthine containing substituents at $C_{(2)}$ and linked to the purine molecule via a heteroatom split off the $N_{(1)}$-methyl group comparatively readily and are converted into the corresponding 2-R-6-chloro-9-methylpurines as a result of heating with phosphoryl chloride without the addition of tertiary amines or phosphorus pentachloride[142]. However, when there is a carbon–carbon bond at $C_{(2)}$, the reaction requires the presence of dimethylaniline and takes place with charring. For example, 2-chloromethyl-1,9-dimethylhypoxanthine (LIX) gives not more than 40% of 6-chloro-2-chloromethyl-9-methylpurine (LXIII)—a compound from which yet another purinylalanine (LXIV) was synthesised according to the following scheme[143]:

The replacement of dimethylaniline by other tertiary amines (cf., for example, Robins and Christensen[144]) in order to eliminate the parallel para-condensation process mentioned above leads to a considerable increase of the yield of the dichloro-derivative (LV). Thus, when dimethylxanthine (LIII) was heated with phosphoryl chloride and triethylamine hydrochloride, compound (LV) was obtained in 70–75% yield[109]. This compound can be obtained also in satisfactory yield (60–65%) when phosphorus pentachloride is employed instead of tertiary amines.

If phosphorus pentachloride is present in the reaction mixture from the very beginning of the heat treatment of compound (LIII) in the presence of phosphoryl chloride, a parallel process involving electrophilic substitution by chlorine at $C_{(8)}$ takes place, the 8-chloro-derivative of compound (LIII) undergoing subsequently the same reactions as the initial compound (LIII). Therefore ultimately, when phosphoryl chloride and phosphorus pentachloride act simultaneously on compound (LIII), one obtains from the reaction mixture, after treatment with water, a mixture which is difficult to resolve and which consists of the monochloro-derivative (LIV), the dichloro-derivative (LV), 2,8-dichloro-1,9-dimethylhypoxanthine (LXV), and 2,6,8-trichloro-9-methylpurine (LXIV)[145,146].

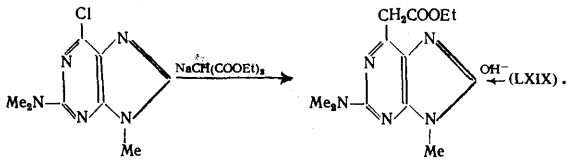
The chloro-derivatives (LXV) and (LXVI) proved to be identical with the specimens of the same compounds synthesised in other ways:

On the other hand, derivatives of 9-methylpurine containing a chloro-substituent in the pyrimidine ring, namely the chloro-derivatives (LIV) and (LV), are incapable of being substituted by chlorine at $C_{(8)}$ on treatment with PCl_5, in contrast to the initial xanthine (LIII), and therefore cannot serve as the starting materials for the synthesis of compounds (LXV) and (LXVI) in this reaction.

These observations agree with the general rules of electrophilic halogenation of the purine system in the 8-position according to which this is possible only when the molecule contains electron-donating groups capable of compensating the electron-accepting influence of the pyrimidine ring relative to the imidazole ring[147]. According to this rule, the presence of a chlorine atom in the pyrimidine ring decreases the nucleophilicity of the $C_{(8)}$ ring carbon atom and prevents halogenation at this position. The chloro-derivative (LIV) can be converted into the 8-chloro-derivative (LXV) only as a result of a prolonged reaction with SO_2Cl_2 (in a yield not exceeding 25%) but not by treatment with PCl_5. The dichloro-derivative (LV) does not react even with SO_2Cl_2.

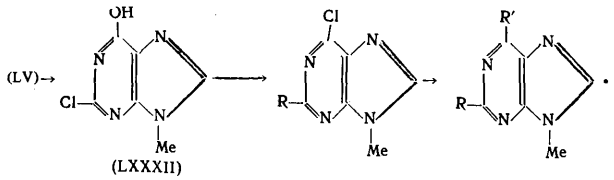
A method for the synthesis of the dichloro-derivative (LV) from dimethylxanthine (LIII) is based on such relations; it consists in heating compound (LIII) with $POCl_3$ until the disappearance of the initial xanthine from the reaction sphere and the subsequent interaction of the reaction mixture with PCl_5.[133]

The replacement of the chlorine atoms in the dichloro-derivative in compound (LV) by identical or different atoms or groups makes it possible to obtain derivatives of 9-methylpurine with various combinations of substituents at the carbon atoms of the pyrimidine ring.



Owing to the much higher reactivity of the chlorine linked to $C_{(6)}$ in the initial chloro-derivative compared with the chlorine at $C_{(2)}$, it is possible to obtain from this compound 6-R′-2-chloro-9-methylpurines (R′ = OAlk, NHR″, SH, etc.) under very mild conditions after which the chlorine at $C_{(2)}$ can be reduced or replaced by other groups under more severe conditions[137,148]. It is self-evident that, when R = R′, both chlorine atoms are substituted simultaneously.

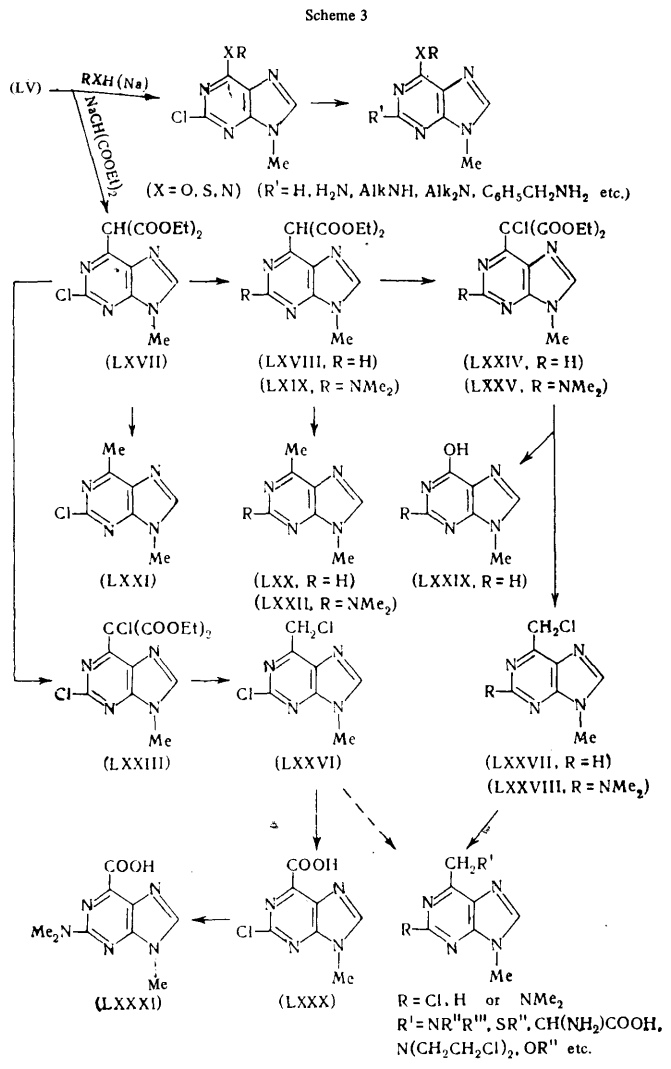
The non-equivalence of the chlorine atoms in the initial compound (LV) makes it possible to obtain from it derivatives of 9-methylpurine substituted at $C_{(6)}$[149,150] via the scheme adopted for the condensation of halogenopurines with sodiomalonic ester (see above). In 2-chloro-9-methylpurine-6-malonic ester (LXVII), the chlorine atom at $C_{(2)}$ may be reduced or replaced by another substituent [for example $N(CH_3)_2$] with formation of the corresponding diesters (LXVIII) and (LXIX). When the diesters (LXVII)–(LXIX) are heated with a dilute inorganic acid, 6,9-dimethylpurine (LXX), 2-R- (LXX), (LXXI, R = Cl), and [(LXXXII, R = $N(CH_3)_2$] are obtained.



On treatment with SO_2Cl_2, the diesters (LXVII)–(LXIX) are converted into the corresponding purine-6-chloromalonic esters (LXXIII)–(LXXV), which are converted by hydrolysis at a low pH into 6-chloromethylpurines (LXXVI)–(LXXVIII). The yield of the conversion of (LXXIV) into (LXXVII) does not exceed 18%, since the main reaction product is found to be 6-hydroxy-9-methylpurine (LXXIX)[149], which is formed as a result of the cleavage of the C–C bond between $C_{(6)}$ of the 9-methylpurine molecule and the carbon atom of the chloromalonic group. Such hydrolytic cleavage of this bond is evidently a result of the high electrophilicity of the $C_{(6)}$ ring carbon atom. It is apparently also responsible for the capacity of the chlorine in the chloromethyl and chloromalonic groups of compounds (LXXIII)–(LXXVIII) to react vigorously as halogen cations and in particular to be reduced rapidly in KI solution with evolution of I_2 (see Scheme 3).

The chlorine in 6-chloromethylpurines (LXXVI)–(LXXVIII) can be substituted comparatively readily whereby the synthesis of a wide variety of $C_{(6)}$ derivatives of 9-methylpurine, including three β-(9-methyl-2-R-purin-6-yl)-α-anilines [(R = Cl, H, and $N(CH_3)_2$] can be achieved comparatively readily.

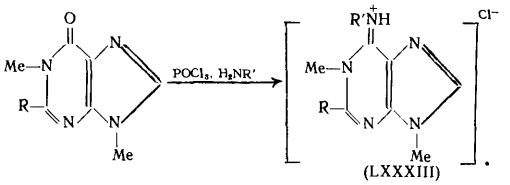
2-Chloro-9-methylpurine-6-carboxylic acid (LXXX) was obtained by the oxidation of the dichloro-derivative (LXXVI) in an alkaline medium and was converted into 2-dimethylamino-9-methylpurine-6-carboxylic acid (LXXXI). It is decarboxylated only on fairly strong heating, in contrast to the corresponding 2-R-9-methylpurine-6-acetic acids [R = Cl, H, and $N(CH_3)_2$], which split off CO_2 extremely readily. Quite stable esters of the latter were obtained from the diesters (LXVII)–(LXIX) by hydrolysis with NaOH in an aqueous-alcoholic medium[150] and one of them [R = $N(CH_3)_2$] is formed also by the condensation of 6-chloro-2-dimethylamino-9-methylpurine with sodiomalonic ester, since the reaction is accompanied by the splitting off of the ethoxycarbonyl group:



2,6-Disubstituted 9-methylpurines with various substituents at $C_{(2)}$ and $C_{(6)}$ can be synthesised from the dichloro-derivative (LV) also via another scheme with the intermediate formation of 2-chloro-6-hydroxy-9-methylpurine (LXXXII). The replacement of the chlorine in this compound at $C_{(2)}$ by various groups and subsequent introduction of chlorine at $C_{(6)}$ by treatment with $POCl_3$ and its subsequent substitution yield 2,6-disubstituted derivatives of 9-methylpurine containing all kinds of substituents at $C_{(6)}$, including the most reactive groups[113]:

The chloro-derivative (LXXXII) is formed in 82% yield after heating the dichloro-derivative (LV) for 5 h with 1 *N* acid. More prolonged heat treatment or the use of more

Scheme 3



concentrated acid leads to the hydrolytic elimination of the second chlorine atom too, i.e. to the regeneration of the xanthine structure.

---o0o---

The reactions of 1,9-dimethylxanthine described in this section do not exhaust the wide variety of processes in which the compound may be involved and all the possibilities of its employment for synthetic purposes. In particular, it does not include certain aspects of the reaction of 1,9-dimethylxanthine with phosphorus chloro-compounds, which require separate consideration and do not fit within the framework of the present review.

Brief mention should also be made of the synthesis of 6-imino(or alkylamino-)-1,9-dimethylpurines (LXXXIII)—analogues of 1-alkyl-6-iminopurines, which were obtained for the first time in the 1960's either by the alkylation of adenosine[151-154] or by synthesis from 3-amino-2-cyano-1-methyl-imidazole[155]. The hydrochlorides (LXXXIII) were formed as a result of treatment with aqueous solutions of ammonia or amines of compounds of the amidochloride type obtained by treating 1,9-dimethylxanthine (LIII) or 2-R-1,9-dimethylhypoxanthines (R = Cl, CH_3, NHAlk, etc.) with phosphoryl chloride[156]:

In contrast to the syntheses described previously, this scheme makes it possible to vary widely the substituents in the exocyclic imino-group of compound (LXXXIII) and at $C_{(2)}$ (cf. Nikolaeva et al.[157]).

Polarographic Catalytic Currents of Complexes of Metals in Catalysis by a Ligand

Ya.I.Tur'yan

This review gives the characteristics of catalytic systems and results on the kinetics and mechanism of electrode chemical reactions, describes methods of determining the instability constants of complexes from the catalytic currents and the analytical use of catalytic boundary waves, and makes a comparison with results on corresponding non-electrode reactions of complex formation.
Among the bulk electrode chemical processes considered are theoretical and experimental results on an electrode reaction with two successive rate-determining chemical stages, and also on a double catalytic effect: that of the ligand and that of an addition of a polarographically active complex which is regenerated at the electrode.
The kinetics and mechanism of processes involving an adsorbed ligand-catalyst have been analysed on the basis of a concept of heterogeneous parallel reactions of complex formation.
There is a bibliography of 168 references.

IV. Determination of the instability constants of complexes	

I. INTRODUCTION

The prewaves of the polarographic wave of the aquo-ions of a metal, linked with the participation of polarographically active complexes (PAC) in the electrode process during catalysis by a ligand, were termed[1,2] catalytic prewaves (points) of the metal complexes. Here we will not consider the catalytic currents of complexes in catalysis by the ions of a metal[3], the catalytic release of hydrogen, and the catalytic effect of the ligand in the presence of an inhibitor of the electron transfer stage[4], although this effect shows certain resemblances[5,6] to the catalytic influence of the ligand in the absence of an inhibitor.

The characteristics of catalytic currents of metal complexes in catalysis by a ligand are: (1) the prewaves arise at potentials that are more positive (cathodic)[7-12] or more negative (anodic)[11] than the reduction or oxidation potentials respectively of the aquo-ions of the metal; (2) a catalytically active ligand can be either charged[7] or electrically neutral[9]; (3) in the PAC the metal ions are reduced or oxidised with regeneration at the electrode of the ligand, which again participates in the formation of PAC[1,2]; however, when there is an excess of the ligand

(prewaves arise either when there is an excess of the ligand or when there is an excess of the metal ions)[13,14] or when the PAC is of low stability this phenomenon does not play a significant part; (4) the prewaves are of a kinetic nature[1,2,7-12], and increase with the concentration of the ligand, in many instances reaching the limit of the diffusion wave of the aquo-ions of the metal. However, when ligand adsorbed on the electrode participates in the formation of PAC, the prewave limiting current, having reached the region of diffusion current corresponding to potentials of maximal adsorption of the ligand, can fall again as the potential is changed, owing to partial desorption of the ligand (minimum on the polarisation curve)[8]; (5) the prewaves can exceed the initial diffusion wave of the aquo-ions of a metal when the solution contains, in addition to the ligand, certain components which regenerate PAC at the electrode. When components which do not form complexes are chosen the nature of the PAC remains unchanged[15,17].

Polarographically catalytic currents of metal complexes in catalysis by a ligand are of theoretical and practical importance: in electrocatalysis (especially chemical factors), electrodeposition (mechanism of the effect of a catalytically active ligand), the chemistry of coordination compounds (new methods of investigation of the instability constants of complexes and of the kinetics of complex formation, including the kinetics of complex formation under heterogeneous conditions), and analytical chemistry (polarographic determination of metals in the presence of catalytically active ligands and in a newer direction—determination of the ligands themselves with the aid of the prewaves). All these aspects of this problem will be covered in the present review.

II. CATALYTIC SYSTEMS

The choice of metal ions for the production of these catalytic prewaves is determined mainly by the presence of a high overpotential in the reduction or oxidation of the corresponding aquo-ions of the metal[18].

Catalytically active ligands can belong to various classes of inorganic and organic compounds, usually readily adsorbed on an electrode.

Usually prewaves have been observed in aqueous solutions, but there have been examples of catalytic currents in non-aqueous or mixed solvents[19-23].

A large number of catalytic systems are known (with the exception of the two examples of an anodic process given below, all cathodic processes): Ni^{II}–NCS^-,[7,10,12,24-29] Ni^{II}–Cl^- (Br^-, I^-),[19,20,23,30] Ni^{II}–pyridine and its alkyl, amino-, and hydroxo-derivatives,[1,2,9,14,21,29,31-42] Ni^{II}–1,2- and 1,5-diaminonaphthalenes,[2] Ni^{II}–3,4-diaminotoluene,[2] Ni^{II}–3,4-diaminobenzoic acid,[2] Ni^{II}–4,4′-diaminostilbene-2,2′-disulphonic acid,[2] Ni^{II}–aminoethylpiperazine,[2] Ni^{II}–2,2′-bipyridyl,[2] Ni^{II}–2-aminoethanol,[2] Ni^{II}–*o*-phenylenediamine,[2,43-51] Ni^{II}–*p*-phenylenediamine,[51] Ni^{II}–ethylenediamine,[52] Ni^{II}–thiourea and its derivatives[53-60], Ni^{II}–cysteine[61], Ni^{II}–selenocysteine[62], Ni^{II}–*o*,*o*′-diethyldithiophosphate[63], Ni^{II}–xanthogenate[22], Ni^{II}–thiosemicarbazide[57], Ni^{II}–rubeanic acid[57], Ni^{II}–unithiol[57], Co^{III}(ammonia complex)–Cl^-(Br^-),[64,65] Co^{II}–ethylenediamine (anodic process),[66] Co^{II}–cysteine and its derivatives[67-70], Co^{II}–selenocysteine[71], Co^{II}–acetylacetone[72], Co^{II}–pyridine[73,74], In^{III}–halide ions[5,8,75-80], In^{III}–NCS^-,[5,77-83] In^{III}–thiourea and its derivatives[6,75,77,79,84], In^{III}–thioacetic and mercaptoacetic acids[77], In^{III}–mercaptoethanol[77], In^{III}–cysteine[84], In^{III}–thiosemicarbazide[56,84], In^{III}–*o*-phenylenediamine[77], In^{III}–2,2′bipyridyl[77], In^{III}–1,10-phenanthroline[77], In^{III}–phthalic acid[75], In^{III}–oxalic acid[77,85-87], In^{III}–tartaric acid[8], In^{III}–acetylacetone[88], Ga^{III}–NCS^-,[89-92] Ga^{III}–halide ions[93], Ga^{III}–N_3^-,[94] Ga^{III}–salicylic and aminosalicylic acids[92], Ga^{III}–methylthiourea[92], Ga^{III}–2-amino-4-hydroxythiazole[92], Ga^{III}–2-amino-4-methyl-5-thiocyanothiazole[92], Sn^{IV}–cysteine[95], Ti^{IV}–NCS^-,[11,17,96-100] Ti^{III}–NCS^- (anodic process),[11] Ti^{IV}–SO_4^{2-},[101,102] Ti^{IV}–F^-,[103] Ti^{IV}–citric acid[15,104], Ti^{IV}–polyphenols[16,104-106], Ti^{IV}–salicylic and sulphosalicylic acids[16,104,105], Ti^{IV}–oxalic acid[104], Ti^{IV}–pyrocatechol[107], Ge^{IV}–polyphenols and their derivatives[108-114], Ge^{IV}–polyhydroxyanthraquinones[113,115], Ge^{IV}–hydroxyflavones[113,116].

III. KINETICS AND MECHANISM OF THE PROCESSES

As in the catalytic liberation of hydrogen[117], the formation of PAC may take place either in the body of the solution (bulk currents; we will thus refer to processes with a reaction layer much thicker than the diffusion part of the electrical double layer[11,15,16,28,66,100]), or with participation of the adsorbed ligand-catalyst (heterogeneous or surface processes)[1,2,35,43-51,62,77-87].

It must be borne in mind that the effect of certain anions and surface-active agents can be linked not only with the surface nature of prewaves, but also with the formation in the solution of new complexes[36-38,51]. Therefore in the present instance it is more important to study the effect of the nature and concentration of the background cation[35,47-50], especially in using alkali metal cations which differ in surface activity[118] but at the same time hardly produce a block-effect and are sufficiently inert to complex formation.

Unlike the catalytic wave of hydrogen with participation of an adsorbed catalyst[119], the temperature coefficient of the limiting current in the heterogeneous reaction for the formation of a PAC is usually sufficiently high (predominance of chemical kinetics)[2,28,35,55,77] but a lower temperature coefficient has also been observed[114] (predominance of the adsorption effect).

The regeneration of a ligand at an electrode is often due to rapid decomposition of the product from the reduction of PAC in the form of the corresponding zerovalent complex[120]. Although extremely unstable zerovalent complexes are usually formed, the difference in the magnitudes of the calculated halfwave potentials of the aquo-ions from a single metal in the presence of different catalytically active ligands[121] allowed the difference in the rate of deactivation of an amalgam[121], or more precisely, in the rate of decomposition of the corresponding zerovalent complexes, to be found. Thus the rates of decomposition of the zerovalent complexes of nickel were found to increase in the following sequence of ligands: pyridine < imidazole < NCS^-.[121]

In many instances the shift in the reduction or oxidation potentials of the PAC is due to the very stable primary hydration of the corresponding aquo-ions of the metals and the weakening (labilisation) under the influence of the ligand of the bonding of the metal ion with the water molecules which remain in the first hydration shell[43,52,122,123]. This conclusion is confirmed by studies[124,125] in which the labilisation of water molecules in a complex was observed with the aid of non-electrochemical methods. For some aquo-ions of metals (for example, Ni^{2+}) which form prewaves, hydration is so strong that in solutions with a high concentration of supporting electrolyte, owing to the marked reduction in the concentration of the aquo-ions of

the metal in the near-electrode layer (the ψ_1-effect[126,127]) a kinetic current was observed: kinetic limitation of the dehydration step[128].

When a PAC is formed in the adsorbed layer, then an electric field evidently exerts a considerable effect on the acceleration of the dehydration[129,130]. It cannot be ruled out that in certain instances the acceleration of the electron transfer stage is linked with the fact that the adsorbed ligand entering into the PAC plays the part of an "electron bridge"[4,131,132]. Attention must be paid to the special state of the adsorbed ligand entering the PAC; it is not impossible that coordination with mercury and with the reacting ion of the metal is effected simultaneously[41,73,133,134]. Some investigators[131,132] pay more attention to the "electron bridge" than to complex formation, although we do not think it very expedient to regard these phenomena as mutually exclusive.

Observations which indirectly characterise the chemical nature of the slow step of the electrode process are of great interest: (1) the steric effect of the ligand (In^{III}–thiourea and its derivatives[84]; Ni^{II}–pyridine and its derivatives[39,39a]). A similar effect was noted in certain complex formation reactions by use of non-electrochemical methods[135]; (2) the relation of the catalytic effect to the structure of isomeric ligands (Ni^{II}–isomers of phenylenediamine[44,45,51]); (3) the inhibition of the catalytic process in the Ni^{II}–pyridine (or its derivatives) systems when the solution is acidified[2,35,39,39a], which is also characteristic for the corresponding non-electrode reactions in complex formation (protonation of the ligand); (4) the inhibition of the catalytic process in the Ni^{II}–thiourea[59] and Ge^{IV}–polyphenol[111] systems on the addition of oxalic, citric, or tartaric acids, in the Ni^{II}–thiourea[36-38], Ni^{II}–pyridine[36-38], Co^{II}–ethylenediamine[66] systems on addition of SO_4^{2-} ions, in the Ni^{II}–thiourea[59] system on addition of NH_3 and Trilon B and the acceleration of the catalytic process under the influence of AcO^- ions (Ni^{II}–pyridine[2,37,38], Ni^{II}–thiourea[37,38], and Ni^{II}–*o*- and *p*-phenylenediamine[51] and N_3^- ions (Ni^{II}–*o*- and *p*-phenylenediamine[51]). Similar effects were also observed in a study of the kinetics of ordinary (non-electrode) complex formation reactions[136-138]; (5) the faster catalytic process in the Co^{II}–pyridine system[74] in comparison with the Ni^{II}–pyridine system[35], which correlates with the kinetics of non-electrode complex formation reactions of particular metal aquo-ions[135].

The bulk catalytic current simplest in mechanism was evidently observed in the Ti^{IV}–NCS^- system[11,96,100]. By use of Koutecky's equation[139,140]:

$$\frac{\bar{i}_k}{\bar{i}_d - \bar{i}_k} = 0.886 \cdot \left(\frac{k_1 \cdot t_1}{K_1'}\right)^{1/2} \cdot c_{NCS^-} \qquad (1)$$

(where $\bar{i}_k$ and $\bar{i}_d$ are the limiting currents, catalytic and diffusion respectively; k_1 and K_1' are the formation rate constant and instability constant of the PAC respectively); it was shown[11,96,100] that the electrode process can be described by the following scheme:

$$Ti^{IV} \xrightarrow[\text{diff.}]{} Ti^{IV} \xrightarrow[k_1]{NCS^-} [Ti^{IV}(NCS^-)] \xrightarrow[\text{red.}]{} \cdot \qquad (2)$$

For simplicity, in scheme (2) and below we do not show the stage of regeneration of the ligand at the electrode and the diffusion noted relates to the transfer of the substance from the depth of the solution to the surface of the electrode (the PAC concentration in the body of the solution is insignificant[141]).

The rate constants for the formation of PAC (scheme 2) calculated by Eqn. (1), are given in Table 1. In addition, Tribalat and Delafosse[11] found the rate constant for the formation of another PAC, $[Ti^{III}(NCS^-)]$, from the anodic catalytic prewave, $k \cong 10^6$ litre mole^{-1} s^{-1} (0.55 M HCl; 21°C).

Table 1. Rate constants for the formation of the complex $[Ti^{IV}(NCS^-)]$ in $HClO_4$ solution at 25°C.

c_{HClO_4}, M	$10^{-3}k_1$, litre mole^{-1} s^{-1}	c_{HClO_4}, M	$10^{-3}k_1$, litre mole^{-1} s^{-1}

0.044	7.9	0.55*	6±2*
0.10	7.3	1.05	4.8
0.51	6.5	2.0	5.2

*HCl[21°][11]

The catalytic prewaves of Ti^{IV} in the presence of pyrocatechol (H_2Ph), pyrogallol (H_3Pg), citric acid (H_4Cit), and sulphosalicylic acid (H_2Ssal^-) in acid solutions ($HClO_4$) also had a bulk nature[15,16]. The PAC in these systems, with the exception of H_2Ssal^- are formed with the participation in the reactions of electrically neutral ligands, with the release (including H_2Ssal^-) of hydrogen ions[15,16]. Like the catalytic systems with Ge^{IV},[113] Ti^{IV} ions form both PAC and polarographically inactive complexes with these ligands[15,16]. As the concentration was increased, the accumulation of the inactive complexes inhibited the electrode process[15,16]. If it is assumed that the stability of the PAC of Ti^{IV} correlates with the stability of the corresponding polarographically inactive chelates, the rate of formation of the PAC correlates with their stability: $H_2Ph < H_3Pg < H_2Ssal^- < H_4Cit$.[16]

Since the first investigation[142] the effect of ClO_3^- (BrO_3^-) ions on the polarographic wave of Ti^{IV} complexes has been investigated repeatedly, but as found earlier[142], under conditions when there is a large excess of the ligand, whereas in the absence of ClO_3^- ions the prewave was reached along the height of the diffusion wave of the Ti^{IV}. The effect of ClO_3^- ions was first studied at a low concentration of the ligand (NCS^-, H_2Ph, H_3Pg, H_4Cit, H_2Ssal^-), that is, under conditions where there is a double catalytic effect on the process: by the ligand and ClO_3^- ions. An increase in the catalytic prewave of Ti^{IV} complexes with increase in $C_{ClO_3^-}$ (maximally by 5–7 times in comparison with the initial prewave) has been observed[15-17]. A similar comparatively small increase in the limiting current was explained (in greatest detail for the NCS^- ions[17]) on the basis of the following scheme for the electrode process:

$$Ti^{IV} \xrightarrow{NCS^-} [Ti^{IV}(NCS^-)] \xrightarrow[(I)]{\bar{e}} [Ti^{III}(NCS^-)] \xrightarrow{(II)} Ti^{III} + NCS^- \qquad (3)$$

(IV) ↑ (III) ↑ ClO_3^-

ClO_3^-: (V)

by assuming that there are parallel reactions for the oxidation of $[Ti^{III}(NCS^-)]$: to PAC (stage III) and to the initial Ti^{IV} (stage IV). The latter, like stage V, makes little contribution to the increase in current, since it is followed by the slow stage (I).

Another example of bulk catalytic prewaves was observed in the Ni^{2+}–NCS^- system (first prewave)[12,28].

This prewave corresponds to an electrode process with two successive rate-determining chemical stages[12,28]

$$\begin{array}{ccccccc} Ni^{2+} & \xrightarrow[(I,\ k_1)]{NCS^-} & [Ni(NCS)]^+ & \xrightarrow[(II,\ k_2)]{NCS^-} & [Ni(NCS)_2] & \xrightarrow{red.} & \\ \uparrow\downarrow diff. & & \uparrow\downarrow diff. & & & & \\ Ni^{2+} & \rightleftarrows^{NCS^-} & [Ni(NCS)]^+ & & & & \end{array} \quad (4)$$

The kinetic equation for a similar electrode process was first obtained in studies[12,143] by the present author and by Tanaka and coworkers but verified experimentally only in other investigations[12,28]; this became especially convenient after appropriate transformations and the development of a graphical solution of the equations obtained[144]: ($c_{NCS^-} \gg c_{Ni^{2+}}$):

$$y = \frac{\bar{i}_d - \bar{i}_k}{\bar{i}_k} \cdot c_{NCS^-}^2 + 1.13 \left(\frac{K_1'}{k_1 t_1}\right)^{1/3} \cdot \frac{\bar{i}_d}{\bar{i}_k} \cdot \frac{c_{NCS^-}^2}{K_1' + c_{NCS^-}} = A + B \cdot c_{NCS^-} \quad (5)$$

where K_1' is the instability constant of the complex $[Ni(NCS^-)]^+$ and A and B are constants:

$$A = 1.13 \cdot K_1' \cdot \left(\frac{K_2'}{k_2 \cdot t_1}\right)^{1/3}, \quad (6)$$

$$B = 1.13 \left[\left(\frac{K_1'}{k_1 \cdot t_1}\right)^{1/3} + \left(\frac{K_2'}{k_2 \cdot t_1}\right)^{1/3}\right]. \quad (7)$$

K_2' is the consecutive instability constant of the complex $[Ni(NCS)_2]$.

When in scheme (4) the diffusion of the second species (the complex) from the depth of the solution can be neglected Eqn. (5) is greatly simplified even when there are still two successive rate-determining stages[145-147].

The rate constants k_1 and k_2 (Table 2) were found[28] by graphical solution on the basis of Eqn. (5) (in the first paper[12] an inaccuracy was introduced in finding k_1 and k_2, since no allowance was made for the distortion of the limiting diffusion current of Ni^{2+} at high concentrations of the supporting electrolyte[128]). The most important conclusion from the results in Table 2 is the similarity between the rate constants obtained from catalytic currents and those found[148] by a non-electrolytic (flow) method (k_1 = 5.6×10^3 litre mole^{-1} s^{-1}; 25°C; ionic strength 0.5). In addition, it is noteworthy that on the basis of the variations in $E_{\frac{1}{2}}$ and c_{NCS^-},[7,31] and also by a potentiostatic method[149], the reduction of the complex $[Ni(NCS)_2]$ in the Ni^{2+}–NCS^- system has been demonstrated, which agrees with the results discussed above.

Table 2. Rate constants for the formation of the complexes $[Ni(NCS)]^+$ (k_1) and $[Ni(NCS)_2]$ (k_2) at 25°C.

0.05	6.5±1.5	4.2±0.4	0.15	3.0±1.0	2.1±0.3
0.075	4.5±0.5	3.1±0.1	0.20	3.0±1.0	1.9±0.3
0.1	5.0±1.0	2.1±0.1			

Since $c_{Ni^{2+}} > c_{Ni(NCS)^+}$, as c_{NCS^-} is reduced, stage (I) in scheme (4) approaches equilibrium[27,29]:

$$\begin{array}{ccccccc} Ni^{2+} & \rightleftarrows^{NCS^-} & [Ni(NCS)]^+ & \xrightarrow[k_2]{NCS^-} & [Ni(NCS)_2] & \xrightarrow{redn.} & \\ \uparrow\downarrow diff. & & \uparrow\downarrow diff. & & & & \\ Ni^{2+} & \rightleftarrows^{NCS^-} & [Ni(NCS)]^+ & & & & \end{array} \quad (8)$$

The kinetic equation for such a process was first considered in studies[150,151] of dicarboxylic acids, and then in an investigation of metal complexes[143]:

$$\frac{\bar{i}_k \cdot (K_1' + c_{NCS^-})}{(\bar{i}_d - \bar{i}_k) \cdot c_{NCS^+}} = 0.886 \cdot \left(\frac{k_2 \cdot t_1}{K_2'}\right)^{1/3} \cdot c_{NCS^-}. \quad (9)$$

It has been shown theoretically[29] that conversion of scheme (4) into scheme (8) is possible at $c_{NCS^-} \ll 0.1$ M ($c_{NCS^-} \gg c_{Ni^{2+}}$); this conclusion has been confirmed experimentally[29] at $c_{NCS^-} \leqslant 1.5 \times 10^{-2}$ M. Although there is no single opinion about the bulk nature of the catalytic prewaves in the Co^{II}–cysteine (or its derivatives) systems[67-70] it is worth noting the relation[68]:

$$\bar{i}_k = k \cdot c_{Co^{II}}^{1/3} \quad (10)$$

characteristic for a bulk process[70,152] under the conditions c_L = const, $c_{CoII} \gg c_L$ (L is the ethyl ester of cysteine) and the high stability of the PAC:[68]

$$Co^{II} \xrightarrow{diff.} CoII \underset{k_1}{\overset{L}{\rightleftarrows}} [Co^{II}(L)] \xrightarrow{redn.} \quad (11)$$

Since $c_{CoII} \gg c_{CoII(L)}$, the effect of the diffusion of the PAC from the depth of the solution can be neglected. k_1 = $(3.7-4.3) \times 10^3$ litre mole^{-1} s^{-1}.[68]

The following bulk reactions correspond to the anodic catalytic process in the Co^{2+}–ethylenediamine(En) ($NaClO_4$) system[66]:

$$\begin{array}{ccccccc} Co^{2+} & \overset{En}{\rightleftarrows} & [Co(En)]^{2+} & \overset{En}{\rightleftarrows} & [Co(En)_2]^{2+} & \overset{En}{\underset{k_3}{\rightleftarrows}} & [Co(En)_3]^{2+} \xrightarrow{oxn.} \\ \uparrow\downarrow diff. & & \uparrow\downarrow diff. & & \uparrow\downarrow diff. & & \\ Co^{2+} & \overset{En}{\rightleftarrows} & [Co(En)]^{2+} & \overset{En}{\rightleftarrows} & [Co(En)_2]^{2+} & & \end{array} \quad (12)$$

and are describable by the kinetic equation[66,153,154]:

$$\frac{\bar{i}_k}{\bar{i}_d - \bar{i}_k} = 0.886 \cdot \left(\frac{k_3 \cdot t_1}{K_3'}\right)^{1/3} \cdot \frac{c_{En}^3}{K_1' \cdot K_2' + K_2' \cdot c_{En} + c_{En}^2}, \quad (13)$$

where K_1, K_2', and K_3' are the consecutive instability constants of $[Co(En)]^{2+}$, $[Co(En)_2]^{2+}$, and $[Co(En)_3]^{2+}$ respectively. $k_3 = 1.85 \times 10^7$ litre mole^{-1} s^{-1}.[66]

A more complex electrode process is associated with the chemical reactions for the formation of PAC in an adsorbed layer (heterogeneous reactions).

The idea of parallel heterogeneous reactions has been formulated[35,58,74,80]:

$$\begin{array}{ccccccc} M & \xrightarrow{diff.} & M & \xrightarrow[(I,\ \bar{k}_1)]{L_{ads.}} & [M(L_{ads.})] & \xrightarrow{redn.} & \\ L\downarrow\uparrow & & L\downarrow\uparrow & & & & \\ [M(L)] & \xrightarrow{diff.} & [M(L)] & \xrightarrow[(II,\ \bar{k}_2)]{L_{ads.}} & [M(L)(L_{ads.})] & \xrightarrow{redn.} & \\ & & L\downarrow\uparrow & & & & \\ & & [M(L)_2] & \xrightarrow[(III,\ \bar{k}_3)]{L_{ads.}} & [M(L)_2(L_{ads.})] & \xrightarrow{redn.} & \\ & & etc. & & etc. & & \end{array} \quad (14)$$

These obviously most completely characterise such catalytic processes. In scheme (14) (the charges of the species are omitted) M denotes the aquo-ions of the metal, L the ligand, [M(L)], $[M(L)_2]$, etc. are complexes in the bulk of the solution, and $[M(L_{ads})]$, $[M(L)(L_{ads})]$, $[M(L)_2(L_{ads})]$, etc. are PAC.

Since surface catalytic prewaves arise most frequently in solutions which contain complexes with a low stability (K_1' not below 10^{-3}–10^{-4}), in scheme (14) the diffusion of only two species from the depth of the solution to the electrode is taken into account: M and M(L). Despite the low stability of the complex [M(L)] and higher complexes, their participation in the electrode reactions for the formation of PAC cannot be neglected in general, since the bulk rate of formation–dissociation of [M(L)], $[M(L)_2]$, etc. can be rather high. In systems which form

complexes which are more stable in the bulk solution a larger number of heterogeneous parallel reactions must be considered[80] and in systems with bulk complexes of lower stability a smaller number of reactions[35,58,74] or even only a single first (I) reaction[43-51].

Owing to the presence in the PAC (scheme 14) of a ligand adsorbed on the mercury or coordinated with the mercury, similar PAC should (as shown above) differ considerably in electrochemical properties from complexes of formally analogous composition adsorbed from bulk solution[41]. The latter are not reduced at prewave potentials[41].

Irrespective of the reduction of the various PAC in scheme (14) at similar potentials (single prewave)[74,79] or at distinguishable potentials (several prewaves)[35,58], we will examine below only the equation for the overall limiting catalytic current.

Assuming in scheme (14) that the bulk reactions of formation and dissociation of complexes are near a state of equilibrium[29,35,58,59]; that the diffusion coefficients of all the species are similar; and allowing for the effect of the electrical double layer structure on the rate of heterogeneous[117,126,155,156] electron transfer steps which are sufficiently rapid in the region of the limiting catalytic current, the following kinetic equation was found[35,80] for scheme (14) (the coefficient 0.81 has been replaced[140] by 0.886):

$$\frac{\bar{i}_k(K_1'+c_L)}{(\bar{i}_d-\bar{i}_k)\cdot\Gamma_L}=0.886\cdot 10^3\cdot\left(\frac{t_1}{D}\right)^{1/6}\left\{\bar{k}_1\cdot K_1'\cdot\exp.\left(-\frac{z\cdot F}{RT}\psi_1\right)+\right.$$
$$\left.+\bar{k}_2 c_L\cdot\exp.\left(-\frac{z_1\cdot F}{RT}\psi_1\right)+\frac{\bar{k}_3}{K_2'}c_L^2\cdot\exp\left(-\frac{z_2F}{RT}\psi_1\right)+\ \ldots\right\} \quad (15)$$

where K_1' and K_2' are the successive instability constants of the bulk complexes, M(L) and M(L)$_2$ respectively; $\bar{k}_1$, $\bar{k}_2$, $\bar{k}_3$, etc. are the rate constants of the parallel heterogeneous reactions (litre mole^{-1} s^{-1}); Γ_L the surface concentration (mole cm^{-2}) of the adsorbed ligand (the existence of an adsorption equilibrium to a first approximation is assumed); for a dropping electrode this assumption is valid only up to a definite lower level c_L, for example, for *o*-phenylenediamine up to $c_L = 1\times10^{-4}$;[46,50] z, z_1, z_2, etc. are the charges of M, [M(L)], [M(L)$_2$], etc., ψ_1 a potential close to that of the Helmholtz outer layer, the value of which has been given[157] for a supporting electrolyte that is not adsorbed; the effect on ψ_1 the potential of the reacting species of their low concentration can often be neglected (the effect of adsorbed thiourea on the ψ_1 potential has been taken into account[55]); c_L the equilibrium ligand concentration (M) at the boundary between the diffusion layer and the diffusion part of the electrical double layer (c_L is close to the total concentration of the ligand; this is also true for a small excess of ligand L, owing to the regeneration of the ligand at the electrode[144]).

Since catalytic currents are usually investigated in the range of very low c_L, Γ_L can be expressed with the aid of the Henry adsorption isotherm[158]:

$$\Gamma_L=10^{-3}K_L\cdot c_L f_z\cdot\exp\left(-\frac{p\cdot F}{RT}\psi_1\right) \quad (16)$$

where K_L is the adsorption coefficient (cm) and ρ the charge of the ligand.

From (15) and (16):

$$y=\frac{\bar{i}_k(K_1'+c_L)}{(\bar{i}_d-\bar{i}_k)\cdot c_L}=0.886\cdot\left(\frac{t_1}{D}\right)^{1/6}\cdot K_L f_z\left\{\bar{k}_1\cdot K_1'\cdot\exp.\left[-\frac{(z+p)F}{RT}\psi_1\right]+\right.$$
$$\left.+\bar{k}_2\cdot c_L\cdot\exp\left[-\frac{(z_1+p)F}{RT}\cdot\psi_1\right]+\frac{\bar{k}_3}{K_2'}\cdot c_L^2\cdot\exp\left[-\frac{(z_2+p)F}{RT}\psi_1\right]+\ \cdots\right\} \quad (17)$$

At ψ_1 = const, Eqn. (17) becomes

$$y=a+b\cdot c_L+dc_L^2+\ \ldots \quad (18)$$

where a, b, and d are constants, which are conveniently determined by a graphical method[80].

By use of Eqn. (18) we showed[80] the presence of three parallel heterogeneous reactions in the In^{III}–NCS^- system—scheme (14), I, II, and III. An analysis of the variation of the surface activity of $NCS^-_{ads.}$ ions (see below) with the potential in concentrated NaNCS solution showed[83] that in this system the heterogeneous catalytic reaction

$$In^{III}\xrightarrow{2NCS^-_{ads.}}[In^{III}(NCS^-_{ads})_2]\xrightarrow[redn.]{} \quad (19)$$

takes place; it should correspond to a kinetic equation of type (18) at $a = 0$ and $d = 0$, that is, schemes (19) and (14) (without stages I and III) are kinetically indistinguishable. However, as we have shown[80], coefficients a, b, and d in Eqn. (18) are significantly different from zero, which suggests that in this system under our conditions[80] (a very low concentration of NCS^-) all three parallel heterogeneous reactions take place.

For the Ni^{2+}–Py,[35] Co^{2+}–Py,[74] Ni^{2+}–thiourea[58], and In^{III}–I^- [80] systems, in which less stable complexes are formed, Eqn. (18) has been found to be applicable—for the Ni^{2+}–thiourea system, Eqn. (15) at $d = 0$ ($\bar{k}_3 = 0$), that is, in these systems only the two parallel heterogeneous reactions (I) and (II) have a significant effect. It is interesting to note that an analysis of the change in the surface activity of the ions I^-_{ads} with the potential has also shown[132] a smaller stoichiometric number for the I^-_{ads} ions reacting with In^{III} than for NCS^-_{ads}.[83]

The even less stable complex [M(L)] in the Ni^{2+}–*o*-phenylenediamine system[46,47] takes almost no part in the heterogeneous process and the applicability of an equation of type (18) at $b = 0$ and $d = 0$ has been demonstrated[46,47].

In a study[83] of the In^{III}–NCS^- system at a high concentration of NCS^- ions (0.1–6.0 M) the surface activity of the NCS^-_{ads} ions (a_{ads}) was introduced into the kinetic equation instead of Γ_{NCS^-}. It was found from the thermodynamic relation[83,132]:

$$\beta=\frac{a_{ads.}}{a_{soln.}}=\lim_{\Gamma_{NCS^-}\to 0}\frac{\Gamma_{NCS^-}}{a_{soln.}} \quad (20)$$

where a_{soln} is the activity of NCS^- ions in the body of the solution. Hence the quantity βa_{soln} replaces a_{ads} in the kinetic equation:

$$v=k\cdot(\beta\cdot a_{soln.})^x \quad (21)$$

where v is the rate of the process in the region of the limiting current at constant activity coefficient of the transition state, a_M = const and $\psi_1 \simeq$ const (concentrated solution); and x the order of the reaction from the adsorbate. Hence, by use of the variation of β with the potential the applicability of scheme (19) ($x = 2$) was demonstrated[83]. Unfortunately, the accuracy of the dependence of β on the potential, found for concentrated solutions of adsorbate on the basis of model representations is evidently inadequate for the development of this interesting concept. In addition, the postulate of the constancy of the activity coefficient of the transition state—Eqn. (21)—as the potential is varied can hardly be justified[159]. We think that investigations in the range of very low catalyst concentrations, where the Henry adsorption equation applies, is preferable in this respect. It should also be noted that for an electrically neutral ligand (Ni^{2+}–thiourea)[55,58] even

in the range of medium packing it was not necessary to replace Γ_L by a_{ads} in the kinetic equation.

We[35,55] were evidently the first to find—Eqns. (15) and (17)—the rate constants of the heterogeneous electrode reactions for the formation of the PAC (Table 3). The similarity of $\bar{k}_1$ for the various ligands (Table 3), is most probably linked, as for bulk reactions[135], with a common rate-determining stage: the removal of H_2O molecules from the Ni^{2+} aquo-ion. This agrees with the kinetics of bulk reactions[125] and the ratio $\bar{k}_2 > \bar{k}_1$ (Table 3).

The total charge of the reacting species, found on the basis of an analysis of the effect of the ψ_1 potential on the kinetics of the process in the Ni^{2+}–*o*-phenylenediamine system[46,47,50], and consequently the charge of the PAC, was equal to $z + p = +1$, which is explained[46,47,50] by the coadsorption of the anion of the supporting electrolyte (ClO_4^- or NO_3^-) together with the electrically neutral ligand. For the Ni^{2+}–Py system[35,40] at a moderate supporting electrolyte concentration ($\leq$ 0.05 M $NaNO_3$), use of Eqn. (17) showed that $z + p = +2$ and $z_1 + p = +2$. Although coadsorption of the anion of the supporting electrolyte was also observed[160] for Py, the results[35,40] refer to more positive potentials and a lower concentration of supporting electrolyte. For the Co^{2+}–Py system[74], owing to its more negative potential, PAC charges ($z + p$ and $z_1 + p$) also equal to +2 were found on the basis of Eqn. (17) over a wide range of concentrations of the supporting electrolyte. Charges $z + p = +2$ and $z_1 + p = +2$ were similarly found for the PAC in the Ni^{2+}–thiourea system[55,58]. It is interesting to note that in the same system with KI supporting electrolyte[59,60] with considerable adsorption of I^- ions charges $z + p = +2$ and $z_1 + p = +2$ were obtained on using Grahame's values[161] of the ψ_1 potential on the outer layer, which again shows the position of the chemical reaction layer close to the outer surface of the compact part of the electrical double layer.

Table 3. Rate constants for heterogeneous reactions for the formation of polarographically active complexes at 25°C. $NaNO_3$ ($\psi_1 = 0$).

$Ni^{2+} + Tm^*_{ads}$	3.8		55

* Thiourea.

Hence the finding by use of Eqns. (15) and (17) for an electrically neutral ligand and doubly charged cation of the expected charges of +2 for the PAC indicates the correctness of the calculation for these reactions of the effect of the electrical double layer under conditions where there are stages with rapid transport of electrons in the range of limiting current.

The complete equation for the catalytic prewave (heterogeneous chemical reaction) with allowance for limitation at the electrochemical stage also is interesting, since this equation, together with an equation of type (17), also allows the charge of the PAC to be found. Such an equation for the simplest process of scheme (14):

$$M^z \xrightarrow{\text{diff.}} M^z \xrightarrow[\bar{k}_1]{L^p_{ads.}} [M(L_{ads.})]^{z+p} \xrightarrow{\text{redn.}} \quad (22)$$

has been obtained[50]. This equation can after simple rearrangements be presented as follows (region of the Henry adsorption isotherm):

$$\frac{\bar{i} \cdot D^{1/2}}{(\bar{i}_d - \bar{i}) \cdot K_L \cdot t_1^{1/2}} \cdot \exp\left[\frac{(z+p) \cdot F}{RT}\psi_1\right] = 0.886 \frac{\bar{k}_1 c_L \cdot k^0_{el} \cdot \exp\left[-\frac{(E-\psi_1)\alpha n_a F}{RT}\right]}{k^0_{el} \cdot \exp\left[-\frac{(E-\psi_1)\alpha n_a F}{RT}\right] + \bar{k}_1} \quad (23)$$

where $\bar{i}$ is the catalytic current at potential E and $\bar{k}_1$ is a rate constant for the reverse reaction (dissociation of PAC).

By choosing the value of $z + p$ in this way, so that the left part of Eqn. (23) reaches a constant value when the negative quantity E is increased, the charge of the PAC is found[50].

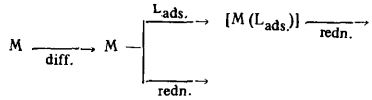
For the approximate estimation of the effect of ligand concentration, Eqn. (23) can be simplified by assuming that in the range of potentials of the rise of the prewave from the half-wave potential ($E_{\frac{1}{2}}$) to the potential for the start of the limiting current the quantities ψ_1 and K_L vary slightly. It has been found[162] that under these conditions [Eqn. (31) in Ref. 162]

$$E_{1/2} \simeq 2.3\frac{RT}{\alpha n_a F} \lg 0.886 \cdot \left(\frac{t_1}{D}\right)^{1/2} k^0_{el} + 2.3\frac{RT}{\alpha n_a F} \lg \frac{c_L \cdot K_L}{\bar{K}_1'} + 2.3\frac{RT}{\alpha n_a F} \lg \frac{\bar{i}_d}{\bar{i}_k'} + \psi_1\left[\frac{\alpha n_a - (z+p)}{\alpha n_a}\right], \quad (24)$$

where $\bar{K}_1'$ is the equilibrium constant for the dissociation of the PAC and $\bar{i}_k'$ the limiting current at a potential close to the beginning of the limiting current region.

A complete equation for the surface catalytic prewave, but at the rapid chemical stage of formation of PAC (with allowance for the parallel reaction for the discharge of M^Z ions) has also been given[6,78,84]:

$$\bar{i} = k \cdot \left(\frac{\bar{i}_d - \bar{i}}{\bar{i}_d}\right)\left[(1 - \theta_{cat.}) + \theta_{cat.} \cdot \exp\left(-\frac{\Delta U_{cat.}}{RT}\right)\right] \times \left\{\exp\left[-\frac{(E-\psi_1)\alpha n_a F}{RT}\right]\right\} \cdot \exp\left(-\frac{zF}{RT}\psi_1\right), \quad (26)$$



where θ_{cat} is the degree of occupation of the surface of the electrode by the adsorbed catalyst. It may be that in some systems a chemical stage, which greatly reduces the activation energy for the electron transfer (the factor ΔU_{cat}), even in the limiting current region, can take place much more rapidly than the electron transfer stage.

An equation has been obtained[71,163] for the bulk catalytic prewave on the basis of the concept of hypothetical diffusion current. Under the conditions of reduction of only the metal ions in the PAC this equation has the form:

$$\bar{i} = N \cdot \bar{i}_k^d \Big/ \left\{1 + \exp\left[(E - E_{1/2})\frac{\alpha n_a F}{RT}\right]\right\}, \quad (27)$$

where $\bar{i}_k^d$ is the diffusion current of PAC in the absence of a catalytic effect, N the number of metal ions which react in the catalytic cycle with one or more (when there are several ligands in the PAC) species of catalyst ligand. Although Eqn. (27) corresponds to the experimental results[71,163] we think it desirable[164] to use a similar equation [Eqn. (70) in Ref. 117] but with the physically real quantity $\bar{i}_{lim}(i_k)$ instead of the hypothetical diffusion current ($N.\bar{i}_k^d$).

This chapter will be concluded by noting that for the commonly encountered catalytic systems in which electrochemical limitation is almost absent in the region of the limiting current, use of equations of the limiting current type (15) and (17) is preferable. When this is done and an increase in potential results in the superimposition of a parallel process of the discharge of the aquo-ions of the metal, there is the possibility of calculating a corrected value of the limiting catalytic current. For example, for the process

(28)

it was found[40,42] that:

$$(\bar{i}_k)_{corr} = \frac{\bar{i}_d \cdot (\bar{i}_{lim.} - \bar{i}_0)}{\bar{i}_d - \bar{i}_0} \qquad (29)$$

where $\bar{i}_{lim}$ is the observable limiting current and $\bar{i}_0$ the current at the same potential but in the absence of a catalyst.

IV. DETERMINATION OF THE INSTABILITY CONSTANTS OF COMPLEXES

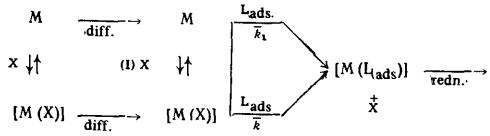
Solution of this problem is facilitated by complexes of low stability usually being formed in the catalytic system itself.

These methods can be divided into two groups: effect of catalytically inactive ions of the metal (method A) and effect of a catalytically inactive ligand (method B).

1. Effect of Metal Ions (Method A)

This method, first proposed by Tribalat[96], is based on the fall in the catalytic current when the catalytically inactive ions of another metal (M′) which bonds the catalyst ligand in a complex [M′(L)] are introduced into the solution. The proportion of the catalyst ligand entering into the complex is easily found from the drop in current and hence the instability constant (K_1') of this complex can be calculated:

$$K_1' = \frac{c_L[c^0_{M'} - (c^0_L - c_L)]}{c^0_L - c_L} \qquad (30)$$



where c^0_L is the total concentration of the ligand (determined from the curve of the catalytic current in the presence of M′ against the total concentration $c^0_{M'}$), and c_L the equilibrium concentration of the ligand (determined from the curve of the catalytic current in the absence of the ions M′). This method was used to determine the instability constants, mainly, of single ligand complexes (K_1'); an excess of M′ ions was used. The results are given in Table 4. The values found for K_1' are close to those obtained by other methods.

2. Effect of the Ligand (Method B)

This direction was first taken by Yatsimirskii and Budarin[165], but they used catalytic systems, which are not discussed in the present review.

Subsequently[36-38] the effect of catalytically inactive ligands on the prewaves of metal ions was investigated and the effects of ligand addition which increase (AcO^-) or decrease (SO_4^{2-}) the currents were used to find the instability constants of the complexes with these ligands[36-38].

Theoretically the solution of this problem was based on the calculation of the parallel process of "religandisation"[36,51,166]. In the simplest example, the entire process can be represented by a scheme proposed simultaneously and independently by Tur'yan and Ruvinskii[36] and by Caja and Mark[51]:

(31)

where X is the polarographically inactive ligand. When $\bar{k} > \bar{k}_1$ the process is accelerated (AcO'); when $\bar{k} < \bar{k}_1$ it is inhibited (SO_4^{2-}).

The equilibrium in stage I (scheme 31) has been characterised[36-38] by use of the same type of kinetic equation as for scheme (14) but with allowance for the parallel reaction of religandisation under conditions different from those of Ref. 166:

$$Z = Z_1 + K_1' \frac{Z_0 - Z}{c^0_X}, \qquad (32)$$

where K_1' is the instability constant of the complex [M(X)], $Z = \bar{i}_k/\bar{i}_d - \bar{i}_k$, Z_L = const at c_Z = const and a constant ionic strength of the solution, $Z_0 = Z$ at $c_{X^0} = 0$, and c_{X^0} is the total concentration of ligand X introduced in an excess in relation to the ions M.

A graphical method was used[36-38] for finding K_1' with the aid of Eqn. (32). The results (Table 4) are close to those obtained by other methods.

V. ANALYTICAL APPLICATION

Catalytically active ligands introduced into a solution in very great excess greatly improve the form of the polarographic wave of a metal and significantly alter the half-wave potential. These advantages are widely used in the polarographic analysis of metals (Ni^{2+}, Co^{2+}, In^{III}, etc.) and have been described in detail in various monographs[168].

A more recent approach considered below is the analytical determination of ligands with the aid of the catalytic prewaves of the metals.

At a low ligand concentration the prewaves were first used[2] for the highly sensitive determination of the ligand (determination of pyridine from the catalytic prewave of Ni^{2+}). The analysis was made with a preliminary calibration graph[44]. Then this method was used for the determination of *o*-phenylenediamine in the presence of a tenfold excess of the *m*- and *p*-isomers (catalytic prewave of Ni^{2+}). With the aim of improving the sensitivity (to 10^{-7} M) it was proposed[45] to use 0.1 M LiI as supporting electrolyte (ψ_1 effect[45,47]). In a further investigation[49] the catalytic prewave of Ni^{2+} in the presence of *o*-phenylenediamine was used for the amperometric titration of *o*-phenylenediamine with the aid of Au^{III} ions. The sensitivity of the determination was 1×10^{-6} M.

The catalytic prewaves of Ti^{IV} in the presence of various ligands have been used[15,16] for the determination of these ligands: citric acid[15], sulphosalicylic acid[16], pyrocatechol[16] and pyrogallol[16]. The additional catalytic effect in the presence of ClO_3^- ions has been used[15,16] to

increase sensitivity. The sensitivity of the determination of citric and sulphosalicylic acids is ~ 1×10^{-5} M, that for pyrocatechol and pyrogallol is ~ 1×10^{-4} M. The method for the determination of citric acid is considerably faster and simpler than the analytical techniques proposed earlier.

The catalytic prewave of In^{III} has been used[77] for the determination of I^- ions (sensitivity 1×10^{-5} M) and also for the determination[86] of oxalic acid (sensitivity ~ 1×10^{-4} M).

Hence the use of the catalytic prewaves of metal complexes has allowed ligands which are polarographically inactive under ordinary conditions to be determined in several instances.

Polarographic Behaviour of Cobalt(II), Nickel(II), and Iron(II)

V.N.Pavlov and V.V.Bondar'

The kinetics and mechanism of reduction of bivalent metals of the iron group at a mercury dropping electrode are examined. The effect of the pH, organic solvent, structure of the double layer, and adsorption of the depolariser on the half-wave potential and limiting currents of the wave for the reduction of cobalt (II), nickel (II), and iron (II) complexes is described. The role of complex formation in depressing the overpotential for the discharge of these metals is considered in detail. Various viewpoints are presented on the mechanism of formation of the catalytic waves of hydrogen, which appear when doubly-charged ions of these metals and various organic substances are present in the solution simultaneously.
There is a bibliography of 93 references.

I. INTRODUCTION

Despite many papers dealing with the mechanism of the reduction of ions of metals of the iron group at a mercury dropping electrode (MDE), there is not a sufficiently detailed and systematic review of these studies. We have tried to fill this gap to some extent.

From the point of view of polarography, the most noticeable general feature is that cobalt, nickel, and iron are almost insoluble in mercury, and the redox potentials of these metals are very similar; there is also much in common in the mechanism of the polarographic behaviour of these metals.

In this review we have examined only certain (we think the most important) aspects of the electrochemical release of cobalt, nickel, and iron from their bivalent state at a mercury dropping electrode.

2. EFFECT OF THE pH OF THE SOLUTION ON THE POLAROGRAPHIC BEHAVIOUR OF COBALT, NICKEL, AND IRON

Brdička[1] was the first to observe that $E_{\frac{1}{2}}$ of the cobalt wave is shifted to more negative potentials when the pH of the solution is decreased. A similar relation between the shift in the discharge potential of cobalt or nickel ions and the pH of the solution was found at a solid cobalt electrode[2] and was also noted in earlier studies[3-5].

Since in aqueous solution the cobalt ion exists as a complex with six water molecules, Brdička[1] explained the decrease in the negative values of $E_{\frac{1}{2}}$ of cobalt when the pH of the solution was increased by the partial dehydration of the hexahydrate with the replacement of one water molecule by an OH^- ion:

$$\underset{(I)}{[Co(H_2O)_6]^{2+}} + H_2O \rightleftarrows H^+ + \underset{(II)}{[Co(H_2O)_5OH]^+}. \qquad (1)$$

He thought that such a complex would be reduced more readily than the hexahydrate.

The polarograms of Fig. 1, taken from Brdička's work[1] show clearly how the wave for the reduction of Co^{2+} is displaced to more negative potentials as the solution is acidified, and finally merges with the background. As the result of the selection of definite values of Co^{2+} concentration, pH of the medium, and temperature, in the absence of strong complex-forming substances splitting of the cobalt wave could be observed. Fig. 2[1] shows the appearance and increase of the wave for the reduction of complexes II (reaction 1) as the temperature is raised.

In certain instances the splitting of the wave could not be observed but semilogarithmic plots of the waves for the reduction of Co^{2+} showed inflections[6-8]; the explanation could be that the observed wave really describes two processes in which two types of complex participate—cf. Eqn. (1).

Our results[8] mainly agree with Brdička's observations[1]: as the pH is increased from 2.9 to 4.0 $E_{\frac{1}{2}}$ for Co^{2+} in a solution of 0.1 N KCl + HCl varies from −1.380 to −1.345 V. In the pH range 4.0–4.5 $E_{\frac{1}{2}}$ hardly alters. We were unable to investigate the variation of $E_{\frac{1}{2}}$ with pH for cobalt in the range pH < 2.9 owing to the superimposition of the hydrogen discharge wave on the cobalt wave.

Interestingly, the transfer coefficient (α), determined from the slope of the graph constructed on coordinates of $\lg i$ against E at the potentials of the start of the cobalt wave, also shows a decrease in the rate of the electrochemical process for the reduction of the cobalt ion in the acidic range of pH (< 4.0).[8] Fig. 3 shows the change in α as the pH of the solution is varied.

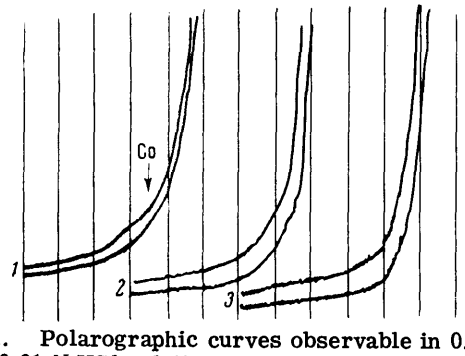

Figure 1. Polarographic curves observable in 0.01 N $CoCl_2$ + 0.01 N KCl solutions at various HCl concentrations: 1) without addition of HCl; 2) 10^{-5} N HCl; 3) 10^{-4} N HCl. The curves start at −0.6 V.

Zytner and Rotinyan[9] used the method of recording electrostatic partial polarisation curves to study the discharge of Co^{2+} ions at a cobalt electrode in 0.6 M cobalt sulphate solution at 56°C in the pH range 2.55–3.80. They found that the cathodic potential for the discharge of cobalt ions shifts in the negative direction as the pH is reduced. The order of the cathodic reaction with respect to Co^{2+} and OH^- ions is 1.1 and 0.9 respectively, that is, close to 1. In explaining the mechanism of the reaction Zytner and Rotinyan[9] started from ideas on the participation of the OH^- ion in a potential-determining stage. Kravtsov and Lokshtanova[10] also noted that in the electrodeposition of cobalt at a cobalt electrode (from 1 N $CoSO_4$ + H_3BO_3) the rate of the process increased as the pH was raised from 3.5 to 4.2, showing that the rate-determining stage of the cathodic process is the transfer of the first electron to Co^{2+}.

An analogous relation between $E_{\frac{1}{2}}$ and pH is also observed for iron[11,12]. $E_{\frac{1}{2}}$ hardly alters as the pH is changed from 4.5 to 5.0 but at pH below 4.5–5.0 it is shifted rather significantly in the negative direction (Fig. 4). However, Dahms[13] did not observe a change in the $E_{\frac{1}{2}}$ of the iron wave.

A variation of $E_{\frac{1}{2}}$ with pH was also noted for all the metals of the iron group in the presence of a complex-forming substance (pyridine).[14]

A variation of $E_{\frac{1}{2}}$ for the nickel ion with the pH at the mercury dropping electrode in the absence of a complex-forming substance could not be observed[23].

At first glance the formation of a complex of a metal with an OH^- ion according to reaction (1) in a solution where the concentration of free hydroxyl ions is negligibly small ($\sim 10^{-11}$–10^{-10} g-ion litre^{-1}) seems improbable. However, allowance must be made for the fact that the process leading to the formation of a complex in which one molecule of water is replaced by a hydroxyl ion is kinetic in nature. Water, the concentration of which is ~ 55 M, participates in this process as a donor of hydroxyl ions. The kinetic nature of the wave for the discharge of the hydroxo-complex is shown by the large temperature coefficient of the limiting current of this wave (cf. Fig. 2). It can also be postulated that the hydroxo-complex is formed as a result of the slow deprotonisation of the hexa-aquo-complex of cobalt.

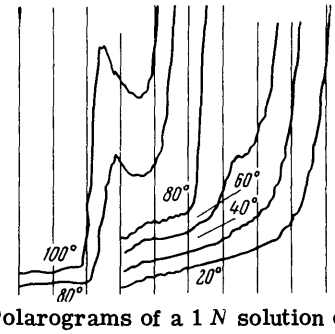

Figure 2. Polarograms of a 1 N solution of $CoCl_2$ at various temperatures. The sensitivity of the galvanometer decreased on going from 60° to 80° and 100°C.

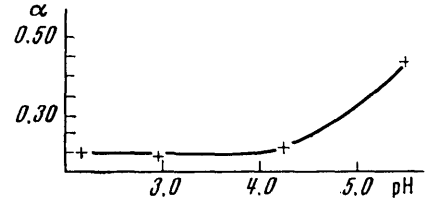

Figure 3. Variation of the transport coefficient α for waves of cobalt (0.64×10^{-3} M) with the pH of 0.1 N KCl + xHCl solution[8].

The decrease in the negative values of the half-wave potential as the pH of the solution is increased evidently reflects the fact that the observable wave is obtained as a result of the superimposition of two waves (the $E_{\frac{1}{2}}$ of which are different), which correspond with the discharge of complexes II (first wave) and I (second wave), according to reaction (1). As the pH is raised there is an increase in the wavelength corresponding to complex II, the $E_{\frac{1}{2}}$ of which is less negative than the $E_{\frac{1}{2}}$ of the hexahydrate wave. This also leads to a shift in the $E_{\frac{1}{2}}$ of the overall wave to less negative values as the pH is raised.

The mixed nature of the waves causes inflections on the curves on the semilogarithmic graphs[6–8] and the lower part of the curve is found by some[1,7,8] to be steeper than the upper, whereas another study[6] shows the lower part of the curve to be the less steep. The differences in the slopes of the initial parts observed by different authors are evidently due to differences in the experimental conditions.

As mentioned above, by choice of the experimental conditions (concentration of the cobalt salt, temperature of the solution, pH) Brdička succeeded in distinguishing the pure wave corresponding to the discharge of complex II (reaction 1). The value of αn_a which we found from the initial part of the graph plotted in coordinates of $\lg i$ against E for this wave is ~ 50 mV. The first wave is appreciably steeper than the main wave. Evidently the process which corresponds to the transfer of an electron to the complex $[Co(OH)(H_2O)_5]^+$ is rather close to reversible under these conditions.

Cosowic and Branica[15] found a charge of $Z = +2$ for the cobalt complex which exists in a phosphate buffer in the presence of 0.5 M $NaClO_4$ and consider the existence of the complex $[Co(OH)(H_2O)_5]^+$ improbable. However, it must be borne in mind that the equilibrium of reaction (1) is evidently shifted to the left, since the wave which corresponds to the reduction of this complex cannot exceed 10 to 20% of the total wave[1,7]; therefore the calculation of the kinetic parameters of the overall wave, despite the existence of a complex with $Z = +1$, can lead to a value of Z close to +2. In addition, as noted by Cosowic and Branica[15] they have been investigated only in a narrow range of pH (6.5–8.14).

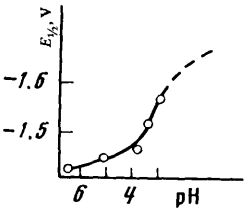

Figure 4. Variation of $E_{\frac{1}{2}}$ for the Fe^{II} reduction wave with the pH. [11]

We have calculated the number Z from Turyan's results[6] with the aid of an equation taken from Mairanovskii[16]:

$$\Delta E_{1/2} = \Delta\psi_1 \frac{\alpha n_a - Z}{\alpha n_a}, \quad (2)$$

where Z is the charge of the species participating in the electrochemical reaction, α the transfer coefficient, n the number of electrons which is transferred in the potential-determining stages, and $\Delta\psi_1$ the potential jump in the diffusion part of the double layer. For a solution[6] of cobalt in 0.04–0.1 M Na_2SO_4 $Z = +1.25$, which evidently reflects the mixed nature of the wave in which both species with charge +1 and species with charge +2 participate.

We think it unusual that a species with one positive charge less should be discharged more readily than an analogous species carrying two positive charges. However, such a phenomenon is also observed when the concentration of the chlorides is increased (see below), when species with a smaller positive or even a negative charge are formed from a hexahydrate with charge +2. The drop in polarisation when water molecules are replaced by a hydroxyl ion is evidently due to several reasons. One of them, discussed below in most detail, is the acceleration of the dehydration on the introduction into the inner coordination sphere of a foreign ligand. In addition, it is necessary to take into account that the presence of an OH^- ion in the composition of a complex firstly allows the reaction centre of the complex—the metal ion—to approach nearer the surface, since the OH^- ion is smaller than H_2O; secondly, the transfer of one electron to the M^{2+} ion using the "relay" nature of the transfer (the OH^- ion transfers its electron to a metal ion, exchanging one electron with the electrode surface). It must be taken into account that a non-symmetric coordination sphere is deformed more readily (with subsequent dehydration) in the field of the double layer than is a symmetric one consisting of six water molecules.

3. ROLE OF COMPLEX FORMATION

Cobalt(II) and nickel(II) are known to exist in an aqueous solution in the absence of other complex-forming agents as the hexahydrates which have a stable octahedral configuration[17]. It has been shown recently[18] that iron(II) exists in aqueous solution also in the form of the hexahydrate. Such a structure for the complex is one of the reasons for the high overpotential of the reduction of the ions of the metals of the iron group. However, only the hydrate of the doubly-charged metal ion is stable in aqueous solution. The complex of the singly-charged ion, which should be formed after the transfer of the first electron (see, for example, Molodov and Losev[19]) in aqueous solutions of perchlorates, sulphates, nitrates, and other anions which do not form stable complexes with this ion, is unstable and immediately acquires a second electron; therefore in aqueous solutions the salts of these ions of cobalt, nickel, and iron give one two-electron (irreversible) wave with diffusion control[6-8,17,20].

According to Gierst and Hurwitz[21-24] the hexahydrate complexes of nickel and cobalt are partly dehydrated before the electrode reaction proper. The rate constant of the dehydration increases with the negative values of the ψ_1-potential (discussed in more detail below).

Attempts were made to determine the number of water molecules detached in stages which precede the transfer of electrons[25,26]. The polarographic curves were used to determine the activation energy of the dehydration of nickel hexahydrate[5,25], the value of which agrees satisfactorily with the activation energy of the isotopic exchange of one molecule of water between the solvent and the first sphere of hydration of nickel hexahydrate, determined by the NMR method[27] to be 11.6 kcal $mole^{-1}$. Hence it is concluded that in the stage which precedes the transfer of electrons into $NaClO_4$ solutions either one water molecule is detached[25] or another molecule of water[26] is introduced into the inner coordination sphere. In either instance the complex loses the stable octahedral configuration, which facilitates the deformation of the inner sphere and the transfer of an electron to the central atom.

The number of waves on the polarogram and their position on the potential axis depends on the nature and concentration of the ligand. The complex-forming substances, which give extremely stable complexes with our metals, for example, various compounds which contain $-NH_2$ or $\geqslant NH$ groups[28], have a greater tendency to form two waves. Halide ions are weaker complex-forming substances than amines; therefore they bring about only a decrease in $E_{\frac{1}{2}}$.

A similar effect was observed on raising the concentration of LiCl or LiBr (from 1 to 20 M) in a cobalt,

nickel, or iron solution [30,31], on increasing the concentration of calcium chloride in a solution of iron salt, and also in the partial replacement of saturated calcium perchlorate solution by calcium chloride in a solution of cobalt, nickel, or iron salts [11,31,32]; increasing the chloride concentration to 0.25 M reduces the half-wave potential of cobalt from −0.9 to −0.7 V. The graph in Fig. 5, constructed from Aylward and coworkers' results [30], shows the variation of $E_{\frac{1}{2}}$ for cobalt with the lithium chloride and bromide concentrations. It is necessary to bear in mind that when there is a considerable increase in the concentration of electrolytes such as lithium [30] or calcium [31] halides an additional shift in $E_{\frac{1}{2}}$ for the waves of the hydrated metal ions can appear due to the dehydrating action at high concentrations of the supporting electrolytes. Since there are six water molecules in the inner coordination sphere of complexes of iron group metals and another 26 molecules in the second sphere (the heat of formation of the second sphere is 240 kcal g-ion^{-1}—almost equal to the heat of formation of the first sphere) [18], the introduction, for example, of electrolytes such as LiCl and $CaCl_2$ [30,31] should lead to an acceleration of the dehydration of the hexahydrate and consequently to a shift of $E_{\frac{1}{2}}$ to less negative potentials.

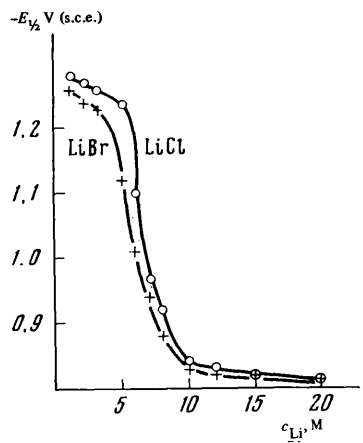

Figure 5. Variation of $E_{\frac{1}{2}}$ of the cobalt wave with the molal concentration of lithium chloride and bromide. [30]

When the concentration of halide ions is increased there is a gradual conversion of the octahedral hexahydrate into the tetrahedral tetrahalide [18,30]. For example, in LiCl and LiBr the transitional region corresponds to 8–14 M. The change from hexahydrate to tetrahalide affects the form of the polarogram: a graph constructed in semilogarithmic coordinates consists of two straight-line portions, the lower of which is the steeper [30]. A CN^- ion in a solution of nickel salt also forms (when its concentration is increased) a doubly-charged complex of tetrahedral structure $[Ni(CN)_4]^{2-}$. [33-37]

It is interesting that despite the anionic nature of the MX_4^{2-} complex (where X = Cl, Br, I, CN, or NCS) which exists in sufficiently concentrated solutions, the half-wave potential of the halogeno-complex is less negative than the half-wave potential of the hexahydrate, which has a charge of +2.

When the solution contains a ligand capable of forming a sufficiently stable bond with a metal ion, the water molecule that has been detached in the inner coordination sphere is replaced by a corresponding molecule or ion which is introduced into the inner coordination sphere. The introduction of the foreign ligand increases the rate constant of the exchange (k_{H_2O}) for the subsequent water molecules [27-29]. For example, for $[Ni(H_2O)_6]^{2+}$ $k_{H_2O} = 2.74 \times 10^4$ s^{-1}, [27] and for the complex in which one water molecule is replaced by glycine $[Ni(Glyc)(H_2O)_5]^{2+}$ k_{H_2O} is 1.2×10^5 s^{-1}. [29] Some investigators think [25,29] that the increase in the rate constant for the exchange of the second and subsequent water molecules is the reason for the decrease in the polarisation in the introduction into aqueous solution of a complex-forming substance (leading in certain instances not only to a shift in the main wave but also to the appearance of new waves in a less negative range of potentials).

On reaching a certain concentration of the ligand the half-wave potential of the ionic complex can reach a limiting value and when the concentration of the ligands is increased further it starts to shift to the side of more negative potentials. However, this shift in the negative direction is small, since $E_{\frac{1}{2}}$ usually remains smaller in magnitude than $E_{\frac{1}{2}}$ of the hexahydrate (see Table, which is constructed from results of Refs. 11 and 31). Despite some shift in the negative direction the degree of reversibility is usually unaltered.

Some electrochemical characteristics of the reduction of doubly-charged ions of iron-group metals.

Compn. of the supporting electrolyte	Ni^{2+}			Co^{2+}			Fe^{2+}			Comparison electrode
	$E_{1/2}$	$\Delta E_{1/2}$	α	$E_{1/2}$	$\Delta E_{1/2}$	α	$E_{1/2}$	$\Delta E_{1/2}$	α

saturated solution of LiCl	−0.410	0.680	1.02	−0.800	0.420	0.88	−1.060	0.270	0.91	»
10N $CaCl_2$	−0.48	—	—	−0.9	—	—	−1.125	—	—	S.C.E.

The limiting current can also depend upon the ligand concentration. Thus, when acetylacetone (HAcac) is added [15] to a 5×10^{-4} M cobalt nitrate solution (in a phosphate buffer + 0.5 M $NaClO_4$) the cobalt wave decreases until the concentration of the free ligand reaches 10^{-4} M. The observed regularity is explained by the competition between the water and acetylacetone. A polarographically inactive complex $CoAcac_2$ is formed. The limiting current is kinetic in nature since the kinetics of formation of $CoAcac^+$ from this complex also determines the height of the wave that is observed [15]:

$$\begin{array}{ccccc} Co(H_2O)_6^{2+} & \rightleftarrows & CoAcac^+ & \rightleftarrows & CoAcac_2 \\ \alpha n_\alpha = 0.8 \downarrow\uparrow & & \downarrow\uparrow \alpha n_\alpha = 1.3 & & \\ Co\,(Hg) & & Co\,(Hg) & & \end{array}$$

For ligands which form stable complexes with the metal ion the dependence of $E_{\frac{1}{2}}$ and the limiting currents

upon the ligand concentration is more complex; a low concentration of the ligand leads to a reconstruction of the hydrate sheath of the ion. The influence of the concentration of diaminopropane[25] on $E_{\frac{1}{2}}$ and the number and form of the nickel waves has been studied in detail[25]. In the range of ligand concentrations where $\lg C_X < -8.1$ (in an acid solution of $NaClO_4 + HClO_4$, $I = 0.5$) a single wave is observed (as in the absence of the ligand), the $E_{\frac{1}{2}}$ of which does not change as the ligand concentration is altered ($E_{\frac{1}{2}} = -1.603$ V). This wave corresponds to the discharge of the hexa-aquo-complex of nickel. In the range $-8.1 < \lg C_X < -7.6$ there are two waves on the polarogram (see Fig. 6), the half-wave potentials of which hardly alter as the concentration of the complex-forming agent is increased. The first wave (that is, the wave at less negative potentials) on the polarogram obtained under the conditions described corresponds to the reduction of the complex with diaminopropane. When the diaminopropane concentration is increased ($\lg C_X > -7.6$) the first wave is displaced to less negative potentials. In the range $\lg C_X > -5.25$ the first wave merges with the second and with a further increase in the ligand concentration this combined wave again starts to shift to more negative potentials.

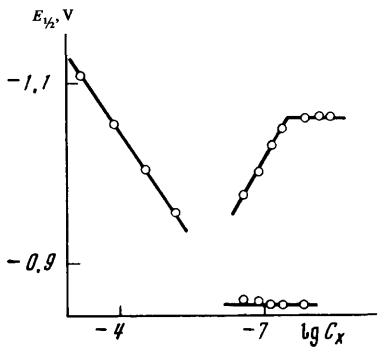

Figure 6. Change in the number of waves and half-wave potentials of nickel ion (1×10^{-4} M) with the logarithm of the ligand concentration (diaminopropane) in a solution of lithium perchlorate[25].

A similar picture is observed in the presence of pyridine. In the polarography of a solution of a nickel salt in the presence of $< 10^{-4}$ M pyridine a single wave with $E_{\frac{1}{2}} = -1.025$ V is observed[38]. An increase in the pyridine concentration by an order of magnitude leads to the appearance of two new waves, the $E_{\frac{1}{2}}$ of which are −0.76 V and −0.86 V respectively. When the pyridine concentration is raised further (to 0.1 M) two of the waves on the polarogram disappear and there remains only the wave observed in the less negative range of potentials; this wave shifts slightly in the negative direction when the pyridine concentration is increased further. Fig. 7, constructed from the results of Kemula and coworkers[38] shows the change in the number of waves and the $E_{\frac{1}{2}}$ of the nickel waves as the pyridine concentration is varied.

However, in several instances only a displacement of the wave along the potential axis is observed. Thus, when a ligand such as the hypophosphite ion ($H_2PO_2^-$) is introduced into a cobalt solution with pH 5.5 only a shift of the wave towards more negative potentials is observed[8].

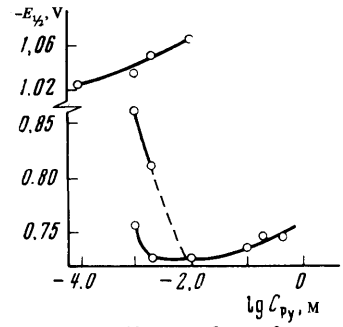

Figure 7. Variation of the number of waves and half-wave potentials in the reduction of a nickel ion with the pyridine concentration[38].

Calculation of the number of hypophosphite ions entering into the complex[8] under the condition that $\alpha = 0.5$ gives a value of 1. The semilogarithmic graph of Fig. 8 shows the change in $E_{\frac{1}{2}}$ of the cobalt wave as the sodium hypophosphite concentration (C_{HPP}) is raised. The curve for a solution with pH 4.5 has an inflection due to the appearance of the polarographic activity of the hypophosphite in a sufficiently acid medium in the presence of cobalt ions[8]; this will be discussed in greater detail below.

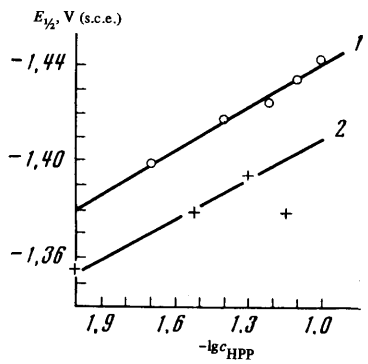

Figure 8. Variation of the half-wave potential of the cobalt ion with the concentration of sodium hypophosphite in solutions with pH 5.5 (curve *1*) and pH 4.25 (curve *2*).[8]

4. INFLUENCE OF ORGANIC SOLVENT

The partial or complete replacement of water by an organic solvent leads to a significant change in the polarographic conditions. On the addition of an organic solvent in a concentration comparable with that of the ion being studied or greater by about an order of magnitude, the organic solvent can be regarded as an ordinary ligand, the introduction of which into the solution leads usually to the

partial dehydration of the hexa-aquo-complex of the metal, and the replacement of even a single water molecule in the inner coordination sphere by a foreign ligand facilitates reduction, that is, leads to a shift in the $E_{\frac{1}{2}}$ of the wave of the complex to more positive potentials. In this nickel shows the greatest tendency towards the formation of complexes, so that $\Delta E_{\frac{1}{2}}$ for nickel ($\Delta E_{\frac{1}{2}} = E_{\frac{1}{2}}^{H_2O} - E_{\frac{1}{2}}^{L}$) has the greatest absolute value. At a higher concentration of the organic solvent [39,40] the polarogram includes a wave having an $E_{\frac{1}{2}}$ several tenths of a volt less negative than the half-wave potential of the hexahydrates of these metals.

Interestingly, the completely solvated ion, like the completely hydrated one, is more difficult to reduce than an ion with a solvate sheath in which there are ligands of two or more kinds. Thus the addition of 8×10^{-4} M xanthate to a 4×10^{-4} M solution of a nickel salt (in a supporting electrolyte of 0.2 M $LiClO_4$) in absolute ethanol shifts $E_{\frac{1}{2}}$ from −0.840 to −0.667 V. [39] In ethanol solution (in the presence of small quantities of 1,10-phenanthroline) the wave corresponding to the transfer of an electron with the formation of a complex of cobalt(I) is irreversible: its $E_{\frac{1}{2}} = -1.02$ V, but when the 1,10-phenanthroline concentration is increased the $E_{\frac{1}{2}}$ is appreciably shifted in the positive direction and the wave acquires a quasireversible nature [40-42].

The introduction into an aqueous solution of an organic solvent capable of the formation of a stable complex, in the presence of other ligands can lead to the appearance of two waves corresponding to complexes of different composition. Thus in 1 M KCNS, taken as supporting electrolyte, nickel gives a single sharp wave with $E_{\frac{1}{2}} = -0.695$ V (s.c.e.), but when acetamide is added there are two waves on the polarogram [43]. The first wave was thought [43] to be due to the reduction of the thiocyanato-complex of the nickel ion, the second wave, which appears at more negative potentials, corresponds to the reduction of the complex of nickel with acetamide. Both waves are irreversible. When the acetamide concentration is increased $E_{\frac{1}{2}}$ of the second nickel wave is shifted monotonically to more negative potentials, from −1.562 V (5% acetamide) to −1.648 V (30% acetamide); there is also an increase in the irreversibility of the electrochemical process.

The opposite behaviour has also been observed [44]: the introduction of an organic solvent (ethanol, ethylene glycol, and especially propanol) leads to the merging of the two waves on the polarogram of nickel in 1–1.5 M solutions of HCOONa, Na_2SO_4, and NaI into a single wave [44].

In anhydrous dimethylformamide (DMF) in the presence of the Cl^- ion nickel also gives two waves [45], the first of which increases as the concentration of Cl^- ion in the solution is increased.

As regards the reversibility of the waves for the reduction of our metals in non-aqueous solvents it is usually considerably higher in comparison with the waves observable in water. Thus it has been noted that the waves of all three metal ions under consideration are reversible in DMF [45]; the cobalt wave is reversible in isobutyronitrile (the slope of the wave is 34 mV, $E_{\frac{1}{2}} = -0.60$ V relative to the s.c.e.) [46], but in this solvent it is not strange that the nickel wave is irreversible, though this has been attributed [46] to the possible presence of traces of water.

Allowance must also be made for the organic solvent exerting a specific action, since when its concentration is increased there is a decrease in the adsorbability of the organic ligands or of the complexes with these ligands, which should lead to an increase in polarisation.

Furthermore, when the concentration of the organic solvent is increased there is a decrease in the dielectric permeability of the medium, in consequence of which the association of our cations with the anions of the indifferent electrolyte is possible.

5. INFLUENCE OF THE STRUCTURE OF THE ELECTRICAL DOUBLE LAYER

In the reduction of cations at a negatively charged surface, the electrostatic action of the field facilitates their approach to the electrode surface [16,47]. On the other hand, on the positively charged surface of the electrode the electrostatic action of the field retards the electrode processes involving the cations and accelerates the processes involving the anions.

The reduction of cobalt, nickel, and iron complexes usually obeys these rules because the complexes of these metals (in a bivalent state) usually have a charge $Z \geqslant 0$ and at the same time the waves of these complexes lie on the negative branch of the electrocapillary curve. An exception is the complex of nickel in solutions of ligands such as Cl^-; for example, $E_{\frac{1}{2}}$ for nickel in a saturated $Ca(ClO_4)_2$ solution +0.25 M in $CaCl_2$ is −0.317 V (s.c.e.). [31]

On the above basis it is easy to explain the fact that when the concentration of the indifferent electrolyte is increased (within certain limits) $E_{\frac{1}{2}}$ for the waves of cobalt, nickel, and iron are shifted to the side of more negative potentials. For example, when the concentration of $CaCl_2$ (taken as supporting electrolyte) is raised to 1 N, the Fe^{2+} wave is shifted by ~ 300 mV in the negative direction. This is accompanied by a decrease in the limiting current, which the investigators attributed to an increase in the viscosity of the solution and a corresponding change in the diffusion coefficient of the iron [48]. A shift in $E_{\frac{1}{2}}$ in a negative direction when the ionic strength is increased is also observed in the reduction of cobalt complexes with cysteine [16] and for the "simple" ions of cobalt [8] and nickel [6].

As regards nickel complexes, the influence of the double layer is somewhat peculiar [49]. The reduction of nickel hexahydrate in dilute solutions is accompanied by the appearance of a single wave [49] with a sharply expressed limiting current plateau. However, as the concentration of the electrolyte is raised the limiting current of the wave falls completely and starts to depend upon the potential [49,50], increasing with increase in the negative potential. At the same time, $E_{\frac{1}{2}}$ for this wave hardly alters (Fig. 9); when the KCl concentration is increased above 0.8 M a second wave also appears, lying in a more negative range of potentials [8]. Splitting of the nickel wave was also observed at high concentrations (1–1.5 M) of sodium formate, sulphate, and iodide, used as supporting electrolyte [44]. In concentrated solutions of the supporting electrolyte the limiting current for the reduction of Ni^{2+} acquires a kinetic nature [49,50], and the magnitude of the kinetic current increases with the cathode potential (cf. Fig. 9). Gierst [21-24] assumes that hydrated nickel ions are partly dehydrated in the field of the double layer before the electrochemical stage proper:

$$[Ni(H_2O)_6]^{2+} \underset{k_b}{\overset{k_f}{\rightleftarrows}} [Ni(H_2O)_x]^{2+} + (6-x)H_2O$$

and the rate of dehydration increases with the absolute magnitude of the negative ψ_1-potential; hence the increase in the limiting current with increase in the cathodic potential is due to an increase in the negative value of the ψ_1-potential. The limiting current for the discharge of nickel

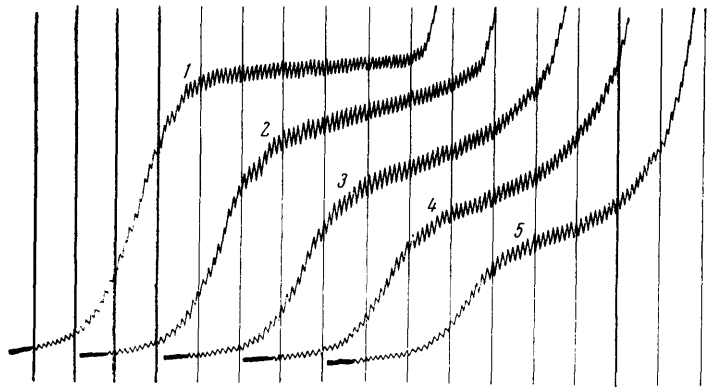

Figure 9. Effect of the concentration of an indifferent electrolyte (NaCl) on the wave for the reduction of 10^{-3} M $NiSO_4$ in the presence of 0.005% gelatin[49]. NaCl concentration, M: 1) 0.1; 2) 0.5; 3) 1.0; 4) 1.5; 5) 2. Each curve starts at −0.7 V (s.c.e.); the distances between the abscissae are 0.2 V.

ions in dilute solutions of an indifferent electrolyte (for example, in 0.1 *N* NaCl) is limited by diffusion, since at low concentrations of the electrolyte the negative value of the ψ_1-potential is so high that the increase in the rate of the preceding reaction brought about by the influence of the double layer has the result that the diffusion of the nickel ionic complex towards the electrode becomes the slowest stage of the process.

Even adsorption of the anion on the mercury surface can occur at a sufficiently high concentration of the indifferent electrolyte. This effect is opposite in sign to the effect of the cation; therefore, for example, when the concentration of chlorides is increased to more than 1–2 M there is a shift in $E_{\frac{1}{2}}$ for iron(II)[48] and cobalt(II)[31] to less negative potentials.

Fig. 10 shows the change in $E_{\frac{1}{2}}$ for iron(II) (curve *1*) as the $CaCl_2$ concentration is varied. Increasing the $CaCl_2$ concentration above 2 *N* shifts $E_{\frac{1}{2}}$ to less negative potentials. However, it is necessary to take into account the complexing action of the anion, which it is difficult to separate from the influence of the double layer during the change in the concentration of the anion[31].

6. INFLUENCE OF THE ADSORPTION OF THE DEPOLARISER

It is also necessary to consider the influence of the adsorption of the complex itself on the kinetics of the electroreduction of the metals concerned. This is especially so in those instances when the ligand is an organic molecule or an organic ion, since organic compounds (especially those which have a sufficiently high molecular weight) are readily adsorbed on the surface of mercury.

Olson[29] observed an increase in the reversibility of the wave for the reduction of the complex of nickel with triethylenetetramine. Since the rate constant for the exchange of the second water molecule is here lower than the rate constant for the exchange of the first water molecule, Olson considers that the reversibility of the wave for the reduction of the complex is due not to the labilisation of the complex but to its specific adsorption at the surface of the electrode. In this instance the reaction centre of the complex is located in the inner Helmholtz plane, where there is a much higher potential gradient, as a result of which the reduction is facilitated.

The influence of the adsorption of pyridine, thiourea[51–53], and diaminopropane[25] on the nickel wave, and of 2,2′-bipyridyl on the cobalt and iron waves[54] has also been noted. Results on the influence of adsorption of complexes of nickel with pyridine are especially numerous[38,51–53].

When 1,10-phenanthroline is present in a Co^{2+} solution a small prewave has been observed[28,29,55,56], which is attributed to the adsorption of the complex $CoPh_n^{+}$, where $n = 2$ or 3.

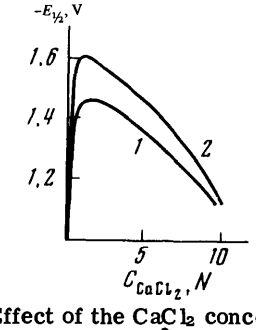

Figure 10. Effect of the $CaCl_2$ concentration on $E_{\frac{1}{2}}$ of the wave for the discharge of Fe^{2+} (1) and hydrogen ions (2); $[Fe^{2+}] = 2 \times 10^{-3}$ *N*, $[H^+] = 1 \times 10^{-3}$ *N*.[48]

7. STEPWISE NATURE OF THE REDUCTION OF COBALT, NICKEL, AND IRON

Two-electron waves are usually observed for the reduction of cobalt(II), nickel(II), and iron(II). However, Losev and Molodov[19] have shown that the transfer of the second electron is not simultaneous with the transfer of

the first, and under certain conditions the successive stepwise reduction of doubly- and multiply-charged cations can be observed.

In the presence of 1,10-phenanthroline two reduction waves are obtained[40-42,55,56] in solutions of Co^{2+} salts, these correspond to the successive transfer of a single electron in each stage. It has been suggested that under these conditions not only a Co^0 complex but also a Co^+ complex is stabilised. The waves have been shown to be irreversible and the limiting current of the first wave is diffusional in nature[40,56].

Single-electron waves were also observed in the investigation of complexes of iron with 2,2'-bipyridyl (Bipy) in an acetonitrile solution with rotating platinum and dropping mercury electrodes in tetraethylammonium perchlorate supporting electrolytes. Three waves are observed, which correspond to the reduction: to Fe^+ ($E_{\frac{1}{2}}^{I} = -1.45$ V) and then to Fe^0 ($E_{\frac{1}{2}}^{II} = -1.70$ V; s.c.e.); as Tanaka and Sato have shown[54], the third wave ($E_{\frac{1}{2}}^{III} = -2.0$ V) corresponds to the reduction of an uncharged complex with the formation of $[Fe(Bipy)_2]^-$.

The formation of a rather stable complex with a metal in a zerovalent state during the reduction of iron-group metals has been advanced repeatedly as a more or less substantiated hypothesis (see, for example, Refs. 25 and 57). The existence of such a complex has been proved[58] unambiguously with the aid of radiopolarography, in the investigation of the cyano-complexes of nickel labelled with ^{63}Ni. As has been shown[58], the ordinary polarogram and radiopolarogram of a solution of 1×10^{-3} M $NiCl_2$ in 0.1 M KCl are almost identical (Fig. 11). However, when 2.5×10^{-3} KCN is added to the solution, instead of a single wave on the ordinary polarogram three waves are observed, whereas on the radiopolarogram there is only one wave with $E_{\frac{1}{2}}$, which almost coincides with the $E_{\frac{1}{2}}$ of the main (second in order) wave. An increase in the concentration of KCN in the solution led to a decrease in the diffusion current of the first wave and to a decrease in the corresponding amount of radioactive nickel in the mercury drop. A further increase in the KCN concentration (to 10^{-2} M) leads to the disappearance of the first and second waves; on the polarogram there is only one wave with $E_{\frac{1}{2}} \simeq -1.5$ V, and the radioactive nickel is completely absent from the mercury drop (Fig. 12). On this basis it was concluded[58] that a stable complex with Ni^0 is formed (at sufficiently high KCN concentrations).

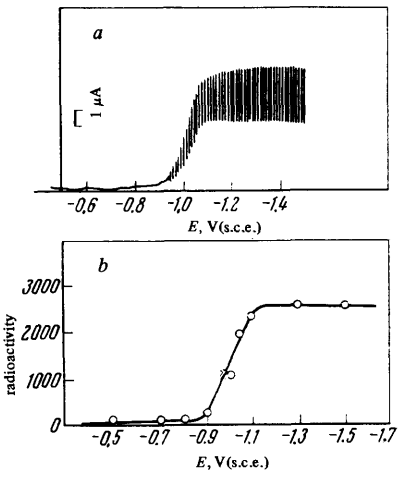

Figure 11. Comparison of the classical polarograms of nickel (a) and radiopolarograms (b); nickel chloride concentration 1×10^{-3} M, supporting electrolyte 0.1 M KCl.[58]

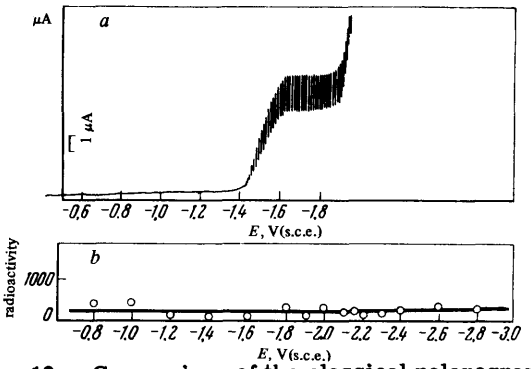

Figure 12. Comparison of the classical polarograms of nickel (a) and of radiopolarograms (b); nickel chloride concentration 1×10^{-3} M, supporting electrolyte 0.1 M KCl + 1×10^{-2} M KCN.[58]

8. FORMATION OF WAVES WHICH ARE CATALYTIC IN NATURE

Catalytic waves which are observed in the polarography of solutions containing cobalt and nickel salts with addition of sulphur-containing amino-acids have been considered sufficiently fully in Mairanovskii's review[59] and also in his monograph[60]. These publications systematised almost the entire literature up to 1965. Consequently, we will only briefly consider the catalytic waves of cobalt in the presence of organic additives. During the period that has elapsed since these two publications there have been no significant changes in opinions on the mechanism of the formation of catalytic hydrogen waves produced by certain organic compounds in the presence of cobalt salts; the mechanism for the production of such waves is still not fully explained.

Brdička[61] was the first to describe (in 1933) the unusual waves observable in the polarography of solutions which contain a cobalt salt and certain compounds with a mercapto-group. Since the wave for the reduction of Co^{2+} precedes the catalytic wave for the release of hydrogen, Brdička[62] and other investigators (see, for example, Ref. 63) have proposed that catalytically active centres form metallic cobalt, which is released at the surface of the mercury drop. To verify this point of view, Brdička[64] made a preliminary electrolysis of a solution at a stationary mercury cathode at a potential at which Co^{2+} is discharged but there is still no catalytic release of hydrogen. In the opinion of Brdička, under these conditions metallic cobalt will accumulate on the surface of the mercury drop. The catalytic wave should rise sharply if the metallic cobalt participates in this reaction. If the preliminary electrolysis were to have no effect on the height and form of the catalytic wave it would indicate that the metallic cobalt is not formed at the surface of the mercury drop. In Brdička's experiments the preliminary electrolysis did not alter the characteristics of the catalytic wave. This work has a definite effect on the formulation of ideas about the mechanism of the catalytic wave formed by certain organic molecules in the presence of cobalt and nickel ions. Most

investigators assume that a complex of the cobalt ion with the organic molecule acts as a catalyst.

Substances which contain a mercapto-group are known [60] to show catalytic activity in the absence of Co^{2+} or Ni^{2+} ions from the solution, but in the presence of the latter the catalytic activity of thiols increases sharply. The increase in the catalytic activity of thiols in their formation of complexes with Co^{2+} is linked, according to Mairanovskii [60], with the increase of the charge of the catalyst by two units, which from the point of view of the influence of the electrical double layer should facilitate the transfer of an electron to these species.

The greatest catalytic activity in the presence of Co^{2+} and Ni^{2+} is exhibited by compounds which simultaneously contain amino- and mercapto-groups. The catalytic effect observable in solutions of such compounds is determined by the action of all the active groups in the molecule. Using the example of the waves produced by cysteine and its derivatives, in which either amino-groups (*NN*-diacetylcysteine) or carboxyl groups (diethyl ester of cysteine) are blocked, Sunahara [65] has shown that blocking of the amino-groups leads to the complete loss of the catalytic activity of the cysteine whereas esterification of the carboxyls has hardly any effect on the characteristics of the catalytic wave. Mairanovskii therefore suggested that in catalysts containing both amino- and mercapto-groups the catalytic activity is due mainly to the amino-groups, whereas the adsorbability of the catalyst is determined mainly by the mercapto-groups. From this point of view, Mairanovskii [66] explains the observed parallelism between the ability of the catalysts to suppress the polarographic maximum, that is, their adsorbability and the height of the catalytic wave they produce. The adsorbability of the catalysts, which under strictly equal conditions determines the limiting catalytic currents is increased (in general) as the size of the catalyst molecule or the number of mercapto-groups in the molecule is increased. As Mairanovskii noted [60], this circumstance is evidently explained by Ito's observation [67] of the approximately proportionate increase in catalytic activity with increase in the number of cysteine residues in the composition of the protein-catalysts.

The height of the catalytic wave increases with the catalyst concentration and the curve for the dependence of the height of the wave on the concentration of the catalytically active substance is reminiscent of a Langmuir adsorption isotherm [60].

The influence of the pH on the catalytic waves due to complexes of cobalt or nickel with thiols is extremely complex. Maximal height of the waves is observed at some definite pH of the solution, as was noted by Březina and Gultjaj [68].

The catalytic activity of cobalt and nickel is usually regarded as an example of complexes with thiols; however, it is known that cobalt and nickel also increase the catalytic activity of pyridine [69], moreover the catalytic activity of pyridine is appreciably higher in the presence of Co^{2+} than in that of Ni^{2+} at the same concentration. It is especially high when both cobalt and nickel are present together in the solution. The catalytic wave which appears in the polarography of solutions of a complex of cobalt or nickel with pyridine has a surface nature. This is shown, for example, by the temperature dependence: as the temperature is raised the height of the catalytic wave falls rapidly and at a temperature above 35°C (in a solution with 0.1 *N* pyridine, 0.1 *N* pyridinium chloride, and 5×10^{-4} M cobalt and nickel salts) the wave is no longer observed [69].

Several new examples of organic compounds (including some which do not contain sulphur) which give catalytic waves in the presence of cobalt or nickel in the solution have recently been observed, e.g. 1,2-pyridylazoresorcinol dimethylglyoxime [70]. In this instance the height of the wave is several orders of magnitude greater than the diffusion current according to the metal ion. This allowed Vinogradova and coworkers [70] to use the catalytic wave of the complex with dimethylglyoxime for the analytical determination of nickel and cobalt in the negligibly small concentration of 2×10^{-8} M.

In certain instances in the presence of organic catalysts nickel gives catalytic waves or prewaves not connected with the release of hydrogen. For example, Tur'yan and coworkers [51,71-74] investigated in detail the nature of the similar catalytic waves observable in the polarography of thiocyanato-, pyridine, and thiourea complexes of nickel. The polarographic catalytic prewaves of nickel in the presence of various organic compounds, which although they contain sulphur in their molecule belong to several different classes of organic compounds, have been investigated [75]. In this study [75] the influence of additions of thioacetamide (Ta), thiourea (Tu), ethylthiourea (TuEt), diethylthiourea ($TuEt_2$), phenylthiourea (TuPh), thiosemicarbazide (Ts), rubeanic acid (dithiooxamide, DTO), unithiol (Ut), and thiocyanate (SCN^-) on the polarographic behaviour of Ni^{2+} (1 M $NaClO_4$; pH 6.25) was investigated. In every instance two catalytic prewaves were observed in the range $E = -0.6$ to -1.0 V (s.c.e.), not connected with the catalytic release of hydrogen. The following sequence of catalytic activity of the sulphur-containing compounds was observed: $Tu \simeq Ta < TuEt < TuEt_2 < TuPh < SCN^- < Ut < Ts < DTK$, which with the exception of SCN^- (Ut and DTO were not investigated in this plan) correlate with the adsorbability of these compounds at the mercury electrode. It was suggested that the catalytic prewaves investigated were due to chemical retardation in the stage of formation of polarographically active complexes, evidently with participation of the adsorbed ligand in most instances.

Calusaru [76] found that Co^{2+} forms a complex with nitrohydroxylamine (in an ammoniacal buffer solution). This leads to some decrease in the Co^{2+} wave and to the appearance of a catalytic wave of hydrogen with a characteristic maximum (in ammoniacal solution and in veronal acetate buffer solutions, starting from pH 6.12). Its height is maximal at pH 8.35 and is independent of the ionic strength of the solution. Nickel also forms a complex with nitrohydroxylamine but this leads only to splitting of the nickel wave [77].

It has been suggested [76,77] that catalytic waves are formed in the reduction of complexes of cobalt with substances which exhibit at least two chelate-forming functional groups. One of them is adsorbed on the mercury and the other shows a donor–acceptor function in relation to hydrogen ions.

Mark and Reilley [78] reported that in the presence of many amines which do not contain sulphur in their molecules Ni^{2+} gives a catalytic wave which appears at more positive potentials than the wave for the discharge of $[Ni(H_2O)_6]^{2+}$. Having studied in detail the mechanism of the electrode process with participation of *o*-phenylenediamine, Mark [79] concluded that the catalytic wave is due to the reduction of a complex formed on the surface of the electrode.

Hence catalytic waves of the most varied nature are formed in solutions of Co^{2+} and Ni^{2+} not only in the presence of thioamino-acids but also in the presence of various

classes of organic and inorganic compounds. The conclusion that the presence of groups which contain sulphur is a necessary condition for the appearance of a catalytic effect[80] is incorrect in the light of recent results.

It must be stated that Brdečka's work[64], in which he carried out a preliminary electrolysis, cannot serve as proof that metallic cobalt does not participate in the formation of a catalytic wave. The fact is that when a solution is electrolysed at a mercury surface the nature of the release of the iron-group metals is more complex than appears at first glance.

Two versions of the formation of a metallic phase in the discharge of ions on mercury can be proposed. In the first, the discharge of the ions is accompanied by the diffusion of metal atoms or their aggregates into the bulk of the mercury, where the cobalt or iron subsequently crystallise, or intermetallic compounds are formed, as happens for nickel.

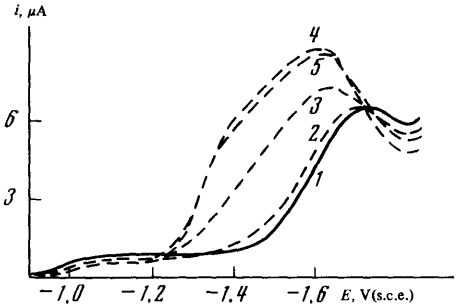

Figure 13. Polarograms of 4×10^{-4} M $CoCl_2$ + 2.3×10^{-4} M cysteine in a borate buffer (pH 9.2) in the presence of various amounts of surface-active substance—poly(vinyl acetate), 10^{-3}%: 1) 0; 2) 1; 3) 2; 4) 3; 5) 4.8.[57]

In the second, the formation of the metallic phase takes place on the surface of the mercury drop. This can be facilitated by the presence of adsorbed layers on the surface of the mercury drop. Owing to the local increase in current density on the mercury, crystallites of the metal will be produced (including nickel; nickel intermetallic compounds are subsequently produced as a result of the reaction of nickel crystals with the mercury).

The existence of a metallic phase on the mercury drop is also a complex phenomenon. The crystallites of the metallic phase are known to "sink" in mercury[81]. It is natural to assume that this process should depend upon the charge at the surface, the nature of the adsorbed layers, and other factors which influence the surface tension of the mercury. At a certain moment of time the nuclei break away from the surface and diffuse inside the mercury drop. Therefore there are no grounds for expecting the accumulation of the solid phase on a suspended mercury drop, as Brdečka[60] did. Under the conditions of his experiment a stationary process was established and the concentration of the metallic phase on the mercury remained constant (it did not depend on the period of electrolysis).

Evidently, when the solution contains a substance which is strongly adsorbed on the mercury it can inhibit the mixing of the solid (cobalt) and liquid (mercury) phases. When at the surface of the mercury there is a solid phase of a metal at which the hydrogen overpotential is considerably less (as happens, for example, for cobalt) than on mercury, then one may expect the discharge of hydrogen ions to be facilitated.

What has been stated above is supported by the fact that the catalytic effect for cobalt is appreciably greater than that for nickel. Cobalt has just as low a solubility in mercury as has nickel, but unlike nickel it does not form intermetallic compounds with mercury[82-85]. Nickel does not exhibit the ability to form compounds with mercury, which hinders the release of nickel on the mercury as an individual phase[82-85].

The recent work of Kolthoff and Mader[57] is extremely interesting in this connection. They recorded a cobalt wave for an insignificant concentration of it in the solution (4×10^{-4} M) in the presence of a little cysteine (2×10^{-4} M), that is, when the catalytic wave of hydrogen is absent from the polarogram. Then a surface-active substance which does not exhibit catalytic properties—poly(vinyl acetate) (PVA)—was added to the cell and a catalytic wave appeared and increased in height (as the PVA concentration was increased) (Fig. 13).

The addition of PVA to a solution which gives catalytic waves when polarographed increases the height of the catalytic wave and shifts this wave to less negative potentials (Fig. 13). However, these investigators start from the determinative role of a complex with zerovalent cobalt. They think[57] that the complex is stabilised in the presence of PVA.

It is noteworthy that iron behaves like cobalt in relation to mercury and consequently if the reason for the appearance of hydrogen waves is the formation of a phase which reduces the hydrogen overpotential, then in the presence of iron salts waves of this type should also be observed.

Ivanov and Ioffe observed this type of wave[48] on polarographing a solution of an Fe^{2+} salt in the presence of a surface active tetrabutylammonium (TBA) cation under conditions when the adsorption of this cation is greatly increased—in concentrated salt solutions (10 *N* $CaCl_2$). A sharp maximum is formed, the height of which is about 50 times that of the limiting diffusion current for iron (Fig. 14, curves *4* and *5*).

On the photomicrographs of a hanging mercury drop obtained[48] at the potential of the peak copious evolution of hydrogen is evident. At a potential more negative than that of the peak the liberation of hydrogen gradually ceases. It must be emphasised that the descending branch of the maximum is in the range of the negative peak of TBA adsorption.

We have also observed waves which are reminiscent in properties of the catalytic waves of hydrogen in solutions of cobalt and iron on the addition of a solution of sodium hypophosphite (curve *3* in Fig. 15); in the absence of these metals sodium hypophosphite is polarographically inactive[86]. The introduction of hypophosphite leads to the formation of the alloy Co_xP_y, insoluble in mercury, playing the part of a new solid phase on the mercury and it was noted earlier[87] that on an alloy of Co and P of a certain composition the overpotential of hydrogen liberation is lower than on cobalt. In every instance a film is formed on the mercury surface and has such a high surface activity that when hypophosphite is introduced into the solution the period of oscillation of the capillary is increased about tenfold, which leads to a change in the form of the wave and an increase in the limiting current (cf. Fig. 15, curves *4* and *5*). The formation of a similar wave for nickel is observed only at high concentrations of

hypophosphite but then the wave mentioned is insufficiently sharp: it almost merges with the background.

In support of the formation of a solid phase on mercury in the discharge of the ions of the Group VIII metals there is the recent work of Astley and Harrison [88]. By combining the method of superimposition of a triangular-wave potential with the impedance method they showed that on an electrode in the form of a hanging mercury drop the cobalt released from a 1×10^{-2} *N* $Co(NO_3)_2$ solution in the presence of KSCN (1–4 M) is formed either as an amalgam or as a phase surface layer of solid cobalt; in the latter instance the process is limited by the rate of nucleation and growth of the cobalt crystals.

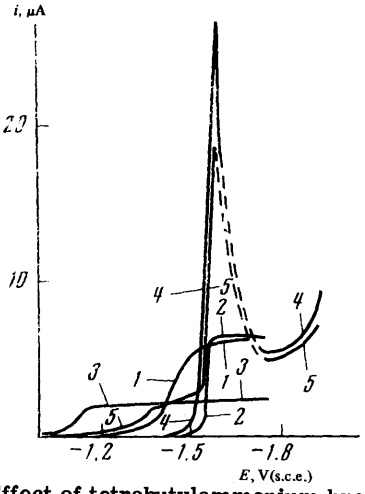

Figure 14. Effect of tetrabutylammonium bromide (TBA) on the kinetics of reduction of Fe^{2+} ions: 1) 1.0 *N* KCl, pH 5.5; 2) 1.0 *N* KCl, 1×10^{-3} *N* TBA; 3) 10.0 *N* $CaCl_2$, pH 5; 4) 10 *N* $CaCl_2$, 0.3×10^{-3} *N* TBA; 5) 10 *N* $CaCl_2$, 0.3×10^{-3} *N* TBA, pH ≃ 3. In every instance $[Fe^{2+}]$ is 2×10^{-3} *N*.[48]

The waves for the release of hydrogen, which resemble in properties the catalytic waves which are also observed in the polarography of solutions of metals of the platinum subgroup [49,89,90], and the heights of these waves are to the first approximation inversely proportional to the solubility of the metal in mercury or its ability to form intermetallic compounds with the mercury. For example, palladium, which is capable of forming intermetallic compounds with mercury, does not give such waves, despite the fact that the overpotential of hydrogen on palladium is appreciably less than that on mercury. The waves for the release of hydrogen in the presence of rhodium chloride [8], which have properties reminiscent of those of catalytic waves, were also observed on the addition of hypophosphite and certain aldehydes and ketones.

Hence it can be assumed that in at least several instances the waves are of a catalytic nature, observable in the presence of metals of Group VIII, due to the depression of the overpotential for the discharge of hydrogen on Group VIII metals, formed on mercury as a result of the discharge of the metallic phase. This conclusion does not contradict Gul'tyai and Mairanovskii's conclusion [91] that Co^{2+} accelerates only those catalytic processes which proceed either on the surface of an electrode with participation of an adsorbed catalyst or in a very thin layer adjacent to the electrode.

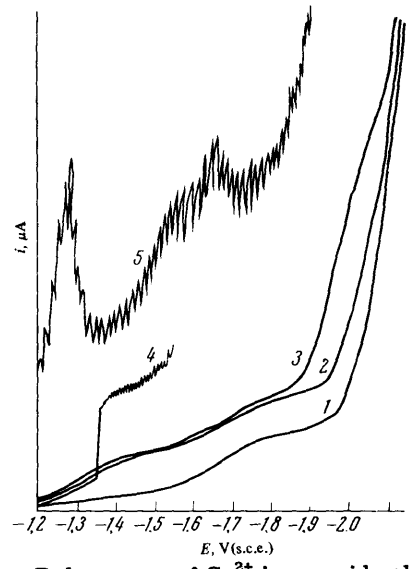

Figure 15. Polarogram of Co^{2+} in an acid solution (pH 2.97) on the addition of sodium hypophosphite. Curves: 1) supporting electrolyte 0.1 *N* KCl + HCl; 2) ditto + Co^{2+} (0.64×10^{-3} M); 3) as for 2 but + 1×10^{-2} M HPP; 4) and 5) as for 3, but the capillary drop period was arbitrarily increased and consequently also the wave height. [8]

There are also results [92,93] on the formation of catalytic hydrogen waves in the presence of chromium(III) (with bipyridyl) so that this property is intrinsic not only for Group VIII metals, but also for all metals, the hydrogen liberation overpotential (or that of other reactions with the participation of a proton) on the surface of which is lower than on mercury. In this instance the presence in the solution of PVA, which forms some similar "grids" which hinder the penetration of the microcrystal inside the mercury drop, is necessary for the appearance of a catalytic current. The magnitude of the effect should depend on the stability of this grid, in addition to other factors.

---o0o---

The ions of our metals lie in the following order of the increase in the negative values of the half-wave potentials: Ni, Co, Fe.

In dilute aqueous solutions, most often used as a saline supporting electrolyte (alkali metal halides and perchlorates), each ion gives one two-electron wave; the $E_{\frac{1}{2}}$ for these ions lie in a rather narrow region of potentials, from −1.1 to −1.4 V (s.c.e.). Under these conditions the electrochemical process is irreversible. The nickel, cobalt, and iron ions exist in the solution as the hexahydrates.

An increase in the concentration of an indifferent electrolyte usually has a marked effect on the half-wave potential and limiting currents; this influence is mainly symbathic for all the three cations considered. In studying the influence of an indifferent electrolyte, it is essential to take into account the following effects which frequently act simultaneously:

1. A decrease in the negative values of the ψ_1-potentials as the concentration of the cation of the indifferent electrolyte is increased leads to a shift in the $E_{\frac{1}{2}}$ of the wave of our ions to more negative potentials; this effect is appreciably noticeable when the cations of the indifferent electrolyte have a charge of +2 or more, as, for example, in using calcium chloride. The limiting currents in concentrated solutions of the supporting electrolyte are lower than in dilute solutions.

2. The adsorption of ions of an indifferent electrolyte, of a foreign ligand, or of a complex formed by the metal ion concerned. As regards the specific adsorption of the ions of an indifferent electrolyte, in the instances we have considered it is usually necessary to take into account the specific adsorption of only the anions on the electrode surface, which occurs despite the negative charge of the electrode surface. This phenomenon is usually encountered in using rather concentrated solutions of halide ions and the specific adsorption increases very markedly in the order F^-, Cl^-, Br^-, I^-. This effect leads to an increase in the negative values of the ψ_1-potential, which in turn causes a shift in $E_{\frac{1}{2}}$ along the potential axis to more positive values.

A shift in $E_{\frac{1}{2}}$ also results from the reconstruction of the hydrate sheath of the ion, the introduction into the inner coordination sphere of a foreign ligand, such as the halide ions, OH^-, CN^-, CNS^-, and also a series of organic and inorganic ligands (those negatively charged and those without a charge), which are capable of forming a rather stable complex with the cation. The introduction of a foreign ligand into the hydrate sheath is facilitated by dehydration, which leads to a decrease in the negative values of the half-wave potential and an increase in the reversibility of the electrochemical process. Usually on the polarogram there appears a second wave at potentials more positive than the $E_{\frac{1}{2}}$ of the wave for the discharge of the completely hydrated ion.

On reaching a certain concentration of the complex-forming substance (the organic ligand or the anion of the supporting electrolyte) the complex formed is more stable than the hexahydrate. This leads to a shift in $E_{\frac{1}{2}}$ in the negative direction along the potential axis and frequently to a decrease in the limiting currents of the corresponding waves.

The influence of the above effects is mainly analogous for all three of the metals being considered. The influence of the composition of the supporting electrolyte is maximal for Ni and gradually falls in the order Ni, Co, Fe, and the reduction of the nickel complexes in sufficiently concentrated chloride solutions takes place in the positive range of the electrocapillary curve. This can facilitate the discharge of the complex of composition $[NiX_4]^{2-}$, whereas reduction of the negatively charged complexes of cobalt and especially iron, which takes place on the negative branch of the electrocapillary curve will experience some retardation. The addition to the solution of a ligand which forms a stable complex with the metal ion can so increase the stability of the intermediate complex with a singly-charged ion that is formed that the two-electron wave is split into individual waves corresponding to the transfer of a single electron. Here there is observed a rise in stability and the complex with the metal is found in the zerovalent state.

The replacement of water by an organic solvent significantly affects $E_{\frac{1}{2}}$, the limiting currents, and the degree of reversibility of the waves for the discharge of iron-group metals. The organic solvent plays the part of a ligand and then its influence obeys the rules listed above. In addition, in the presence of an organic solvent there is a decrease in the adsorbability of the organic ligands or complexes with such ligands, which usually leads to an increase in the polarisation.

Under certain conditions (the presence of surface-active substances, optimal conditions of electrolysis) the release of Group VIII metals at the surface of a mercury drop leads to the formation of a new phase which adopts the role of an electrode with greatly different characteristics from a liquid mercury electrode. The formation of a solid phase leads to the appearance of new waves on the polarogram—catalytic waves for the discharge of hydrogen. The appearance of a new phase also affects the reversibility of the discharge of the metal ion.

Topological Ideas in Stereochemistry

V.I.Sokolov

In commemoration of the centenary of the birth of Lev Aleksandrovich Chugaev

An attempt is made to assemble data for various branches of organic and biological chemistry which can be related directly to the ideas of topology. Consideration is given to problems of topological isomerism and the topological chemical bond, as well as to routes for the synthesis of molecules similar in structure to various geometrical figures. Special attention is paid to catenanes, rotaxanes (hooplanes), and knots. Information is given on the occurrence of topological structures and mechanisms in Nature. A list of 117 references is included.

1. INTRODUCTION

Stereochemistry examines the spatial relations between atoms and groups within a molecule and also between different molecules. The spatial relations of idealised entities (points, lines, figures) constitute the subject of geometry. Therefore stereochemistry, so long as it is not concerned with dynamic processes, i.e. static stereochemistry, can be regarded as the geometry of molecular entities. That branch of dynamic stereochemistry which is confined to examining processes involving only a change in the internal coordinates of the molecule, conformations—but not chemical reactions—corresponds to introducing the ideas of motion into geometry.

As stereochemistry developed, it became increasingly clear that the relative arrangement of entities was especially important, but, within certain quite wide limits, metrical data (bond lengths, angles) were of little significance. The requirements of configurational stereochemistry are substantially similar to those of topology. This suggests that topology is an adequate mathematical foundation for stereochemistry.

Certain aspects of chemical topology were first discussed in 1961 by Frisch and Wasserman [1]. In a broad sense attention was attracted to topology as a mathematical basis for stereochemistry by a series of articles and papers by the eminent Swiss chemist V. Prelog during 1967–1969 (see e.g. "Problems of Chemical Topology", a lecture given in Dublin on 3rd April 1968 [2]). We shall briefly examine the main stages in the development of stereochemistry from this point of view.

The first step was the formulation of a structural theory, going back to Butlerov (1891). Based on the concept of valency, it established that only n atoms of the total present in the molecule were in a special relationship with a given atom A, where n is the valency of A. Thus the establishment of a topological concept—bond order in general—constituted the essence of the first formulation of a structural theory. The actual arrangement of the atoms—bond lengths and valency angles—is still completely unspecified. In general, nothing prevents directly bound atoms from being further apart than unbound atoms. Only the property of connectedness with respect to A distinguishes these n atoms from the whole set. Hence in the first stage the concept of bonding between atoms is topological rather than chemical.

Let N points belonging to n classes be located in a space (or on a plane, as in the original draft of a structural theory). The valency of a point of the nth class is n, and the number of points of this class a_n, where

$$\sum_n a_n = N.$$

The points may be joined in pairs by a chemical bond without further restriction. This set of points will represent a molecule only if the valency of each point is n (possible variability of valency is ignored for simplicity). The necessary formal condition for the existence of a molecule is $\Sigma n a_n = 2k$, where k is an integer: i.e. the sum of the products should be an even number.

The discovery of optical activity and the isolation of optical isomers, both preceding the development of a structural theory, demanded explanations of the number of structural isomers, which this theory was initially unable to explain. The problem was solved with the emergence of configurational stereochemistry (1875). The geometry of the immediate environment of a given atom—the arrangement solely of the directly bound n atoms (for carbon $n = 4$)—was specified in the tetrahedral model. In this well known history the difference between the van't

Hoff and Le Bel models is interesting for the purposes of this Review. Significantly, it is immaterial for configurational stereochemistry whether the valence tetrahedron of carbon is regular (van't Hoff) or irregular (Le Bel). Strictly speaking, the tetrahedron is always irregular if the substituents are different. A typical feature of stereochemistry—the neglect of metrical relations—is clearly apparent here. The valence angles of the tetrahedron can vary within very wide, though fully determinable, limits without change in configuration. A limit is reached when a coplanar arrangement of the substituents is achieved, when the system becomes achiral†. It is noteworthy that disregard of the metrical aspect of relations between entities is characteristic of topology.

It is appropriate here to define the most important stereochemical concept, configuration. In the Reviewer's opinion an adequate definition is lacking, at least in Russian-language textbooks. The following formulation may be suggested: *the configuration of a fragment is the short-range arrangement of the atoms, which is invariant with respect to the operation of rotation about single bonds*. The absence of superfluous detail enables systems possessing central and other types of chirality to be covered by this formulation.

The van't Hoff–Le Bel tetrahedral model played a decisive part in the practical development of stereochemistry, although the detailed geometry was in some sense a retrograde step in comparison with Pasteur's general ideas on molecular asymmetry as the cause of optical activity.

A direct development of the van't Hoff–Le Bel approach was Werner's coordination theory, which was based on the octahedron ($n = 6$). The success of this theory, which brought harmony into the previously chaotic world of complex compounds, was the first evidence of the universality of stereochemistry, rapidly extending beyond the limits of organic chemistry. When experimental workers came to study compounds of elements in higher periods, they encountered structures in which coordination numbers other than 4 and 6 were realised.

A trend became established to synthesise new molecules corresponding to well known geometrical figures. The progress made in this direction will be examined in Section 2. Subsequent Sections will be concerned with molecular entities for which the concept of topological isomerism is significant, together with their real analogues (catenanes–rotaxanes, isomers of clathrate type connected with the concepts of "inside" and "outside", etc.).

The examination of topological structures is not only intrinsically of great cognitive interest, in the sense of the opportunities for realising mathematical entities in a material, molecular form (where will the limits be reached?). It is no less significant that the actual properties of molecular systems may cause behaviour which is topologically indeterminate but nevertheless almost the same as for a topologically ideal system. This appreciably broadens the range of application of topological ideas and concepts. The clearest example is provided by rotaxanes (see later). While being a combination of cyclic and acyclic molecules mutually arrange in a definite fashion, they behave in effect as catenanes, since the very great steric hindrance makes destruction of this combination impossible without breaking a chemical bond. A less strict analogy to the "atom in cage" topological type is found in clathrates, in particular the subtype of compounds which could be termed "conformational clathrates". Each Section will consider both ideal topological entities and their real analogues.

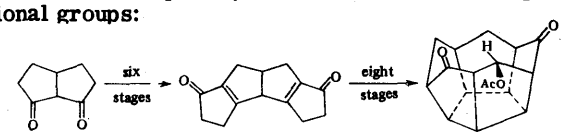
Several important questions are completely ignored in the Review–the formal concept of Möbius cyclic π-electron systems first formulated by Heilbronner [7] and developed by Zimmerman [8,9] especially in relation to organic photochemistry, topological aspects of aromaticity [10], the systematic formalisation of stereochemistry in terms of topology developed in a series of papers on "Chemistry and Logical Structures" by Ugi et al. [11] on the basis of the concepts of Bourbaki's French school of mathematics.

2. REALISATION IN CHEMICAL MATERIAL OF RIGID THREE-DIMENSIONAL STRUCTURES NOT REQUIRING THE CONCEPT OF TOPOLOGICAL ISOMERISM

During recent years several authors [12–16] have discussed the problem of the polyhedra corresponding to various coordination numbers and the rearrangements of ligands occurring in such systems ("polytopic rearrangements"). A fundamental mathematical condition here is Euler's theorem—the first theorem of topology—according to which $V + F = E + 2$, where V, F, and E are the numbers respectively of vertices, faces, and edges.

There exist five regular convex polyhedra—tetrahedron, cube, octahedron, dodecahedron, and icosahedron—whose faces are respectively triangles, rectangles (squares), triangles, regular pentagons, and triangles. With the exception of the dodecahedron, they are all represented in molecular structures. Unsubstituted cubane was synthesised in 1964, [17] and its chemistry has since been developed considerably. Published data on simple derivatives of tetrahedrane are contradictory [18–20]. However, the existence of the tetrahedral ligand P_4 has been proved in complexes of platinum-group metals [21]. Several types of octahedral molecules are known, besides complexes of metals having coordination number 6, corresponding to a centred octahedron. The purely carbon octahedrane, which would have represented a C_6 molecule, is merely a fragment of the diamond lattice. Nevertheless, the octahedral molecule $C_2B_4H_6$ is known [22]. Carboranes-12, having the form of an icosahedron, have been widely studied‡.

In 1964 Woodward et al. [24] synthesised the unsaturated hydrocarbon triquinacene $C_{10}H_{10}$, which forms, as it were, half a dodecahedral molecule



and may be a convenient precursor thereof. The same paper [24] reported the intention of subsequently studying the behaviour of triquinacene as an olefinic ligand in metal complexes, but further communications have not followed. However, such complex formation would have opened up prospects for dimerisation and also for obtaining compounds of "caged atom" type.

A different route for synthesising dodecahedrane, from two subunits—C_5 cyclopentane and a C_{15} fragment termed "peristylane"—has been chosen by Eaton and Mueller [25].

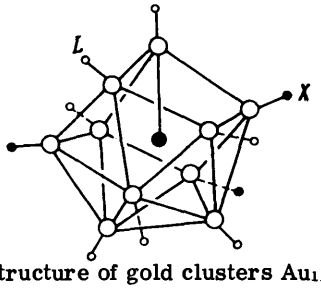
†Estimation of the energy required to convert tetrahedral into planar carbon shows that it exceeds the dissociation energy of the carbon–carbon bond [3]. The possibility of achieving a planar configuration of carbon has been examined by Hoffmann et al. [4,5], who have also discussed the possible stabilisation of a trigonal pyramid [6]

‡A review has appeared [23] on polyhedral organic molecules.

Starting from *cis*-bicyclo[3,3,0]octane-2,8-dione, they obtained the chosen peristylane derivative containing three functional groups:

(the structural similarity between peristylanes and [5]circulenes is obvious—see later). No information was given on the further plan of synthesis. High thermal stability was predicted[12] for dodecahedrane, with a stable carbanion consequent on effective delocalisation of the charge over the surface.

The requirement that the quadrivalency of carbon should be maintained probably makes the existence of a purely carbon icosahedron impossible. According to Euler's theorem this figure has 20 faces and 30 edges, with 5 edges meeting at each vertex, which implies that every atom is directly bound to at least 5 neighbours. Because of the variation in the type of bond this geometry becomes possible for carboranes $C_2B_{10}H_{12}$, in which all the atoms, including the carbon atoms, are formally six-coordinate. One valence is directed towards a group situated outside the ring system. However, $MC_2B_9H_{11}$ systems have been obtained in which the metal atom is unsubstituted[26,27]; derivatives of lower carboranes with an unsubstituted carbon atom have also been prepared[28]. The diversity of carborane structures is probably far from exhausted. The possibility of realising rigid non-convex polyhedra is of great interest from the point of view of structural topology. There are certainly no formal prohibitions of their existence with a sufficiently large number of vertices, and the availability of experimental methods for partly breaking down the structure of polyhedra (e.g. by removing one boron atom) may pave the way to the preparation of rigid non-convex polyhedra.



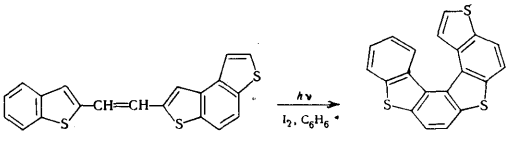


Figure 1. Structure of gold clusters $Au_{11}L_7X_3$ (where L = triphenylphosphine, and X is an anionic group).

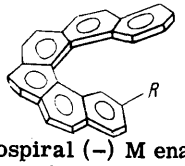
Clusters form a special group of organometallic compounds, whose chemistry has been developed only during the past decade[29]. These molecules contain closed systems of metal atoms (usually of a single metal). At first only planar clusters were known, but now three-dimensional clusters have also been obtained, whose structure has been established by X-ray examination. Gold clusters have been studied fairly thoroughly, e.g. $Au_{11}L_7X_3$,[30-32] which has been interpreted as a centred icosahedron in which the site of three vertices is occupied by a single atom (Fig. 1). Another example of a metal cluster will be considered later in connection with "atom in cage" isomerism. Although ideas on the nature of the bond between the metal atoms in clusters are still fairly vague, there is no doubt about the existence of this bond, covering the whole cluster system, as is indicated in particular by the close similarity of all distances between metal atoms, including the internal atoms.

A clear example of the realisation of three-dimensional geometrical models is provided by the helicenes—molecules having the form of a fragment of an infinite screw surface—the first and for a long time the only representative of which, hexahelicene, was prepared and resolved into optical enantiomers by the brilliant work of Newman and his coworkers[33-35]. A characteristic property of this molecule—optical activity due to the presence of an actually asymmetric chromophore, which reflects the chirality of the screw surface—immediately attracted the attention both of theoreticians and of experimentalists. However, the investigations were complicated by the difficult accessibility of the compounds. Theoretical calculations of the absolute configuration of hexahelicene by different methods[36-41] gave discordant results.

More rapid progress has been made with heterohelicenes, mainly containing one or more thiophen rings, which have proved especially suitable for the necessary synthetic procedures. This route

has been developed in the laboratory of the Dutch chemist Wynberg[42-45]. In the course of this work the absolute configuration of a molecule of helicene type, [*d*]naphtho-[1,2-*d'*]benzo[1,2*b* : 4,3-*b'*]dithiophen, has been determined for the first time[44] from the anomalous dispersion. The same method has recently been used to establish the absolute configuration of 2-bromohexahelicene, which has been converted into hexahelicene[46,47]. With all three molecules the (−)-enantiomer forms a left-hand spiral, with absolute configuration M (Fig. 2). Thus the problem of hexahelicene, posed fifteen years ago, has been solved.



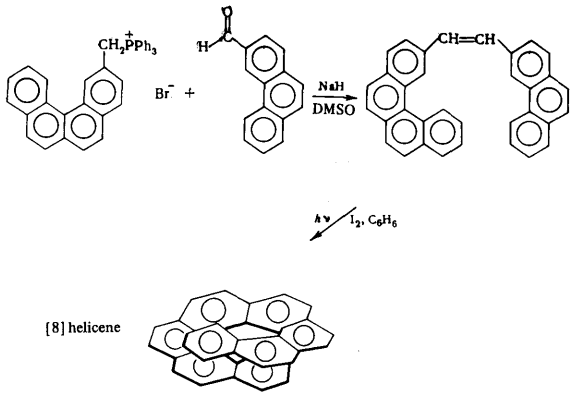


Figure 2. Laevospiral (−) M enantiomer of hexahelicene and 2-bromohexahelicene (R = H, Br).

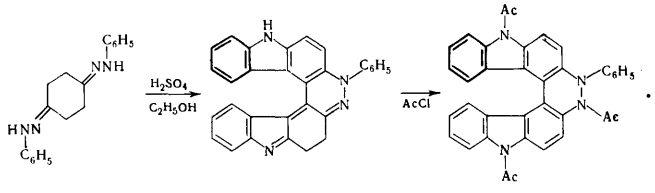
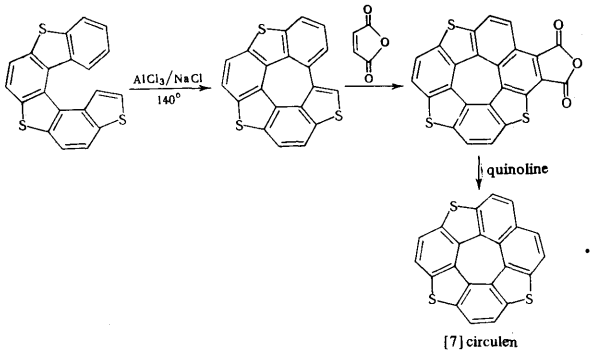


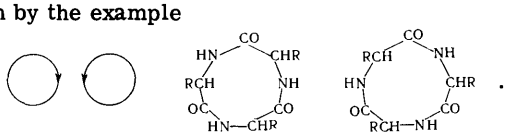
Martin et al.[48-50] have achieved considerable synthetic success in developing a new route to helicenes based on

the oxidative photocyclisation of 1,2-diarylethylenes:



This method has already yielded homologous helicenes right up to [13]helicene, which consists of two turns of a screw surface.

It is interesting that the higher helicenes are spontaneously resolved into enantiomers on crystallisation. A good method for the optical resolution of helicenes is to crystallise them from an optically active solvent. Steric hindrance in these molecules is obviously so great that the packing together of molecules of different configurations in the same crystal becomes disadvantageous. Spontaneous resolution into enantiomers had previously been observed extremely rarely [51]. Azahelicenes have also been obtained in optically active form by a different method [52]:



An interesting type of molecule is a circulene, a general name given by Dopper and Wynberg [53] to molecules comprising aromatic or similar rings fused on each side of a polygon. These workers examined cases in which the number of sides was n = 5–7. With a hexagon the planar aromatic molecule coronene, already known for quite a long time [54], is obtained. With n = 5 an example of a [5]circulene is corannulene [55]. The resulting stress forces the molecule out of a plane, making it buckle into a bowl shape. There is an obvious structural relation between [5]circulenes and peristylane, hetero-substituted derivatives of which can be obtained by further hydrogenation of hetero[5]circulenes. The first synthesis has been reported [53] of [7]circulenes, which should have a folded, corrugated form. In this case the perimeter of the molecule is longer than that of the planar coronene, whereas with corannulene the perimeter is shorter than in coronene. A [7]circulene has been obtained both by photocyclisation and from a [6]heterohelicene [53], which establishes a relation between two interesting classes of compounds:

3. TOPOLOGICAL ISOMERISM AND THE TOPOLOGICAL BOND

The widespread representation of molecules as geometrical figures, especially if all the atoms in the chain are identical, is generally used for carbon rings. However, the introduction of other structural entities (substituents, heteroatoms, etc.) leads to an internal orientation of the molecule, in which a definite direction of travel is distinguished. Such structural orientation assimilates a molecule to a path in the topological sense. The importance of structural orientation for stereochemistry is shown by the example

The two circles of the same radius are not congruent when displaced in a plane, if the direction of motion indicated by the arrow is taken into account: they are enantiomorphous if escape from the plane is forbidden. If the circles are replaced by cyclic molecules, an analogous orientation of the ring can be effected by means of different fixed sequences of non-equivalent groups. In *space* the above molecules (cyclotriglycines) can be superimposed as before. The situation is different, however, if the ring contains chiral centres differing in configuration. Combined with the fixed sense of the ring this leads to the appearance of a new type of isomerism, cyclostereoisomerism, which was actually discovered in cyclopeptides and their analogues [56, 57].

A most interesting branch of structural topology relates to information on the preparation and properties of molecules for which the concepts of topological isomerism and topological bonding are essential. Topology considers only those properties of a geometrical configuration which are preserved during deformations not involving rupture of lines and bonds§.

In general, two chemically non-bonded molecules can usually occupy independently any relative positions in space. However, a mutual arrangement is possible such

§Configurational stereochemistry presents more rigorous demands, since it takes into account the difference between enantiomers.

that it is not possible by any continuous transformation to achieve *all* relative positions: a chemical bond must be ruptured. In this case the combination of two species constitutes a new individual though composite molecule, whose integrity is accomplished by a new type of bonding, topological. This composite molecule is a topological isomer of the sum of the two separate component molecules [58]. According to Schill and Zürcher's definition [59] a characteristic feature of compounds having a topological bond is the property¶ that "main valency bonds must be broken in order to separate the complete molecule into its components, although no chemical bond is present between the two moieties".

We shall consider three types of topological isomerism. One depends on the relative arrangement of linear (one-dimensional) entities in space—whether looped or knotted—and is fundamentally impossible on a two-dimensional plane†. It includes catenanes, the first class of topologically bound molecules to be studied. They consist of at least two simple closed curves. Knotted lines are topologically isomeric with one simple closed curve, into which, however, they cannot be transformed without breaking the line.

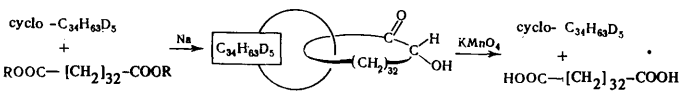
The second type of topological isomerism is associated with the concepts of "inside" and "outside". It is realised even in a two-dimensional model, as is evident from the example

of topological isomerism in a plane. Chemistry is interested in the three-dimensional case of a "molecule in a cage". This type of topological isomerism, in contrast to catenanes, can be achieved only because atoms are real physical bodies, not geometrical points. The set of spheres formed by the van der Waals radii of chemically non-bonded atoms in a molecule effectively create a closed surface. As a consequence, an atom or a molecule in the inner region‡ is unable to pass into the outer region, since it is of finite size. From a purely chemical point of view a "molecule in a cage" represents an intramolecular analogy to inclusion compounds—clathrates.

Whereas in the first type of topological isomerism entities were represented by two lines, and in the second type by at least one closed surface, open surfaces appear in the third type. It is fairly obvious that segments of cylindrical surfaces can be joined on the catenane principle: this is a trivial analogue of the linear case. It is more interesting that they can be twisted any number of times n. Thus a cylinder ($n = 0$) is topologically isomeric with a Möbius strip ($n = 1$) and with all higher figures having $n > 1$. The upper limit of n is imposed by the width of the strip and the diameter of the cylinder.

¶This definition, which was given for catenanes, is valid for other classes, and also in some measure for analogues, of compounds having a topological bond, e.g. rotaxanes (see later).

†For non-self-intersecting figures.



‡It is implied that the enclosing molecule forms a two-sided closed surface, to which Jordan's three-dimensional theorem applies.

4. CATENANES, ROTAXANES, AND KNOTS

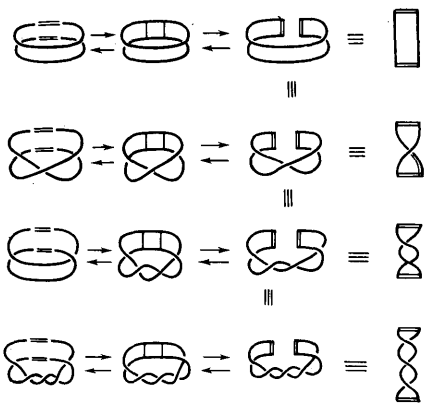
Ideas on the synthesis of such molecules, which consist of two entwined rings, i.e. mechanically rather than chemically bound compounds, like links in a chain—hence the name *catenanes*—have been expressed more than once by different scientists, beginning at the latest with Willstätter [1]§. However, experimental work on this problem began only little more than a decade ago. In view of the availability of a review [59] and a monograph [61], of which the latter has been translated into Russian, it appeared advisable to present a somewhat abridged account of the problem of catenanes.

In order that steric hindrance by non-bonded atoms should enable one ring to pass through another, both rings should be large, each containing more than twenty atoms. A prerequisite for such investigations, therefore, was the development of methods for the synthesis of macrocyclic compounds, which was largely accomplished by the 1950s.

Two principles—statistical and directed—are now known for the synthesis of catenanes. In 1960 Wasserman [58, 62] obtained the first reliable evidence for the formation of a catenane, by subjecting the diester $ROOC.[CH_2]_{32}.COOR$ to acyloin condensation in the presence of the partly deuterated cyclic hydrocarbon $C_{34}H_{68}$:

In a random synthesis the probability that a linear molecule will undergo cyclisation at the same time as it has passed through a macrocyclic ring is extremely small. The yield of catenane in this method of synthesis is therefore negligible, and its formation was proved by isotopic labelling and mass spectrometry.

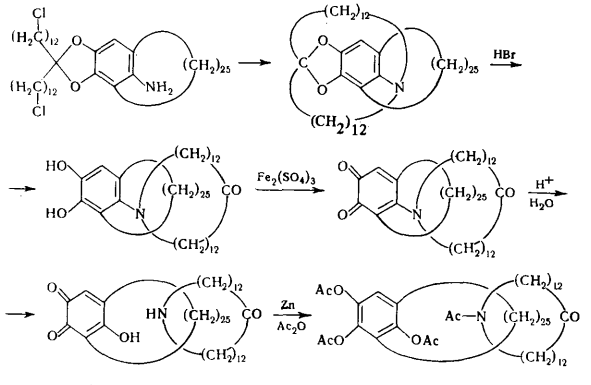
Further work on statistical synthesis used the metathesis of alkenes on catalysts including compounds of transition metals [63]. Wasserman, Ben-Efraim, and Wolovsky [64, 65], using intermediate cycloalkenes and a catalyst comprising tungsten hexachloride, ethylaluminium dichloride, and ethanol, obtained a mixture of cyclic oligomers up to at least C_{120}. Metathesis on transition metals is an intermolecular reaction. With a sufficiently large ring, however, this may be followed by intramolecular reactions. Some of them may yield catenanes, knots ("nectinodanes"), and Möbius strips ("plectanes"), as can be seen from Scheme 1. [65]



Although a circle can be deformed continuously into the edge of a Möbius strip, the statistical probability of achieving such a conformation is very small. It is another matter if some favourable factor is operating, e.g. coordination of double bonds of the cyclic molecule with a metal. In 1970 Wolovsky [65] and Wasserman et al. [66] published simultaneously very similar results on the metathesis of *cis*-cyclododecene on a tungsten catalyst, which indicated the formation of catenanes. The xylene-soluble fraction of the product was subjected to continuous mass-spectrometric analysis¶ while the temperature was gradually raised. A monotonic increase in the mass

§An interesting essay on these questions appears in Kostyanovskii's booklet [60], directed at the non-specialist reader; some historical information will also be found.

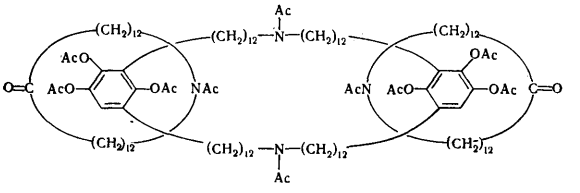
¶Kostyanovskii [67] in 1965 mentioned mass spectrometry as a convenient method for detecting catenanes.



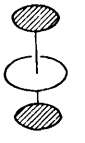
number of the most intense peak was found. At a certain temperature, however, peaks corresponding to lighter masses also showed a sharp increase in intensity. This phenomenon was explained by thermal rupture of the catenanes, the most abundant of which probably comprised C_{72} and C_{84} single rings. If the reason had been irregular cracking of monocyclic hydrocarbons, the mass spectrum would have shown an increase in intensity of a whole group of ions of closely similar mass. These workers adduced other arguments in support of the formation of catenanes (including multicatenanes), which will not be discussed here. It depends on the probability that a macrocyclic ring will buckle in a certain way, and this distinguishes it from Wasserman's first synthesis [58], which was governed by the probability that a chain would pass through a ring. Other aspects of the statistical synthesis of catenanes have been discussed [68, 69].

Scheme 1

A fundamentally different route was used in the directed synthesis of individual catenanes. Work on this problem began in the laboratory of Lüttringhaus during the 1950s as a development of the synthesis of "ansa" compounds. For a long time the desired result could not be obtained [70]. Success was finally achieved by Schill [71, 72], who synthesised the first [2]catenane by the sequence of reactions in Scheme 2. This synthesis made use of



Scheme 2



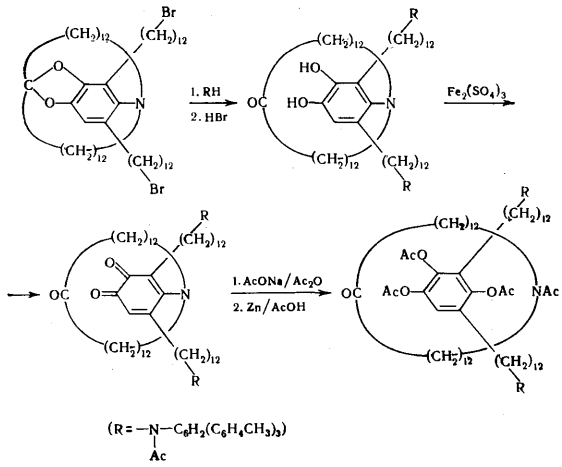
special supports or "scaffolding", by means of which the required groups were retained in a fixed position. They were then selectively removed by procedures which did not affect the remainder of the molecule. As a result it was possible to achieve the synthesis of two interlinked macrocyclic rings joined by a bridge, which was eliminated in later stages.

The "scaffolding" method requires great selectivity and great experimental skill. It ensures correct assignment of structure and provides an approach to the synthesis of higher catenanes. The first [3]catenane was obtained by Schill and Zürcher [73] (Scheme 3). The actual working out of a route for a directed synthesis is an extremely difficult task. In practice Schill's group have used the same chemical reactions in all their syntheses of catenanes and rotaxanes.

Scheme3

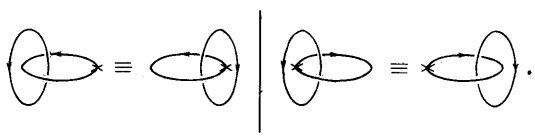
Wasserman [58] had previously and with complete justification defined a catenane as a topological isomer of two uncombined cyclic molecules. The molecular nature of the entities, however, leads to the curious situation that, if a linear molecule with bulky groups at its ends (dumbbell-shaped) passes through a macrocyclic ring, the resulting system

behaves analogously to a catenane: its components also cannot be separated without rupture of a chemical bond. Such systems are termed *rotaxanes*†.



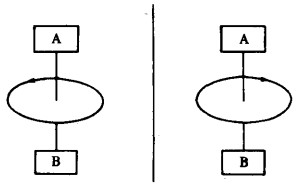
Schill and Zollenkopf's synthesis [74] is shown in Scheme 4. Nevertheless, in contrast to catenanes, rotaxanes are topologically indistinguishable from the simple sum of linear and cyclic molecules. This is shown especially clearly by work on the statistical synthesis of rotaxanes [75, 76]. A macrocyclic C_{30} acyloin was bonded to a polymeric carrier—Merrifield's resin—and subjected to repeated treatments with decane-1,10-diol and triphenylmethyl chloride in a solvent containing pyridine. Mild alkaline hydrolysis was followed by the chromatographic isolation of 6% of a rotaxane, in which either the ring or the linear portion could be broken selectively. Harrison [76] has recently detected extraordinary selectivity with respect to the size of the ring. Simply heating the macrocyclic hydrocarbon with 1,10-bistriphenylmethoxydecane in solution to 120°C leads to *equilibrium* between the rotaxane and the separate components *only for* C_{29}.

---

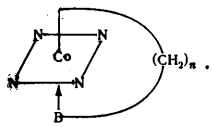


†Inclusion compounds with cyclodextrins are directly relation to rotaxanes (see later).

In the presence of trichloroacetic acid the reversible removal of one triphenylmethyl group makes it possible to obtain rotaxanes with C_{25}–C_{29}. With a larger ring the triphenylmethyl group will obviously pass through freely. The remarkable simplicity of this synthesis of rotaxanes should stimulate further investigations on these lines.

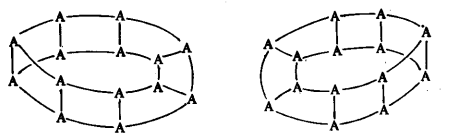


Scheme 4



All catenanes and rotaxanes known hitherto have contained at least one ring of symmetrical structure, so that problems of chirality were not directly involved in these systems. If, however, this ring were oriented by unsymmetrically arranged heteroatoms or groups (indicated by an arrow in Scheme 5), the possibility of enantiomerism would arise, as is shown by the rotaxane in Scheme 5. A [2]catenane will likewise be enantiomeric if its two rings are not identical and are oriented:

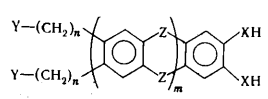
Scheme 5



Coordination compounds of metals can be used as "scaffolding" for building up catenoid structures. A system consisting of a metal atom fixed in a planar quadridentate ligand, with the two remaining positions in the coordination octahedron joined by a long chain, would be analogous to a catenane. The best simple example of such a complex, the approach to whose synthesis is self-evident, is an amminepolymethylenecobalt derivative of the type

The macrocycle is completed at the cobalt atom by means of a σ-bond with carbon and a donor-acceptor bond with a basic group B (e.g. phosphine or amine). This structure is formally of the catenane type, but differs in having nitrogen–cobalt coordinate bonds between the two rings.

Catenanes are the only class of topological molecular structures that have yet been synthesised. It would be an extremely interesting problem to construct a molecule having the geometry of a one-sided surface—the Möbius strip



Double cyclisation of a long molecule in the form of a fairly stiff band can be effected two ways—XY, X′Y′ to give a cylinder, and XY′, X′Y a Möbius strip

(cf. scheme of metathesis of cycloalkenes). In this statistical method of synthesis the probability of each mode of cyclisation would be close to 0.5 (in contrast to catenanes).

A suitable model molecule, which can easily undergo conformational flexing, can be constructed by introducing for instance aromatic fragments. Thus the A–A units can conveniently be benzene rings joined by short bridges comprising one or two atoms. These compounds are evidently oligomers (in particular oligoarylates) in size and structural form. For example, the edge of the cylinder for the molecule

will contain $N = 4m + n + 4 = 4(m + 1) + n$ atoms, and the edge of the Möbius strip twice this number. If we assume that $N = 20$, which seems quite reasonable, we have

$m = 1;\ 2;\ 3;\ 4.$
$n = 12;\ 8;\ 4;\ 0.$

It must be borne in mind, however, that the overall rigidity of the system increases with increase in m, owing to the accumulation of aromatic rings, and N should increase. The connecting bridges could be either oxygen atoms or methylene groups.

Another aspect of the problem of the Möbius strip concerns the occurrence of conformational transitions of macrocyclic compounds in solution, not the construction of a rigid molecule. This applies to the case in which the A–A units are interlinked not covalently but by weaker interactions, e.g. of donor–acceptor type. With a suitable arrangement of heteroatoms and functional groups a large ring (having $N \simeq 40$ or more) may assume the conformation of the edge of a Möbius strip.

Finally, it must be noted that the Möbius strip should exist as two enantiomeric forms, and therefore possess inherent optical activity, as a consequence of its property of orientability, even when constructed of identical atoms.

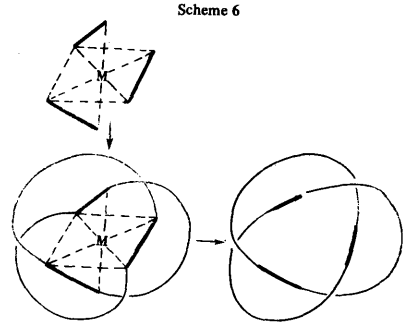
It has been shown above that, as in the metathesis of cycloalkenes, not only catenanes but also knotted molecules ("nectinodanes") and twisted molecules ("plectanes") can be obtained [65,78]. These possibilities follow directly from solving the geometrical problem of cutting a cyclic strip which has been twisted n times. Such molecules have not yet been synthesised. In an early paper Wasserman [62] estimated the minimum number of atoms from which the simplest knot, a trefoil, can be formed as $n \geqslant 50$. The first search for a knotted molecule was then undertaken in the random cyclisation of a C_{66} diester.

A remarkable property of knots is their chirality. Because it has been twisted in a definite direction, a knotted molecule should possess intrinsic optical activity. The optical rotation of the trefoil knot $[CH_2]m$ has been calculated [78] on Kirkwood's theory. With $m = 66$, when interactions of non-bonded atoms produce no appreciable distortions in the structure, the calculation gives $[\alpha]_D = +2.1°$, i.e. $[M]_D = +19.4°$, for the absolute configuration depicted on the left-hand side of

The smallness of the absolute rotation introduces uncertainty into the assignment of configuration, since even slight departures from the ideal structure employed in the calculation may produce a change in sign. Optical activity may be an indication of the formation of knotted molecules in random synthesis [62].

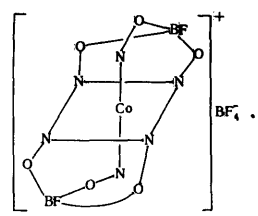
No attempt at directed synthesis has been reported. Scheme 6 suggests a synthesis for a trefoil knot using an octahedral metal complex as matrix.

5. TOPOLOGICAL ISOMERISM CONNECTED WITH THE CONCEPT OF "INSIDE" AND "OUTSIDE"



No single example is yet known of purely topological isomerism due to the enclosure of one molecule (or atom) in the space bounded by another molecule, without specific interactions between them. We shall therefore consider here more or less close analogies arising in real systems.

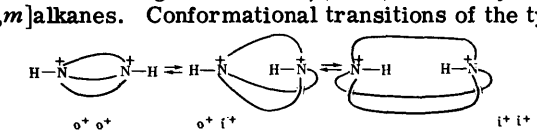
Inclusion compounds or clathrates have long been known [79], in which molecules are located in the cavities of a crystal lattice formed by molecules having a different structure. Clathrates, whose structure was understood more than twenty years ago, are of no special topological interest, since the intermolecular bonds usually are easily broken when the crystalline state is disturbed.



Cases are possible in complicated, conformationally mobile systems where some species may be "trapped" and retained by forces weaker than a covalent bond. An interesting example is the selective bonding of a xenon atom by myoglobin [80], which probably has a clathrate structure. Capture is accomplished in solution or in the crystal by the conformational mobility of the protein molecule. Hydrophobic interactions may play an important part here. Other examples provided by natural compounds will be discussed in the final Section of the Review.

Mention must be made of interesting systems in which isomerism of the "inside–outside" type is effected by a coordinate bond (encapsulation reactions). In 1967 Pedersen [81] discovered the class of cryptates, introducing into practice macrocyclic ligands containing several ethereal oxygen atoms ("crown ethers"). With suitable size and conformational mobility of the ring they form stable complexes with metal ions, mainly of Groups I and II, the selectivity depending on the structure of the ligand. Research on cryptates is developing rapidly [82–84], and analogous principles of complex formation have proved to be of biological importance (see later).

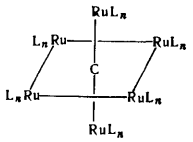
Scheme 6



Boston and Rose [85] obtained a kind of clathratochelate containing a cobalt ion

The synthesis is based on the principle of treating an ordinary octahedral complex, having three bidentate ligands, with a reagent capable of "locking" the three ligands located on opposite faces of the octahedron.

In the same year 1968 Park and Simmons [86] studied the isomerism arising in salts of 1, $(k + 2)$-diazabicyclo-$[k,l,m]$alkanes. Conformational transitions of the type

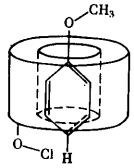


are possible in such macrobicyclic diamines when $k, l, m > > 6$‡. These equilibria have been studied in solutions of various acids by proton magnetic resonance. It is especially remarkable that encapsulation of halide ions occurs when $k = l = m \geqslant 9$. The corresponding isomeric salts, catapinates, are more sparingly soluble and are precipitated from solution. The [9,9,9]diamine will yield $i^+Cl^-i^+$[9,9,9]Cl^- only after standing at 25°C for five days, the reaction is more difficult with the bromide, and no catapinate is formed at all with the iodide, whereas the [10,10,10]diamine rapidly gives encapsulation products of Cl^-, Br^-, and I^-. Thus the steric requirements of the bicyclic molecule are fairly definite. It is very likely that the anion is retained in the "interior" by two hydrogen bonds.

‡Hydrogen or nitrogen directed outwards is denoted by o^+, and inside the molecule by i^+.

The inclusion compounds of graphite [87,88] form a peculiar class closely resembling clathrates. The occluded molecules are trapped in them by a single macromolecule, which does not in general enclose a portion of space. However, the actual conditions are such that escape of occluded molecules from the space between the layers is in practice difficult (e.g. high temperatures are required). During recent years analogous layer compounds (intercalation complexes) based on niobium and tantalum disulphides and diselenides have been discovered. The occluded molecules may be amines, e.g. pyridine or aniline [89,90]. Hardly any work has yet been done on these complexes, but they are attracting attention in connection with the problem of superconduction.

Several structures are known formally corresponding to the "atom in cage" type. They include the interesting organometallic carbide clusters [91]. The carbon atom situated at the centre of a regular octahedron formed by six ruthenium atoms



appears to correspond to the topological condition. However, the carbon–ruthenium distances are too small (1.88–2.12 Å), which undoubtedly indicates the presence of a chemical bond.

Organometallic chemistry is in general a suitable field of activity for seeking topological isomerism of the "inside–outside" type. Early attempts were made [92] to synthesise "cage" structures based on metallocenes. This is a practicable approach. An especially useful property of many organometallic compounds is their reducibility to the metal. If a compound is thus obtained in which the metal inside the cage is bound by a chemical bond (σ or π), a reducing attack on this bond can be conducted from outside the molecule, e.g. by electron transfer. However, it is not clear beforehand whether the resulting metal atom is sufficiently inert not to demolish the cage. In any case, the current state of the science allows such a problem to be investigated experimentally.

6. TOPOLOGICAL STRUCTURES AND MECHANISMS IN NATURE

An important factor for naturally occurring molecules, especially for macromolecules with their abundant possibilities of variation in conformation, is the relative arrangement, quite often a prerequisite for chemical interaction. Such systems are of direct interest in connection with the problems under discussion.

Natural complexes of clathrate type were the earliest to become known. Dextrin polysaccharides include cyclodextrins having cylindrical macromolecules. Molecules of a certain size are able to penetrate inside the cylinder [93], and their retention is assisted by hydrophobic interactions. The formation of such inclusion compounds with cyclodextrins or cycloamyloses has been used to resolve certain chiral molecules into enantiomers [94]. Breslow [95,96] has applied the formation of cyclodextrin clathrates to effect a kind of catalysis. If the linear portion of a molecule is placed inside the cylindrical macromolecule of a cyclodextrin, the groups outside (usually inert) are close to the agent and undergo uncharacteristic reactions. In this way it has proved possible to substitute chlorine in anisole solely in the *para*-position by the action of hypochlorous acid

and more rapidly than in the uncomplexed substrate. Breakdown of the clathrate gave a high yield of *p*-chloroanisole [95].

Preliminary clathrate formation has also enabled model esters to be hydrolysed with rate constants comparable with those found in the hydrolysis of esters by esterases [96]. The principle of preliminary favourable orientation of reactant molecules is adopted by enzymes. The high rates of enzymatic reactions are in fact known to be due to the formation of an enzyme—substrate complex, which can in some sense be regarded as a conformational but not a topological isomer of the separate enzyme macromolecule and substrate molecule§.

The great conformational mobility of biological macromolecules and the abundance of functional groups are closely connected with their biological functions. Thus it has been found quite recently [98,99] that the biological activity of peptide antibiotics of the valinomycin type involves the selective formation of simple complexes of cryptate type with alkali-metal ions, and ultimately the transport of these ions across cell membranes.

The formation in Nature's laboratories of extraordinarily complicated and highly specialised molecules suggests the probable occurrence of topological structures and mechanisms. Their identification, of course, involves very great difficulties. In fact, the disruption of the integrity of biological entities during study may change their structure beyond recognition. Nevertheless, clear evidence has now been obtained of the existence of catenoid deoxyribonucleic acids in the mitochondria of several cells, both pathogenic and normal. These first natural catenanes were discovered in 1967 by the American biochemist Vinograd and his coworkers [100,101], who obtained their electron micrographs. Individual macrocycles reached 5 μm. The micrographs clearly revealed also higher linearly linked catenanes up to a [7]catenane. Further work has shown that catenoid DNA are widely distributed.

Schill and Zürcher [59] have suggested a possible mechanism for the biogenesis of catenoid DNA on the basis of known properties of the Möbius strip. The hypothesis that cyclic DNA are constructed on this principle was first put forward some time ago by Wasserman [62]. Eight years later Burdick showed that it would not contradict the known properties of cyclic DNA [102]. If a Möbius strip twisted n time is cut along the midline, catenanes are formed whenever n is an even number; when n is unity, a single ring is obtained with a double circumference; and other odd values of n yield various knots [78]. The replication of double-strand Möbius DNA, which is equivalent to this slitting, thus naturally yields catenoid and knotted macromolecules (the latter have not yet been detected).

§During recent years experimental methods have been developed enabling a detailed study to be made of the character of the effective surface of macromolecules. It is advisable to term such work study of the topography of the surface of the molecule [97]: use of the term "topology" in these cases is incorrect.

In view of the probable existence in Nature of molecules simulated by one-sided surfaces like the Möbius strip, the existence of closed one-sided surfaces does not appear improbable. In three-dimensional space such surfaces can be realised only with self-intersection: i.e. the three-dimensional Jordan theorem is not applicable to them, and they do not divide space into internal and external regions.

The postulated possible existence of structures having such properties is directly related to the problem of membrane transport. The proposed topological hypothesis makes no demands on the size of the species to be transported (the migration of large molecules across membranes has recently become known[103]). The main idea is that, at least in some cases, no real penetration takes place *through* the membrane, which is a one-sided surface. We suppose that a particle Z is firmly attached to a site on the "outside" of the membrane (Fig. 3*a*). If a change in the conformation of the surface is now induced by this bonding or some other cause, the site may move "inside" (Fig. 3*b*), where the particle is removed from the membrane. Thus the apparent result is the penetration of Z through the membrane¶, which is actually a consequence of the conformational change in the surface—a special kind of allosteric effect.

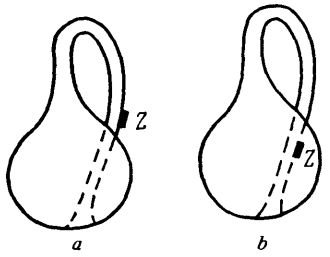


Figure 3. Illustration of the topological hypothesis of membrane transport.

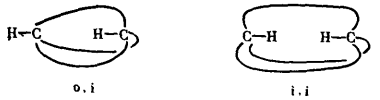
The energy relations observed in membrane transport may be an indication of the energetics of this conformational change. Certain consequences can be deduced from the suggested model: (1) substances that change the permeability of membranes should exert an allosteric action and/or combine selectively with certain molecules or ions; (2) certain molecules known as good complexing agents will not, however, increase appreciably the permeability of membranes for the corresponding ions, owing to the absence of an allosteric effect; and (3) strong effectors will accelerate non-selectively the transport of various species owing to the enhanced conformational lability of the membrane. The specific chemical mechanisms of bonding both effectors and transportable species with the membranes can obviously be extremely varied. The separation of allosteric and complexing effects may assist a better understanding of the problem.

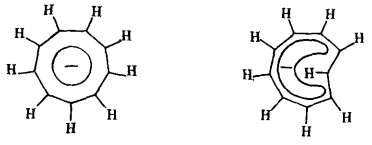
---o0o---

¶Simple penetration of molecules through channels connecting "internal" and "external" regions may be prevented by the size of these channels.



In the Reviewer's opinion structural topology is one of the growth points of modern stereochemistry. The technical difficulty of synthesising model compounds has hitherto been a strong restraining factor. The difficulties will probably diminish considerably during the next few years, after which rapid developments in this field must be expected, especially in the investigation of the chirality of topologically isomeric molecules. Without depending on the rate of experimental development, ideas arising from topology play an important part in the complex of concepts involved in modern stereochemistry.

ADDENDUM



The ideas forming the subject of this Review have been further examined in several recent papers.

Schill et al.[104] have continued their directed synthesis of a catenane (Scheme 3), passing to a simpler compound by ozonolysis of the aromatic ring followed by reduction of the carbonyl groups to methylene. In this way they have obtained the ancestral [28, aza-25]catenane.

Park and Simmons[105] have extended their investigations of the conformational isomerism of macrobicyclic compounds, begun on diamines[86], to purely carbon systems. They have selectively synthesised i,i- and o,i-bicyclo-[8,8,8]hexacosanes

isomers whose structure is confirmed by the carbon-13 nuclear magnetic resonance spectra. Interconversion of the isomers has not yet been reported. A similar system, in which a hydrogen atom attached to a bridgehead carbon faces the interior of a rigid bicyclic molecule, has been prepared by Gassman and Thummel[106]. In this connection it is interesting that isomerism associated with the convexity or concavity of a planar polygon has already been observed[117] in the cyclononatetraenide anion

Research on cryptates is being vigorously pursued, both in the synthesis of new multidentate macrocyclic ligands and in their use for preparative purposes[107-111].

No weakening of interest is apparent in the preparation of polyhedra and other three-dimensional molecules, especially of the cluster type[112-115]. The trideca-atomic polyhedron of the carborane class is probably not convex[116].

Ring-Chain Isomeric Conversions of Aldehydo-carboxylic and Keto-carboxylic Acids and Their Derivatives

R.E.Valter

Ring-chain isomeric (including tautomeric) conversions of aldehydo- and keto-carboxylic acids and their chlorides, amides, hydrazides, esters, and mixed anhydrides are reviewed. The possibilities of using physical methods (ultraviolet, infrared, and proton magnetic resonance spectroscopy) for the identification and quantitative determination of isomers are discussed. The effect of structural factors on the relative stability of isomers is analysed. Conditions are elicited under which interconversion occurs or equilibrium is observed. A list of 207 references is included.

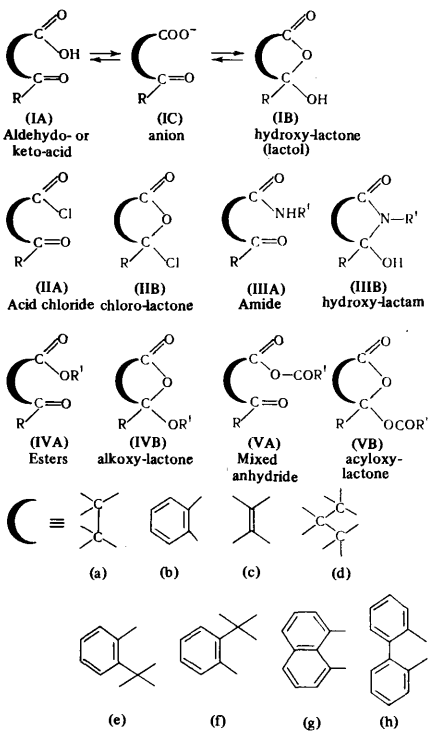
I. INTRODUCTION



Ring-chain isomeric conversions are observed in organic molecules containing a multiple bond and a functional group capable of intramolecular addition at this bond. The structure of the molecule should enable the two groups to assume a relative arrangement suitable for the reversible intramolecular addition.

Ring-chain isomeric conversions are often termed ring-chain tautomerism [1]. Depending on the polarity of the bonds of the interacting functional groups, electronic and steric effects of substituents, and several other factors, however, three types of isomeric conversions may be observed. (1) In ring-chain tautomerism, equilibrium is rapidly established between open (A) and cyclic (B) forms in solution at room temperature. (2) In reversible ring-chain isomerism [2] both forms can be obtained separately, and are stable in neutral solvents at room temperature. The isomerisations A → B and B → A are effected by the action of acid or basic catalysts, by specific reagents, or on heating. (3) In irreversible ring-chain isomerism both forms are stable, but their interconversion can be achieved only in one direction (A → B or B → A).

Isomeric and tautomeric conversions must be clearly distinguished. Absence of tautomeric equilibrium can be reliably assessed, of course, only when both isomers have been isolated and it has been established that they are both stable in solution. If only one isomer has been isolated, e.g. A, and its stability in solution has been demonstrated, occurrence of the equilibrium A ⇌ B is still possible, displaced so far towards A that the concentration of the isomer B is below the limit of sensitivity of the method of identification used.

A previous review [1] did not differentiate between tautomeric and isomeric conversions. It had the defect of an uncritical approach to the results of early investigations, in which the structure of the isomers had been demonstrated only by chemical methods. The use of such methods to establish the structure of compounds capable of isomeric conversions is unreliable and a frequent source of error. As early as 1956 Hammond [3] wrote that, since spectroscopic methods had been developed after the period

Scheme 1

of the most active studies of ring-chain tautomeric conversions, there were grounds for expecting that in the near future a new stage would begin in the general investigation of these problems. Actually, quite a large number of investigations have been published during the last decade in which structures of open-chain and cyclic isomers and their interconversion have been examined by ultraviolet, infrared, and proton magnetic resonance spectroscopy.

The present Review summarises results only of those investigations, published mainly during the past decade,

in which the structure of the isomers was reliably established by spectroscopic methods. Attention has been paid mainly to—(i) spectroscopic characteristics enabling cyclic and open-chain forms to be identified and determined in mixtures, (ii) the relative stability of the isomers, i.e. the character of the equilibrium, (iii) the conditions under which isomeric interconversions occur, and (iv) the influence on the relative stability of the isomers exerted by the electronic and steric effects of substituents attached to the interacting functional groups and by the structure of the bridge connecting them. In order to analyse these questions in greater detail, we restrict our survey to aldehydo- and keto-carboxylic acids and their acid derivatives. Scheme 1 gives the general structures of the open-chain (A) and cyclic (B) forms examined (I)–(V) and the structures of the bridging units (a)–(h) joining the two functional groups. The structures (a)–(h) enable us to expect the existence of cyclic forms, but undoubtedly do not exhaust all possible cases.

II. ALDEHYDO- AND KETO-CARBOXYLIC ACIDS

γ-Aldehydo- and γ-Keto-carboxylic Acids (Ia–c)

Nucleophilic intramolecular addition of a carboxy-group to a carbonyl group is a rapid and reversible process[4], and the tautomeric equilibrium IA ⇌ IC ⇌ IB is established in solutions of γ-aldehydo- and γ-keto-acids. Independently of the structure of the molecule and of the substituent R, the carboxylate anion always has the open-chain structure (IC)[4–15]. Pascal[16] found that the equilibrium

$$\underset{\text{dimer of keto-acid}}{\text{IA...IA}} \rightleftharpoons \text{IA} \rightleftharpoons \text{IB} \rightleftharpoons \underset{\text{associated lactol (C=O...H–O)}}{\text{IB...IB}} \quad (A)$$

is established in solutions of methyl-substituted γ-oxovaleric acids in solvents of low polarity.

It was suggested[16] that the tautomeric equilibrium constant $K_T = a_B/a_A$ of aldehydo- and keto-carboxylic acids in solution should be determined using the equation

$$\lg(K_T + 1) = pK_a - pK'_a \quad (1)$$

where K_a is the acid ionisation constant of the carboxylic acid determined potentiometrically, and K'_a the true (theoretical) acid ionisation constant of the carboxylic acid A in the absence of the tautomeric equilibrium IA ⇌ IB. Use of the method[4,16–18] is restricted by the fact that it is extremely difficult to determine accurately the constant K'_a from the acidity constants of model acids of similar structure that are incapable of cyclisation. This has been done most accurately for *cis*-β-acylacrylic acids from the experimental acidity constants of the corresponding *trans*-acids[19]. Bell[4] determined the constant K'_a of *o*-formylbenzoic acid from a kinetic investigation of its catalytic action in the decomposition of nitramide and the mutarotation of glucose, whence he calculated the tautomeric equilibrium constant in aqueous solution (K_T = 14.8). This method is claimed to be more accurate.

Bowden[20,21] solved the opposite problem by substituting in Eqn. (1) values of K_T determined by proton magnetic resonance and the constants K_a determined potentiometrically: he calculated the true acid ionisation constants K'_a of several *o*-acylbenzoic and *cis*-β-aroylacrylic acids in 80% aqueous 2-methoxyethanolic solution.

The ketonic carbonyl band disappears from the infrared spectrum in the tautomeric conversion IA → IB of γ-keto-acids. Owing to the bending stress on the >C=O bonds in the five-membered ring of IB, the lactonic carbonyl bond is shifted to higher frequencies (1800–1770 cm^{-1}) than in the carboxy-group in the open-chain form IA (Table 1).

Table 1. Frequencies (cm^{-1}) of C=O bands in infrared spectra of γ-keto-acids in solution.

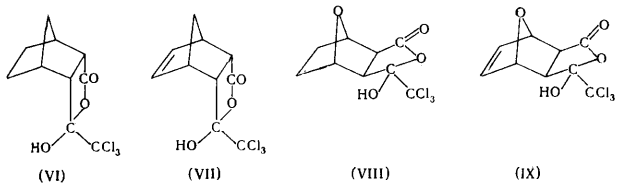
*β-Benzoyl-α-methylpropionic acid.
**sh = shoulder.

Determination of the tautomeric equilibrium constants of *o*-aroylbenzoic[26,27], *o*-acylbenzoic[20], and *cis*-β-aroylacrylic[21] acids from the infrared spectra is based on the postulated equality of the integrated intensities of the carbonyl bands in the spectra of esters of cyclic (IVB: νC=O = 1780 cm^{-1}) and open-chain (IVA: νCOOR = 1730 to 1720 and νC=O = 1700–1675 cm^{-1}) structure and the corresponding tautomeric forms (IA and IB) of keto-carboxylic acids. The reproducibility of the determination of the content of tautomeric forms is ±2–3%.[20,27] Satisfactory correlation is observed between the tautomeric equilibrium constants of *o*-*m*′(or *p*′)-X-benzoylbenzoic acids and the σ_m and σ_p constants of the substituents X respectively[26,27].

When proton magnetic resonance is used to analyse ring-chain tautomeric systems, it must be borne in mind that two cases are observed depending on the rate of the tautomeric conversion[28]: (i) with slow tautomeric conversions (on the p.m.r. time scale) the proton signals of the two forms are observed separately, and the tautomeric composition is determined from their relative intensities; (ii) with rapid conversions the proton signals of the two forms coalesce into a single signal, characterised by the mean chemical shift. Replacement of a less polar by a more polar solvent or additions of catalytic quantities of acids or bases may influence the rate of the tautomeric changes, and thereby change significantly the pattern of the p.m.r. spectrum[12,20,29].

The forms (IA) and (IB) are most often identified and determined by means of the signals from protons in the groups CH_3CO (IA) and $CH_3C(OH)O$ (IB: R = CH_3) (or in general AlkCO and AlkC(OH)O) for keto-carboxylic acids[13,16,17,20,29–32] and in the groups HCO (IA) and HC(OH)O (IB: R = H) for aldehydo-acids[9,11,12,14,15,18,22]. Signals of protons in other groups have been used more rarely[21,33]. In the p.m.r. spectrum of *o*-acetylbenzoic acid dissolved in hexadeuteriated dimethyl sulphoxide

Finkelstein[29] observed proton signals at 2.45 ppm† (CH_3CO) and 1.78 ppm ($CH_3C(OH)O$). The constant was determined from the signal intensities as $K_T = 2$. After catalytic quantities of hydrochloric acid had been added to the solution, the two signals coalesced into a single signal with a chemical shift of 2.02 ppm. In the p.m.r. spectra of keto-carboxylic acids, however, one common signal is most often observed, indicating the occurrence of rapid tautomeric conversions[16,17,20,31,32]. In the determination of the constant K_T it is assumed that the contents of the forms (IA) and (IB) in the tautomeric mixture are inversely proportional to the distances of their common signal from the corresponding signals in the spectra of fixed models, the esters (IVA) and (IVB)[20,31]. The constant K_T for β-formylpropionic acid[22] was determined from the intensity ratio of the signals of aldehydic and methine protons (9.54–9.66 and 5.66–5.83 ppm respectively).



The disappearance of the chromophoric group (C=O) in the conversion of IA into IB is responsible for corresponding changes in the ultraviolet spectrum. However, absorption in the ultraviolet, governed by electron transitions in conjugated systems, cannot be interpreted as clearly as infrared absorption, where the presence of a particular multiple bond can be assessed unambiguously. The use of ultraviolet spectroscopy to determine the constants K_T in tautomeric systems of aldehydo- and keto-carboxylic acids is based on the postulate that the absorption by fixed models—the esters (IVA) and (IVB)—and the absorption by corresponding tautomeric forms of the acids (IA) and (IB) do not differ appreciably[22,31,34].

Little work has been done on the effect of the solvent on the tautomeric equilibrium. In more polar solvents the equilibrium is displaced towards the cyclic form[26,27,35]. However, contrary results have also been obtained[36]. The mechanism of the action of the solvent on the tautomeric system IA ⇌ IB is complicated. Intermolecular hydrogen bonds may play an important part in stabilising a particular form, the cyclic isomer showing a greater tendency to form such bonds involving both carbonyl and hydroxyl groups. Dilution of the solution[6,7,22], the use of pyridine or triethylamine as solvent, or their addition to existing solutions displaces the equilibrium towards the open-chain form[15,22]. In acid media the equilibrium is shifted in favour of the less acidic cyclic form[7]. No correlation could be found between the structure of *o*-acylbenzoic acids and the temperature dependence of the ring–chain tautomeric equilibrium[36,37].

Structural factors promoting intramolecular nucleophilic addition of the carboxyl to the carbonyl group can be divided into three types—(i) factors that enhance the electrophilic character of the aldehydic or ketonic carbon atom (the presence of electron-accepting substituents R, the absence of conjugation between the carbonyl group and an aromatic ring, etc.), (ii) factors that enhance the nucleophilic character of the oxygen atoms in the carboxy-group, and (iii) factors that bring carboxyl and carbonyl groups closer together in space, which is most favourable for intramolecular attack.

The carbonyl carbon atom becomes less electrophilic with the squence of substituents R = H, Alk, Ar. The equilibrium IA ⇌ IB is established in solutions of β-formylpropionic acid[22] and its chain-substituted derivatives[16,18,38]. The cyclic form is not detected in solutions of γ-oxovaleric acid[16]. The accumulation of two or three methyl groups in the chain brings about a steric approach of carboxyl and carbonyl groups (the *gem*-dimethyl effect[3,39]), and for ααβ-trimethyl-γ-oxovaleric acid[16] in 80% aqueous 2-methoxyethanol $K_T = 7.7$. Infrared spectroscopy provides evidence that β-aroylpropionic acids[23,40,41] and several of their more complicated analogues[42] have the open-chain structure in the crystalline state and in solution.

An increased tendency to form the cyclic modification has been observed[10,24] in a series of β-trichloroacetylcarboxylic acids. The −*I* effect of the trichloromethyl group is obviously operating here. The relatively high stability of the ring forms of the bicyclic keto-carboxylic acids

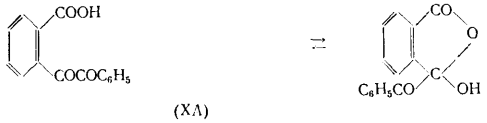
(VI) (VII) (VIII) (IX)

is due to the completely protected conformations of the *cis*-substituents (COOH and CCl_3CO) attached to the second and third carbon atoms of 1,4-*endo*-methylene- and 1,4-*endo*-oxo-cyclohexanes and -enes, which create the most favourable conditions for intramolecular nucleophilic attack.

Because of the steric approach of carboxyl and carbonyl groups, *o*-acylbenzoic acids (Ib), and especially *cis*-β-acylacrylic acids (Ic), show a greater tendency than do β-acylpropionic acids (Ia) to form the cyclic modifications. Three-dimensional models show that the open-chain forms of these acids (Ib–A and Ic–A) are able to exist only in the energetically disadvantageous non-coplanar form, which excludes conjugation of the π-bonds[43].

In solutions of *o*-formylbenzoic (Ib: R = H)[4,8,11,12,15,44,45] *o*-acylbenzoic (Ib: R = Alk),[5,20,29,31,32,35,45–50] and especially *cis*-β-acylacrylic (Ic: R = H, Alk)[17,19,25] acids the tautomeric equilibrium is displaced towards the cyclic form. The ketonic carbon atom in *o*-aroylbenzoic acids (Ib: R = Ar) is less strongly electrophilic owing to conjugation with both aromatic rings. In the absence of specific structural factors stabilising the ring form, *o*-aroylbenzoic acids have predominantly the open-chain structure in the crystalline state and in solution[20,27,31,34,45,51–56]. The tautomeric equilibrium constants of *o*-*m*'- or *o*-*p*'-X-benzoylbenzoic acids[26,27] in dioxan have values of 0.03–0.10, and those of *cis*-β-*p*-X-benzoyl-α(or β)-methylacrylic acids[21] lie in the range 1–26, the higher values being observed with acids having electron-accepting substituents X.

A methyl group in the 3- or 6-position of a 2-aroylbenzoic acid exerts a steric effect on the carboxyl and carbonyl groups, so that the equilibrium is shifted in favour of the ring form, with a 6-methyl group having the stronger effect. Methyl groups in the 2'- and 6'-positions of the aroyl substituent shield the carbonyl group sterically, and hinder cyclisation[34,52,57]. Predominance of the cyclic form has been noted in 2-benzoyl-3,4,5,6-tetrachlorobenzoic acid[27,31].



The series of 2-acetyl-6-X-benzoic acids shows[29] increase in the stability of the ring form with strengthening of the electron-donating power of the substituent X, i.e. with enhancement of the nucleophilic character of the oxygen atoms in the carboxy-group. Nitro-groups, independently of their position in the phthaloyl ring,

†Chemical shifts are always indicated on the δ-scale relative to TMS.

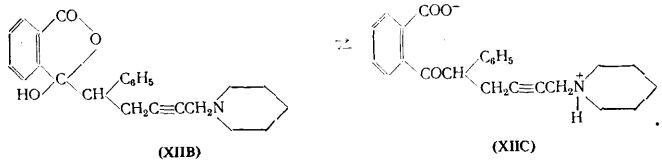
stabilise the open form [27,29,31,56]; the reason for this is not entirely clear.

Infrared spectroscopy has been used to investigate the structure of *o*-acylbenzoic acids in the crystalline state [31,45,58]. The isolation of one tautomeric form of an aldehydo- or keto-carboxylic acid in the crystalline state does not prove that this same form predominates in solution [3,31,35,49]. Interpretation of the infrared spectra is complicated by the presence in the lattice of stable intermolecular hydrogen bonds O–H...O=C (lactol), which split the carbonyl band of the lactol and shift it to lower frequencies than in solutions [31,42,45]. The spectra of concentrated solutions of keto-carboxylic acids in weakly polar solvents contain, besides the free carbonyl band of the lactol (1780–1770 cm^{-1}), also a band at 1750 cm^{-1} due to a bound carbonyl group [16,32,35]. The latter becomes less intense with dilution of the solutions, which distinguishes this band from absorption by monomeric carboxyl observed [16] in the same region. The main evidence of the ring structure (IB) in the spectra of crystalline compounds is the presence [6,31,58] of an intense, broad band due to a bound hydroxy-group (OH...O=C) at 3350–3150 cm^{-1}. In the spectra of crystalline keto-carboxylic acids (IA) the hydroxy-absorption of the dimeric carboxy-groups is apparent as a diffuse band at lower frequencies (3000 to 2600 cm^{-1}).

o-Formylbenzoic [44,45,58] and *o*-acetylbenzoic [29,31,32,45,58] acids have the ring structure in the crystalline state. Some *o*-acylbenzoic acids (Ib: R = Alk or more complicated substituent) have been obtained in the crystalline state as the cyclic modification [5,10,24,59], and others in the open form [35] or as a mixture with one form predominating [35,47–50,60]. Both isomers of benzil-*o*-carboxylic acid

(XA) (XB)

have been obtained in crystalline form [58,61], and the thermal isomerisation XB → XA has been accomplished.

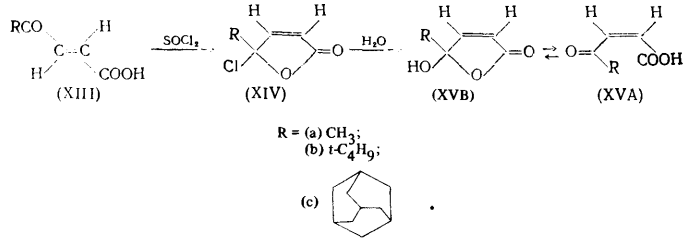


Three crystalline modifications of *o*-β-*N*-t-butylcarbamoyl-α-phenylpropionylbenzoic acid have been described which differ in their content of the tautomeric forms

(XIA) (XIB)

and in the involvement of the various carbonyl groups in the formation of intermolecular hydrogen bonds [50].

It is interesting that the acid (XII) can be isolated, depending on the conditions, as the lactol (XIIB) or the betaine (XIIC)[62]



(XIIB) (XIIC)

The effect of the conditions of isolation on the isomeric composition of crystalline aldehydo- and keto-carboxylic acids has not yet been adequately studied. It is of interest to ascertain the effect of the temperature régime of crystallisation, the nature of the solvent, the temperature of the alkaline solution from which the acid is isolated by acidification, the pH of the medium after acidification, etc. These conditions probably play an important role, neglect of which makes nonsense of the search for rules relating the structure of the acids to their isomeric composition in the crystalline state.

cis-β-Formylacrylic acid [25,63,64], its αβ-substituted derivatives [9,15,65–68], and *cis*-β-acetylacrylic acids [13,17,69–71] in the crystalline state have the cyclic structure, which predominates even in solution. *cis*-β-Aroylacrylic acids have been isolated in the crystalline state either as the cyclic or as the open-chain isomer [6,7,72–75].

The geometrical isomerism of β-acylacrylic acids complicates the study of their ring–chain tautomerism. It is necessary to distinguish not only open-chain and cyclic forms but also *cis*- and *trans*-isomers of the form (IA). This problem is solved by proton magnetic resonance: the spin–spin interaction constant of the olefinic protons for αβ-unsubstituted *cis*-β-acylacrylic acids is 5.5–7 Hz, and that for the *trans*-isomers 16 Hz. [13,17,70,71] The *trans*-configuration has been identified [36,37] also from the infrared band due to out-of-plane deformation vibrations of the carbon–hydrogen bond at 980 cm^{-1}.

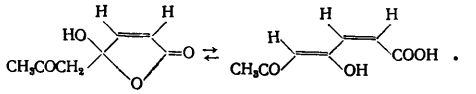
Scheffold [17] obtained the cyclic chloride, 5-chloro-2,5-dihydro-5-methylfuran-2-one (XIVa), by the action of thionyl chloride on *trans*-β-acetylacrylic acid (XIIIa):

(XIII) (XIV) (XVB) (XVA)

R = (a) CH_3; (b) $t\text{-}C_4H_9$; (c)

Careful hydrolysis of the chloride yields *cis*-β-acetylacrylic acid in the ring form (XVa–B). This compound is converted back to the thermodynamically more stable *trans*-isomer (XIIIa) on sublimation. Crystalline *cis*-β-acetylacrylic acid could not be obtained in the open-chain form (XVa–A).

Sugiyama [71] accomplished the isomerisation XIIIa → → XVa–B by exposing *trans*-β-acetylacrylic acid to a mercury lamp. An attempt to obtain the open-chain *cis*-isomer by the isomerisation of *trans*-β-pivaloylacrylic acid (XIIIb) was also unsuccessful. These experiments confirm the extraordinary stability of the cyclic forms of *cis*-β-acylacrylic acids.



Kuchař [76] obtained a mixture of three isomers—(XIIIc), (XVc–A), and (XVc–B)—on acidifying an alkaline solution of 4-adamant-1'-yl-4-oxobut-2-enoic acid, but the evidence for the presence of the open-chain *cis*-form (XVc–A) was not entirely rigorous. Equilibria between cyclic and open forms were observed in acid and alkaline solutions of the 2- or 3-halogenated acids [33,37], but unfortunately the configurations of the open-chain isomers were not established.

Bowden [19] obtained unexpectedly high tautomeric equilibrium constants for *cis*-β-pivaloylacrylic acid (K_T = 94 ± 11) and *cis*-4-adamant-1'-yl-4-oxobut-2-enoic acid (70 ± 8) in 80% aqueous 2-methoxyethanol solution.

The introduction of methyl groups [6,7,17,19,21] and also of halogen atoms [33,77] as substituents attached to the olefinic carbon atoms in *cis*-β-acylacrylic acids stabilises the

cyclic form, a substituent having a greater effect in the β than in the α position.

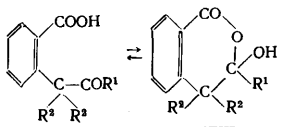
Simultaneous ring–chain and keto–enol tautomerism has been observed [78] in maleoylacetone:

(XVIB) (XVIA)

δ-Aldehydo- and δ-Keto-carboxylic Acids (Id–g)

Pentin [40,79–81] used infrared and ultraviolet spectroscopy to investigate the series of saturated δ-keto-carboxylic acids

(XVII)



(R^1 = Alk, Ar; R^2 = H, Alk, Ar; R^3 = H, Br)

and found that they had the open-chain structure in the crystalline state, and when dissolved in chloroform and in carbon tetrachloride the cyclic form was not detected. The chain of three sp^3 carbon atoms evidently does not create sterically suitable conditions for the cylic form to be produced. Unfortunately, δ-keto-carboxylic acids having *gem*-dialkyl substituents on the chain carbon atoms were not examined, although they might be expected, by analogy with γ-keto-carboxylic acids [16], to form the cyclic isomers.

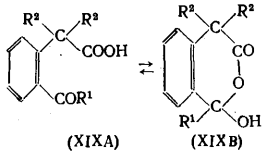


Table 2.

Compound	R^1	R^2	Structure in cryst.	Compound	R^1	R^2	Structure in cryst.
XVIII a	C_6H_5	H	A	XIX a	CH_3	H	A
XVIII b	CH_3	CH_3	B	XIX b	C_6H_5	H	A
XVIII c	C_6H_5	CH_3	B	XIX c	CH_3	CH_3	B
				XIX d	C_6H_5	CH_3	A

Infrared spectroscopy has been used to investigate the structure of crystalline *o*-acetonylbenzoic and *o*-phenacylbenzoic acids (XVIIIa–c in Table 2) and *o*-acylphenylacetic acids (XIXa–d) [82–85]

(XVIIIA) (XVIIIB)

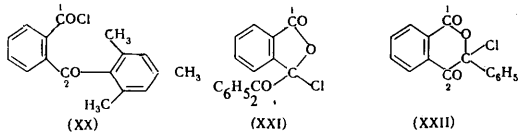
(XIXA) (XIXB)

The state of equilibrium IA ⇌ IB was analysed [82,83] only from the results of chemical reactions. The acids (XVIIIb, c) and (XIXc), which contain a *gem*-dimethyl fragment, have the cyclic structure in the crystalline state. The acid (XIXd), in which the keto-group is conjugated with two aromatic rings, has the open structure, in spite of the presence of a *gem*-dimethyl fragment. Among the acids (XVIIIa–c) and (XIXa–d) only *o*-αα-dimethylacetonylbenzoic acid (XVIIIb) reacts with diazomethane to form a cyclic ester, 3-methoxy-3,4,4-trimethylisochroman-1-one. In solutions of the acid (XVIIIb) the equilibrium is supposed [83] to be displaced completely in favour of the cyclic form, owing to the absence of conjugation between the keto-group and the aromatic ring.

Spectroscopic [30] and indirect chemical [57,86,87] evidence indicates that tautomeric equilibrium is established in the 8-acylnaphthoic acids (Ig) and is absent from *o'*-acylbiphenyl-*o*-carboxylic acids, which have the open structure (Ih–A). Data on the possible formation of cyclic isomers by completion of a seven-membered ring are contradictory [88,89].

III. ACID CHLORIDES

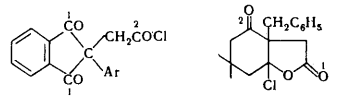
Chlorides of γ-Aldehydo- and γ-Keto-carboxylic Acids (IIa–c)



Formation of the cyclic modification of chlorides of keto-carboxylic acids is favoured by factors making the carbon atom of the COCl group more strongly electrophilic and the oxygen atom of the keto-group more strongly nucleophilic. Because the former is so strongly electrophilic, owing to the $-I$ effect of the chlorine atom, chlorides of β-acylpropionic [22,90–94], *o*-acylbenzoic [45,51,55,56,95–101], and *cis*-β-acylacrylic [6,7,17,25,75,76] acids have exclusively the cyclic chloro-lactone structure (IIB) in the crystalline state and in solution.

The infrared spectra of γ-chloro-lactones (IIa–c–B) are characterised by an intense lactonic carbonyl band at 1820–1805 cm^{-1} (IIa–B), 1810–1790 cm^{-1} (IIb–B), and 1800–1760 cm^{-1} (IIc–B, the band sometimes being split [17]) and the absence of absorption by the ketonic or aldehydic carbonyl in the range 1725–1660 cm^{-1}. The state of aggregation of the compound has little effect on the carbonyl frequency of γ-chloro-lactones.

γ-Chloro-lactones form two series of derivatives with nucleophilic reagents [6,98,102]. Since it has been demonstrated spectroscopically that the tautomeric equilibrium IIA ⇌ IIB is not present in solutions, the formation of two series of derivatives can be explained by the presence of two electrophilic centres—the carbon atoms of the C=O and C–Cl groups—in the chloro-lactone molecule. Stronger nucleophiles polarise the carbonyl group and attack its carbon atom preferentially; weaker nucleophiles attack the carbon of the C–Cl group. Reactions with primary amines, for example, yield *N*-monosubstituted amides (IIIA or IIIB) in the former case; in the latter case amino-lactones are obtained, for which in solution the tautomeric equilibrium amino-lactone ⇌ imino-acid is established [6,102].



o-2′,4′,6′-Trimethylbenzoylbenzoyl chloride has the open structure (XX) owing to steric shielding of the keto-group [55,57,96], and is almost the sole exception [57] in the series of *o*-acylbenzoyl chlorides. It has recently been established [101] that, contrary to early investigations [61], both chlorides of benzil-*o*-carboxylic acid have cyclic

structures, 3-benzoyl-3-chlorophthalide (XXI) and 3-chloro-1,4-dioxo-3-phenylisochroman (XXII).

2-Aryl-1,3-dioxoindan-2-ylacetyl chlorides (XXIII) [42] have the open structure, whereas 2-benzyldimedon-2-ylacetyl chloride [103], in which conjugation of the keto-groups with the aromatic ring is absent, has the cyclic structure (XXIV).

Chlorides of δ-Aldehydo- and δ-Keto-carboxylic Acids (IId–g)

These compounds have been insufficiently studied [104]. The action of thionyl chloride on γγ-dimethyl-δ-oxo-δ-phenylvaleric acid yields a mixture of chlorides of open and cyclic structure [105]. The chlorides of the acids (XVIIIb, c) and (XIXc, d) have the cyclic structure (XXV) and (XXVI) [82,83].

(XXV) (XXVI)

$\nu_{C=O}$ 1750 cm^{-1} (CCl_4) $\nu_{C=O}$ 1770 cm^{-1} (CCl_4)

8-Acylnaphthoyl chlorides [57,87] have the cyclic structure (IIg–B), whereas chlorides of o'-acylbiphenyl-o-carboxylic acids [57] have the open structure (IIh–A).

IV. AMIDES AND HYDRAZIDES

Amides and Hydrazides of γ-Aldehydo- and γ-Keto-carboxylic Acids (IIIa–c)

Amides of aldehydo- and keto-carboxylic acids, whether unsubstituted or substituted on the nitrogen atom, are more stable than the acids themselves, which in solution undergo the tautomerisation IA ⇌ IB. There are a few reports [37,106–108] that the tautomeric equilibrium IIIA ⇌ IIIB is established in solution, but in most cases both isomeric forms (IIIA) and (IIIB) are stable in neutral solvents at room temperature. Aldehydo- and keto-amides are most often obtained only in a single form—(IIIA) or (IIIB)—and only rarely can both isomers be isolated [99,106,109–113].

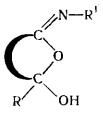
‡Infrared bands (cm^{-1}) of solutions in dioxan. Integrated intensities in practical units of measurement 10^4 M^{-1} cm^{-2} (ln) indicated in parentheses.

The true structure of β-acylpropionamides and o-benzoylbenzamides could not be established by chemical methods. Erroneous conclusions were reached also from polarographic examination [114], the use of which to establish the structure of compounds capable of isomeric or tautomeric conversions requires caution [115]. The structures of these compounds, first prepared long ago, have since been refined by spectroscopic methods [102,106,116–118].

Infrared spectroscopy is most often used to establish reliably the structures (IIIA) and (IIIB) (general frequency data will be found in Refs. 99 and 106). The main evidence of the open structure (IIIA) in N-monosubstituted keto-amides is the presence [55,99,106,110,117,119,120] of the amide-II band (νC-N + δN-H) at 1570–1520 cm^{-1}. In the spectra of the crystalline compounds [99,120], moreover, comparatively narrow N—H bands at 3500–3150 cm^{-1} (IIIA) are easily revealed and distinguished from the broad O—H bands (IIIB) in the same region. Because of angular strain of the >C=O bonds in the five-membered ring the C=O band of the lactam in the spectra of solutions of (IIIa–c–B) is shifted to higher frequencies than the amide-I band in the spectra of the open isomers (IIIa–c–A). The integral intensities of these bands have been measured [91,100,101,103,109,110,121].

The use of carbonyl bands to establish the structure of crystalline keto-amides is complicated by the presence of stable intermolecular hydrogen bonds O–H...O=C (lactam) in the lattice of the cyclic isomers (IIIB). [17,55,99–103,110,121] This displaces the carbonyl band to lower frequencies (than in the spectra of solutions) or even splits it into two bands representing absorption by bound and by free C=O groups. The band due to a bound carbonyl group in the spectra of crystalline o-benzoylbenzamides, which actually have the cyclic structure [99,102,106,118], was wrongly accepted [98] as the total band (νC=O ketone + νC=O amide) in the form (IIIb–A). This led to the erroneous conclusion [27,98] that these amides have the open structure in the crystalline state. For the same reason the infrared spectra of crystalline cis-β-aroylacrylamides were wrongly interpreted [122].

The frequencies and intensities of the carbonyl bands of hydroxy-lactams (IIIB) must be measured in dioxan. As a result of the formation of intermolecular hydrogen bonds with the solvent

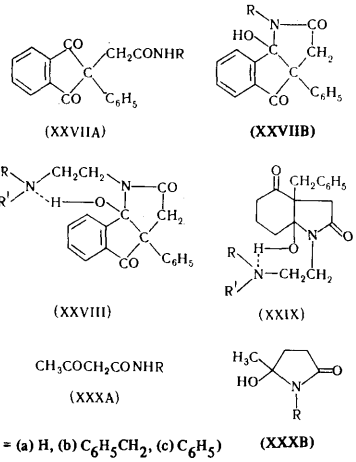


only the absorption due to free carbonyl groups is observed in the spectrum. A shift to lower frequencies, increase in intensity, and splitting of the carbonyl bands in the spectra of hydroxy-lactams (IIIB) due to intermolecular hydrogen bonds have been observed [110,118] also in solvents of low polarity. They were incorrectly explained [119] by the equilibrium IIIA ⇌ IIIB.

The infrared spectra of crystalline amides having the open structure (IIIA) exhibit [35,55,99,110] a decrease in frequency and splitting of the amide-I band with an increase in frequency of the amide-II band. This indicates the presence of intermolecular hydrogen bonds N–H...O=C (in the amide). Complications in interpreting the infrared spectra of the open isomers (IIIA) in solution sometimes arise from the coalescence of the two carbonyl bands (ketone and amide) [55,56,99,117,119]. In such cases it is advisable to measure the integrated intensity of the whole band [99]. It has been possible in this way to explain the infrared spectra of o-benzoyl-N-t-butylnitrobenzamides [56]. In these spectra the two carbonyl bands appear together and, furthermore, the amide-II band overlaps the band due to antisymmetric stretching vibration of the nitro-group.

In addition to infrared spectroscopy, ultraviolet spectroscopy [6,51,107,117,119,123-125], proton magnetic resonance spectra [37,106,108,111-113,119,123,124], and mass-spectrometric data [113] have been used to establish the structure of keto-amides.

It has recently been reported [108] that the presence of a third tautomeric form



(IIIC)

in solutions of $\beta\beta$-dimethyl-γ-oxovaleramides [125] has been confirmed by proton magnetic resonance. However, formation of this isomer is improbable, so that more rigorous proof, using different spectroscopic methods, is necessary for its confirmation.

Formation of the cyclic modification of keto-amides (IIIB) is favoured by factors tending to make the ketonic carbon atom more strongly electrophilic, make the nitrogen atom more strongly nucleophilic, and bring the two groups closer together in space. *N*-Unsubstituted β-formyl-β-R-butyramides have the ring structure [126,127]. β-Acylpropionamides have either the cyclic or the open structure depending on the substituent R attached to the keto-group and the substituent R′ on the nitrogen atom, and also on the presence or absence of alkyl substituents on the chain carbon atoms [48,50,93,106,111-113,116,117,119-121,124,128-138].

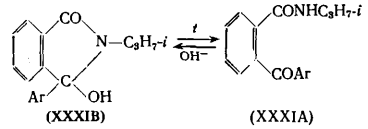
Chiron [119] has found that, among a broad group of β-aroylpropionamides, only the *N*-methylamides§ have the ring structure, which he explains by hyperconjugation. Another explanation has been suggested [139]: the stability of the cyclic form improves with increase in the $+I$-effect of the substituent R′ on the nitrogen atoms ($H < CH_3 < C_2H_5 <$ iso-C_3H_7). On the other hand, increase in the effective steric volume of R′ destabilises the ring form [48,99,110,140]. Aggregating these effects—electronic and steric—may lead to enhanced stability of the cyclic forms of *N*-methylamides. As would be expected, the introduction of methyl groups at the α and β carbon atoms in β-acylpropionamides improves the stability of the cyclic forms [120,124].

Both isomers stable in solution were first obtained [110,141] in a series of *N*-alkyl-1,3-dioxo-2-phenylindan-2-yl-acetamides (XXVIIA) and (XXVIIB). The isomerisation XXVIIB → XXVIIA is accomplished by heating [37,106], and the isomerisation XXVIIA → XXVIIB by the catalytic action of bases. Owing to thermal isomerisation several hydroxylactams (XXVIIB) have two melting points: i.e. after fusion the substance crystallises again, and then melts at the melting point of the corresponding open isomer (XXVIIA). Sometimes it is quite impossible to determine the true melting points. The presence of bulky s- or t-alkyl groups on the nitrogen atom prevents the isomerisation XXVIIA → XXVIIB. [48] The cyclic forms of the *N*-2-dialkylaminoethylamides (XXVIII) and (XXIX) are stabilised by an intramolecular hydrogen bond [109,121,142].

(XXVIIA) (XXVIIB)

(XXVIII) (XXIX)

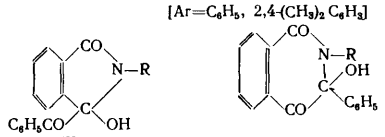
CH_3COCH_2CONHR



(XXXA)

(R = (a) H, (b) $C_6H_5CH_2$, (c) C_6H_5) (XXXB)

Both isomers have been isolated in the case of the γ-oxovaleramides (XXXa) [106], (XXXb) [111,112], and (XXXc) [113]. Flitsch [106] used proton magnetic resonance to detect the equilibrium A ⇌ B in a solution of the amide (XXXc–A) in hexadeuteriated dimethyl sulphoxide. Later Prelog [113], having isolated both isomers (XXXc–A) and (XXXc–B), established that they were stable at room temperature in the crystalline state and in neutral solvents. Equilibrium was observed between the two forms in the presence of acidic (trifluoroacetic acid) or basic (pyridine) catalysts and also on the surface of silica gel. Isomerisation of the open into the ring form (XXXc–A → XXXc–B) was effected by passing a solution in chloroform through a column packed with an acid ion-exchange resin (Dowex-50W).

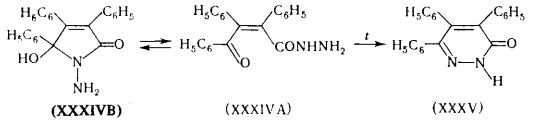


N-Monosubstituted and unsubstituted *o*-formylbenzamides [97,106,111,143,144] and *o*-acylbenzamides [50,51,55,56,99-102,106,111,118,145-152] exist, both in the crystalline state and in solution, in the cyclic form as 3-hydroxy-3-R-2-R′-isoindolinones. Exceptions are *N*-t-alkyl-*o*-acylbenzamides [55,56,99,100] and unsubstituted and *N*-substituted *o*-2′,4′,6′-trimethylbenzoylbenzamides [55], which have the open structure because of steric shielding of the nitrogen atom or the ketonic carbon atom, and are incapable of the transition IIIA → IIIB under the conditions of basic catalysis.

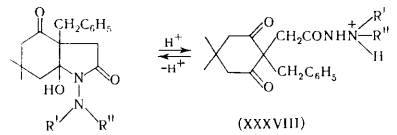
3-Aryl-3-hydroxy-2-isopropylisoindolinones (XXXIB) isomerise thermally into the *N*-isopropylamides (XXXIA) [55,99]. The reverse isomerisation is effected by the action of bases. Increase in the bulk of the substituent on the nitrogen atom facilitates the isomerisation B → A, for thermal isomerisation cannot be achieved in the case of 2-n-alkyl-3-hydroxy-3-phenylisoindolinones [99].

(XXXIB) (XXXIA)

[Ar = C_6H_5, 2,4-$(CH_3)_2C_6H_3$]

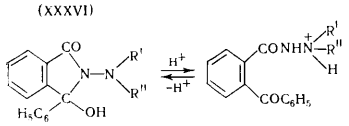


(XXXII) (XXXIII)



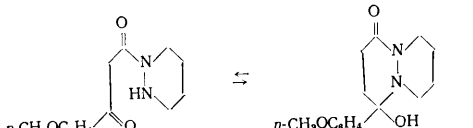
Amides of benzil-*o*-carboxylic acid [101] have been obtained in the cyclic forms (XXXII) and (XXXIII). The six-membered rings are easily isomerised into the more stable five-membered forms (XXXIII → XXXII).

§This relates to *N*-methylamides only of those acids in which the substituted aromatic ring does not possess a strong $+C$-effect.

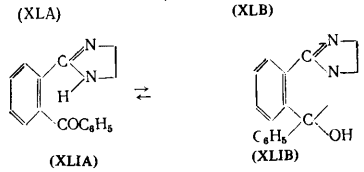


All known *cis*-β-acylacrylamides, whether *N*-substituted or unsubstituted, have the cyclic structure of 5-hydroxy-5-R-1-R′-$\Delta^{3,4}$-pyrrolin-2-ones both in the crystalline state and in solution [6,17,75,123,125,153–159]. Conclusions on the open form of the amides [122,156,160–162] need to be reconsidered.

(XXXIVB) (XXXIVA) (XXXV)



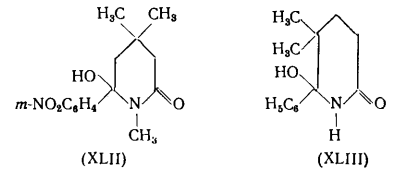
(XXXVI) (XXXVIII)



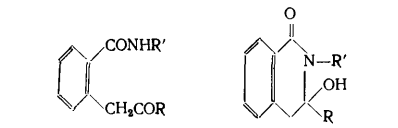
(XXXVII) (XXXIX)

cis-β-Benzoyl-αβ-diphenylacrylohydrazide [75], which has the cyclic structure (XXXIVB), is converted thermally into the dihydro-oxopyridazine (XXXV). *N′N′*-Dialkyl-1,3-dioxo-2-phenylindan-2-ylacetohydrazide (XXVII: R = NR′R″) have been obtained in both isomeric forms A and B [107]. Their interconversion has been accomplished. It is curious that isomerisation of the open into the ring form is effected merely on boiling solutions in ethanol by the autocatalytic action of the basic group NR′R″. Slow establishment of the equilibrium A ⇌ B was observed in solution. *N′N′*-Dialkylhydrazides of 2-benzyldimedon-2-ylacetic and *o*-benzoylbenzoic acids [104] have the cyclic structure (XXXVI) and (XXXVII). When the dialkylamino-group is protonated, the strong $-I$ effect of the substituent on the nitrogen atom effects ring opening with formation of the protonated hydrazides (XXXVIII) and (XXXIX). Deprotonation is accompanied by the reverse process.

(XLA) (XLB)



(XLIA) (XLIB)



Little study has been made of the structure of *NN′*-dialkylhydrazides of γ-keto-carboxylic acids, where a six-membered ring may be formed. The open form (XLA) predominates [163] in the case of the hexahydropyridazide of β-*p*-methoxybenzoylpropionic acid. The tautomerism XLIA ⇌ XLIB is observed [164] in solutions of *o*-benzoyl-benzamidine.

Amides of δ-Keto-carboxylic Acids (IIId–g)

Spectroscopic examination of a wide range of γ-acyl-butyramides, their *N*-monosubstituted derivatives [120,165], and amides of more complex δ-keto-carboxylic acids [35] has shown that they all have the open structure (IIIA). Only two δ-keto-amides, with a chain of three sp^3 carbon atoms between the carbamoyl and ketone groups, are known in the ring form (XLII) [120] and (XLIII) [166]; both compounds have *gem*-dimethyl groups.

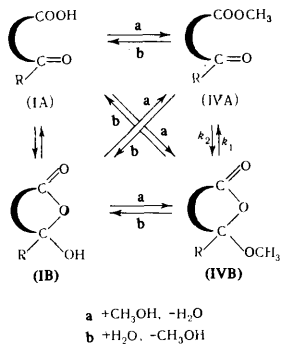
(XLII) (XLIII)

(XLIVA) (XLIVB)

(R=C_6H_5, R′=iso-C_3H_7; R=*p*-$CH_3OC_6H_4$, R′=C_2H_5, *n*-C_3H_7, *n*-C_4H_9, $C_6H_5CH_2$) (R=C_6H_5, R′=CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, $C_6H_5CH_2$; R=*p*-$CH_3OC_6H_4$, R′=CH_3)

N-Monosubstituted *o*-phenacylbenzamides [139,167,168], with the exception of the *N*-isopropylamide, have the ring structure (XLIVB). Among *o*-*p*′-methoxyphenylbenzamides, in which the ketonic carbon atom becomes less strongly electrophilic under the influence of the +*C*-effect of the methoxy-group, only the *N*-methylamide has the cyclic structure (XLIVB). The isomers (XLIVA) and (XLIVB) are stable in solution. Among *N*-monosubstituted *o*-acylphenylacetamides (IIIf) α-*o*-benzoylphenyl-α-phenylacetanilide has been prepared [169], and exists in the open form.

The structure of the amides (IIIg, h) has not been studied, but it may be supposed that the amides (IIIg) will have the cyclic structure, and (IIIh) the open structure.

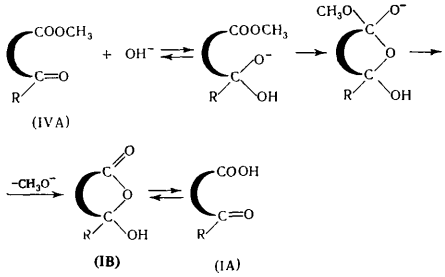


V. ESTERS

Esters of β-acylpropionic [18,22,94,170], *o*-acylbenzoic [27,31,34,51,52,57,61,98,171–175], *cis*-β-acylacrylic [6,7,13,19,21,69,74,75,176–178], and δ-keto-carboxylic [30,82,83,179,180] acids are obtained both in open (IVA) and in cyclic (IVB) forms. Both isomers are stable in neutral solvents at room temperature. The equilibrium IVA ⇌ IVB is established in acid and alkaline media [52,74,94,171] or on heating [177]. Isomers are identified by ultraviolet spectroscopy [7,22,31,34,69,125,177], infrared spectroscopy [7,13,21,22,27,30,34,51,58,69,70,75,82,83,98,171,177], and proton magnetic resonance [21,22,30,31,52,69,70,92,171,177,181], and are determined by gas–liquid chromatography [171], infrared spectroscopy [34], and proton magnetic resonance [31,52,171].

Methods are known [1] for esterifying keto-carboxylic acids to obtain predominantly a certain isomer. Open isomers are formed by the action of alkyl halides on the silver salts [7,25,69] or by esterification of the acids with diazomethane [7,22,30,34,69,75,82,177]. Exceptions have been observed [83] in the latter reaction. Beška [177] found that the esterification of β-formyl-αβ-dihalogenoacrylic acids with diazomethane at 0°C yields predominantly the open isomers, but at higher temperatures the proportion of cyclic isomers in the reaction mixture increases. Thermal isomerisation IVA → IVB of the open esters of these acids has been accomplished. Esters of open structure are obtained by esterifying *o*-formyl- and *o*-acetyl-benzoic acids with methyl iodide in the presence of potassium carbonate [174,182].

Cyclic esters are formed predominantly by the alcoholysis of chloro-lactones (IIB), which is usually conducted in the presence of pyridine [6,7,27,51,57,75,82,83,98,170,180], though urea has also been suggested [183] as base. Cyclic γ-oxovaleric esters are obtained by the alcoholysis of α-angelica lactone [170].



Scheme 2

a +CH_3OH, -H_2O
b +H_2O, -CH_3OH

The esterification of keto-carboxylic acids by alcohols in the presence of hydrogen chloride (Fischer–Speyer method) or other acid catalysts usually leads to mixtures of the two isomers. Their content in the mixture depends on the duration of the reaction (kinetic or thermodynamic control) and is determined by the equilibria [31,52,171,184] in Scheme 2 (intermediate stages not indicated). This scheme shows the possibility of nucleophilic attack at both electrophilic carbon atoms in the molecules (IA) and (IB). Kinetic investigations show [173,174,178,185–191] that a neighbouring carbonyl group accelerates the hydrolysis of esters (IVA). The reason for this effect is that the nucleophilic reagent first attacks the ketonic carbon atom, and the mechanism of alkaline hydrolysis is represented by Scheme 3.

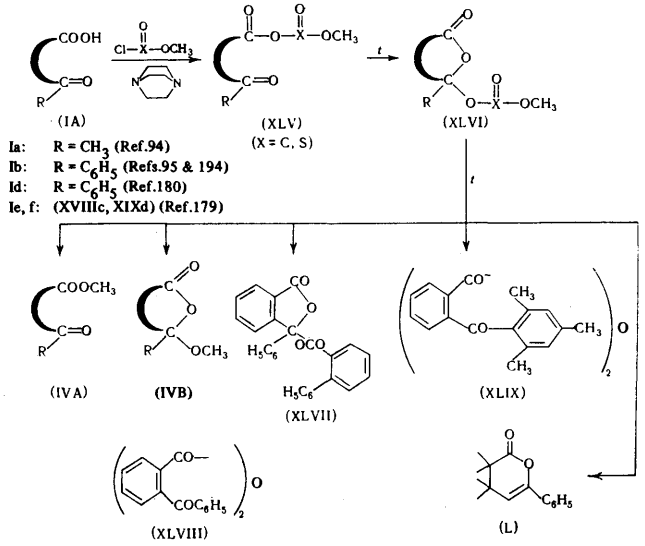
Scheme 3

In thermodynamically controlled Fischer–Speyer esterifications, in the presence of a large excess of methanol, the equilibrium IVA ⇌ IVB plays a decisive role in determining the isomeric composition of the products. Bowden [171] has studied this reversible isomerisation of methyl *o*-acylbenzoates (IVb: R = CH_3, C_2H_5, iso-C_3H_7, t-C_4H_9, $C_6H_5CH_2$, and C_6H_5) under conditions of acid and alkaline catalysis. The equilibrium constants (K = [IVB]/[IVA] = 1.7–8.1 with R = Alk and 0.02 with R = C_6H_5) are almost equal for acid and alkaline catalysis. They increase with the size of the substituent R (CH_3 < C_2H_5 < < iso-C_3H_7 < t-C_4H_9). The explanation is that a bulky substituent destabilises the open form, since the COR group is forced out of the plane of the aromatic ring [43]. The equilibrium constants correlate with the Taft steric constants E_S of the substituents ($\delta = -0.35 \pm 0.05$). The isomerisation rate constants k_1 and k_2 (rates of formation of IVA and IVB) have been measured under conditions of acid catalysts, and are found to fall with increase in the volume of the substituent R, while $k_2 > k_1$. Increase in the volume of R has a greater effect on k_1 than on k_2 (δ = 0.9 and 0.5 respectively).

Unfortunately, such detailed investigations are lacking for esters of other keto-carboxylic acids. However, the equilibrium constant of the reversible isomerisation of keto-carboxylic esters and the tautomeric equilibrium constant K_T of the free acids are determined in general by the same structural factors. There is thus a correlation between the predominant tautomeric form of keto-carboxylic acids and the predominant isomer in the products of thermodynamically controlled Fischer–Speyer esterifications [31]. This explains the preferential formation of open isomers (IVA) in the esterification of γ-oxovaleric [94,170], *o*-aroylbenzoic [27,31,34,52,57,173], *cis*-β-aroylacrylic [21,178], and γ-benzoylbutyric [180] acids. *o*-Acylbenzoic (Ib: R = H, Alk) [20,31,171], *cis*-β-acylacrylic (Ic: R = H, Alk) [69,176,177], and 8-acetylnaphthoic [30] acids, for which the tautomeric equilibrium IA ⇌ IB is displaced towards the cyclic form, on esterification yield predominantly the ring isomers (IVB). The isomerisations IVA → IVB (*cis*-β-formylacrylic esters [177]) and IVB → IVA (γ-oxovalerates [94,170], *o*-aroylbenzoates [51], and *cis*-β-aroylacrylates [7,74]), catalysed by acids or alkalis, are explained by displacement of the equilibrium IVA ⇌ IVB towards the thermodynamically more stable isomer.

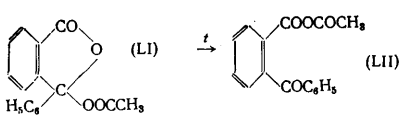
VI. MIXED ANHYDRIDES

Mixed anhydrides of keto-carboxylic acids (VA) and their more frequently encountered cyclic isomers—acyloxy-lactones (VB)—are easily identified by infrared spectroscopy. The infrared spectra of the former (VA) are characterised by anhydride carbonyl bands at ~1820 and 1750 cm^{-1} and carbonyl absorption of the aldehydo- or keto-group at 1725–1660 cm^{-1}. Absence of absorption in the range 1725–1660 cm^{-1} is the main evidence for the ring structure (VB). The infrared spectra of (Va–c–B) contain a lactonic carbonyl band at 1810–1775 cm^{-1} and a carbonyl band of the acyloxy-group at 1770–1745 cm^{-1}; [7,22,25,35,69,75,192] sometimes the two bands overlap [35].



The acylation of β-formylpropionic [22], *o*-acylbenzoic [35,57,59,192,193], *cis*-β-acylacrylic [7,25,69,75,176], and α-*o*-benzoylphenyl-α-methylpropionic [84] acids by means of acetic anhydride [22,59,69,176,193] or mixtures of the anhydride with pyridine [35,57,75,84,192], sodium acetate [192], acetic acid in the presence of sulphuric acid [7], or acetyl or benzoyl chloride [25] gives acyloxy-lactones (VB). A specific method for their preparation is the reaction of cyclic chloro-anhydrides (IIB) with silver acetate [7,193].

Mixed anhydrides of open structure (VA) are obtained by the action of a keten on β-formylpropionic acid [22], by the acetylation of β-benzoyl-αβ-diphenylpropionic acid with acetic anhydride [75], and by the action of acetyl chloride on silver benzil-*o*-carboxylate [193].



Newman [94–96,180,194] prepared mixed anhydrides of γ- and δ-keto-carboxylic acids (XLV) by the action of methyl chloroformate or chlorosulphite on the acids in the presence of a base, 1,4-diazabicyclo[2,2,2]octane, or directly on their sodium salts.

Heating converts the mixed anhydrides (XLV) into the cyclic isomers (XLVI) (not in all cases isolated). At higher temperatures the latter undergo pyrolysis to form a mixture of esters (IVA) and (IVB). Pyrolysis of the mixed anhydride (XLV: X = C) obtained from *o*-benzoylbenzoic acid yields not only IVA and IVB but also *o*-benzoylbenzoyl anhydride (XLVII), in which one acid radical has the cyclic structure, and the other the open structure. The anhydride (XLVII) is obtained also by the action of ethoxyacetylene on *o*-benzoylbenzoic acid, by the reaction of 3-chloro-3-phenylphthalide (IIb–B: R = C_6H_5) with *o*-benzoylbenzoic acid in the presence of pyridine [95], and by the action of sodium nitrite on 3-chloro-3-phenylphthalide [98]. The structure (XLVIII) (Scheme 4) had previously been attributed to the anhydride (XLVII) on the basis of ultraviolet spectroscopy [193] and polarographic results [195]. Pyrolysis of the mixed anhydride of *o*-2′,4′,6′-trimethylbenzoylbenzoic acid (XLV: X = C) gives as sole product the anhydride (XLIX). The mixed anhydrides of γ-benzoylbutyric acids and their *gem*-dimethyl derivatives yield unsaturated lactones (L) as well as the corresponding esters (IVd–B).

Scheme 4

Schmid [193] showed that 3-phenylphthalid-3-yl acetate (LI) undergoes thermal isomerisation into the mixed anhydride (LII):

in the opposite direction to that of the mixed anhydrides of methoxyformic acid studied by Newman.

Published information does not reveal the effect of the structure of the acyl residue (the substituent R′ in formula V) on the stability of the mixed anhydrides (VA) and (VB) or the conditions of their isomeric interconversion.

ADDENDUM

Several papers were published while this Review was being prepared for the press, and are briefly surveyed below.

The electronic and steric effects of substituents near the keto-group and in the ring on the position of ring–chain tautomeric equilibrium in a series of aromatic *o*-ketocarboxylic acids have been discussed [196]. The relative reactivities of ring and chain isomers of α-*gem*-disubstituted β-formylpropionic acids and their esters have been studied [197].

The presence of an intramolecular hydrogen bond has been established [198] in *N*-aryl-β-aroylpropionamides. A study has been made of the chemical properties of several *m*-acylbenzamides existing in the ring form [199,200]. Both isomers (IIIA and IIIB) of the 3,4-dimethoxyphenethylamide of 3-oxocycloheptanecarboxylic acid have been isolated [201].

A review [202] lists papers on the use of nuclear magnetic resonance spectroscopy for the study of ring–chain tautomeric phenomena.

Structure and ring–chain isomerism have been studied in amides of β-formylpropionic [203,204] and $\beta\beta$-dimethyl-γ-oxovaleric [205] acids. Both isomers of phenyl *o*-benzoylbenzoate have been prepared [206]. The cyclic isomers of *cis*-β-formylacrylic acids exhibit an extraordinarily strong tendency to associate [207].

The Synthesis of Unsaturated Carbohydrates

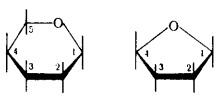
Yu.A.Zhdanov and V.G.Alekseeva

The review deals with modern achievements in the chemistry of unsaturated carbohydrates. The methods of synthesis of these compounds, their use for the preparation of compounds of other classes, and in a few cases their properties have been analysed. A systematic account is given of the available data on the basis of the method employed, i.e. on the basis of the reactions used to form multiple bonds. The methods for the elimination of various groups, Grignard syntheses, the Knoevenagel - Doebner condensation, and the Wittig reaction are analysed in succession. Considerable attention has been devoted to the discussion of conformational effects and reaction mechanisms.
The bibliography includes 204 references.

CONTENTS

I. Introduction 477
II. Structural types and structure of unsaturated carbohydrates 477
III. Methods of synthesis of unsaturated sugars 478

I. INTRODUCTION



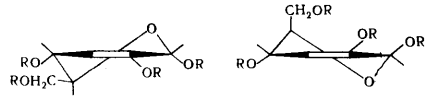
The chemistry of unsaturated monosaccharides has now become an extensive and fairly independent branch of carbohydrate chemistry. The interest in these sugar derivatives is due to the fact that their reactions constitute the basis of convenient methods for the synthesis of many biologically important compounds—deoxy- and amino-sugars, sialic acids, nucleosides, branched carbohydrates, sphingosines, etc.[1,2] Derivatives of unsaturated monosaccharides have been isolated from natural raw materials both in a free form (ascorbic and shikimic acids)[3] and as components of antibiotics (angustmycin[4], blasticidin[5]). Unsaturated carbohydrates are actively involved in the metabolism of the living cell, since the biosynthesis of aromatic compounds is associated with their various reactions[6]. Moreover, it has been shown recently that unsaturated monosaccharides play an important role in the acid and alkaline degradation of carbohydrates[7].

Many methods of synthesis of unsaturated monosaccharides are known at present. (We have covered the literature up to October, 1970, inclusive.) The aim of the present review is a systematic account of experimental data on the basis of reaction types and not the classes of unsaturated carbohydrates as in previous reviews[1,2]. This makes it possible to consider the problem from the standpoint of the general characteristics of organic synthesis.

The most modern carbohydrates nomenclature[8], proposed in 1963, is largely employed in the review, although trivial names are sometimes used.

II. STRUCTURAL TYPES AND STRUCTURE OF UNSATURATED CARBOHYDRATES

The unsaturated carbohydrates known at present can be divided into two independent groups in accordance with their structural features: cyclic and acyclic compounds. The first group has a greater variety of structures. It includes compounds with endo- and exo-cyclic double bonds. Pyranose (I) and furanose (II) structures are known with all possible types of location of the endocyclic double bond, i.e. $\Delta^{1,2}$-, $\Delta^{2,3}$-, $\Delta^{3,4}$-, and $\Delta^{4,5}$-derivatives (compounds of the last type are naturally only pyranose derivatives). $\Delta^{1,2}$-Derivatives are usually called glycals. $\Delta^{1/2}$-Derivatives of pyranoses and furanoses and also $\Delta^{3,4}$-derivatives of furanoses and $\Delta^{4,5}$-derivatives of pyranoses are essentially cyclic vinyl ethers. In compounds with an exocyclic double bond, the latter either adjoins directly the ring [compounds (III)] or is separated from it by one or several carbon atoms [compounds (IV)].

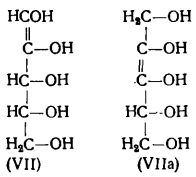


(I) (II)

R=CHR' (III) R = (I) or (II)
RCH=CHR' (IV) R' = H, Alk.

The following classes may be distinguished among unsaturated acyclic carbohydrate derivatives: polyols[1], aldehydo-forms[9], hydrazones[10], nitroalcohols[1], sulphones[11], keten dithioacetals[12], and aldonic[13] and glycaric acids[14].

Since unsaturated carbohydrates contain trigonal carbon atoms (sp^2-hybridisation), their conformations are distorted compared with the usual sugars. This is because the ethylene carbon atoms and two adjacent carbon atoms must be in the same plane. On the basis of general considerations[15], the half-chair conformations H1 and 1H are the most probable for the cyclic unsaturated carbohydrates of types (I) and (II). Recently NMR spectroscopic studies have been begun in order to establish the exact conformations of unsaturated sugars[16-19]. In particular, on the basis of the large coupling constant $I_{4,5}$ (6—10 Hz) for α-anomers of various derivatives of 3-deoxy-D-*erythro*-hex-2-enopyranose, Ferrier[18] suggested the occurrence of H-4 and H-5 diaxial interactions. From this it follows that the above compounds exist preferentially in the H1 conformation (V). β-Anomers of the same carbohydrate derivatives have low values of $I_{4,5}$ (1.5—2 Hz) and therefore are more likely to have the 1H conformation (VI):



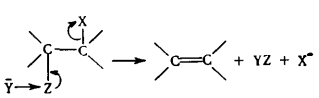
(V) (VI).

(R = Ac, Bz)

The results obtained are consistent with the general hypothesis[6] concerning the relative stabilities of the conformations of the α- and β-anomers (the anomer effect).

In a study and interpretation of the reactivities of unsaturated carbohydrates, account must be taken, together with steric factors, also of the distribution of electron density over their carbon atoms. The first attempt to perform a quantum-mechanical calculation of electron distribution in the molecules of unsaturated carbohydrates was made by Zhdanov and coworkers[20,21]. The results of calculations on endiols of types (VII) and (VIIa) show appreciable positive σ charges on the carbon atoms of the double bond. Structure (VII) may be regarded as analogous to that of a glycal for which attack by a proton on the second carbon atom is typical in electrophilic addition reactions. This may be explained by the fact that the π electron cloud, which interacts initially with the proton, is displaced to the $C_{(2)}$ atom with its high positive charge:

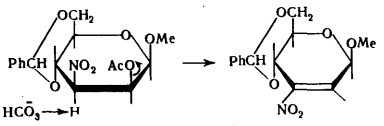
(VII) (VIIa)



III. METHODS OF SYNTHESIS OF UNSATURATED SUGARS

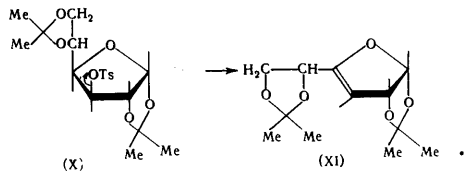
There are two fundamentally different methods for synthesising unsaturated carbohydrates. These are firstly the elimination of various groups from substituted monosaccharides—the classical procedure for the formation of a double bond. Such reactions do not of course involve a rearrangement of the carbon skeleton of carbohydrates. The second method is based on a wide variety of condensations involving the carbonyl group of sugars which take place with a simultaneous increase in the length of the carbon chain.

1. ELIMINATION REACTIONS



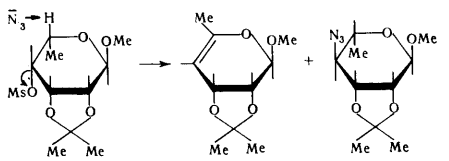
a. $\alpha\beta$-Elimination

Most elimination reactions leading to the formation of unsaturated sugars proceed via an $\alpha\beta$-elimination mechanism:

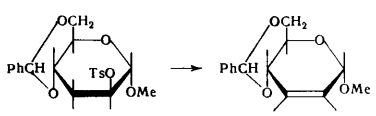


(X = OAc, OTs, OBz; Z = H, Hal).

The E_2 synchronous elimination mechanism, which reduces to a single-stage reaction of a base (Y^-) and the carbohydrate molecule, is the most probable. The most important condition for such eliminations is known to be a *trans*-diaxial disposition of the X and Z groups to be eliminated. Hence it follows that the E_2 mechanism occurs most frequently in rigid cyclic systems. Thus the elimination of acetic acid from the cyclic nitropyranoside (VIII) takes place readily[22,23] in the presence of a weak base such as sodium bicarbonate with a yield of 70—80%. In this case, elimination is evidently facilitated not only by the *trans*-diaxial disposition of the groups eliminated but also by the presence of the nitro-group which increases the acidity of the proton at $C_{(3)}$.

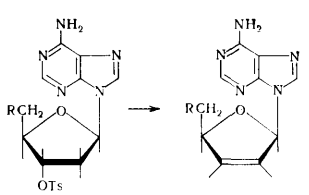


(VIII) (IX)



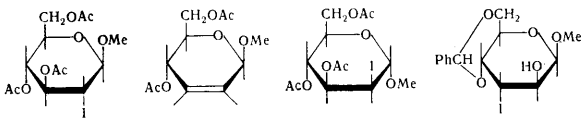
(X) (XI)

When there is no activation of this type, stronger bases are required: soda-lime, alkoxides, and azides. For example, on heating with soda-lime, the furanose (X) is converted[24] into 1,2:5,6-di-*O*-isopropylidene-3-deoxy-α-D-*erythro*-hex-3-eno-1,4-furanose (XI) and treatment of methyl 6-deoxy-1,2,3-*O*-isopropylidene-4-*O*-methanesulphonyl-α-L-talopyranoside (XII) with sodium azide yields[25] an unsaturated product (XIII) together with the azide (XIV) in proportions of 3:1 respectively:



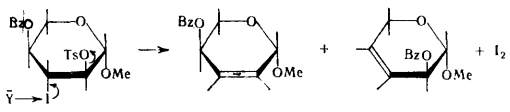
(XII) (XIII) (XIV)

In this case the deoxy-unit serves as the proton donor; other similar examples may be quoted[26,27]:



(XV) (XVI)

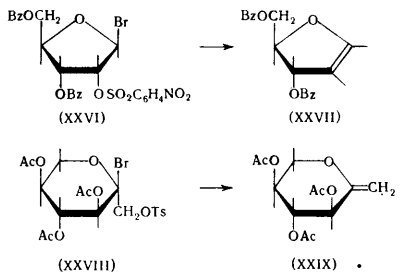
(XVII) (XVIII)



The elimination reaction where the first stage is the elimination of the halide ion (Z = Hal, left column) is also frequently used to form a double bond in the carbohydrate molecule. Thus when the pyranoside (XIX) was treated with $NaCo(CO)_4$, the product was methyl 4,6-di-*O*-acetyl-2,3-dideoxy-β-D-*erythro*-hex-2-enopyranoside (XX). The analogous derivative of mannose (XXI) forms a $\Delta^{2,3}$-unsaturated compound under more severe conditions[28] owing to the *cis*-disposition of the groups eliminated. When an attempt was made to obtain the 2-*O*-methanesulphonyl derivative from the pyranoside (XXII) by treatment with

methanesulphonyl chloride in pyridine, methyl 4,6-*O*-benzylidene-β-D-*threo*-hex-2-enopyranoside was isolated[29]:

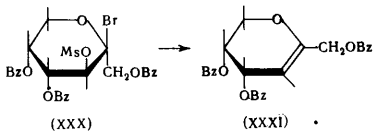
(XIX) (XX) (XXI) (XXII)



Sodium iodide in acetone is very often employed as the nucleophilic agent for the elimination reaction. Dimitrievich and Taylor[30] obtained by this procedure methyl 4-*O*-benzyl-2,3-dideoxy-β-L-glyceropent-2-enoside (XXIV) from the 3-iodo-derivative (XXIII) and also isolated the side product (XXV). The formation of two isomeric unsaturated sugars (XXIV) and (XXV) can be explained by the allyl rearrangement of the benzyl group in (XXIV) with formation of an equilibrium mixture of the $\Delta^{2,3}$- and $\Delta^{3,4}$-derivatives:

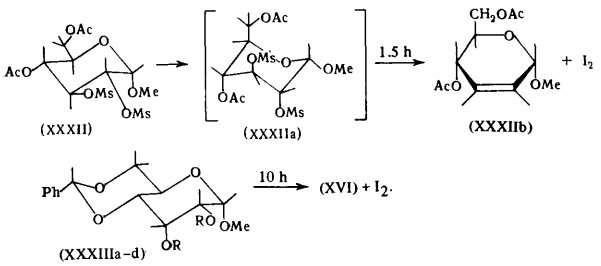
(XXIII) (XXIV) (XXV)

When tosyl derivatives of type (XXVI) are treated with sodium iodide in acetone, an unsaturated sugar (XXVII) and elemental iodine are also formed[31]. In this case the tosyl group is probably replaced by iodine and the resulting iodo-derivative undergoes elimination by the mechanism quoted above.



Using this possibility, Ness and Fletcher[31] obtained the furanal (XXVII) from the tosyl derivative (XXVI). Earlier attempts to synthesise (XXVII) by the usual methods for glycals (zinc in acetic acid) proved to be inapplicable owing to the lability of (XXVII) in acid media:

(XXVI) (XXVII)

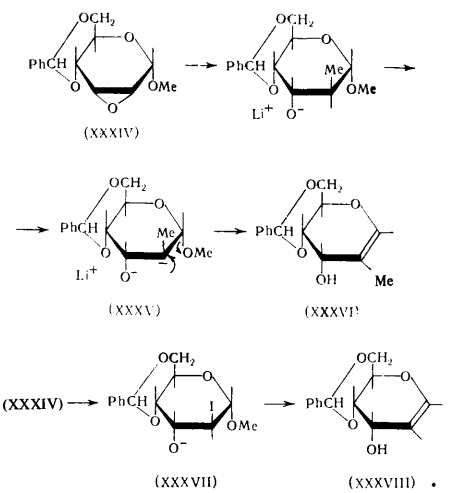


(XXVIII) (XXIX)

Using the method Ness and Fletcher, Tokuyama et al.[32] obtained 3,4,5-tri-*O*-acetyl-1,2-dideoxy-L-*xylo*-hex-1-enopyranose (XXIX) from 3,4,5-tri-*O*-acetyl-1-*O*-(*p*-tosyl)-α-L-sorbopyranosyl bromide (XXVIII). The glycal (XXXI) with an endocyclic double bond was obtained similarly from the bromide (XXX):

(XXX) (XXXI)

In this case, when both groups eliminated are identical (X = Z = OTs, OMs, *p*-$BrC_6H_4SO_2$, or *p*-$NO_2C_6H_4SO_2$), more severe conditions are required for the elimination process. Tipsom and Cohen[34] suggested that a 20% solution of sodium iodide in dimethylformamide (DMF) in the presence of zinc must be employed. The first step in this reaction is probably the replacement by iodine of one of the groups eliminated with formation of an iodide (see above). The latter is attacked by the nucleophilic agent, yielding an unsaturated derivative. Zinc is required to bind the iodine eliminated, which can add under the reaction conditions (boiling DMF) to the unsaturated carbohydrate formed, reducing its yield. Methyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (XXXIIIb) was obtained in this way from methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methanesulphonyl-α-D-*gluco*-pyranoside (XXXII).[35] It is interesting to note that the elimination reaction with 4,6-*O*-benzylidine derivatives (XXXIII, a—d) is much slower[36] than with (XXXII), probably because the presence of the rigid *trans*-junction of two six-membered rings prevents the methanesulphonyl groups from occupying the *trans*-diaxial positions. The 4,6-diacetates (XXXII) can have the $C_{(1)}$-conformation (XXXIIa) at the instant of reaction, where both methanesulphonyl groups are *trans*-diaxial, which of course accelerates the elimination reaction.

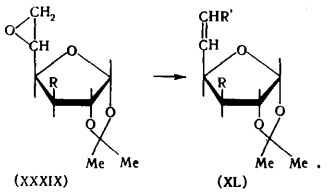


(XXXII) (XXXIIa) (XXXIIb)

(XXXIIIa-d)

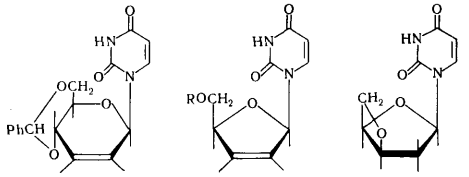
(a) R = Ts; (b) R = Ms; (c) R = *p*-$NO_2C_6H_4SO_2$; (d) R = *p*-$BrC_6H_4SO_2$.

Epoxides are frequently used to synthesise unsaturated carbohydrates. *trans*-Diaxial ring-opening products (the Reichstein rule) are probably formed as intermediates in this process and subsequently undergo elimination by the mechanism described above (p. 478). For example, Horton and coworkers[36] treated the epoxide (XXXIV) with potassium ethylxanthate and obtained the $\Delta^{2,3}$-derivative (XVI). On the other hand, the use of methyl-lithium to open the ring of the epoxide (XXXIV) unexpectedly leads to the $C_{(2)}$-substituted glycal (XXXVI),[37-39] instead of the $\Delta^{2,3}$-derivative (XVI). The mechanism of this reaction has not been elucidated. The first stage is probably *trans*-diaxial opening of the epoxide ring with subsequent elimination of a proton from $C_{(2)}$. The resulting dianion (XXXV) is subsequently converted into the glycal (XXXVI) following the loss of a methoxide ion, as shown in the scheme below:



(XXXIV) (XXXV) (XXXVI)

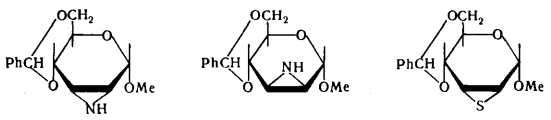
(XXXVII) (XXXVIII)



If the methyl-lithium solution contains lithium iodide, the initial epoxide (XXXIV) gives rise initially to the iodohydrin (XXXVII), with subsequent formation of the glycal (XXXVIII).

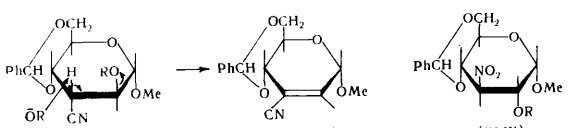
Methyl-lithium has been successfully used[40] also to open the terminal epoxy-ring of 5,6-anhydro-3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucose (XXXIX, R = OBz) to give the unsaturated furanoside (XL, R = OBz, R′ = H):

(XXXIX) (XL)



Unsaturated nucleosides (XLI) and (XLII, R = Bz, Tr, or H) have been synthesised by the reaction of epoxides with various nucleophilic agents[41,42]:

(XLI) (XLII) (XLIII)

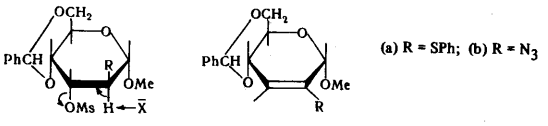


Horwitz et al.[43] described an interesting case of the ring opening of the anhydro-derivative (XLIII) by potassium t-butoxide in dimethyl sulphoxide (DMSO), which is also accompanied by the formation of the unsaturated nucleoside (XLII, R = H).

Together with the reactions of epoxides, the interaction of aziridine compounds of types (XLIV) and (XLV) and of the thi-iron (XLVI) with nucleophilic agents also gives rise to the corresponding unsaturated derivatives[36,44]:

(XLIV) (XLV) (XLVI)

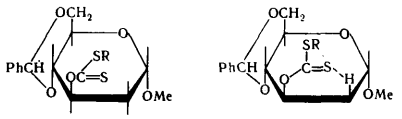
All the reaction discussed above are examples of *trans*-elimination, characteristic of reactions proceeding via the E_2 mechanism. However, since, apart from steric conditions, the elimination reaction is controlled also by electronic factors, cases of *cis*-elimination are likewise possible. They occur mainly when the group eliminated (usually the proton) is activated by an electron-accepting substituent. For example, when an attempt was made to carry out epimerisation at the second carbon atom of the pyranoside (XLVII) with sodium methoxide, the cyano-olefin (XLVIII) was obtained instead of the expected epimer[45]:



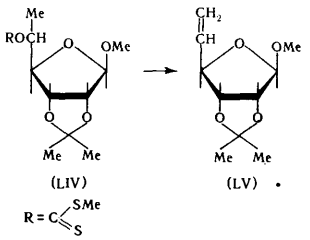
(XLVII) (XLVIII) (XLIX)

(R = H, Ac, Ts)

Despite the *cis*-disposition of the groups eliminated in the nitroglycoside (XLIX), the elimination process can nevertheless be carried out[46-50] albeit under more severe conditions (alumina in boiling toluene) than for the galactose derivative (VIII).



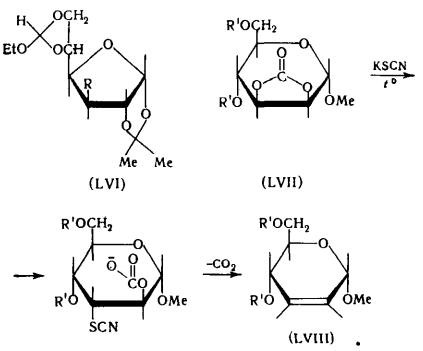
Hanessian[51] described the formation of the vinyl thioether (LIa) from compound (La) and an unsaturated azide (LIb) from (Lb) via *cis*-elimination under the influence of 1,5-diazabicyclo[4,3,0]nonene in dry DMSO. Owing to the large bulk of the nucleophilic agent employed, the competing nucleophilic substitution reaction was ruled out:



(a) R = SPh; (b) R = N_3

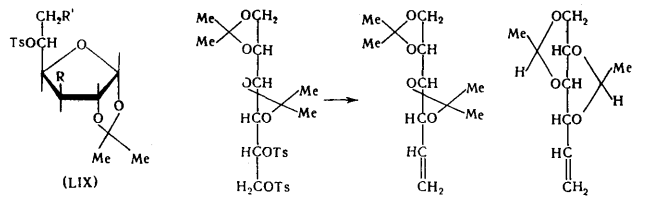
(L) (LI)

A classical example of *cis*-elimination in carbohydrates is the pyrolysis of sugar xanthate esters (the Chugaev reaction). Under these conditions, the hydrogen of the deoxy-units is as a rule involved in the elimination process. Thus the xanthates (LII) and (LIV) yield[52,53] methyl 4,6-*O*-benzylidene-α-D-*threo*-hex-2-enopyranoside (XVI) and methyl 2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranoside (LV). *cis*-Elimination can be readily accounted for by the formation of a six-membered intermediate transition state (LIII):



(LII) (LIII)

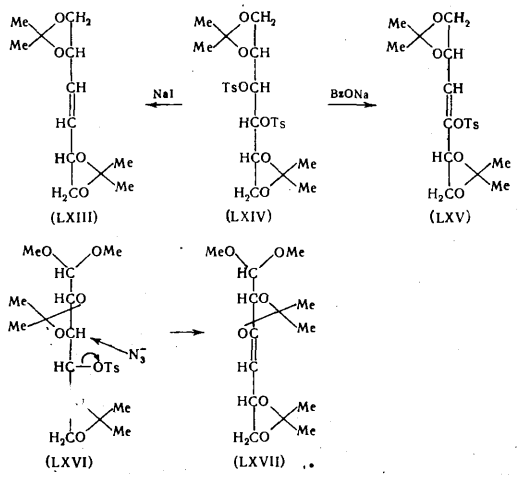
(LIV) (LV)



An unusual method for the conversion of a glycol group into a double bond involves the hydrolysis of cyclic orthoformates on heating the latter with acids. The furanoside (LVI) was converted in this way into an olefin (XL, R = OMe, or OCH_2Ph, R′ = H). Klemer and Mersmann[55] employed cyclic sugar carbonates to synthesise unsaturated carbohydrates. By treating methyl α-D-*manno*-pyranoside 2,3-carbonate (LVII) *in vacuo* at 120°C with potassium thiocyanate, they obtained the unsaturated methyl α-D-*manno*-pyranoside (LVIII). According to the mechanism proposed by the authors, in the first stage nucleophilic substitution takes place at $C_{(3)}$ with subsequent formation of (LVIII) and carbon dioxide:

(LVI) (LVII) (LVIII)

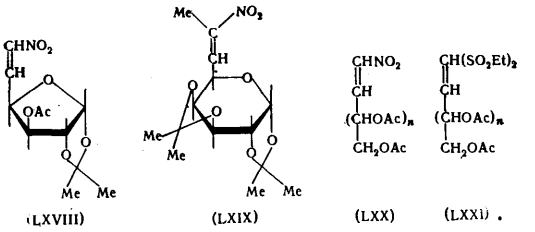
(R = H, COOBzl)



In cyclic systems, the *trans*-diaxial disposition of the groups eliminated, which is necessary for a successful elimination reaction, restricts the choice of the starting compound. Since in acyclic carbohydrate derivatives there is a possibility of free rotation of the substituents about the single carbon—carbon bond, this limitation is removed. In particular 5,6-dideoxy-1,2-*O*-isopropylidene-*α*-D-*xylo*-hex-5-enofuranose (XL, R = OH, R′ = H) and its 3-azido- and 3-*O*-methanesulphonyl derivatives are readily formed[56-58] when 5,6-ditosyl derivatives of type (LIX) are treated with sodium iodide in acetone. The mannitol (LXI) and sorbitol (LXII) derivatives have been synthesised similarly. According to the data of Foster and Overend[59], the reaction mechanism is similar to that quoted on p. 479.

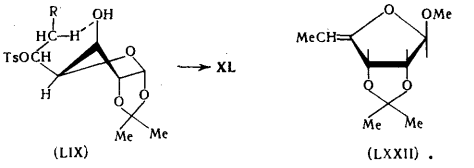
(LIX) (R = OH, N_3, OMs; R′ = OTs, OMs) (LX) (LXI) (LXII).

When 1,3:2,4-di-*O*-ethylidenesorbitol 5,6-dinitrate is employed, an olefin (LXII) is also formed[60]. The initial reaction stage may be the replacement of the primary nitro-group by iodine but this intermediate has not been isolated. It is probably unstable and may be immediately converted into the olefin (LXII).



Since the secondary *p*-toluenesulphonyl group is replaced by iodine with considerable difficulty (p. 479), the synthesis of the polyol (LXIII) with a non-terminal double bond from compound (LXIV) requires more severe conditions of the kind used earlier for cyclic ditosyl derivatives of type (XXXIIIa). For example, Tipson and Cohen[34] converted 1,2:5,6-di-*O*-isopropylidene-D-mannitol 3,4-di(toluene-*p*-sulphonate) (LXIV) into 1,2:5,6-di-*O*-isopropylidene-*trans*-hex-3-ene-D-*threo*-1,2,5,6-tetrol (LXIII) by heating (LXIV) with a 20% solution of sodium iodide in DMF in the presence of zinc. Treatment of the product (XLIV) with sodium benzoate in DMF yields[61] an olefin (LXV) having a different structure, the formation of which can be accounted for by the classical E_2 mechanism.

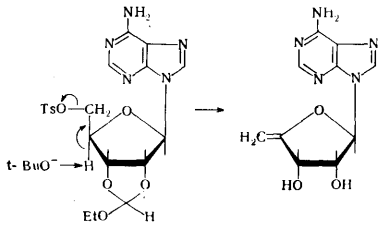
(LXIII) (LXIV) (LXV) (LXVI) (LXVII).



Paulsen[62,63] showed that, in the synthesis of the azide from the 4-*O*-tosyl derivative (LXVI), an unsaturated polyol (LXVII) is formed together with the expected product.

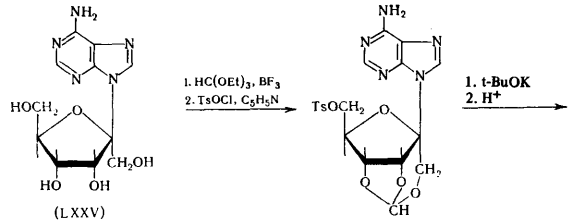
An increase of the acidity of the proton eliminated facilitates the elimination process. Thus the formation[64-71] of unsaturated nitro-compounds (LXVIII), (LXIX), and (LXX) proceeds equally readily regardless of the configuration of the initial carbohydrate. Acetic acid is eliminated even more readily[11,72], from sugar sulphone acetates with formation of a product of type (LXXI):

(LXVIII) (LXIX) (LXX) (LXXI).



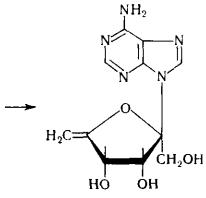
The elimination may be facilitated by the simultaneous involvement of adjacent groups[73-76]. For example, a number of workers[73,75] have shown that in the synthesis of olefins (XL, R = OH, R′ = OBz, H, or OTr) from 5-*O*-tosyl derivatives (LIX, R = OH, R′ = H, Bz, or OTr), the concentration of sodium methoxide employed as a base plays a significant role. In particular, an increase of the concentration of methoxide ions from one to four moles per mole of the initial tosyl derivative (LIX) increases sharply the yield of the olefin (XL). On the other hand, when the substituent at $C_{(3)}$ is resistant to alkalides, the corresponding olefin is hardly formed. All the above remarkable findings can be accounted for by the involvement in the elimination reaction of the hydroxyl at $C_{(3)}$ which facilitates the partial dissociation of the hydrogen atom at $C_{(6)}$, as shown in the scheme below:

(LIX) (LXXII).



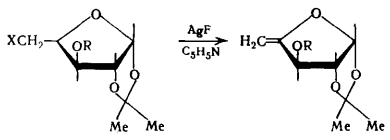
One should expect the elimination of the proton at $C_{(4)}$, but in this case the *trans*-orientation of the proton of the tosyl group is impossible owing to steric hindrance of the substituent at $C_{(3)}$. The reason for the formation[74] of the derivative (LXXII) on treating methyl 6-deoxy-2,3-*O*-isopropylidene-5-*O*-tosyl-*β*-D-*allo*-furanoside (LIV, R = Ts) with alkoxides in hot alcohol is understandable from this standpoint. Here the simultaneous involvement of the hydroxy-group at $C_{(3)}$ is naturally impossible, while, on the other hand, the *trans*-orientation of the tosyl group and of the hydrogen atom at $C_{(4)}$ is quite likely, since the asymetric $C_{(3)}$ atom has the D-configuration. Compound (LXXII) is interesting because it is a structural analogue of the carbohydrate component of the nucleosidic antibiotic decoyinine[4] (XXVI). A closer analogue of decoyinine

(LXXIV) has been synthesised[77] from the 5-*O*-tosyl derivative (LXXIII):

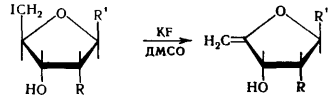


(LXXIII) (LXXIV)

On the basis of these preliminary studies, Robins and coworkers[77] achieved an elegant synthesis of decoyinine (LXXVI) from psicofuranine (LXXV):



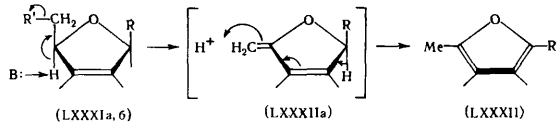
(LXXV)



(LXXVI)

5-Halogeno-derivatives (LXXVII, a and b) and (LXXIX) can be employed[78-82], apart from tosyl derivatives, to introduce an exocyclic 4-methylene group:

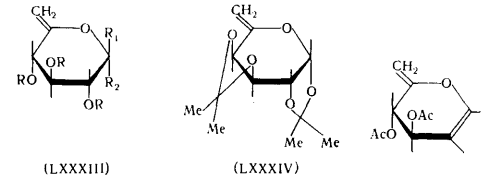
(LXXVII) (LXXVIII)



(LXXVIIa), L-configuration at $C_{(4)}$, X = I, R = H
(LXXVIIb), D-configuration at $C_{(4)}$, X = Br, R = Me

(LXXIX) (LXXX)

(a) R = H, R' = thymidyl
(b) R = OH, R' = uridyl

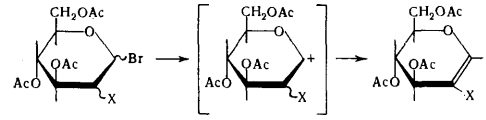


When an attempt was made to carry out a similar reaction[27,83] with unsaturated nucleosides of (LXXXI, a and b), only the furan derivatives (LXXXII) were obtained. Probably the product (LXXXIIa) formed initially readily loses a proton at $C_{(1')}$, yielding a stable nucleoside of type (LXXXII):

(LXXXIa, b) (LXXXIIa) (LXXXII)

(LXXXIa), R = thymidyl, R' = I
(LXXXIb), R = adenyl, R' = H or SEt.

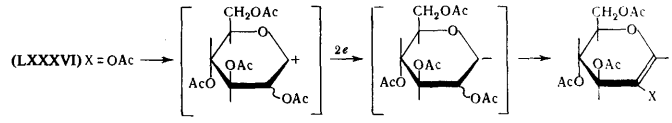
The elimination of hydrogen halides under the influence of silver fluoride in pyridine has been used[1,84] also in the syntheses of numerous unsaturated derivatives of aldoses and aldosides of types (LXXXIII), (LXXXIV), and (LXXXV):



(LXXXIII) (LXXXIV)

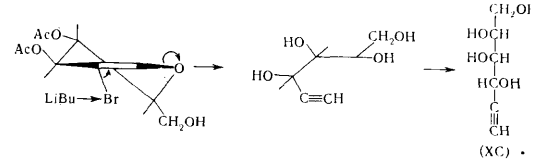
(a) R = Ac; R_1 = H, R_2 = OMe;
(b) R = Ac; R_1 = OMe, R_2 = H

(LXXXV).



The well known derivatives of 2-hydroxyglycals (LXXXVIII) can be obtained by the elimination of hydrogen bromide from glycosyl bromides under the influence of diethylamine[1]:

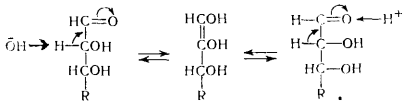
(LXXXVI) (LXXXVII) (LXXXVIII).



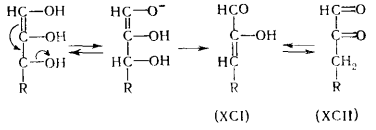
(X = OAc, NO, NO_2, Cl, SCN)

The rate of elimination of hydrogen bromide increases[85] following the addition of polar solvents. This finding is consistent with the E_1 mechanism via the intermediate sugar cation (LXXXVII), which the authors proposed. The elimination of hydrogen bromide from glycosyl bromides of 2-deoxy-sugars can yield an important class of unsaturated hydrocarbons—glycals (LXXXVIII, X = H). However, this reaction is of no preparative value, since the initial 2-deoxyglycosyl bromides are themselves obtained from glycals. The latter are usually synthesised by treating acetohalogenoses (LXXXVII, X = OAc) with zinc dust in acetic acid. As in the synthesis of 2-hydroxyglycals, the dissociation of the initial glycosyl bromide results in this case in the intermediate formation[1,86] of the sugar cation (LXXXVII, X = OAc). Subsequently a zinc atom transfers two electrons to this cation. The resulting carbanion (LXXXIX) is stabilised by the elimination of an acetate ion with formation of the glycal (LXXXVIII, X = H):

(LXXXVI) X = OAc (LXXXVII) (LXXXIX) (LXXXVIII).



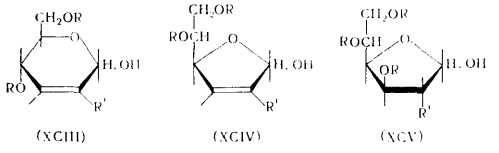
The 2-bromoglycal (LXXXVIII, X = Br) can be subjected[87] to a repeated elimination reaction by treatment with an excess of butyl-lithium. This results in the formation D-*lyxo*-hex-5-yno-1,2,3,4-tetritol (XC). The reaction constitutes a new method of synthesising carbohydrates with triple bonds:



(XC).

b. β-Elimination

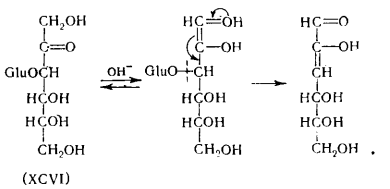
Many important unsaturated carbohydrates can be obtained as the result of 1,3-elimination reactions characteristic of all β-hydroxyaldehydes and β-hydroxyketones. These reactions, frequently referred to as β-elimination, are catalysed by both acids and bases. Their first stage is 1,2-enolisation, which accounts for the acid–base type of catalysis of these processes:



Next follows the elimination of the hydroxyl at $C_{(3)}$ with formation of the enol (XCI) which is in tautomeric equilibrium with the 3-deoxy-2-ketoglycose (XCII):

(XCI) (XCII)

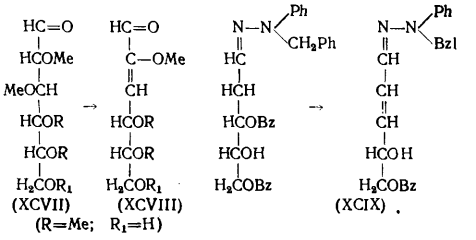
The enol (XCI) can be isolated on a preparative scale only in the presence of a substituent at $C_{(2)}$, which prevents the conversion of (XCI) into (XCII). For example, in the presence of calcium hydroxide 2-*O*-methyl-D-glucose gave a high yield[88,89] of the 2-*O*-methyl ether of the enol, which exists, according to NMR spectroscopic data, as a mixture of the pyranose (XCIIIa) and furanose (XCIVa) forms, with the latter predominating:



(XCIII) (XCIV) (XCV)

(a) R = H, R' = OMe; (b) R = Me, R' = OMe
(c) R = Ac, R' = NHAc

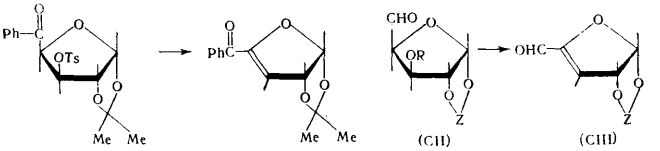
(a) R = Me, R' = OMe
(b) R = Ac, R' = NHAc.



Under the influence of lime water, 2,3,5,6-tetra-*O*-methyl-D-glucose (XCVa) is rapidly converted[90,91] into the unsaturated derivative (XCIVb). On treatment with alkalies, the glucosamine derivative (XCVb) yields[92] the enamine (XCIVc).

The rate of β-elimination is determined by many factors. Thus, 2,3-di-*O*-methylglucose is converted into the enol much faster than 2-*O*-methylglucose. Hence, in order to accelerate β-elimination, it is necessary to have a substituent at the third carbon atom. Disaccharides, particularly 3-*O*-substituted derivatives, exhibit a similar behaviour. For example, 3-*O*-glucopyranosyl-D-fructose (XCVI) undergoes β-elimination in the presence of calcium hydroxide 23 times faster than D-fructose[93,94]. This also accounts for the extremely high sensitivity of such disaccharides to alkaline hydrolysis:

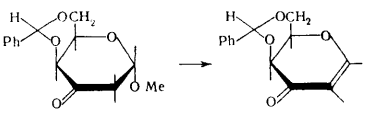
(XCVI)



One of the factors controlling the rate of β-elimination is probably the concentration of the acyclic carbonyl form of the sugar, since this species is in fact involved in the enolisation reaction. Numerous experimental data confirming this hypothesis are now available. For example, 2,3,4,5-tetra-*O*-methylglucose (XCVII), which is distinguished by an enhanced content of the acyclic carbonyl form owing to the instability of the septanose ring, is very labile in alkalies. According to Anet's data[95], it is fully converted into the enol (XCVIII) after 2 min:

(XCVII) (XCVIII) (XCIX)
(R=Me; R_1=H)

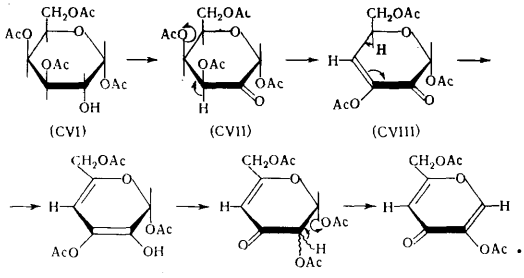
2-Deoxy-sugars and pentoses, in which the content of the aldehydo-form is higher than in hexoses, show a very high tendency[93] to undergo β-elimination. This explains the formation of unsaturated hydrazones of type (XCIX) when attempts are made to prepare the hydrazones of 2-deoxy-sugars.



Naturally, fixed acyclic forms of hydrocarbons (the aldehydo-forms) undergo β-elimination most readily, which is sometimes employed for preparative purposes. For example, Anet[9] obtained the derivative (XCVIII, R = R_1 = Me) from the methylated aldehydo-form of glucose (XCVII, R = R_1 = Me) and Inch and Rich[96] synthesised the unsaturated ketone (CI) by heating the ketoaldose (C) with sodium carbonate in DMF. It was also shown that the dialdose derivative (CII) undergoes a similar reaction in the presence of alkalies with formation[97] of an αβ-unsaturated aldehyde (CIII):

(C) (CI) (CII) (CIII)

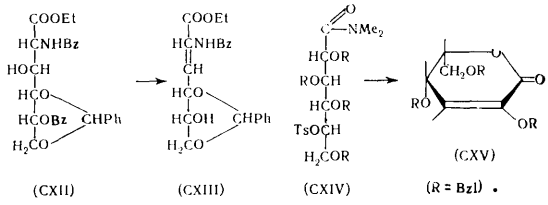
(R = Ts, Bzl; Z = CMe_2, C_6H_{10}).



The group removed in the β-elimination reaction can also be the hydroxymethyl group at the glycosidic centre. Thus, in the presence of acids, the aldoketose (CIV) has been converted[98] into the derivative (CV):

(CIV) (CV)

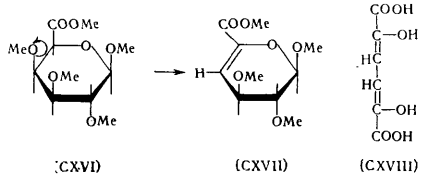
Double β-elimination is possible in some cases. In particular, in the oxidation of the tetra-acetate (CVI) with DMSO in acetic anhydride in order to obtain the ketose (CVII), the diacetate of kojic acid (CXI) was obtained[99] in 84% yield. This unexpected result can be explained as follows. The ketone (CVII) formed initially undergoes β-elimination, yielding the acetate of the ketoenol (CVIII). The latter enolises further with formation of the acetate (CIX) in which the acetyl group undergoes intramolecular migration from $C_{(3)}$ to $C_{(2)}$. This results in the formation of the isomer (CX), which yields (CXI) after repeated



β-elimination. Since kojic acid does not contain an asymmetric carbon atom, any monosaccharide can be used to prepare it in this way:

(CVI) (CVII) (CVIII)

(CIX) (CX) (CXI)

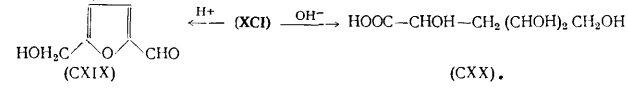


Apart from unsaturated aldoses and ketoses, unsaturated uronic, aldonic, and glycaric acid can be synthesised by the β-elimination reaction. The process proceeds via a mechanism analogous to that described above but is catalysed as a rule by bases (pyridine, sodium methoxide) or acetic anhydride. Thus methanesulphonation of ethyl 2-benzamido-4,6-*O*-benzylidene-5-*O*-benzoyl-2-deoxy-D-gluconate (CXII) led to the isolation of the unsaturated ether[1] (CXIII) instead of the expected 3-*O*-methyl derivative[1]:

(CXII) (CXIII) (CXIV) (CXV) (R = Bzl).

Treatment of the amide (CXIV) with potassium acetate in DMF gave[100] the product (CXV), which has the structure of an αβ-unsaturated lactone. A multistage mechanism has been proposed for this unusual reaction, but it requires further evidence.

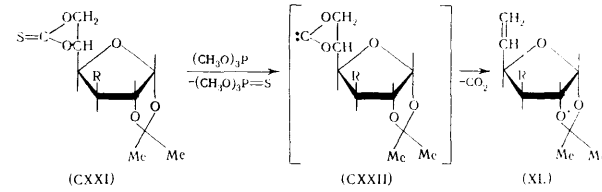
It was shown above (see p. 483) that the hydrogen atom at $C_{(4)}$ in furanoses of types (C) and (CII) is acidic owing to the adjoining ring oxygen atom and an electron-accepting group. It is therefore not surprising that uronic acids can also undergo β-elimination in the presence of bases. Best results were obtained[101-103] by treating 2,3,4-tri-*O*-methyl derivatives of type (CXVI) with sodium methoxide in methanol:



(CXVI) (CXVII) (CXVIII).

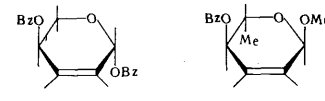
4,5-Unsaturated uronic acids of type (CXVII) have been isolated[104] following the enzymatic degradation of mucopolysaccharides. This is why conditions governing the synthesis of these interesting derivatives and the various related carbohydrates have been so carefully ascertained.

Naturally, in the deacetylation of the acetates of glycaric acids with alcoholic alkali[14], double β-elimination takes place with formation of a dienol (CXVIII).



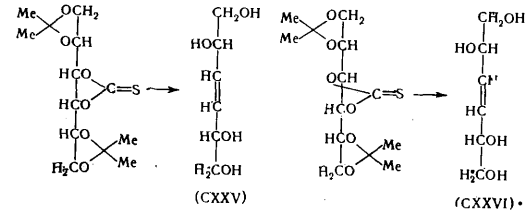
Thus a tendency towards β-elimination is characteristic of a wide variety of carbohydrates. Although frequently undesirable, this property of many sugars can be used for the preparative synthesis of unsaturated carbohydrates. However, the importance of β-elimination is not restricted to this factor. The concept of β-eliminations plays an important role in the explanations of processes such as acid and alkaline degradations of carbohydrates, which are at first sight different. As stated above (p. 483), in both cases the initial intermediate is the enol (XCI), subsequently converted either into furfural (CXIX) (or its derivatives) (acid medium) or into a glycaric acid (CXX) (alkaline medium):

(CXIX) (CXX).



c. Elimination via the Carbene Mechanism

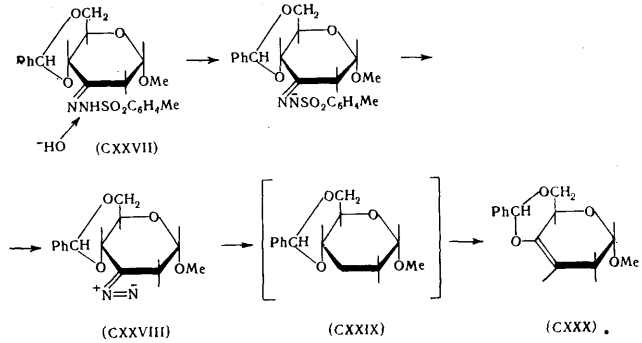
Among the wide variety of methods for synthesising unsaturated sugars, the formation of a double bond on stabilisation of various carbohydrate carbenes plays an important role. Sugar thiocarbonates can serve as a source of carbenes. According to the data of Horton and Turner[105,106], desulphuration of the thiocarbonate (CXXI) takes place under the influence of trimethyl phosphite. The resulting carbene (CXXII) is then stabilised by the elimination of carbonic acid, which yields 5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose (XL, R = OH):



(CXXI) (CXXII) (XL)

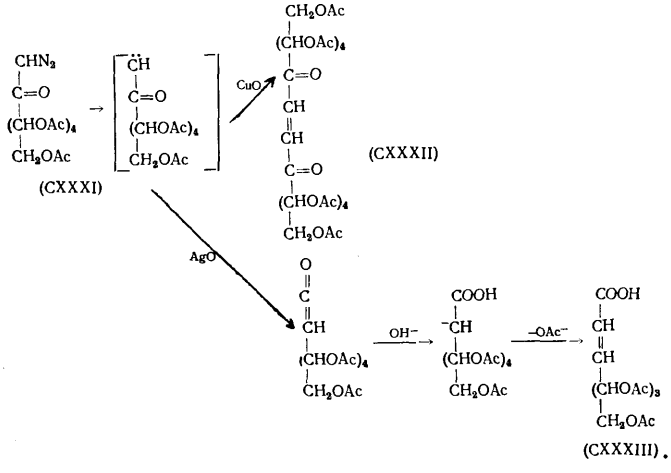
Methyl 4,6-*O*-benzylidene-α-D-*threo*-hex-2-enopyranoside (XVI),[36] benzyl 4-*O*-benzyl-β-L-*glycero*-pent-2-enopyranoside (CXXIII), methyl 4-*O*-benzyl-6-deoxy-α-L-*threo*-hex-2-enopyranoside (CXXIV),[107] and even the Δ²,³-unsaturated nucleoside (XLII, R = Tr)[108] have been obtained similarly:

(CXXIII) (CXXIV).



Haines[109] employed successfully the thionocarbonate method for the synthesis of the *cis*- and *trans*-isomers of 3,4-dideoxy-3,4-didehydro-D-*threo*-hexitol [compounds (CXXV) and (CXXVI)] which were isolated in the hydrolysis of substances characteristic of the blood groups:

(CXXV) (CXXVI).

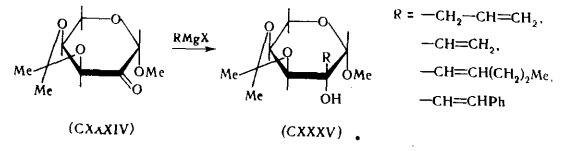


The thionocarbonate method is not the only example of the employment of carbenes for the conversion of carbohydrates into olefins. Ferrier[52] proposed a synthesis of unsaturated sugars based on the capacity of carbohydrates tosylhydrazones to yield olefins in the elimination reaction

catalysed by alkalies (the Wolff—Kishner reaction). The olefin (CXXX) was obtained in this way from the hydrazone (CXXVII). The mechanism of this elimination consists in the initial abstraction of a proton by the alkali and conversion into the diazo-compound (CXXVIII), which decomposes to the olefin (CXXX) via the intermediate carbene (CXXIX):

(CXXVII) (CXXVIII) (CXXIX) (CXXX).

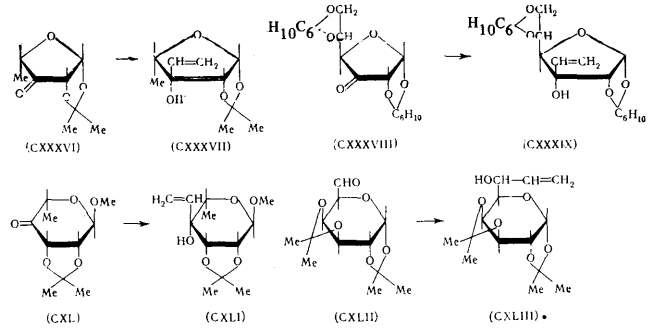
The intermediate formation of a carbene has been observed[110] also in the decomposition of the acetates of 1-diazo-1-deoxyketoses (CXXXI) in the presence of copper(II) oxide, as shown by the isolation of the product (CXXXII). The decomposition of these diazoketoses in the presence of silver oxide (the Wolff rearrangement) yields[111] unsaturated acids (CXXXIII) via the mechanism



(CXXXI) (CXXXII) (CXXXIII).

2. NUCLEOPHILIC ADDITION VIA THE CARBONYL GROUP

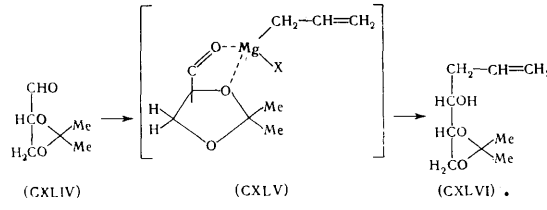
The addition of nucleophilic agents via the carbonyl group of carbohydrates supplements significantly the methods described above for the conversion of sugars into olefins, since, apart from the introduction of a double bond, it involves an increase in the length of the carbon chain of the carbohydrate.



a. Interaction with Unsaturated Grignard Reagents

The condensation of the carbonyl forms of sugars with unsaturated Grignard reagents is as a rule stereospecific and therefore is frequently employed in the syntheses of carbohydrate derivatives; the method is applicable to the synthesis of streptose, 2-deoxyribose, and L-hamamelose. In their studies designed to develop the synthesis of L-hamamelose, Burton et al.[112] obtained a series of unsaturated sugar derivatives of type (CXXXV) by the condensation of methyl 3,4-*O*-isopropylidine-β-D-*erythro*-pentulopyranoside (CXXXIV) with unsaturated Grignard reagents. The preferential formation of isomers with the D-configuration at $C_{(2)}$ can be explained by the fact that the carbonyl group is screened below by the methoxy-group. Therefore only axial attack on the keto-group by the Grignard reagent is possible:

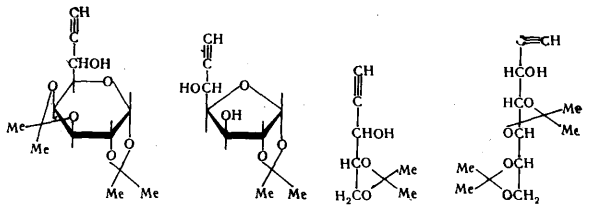
(CXXXIV) (CXXXV).



Unsaturated sugars of type (CXXXVII), (CXXXIX), and (CXLI) have been obtained by a similar procedure from the aldoketoses (CXXXVI), (CXXXVIII), and (CXL) respectively[113–115]:

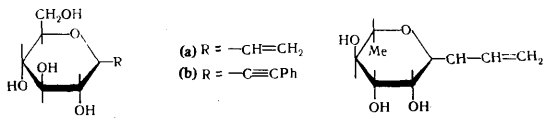
(CXXXVI) (CXXXVII) (CXXXVIII) (CXXXIX)

(CXL) (CXLI) (CXLII) (CXLIII).



Apart from ketones, the aldehydo-forms of carbohydrates have been used for condensation with unsaturated organometallic compounds. The condensation of vinylmagnesium bromide and the dialdose (CXLII) yields[64,116] a mixture of isomeric unsaturated carbohydrates in which compound (CXLIII) predominates. Hough[3] obtained 1,2-*O*-isopropylidinehex-5-ene-1,2,3-triol (CXLVI) from isopropylidene-D-glyceraldehyde (CXLIV) and allylmagnesium bromide. The preferential formation of the isomer with the D-*ribo*-configuration becomes understandable if one postulates the existence of an intermediate magnesium complex (CXLV), proposed earlier[117,118] to account for similar reactions:

(CXLIV) (CXLV) (CXLVI).

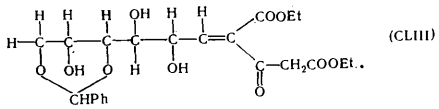


So far the Grignard reaction is the only general method for the introduction of a triple bond into the carbohydrate molecule. Thus the interaction of various aldehydo-forms of sugars with ethynylmagnesium bromide yielded[119–123] a

series of ethynyl derivatives of carbohydrates of the type (CXLVII)—(CL):

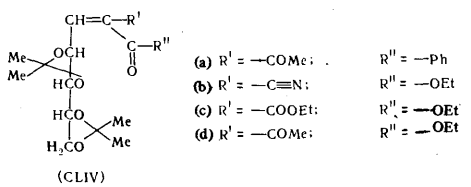
(CXLVII) (CXLVIII) (CXLIX) (CL)

It is interesting to note the preferential formation of the product (CXLVIII) with the D-configuration at $C_{(5)}$, which can also be accounted for by the formation of a magnesium complex analogous to (CXLV). The interaction of acetohalogenoses with unsaturated organomagnesium compounds constitutes a remarkable complication of the Grignard reaction in carbohydrate chemistry. Compounds (CLI, a and b) and compound (CLII) were obtained respectively from acetobromoglucose[124,125] and acetobromorhamnose[126]:



(a) R = —CH=CH$_2$
(b) R = —C≡CPh

(CLI, a and b) (CLII)

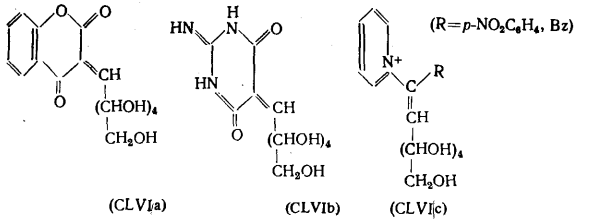


b. The Knoevenagel—Döebner Condensation

The reactivity of the carbonyl forms of sugar have also been used to synthesise unsaturated carbohydrates by the Knoevenagel—Döebner reaction. The interaction of 4,6-*O*-benzylidene-D-glucose with acetonedicarboxylic acid ester in the presence of piperidine yielded[127,128] the unsaturated ketoacid (CLIII):

(CLIII)

Zimmer et al.[129] investigated the reaction of a series of compounds with an active methylene group (benzoylacetone and malonic, cyanoacetic, and acetoacetic esters) with the al-form of 2,3:4,5-di-*O*-isopropylidene-D-arabinose. They isolated the unsaturated branched-chain sugars (CLIV, a—d):



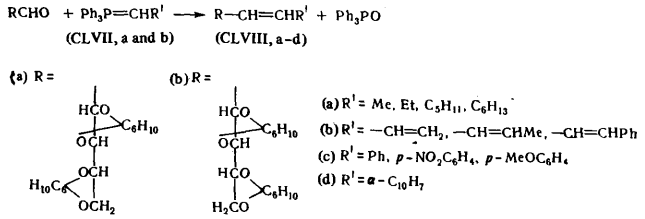
(a) R' = —COMe; R'' = —Ph
(b) R' = —C≡N; R'' = —OEt
(c) R' = —COOEt; R'' = —OEt
(d) R' = —COMe; R'' = —OEt

(CLIV)

When malonic acid was employed, unsaturated acids of type (CLV) were obtained similarly[130,131]:

R—CH=CHCOOH (CLV) (R = sugar residue).

A whole series of unsaturated sugars with heterocyclic groups (CLVI, a—c) have been synthesised by condensing the acetates of the aldehydo-forms of hexoses with the active methylene groups of 5-hydroxycoumarin[132], iminobarbituric acid[133,134], and Kröhnke [sic] salts[135]:

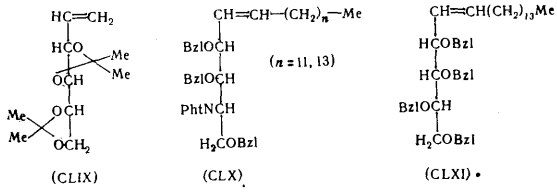


(CLVIa) (CLVIb) (CLVIc)

C-glycosylated 4-hydroxycoumarins (CLVIa) exhibit a high anticoagulant activity, surpassing somewhat heparin in the duration of its activity.

c. The Wittig Reaction

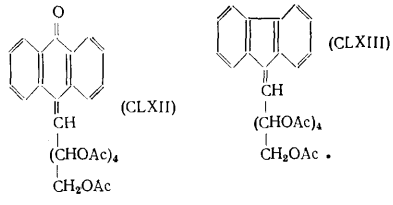
Among other condensation methods for synthesising unsaturated hydrocarbons, the most elegant and modern techniques involve the interaction of phosphoranes with the carbonyl forms of sugars (the Wittig reaction)[136]. The process is interesting because it is universal, takes place under mild conditions, and makes it possible to introduce a double bond into the monosaccharide molecules in a specific position. Intense studies on the conversion of carbohydrates into olefins by the Wittig reaction[137] showed the possibility of the synthesis of a wide variety of unsaturated sugar derivatives—*C*-glycosylated derivatives of aliphatic, aromatic, and heterocyclic compounds, and unsaturated aldoses, ketoses, and aldonic acids. Cyclic and acyclic aldehydo-forms of carbohydrates are usually employed as the carbonyl component. Free monosaccharides are inconvenient, since the products with a polyol residue obtained from them are unstable under the conditions of the Wittig reaction (p. 490). The choice of the aldehydo-form in each specific case depends on the reaction conditions and the reactivity of the phosphorane employed. For example, only the aldehydo-forms with acetal, methyl, and benzyl protecting groups can be employed for condensation[138] with reactive group I phosphoranes, since with acetylated aldehydo-forms of the sugars the phosphoranes are involved in side reactions with the protecting groups. In particular, condensation of 2,3:4,5-di-*O*-cyclohexylidene derivatives of the aldehydo-forms of L-arabinose and D-xylose with a wide variety of group I phosphoranes enabled Zhdanov and coworkers[139-144] to synthesise a series of unsaturated polyols with the general formula (CLVIII, a—d). Depending on the structure of the group R', the products obtained can be assigned to various classes of organic compounds: *C*-glycosylated ethylenes (CLVIIIa), butadienes (CLVIIIb), styrenes (CLVIIIc), and vinylnaphthalenes (CLVIIId):



RCHO + Ph$_3$P=CHR' → R—CH=CHR' + Ph$_3$PO
(CLVII, a and b) (CLVIII, a-d)

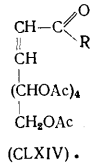
(a) R = (b) R =

(a) R' = Me, Et, C_5H_{11}, C_6H_{13}
(b) R' = —CH=CH$_2$, —CH=CHMe, —CH=CHPh
(c) R' = Ph, *p*-NO$_2$C$_6$H$_4$, *p*-MeOC$_6$H$_4$
(d) R' = α-C$_{10}$H$_7$



Tronchet et al.[145] synthesised similarly 1,2:3,4-di-*O*-isopropylidene-$C_{(1)}$-vinyl-L-*arabino*-tetritol (CLIX). The condensation of the aldehydo-forms of 2,3,5-tri-*O*-benzyl-4-phthalimido-L-ribose and of

2,3,4,5-tetra-*O*-benzyl-L-lyxose with triphenyl-, n-tridecylidene-, or n-pentadecylidene-phosphoranes yielded[146,147] unsaturated derivatives of the polyols (CLX) and (CLXI) used subsequently in the syntheses of phytosphingosines:

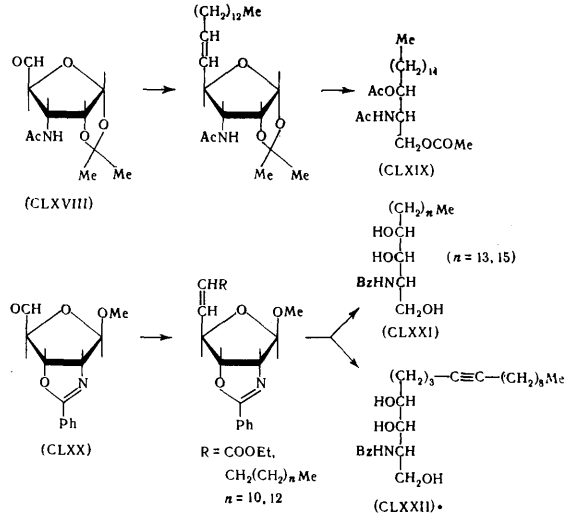


(CLIX) (CLX) (CLXI).

C-Substituted unsaturated polyols can be synthesised also with the aid of certain relatively inactive group III phosphoranes. In this case one can employ the aldehydo-forms of carbohydrate acetates; thus compound (CLXII), similar in structure to natural aloins, was obtained in this way from 10-anthronylidenetriphenylphosphorane and the penta-acetate of the aldehydo-form of D-galactose[148]. A fluorene derivative (CLXIII) was synthesised by a similar procedure[148]:

(CLXII) (CLXIII)

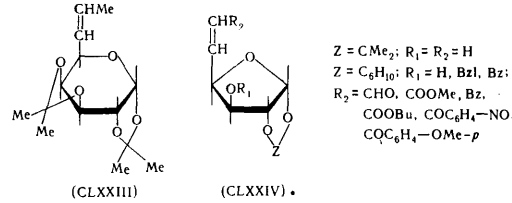
The Wittig reaction is particularly valuable as a method for the introduction into the carbohydrate molecule of active functional groups together with the double bond. One employs for this purpose phosphoranes of the second kind which are stable under the usual conditions and are fairly reactive. Thus the Wittig reaction has proved convenient for the synthesis of higher unsaturated $C_{(1)}$-substituted ketoses. According to the data of Zhdanov and coworkers[149-152], the interaction of the acetates of the aldehydo-forms of hexoses with acetyl-, aroyl-, and acyl (from heterocyclic acids) derivatives of methylene phosphoranes constitutes a preparative synthesis of these interesting carbohydrate derivatives having the general formula (CLXIV):



R=Me, Ph—NO_2-*p*, Ph—Br-*p*, Ph—(OMe)-*p*, $C_6H_2(OMe)_3$, $C_6H_3(OMe)_2$, α-thienyl or fury

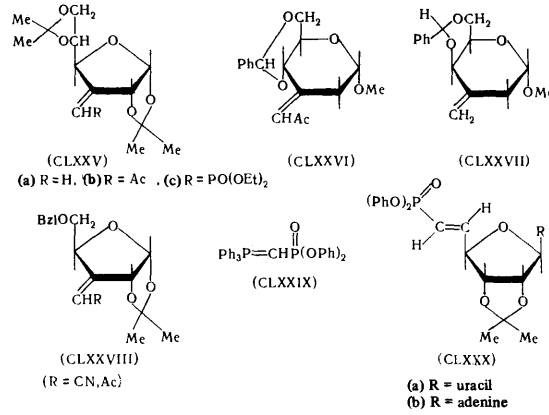
(CLXIV).

The condensation of formylmethylenetriphenylphosphorane with the aldehydo-forms of (CII) and (CLVII) can serve as a general method of synthesising[142,153] unsaturated aldoses of type (CLXIV), which are difficult to obtain:



RCH=CH—CHO (CLXV) (R = carbohydrate residue)

The use of partly protected dialdoses and their derivatives greatly extends the scope of the Wittig reaction in the series of carbohydrates. One then introduces into the condensation with phosphoranes only one aldehyde group, while the second, which is temporarily protected, can be subsequently used for further reactions. The sphinogisines (CLXIX), (CLXXI), and (CLXXII) were synthesised in this way from the corresponding dialdoses (CLXVIII) and (CLXX):



(CLXVIII) (CLXIX) (CLXX) (CLXXI) (CLXXII).

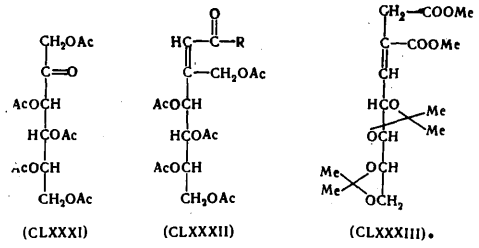
A series of unsaturated aldoses of types (CLXXIII) and (CLXXIV) were obtained also from dialdoses of a similar structure[150,157-159]:

(CLXXIII) (CLXXIV).

Branched-chain sugars (CLXXV)—(CLXXVIII), which are difficult to obtain, have been synthesised from ketoaldoses by the Wittig reaction[157,160-164]:

(CLXXV) (CLXXVI) (CLXXVII)

(a) R=H, (b) R = Ac, (c) R = PO(OEt)$_2$

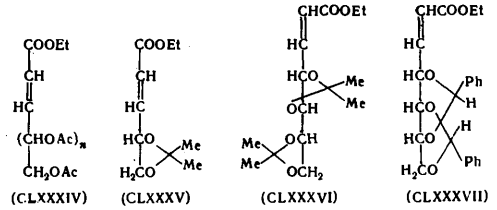


(CLXXVIII) (CLXXIX) (CLXXX)

(R = CN, Ac) (a) R = uracil (b) R = adenine

The branched-chain monosaccharides with a C—P bond (CLXXV), synthesised[165] from 1,2:5,6-di-*O*-isopropylidene-D-*ribo*-3-hexulofuranose and tetraethyl methylenediphosphonate are of considerable interest. The unsaturated carbohydrate phosphonate (CLXXV) was used further to synthesise modified nucleotides. Jones and Moffatt[166] showed that the condensation of phosphonylmethylenephosphorane (CLXXIX) with $C_{(4)}$-formyl-2,3,-*O*-isopropylidene-derivatives of uridine and adenosine yields 5′-deoxy-5′-(*OO*-diphenylphosphonomethylene)uridine (CLXXXa) and the analogous adenosine derivative

(CLXXXb). Similar condensations lead to convenient pathways to the synthesis of modified nucleotides.

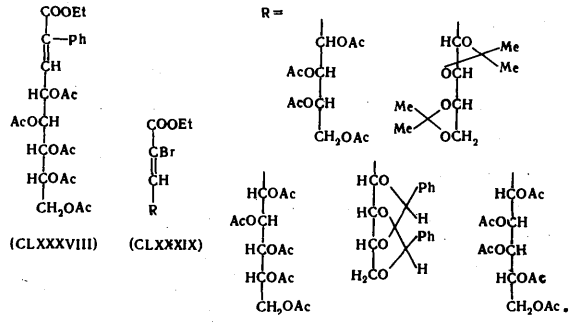


On treatment with an acylmethylenephosphorane, the penta-acetate of the keto-form of L-sorbose (CLXXXI) also yields[167] a sugar with an olefinic bond (CLXXXII):

(CLXXXI) (CLXXXII) (CLXXXIII).

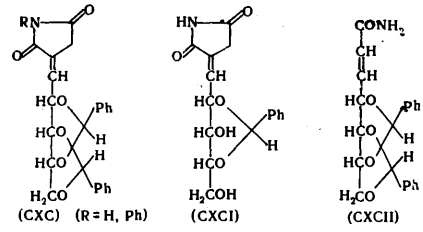
The methyl ester of 3,4-dehydro-2,3,4-trideoxy-5,6:7,8-di-*O*-isopropylidene-3-methoxycarbonyl-L-*arabino*-octonic acid (CLXXXIII) was obtained by a similar procedure from phosphoranes with an iso-structure and the aldehydo-form of 2,3:4,5-di-*O*-isopropylidene-L-arabinose[167].

The bulk of the studies on the Wittig reaction in carbohydrate chemistry concern the synthesis of $\alpha\beta$-unsaturated acid esters. Kochetkov and Dmitriev[168] developed on the basis of these compounds a new and convenient method of synthesising higher sugars. Starting with a wide variety of aldehydo-forms of carbohydrates and alkoxycarbonylmethylenetriphenylphosphoranes, they obtained[169-175] a series of esters of *trans*-2,3-didehydro-2,3-dideoxyaldonic acids of types (CLXXXIV, a and b)—(CLXXXVII):



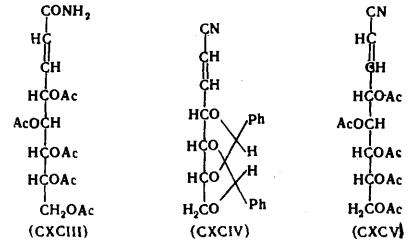
(CLXXXIV) (CLXXXV) (CLXXXVI) (CLXXXVII)

(a) $n = 3$, L-*arabino*-, D-*arabino*-



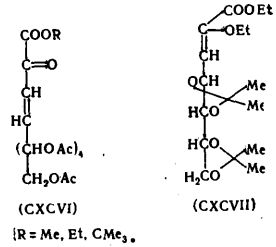
(b) $n = 4$, D-*gluco*-, D-*galacto*-

The employment of modified alkoxycarbonylmethylenetriphenylphosphoranes makes it possible to obtain[176,177] interesting derivatives of $\alpha\beta$-unsaturated acids (CLXXXVIII) and (CLXXXIX). The latter were used by Kochetkov and Dmitriev[177] to synthesise aziridine derivatives of carbohydrates:



(CLXXXVIII) (CLXXXIX)

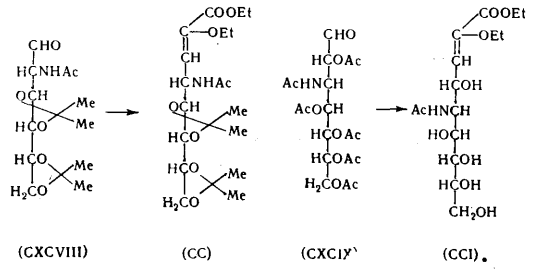
A series of unsaturated carbohydrates (CXC)—(CXCV) have been obtained from phosphoranes with maleimide, amide, and nitrile substituents[175,178]. The derivatives (CXC) and (CXCI) were synthesised for further use in the synthesis of the antibiotic Showdomycin[175]:



(CXC) (R = H, Ph) (CXCI) (CXCII)

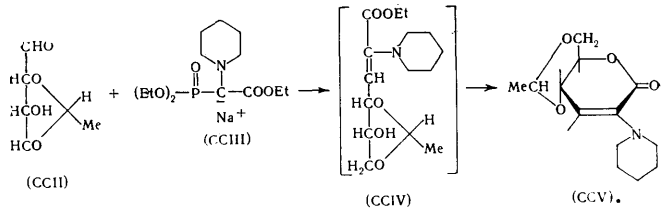
(CXCIII) (CXCIV) (CXCV)

Interesting pathways to the synthesis of 3-deoxy-2-oxoaldonic acids and their amino-derivatives (sialic acids), which are widely distributed[3] in nature, have been outlined on the basis of the Wittig reaction. These acids are formed in the organism by the condensation of monosaccharides with phosphoenolpyruvic acid. Therefore it was natural to investigate the interaction of the aldehydo-forms of carbohydrates with alkoxycarbonyloxomethylenephosphoranes obtained from bromopyruvic acid esters. This led to the synthesis[179,180] of unsaturated ketoacids of the general formula (CXCVI). Further reactions of these products, investigated by Kochetkov and coworkers[181-183], led to the synthesis of 2-deoxy-3-oxoaldonic acids identical with the natural products:



(CXCVI) (CXCVII)

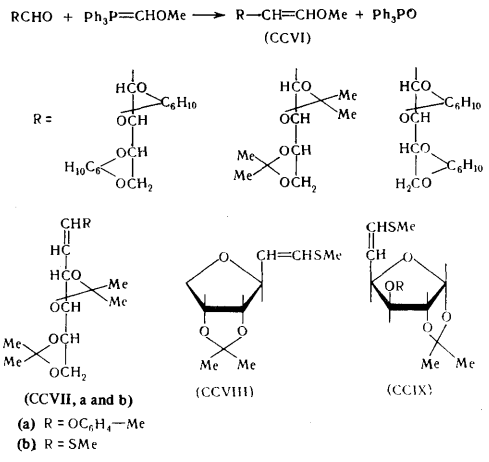
(R = Me, Et, CMe_3).



Samokhvalov and coworkers[184] obtained the fixed enolic forms (CXCVII) of an α-ketoacid from the aldehydo-forms of 2,3:4,5-di-*O*-isopropylidene-D-arabinose and ethoxycarbonylethoxymethylenetriphenylphosphorane. They demonstrated that the product (CXCVII) is also convenient for the synthesis of 2-deoxy-3-oxoaldonic acids. The use of derivatives of the aldehydo-forms of glucosamine (CXCVIII) and heptosamine (CXCIX) [185,186] for condensation with ethoxycarbonylethoxymethylenetriphenylphosphorane permits the synthesis of the starting materials (CC) and

(CCI) for the preparation of neuraminic acid and its analogues:

(CXCVIII) (CC) (CXCIX) (CCI).

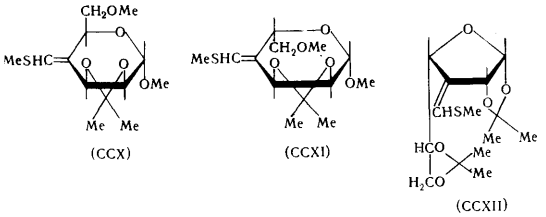


The simplest and novel synthesis of 3-deoxy-2-octoaldonic acids was proposed by Baschang and Tritz[187], who employed for this purpose the condensation of the sodium salt of ethyl *OO*-diethylphosphonopiperidinoacetate (CCIII) with 2,4-*O*-ethylidene-D-erythrose (CCII). They obtained as a result the enaminolactone (CCV) without isolating the intermediate enaminoester (CCIV):

(CCII) (CCIII) (CCIV) (CCV).

The enaminolactone (CCV) can be subsequently converted under mild conditions into the corresponding 3-deoxy-2-oxoaldonic acid. Further development of this reaction may lead to the elaboration of a convenient method of synthesising 3-deoxyhexulonic acids, including sialic acids.

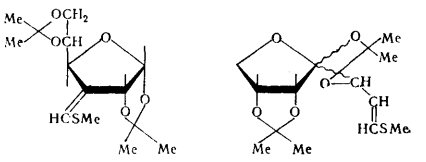
The vinyl ethers employed in the syntheses of 2-deoxyaldoses are also unsaturated carbohydrate derivatives obtained by the Wittig reaction. The condensation of derivatives of the aldehydo-forms with methoxymethylenetriphenylphosphorane yielded[141,145,188-190] the vinyl ethers (CCVI) and the interaction of the aldehydo-form of 2,3:4,5-di-*O*-isopropylidene-L-arabinose with methylenetriphenyltolyloxyphosphorane gives[191] aromatic vinyl ethers of type (CCVIIa):



(CCVII, a and b)
(a) R = OC_6H_4—Me
(b) R = SMe

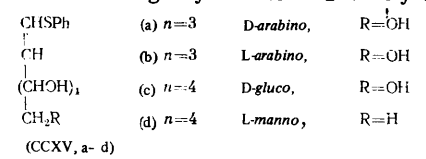
(CCVIII) (CCIX)

In the search for other precursors of 2-deoxy-sugars, attention was turned to methylenemethylthiotriphenylphosphorane, which was employed by Tronchet and coworkers[190,192] for condensation with various aldehydo-forms. The methylthio-derivative (CCVIIb) was prepared in this way[190] from the aldehydo-form of 2,3:4,5-di-*O*-isopropylidene-L-arabinose. A similar treatment of 2,5-anhydro-3,4-*O*-isopropylidene-D-ribose and 1,2-*O*-isopropylidene-3-*O*-methyl-(and 3-*O*-benzyl-)-α-D-*xylo*-pentodialdo-1,4-furanoses led[192] to the synthesis of the corresponding vinyl thioethers (CCVIII) and (CCIX).



The interaction of methylenemethylthiotriphenylphosphorane with certain protected keto-sugars proved to be more complex. Thus 2,3-*O*-isopropylidene-6-*O*-methyl-α-D-*lyxo*-3-hexulopyranoside gives the vinyl thioethers[193] (CCX) and (CCXI) in a yield of only 20%:

(CCX) (CCXI) (CCXII)

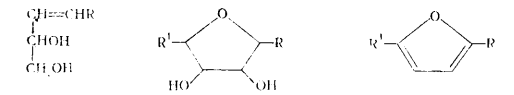


The formation of the side product (CCXI) is probably a result of the epimerisation of a similar ketose at $C_{(5)}$ in the course of enolisation induced by the basic medium.

It is interesting that epimerisation is not observed with 1,2:5,6-di-*O*-isopropylidene-α-D-*xylo*-3-hexulofuranose, since only the normal reaction product (CCXII) has been isolated[194]. The same reaction with 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-3-hexulofuranose proved to be much more complicated[195,196], since, apart from the expected vinyl thioester (CCXIII), the $C_{(5)}$ epimer (CCXII) was isolated as well as the unexpected rearrangement product (CCXIV):

(CCXIII) (CCXIV)

Apart from methylenemethylthiotriphenylphosphorane, methylenephenylthiotriphenylphosphorane can be used to synthesise vinyl thioethers. Thus, according to the data of Bestmann and Angerer[197], this phosphorane reacts smoothly even with the free sugars in DMSO, forming the corresponding aryl vinyl thiovinyl ethers (CCXV, a—d). Since the products (CCXVa) and (CCXVb) were converted further into 2-deoxy-D-(and L-)-*arabino*-hexoses, it is a very convenient two-stage synthesis of 2-deoxy-sugars:



(CCXV, a- d)

(a) $n=3$	D-*arabino*,	R=OH
(b) $n=3$	L-*arabino*,	R=OH
(c) $n=4$	D-*gluco*,	R=OH
(d) $n=4$	L-*manno*,	R=H

A number of studies by Kochetkov and coworkers[189,199], who made a detailed investigation of the condensation of alkoxycarbonylmethylenetriphenylphosphoranes with D-arabinose, D-ribose, D-glucose, D-galactose, D-glycero-D-*gulo*-heptose, and 2-acetamido-2-deoxy-D-glucose, were devoted to the employment of free and partially protected sugars in the Wittig reaction. They obtained the corresponding esters of *trans*-2,3-didehydro-2,3-dideoxyaldonic acids in yields of 45%. The decrease of yield is probably due to the formation of cyclic side

products. To prevent such cyclisation, partly protected sugars were employed. For example, the use of 2,3,4,6-tetra-*O*-acetyl-D-galactose instead of free D-galactose increases the yield of the required product to 80%. Similarly when 2-acetamido-2-deoxy-D-glucose is replaced by its 4,6-*O*-benzylidene derivative, the yield of the normal product of the condensation with methoxycarbonylmethylenetriphenylphosphorane increases from 30 to 50%.

The problem of the employment of free and partly protected sugars in the Wittig reaction with alkoxycarbonylmethylenetriphenylphosphoranes was investigated in greater detail by Zhdanov and coworkers[200-204], who showed that the required product is formed only with DL-glyceraldehyde (CCXVI):

(CCXVI) (CCXVII) (CCXVIII)

(R = CO Me, COPh) (R = CH_2OH, $(CHOH)CH_2OH$ (R = Me, Ar; R^1 = CH_2COAr, CH_2COMe) R^1 = $(CHOH)_n CH_2OH$)

When various pentoses and hexoses were allowed to interact with group II phosphoranes, the anhydro-derivatives were isolated, compounds of type (CCXVII) being formed preferentially. During the reaction, these anhydro-derivatives are dehydrated, probably under the influence of the excess phosphorane, with formation of substituted furans (CCXVIII). Thus the results show that conformational factors, and particularly the preference for specific conformations in the opening of the cyclic forms of aldoses at the instant of reaction, play a decisive role in the formation of a particular product.

Methods of Synthesis of Pyrimidine Nucleosides

B.N.Stepanenko, E.M.Kaz'mina, and Z.S.Dubinkina

The review describes the present state of knowledge about the synthesis of pyrimidine nucleosides. Together with a description of various methods of synthesis, their comparative characteristics are stated briefly. The bibliography includes 188 references.

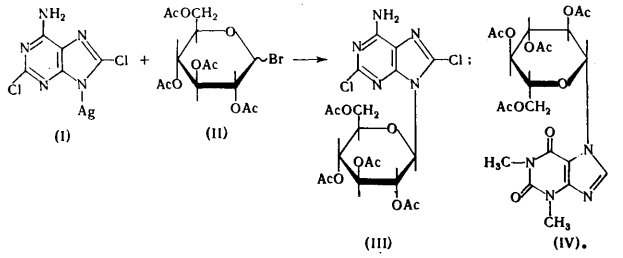
I. INTRODUCTION

The chemistry of nucleosides and nucleic acids is at present one of the most vigorously developing fields despite the considerable difficulties facing investigators engaged in it. The interest in the chemistry of nucleosides is quite understandable. There are good grounds for attributing to the analogues of nucleosides the capacity to influence heredity, to act on the development of viruses, and to suppress the growth of malignant tumors. Finally the availability of a large set of various nucleosides constitutes an essential condition for theoretical studies on the mechanism of the biosynthesis of nucleic acids and proteins, on the specificity of the relevant enzymes, etc.

In view of the great interest in the chemistry of nucleosides, the literatures in this field is exceptionally large. The compilation of a detailed review on the chemistry of all the groups of nucleosides became difficult a long time ago [1-6]. This is undoubtedly the reason why it has already been possible for some time to publish in the periodical literature reviews dealing with a particular single group of nucleosides [1,7,8] or one of the methods of synthesis [9,10]. Thus a very good review by Fox and Wempen [1], dealing only with the methods of synthesis of pyrimidine nucleosides (and yet including 6-7 pages of references), was published in 1959 in Advances in Carbohydrate Chemistry.

During more than ten years which have elapsed since the publication of the review, a number of earlier methods of synthesis have been further improved and have been given a theoretical basis (for example the metal salts and the Hilbert-Johnson methods). The silyl modification of the Hilbert-Johnson method has been developed.

The method involving the modification of existing nucleosides has been supplemented by a number of new reactions, for example nucleosides containing the 5',6- and 2',6-anhydro-linkages [11-15], sulphur [16,17], halogens [18,19], a double bond in the sugar residue [20], etc. have been obtained.



Considerable practical advances have been made in nucleoside chemistry. The possibility of clinical application of nucleosides as antiviral agents was demonstrated for the first time for the familiar thymidine analogue 2-deoxy-5-iodouridine in the treatment of herpetic affections of the eyes [21].

Data on the biological activities of a large number of synthetic nucleosides and the possibility of their clinical application can be found in a number of reviews [22-24].

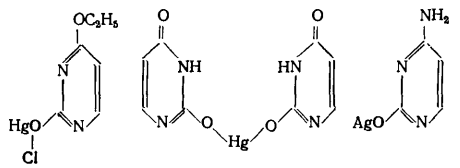
The aim of the present review was to describe the present state of knowledge of the synthesis of pyrimidine nucleosides, including the literature up to the middle of 1971.

II. THE METAL SALTS METHOD

Fischer and Helferich [25] were the first to achieve the condensation of the silver salt of 2,8-dichloroadenine (I) and theophylline with 2,3,4,6-tetra-*O*-acetylglucopyranosyl bromide (II) which led to the synthesis of 2,8-dichloro-9-(2',3',4',6'-tetra-*O*-acetyl-β-D-glucopyranosyl)adenine (III) and 7-(2',3',4',6'-tetra-*O*-acetyl-β-D-glucopyranosyl)-theophylline (IV) respectively:

(I) (II) (III) (IV).

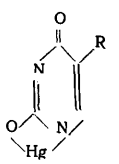
After deactylation and dehalogenation of compound III, 9-(β-D-glucopyranosyl) adenine, the first synthetic nucleoside, was obtained.



However, it was found that the silver salts of purines and pyrimidines containing the tautomeric group $-\overset{|}{N}-\overset{\|}{C}- \rightleftharpoons -N=\overset{|}{C}-$ (H, O, OH), such as uracil, cytosine, and theobromine, react with acetohalogeno-sugars to form products which reduce Fehling's reagent and are labile in relation to acids and alkalis. Fischer [26] suggested that these derivatives are probably *O*-glycosides.

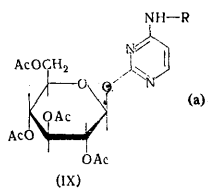
Levene and Sobotka [27] reached the same conclusion on the basis of experiments in which the silver and potassium salts of cytosine and certain substituted uracils were condensed with glycosyl halides to form unstable products.

For this reason, the reaction of metals salts of pyrimidines with glycosyl halides was not investigated until the successful synthesis of nucleosides using mercury salts of purines [28] led to the investigation of the analogous pyrimidine derivatives and it was found [29,30] that



N-glycosides can be obtained from them in satisfactory yields; for example, thyminyl riboside and thyminyl xyloside were synthesised from dithyminylmercury and cytidine was obtained from *N*-acetylcytosinylmercury. It was noted that the reactions of certain mercury salts with deoxyribosyl halides take place with formation of *O*-deoxyribosides and not *N*-deoxyribosides [31]. In order to obtain *N*-deoxyribosides, it is necessary to employ the mercury salts of pyrimidine containing the pyrimidine base and mercury in proportions of 1 : 1. [32,33]

A number of hypotheses have been put forward to account for these results and the finding that the silver and mercury salts yield different products [34-36]. It was suggested that the chloromercury salt (V) of a pyrimidine, the dipyrimidine mercury compound (VI), and the silver salt (VII) of a pyrimidine are oxygen derivatives which react with glycosyl halides with the initial formation of *O*-glycosides, most of which rearrange to *N*-glycosides under the reaction conditions:

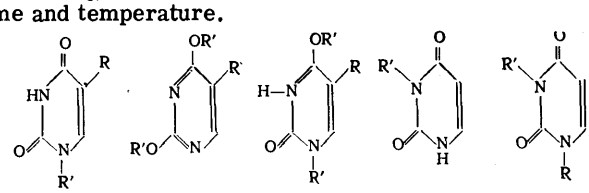


(V) (VI) (VII).

Since in monopyrimidine compounds of mercury, the heavy metal is probably also linked to the nitrogen atom, as in compound (VIII), these substances yield *N*-glycosides directly [37]:

(VIII) (R=H,CH$_3$, F, Br, I).

Fischer's method [26] (the preparation of the silver salt of cytosine and its condensation with acetobromoglucose in boiling xylene) was modified [38] but, as in Fischer's original work, the final product was an *O*-glycoside (IXa): [39]



(a) R = H; (b) R = CH$_3$CO.

(IX)

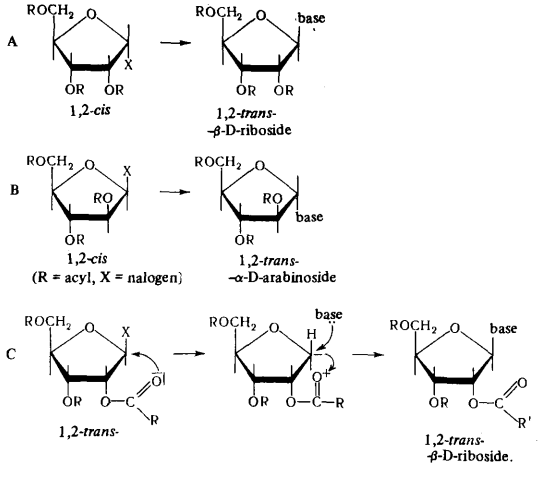
On heating with mercury(II) bromide in xylene, the acetylated nucleoside (IXa) isomerises to an *N*-nucleoside with a very low yield. The best result was obtained in the condensation of the silver salts of *N*-acetylcytosine with acetobromoglucose in boiling xylene, compound (IXb) being formed. The reaction of the chloromercury salt of uracil (V) with acetobromoglucose, which has been reinvestigated, is of practical interest, but Ukite et al. [40] found that Fox's method [condensation of the chloromercury salt of 4-ethoxy-2(1*H*)-pyrimidinone with acetobromoglucose in boiling xylene] is not adequately reproducible.

Interesting data were obtained in a study of the reaction of metal salts of uracil and thymine [41-43] and also of 2-thiouracil [44] with acetobromoglucose and tribenzoylribofuranosyl chloride. The reaction of the silver salt of uracil with acetobromoglucose in toluene gives a mixture of five products [(Xa), [45] (XIa), (XIIa), (XIII), and (XIV) [42,43]], the proportions of which vary with reaction time and temperature.

(X) (XI) (XII) (XIII) (XIV).

[R' = 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl; (a) R = H; (b) R = CH$_3$]

A similar reaction with thymine yields the known compounds (Xb), [29] and (XIb) [46] and compound (XIIb), which was not characterised previously.



In the reaction of the silver salts of uracil and thymine with tribenzoylribofuranosyl chloride [41] in boiling xylene for 7 h, satisfactory yields of 1-(2',3',5'-tri-*O*-benzoyl-β-D-ribofuranosyl)-uracil and -thymine were obtained. Thus the views expressed in literature that the silver salts of uracil are incapable of undergoing the *N*-glycosylation reaction under the influence of acylglycosyl halides were disproved yet again [3]. The use of the mercury salt in the reaction with acylglycosyl halides leads to the formation of a more complex mixture of products and to a sharp decrease of the yield of the *N*-nucleoside [41].

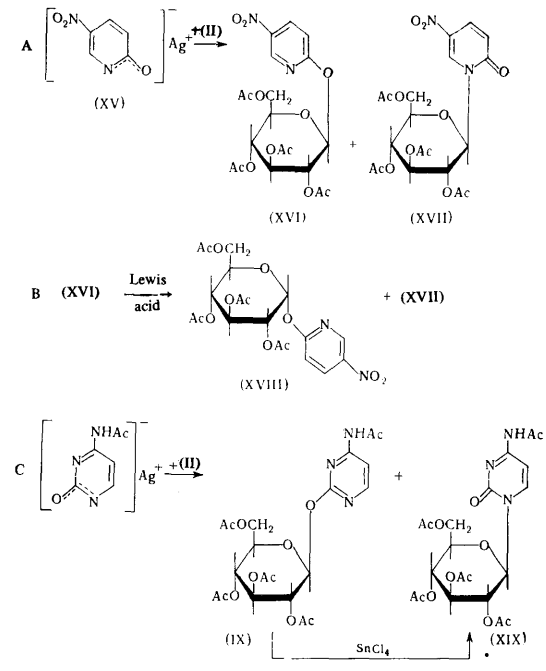
A modification of the Helferich method [47-50], which was first employed by Fox and coworkers [47] to synthesise acylated pyrimidine nucleosides, is nowadays used fairly often for the synthesis of pyrimidine nucleosides. This method is suitable for the preparation of thymine and uracil derivatives without the preliminary isolation of mercury derivatives of the heterocyclic bases. Free bases are used in the synthesis but in the case of amino-derivatives it is desirable to protect the amino-group by acylation before the condensation reaction. However, it was shown recently that 2-thiocytosine [49] can be introduced into the reaction directly. Particularly high yields are obtained for pyrimidines containing electronegative groups at C$_{(5)}$.

1. Stereochemistry of the Synthesis of Nucleosides

The synthesis of nucleosides from acetobromoglucose having the α-configuration at C$_{(1)}$ leads to compounds with the β-configuration and therefore the reaction presumably involves an S$_N$2 mechanism with direct attack by the electrophilic C$_{(1)}$ atom of α-acetobromoglucose on the nucleophilic nitrogen atom of the pyrimidine or purine derivative. In the synthesis of natural β-nucleosides, syrupy ribofuranosyl halides containing a mixture of α- and β-forms are used as starting materials. In the synthesis of puromycin [51], crystalline 2,5-di-*O*-benzoyl-3-deoxy-3-phthalimido-β-D-ribofuranosyl chloride yields exclusively the β-nucleoside. To account for these observations, Baker and coworkers [52,53] suggested that, in the condensation of the purine (or pyrimidine) derivative of a heavy metal with an acetylated glycosyl halide, the product is a nucleoside with a C$_{(1)}$-C$_{(2)}$-*trans*-configuration of the sugar regardless of the initial configuration of these atoms. Usually in the reactions of halogeno-sugars with the C$_{(1)}$-C$_{(2)}$-*cis*-configuration, there is a simple Walden inversion and the resulting nucleoside has the C$_{(1)}$-C$_{(2)}$-*trans*-configuration, which can be either the α- or β-form depending on the configuration of the sugar

(mechanism A and B).[2] $C_{(1)}$ -$C_{(2)}$-*trans*-halogeno-sugars are involved in two S_N2 reactions (with a double Walden inversion); initially the configuration at $C_{(1)}$ is inverted with participation of the adjacent $C_{(2)}$-acyloxy-group and the formation of an orthoester ion and then in the reaction of the base a second inversion takes place (mechanism C).[2]

Although the reaction mechanisms are completely different for the two anomeric halides, a nucleoside with a *trans*-arrangement $C_{(1)}$ and $C_{(2)}$ is formed in both cases regardless of the configuration of the anomeric halide at $C_{(1)}$ when the halogen atom is replaced by nucleophilic groups.



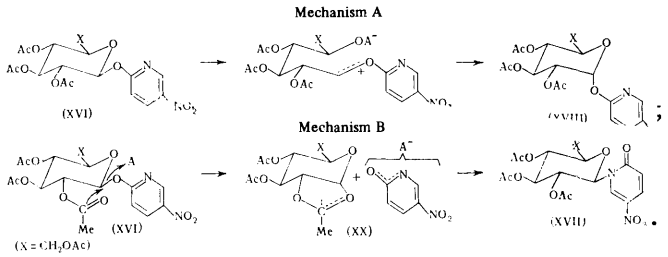
It has been shown that the rule is well founded and is actually employed at present to demonstrate a particular configuration. However, in certain cases a small amount of the other anomer is formed together with the one expected. Thus in the ribofuranosyl halide having a 2,3-cyclocarbonate protecting group and also in derivatives of 2-deoxy-D-ribose, there is no directing effect of the 2-acyloxy-group; in such cases the α- and β-forms of the nucleosides should be obtained and are in fact obtained[54,55].

2. The Mechanism of the Synthesis of Nucleosides

The mechanism of the synthesis of nucleosides and similar glycosides from glycosyl halides and metal salts of heterocyclic bases containing the $-\underset{|}{\overset{H}{N}}-\overset{\|}{\underset{O}{C}}-$ group has been investigated extensively in recent years[2,36,38,56,57,58]. It was shown in early investigations that mercury halides catalyse the O → N glycosyl rearrangement. Wagner and coworkers[59] demonstrated the possibility of such rearrangements for various heterocyclic systems.

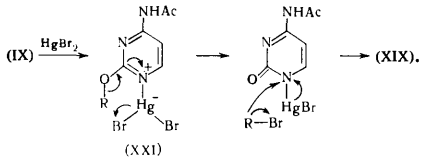
It was observed that in certain cases heterocyclic *O*-glycosides do not rearrange to *N*-glycosides in the presence of mercury halides, products which are anomeric *O*-glycosides being obtained instead[60]. Thacker and Ulbricht reinvestigated the glycosides of 5-nitro-2-pyridone[57,58], since in Wagner's studies the aglycones (including 5-nitro-2-pyridone) were powerful electron acceptors.

The reaction of the silver salt of 5-nitro-2-pyridone (XV) with acetobromoglucose (II) is the *O*-glucoside (XVI) which was believed[60] to be the α-anomer on the basis of the method of synthesis (mechanism A). Treatment of this product with a Lewis acid (mercury bromide) in boiling xylene gives the isomeric *O*-glucoside (XVIII) which was assumed[60] to be the α-anomer (mechanism B)



It was established by the NMR method[58] that compounds (XVI) and (XVIII) are in fact the β- and α-anomers and in addition thin-layer chromatography revealed the presence, together with compound (XVIII), of a product (XVII) which is a β-*N*-glycoside. Consequently an O → N rearrangement takes place in this case, its occurrence depending on the temperature, time, and the concentration of mercury bromide. The *N*-glucoside (XVII) was also isolated in a small amount when compound (XVI) was synthesised from the silver salt (XV).

The O → N rearrangement was studied using different Lewis acids[58]. When the pyridyl β-*O*-glucoside (XVI) was treated with tin(II) chloride, both anomerisation and rearrangement took place, while in the presence of $HgBr_2$ as the catalyst the anomerisation occurred virtually without rearrangement. The crystalline α-*O*-glucoside (XVIII) was obtained only when $HgBr_2$ was used as a catalyst, while in the presence of other Lewis acids the formation of the α-anomer was detected only by paper chromatography. The amount of the α-anomer formed when various catalysts are used decreases in the following sequence: $HgBr_2 > ZnBr_2 > CdCl_2 > SnCl_4 > SbCl_5 > TiCl_4$.

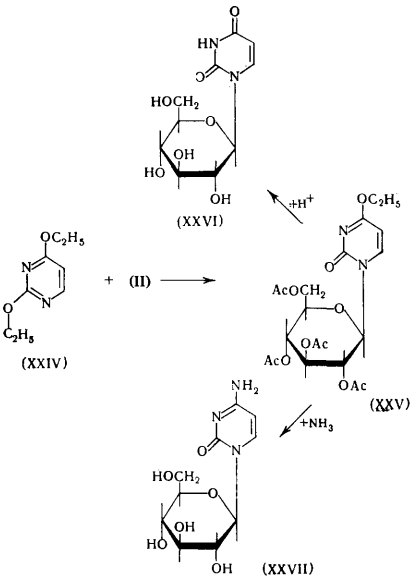


N-Acetylcytosinyl *O*-glucoside (XIX) also undergoes a rearrangement under the influence of tin(II) chloride to the β-*N*-isomer (IX) (mechanism C) but anomerisation was not observed under these conditions. The O → N glycosyl rearrangement catalysed by heavy metal salts ($SnCl_4$, $HgCl_2$, $HgBr_2$) was achieved by Schmidt and Farkas[46] [the di-*O*-glycosides of thymine (XIb) were converted into

thyminyl mono-*N*-glycosides (Xb)]. The thermal O → N glycosyl rearrangement of the readily hydrolysed *O*-glycoside 2-(tetra-acetyl-β-D-glucopyranosyl)hydroxypyrimidine was described recently[61]. The finding that in many cases the β-*O*-glycoside anomerises to the α-*O*-glycoside, while the α-*N*-isomer is not detected and that the rearrangement and the anomerisation take place at different rates and in different ways under different reaction conditions confirmed that two different mechanisms can operate in this case: (a) the formation of a complex of the catalyst and an oxygen atom of the sugar ring with subsequent ring opening and closure (anomerisation, mechanism A) and (b) the formation of a complex of the catalyst and the glycosidic oxygen, the formation of an ion pair, and the involvement of the adjacent 2-acyloxy-group (stereospecific rearrangement, mechanism B):

According to Wagner[59], the two products (XVII) and (XVIII) can be formed from the cyclic ion (XX), but in this case it is difficult to account for the formation of the α-*O*-glucoside and the absence of the α-*N*-glucoside.

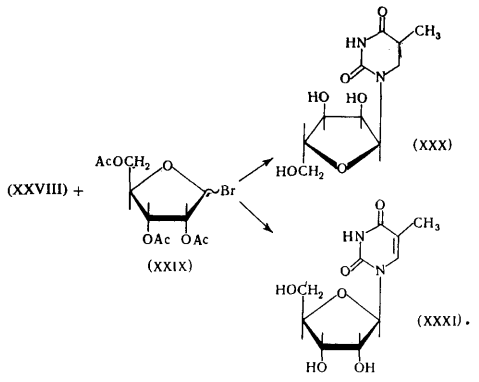
The mechanism of the O → N glycosyl rearrangement, proposed previously by Ulbricht[36,38,56] and involving the formation of a complex of the catalyst with the ring nitrogen atom of the aglycone (XXI), was shown[61-65] to be inapplicable in all cases.



(R = 2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl)

III. THE HILBERT–JOHNSON METHOD

Previously it was believed that the glycosylation of the $N_{(1)}$-pyrimidine ring atom is impossible with pyrimidines containing the lactam—lactim tautomeric system $-\overset{\|}{C}(O)-\overset{|}{N}(H)- \rightleftharpoons -\overset{|}{C}(OH)=N-$. However, Hilbert and Johnson[66,67], who restricted the tautomeric shift by employing 2,4-dialkoxypyrimidines, extended this reaction to *O*-acylglycosyl halides[45] after the successful synthesis of 4-alkoxy-1-methyl-2(1*H*)-pyrimidinone (XXIII) by treating 2,4-dialkoxypyrimidine (XXII) with methyl iodide.

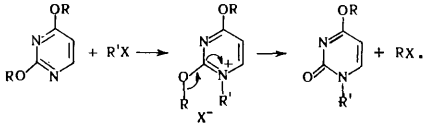


Thus, when 2,4-diethoxypyrimidine (XXIV) was treated with acetobromoglucose (II) (50°C, 48 h in the absence of a solvent), the $N_{(1)}$-glycosyl derivative (XXV) was obtained:

Treatment of compound (XXV) [45,68] with a solution of hydrogen chloride in ethanol or with a solution of ammonia in ethanol leads to the D-glucosides of uracil (XXVI) or (cytosine (XXVII). Many years later, Davoll et al.[69] reproduced these experiments[45,68] and established that the compounds obtained have the β-configuration.

Subsequently the reactions of 2,4-diethoxypyrimidine with L-arabinopyranosyl bromide, α-D-xylopyranosyl bromide, D-ribopyranosyl bromide, and α-D-galactopyranosyl bromide were carried out[70]. The first natural nucleoside obtained by the Hilbert–Johnson reaction was cytidine[71]. Its successful synthesis gave rise to further studies on the synthesis of pyrimidine nucleosides. For example, when 2,4-diethoxy-5-methylpyrimidine (XXVIII) was treated with 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide (XXIX) (at 60°C in the absence of a solvent), "5-methyluridine" (A) (XXX) was isolated after hydrolysis[72]. In contrast to compound (A), the thymine nucleoside (C) obtained enzymatically from thymine and ribosyl phosphate was cleaved by the nucleosidase from *Escherichia Coli* and had a different melting point. 5-Methyluridine (C), synthesised later by the mercury method[29], was found to be identical with compound (B). By converting compound (C) into spongothymidine [1-(β-D-arabinofuranosyl)thymine],[74] the β-configuration of compounds (B) and (C) was demonstrated. Compound (A) was identified as the α-anomer[75] and it was observed that 1-(α-D-ribofuranosyl)thymine (XXX) and 1-(β-D-ribofuranosyl)thymine (XXXI) are obtained in yields of

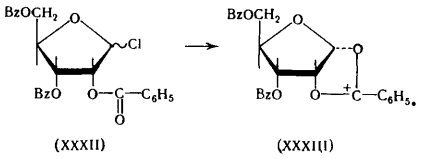
8.5 and 8% respectively when the reaction is carried out in benzene:



A mixture of 1-(α-D-ribopyranosyl)thymine and 1-(β-D-ribopyranosyl)thymine was obtained similarly from 2,3,4-tri-*O*-benzoyl-D-ribopyranosyl bromide [76].

Recently Sorm and coworkers [77] made a systematic study of the Hilbert–Johnson reaction. They investigated the role of the solvent, of various substituents in the 5-position of the pyrimidine ring, and of various protecting groups in the sugar component and studied the reaction yield and the ratio of the α- and β-anomers.

1. Reaction Mechanism



The reaction of 2,4-dialkoxypyrimidines with halogenoses (or with alkyl halides) was shown by Hilbert [78] to involve the formation of a quaternary salt as an intermediate. Later the mechanism of the Hilbert–Johnson reaction was investigated by Ulbricht [79]. His mechanism involves the formation of a quaternary nitrogen atom with subsequent attack by the halide ion:

It was shown recently [80] that a 2-alkoxy-group in the quaternary salt may be replaced by 2-oxo, 2-thio, and 2-amino-groups.

2. Stereochemistry of the Hilbert–Johnson Reaction

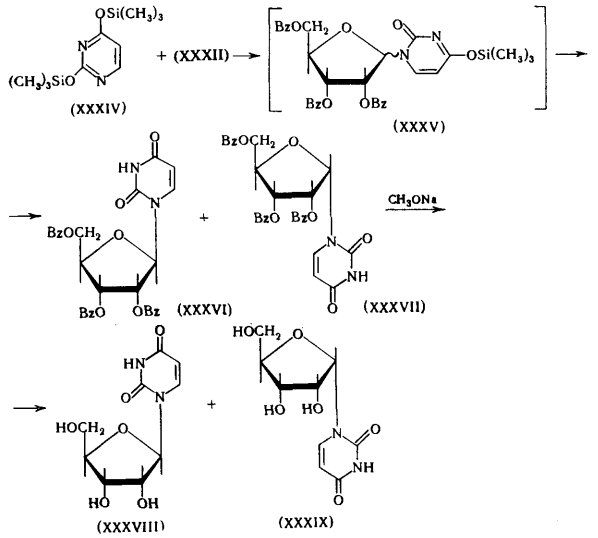
The effect of various factors on the ratio of the α- and β-anomers obtained by the Hilbert–Johnson reaction was investigated by Sorm and coworkers. The first papers [77,81] of this series were devoted to the synthesis of 2-deoxyuridine and thymidine, where the α-anomer predominates (for deoxy-sugars). It was established that the ratio of the α- and β-anomers in the Hilbert–Johnson method depends on the polarity of the solvent [81,82]. If, for example, the reaction of the halogenose (XXXII) with the base is carried out in benzene, a small amount of the corresponding α-anomer accompanies the main reaction product—the β-anomer. On the other hand, in a polar solvent the halogenose (XXXII), which is predominantly present in the β-configuration, gives rise to the ortho-ester cation (XXXIII), from which only the β-anomer may be formed.

The formation of the anomers is also influenced by the nature of the base and of the sugar component and by the protecting groups in the sugar residue [9]. Baker's "*trans*-rule" [52,53] is of limited applicability in the Hilbert–Johnson reaction, a mixture of α- and β-anomers being usually reformed.

3. Conditions of the Hilbert–Johnson Reaction

The absence or presence of the solvent plays an important role in the Hilbert–Johnson reaction. Best results are largely obtained in the presence of solvents although unfortunately systematic studies have not so far been made on this question. The reactions are carried out at temperatures ranging from 20° to 115°C. The reaction time was varied very markedly by investigators depending on the stability and reactivity of the halogenose employed. For example, the Hilbert–Johnson reaction of 2,4-dimethoxypyrimidine (in acetonitrile at room temperature) with 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride requires 1–2 h, [83] while the reaction mixture with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride must be kept for several days [81,82]. If the halogenose is relatively stable and less reactive, the reaction must be carried out at an elevated temperature, for example in a boiling solvent, while with a reactive and relatively unstable halogenose the condensation is carried out at room temperature.

The application of molecular sieves [82–86] as hydrogen chloride acceptors gave satisfactory results because the formation of side products was largely suppressed. The use of mercury bromide (in acetonitrile and benzene) was recently investigated [82,84,86]. Thus, when compound (XXII) reacted with 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride, the rate of reaction was higher in the presence of one or two equivalents of mercury bromide, but the yield of the anomer mixture was appreciably reduced owing to the rapid decomposition of the deoxyhalogenose. The amount of the β-anomer in the mixture increases under these conditions. In the reactions with stable halogenoses, the use of mercury(II) bromide gives rise to the possibility of reducing the reaction time (without lowering the yield) [86].



The side products usually formed in the Hilbert–Johnson reaction can be divided into four groups [9]: (1) substances obtained from the bases [for example uracil, 1-alkyluracils [45,70], 1,3-dialkyluracils [83], 4-alkoxy-2(1*H*)-pyrimidinones, and 4-alkoxy-1-alkyl-2(1*H*) pyrimidinones [70,84] may be formed from 2,4-dialkoxypyrimidines]; substances formed from the sugar component [84]; (3) side products obtained from the protected intermediate 4-alkoxy-1-glycosyl-2(1*H*)-pyrimidinones; (4) the *O*-glycosides mentioned above (they were first reported by Hilbert and Rist [87], who called them "*O*-nucleosides").

IV. THE TRIMETHYLSILYL METHOD

The trimethylsilyl method of synthesising nucleosides, the principle of which was discovered by Birkofer and coworkers [88-91] in studies on other nitrogen-containing compounds, was described by Nishimura and coworkers [92-97] and independently by Wittenburg [98-103]. The method is a modification of the Hilbert–Johnson method, but has a number of advantages. Silyl derivatives of pyrimidine bases can be obtained in high yields directly from pyrimidines such as uracil, thymine, and cytosine, the silyl derivatives being able to react with halogenoses under more severe conditions than their alkoxy-analogues. Compared with the Hilbert–Johnson method, the stage involving the hydrolysis of the alkoxy-group is virtually eliminated (the trimethylsilyl group is readily split off on treatment with aqueous alcohol).

Pyrimidine bases are sparingly soluble in organic solvents and have fairly high melting points. Their trimethylsilyl derivatives are liquids which can be distilled or crystals with a low melting point. Moreover, they dissolve readily in non-polar solvents, being completely decomposed by alcohol or water even in a neutral medium with liberation of the base.

The products of the silylation of dihydroxypyrimidines have the structure of bis-*O*-trimethylsilyloxypyrimidines (XXXIV).[92] The conversion of uracil into uridine (XXXVIII) and its anomer (XXXIX) may serve as an illustration of the trimethylsilyl method for the synthesis of nucleosides:

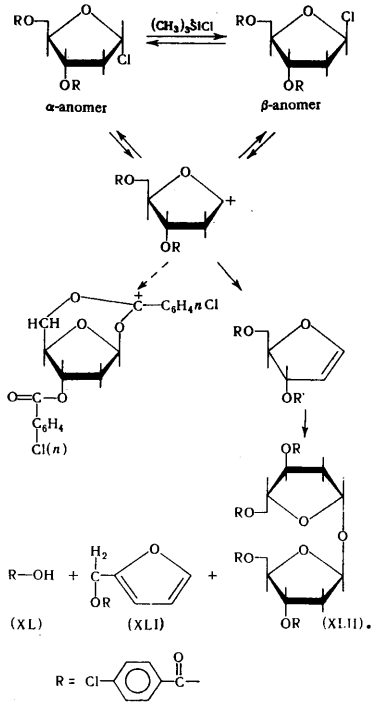
On treatment with chlorotrimethylsilane, uracil is readily converted into 2,4-bis(trimethylsilyloxy)pyrimidine (XXXIV) which on fusion (190°C) with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride yields the protected nucleoside (XXXV); on dissolution in ethanol the latter gave a benzoylated nucleoside in the form of a mixture of anomers (XXXVI) and (XXXVII). They were separated and deacylated with formation of uridine (XXXVIII) and 1-(α-D-ribofuranosyl)uracil (XXXIX).

Using the trimethylsilyl method for the synthesis of nucleosides, Wittenburg suggested the following versions of the condensation reaction [98,102]. Method A: prolonged heating of the components in dry solvents such as benzene, toluene, dimethylformamide (DMF), nitromethane, and others; method B: fusion of the components at 90–100°C *in vacuo*; method C: reaction carried out in an absolute inert solvent (benzene) in the presence of silver perchlorate at room temperature; method D: interaction of the starting materials at room or elevated temperature in a solvent in the presence of mercury(II) compounds, such as HgO, mercury(II) acetate, $HgBr_2$, and $HgCl_2$.

These methods were investigated in the reaction of 2,4-bis-*O*-trimethylsilylthymine with α-acetobromoglucose and β-acetochloroglucose. The yields were 27 and 41% by methods A and B and 56–86% by methods C and D. The use of polar solvents (DMF, acetonitrile) in method A accelerates the reaction but lowers the yield owing to the easier decomposition of the halogeno-sugars.

The technique of the fusion method B resembles that of the Hilbert–Johnson reaction. On fusion of bistrimethylsilylthymine with acetobromoglucose at 110°C, the reaction begins after several minutes and terminates after 1–3 h. The yield increases when the reaction is performed in benzene in the presence of one equivalent of silver perchlorate (method C). The reaction proceeds very rapidly even at room temperature and heat is evolved. Presumably silver perchlorate initially reacts with acetobromoglucose to form silver bromide and tetraacetylglucosyl perchlorate ($AgClO_4$ and silylpyrimidine do not react with one another) [91]. Since acetylglucosyl perchlorate is highly reactive [104], a further reaction with formation of a 4-*O*-silylnucleoside and trimethylsilyl perchlorate takes place.

The reaction in which mercury compounds are used as catalysts [HgO, mercury(II) acetate, $HgBr_2$, $HgCl_2$] (method D), particularly when an almost equimolar mixture HgO and $HgBr_2$ is employed, takes place more smoothly. The bromotrimethylsilane formed initially is converted into hexamethyldisiloxane in the presence of mercury(II) oxide and the acetylated products is isolated in a very satisfactory yield in consequence of a shift of the reaction equilibrium.



Wittenburg, who investigated the glycosylation of silyl derivatives of 6-substituted uracil derivatives [105] (6-methyluracil, 5,6-dimethyluracil, 5-bromo-6-methyluracil, 5-iodo-6-methyluracil, barbituric acid, and orotic acid and its esters) with acetobromoglucose or tribenzoylribofuranosyl chloride (method D was employed for glycosylation), concluded that the course of the reaction depends on the nature and position of the substituent in the pyrimidine ring. For example, in the glycosylation of the silyl derivative of 5,6-dimethyluracil under the above conditions, the $N_{(1)}$-glycoside was obtained almost exclusively, while in the reaction with 6-methyluracil the $N_{(3)}$-glycoside was formed preferentially together with appreciable amounts of the $N_{(1)}$-glycoside and the $N_{(1,3)}$-diglycoside. Other silyl derivatives listed above do not react with halogeno-sugars or with methyl iodide under the above conditions. Winkley and Robins [106] obtained similar results with silyl derivatives of 5,6-dimethyluracil and 6-methyluracil.

In this connection, it is noteworthy that the required $N_{(1)}$-glycosides of 6-methyluracil, barbituric acid [107], and orotic acid [108] were not obtained by the Hilbert–Johnson method either. However, Winkley and Robins [109] succeeded in synthesising 1-(β-D-ribofuranosyl)barbituric acid by the silyl method via condensation in acetonitrile at room temperature. Azacytidine [110], 2-deoxy-5-hydroxymethyluridine [111], and other derivatives of pyrimidine bases [112] were synthesised under these conditions.

Vorbruggen and Niedballa [113-115] suggested that the silyl derivative of pyrimidine bases be condensed with protected sugars in the presence of the Friedel–Krafts catalyst.

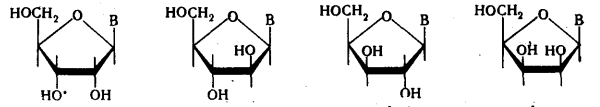
Stereochemical aspects. According to Wittenburg's data[102], a nucleoside with the $C_{(1)}-C_{(2)}$-*trans*-configuration was isolated as the main product in the interaction of 2,4-bis-(*O*-trimethylsilyl)thymine with α-acetobromoglucose. Traces of the α-anomer with the $C_{(1)}-C_{(2)}$-*cis*-configuration (i.e. traces of tetra-acetyl-α-D-glucopyranosylthymine), which proved to be identical with the α-glucopyranosylthymine obtained by Schmidt[46] by a modified Hilbert–Johnson method, were detected only in experiments by methods C and D. Treatment of bis-(trimethylsilyl)thymine with β-acetochloroglucose led to the same results. Hence Wittenburg concluded (without taking into account the amount of the anomers, which were detected by the chromatographic method alone) that the silyl method for the synthesis of pyrimidine nucleosides is rigorously stereospecific and fully obeys Baker's rule[52,53]. Nevertheless Nishimura and coworkers isolated α- and β-nucleosides[95,97] using adenine[96], uracil[95,97], and thymine[97] as aglycones. The Japanese workers concluded that the silyl method yields not only the β-anomers but also the α-anomers having the $C_{(1)}-C_{(2)}$-*cis*-configuration. Probably the formation of anomeric nucleosides depends to a very large extent on the reaction conditions (temperature, solvent, and catalyst).

A study of the factors influencing the stereospecificity of the silyl method for the synthesis of deoxynucleosides was made using as an example the reaction of 3,5-di-*p*-chlorobenzoyl-2-deoxy-α-D-ribofuranosyl chloride with the silyl derivatives of 5-mercaptouracil and thymine[116]. It was established that chlorotrimethylsilane has a major influence on the stereospecific course of the reaction. Under reaction conditions promoting the rapid removal of chlorotrimethylsilane from the reaction medium, the β-anomer is formed preferentially or exclusively. On the other hand, the addition of chlorotrimethylsilane to the reaction mixture promotes the formation of the α-anomer. It was found that chlorotrimethylsilane can cause the anomerisation of the halogenose under the reaction conditions;

To investigate the influence of chlorotrimethylsilane on the glycosyl chloride, the latter was allowed to stand in benzene in the presence and absence of chlorotrimethylsilane for several hours at room temperature. When the halogenose was allowed to stand for a long time in the absence of chlorotrimethylsilane in benzene solution (see scheme above), a small amount of compound (XLII) was isolated in addition to *p*-chlorobenzoic acid (XL) and furfuryl-*p*-chlorobenzoic acid. A carbonium ion can participate as an intermediate in the formation of all the degradation products of the glycosylhalogenose; the presence of chlorotrimethylsilane prevents the formation of the carbonium ion, stabilising the halogenose in the form of an equilibrium mixture of α- and β-anomers. In the condensation reaction, β-halogenose reacts much faster with bistrimethylsilylpyrimidine than the α-anomer and, as the latter is consumed, chlorotrimethylsilane is used to restore the equilibrium with inversion of the α-anomer to the β-anomer. Chlorotrimethylsilane does not anomerise the complete nucleoside.

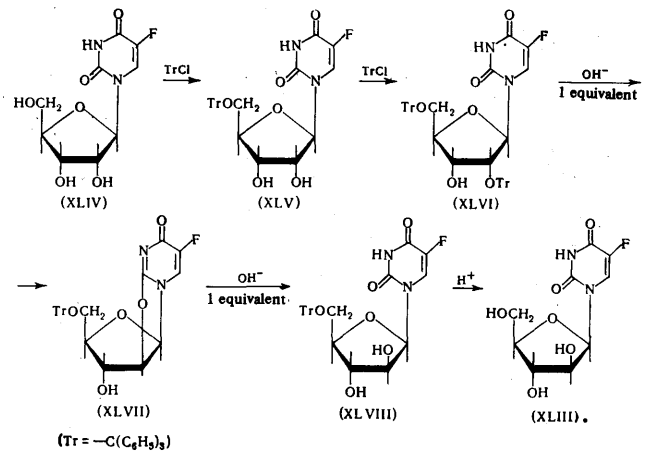
Consequently the stereospecific formation of α- or β-deoxynucleosides can be explained solely on the basis of an S_N2 mechanism. Bearing in mind that the condensation reaction involves a nucleophilic attack by silylpyrimidine on glycosyl chloride with a single Walden inversion, the reaction of the pure α-halogenose should lead to the formation of the β-nucleoside; on the other hand, the reaction of the β-halogenose should tend to form the α-nucleoside.

Japanese workers found that, when bis(trimethylsilyl)-uracil and tribenzoylribofuranosyl chloride are fused together[95], bis(tribenzoylribosyl)uracil is formed together with the α- and β-anomers. The ultraviolet absorption spectrum of the debenzoylated product resembles that of 1,3-dimethyluracil[117]. However, the *O*-glycosides[102] formed when the mercury method is employed were not detected in the silyl method. Possibly, in the condensation of *O*-silyl derivatives with halogeno-sugars, there is a very fast migration of the sugar residue from the oxygen atom to the nitrogen atom with formation of an *N*-glycoside.



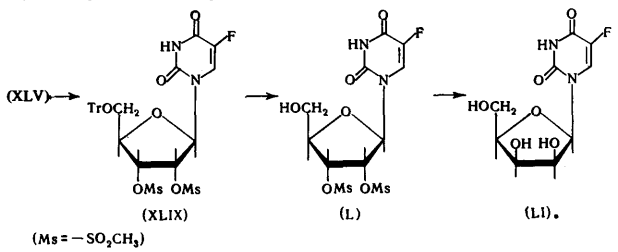
V. METHOD INVOLVING THE MODIFICATION OF THE SUGAR OR BASE IN THE COMPLETE NUCLEOSIDE

In nucleoside chemistry, there are many examples of reactions of nucleosides which involve changes both in the aglycone (halogenation, methylation, introduction of sulphur, deamination, etc.) and in the sugar component of the nucleoside, associated with the formation of anhydronucleosides (for example, a change in the configuration of the sugar residue or the introduction of a new functional group into the sugar moiety). Moreover, the changes in the aglycone are frequently results of the formation of anhydronucleosides.

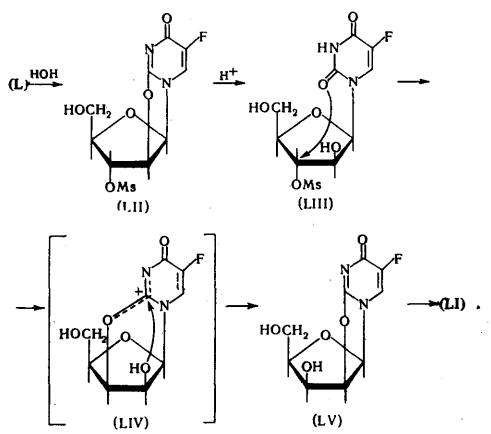


1. Transformations of Pyrimidine Nucleosides via Anhydronucleosides

The inversion of a hydroxy-group of the sugar was first described for thymidine; it occurred as a result of the formation of the 2,3′-anhydronucleoside, which is converted into 1-(β-D-deoxyxylofuranosyl)thymine on alkaline hydrolysis[118]. Subsequently similar results were obtained with ribonucleosides from which pyrimidine

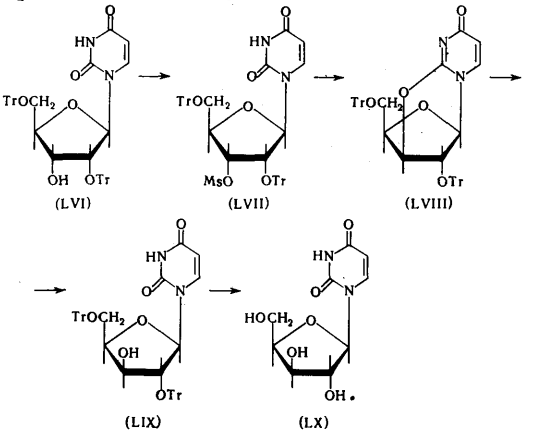


nucleosides with *lyxo*-, *xylo*-, and *arabino*-configurations are formed via the 2,2'- and 2,3'-anhydronucleosides.

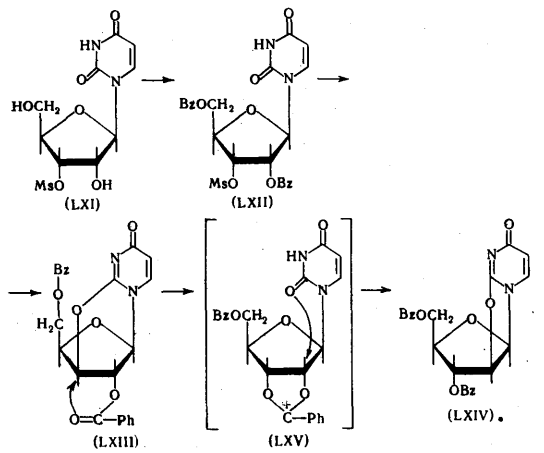


Thus 1-(β-D-arabinofuranosyl)urasil (spongouridine) [119] and 1-(β-D-arabinofuranosyl)thymine [120] were obtained in this way via the 2,2'-anhydronucleoside. A scheme for the synthesis of 1-(β-D-arabinofuranosyl)-5-fluorouracil (XLIII) [121] from 1-(β-D-ribofuranosyl)-5-fluorouracil (XLIV) via the trityl derivatives (XLV)–(XLVIII) is presented below:

When 5-fluoro-5'-trityluridine (XLV) was treated with methanesulphonyl chloride, 2',3'-dimethanesulphonyl-5'-tritylribofuranosyl-5-fluorouracil (XLIX) was obtained, its detritylation yielding the riboside (L); the removal of the methanesulphonyl groups by heating in water gave rise to 1-(β-D-lyxofuranosyl)-5-fluorouracil (LI):

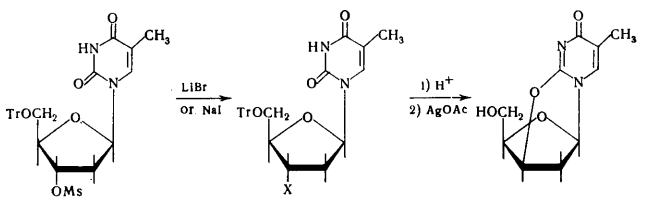


Compound (L) is converted into compound (LI) via a series of successive reactions [122]:



The first stage is the formation of the 2,2'-anhydronucleoside (LII) with liberation of methanesulphonic acid; next, in the presence of an acid catalyst, compound (LII) is cleaved to (LIII) and nucleophilic attack by the 2-carbonyl group on the $C_{(3)}$ carbon atom of the latter yields the 2,2'-anhydrolyxonucleoside (LIV). It is converted into the 2,2'-anhydrolyxonucleoside (LV) as a result of the attack by the OH group at $C'_{(2)}$ on the carbonium ion (LIV). Hydrolysis of compound (LV) leads to (LI).

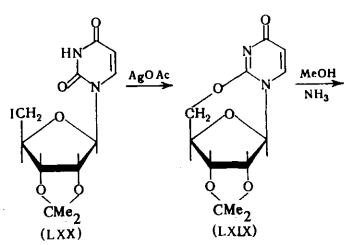
3-*O*-Methanesulphonyl derivatives of uradine are frequently employed to obtain 2,3'-anhydronucleosides, which are intermediates in the synthesis of both xylofuranosyl and arabinofuranosyl nucleosides [123]. Tritylation of uridine under appropriate conditions leads to crystalline 2',5'-di-*O*-trityluridine (LVI) which on methanesulphonation is converted into 3'-*O*-methanesulphonyl-2',5'-di-*O*-trityluridine (LVII). On treatment with sodium benzoate in dimethylformamide, (LVII) is converted into 2,3'-anhydro-2',5'-di-*O*-tritylxylonucleoside (LVIII). Its treatment with alkali and subsequent detritylation yields a single product—1-(β-D-xylofuranosyl)uracil (LX).



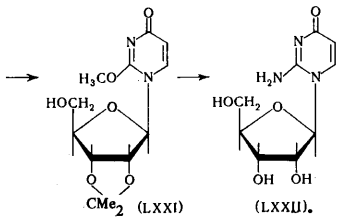
Detritylation of (LVII) yielded 3'-*O*-methanesulphonyluridine (LXI), the 3',5'-dibenzoyl derivative (LXII) of which gave the 2,3'-anhydroxylonucleoside (LXIII) on treatment with sodium benzoate [compound (LXIII) can be obtained also by the direct benzoylation of 2,3'-anhydroxylosyluracil]. When the anhydroxylonucleoside (LXIII) is heated up to its melting point, it isomerises rapidly to 2,2'-anhydro-3',5'-di-*O*-benzoylarabinonucleoside (LXIV), probably via a stage involving the formation of the orthoester ion (LXV) with participation of the adjacent acyl group.

The anhydronucleosides of pyrimidines proved to be convenient not only for the specific inversion of the hydroxy-groups of the sugar but also in the synthesis of 2-deoxynucleosides. Treatment of 5′-*O*-acetyl-2′-*O*-tosyluridine with sodium iodide leads to 5′-*O*-acetyl-2′-deoxy-2′- iodouridine from which 2-deoxyuridine is formed after hydrogenation and deacetylation [124]. The same iodo-derivative (with the ribose configuration) was obtained by treating with sodium iodide and acetic acid the 5′-*O*-acetyl-2,2′-anhydroarabinonucleoside, which can be formed from the iodo-derivative under the influence of a base [125]. Probably the anhydronucleoside is an intermediate in the substitution of toluene-*p*-sulphonyloxy-group by iodine, the final product being formed as a result of two substitutions at $C_{(2)}$.

Thymidine was synthesised by the same method from 5′-*O*-acetyl-1-(β-D-ribofuranosyl)thymine [124]. 2,3′-Anhydroxylonucleoside is the initial compound in the synthesis of 3′-deoxyuridine [126].



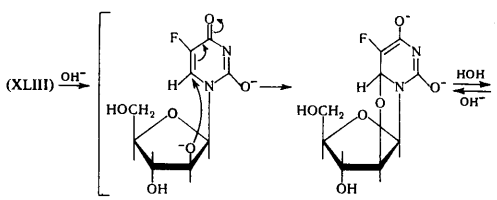
Anhydronucleosides can be used for the stereochemically controlled introduction of functional groups into secondary positions in the sugar residue. Michelson and Todd [118] synthesised 3′-deoxy-3′-halogenothymidine (LXVII) by treating 3′-methanesulphonyl-5′-tritylthymidine (LXVI) with sodium iodide or lithium bromide in acetone at 100°C. They suggested that (LXVI) has the *ribo*-configuration, since it can be inverted to give the 2,3′-anhydro-derivative (LXVIII):

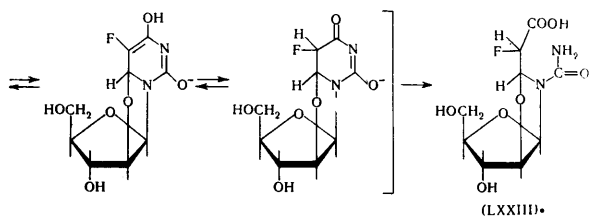


(LXVI) (X = Br, I) (LXVII) (LXVIII).

When 2,2′-anhydronucleosides are treated with anhydrous HBr, HCl, and HI, high yields of 2′-deoxy-2′-halogenonucleosides are formed [127]. It proved possible to obtain 3′-amino-3′-deoxythymidine and the 3′-deoxy-3′-phthalimidonucleoside from thymidine via the 2,3′-anhydro-derivative [128,129].

Anhydronucleosides are also used to replace the oxygen atom at the $C_{(2)}$ atom of the base by various substituents. Brown et al. showed that, when 2,5′-anhydro-2′,3′-isopropylidineuridine (LXIX) obtained from compound (LXX) is treated with a methanol solution of ammonia, the isocytosine derivative (LXXII) is formed via the 2-methoxy-nucleoside (LXXI). [126,130] 1-(β-D-Arabinosyl)isocytosine was synthesised from 2,2′-anhydroarabinosyluracil under the same conditions. Sulphur can be introduced into the heterocyclic ring via the 2,2′- and 2,5′-anhydronucleosides.

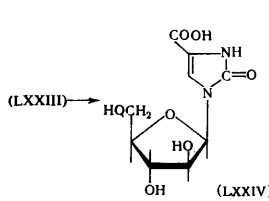




(LXX) (LXIX)

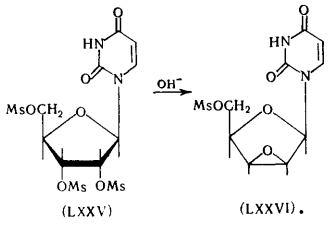
(LXXI) (LXXII).

Fox and coworkers made a detailed study of the behaviour of 5-halogeno-derivatives of spongouridine in an alkaline medium and showed that such nucleosides and their precursors (2,2′-anhydronucleosides) are unstable under these conditions [14,131-134]. For example, on treatment with alkali, 1-(β-D-arabinofuranosyl)-5-fluorouracil (XLIII) is converted into the 2′,6-anhydro-5-fluoro-5,6-dihydro derivative (LXXIII). It was suggested that the process proceeds via a 1,4-addition mechanism:

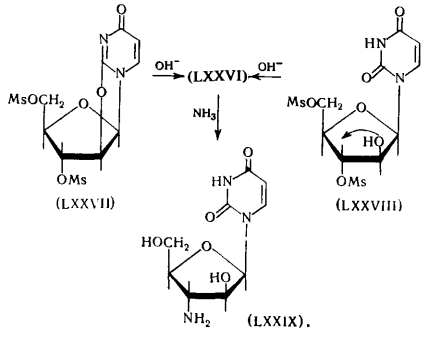


(LXXIII).

Compound (LXXIII) was one of the first products with a 2′,6′-anhydro-linkage obtained from nucleosides. The double bond is not reduced under the reaction conditions while the 3,4-bond is cleaved. The ease with which the 2′-OH anion having the *arabino*-configuration participates in the reaction is probably a property of pyrimidine nucleosides having the aglycone and 2′-OH in the *cis*-positions.

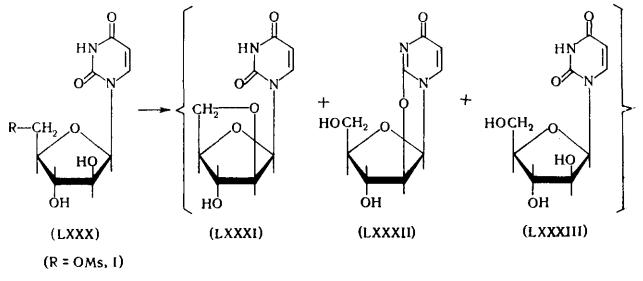


The study of the properties of the 2′,6-anhydro-5-fluoro-5,6-dihydro-derivative (LXXIII) led to the discovery of a new rearrangement of the aglycones of 5-halogeno-derivatives of arabinosyl nucleosides. The reaction of (LXXIII) with 1 *N* NaOH for 20 min at 60°C gives a crystalline halogen-free product (LXXIV):

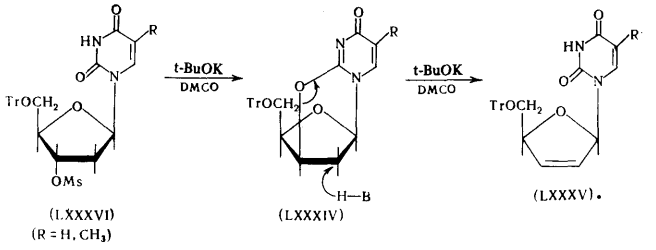


(LXXIV).

A possible mechanism of the conversion of (LXXIII) into (LXXIV) consists in the nucleophilic attack by the amide nitrogen on the $C_{(5)}$ atom with substitution of the fluorine and subsequent cyclisation, dehydrogenation, and cleavage of the 2′,6-anhydro-linkage [14,132]. Anhydronucleosides can be used to synthesise epoxy-derivatives

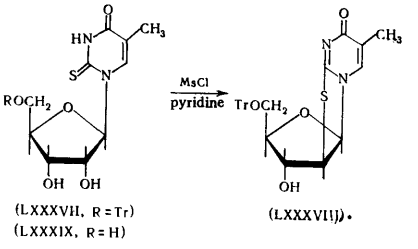


of nucleosides. Treatment of tri-*O*-methanesulphonyluridine (LXXV) with three equivalents of alkali gives a high yield of the 2′,3′-epoxide (LXXVI):[135,136]

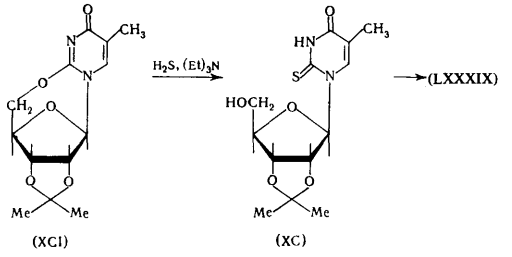


This reaction can probably proceed via the anhydronucleoside (LXXVII) and the arabinonucleoside (LXXVIII), since each is converted into an epoxide on treatment with alkali. On treatment with an alcoholic solution of ammonia at an elevated temperature, the epoxide is converted into 1-(3′-amino-3′-deoxy-β-D-arabinofuranosyl)uracil (LXXIX):[135]

In the course of a study of the hydrolytic cleavage of the 5′-iodo- or 5′-methanesulphonyloxy-derivatives of arabinosyluracil, evidence was obtained for intramolecular reactions involving anhydronucleosides[137]. Treatment of compound (LXXX) with boiling water results in the formation of three products: 2′,5′-epoxynucleoside (LXXXI), 2,2′-anhydronucleoside (LXXXII), and 1-(β-D-arabinofuranosyl)uracil (LXXXIII). The last compound can be obtained by the hydrolysis of (LXXXII).

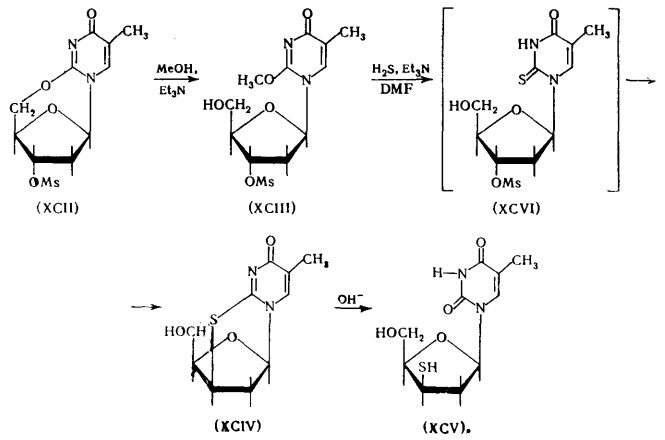


Recently Horwitz and coworkers showed[138,139] that certain anhydronucleosides can be used to synthesise derivatives unsaturated in the sugar moiety by a base-catalysed elimination reaction. Thus, on treatment with potassium t-butoxide in dimethyl sulphoxide (DMSO), the anhydronucleoside (LXXXIV) gives rise to a high yield of the Δ2′,3′-nucleoside (LXXXV), which can also be obtained from the nucleoside (LXXXVI) under the same conditions:



Detritylation of compound (LXXXV) yields "thymidinene" and "uridinene" respectively.

The first synthesis of an anhydronucleoside containing a sulphur atom instead of oxygen in the anhydride bridge was achieved by Shaw and Warrener, who observed that the $S_{(2)}$, 2′-anhydronucleoside (LXXXVIII) is formed in high yields on methanesulphonation of 5-methyl-2-thio-5′-*O*-trityluridine (LXXXVII).[140,141]



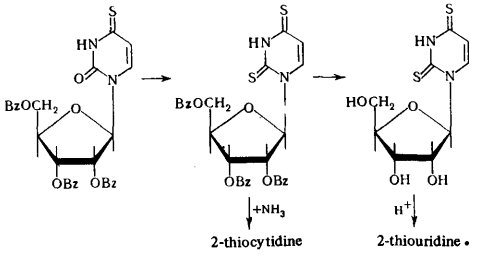
The initial compound (LXXXVII) was obtained by the tritylation of the thionucleoside (LXXXIX), which was synthesised from isopropylidene-2-thiouridine (XC), one of the products of the interaction of 2,5′-anhydro-2′,3′-isopropylideneuridine (XCI) with hydrogen sulphide in the presence of triethylamine:

When the 2,5′-anhydronucleoside (XCII) is heated with methanol containing triethylamine, a high yield of the 2-methoxynucleoside (XCIII) is obtained; its treatment with hydrogen sulphide and triethylamine in DMF in 65°C for several hours leads to the $S_{(2)}$,3′-anhydronucleoside

(XCIV). The cleavage of the sulphide bridge with 0.1 *N* solution of alkali gives the 3′-mercaptonucleoside (XCV):

The 2-thionucleoside (XCVI), which was synthesised from compound (XCII) by treatment with hydrogen sulphide (in DMF) and triethylamine at room temperature, is an intermediate in the conversion of (XCIII) into (XCIV). Compound (XCVI) was converted into compound (XCIV) by refluxing in ethanol containing triethylamine.

The introduction of sulphur into the $C_{(4)}$-position in the pyrimidine ring is used as an intermediate reaction in the general method for the conversion of various uracil nucleosides into their cytosine analogues [142]. As a rule, treatment of uracil and its derivatives with phosphorus pentasulphide results in the introduction of the thio-group in the 4-position.



In model experiments with 1-methyluracil, the introduction of sulphur followed by amination yielded 1-methylcytosine; hence it was concluded that this reaction can be used also to synthesise nucleosides. In the latter case the hydroxy-groups of the sugar residue must be protected (with the benzoyl group) and pyridine must be employed as the reaction medium.

As a result of the introduction of the thio-group into ribo- and deoxyribopyrimidine nucleosides, reactive intermediates are obtained from which one can synthesise not only the principal natural nucleosides but also various 4-substituted analogues. Thus the 4-thio-compound was obtained from 3′,5′-di-*O*-benzoylthymidine and was converted by treatment with an alcoholic ammonia solution into 2-deoxy-5-methylcytidine. Uridine and 1-(β-D-ribofuranosyl)thymine were converted in this way into cytidine and 5-methylcytidine; likewise glycosyl-5-fluorocytosines were obtained from 5-fluorouridine and 2-deoxy-5-fluorouridine [143]. 5-Azacytidine is obtained in a similar way following the introduction of the thio-group into tri-*O*-benzoyl-5-azauridine with subsequent amination and debenzylation [144,145].

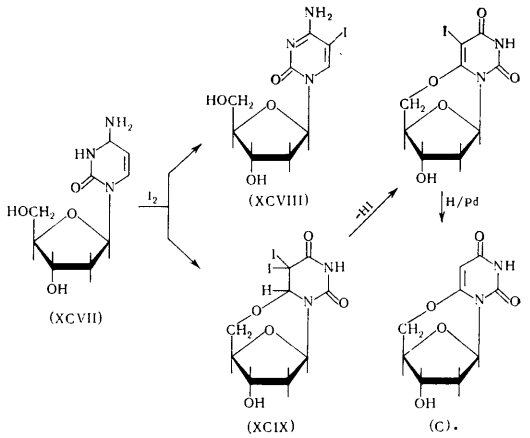
When acylated 4-thionucleosides (including 2-deoxy-derivatives) are treated with appropriate reagents, 4-alkylamino-, 4-hydrazino-, 4-hydroxylamino-, and other derivatives are formed [143].

When the thio-group in 4-thiothymidine and 4-thiouridine is removed with activated Raney nickel, the heterocyclic ring is fully hydrogenated with formation of 2-oxohexahydropyrimidine nucleosides. Such ready and extensive reduction is characteristic of 4-thiouracils and 2-hydroxypyrimidines and does not occur with 2-thiouracils and 4-hydroxypyrimidines [146].

Brown and Herper [147] succeeded in introducing sulphur directly at the $C_{(2)}$-position in 1-methyluracil by treatment with P_2S_5 in tetralin [147]. In 1968 Japanese workers achieved this reaction with the corresponding nucleosides [148]:

2. Halogenation of Nucleosides

In 1907 Wheeler and Johnson observed for the first time the decolorisation of bromine water by uracil and cytosine. Since then, this reaction has been used as a qualitative test for these substances. The colorimetric method for the determination of uracil and cytosine is also based on it [149]. The reaction likewise plays an important role in the synthesis of nucleoside derivatives, in particular 5-bromouridine [150].



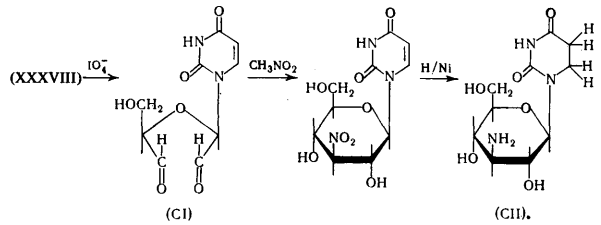
The halogenation of pyrimidine nucleosides takes place readily and leads to a modification of the heterocyclic ring without its cleavage. Usually nucleosides and bases are halogenated with the free halogen in an anhydrous solvent (the iodination reaction is an exception) in which substitution at the fifth carbon atom, where there is an excess of electron density, takes place [151-154].

The bromination of nucleosides usually occurs under very mild conditions and can be achieved in several ways: (a) in anhydrous solvents, for example in DMF, pyridine, formamide, and alcohol [155,156]; 5-bromo-derivatives of cytidine and deoxycytidine were obtained under the same conditions [155-157]; (b) with bromine water and subsequent lyophilisation [158] and (c) with simultaneous irradiation by ultraviolet light [159,160]. The mechanism of the halogenation reaction has been investigated in detail for the bromination of pyrimidine nucleosides [161-163].

As a rule uracil derivatives are chlorinated with a chlorine solution in dry carbon tetrachloride, which is added to a solution of the initial compound in glacial acetic acid. The reaction proceeds readily and terminates after several hours at room temperature or after several minutes on heating. It proved possible to obtain in this way 5-chlorouridine [158,164] and 5-chlorodeoxyuridine [165]. 5-Chlorocytidine cannot be obtained under similar conditions [159], because cytidine exists in a protonated form in glacial acetic acid and electrophilic attack is difficult. However, when the reaction mixture containing cytidine is irradiated by ultraviolet light, the reaction takes place smoothly, probably owing to a change in reaction mechanism, with radical substitution instead of electrophilic substitution.

The iodination of pyrimidine nucleosides takes place under much more severe conditions. Iodination methods have been developed and introduced into the synthetic chemistry of nucleosides by Prusoff [166,167]. The commonest iodination procedure involves heating the nucleosides with a chloroform solution of iodine in the presence of nitric acid. Modifications of this method consist in using different solvents, different nitric acid concentrations, or different heating times [166-170]. 5-Iodo-derivatives of uridine, deoxyuridine, etc. have been obtained in this way.

Another possible iodination procedure involves treatment with iodine in the presence of alkalis [166]. However, these methods cannot be used to synthesise 5-iodo-derivatives of cytidine and deoxycytidine, since under these iodination conditions the *N*-glycosidic bond is broken [171]. The replacement of nitric acid by another oxidising agent (for example iodic-acid) which does not affect the glycocidic linkage permits the successful iodination of cytidine and deoxycytidine (XCVII). [172] Together with deoxy-5-iodo-cytidine (XCVIII), a side product was isolated, which proved to be the anhydrodi-iodonucleoside (XCIX); the latter can be converted into the deiodinated product (C): [13]



Bromine chloride and iodine chloride have been used as mild iodinating and brominating agents. Joshida et al. [173] believe that electrophilic substitution takes place in this case and suggest that in iodination and bromination by this method in DMF the formation of 5-halogenouridines is accompanied by the formation of 5-halogeno-5,6-dihydro-6-hydroxyuridine, as in bromination in aqueous solvents.

N-Halogenoamides and *N*-halogenoimides are effective halogenating agents, which made it possible to replace the hydrogen atom at the $C_{(5)}$-position of the pyrimidine ring under extremely mild conditions. Thus the use of *N*-chloro- and *N*-bromo-succinimides permits the synthesis of 5-chloro- and 5-bromo-derivatives in almost quantitative yields [174-180]. For iodination with *N*-iodo-succinimide in DMSO, it is necessary to add catalytic amounts of di-n-butyl disulphide [178,181], which is probably required to form an intermediate halogenating agent—n-butylsulphenyl iodide.

Fluorine-containing nucleosides are usually obtained from the corresponding fluoro-derivatives of pyrimidine using one of the direct methods of synthesis discussed above.

3. Oxidation of Nucleosides

Fox and coworkers [182] obtained nucleosides derived from 3'-amino-3'-deoxyaldoses by the periodate oxidation of uridine to the dialdehyde (CI) without the cleavage of the glycosidic linkage; the addition of nitromethane leads to cyclisation. 1-(3'-Amino-3'-deoxy-β-D-glucopyranosyl)-5,6-dihydrouracil (CII) was obtained after the reduction of the nitro-group:

Among the methods of synthesis of pyrimidine nucleosides discussed above, the silyl method is the most advantageous. This is clearly seen from the synthesis of 1-(β-D-xylofuranosyl)uracil and 5-bromouracil tribenzoates [183-187]. The yield of the first compound was 77% by the silyl method and 28% by the mercury method; in the synthesis involving the modification of the ribose residue of uridine, this compound was obtained in a yield of only 8%. [188]

As a preparative method, the modification procedure suffers from many disadvantages among which the large number of stages in the processes and the low yield of products are of primary importance. Nevertheless, this method permitted an appreciable expansion of the chemistry of nucleosides and led to the possibility of a wide variety of chemical transformations of the compounds.

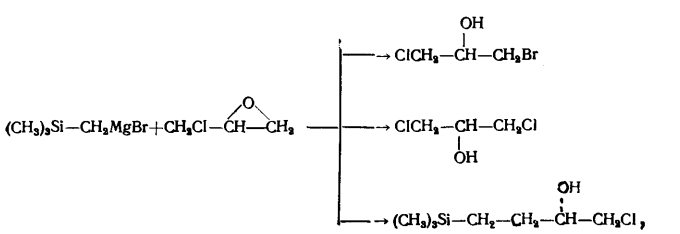
Organosilicon Epoxy-compounds

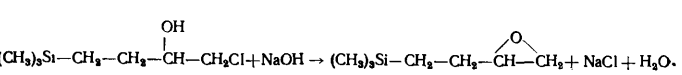
L.V.Nozdrina, Ya.I.Mindlin, and K.A.Andrianov

The review deals with methods for the synthesis of monomeric organosilicon epoxy-compounds and some of their reactions. The possibility of employing these compounds for the synthesis of organosilicon polyepoxides is demonstrated and some of their properties are described.
The bibliography includes 46 references.

CONTENTS



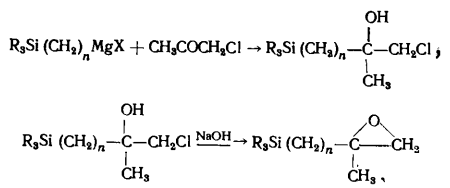
1. Introduction 509
2. Dehydrohalogenation of organosilicon chlorohydrins 509
3. Reactions of functional groups at the silicon atom with epoxy-compounds 509
4. Interaction of epichlorohydrin with functional groups in the side chain at the silicon atom 510
5. Addition of silanes to unsaturated epoxy-compounds 510
6. Oxidation of unsaturated silicon compounds 511
7. Reactions of organosilicon epoxy-compounds 511



1. INTRODUCTION

Organosilicon polymers have found many applications in industry in view of their thermal stability and good dielectric properties. However, owing to their low mechanical strength and poor adhesion to glass and metals, the scope of their applications is significantly restricted. Materials formed on the basis of epoxy-resins are known to have a very high strength and satisfactory adhesion characteristics. Therefore at the present time much attention is being devoted to the synthesis of monomeric organosilicon compounds containing heterofunctional groups, particularly epoxy-groups, in the side chain at the silicon atom. Among the methods described for the synthesis of organosilicon epoxy-compounds, several trends may be distinguished.

2. DEHYDROHALOGENATION OF ORGANOSILICON CHLOROHYDRINS

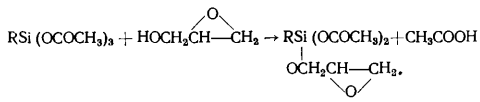


A widely employed method of synthesising epoxyalkanes is based on the dehydrohalogenation of halogenohydrins in the presence of alkaline agents. The first epoxysilylalkane was obtained by the interaction of the corresponding Grignard reagent with epichlorohydrin and subsequent dehydrohalogenation. The reaction resulted in a large amount of side products together with the desired substance:

The yields of the organosilicon chlorohydrins and of the corresponding epoxide did not exceed 25–30%.

The possibility of obtaining the halogenohydrin by the reaction of the Grignard reagent derived from the halogenoalkylsilane with monochloroacetone has been demonstrated[2]. The unambiguous course of this reaction makes it possible to obtain epoxides in high yields according to the scheme:

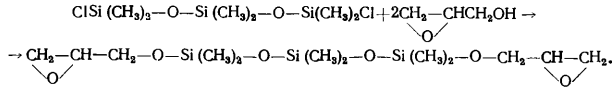
Ethynylepoxides have been obtained in this way[3,4].



The attempt to obtain an epoxide from $R_2Si(OH)-CHCl-CH_3$ was unsuccessful[2]. Sodium hydroxide hydrolysed the Si–C bonds, while in the presence of calcium hydroxide the initial compound underwent no changes.

A method based on the addition of silanes to unsaturated halogenohydrins has also been used to synthesise organosilicon halogenohydrins. When trialkylsilanes react with $\delta\epsilon$-unsaturated halogenohydrins in the presence of H_2PtCl_6, products resulting from both addition to the multiple bond and dehydrocondensation are formed. The reaction of silanes with $\gamma\sigma$-unsaturated halogenohydrins yields only dehydrocondensation products[5,6].

3. REACTIONS OF FUNCTIONAL GROUPS AT THE SILICON ATOM WITH EPOXY-COMPOUNDS

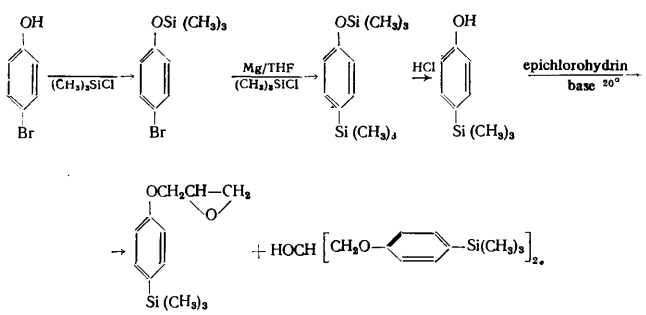


Tetra-alkoxysilanes (for example, tetraethoxysilane) or poly(silyl ethers) containing lower alkoxy-groups (methoxy-, ethoxy-) undergo complete or partial transetherification with glycidol *in vacuo* at a low temperature in the presence of transetherification catalysts (alkoxides)[7]. The compounds obtained readily harden on heating with maleic anhydride, forming polymers with satisfactory physicomechanical properties[8,9].

Acetoxyalkylsilanes also react with glycidol[10] forming glycidyl derivatives of silanes as follows:

With decrease of the number of acetyl groups in alkylacetoxysilanes, their replacement by glycidyl residues becomes more difficult. Thus the acetoxy-groups in triacetoxymethylsilane and triacetoxyvinylsilane are fully replaced by glycidyl groups, while in diacetoxydimethyl- and diacetoxymethyl-silanes they are replaced only to the extent of 70–75%; in triacetoxytrimethylsilane no substitution takes place at all.

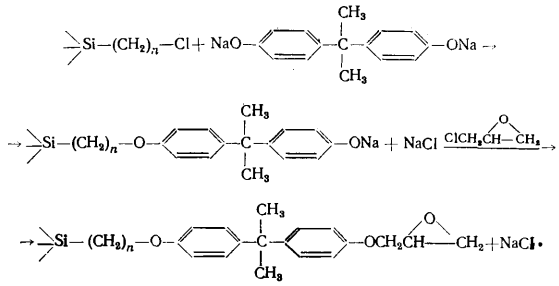
Yamamoto[11] and Martin[12] isolated glycidylsilanes after allowing chlorosiloxanes to react with glycidol in the presence of tertiary amines as catalysts:



Rogers and Lewis[13] extended the scope of the synthesis of such silicon compounds. They suggested that glycidylsilanes be obtained by the reaction of glycidol or epichlorohydrin with organosilicon compounds containing not only halogeno-, alkoxy-, and acyloxy-groups at the silicon atom but also amino-, aryloxy-, and hydroxy-groups. The reaction is catalysed by alkali and is carried out at high temperatures. The resulting organosilicon epoxy-derivatives can be used as casting resins or for the preparation of laminated plastics.

Glycidylsilanes are hydrolytically and thermally unstable.

4. INTERACTION OF EPICHLOROHYDRIN WITH FUNCTIONAL GROUPS IN THE SIDE CHAIN AT THE SILICON ATOM

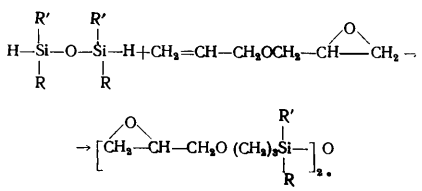


Aryl glycidyl ethers, obtained by the interaction of epichlorohydrin, aromatic hydroxy-compounds, and alkali, have become the main starting materials for the preparation of epoxy-resins. It was interesting to obtain the organosilicon analogues of such resins.

A report on the synthesis of glycidyl 4-trimethylsilylphenyl ether according to the following scheme has been published[14]:

Glycidyl 4-triphenylsilylphenyl ether has been synthesised in the same way[15].

Daniel[16] has proposed a convenient and simple method for the synthesis of interesting organosilicon derivatives of glycidol:



The initial organosilicon halides can be linear, cyclic or branched.

The polymers obtained from these monomers, which can be hardened by amines, are highly resistant to the action of chemical agents and have excellent adhesion properties and thermal stability. They are employed in engineering as insulating materials. Unfortunately the authors of this study do not quote quantitative estimates of the properties of the polymers.

5. ADDITION OF SILANES TO UNSATURATED EPOXY-COMPOUNDS

Silanes add to the double bonds of epoxyolefins in the same way as to other unsaturated compounds, in the presence of peroxide or platinum catalysts. The addition takes place under relatively mild conditions and the epoxy-group remains unchanged[17]. This reaction is applicable to silanes, alkoxysilanes, acyloxysilanes, and siloxanes, but not to chlorosilanes.

The attempt to isolate[18] $\alpha\omega$-bisepoxides after the reaction of allyl glycidyl ether with HRR'SiOSiR'RH in the presence of 0.1 *N* H_2PtCl_6 solution yielded polymeric products, probably as a result of the rupture of the epoxy-ring. It proved possible to obtain a bisepoxide of this kind by the following reaction using Pt/C containing 20% Pt as a catalyst:

By employing various epoxyolefins, it is possible to obtain a wide variety of organosilicon epoxides. In particular, Plueddemann and Fanger[17] obtained such compounds by the interaction of silanes with the monoepoxy-derivative of butadiene, allyl glycidyl ether, the monoepoxy-derivative of limonene, the monoepoxy-derivative of vinylcyclohexene, and 2-allylphenyl glycidyl ether. Other workers synthesised aminoepoxy-siloxanes[18–20], chlorine-containing organosilicon epoxides[21], and unsaturated organosilicon epoxy-derivatives[22]. Polymeric products derived from the latter can be obtained not only as a result of the opening of the epoxy-ring but also via the multiple bond.

Plueddemann[23] isolated individual cyclic, branched, and linear glycidylpropylsiloxanes containing less than six units. When these siloxanes hardened, it was found that cyclic polyepoxysilanes exhibit the highest hardness,

thermal stability, and impact strength. The Martens thermal stability of the polymers of lower epoxysilanes is lower than that of the usual epoxy-resins, but that of the higher polymeric epoxy-silanes is higher.

Epoxy-siloxanes synthesised by the addition of silanes have been recommended as active solvents for casting and adhesive epoxy-resins (in particular epoxynovolac resins[24]), as components of phenolic[25], alkyd, and polyester resins[26] to impart to them a higher thermal stability, as modifying agents for silicone resins to improve their adhesion and mechanical properties, and for other purposes. In 1958, epoxy-compounds of this kind were produced in France on an industrial scale[26].

6. OXIDATION OF UNSATURATED SILICON COMPOUNDS

Organosilicon epoxy-compounds with the smallest organic groups can be obtained by oxidising a multiple bond. The Prilezhaev epoxidation of silylolefins by peracids has been described. Organic peracids are electrophilic agents, the rate of reaction with such acids increasing appreciably as the nucleophilic properties of the olefin are enhanced following the substitution of the hydrogen atoms at the double bond by electron donating groups[27]. The silicon atom linked to the unsaturated aliphatic group should facilitate its oxidation by peracids.

Wende and Gesierich[28] showed that allyltriphenylsilane interacts with perbenzoic acid at a higher rate than the analogous carbon compound 1,1,1-triphenylbut-3-ene. The authors explained the increase of the rate of reaction by the negative charge on the double bond induced by the silicon atom. Under the same conditions, the vinylsilicon derivative reacts with a peracid (peracetic[17] and perbenzoic[28]) much more slowly than the allyl derivative.

In organosilicon compounds where the double bond is separated from the silicon atom by more than two carbon atoms, the silicon atom has no effect on the oxidation of the unsaturated group[17]. Organosilicon compounds containing two unsaturated groups[28] are oxidised faster than those containing one unsaturated group.

A study of the epoxidation of dimethyldivinylsilane with perbenzoic acid established[29] that the first vinyl group is oxidised much faster; the amount of monoepoxide formed is 5–6 times greater than that of the diepoxide.

In the oxidation of tetravinyldisiloxane, the first two vinyl groups are readily oxidised, while the third and particularly the fourth group are oxidised much more slowly.

When epoxy-rings accumulate in the molecule, the stability of the compound diminishes.

The general characteristics of the epoxidation reaction hold for unsaturated siloxane derivatives. The introduction into the silane molecule of the electrophilic phenyl group decreases the reactivity of the vinyl group at the silicon atom; the bulky trimethylsilyl group has a similar effect. On the other hand, when the small electron-donating methyl group is present, the rate of epoxidation increases[30].

The rate of oxidation of silanes containing one unsaturated group by perbenzoic acid decreases in the following sequence: trimethylsilane > tripropylsilane > triethylsilane > tribenzylsilane > triphenylalkylenesilane[28].

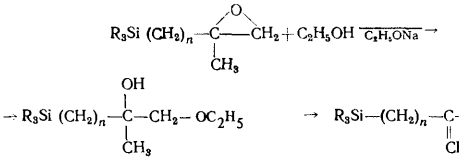
Numerous studies have established[31] that the rate of reaction between peracids and olefins follows a second-order equation (the reaction is of first-order with respect to each component). Kinetic data for the oxidation of the vinyl group in silylolefins by perbenzoic acid[30] have shown that the reaction involving organosilicon compounds is also of second order and can be represented by the following kinetic equation:

$$-\frac{dx}{d\tau} = k\,(C_3H_5CO_3H)\ \text{(silyl olefin)}.$$

The rate constant depends on the number and nature of the substituents in the reacting molecule and on the strength of the acid oxidising the olefin[32].

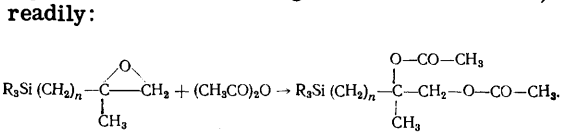
The epoxidation of unsaturated silicon compounds by perbenzoic[33–36], perphthalic[37], 40% peracetic[17], and peroxytrifluoroacetic[38] acids has shown that peroxytrifluoroacetic acid is the best epoxidising agent. The oxidation with perbenzoic acid is as a rule carried out at 0–20°C over a period of several days.

The epoxidation of vinylsiloxanes with 40% peracetic acid in acetic acid is very slow and gives a very low yield of epoxy-derivatives (less than 20%). Temperature and time play an important role. On raising the temperature and reaction time, there is an increased contribution due to decomposition side reactions and the yield of the epoxy-product falls appreciably[38]. Therefore one must employ the most reactive peracid and the optimal reaction conditions must be determined.



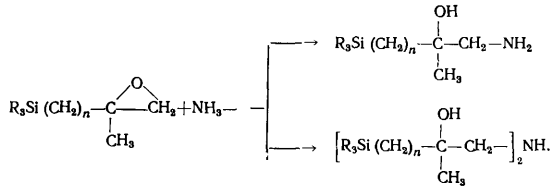
The reaction of unsaturated silicon compounds with perbenzoic acid takes place in chloroform and carbon tetrachloride much faster than in other solvents, but by employing a less active solvent (ether, tetrahydrofuran) it is possible to eliminate the side reactions.

Epoxy-organosiloxanes obtained by the oxidation of the vinyl group give rise to absorption bands in the infrared close to 758, 815, and 1138 cm^{-1}, which are characteristic of the epoxy-group[39]. Compounds of this class can be used as plasticisers, coatings, adhesives, and casting resins[39]. They are also suitable as agents imparting to coatings based on siloxanes an enhanced stability to wear[40].

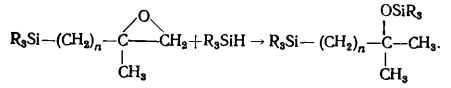


7. REACTIONS OF ORGANOSILICON EPOXY-COMPOUNDS

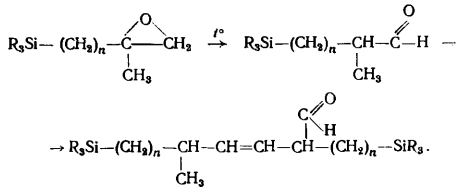
The epoxy-group in organosilicon compounds enters into its characteristic reactions with alcohols, phenols, acids, amines, and other compounds in the presence of appropriate catalysts[18,26,41].



On treatment with alcohols in the presence of sodium alkoxides, organosilicon epoxy-compounds form ether-alcohols which are dehydrated on heating in the presence of $KHSO_4$ with formation of unsaturated organosilicon ethers[42]:

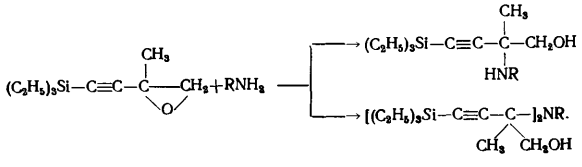


The reaction of epoxysilanes with acetic anhydride, resulting in the formation of organosilicon diacetates, takes place readily:

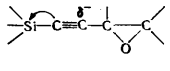


On prolonged refluxing of organosilicon epoxy-compounds with ammonia, organosilicon mono- and di-amino-alcohols are produced:

Organosilicon epoxy-compounds readily combine with silanes, forming an ether and not an alcohol[2]:

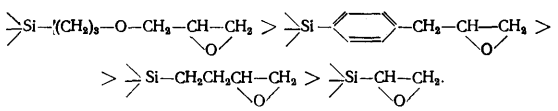


On prolonged heating up to the boiling point (at atmospheric pressure), organosilicon epoxy-compounds isomerise to aldehydes, which then undergo partial crotonic condensation[42]:

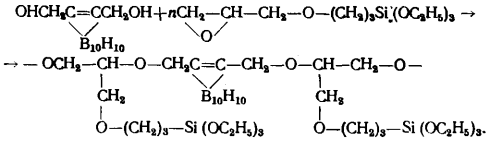


In order to assess the electronic influence of the silicon atom on the properties of the adjacent epoxy-group, a study was made of the reduction of a number of epoxyethylsilanes with lithium aluminium hydride[43]. In monosubstituted epoxides, the sterically more accessible carbon atom is usually subjected to hydride attack with formation of a secondary alcohol. When epoxyethylsilanes are reduced, a primary alcohol $R_3SiCH_2CH_2OH$ is formed unambiguously in a high yield. It would appear that steric factors should favour attack on the primary carbon atom in epoxyethylsilanes, but it has been established that in the reduction with lithium aluminium deuteride a primary alcohol is formed as a result of direct attack by the hydride ion on the carbon atom linked to silicon; this anomalous behaviour of epoxyethylsilanes can be explained by the electronic influence of the silicon atom on the epoxy-group.

The epoxy-ring of organosilicon ethynylepoxides[3], where the silicon atom is linked directly to a triple bond, is opened under the influence of aliphatic amines at the carbon atom linked directly to the triple bond (contrary to the Krasusskii rule):



This phenomenon can be explained by a specific intramolecular interaction of the triple bond π electrons with the free *d*-orbital of the silicon atom, which leads to an enhanced polarisability of the C–O bond on the side of the more substituted carbon atom:



The proximity of the silicon atom lowers the reactivity of the epoxy-group in relation to the aromatic amine[44].

Organosilicon epoxy-compounds can be arranged in the following sequence in terms of their reactivity in the presence of the aromatic amine $H_2N-C_6H_4-OSi\equiv$ at 100°C:

Epoxy-organosilanes form optically active polymers[45] in the presence of a catalytic system comprising an organometallic compound and a complex-forming agent. A study of the migration polymerisation of triethoxyglycidylpropylsilane in the presence of bishydroxymethylcarborane showed[46] that in the first stage of the polymerisation the epoxy-groups interact with the hydroxy-groups of the carborane with formation of a linear polymer in accordance with the following scheme:

In the second polymerisation stage, where the content of epoxy-groups reaches a minimum, the ethoxy-groups are alcoholysed, the product changing from a viscous liquid to an elastic form.

In the absence of compounds with active hydrogen (amines, alcohols, etc.), the siloxane moiety of epoxy-organosilanes can undergo a rearrangement catalysed by alkali without the opening of the oxiran ring[17]. Alkoxysilyl groups can also be hydrolysed under mild conditions without the involvement of the epoxy-component of the molecule[17,26].

Topochemistry of the Thermal Decomposition of Solid Substances

V.V.Boldyrev

Factors which determine localisation and autolocalisation in topochemical processes are considered systematically in this review. The specific features of the formation and growth of nuclei in topochemical reactions, the role of the anisotropy of the properties of the initial crystal, and various versions of the catalysis of solid and gaseous products during the thermal decomposition of solid inorganic substances are given. Promising investigations in this region are noted. Bibliography of 83 references.

CONTENTS

I. Localisation and autolocalisation of topochemical processes 515
II. Causes of the autolocalisation process in the thermal decomposition of solid substances 516

I. LOCALISATION AND AUTOLOCALISATION OF TOPOCHEMICAL PROCESSES

A characteristic feature of many solid-state chemical reactions is their localisation in definite parts of the crystal. This distinguishes solid-state reactions from those in liquids and gases, the reaction zone in which is uniformly distributed throughout the entire volume.

The localisation of chemical reactions in the solid state, owing to which these reactions have been termed topochemical (from the Greek word "topos", meaning place) is apparent both in the reaction starting at individual points of the solid body which are characterised by increased reactivity and are usually found at the surface, and in that having started at a definite site of the crystal the reaction proceeds by advancement of the reaction zone from the centre at which the reaction started into the neighbouring regions of the crystal. Such a unique nature of the development of topochemical reactions leads in their kinetic analysis to the necessity of considering the process not only in time coordinates (as is done in ordinary chemical kinetics) but also in spatial coordinates. Although this feature of topochemical reactions is well known and one of the main problems of the kinetic analysis of solid-state chemical reactions is the finding of the relation between the rate of formation of the nuclei of the new phase and their growth rate, the physicochemical causes which lead to the localisation of the process have in many instances not yet been studied. In the investigation of specific topochemical reactions it is usually difficult to state beforehand how the initial centres in a solid will be distributed and which factors will be responsible for the occurrence of a process in which the reaction, having started in some part of the crystal, continues to develop in the same place or its immediate surroundings. Moreover, the development of investigations in this direction is important, since it allows both the planning of new methods of directed regulation of the rate of reaction in a solid phase and also the obtaining of a solid decomposition product with previously specified morphological properties.

To the first approximation two groups of factors can be distinguished on which the degree and nature of the localisation process in topochemical reactions can depend. The first group includes those which depend on the potential conditions which exist in the solid until the start of the reaction. These factors are determined by the difference between the reactivities of the various parts of the initial solid substance. They include primarily the difference between the properties of the surface of the solid and

those of its bulk, the non-equivalence of the reactivity of different points of the surface and the bulk of the crystal, associated with the presence of defects of the crystal and defects of the crystal lattice, which determine the mobility of the lattice elements, etc.

The influence exerted by these factors on the reactivity of solids has been examined in detail in many papers concerned with the correlation between the real structure of a crystal and the kinetics of solid-state chemical reactions[1-4]. These questions will not therefore be discussed in the present review.

The second group comprises the factors which determine the change in the degree of localisation during the course of the process. In other words, this group of factors includes those which determine the probability that when the process has started at some point on the surface of the crystal or in its bulk it will continue to develop at the same place or close to it.

In comparison with the factors which belong to the first group, those which are due to the change in the degree of localisation during the course of the process, usually autolocalisation, have been studied much less, although the need for investigations to be made in this direction was stated long ago, starting with the earliest papers dealing with the study of topochemical reactions[5-8].

Not only have the reasons for the autolocalisation of the topochemical reactions been little studied, but in many instances the criteria which characterise the change in the degree of localisation with time remain obscure. Presumably the autolocalisation process, which leads to the formation of nuclei and their growth, is a function of the ratio of the rate constant for the formation of the nuclei to the rate constant for their growth. However, such a determination can hardly be regarded as sufficient and complete, since it is based on an extremely primitive model of topochemical reactions and does not take into account other forms of the autolocalisation process (for example, the change in the degree of "compactness" in the distribution of nuclei in the solid body).

In addition, it remains unknown whether there is a reason for the difference in the nuclei formation and growth constants, that is, that in one instance the development of a reaction proceeds by the growth of a small number of reaction nuclei and in another the reaction develops mainly by nuclei formation. There have been many hypotheses and conjectures along these lines. The most general was advanced by Sakovich[9], in which the change in the degree of localisation of the process was determined as a function of the ratio of "crystal-chemical" and "thermal" components of the activation. The "thermal" component of the activation in the thermolysis of solids is determined by the change in the energy distribution of the phonons in the lattice of the solid and should generally be assigned to the entire volume of the crystal. The "crystal-chemical" component of the activation is the consequence of the breakdown of that equilibrium which existed until the occurrence of a chemical act between the structural units (molecules, atoms, or ions) situated in the bulk of the crystal and the associated change in the reactivity of the structural units adjacent to the lattice node at which the reaction has just taken place. Hence when the thermal component of the activation predominates during the thermolysis, then according to Sakovich it should be delocalised and the reaction must be expected to proceed throughout the entire volume. When the crystal-chemical component of activation predominates an autolocalisation process and its development by the formation and growth of nuclei must be expected.

Despite the obvious merit of Sakovich's scheme, it needs further additions and development. Above all, the hypothesis about the equilibrium distribution in the crystal of the "thermal" constituent of activation is really quite approximate, and as we have already noted[10] the function which corresponds to it should be modelled with allowance for the distribution in the crystal of various types of defects. In addition the crystal-chemical component of activation can also have the most diverse nature and for each specific instance its physical significance should be defined precisely and the factors which could be the cause of autolocalisation found.

II. CAUSES OF THE AUTOLOCALISATION PROCESS IN THE THERMAL DECOMPOSITION OF SOLID SUBSTANCES

The causes of the autolocalisation process in the thermal decomposition can be most diverse. As a first approximation they can be divided into three groups: (a) autolocalisation of thermal decomposition due to crystal-chemical features of the structure of the crystals of the initial substance; (b) autolocalisation of the process due to release of a product during the course of the reaction; (c) autolocalisation of the process, the reason for which is a change in the reactivity of the initial solid substance due to the gaseous products released during the reaction.

We will examine these reasons in more detail.

1. AUTOLOCALISATION OF THE PROCESS OF THERMAL DECOMPOSITION DUE TO CRYSTAL-CHEMICAL FEATURES OF THE STRUCTURE OF THE INITIAL SOLID SUBSTANCE

One of the reasons for the autolocalisation of topochemical processes in general, and of thermal decomposition reactions in particular, can be connected with the anisotropy of the crystal. Thanks to this faces which exhibit increased reactivity can develop during the process. Buntin[7] was interested in the possibility of an autolocalisation of this type during the occurrence of topochemical reactions. This type of autolocalisation has been examined in greater detail in Pavlyuchenko's studies[11,12]. Different places on the surface of a crystal are known to be non-equivalent in reactivity. For example, if the crystal is a cube the particles situated at its vertices are more reactive in thermal decomposition than those situated on the edges. In turn, the particles situated on the edges are more active than those on the faces of the crystal, etc.

We will assume that the reaction starts at the most active sites in the crystal—its vertices. When as a result of the first reaction act a particle is removed from a vertex of the crystal, this brings about the appearance of three new particles which are equivalent in reactivity to that which has disappeared. When these three particles are also removed as a result of chemical reaction, there are then six such particles in the next layer, and so forth (Fig. 1). Since the reactivity of these particles is higher than that of the particles situated in the remaining parts of the crystal the localisation of the thermal decomposition takes place at this particular site.

Hence the mechanism of thermal decomposition is regarded as analogous to that previously developed in studies of the mechanism of dissolution of ionic crystals[13-15]. Therefore, just as in the dissolution of a crystal, as a result of the merging of reaction zones, which

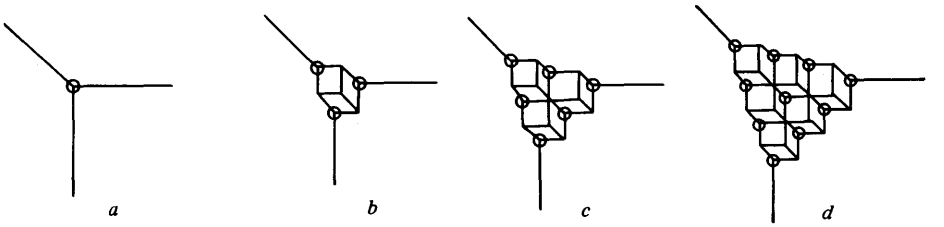

Figure 1. Autolocalisation of the thermal decomposition due to crystal-chemical features of the structure of the initial substance. *a*) Start of the reaction; *b*), *c*), and *d*) separate stages in its development.

are sometimes characterised as a form of negative crystals[16], the crystal ultimately acquires a spheroidal form and the further development of the process is described by the law of contracting spheres.

Thermal decomposition with such a process of autolocalisation is usually characterised by the absence of catalysts among the solid and gaseous products which are formed in the thermal decomposition.

The thermolysis of mercury(II) oxide crystals[16] can serve as an example of this type of process. The decomposition of mercury(II) oxide crystals was found to start at the defect sites on the surface of the crystal and to develop with different rates in different crystallographic directions with the formation of decomposition figures analogous to etch figures and negative crystals. In later studies[17] it was shown that when the temperature was raised the decomposition proceeded over the entire surface. An analogous picture is observed in the thermal decomposition of silver cyanamide[18,19] and in the sublimation of certain ammonium salts, for example, ammonium perchlorate[20]. For the latter it has been shown that when the decomposition (sublimation) takes place at low temperatures the reaction is localised in the zone of dislocations.

2. AUTOLOCALISATION OF THERMAL DECOMPOSITION DUE TO THE FORMATION OF A SOLID PRODUCT DURING THE COURSE OF THE REACTION (AUTOCATALYSIS BY A SOLID PRODUCT OF THE REACTION)

a. General Positions of the Theory of Phase Transformations

The possibility of the autolocalisation of the process of thermal decomposition due to the formation of a solid product during the reaction has been discussed repeatedly[5,8,21,22]. This has been thought[6] to follow from the analogy between the occurrence of topochemical processes and other types of phase transformation (for example, crystallisation from aqueous solutions or from melts, polymorphic transformations, etc.). And although later investigations have shown that this analogy is by no means always complete we will employ it in the present review, mentioning as we go those factors specific for solid-state chemical reactions, which must be taken into account in studying this type of phase transformation.

As follows from the general theory of phase transformations[23-25], the formation of nuclei of a new phase can be regarded as the result of local fluctuations in temperature or concentration in the system, due to which nuclei of a new phase are formed. The change in free energy (the magnitude of which ultimately determines the formation of a new phase) can be written as a sum:

$$\Delta g = \Delta g_v + \Delta g_s,$$

where Δg_v is the change in free energy due to the chemical reaction pertaining to the entire volume, and Δg_S the change in free energy due to the formation of the surface of the new phase.

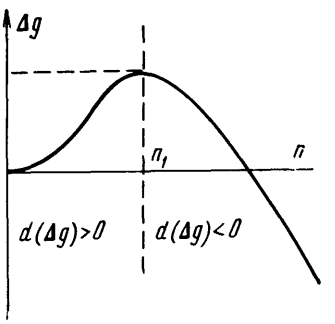

Figure 2. Change in free energy in the formation of nuclei of a new phase during the course of a phase transformation.

The change in free energy for the processes of condensation of vapour and crystallisation from a liquid medium can be written:

$$\Delta g = n(\mu_1 - \mu_2) + \alpha\gamma n^{2/3},$$

where n is the number of moles of reaction product, μ_1 and μ_2 are the chemical potentials of the initial substance and reaction product, α is a coefficient which depends upon the form of the nuclei, and γ the surface energy.

When the solution is supersaturated, $\mu_2 > \mu_1$, the first term in the right-hand part of the equation has a minus sign, and therefore Δg in the change of dimensions of the nuclei is characterised by some extremal value, after reaching which the nuclei become capable of stable growth (Fig. 2).

For the nuclei to reach a dimension greater than the critical one it is necessary to expend energy not only in its formation (Δg) but also the additional amount of energy necessary for the transfer of the particles of the new

phase from the solution or melt through the phase separation boundary. Therefore the rate of formation of the nuclei can be described by the equation:

$$w = c \cdot e^{-\frac{(\Delta g + u)}{kT}}$$

For certain types of phase transformation, for example, in crystallisation from a melt or in the polymorphic change from a high-temperature form into a low-temperature one, the changes $-\Delta u/kT$ and $-\Delta g/kT$ proceed differently (the change in Δg proceeds antibathically to the change in Δu) and as a result a maximum appears on the rate curves—supersaturation. For certain other phase transformations, in particular, in thermal decomposition, this antibathic relation and consequently the maximum may not exist[26].

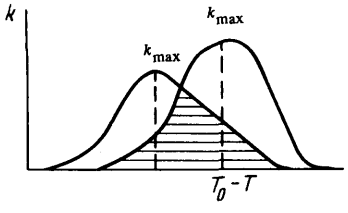

Figure 3. Temperature dependence of the constants for the formation of nuclei and for their growth.

The growth of a nucleus after it has been formed and reached critical dimensions can be regarded as the result of the formation of two-dimensional nuclei on the crystal surface. The change in free energy for the formation of two-dimensional nuclei can be written as

$$\Delta g_2 = n(\mu_1 - \mu_2) + \gamma n^{1/2}$$

and the rate:

$$w = c_2 \cdot e^{-\frac{(u_2 + \Delta g_2)}{kT}},$$

passes through a maximum, just as does the rate for three-dimensional nuclei. Since the dependence of Δg_1 and Δg_2 on supersaturation is different, u_1 and u_2 are different, and so are c_1 and c_2; in general, the positions of these maxima do not coincide (Fig. 3) and therefore either the formation or the growth of nuclei, or both processes together, can take place, depending upon the supersaturation in the system (shown on the Figure by the departure of the temperature from the equilibrium value in crystallisation, induced by cooling of the system).

b. Phase Transformations in the Thermal Decomposition of Solid Substances

When this theory is used for other types of phase transformation, and, in particular, for thermal decomposition, allowance must be made for those specific factors which can significantly alter the general picture of the transformation.

Formation of clusters. Topotaxy. An important factor, which determines both the relation of the chemical and phase stages and also the general nature of the influence exerted by the nuclei of the reaction product on the properties of the initial crystal is the presence of a coherent bond between the lattices of the initial substance and the reaction product.

The possibility of the appearance of this factor depends, firstly, upon some specific features of the formation of nuclei of a new phase in the occurrence of solid-phase processes, and secondly, upon the possibility of effecting an approximate correspondence between the lattice of the initial substance and the lattice of the product.

By analogy with the processes which take place in crystallisation from a melt or a solution when the heterophase fluctuations are the result of the motions of individual atoms or molecules, nuclei are also formed when processes occur in the solid phase. However, the results of more detailed investigations showed that in fact the formation of nuclei in solid-phase reactions is a more complex process, which includes the stage of aggregation in clusters of point defects or dissolved atoms, which become especially significant at the moment of the transformation preceding the formation of a nucleus of the new phase. The interaction can be different in nature but also appears for monotypical defects and for defects of different types.

For identical defects (or atoms) in a polar crystal it comprises the forces of repulsion due to the interaction of the coulombic field and the field of the elastic stresses which surround the defects in the crystal and the attractive forces due to the quantum-chemical interaction. When the attractive forces are greater than the repulsive forces the curves of the potential energy of interaction will be characterised by a minimum. When the depth of this minimum is greater than the mean energy of the phonons in the lattice (κT) the defects can be expected to form clusters[27,28].

For defects of different signs the possibilities of interaction are increased to an even greater degree, for both elastic and coulombic interaction in this instance can lead to attraction and the probability of the formation of clusters is increased accordingly.

In this sense the dependence of cluster formation and in particular of the structure of the clusters in the very first stages on the conditions under which separation of the new phase takes place is extremely important, although there is almost no information about this. Among the few papers in this direction is that of Johanneson and Person[29], who used an electronic computer to model the growth of atomic clusters in the deposition of thin films of silver on the surface of alkali halide crystals. For the modelling they took a relatively simple model, in which the interaction between the adsorbed silver atoms was given by the Morse function

$$\Phi(r) = D[\exp -2\alpha(r - r_0) - 2\ \exp -\alpha(r - r_0)],$$

the calculated values of which for silver are known, the interaction between the adsorbed atoms and the surface is given by the potential function:

$$V(x, y, z) = -\left[Q_d/4\left(\sin\frac{2\pi x}{x_0} + n\frac{2\pi y}{y_0}\right) + Q_{ads} - Q_{dif}/2\right]\exp(-z/z_0)$$

where x_0, y_0, and z_0 are the lattice constants in the direction of the three geometric axes, and Q_{dif} and Q_{ads} are the activation energies of the diffusion and adsorption of the atoms on the surface.

The variation, as parameters of the system in the determination of the energy minimum, of Q_{ads}, Q_{diff}, and d (periodicity of the lattice) showed that not only two-dimensional but also three-dimensional, nuclei can be stable, and that of the three parameters being varied the most important is the interatomic distance of the lattice (d), on which the adsorption takes place. It has been shown[29] that as a result of the change in d the form of the primary cluster consisting of six atoms changes from rectangular to orthorhombic. The form of the cluster is also extremely sensitive to the number of atoms forming the cluster and its dimensionality. What is significant in this is that the three-dimensional nuclei-clusters can be just as stable as the two-dimensional and the addition of each new atom, at least in the initial stage, significantly affects the form of the cluster.

It is quite natural that a similar type of estimation can also be made when we are considering not the deposition of metal atoms from the gas phase on the surface of a crystal, but a solid-phase reaction in which clusters are formed from the defects, for example, from internodal ions, ionic vacancies, and not in a vacuum, but within the crystal lattice. The number of parameters being varied in this instance should be changed and the value of the Morse function should be found for the interaction of the internodal ions, vacancies, etc. Evidently, in principle the approach used for calculating the form of the clusters in the epitaxial growth of thin films is applicable also for topochemical reactions.

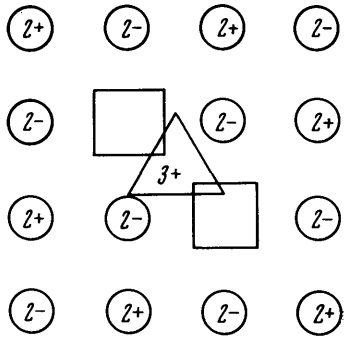

Figure 4. Elementary stages of the formation of Fe_3O_4 in the decomposition of FeO.[28]

As an example, now classical, there is the formation of nuclei of a magnetite phase in the decomposition of wüstite[30]. In the decomposition, which proceeds by the overall scheme:

$$4FeO \rightarrow Fe + Fe_3O_4,$$

the composition of the wüstite phase becomes $Fe_{1-x}O$, where x denotes a position in the lattice occupied by Fe^{3+} ions and cationic vacancies, the formation of which is necessary for the compensation of the charge. Being found at the normal node of the lattice and having smaller dimensions than Fe^{2+}, the Fe^{3+} ion tends to go to an internodal position with the formation of a complex from the Fe^{3+} ion and two cationic vacancies situated symmetrically relative to it. The Fe^{3+} ion occupies the positions which are typical for the tetrahedral node of the spinel formed (Fig. 4). Similar examples are also known for other solid-phase reactions[31].

In addition to the crystal-chemical aspect of the significance of clusters it is also important to bear in mind the thermodynamic aspects[31], which lead to an increase in the probability of the surmounting of the energetic barrier for attaining nuclei of critical dimensions.

An orientation correspondence of the crystal-chemical parameters of the old and new phases is extremely important not only for the formation of these phases but also to an even greater extent for their growth in ensuring that the lattices of the new and old phases are coherent.

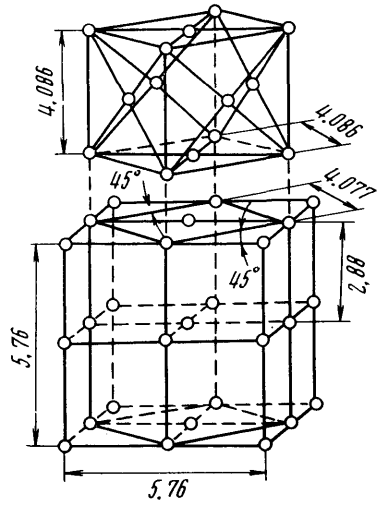

Figure 5. Orientation correspondence between the lattices of silver bromide and silver.

The condition under which there is an orientation correspondence which ensures the uninterrupted change from a phase of the initial substance to a phase of the reaction product was formulated by Dankov[32,33]. According to Dankov, chemical changes on the surface of a solid body develop in such a manner that the configuration of the atoms of the initial phase is retained (or more precisely, almost retained) in the new solid phase. The crystal lattice of the new phase formed in this process is joined with that of the initial phase by similar crystal planes, the parameters of which remain minimal. As an example of the orientation correspondence in decomposition reactions, there is the orientation growth of silver on the surface of silver bromide (Fig. 5). Whether two-dimensional nuclei of a new phase will be orientated according to the lattice of the initial substance or whether independent nuclei will be formed depends on the deformation energy of the two-dimensional lattice of the new phase E and the work of formation of the independent three-dimensional nucleus A. If $E < A$ there will be an orientation correspondence and the epitaxial and topotaxial growth of the nuclei of the new phase will be possible; if $E > A$ then the formation of the nuclei of the new phase will proceed independently of the lattice of the initial substance.

This principle was developed further[34,35], and it was found that when the orientation correspondence is observed the lattice of the product can correspond with the lattice of the initial substance in two (epitaxy) or three (topotaxy) measurements. Many examples of topotaxial transformations in solid-state chemical reactions (including those of thermal decomposition) are now well known and have been reviewed[36,37].

Owing to the topotaxial change from one crystal lattice to another there is always a decrease in the activation energy of transformation, which for non-topotaxial transformations should be equal to or greater than the heat of the phase transformation[38,39].

It is often possible for there to be produced a fine structure of the lattice of the reaction product under the lattice of the initial substance and for topotaxy to be guaranteed not only in the initial part of the process but also in its subsequent stages. This occurs when there is disparity between the lattice parameters of the initial substance and the transformation product, which can increase with growth of the product lattice along the phase separation boundaries, will be removed by the formation of dislocations at the separation boundary of the lattices[40], and especially will ensure retention of continuous contact between the lattice of the initial substance and the reaction product.

Thickness and structure of the interfacial zone. For many processes which take place in the solid phase, including thermal decompositions, the rate of the chemical reaction can be much greater than the rate of the phase stage and therefore the stages will not agree in either time or space. The possibility of the occurrence of topochemical decomposition reactions in this manner was noted by Roginskii[41].

Such processes were studied in detail later by Frost and coworkers[42-44]. Owing to the separation of the chemical and phase stages of the process it appears that an intermediate layer is formed instead of an interfacial surface which separates the lattice of the solid reaction product and the initial substance. Sometimes, when the chemical and phase stages are separate and the localisation of the process at the phase separation boundary is not connected with the catalytic action of the solid product there is almost complete agreement of the activation energy of thermal decomposition with the change in enthalpy during the process. As examples of this type of thermal decomposition, there are the decompositions of silver carbonate[44] ($\Delta H = \Delta E = 20$ kcal mole^{-1}), calcium carbonate ($\Delta H = \Delta E = 50$ kcal mole^{-1}),[45] ($\Delta H = \Delta E = 42.5$ kcal mole^{-1}) and cobalt[46] and zinc sulphates ($\Delta H = \Delta E = 54$ kcal mole^{-1}).

A similar agreement of the activation energy with the change in enthalpy is also observed for other phase transformations in the solid phase (for example, the polymorphic transformations of sulphur, 2-nitroaniline into 3-nitroaniline, etc.[39]), when the possibility of a topotaxial transformation from the initial substance to the reaction product is absent and the formation of the lattice of the new phase precedes the complete breakdown of the initial lattice.

The reasons for the formation of a layer instead of a surface of separation of an initial crystalline phase and a reaction product can be various. On the one hand, as Cahn and Hillard[49] have shown, thermodynamic causes linked with the need for minimising the free energy at the phase separation boundary can lead to the appearance of a layer between the initial substance and the reaction product. According to this condition the minimum free energy at the separation boundary occurs at a strictly definite thickness and composition of the separation boundary, and these ultimately are functions of the temperature and the heat of mixing of the initial substance and reaction product.

On the other hand, after the appearance of the transitional layer which separates the phase of the initial substance and the phase of the product, kinetic factors can also be responsible. Their effect will appear when, for example, the change of the product phase from metastable amorphous or cryptocrystalline into the thermodynamically stable crystalline state is hindered for some reason.

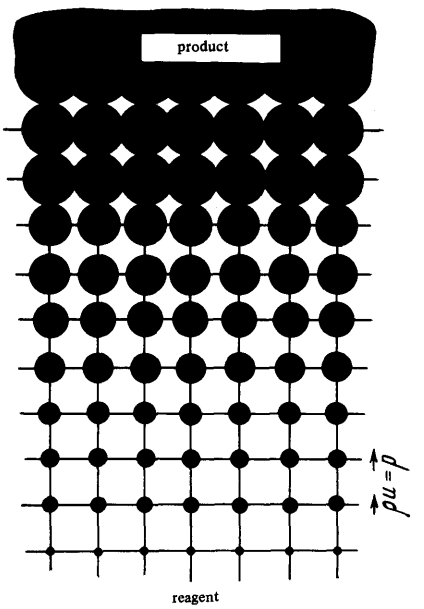

Figure 6. Diffuseness of the reactivity zone at the separation boundary between the initial substance and the reaction product[53].

The possibility of allowing for this factor can be shown by the example of the dehydration of a crystalline hydrates[50,51]. In this thermal decomposition the probability of the separation of chemical and phase stages ultimately is greater the stronger the bonding with one another of the atoms in the dehydration products formed. When this bond is strong enough, as is observed for the products obtained in dehydrating zeolites, the phase stage generally cannot start until after the complete removal of the water. On taking a crystal hydrate in which the structural components in the anhydrous residue are still bonded but much more weakly than in the zeolites (for example, magnesium sulphate heptahydrate) the phase stage will be observed but with some lagging behind the chemical one, and between the lattices of the initial crystal hydrate and of the dehydration product an intermediate amorphous layer is formed.

If we take such a crystal hydrate, in which the energy of the bond between the elements of the lattice is low (for example, copper chloride dihydrate) the chemical and

phase stages can proceed at similar rates and therefore in this instance the thickness of the intermediate layer between the initial substance and the reaction product can be extremely low.

The separation of the chemical and phase stages and the associated conversion of the interfacial surface into a layer can affect the kinetics of the thermal decomposition in various ways. Firstly, the separation of the crystalline phase of the reaction product from the initial substance also reduces the probability of the catalytic action of the reaction product on the initial substance (this will appear particularly when the mechanism of catalysis is connected with the orientation-deformation interaction of the lattices of the initial substance and reaction product). Secondly, the conversion of the planar reaction zone into a layer implies the existence of significant changes in the models which are now used for the kinetic analysis of topochemical reactions (in most of these it is assumed that the interfacial surface is planar).

de Boer[52] was interested in such special instances of the occurrence of topochemical changes. Hill[53,54] showed that the diffusion of the reaction zone (see Fig. 6) and the change from a planar reaction zone to a layer can occur when there is a drift of atoms or ions from the layer of the product into the layer of the initial substance, as a result of which there is continuous formation of nuclei of the new phase around the main reaction front. At a certain ratio of the rates of nuclei formation, the rate of diffusion of ions which "contaminate" the initial substance, and the rate of motion of the interphase surface, a diffusion layer is formed between the initial substance and reaction product; this layer consists of a mixture of the initial substance and nuclei (of various sizes) of the reaction product. The result of this can be many kinetic anomalies, for example, the anomalously high values of the pre-exponential factor in the dehydration of chromium alum, observed by Anous and coworkers[54].

When the decomposition can proceed not only on the surface of the solid body but also within its bulk and the diffusion coefficient of the volatile product which is formed is sufficiently great the situation can arise in which a diffusion layer is also formed instead of a smooth separation surface. It is easy to understand that the profile of the gradient of the concentration of the reaction product removable from the system will be the reverse of that examined by Hill. A diffusion-kinetic model of such reactions was recently given by Mandelis and Strunin[55].

Deformation of the lattice close to a growing nucleus. In the formation of crystals of a new phase from a gas, solution, or melt, the volume changes are readily compensated as a result of flow of the liquid or gas. When the initial substance is a crystal then the relaxation of the deformations which occurs during the course of the transformation can be effected either by elastic deformation or plastic flow, or alternatively by diffusion processes[56]. Therefore the equation for the free energy of nuclei formation for solid-phase processes contains yet another term Δg_e connected with the deformation of the surrounding medium by the growing nucleus:

$$\Delta g = \Delta g_v + \Delta g_s + \Delta g_e$$

The second term Δg_S for solid-phase processes also has a somewhat different physical significance, since instead of the surface energy it includes the energy of the surface of separation between the two crystalline phases.

Usually this energy is represented as the sum of chemical and structural constituents[57]. The chemical constituent can be found when the crystal structures of the initial phase (α) and the reaction product (β) have the same symmetry and lattice parameters. In this instance the surface energy at the $\alpha-\beta$ phase separation boundary can be evaluated simply to the first approximation as the energy of interaction of nearest neighbours:

$$\sigma_{\alpha\beta} = n_s z_s [\varepsilon_{\alpha\beta} - {}^1/_2(\varepsilon_{\alpha\alpha} + \varepsilon_{\beta\beta})],$$

where n_S is the number of atoms per unit area of the interfacial surface, z_S the number of $\alpha-\beta$ bonds per α or β atom in the plane of the $\alpha-\beta$ phase boundary; and $\alpha\beta$, $\alpha\alpha$, and $\beta\beta$ are the energies of the bonds between the different types of atoms in the system at 0°K. Since these energies are difficult to determine directly, the formula for calculating the energy of dissolution ΔE per g-mole or g-phase of β in an infinitely dilute solution of α and β can be used for the experimental determination of $\sigma_{\alpha\beta}$:

$$\Delta E = NZ_1[\varepsilon_{\alpha\beta} - {}^1/_2(\varepsilon_{\alpha\alpha} + \varepsilon_{\beta\beta})],$$

where N is Avogadro's number and Z_1 the coordination number. On combining these equations, we have:

$$\sigma_{\alpha\beta} = \frac{n_z \cdot Z}{NZ_1}\Delta E$$

To calculate the structural constituent, we assume that the lattice parameters of phases α and β at the phase separation surface are different although the arrangement of the atoms in the two lattices are similar. Then the parameter of non-correspondence of the lattices (maladjustment) is determined as:

$$\Delta = (a_\alpha - a_\beta)/a_\alpha,$$

where a_α and a_β are the atomic distances in the regions in contact. Since the density of dislocation is proportional to $1/\Delta$, then knowing the energy necessary for the formation of a single dislocation the structural constituent can also be calculated. $\sigma_{\alpha\beta}$ can also be approximately represented as the difference in energy of the lattices of the phases in contact per unit interfacial surface[58].

The deformation of the lattice both owing to the energy at the phase boundary and owing to the difference in molecular volumes of the initial substance and reaction product can be calculated when the volume change, the form of the region in which the change took place, and the form of the crystal of the new phase are known (the possibility of such a calculation has been shown for certain examples of phase changes in metals and alloys[56]).

According to Nabarro's work[59], the form of the nuclei which are formed should depend mainly upon the two main components bringing about the deformation of the lattice which surrounds the growing nucleus: the components of the deformation K_S, associated with the interfacial energy, and the components of dilatation K_V due to the change in volume during the transformation. When K_S is large, the nuclei will tend to adopt the form with the minimal ratio between the surface and the volume, that is, when the medium in which its growth takes place is isotropic, the form of a sphere. When K_V is large, the tendency to the minimisation of the energy of deformation will result in the nuclei formed being planar and extended along the surface. The combination of these factors with the anisotropy of the deformability of the initial substance will lead to various forms of nuclei, which are observed in experimental investigations.

The deformation of the lattice of the initial crystal as the nuclei of a new phase grow in it has been observed

experimentally in certain instances, for example, by Morrison and Nakayama[60], who studied the topochemical interaction of gaseous chlorine with a potassium bromide crystal and used birefringence for observing the deformation of the bromide crystal around the growing nucleus. As Fig. 7 shows, there is especially pronounced deformation in the region of the crystal adjacent to the corners of the growing nucleus.

Figure 7. Formation of a deformation zone around the growing nucleus.

The deformation of the lattice around a nucleus can lead to a change in the reactivity of the crystal in this region. The low-temperature transformation of austenite into martensite is the classical example of how significant is the elastic deformation of the lattice close to the growing nucleus for the development of solid-state processes[61]. The peculiarity of this process is that the transformation of the initial substance (austenite) into martensite proceeds without diffusion and for it to occur only requires some movement of the iron atoms in the lattice by a distance less than the parameters of the lattice (Fig. 8). The elastic stresses which arise in austenite as a result of the appearance of the nuclei of a new phase and which are situated in advance of the phase transformation front help the transformation to become collective and the rate of transformation to become very large, approaching the rate of propagation of sound in austenite.

Dislocations evidently may occur as a result of the relaxation of lattice deformations in the region around growing nuclei. This is confirmed by the experimental results on the increase in the density of dislocations close to the growing nucleus, which have been obtained for several systems[62-64].

The formation of dislocations in a crystal close to a growing nucleus can significantly alter the reactivity in this place, particularly when the decomposition takes place at low temperatures. In a thermal decomposition the formation of dislocations simultaneously alters both the conditions of transport of the reagents and reaction products in the mass of the crystal and also has an action on the decomposition of the solid solution and reconstruction of the lattice of the initial substance, which usually accompanies the thermal decomposition.

Possible paths for the influence of dislocations on the thermal decomposition have been examined frequently. It has been thought that in the thermolysis of certain ionic crystals, for example, lead azide and sodium bromate at very low temperatures, the dislocations will be the only places in the crystal where it is possible to expect development of a reaction[65]. The dislocations can be channels through which rapid migration of the product ions can occur, from the "contaminated" non-reacted region of the initial crystal, according to Hill's hypothesis, which we have already mentioned. The appearance of channels by which ions can move at rates many times greater (this difference can reach several orders of magnitude) than in the bulk of the crystal enables dislocations to play a significant part in the supply of material needed for the construction of the lattice of the reaction product. This is necessary to ensure the normal growth of the nuclei for the thermal decompositions in which the stoichiometry of the nuclei growth process proceeds owing to one of the elements of the lattice and the aggregation of these atoms or ions is a necessary stage. For example, such happens in the thermal decomposition of metal salts to the metal (for example, in the thermolysis of silver oxalate).

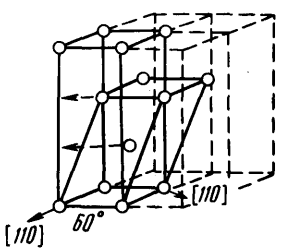

Figure 8. Scheme of the martensitic transformation.

In addition to the influence on the transfer process of dislocations which arise as a result of the relaxation of elastic strains in the lattice of the initial substance around the growing nucleus, the thermal decomposition can be accelerated by impurities and dissolved atoms and ions from the lattice accumulating in the zone of extension of the dislocations. Since in this part the most favourable conditions for the breakdown of the solid solutions and reconstruction of the lattice are set up, the place where the dislocations emerge at the surface are often potential centres at which formation of the nuclei of a new phase occurs during thermal decomposition. The change in the topography of the position and density of the dislocations in the crystal (for example, owing to polygonisation in annealing and the physical ageing of the crystals) is reflected in the kinetics of the thermal decomposition.

An illustration of what has been said is given by the results of our experiments, which showed a connection between the change in the density of the dislocations in crystals of lead oxalate and the kinetic parameters of the thermal decomposition of this salt (cf. Ref. 66 and pp. 124–157 of Ref. 1) and also the work of Thomas which was specially concerned with the appearance of dislocations in various topochemical reactions[67-71].

c. Other Forms of Autolocalisation Process Connected with the Influence of a Solid Reaction Product

In addition to the deformation action associated with the orientation interaction at the separation boundary of two phases and the volume changes throughout the process in certain types of topochemical transformations of a solid reaction product there are other specific influences on the reaction rate. When the thermal decomposition is a redox reaction the solid product which is formed can alter the conditions under which an electronic transition takes place and thereby accelerate or inhibit the thermal decomposition.

As an example of such an effect, which arises in the formation of a solid product, we can examine the development of the thermal decomposition of barium azides. According to the ideas of Torkar and his coworkers[72,73] the formation of nuclei in the thermolysis of barium azide takes place as a result of the capture of the excited state of the azide ion on a defect, which can, for example, be an anionic vacancy. Owing to this, as a result of the transfer of an electron trap

$$N_3 + \text{phonon} \rightleftarrows N_3^{-*} + \square \rightleftarrows [\square N_3^{-*}],$$
$$[\square N_3^{-*}] \rightarrow [\square e]\, N_3^0,$$

and then its localisation on a neighbour with a cation trap, formation of a Ba^+ ion takes place:

$$[\square e]\, N_3^0 + Ba^{2+} \rightarrow [\square Ba^+]\, N_3,$$
$$2N_3^0 \rightarrow 3N_2,$$

and the azide radical is converted into nitrogen. It is assumed that the complexes

$$[\square e\, Ba^{2+}] \rightleftarrows [\square Ba^+]$$

are nuclei of the last thermal decomposition. Since the Ba^+ level should represent an acceptor level in the lattice lying at the limits of the forbidden band, its presence will facilitate the last transfer of an electron from a neighbouring azide ion at this level:

$$\square_a Ba^+ + N_3^- \rightarrow \square_a\, BaN_3^0 \rightarrow \square_a Ba\square_a + {}^3/_2\, N_2,$$

as a result of which a complex is formed from a metal atom and two anionic vacancies:

$$\square_a Ba\square_a + Ba^{2+} \rightarrow [\square_a BaBa\square_a]^{2+} \rightarrow \square_a Ba^+ Ba^+ \square_a$$

As a result of the process, stabilisation of the complex and regeneration of its acceptor properties takes place (Fig. 9). This ensures maintenance of the conditions for the autolocalisation of the process at the place where the nucleus arises and determines its growth. Since the conversion of barium azide into the metal proceeds topotaxially and diffusion processes do not play a significant part, the limiting rate of growth of the stages is the redox process at the metallic barium—azide boundary. The nature of the development of the process described above corresponds to activation energies of formation (63 ± 5 kcal mole^{-1}) and growth (26 ± 1 kcal mole^{-1}) of nuclei of metallic barium in the thermolysis of the azide.

If the solid substance which undergoes thermal decomposition is an electron or hole semiconductor and the reaction for the decomposition is a redox reaction then the solid product which is formed in the decomposition can alter the reactivity of the substance in the region adjacent to the place where formation of the reaction product occurred, owing to the changes in the concentrations of electrons and holes close to the phase boundary. An example of this process is the thermolysis of potassium permanganate, the mechanism of the decomposition of which was studied in detail in our laboratories[74]. According to the scheme proposed, the thermal decomposition of potassium permanganate, which is an n-type semiconductor[75,76] takes place owing to the transfer of an electron from one permanganate ion to another:

$$MnO_4^- + MnO_4^- \underset{k_2}{\overset{k_1}{\rightleftarrows}} MnO_4^0 + MnO_4^{2-}$$
$$\downarrow$$
$$MnO_2 + O_2$$

As a result of the transfer the unstable MnO_4^0 is formed, which immediately decomposes into MnO_4 and O_2. On making the natural assumption that the electronic decomposition is rapid and the rate-limiting stage is the decomposition of the MnO_4^0 radicals then a stationary state is established in the system.

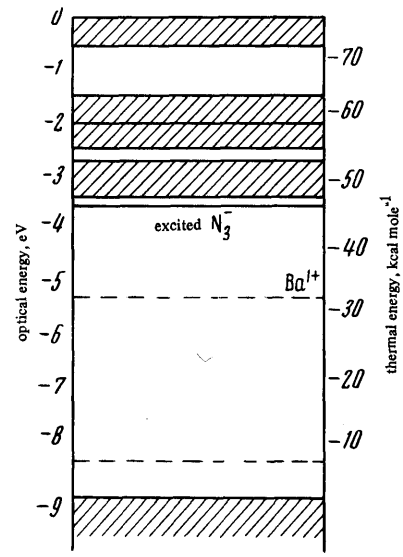

Figure 9. Scheme of the energy levels in barium azide.

It is easy to see that the overall rate of the process will be increased by the shift of the electron—hole equilibrium k_1/k_2 to the right and decreased when it is shifted to the left. The condition for such a shift in the equilibrium can arise, for example, owing to the contact potential difference at the separation boundary between the initial permanganate—and the solid reaction products, which are MnO_2 and the double salt $K_3(MnO_4)_2$, which is an ion associated with the MnO_4^{2-} ion.

Measurement of the electron work functions of potassium permanganate, manganate (as the double salt), and manganese dioxide showed (Fig. 10) that under conditions close to those for thermal decomposition the electron work function of manganese dioxide is greater than that for permanganate, but that from manganate, on the other hand, is less. In accordance with this and our scheme of thermolysis of permanganate, MnO_2 should be an acceptor of electrons and therefore should catalyse the thermal decomposition of permanganate, whereas manganate should be a donor of electrons and inhibit thermolysis. Actually, as is clear from the results (Fig. 11) on the thermolysis of potassium permanganate with additions, the addition of

MnO_2 accelerates the thermal decomposition of permanganate, but additions of manganate, on the other hand, retard it. Therefore the well-known phenomenon of autocatalysis in the thermal decomposition of permanganate is itself the superimposition of the catalytic action of one of the reaction products and the inhibiting action of the other.

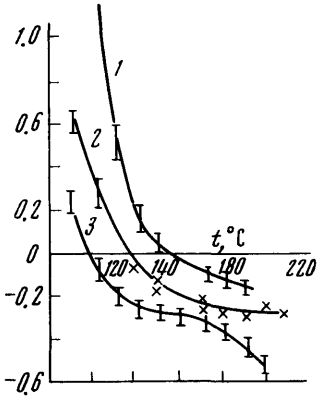

Figure 10. Work function from permanganate and its decomposition products: *1*) $K_3(MnO_4)_2$; *2*) $KMnO_4$; *3*) MnO_2.

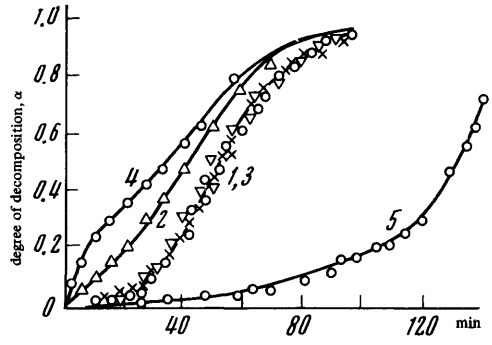
A peculiarity of the autolocalisation in this instance is that the influence of the solid product of the reaction is not limited to the surface layer of the initial substance adjacent to the product but extends into the depth of the initial solid phase according to the length of the screening charge and therefore the formation of MnO_4^0 radicals can take place in the bulk of the crystal at some distance from its surface. Since the decomposition into MnO_2 and O_2 is almost irreversible, the liberation of gas in the bulk of the crystal ultimately leads to the dispersion of the crystal during its thermal decomposition. This and not the difference in the lattice parameters of the product and the initial substance, which, judging from our results, will hardly be significant, is the true reason for the self-shattering of permanganate.

In addition to what has been described, there can be other forms of autolocalisation of a process, for example, those linked with special conditions for proton transfer, which exist at the phase separation boundary in the dehydration of crystal hydrates and oxide hydrates, the presence in this place of anomalous valence states of the elements, etc.[77,78] However, these factors have been insufficiently studied.

The following conclusions can be drawn on the basis of the above considerations: the influence of the reaction product depends very strongly on the degree of its contact with the initial substance. Therefore to the first approximation all the thermal decompositions can be divided into two classes, depending upon whether the coherency of the lattices of the product and initial substance during the course of the process are maintained or not. It is quite natural that the coherency, and consequently the contact, will be ensured to the greatest extent when the formation of a product from the initial substance takes place topotaxially. However, here only some of the properties will be altered by the discontinuity at the separation boundary. For example, in the thermal decomposition of barium azide, the lattice parameter changes smoothly at the separation boundary but the electrical properties change suddenly. With growth in the layer of reaction product the necessary orientation correspondence can be ensured by the substructure of the lattice of the product under the lattice of the initial substance (or the reverse), for example, owing to the formation of dislocations at the phase separation boundary.



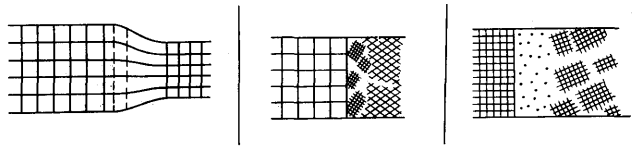


Figure 11. Kinetic curves of the influence of MnO_2 and K_2MnO_4 on the decomposition of $KMnO_4$. *1*) Decomposition of permanganate at 220°C; with addition of MnO_2 (reagent); *2*) the same with addition of MnO_2, obtained in the thermal decomposition of $KMnO_4$; *3*) with addition of MnO_2 obtained by heating $Mn(NO_3)_2$ at 170°C; *4*) with addition of MnO_2 made by oxidation of 5% $MnSO_4$ heated to 60°C; *5*) with addition of K_2MnO_4 (cocrystallised); *6*) decomposition of permanganate without any additions (below *1*, *3*).

Table 1.

Nature of the formation of a solid reaction product

coherent (topotaxy)		incoherent

Factors leading to a change in the reactivity of a solid substance close to incipient nuclei of the product

(a) deformation connected with energy of interfacial orientation interaction of the two lattices; (b) deformation connected with change in volume; (c) change in the conditions for the occurrence of electronic and ionic processes in the near-contact region at the phase separation boundary.	(a) deformation connected with the change in volume; (b) change in the conditions for the occurrence of electronic and ionic processes in the near-contact region.	(a) change in the conditions for the occurrence of electronic and ionic processes in the near-contact region.

Another extreme instance is the complete destruction of the lattice of the initial substance as a result of the thermal decomposition and absence of coherency between the lattices of the initial substance and the reaction product. In this instance, depending upon the ratio of the

rates of the chemical and phase stages observable as a result of the reaction of the amorphised layer, the product can either be found in contact with the initial substance or will be separated from it by a layer of the amorphous material: depending upon which of these two distinct possibilities arises so will the influence of the solid product of the reaction on its rate be determined (Table 1).

If there is a coherency between the lattice of the product and the lattice of the initial substance it is to be expected that the energy of interfacial interaction will greatly affect the properties of the initial substance. When as a result of the reaction there is a considerable increase in the specific volume of the reaction product in comparison with the volume of the initial substance, there can prove to be a significant associated deformation of the lattice of the initial substance, which will happen even in the absence of coherency.

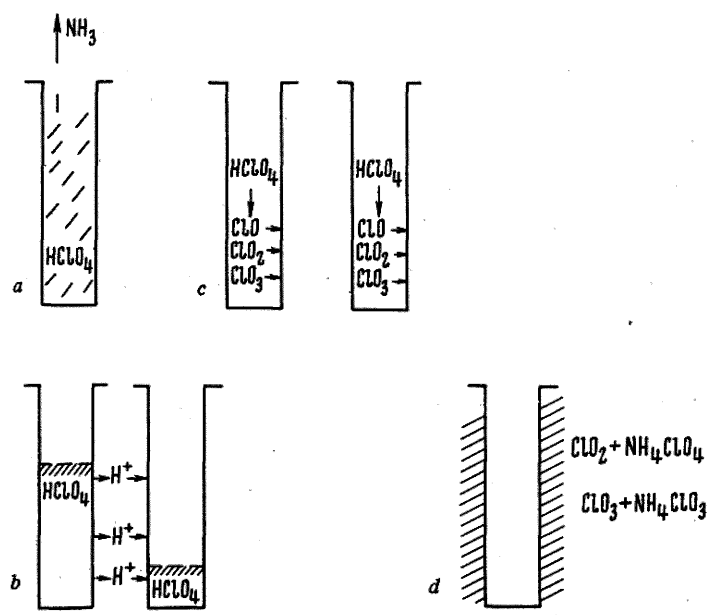
Finally, the change in the nature of the occurrence of electronic and ionic processes in the region near the contact can appear when the phase and chemical stages do not coincide.

3. AUTOLOCALISATION OF THE THERMAL DECOMPOSITION DUE TO THE RELEASE OF GASEOUS PRODUCTS DURING THE COURSE OF THE REACTION (AUTOCATALYSIS BY GASEOUS PRODUCTS)

When the gaseous products formed during the thermal decomposition undergo further chemical change and the resulting products interact with the substance that has not yet reacted, this can also be a reason for the autolocalisation of the thermal decomposition.

An example of this type of autolocalisation is the formation of nuclei in the low-temperature thermal decomposition of ammonium perchlorate. Bircomshaw[79] showed that the low-temperature decomposition of ammonium perchlorate is accompanied by the formation of cigar-shaped nuclei. More detailed microscopical observations showed that each such nucleus is itself an aggregate consisting of finer nuclei and the growth of a nucleus takes place by the appearance of new nuclei around the edges of the aggregate[20]. Since ammonium perchlorate decomposes without the formation of a solid reaction product, the formation of nuclei in the low-temperature thermal decomposition could not be connected with the catalytic influence of the solid reaction product, the nature of the development of the nucleus does not provide the possibility of relating the localisation of the low temperature thermal decomposition with the anisotropy of the properties of the initial crystal. It was therefore postulated that the reason for the autolocalisation process in the low-temperature decomposition of an ammonium perchlorate could be the action, during the course of the process, of gaseous products formed during the course of the reaction (for example, the oxidation of ammonia by the products of the thermal decomposition of perchloric acid from the ammonium perchlorate that has not yet reacted, Fig. 12).

In the investigation of low-temperature thermal decomposition[80] it was shown that in this instance, when the dissociation of ammonium perchlorate takes place on the inner, not the outer, surface of the crystal (for example, at the boundaries of blocks, dislocation nuclei, etc.), since the molecular weights of ammonia and perchloric acid are different, it could be expected that during the course of the process in these parts there will initially be



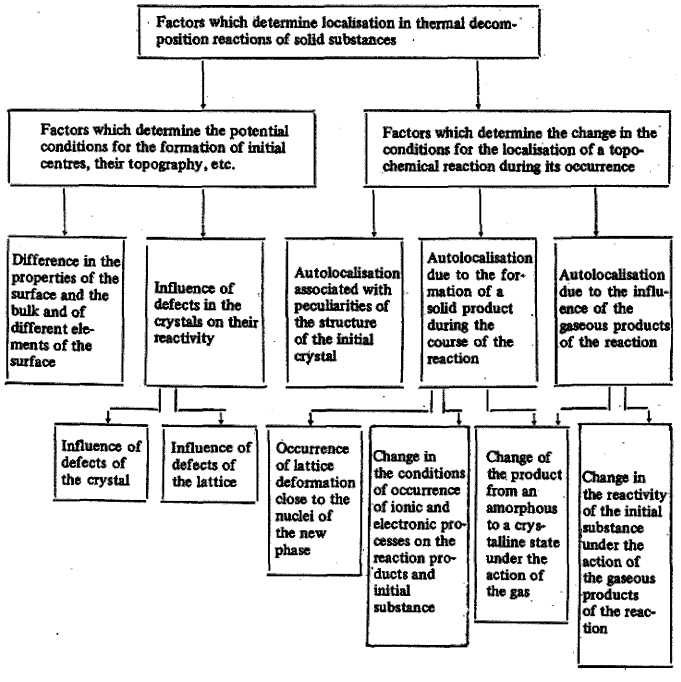


Figure 12. Scheme of low-temperature decomposition of ammonium perchlorate: *a*) separation of ammonia and perchloric acid in a pore due to the difference in the diffusion rates; *b*) migration of perchloric acid into a neighbouring pore; *c*) decomposition of perchloric acid; *d*) interaction of the decomposition products of perchloric acid with unreacted ammonium perchlorate.

an accumulation of perchloric acid and then its decomposition. Simultaneously with the decomposition owing to the proton conductivity[81,83] which is specific for ammonium perchlorate migration of the acid to the neighbouring potential centre (for example, a dislocation nucleus) and the initiation of the reaction in it can occur. The decomposition products of perchloric acid (for example, ClO, ClO_2, and ClO_3) react with ammonium perchlorate on the walls of dislocations of the boundaries of blocks, and subsequently thermal decomposition takes place owing to this reaction. It is extremely significant that during the course of the reaction there can be regeneration of the molecules of perchloric acid or chlorine oxide (for example, according to the scheme of Koroban and Svetlov[83]), which ensures decomposition of the chain, thanks to which the growth of a nucleus, as distinct from its formation, is much less dependent upon the equilibrium pressure of perchloric acid.

Table 2.

Hence whereas the formation of a reaction nucleus is connected with the dislocation processes of ammonium perchlorate and the subsequent decomposition of perchloric acid, the growth of nuclei proceeds due to the interaction of the products of perchloric acid with ammonium perchlorate.

The difference in the chemistry of these processes corresponds to different activation energies—50 ± 5 kcal $mole^{-1}$ for the formation of reaction nuclei and 30 ± 2 kcal $mole^{-1}$ for their growth process. This also is responsible for the experimentally observable autolocalisation process, which continues to develop preferentially at the place where the reaction started.

---o0o---

Table 2, which we give at the end of the review, shows the mutual relation between the various factors which determine the localisation in the thermal decomposition of solid substances.

The study of the physicochemical reasons responsible for the localisation and autolocalisation of the thermal decomposition is an extremely important task. Its solution allows us to understand more thoroughly the peculiarities of the development of topochemical reactions and to note the path of their directed regulation. Should this problem be solved, then (a) conditions will be created for the quantitative study of the rates of topochemical reactions; (b) new possibilities of regulating the rates of topochemical reactions during their occurrence will be discovered. Until then in most instances the directed regulation is limited by the initial stage of the process and is carried out at the qualitative level.

The experimentally observable autolocalisation process considered above which is recorded by investigators as the ratio between the formation rates and growth rates or as the "compactness" (that is, the formation of new nuclei around the old ones), can be the result of superimposition of several factors which alter the reactivity of the initial substance.

Depending upon the nature of the long-range action of various factors due to autolocalisation, in some instances there will be growth of the nuclei which are formed, and in others there will be a change in the compactness. Therefore in any investigation in the field of topography of solid-state chemical reactions and in particular of thermal decompositions, it is important to investigate the contribution being made by each factor to the change in reactivity around the growing nucleus. The directed regulation of the development of topochemical processes not only in time but also in space is a possibility. This would permit the regulation of the morphological properties of the solid product formed, which is important in the use of thermal decomposition in the preparation of catalysts for obtaining highly active oxide masses in the metallurgy of rare metals, in the preparation of ceramic materials of the ferrite type, etc. Finally, the development of these studies can even lead to the creation of technological processes new in principle, in which the stages of the production of a substance and the formation of articles from it will be combined.

Mass Spectra of Organometallic Compounds of Group IVb

V.Yu.Orlov

Characteristic features of the dissociation of ions of organometallic compounds with silicon, germanium, tin, and lead are considered. Cyclic compounds are discussed separately; results on the following aspects are surveyed: rearrangements, metastable and multiply-charged ions, products of ionic-molecular reactions, and also the mass spectra of negative ions and correlations between ion decomposition processes and the thermal decomposition of the molecules of the compounds concerned.
There is a bibliography of 115 references.

INTRODUCTION

The development of the chemistry of the organometallic compounds of the Group IVb elements stimulated interest in their mass spectrometric investigation, occasioned by the uniqueness of their mass spectra, by the practical objectives of the structural analysis of these compounds, and also by the correlations observable between the breakdown of the ions in the chamber of the mass spectrometer and processes such as thermolysis. Hundreds of derivatives of silicon, germanium, tin, and lead have been studied in recent years; the mass spectra of over 300 compounds were published in 1968—1970 alone. The number of papers decreases appreciably with increase in both the atomic number of the metal and the number of metal atoms in the molecule; most of the investigations relate to compounds of the R_4E type, where R stands for alkyl, aryl, and other substituents, and also to the trimethylsilyl derivatives of all possible compounds.

Although the general rules of dissociative ionisation also extend to organometallic compounds, the presence in the molecule of one or more Si, Ge, Sn, or Pb atoms confers considerable singularity on the mass spectra. Review papers[1-3] have mentioned a series of features of the mass spectra associated with the decrease in ionisation potentials and bond strengths of the metal atoms on going from C to Pb, such as charge localisation on metal-containing species, intensive rearrangements, and abundance of metastable and multiply-charged ions.

The present review examines certain features of the mass spectra of the organometallic compounds of Group IVb with an account of recent results. A quarter of the papers cited in this review are from Soviet investigators.

GENERAL SCHEME OF DECOMPOSITION

Almost all the ionic current in the mass spectra of these compounds is carried by species which contain a metal atom (atoms). There is every basis for assuming that, in even-electron ions at least, the charge is localised on the metal atoms. This agrees with the fact that doubly and triply charged ions are usually observed solely for compounds which contain respectively not less than two or three metal atoms[4-6]. The fraction of hydrocarbon or other organic metal-free ions in the mass spectra of organometallic compounds with a single metal atom usually does not exceed a few per cent; it is even less for more complex molecules. This is connected with the low (in comparison with carbon) ionisation potentials of the atoms Si, Ge, Sn, Pb (respectively[7] 8.15, 7.88, 7.34, and 7.42 eV), the orbitals of which make a large contribution to the higher occupied molecular orbitals[3]. Only when the species formed are extremely stable metal-free fragments (usually aromatic) which are characterised by a low ionisation potential can the latter make a significant contribution to the total ionic current. Such are, for example, the fluorocarbon ions in the mass spectra of $(C_6F_5)_4Si$, $(C_6F_5)_4Ge$,[8,9] and the $[(C_6H_4)_2O]^+$ ion in the mass spectrum of SnSn-dichloro-oxastannadihydroanthracene[10]. Hydrocarbon ions observable in the mass spectra of organometallic compounds are characterised by considerable unsaturation (C_nH_{2n-3}, etc.).

The presence of many rather intense metastable ions in the mass spectra of organometallic compounds allows a genetic connection to be found between many fragment ions at the individual stages of the dissociation and is widely used for compiling decomposition schemes for the individual molecular ions. However, caution must be observed in doing this[3]. When a cascade (series) of metastable transitions $A^+ \rightarrow B^+$, $B^+ \rightarrow C^+$, $C^+ \rightarrow D^+$, is observed simultaneously then in addition to this there can also exist rather rapid direct transitions of the type $A^+ \rightarrow C^+$, $B^+ \rightarrow D^+$, $A^+ \rightarrow D^+$, not reflected by breakdowns of metastable ions; in addition, as estimates for some fragment ions of n-alkanes show, series of successive breakdowns composed of observable metastable ions, can lead to increased appearance potentials[11].

The intensity of the molecular ions for acyclic compounds of Si, Ge, Sn, or Pb is usually low[12-21], although higher than that of their hydrocarbon analogues[22]. It is significant only for certain heterocyclic compounds and for molecules with aromatic groups.

The first stage of the decomposition of the initial cation-radical is almost always the detachment of the radical; in the presence of several substituents the most weakly bound (usually, the heaviest[23,24]) group is detached first. One of the bonds with a metal atom is the weakest here. The even-electron ion that is formed is the origin of the remaining lighter fragment ions. For certain compounds (aromatic, heterocyclic) only is a significant part played by the primary splitting of molecules—C_6H_6 from Ph_3GeH, Ph_2 from Ph_4Ge, $[PhCH_2]_2$ from *m*- and *p*-Tol_4Ge, C_2H_4 from sila- and germa-cycloalkanes and spiranes with a central metal atom, etc.[25-33], however, usually these processes are characteristic solely for the subsequent stages of the decomposition. Further decomposition also usually leads to an even-electron ion, and the neutral fragments in its composition correspond to molecules of alkenes, alkanes, aldehydes, water, and other (including organometallic) compounds, some of which are unstable (considered in more detail below)†. The detachment of a

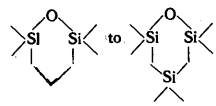
†The splitting of neutral hydrocarbon fragments from molecules with an alternative chain (for example, from cyclocarboxyloxanes[34]) proceeds primarily at the organic framework of the molecules and not the methyleen links.

radical from an even-electron ion, especially for organosilicon compounds, is seldom observed; in addition to the examples given by Chambers and coworkers[2] the following decompositions can be added:

$$[Me_3Si_3(CH_2)_3]^+ \rightarrow [Me_4Si_3]^{+\cdot} + C_2H_2^{\cdot}\ (Ref.28),$$

$$[(CH_3)_3SiCH_2CHCH_2]^+ \rightarrow [CH_2CHSiCH_2CHCH_2]^{+\cdot} + H^{\cdot}\ (Ref.20),$$

$$[Tol_{9,11}Ge_4]^+ \rightarrow [Tol_{8,10}Ge_4]^{+\cdot} + Tol^{\cdot}\ (Ref.35).$$



On going from compounds of silicon to compounds of tin or lead, the dissociation, and particularly the successive detachment of radicals, are less dependent upon the fragments formed having an even number of electrons[31,36]. The maximum intensity of the ions is shifted to the lighter ions of the mass spectrum; in particular, the intensity of the E^+ ions increases[2,31]. The number of decomposition paths decreases and the spectrum is simplified (it is made more "selective")[9,20,31,37].

CYCLIC COMPOUNDS

Let us examine in somewhat greater detail the cyclic compounds which occupy an important place in the chemistry of the transition elements of Group IVb; cyclic organosilicon compounds and heterocyclic compounds with metal atoms in the ring have been reviewed before[38,39].

The decomposition under electron bombardment of about a hundred cyclic compounds of Si, Ge, Sn, and Pb has been studied recently. They include cyclo-silanes, -germanes, and -stannanes of general formula $(R_2E)_n$ (R = Me, Ph, *p*-Tol; *n* from 5 to 7 [35,40-43]), cyclo-siloxanes and -germoxanes $(R_2EO)_n$ (R = Me, Pri; $n = 3-5$ [6,15,16]), cyclocarbosiloxanes $(R_2Si)_n(CH_2)_mO_{n-m}$ (where R = Me, $n = 3$ or 4, $m \leqslant n$ [34]), cyclocarbosilanes $(R_2SiCH_2)_n$ (R = H or Me, $n = 2-4$ [44,45]), cyclosilazanes $(R_2SiNR')_n$ (R = Me; R′ = H or Me_2ClSi; $n = 2$, 3, or 4 [46]), tetra-aza-3,6-disilacyclohexanes $[MeRSi(NR')_2]_2$ (R = Me or Vin; R′ = Ph, *m*-Tol, or *m*-Anisyl[47]), 1,4-disila- and 1,4-digerma-cyclohexadienes $[R_2E(CR')_2]_2$ (R = Me, Et, I; R′ = H, Ph [48]), sila- and germa-cycloalkanes $R_1R_2E(CH_2)_n$ ($R_1 = R_2 = H$; $n = 3$ or 4 [25,26]; R_1, R_2 = H, CH_3; $n = 3-5$ [27,28]; R_1, R_2 = H, C_3H_7, C_4H_9, C_6H_5, C_2H, Cl, Br [29,30]), germacyclopentenes[30], disila- and digerma-cyclopentanes $M_4E_2(CH_2)_3$,[28] sila-, stanna-, and plumba-spiroalkanes[31-33], derivatives of anthracene and phenanthrene[10,49-52], disilabicyclo-octadienes[53], tetrasila-adamantanes[54], cage polysilanes and carboxyloxanes[55,56], and certain other compounds[57-59].

Most of the cyclic organometallic (like organic) compounds show a marked resistance to dissociation, which appears in an increased intensity of either the molecular ion or of ions which contain the complete cyclic skeleton of the molecule. The molecular-ion peak is significant in the mass spectra of several compounds but it appears as the base (maximal) peak solely in the mass spectra of the cyclic organosilicon molecules with aromatic groups and 1,4-disilahexadienes[47,48,51,56,57,59]. On the other hand, in the mass spectra of cyclosiloxanes, cyclocarboxyloxanes, cyclosilazanes, and other molecules with an organic skeleton the intensity of the molecular ions is negligible, but the removal of one radical (or, respectively, of two radicals for doubly-charged ions) stabilises the $[M-R]^+$ residue, since it gives the base peak. This ion dissociates further very little and its decomposition is mainly connected with the elimination or organic molecules with retention of the initial organometallic skeleton of the molecule[6,15,16,34,44-46]. The intensity of the molecular ions also depends on the size of the initial molecule, falling markedly as the number of units is increased within the limits of a single homologous series, for example[45], for cyclocarbosilanes $[Me_2SiCH_2]_n$ from ~10% of the total ionic current at $n = 2$ to less than the error of measurement at $n = 3$ or 4. With a further increase in the number of units there is an increase in the intensity of the ions formed by breakdown of the $[M-R]^+$ ion[6,34]. The replacement of CH_2-groups by an oxygen atom in cyclocarboxyloxanes reduces the probability of decomposition associated with the destruction of the cyclic structure and the spectrum becomes more selective. The change from

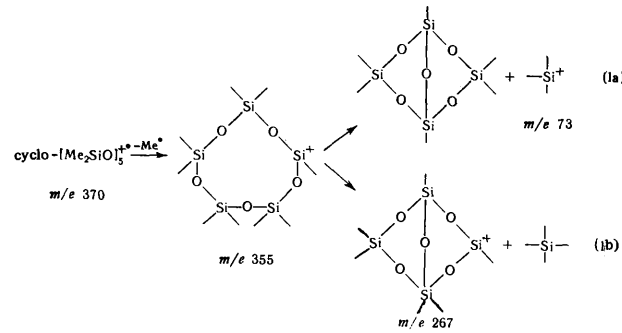
leads to a marked decrease in the intensity of both molecular and also the fragment ions lighter than $[M-Me]^+$.[34,58]

For monosila-, disila-, and mono-germa-cycloalkanes[25-30,58] and for spiro-compounds with a central metal atom[31-33] the structure of which includes the $-[CH_2]_n-$ chain the decomposition is primarily due to the loss of molecules of C_2H_4, C_3H_6, or their combinations; its products are ion-radicals. On going from silicon to tin and lead in the spiro-compounds this process becomes the only decomposition process, and the fraction of even-electron ions in the mass spectrum falls to 4% for $[CH_2]_4 > Pb < [CH_2]_4$.[33]

REARRANGED IONS

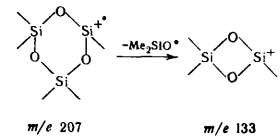
There have been repeated reports[2] of the ease of occurrence of rearrangements which are accompanied by the dissociation of organometallic compounds, greatly impeding their mass-spectral structural analysis. There may be no corresponding rearrangements of the ions for carbon analogues[60]. In certain instances almost the entire mass spectrum is formed by rearranged ions (for example, decamethylcyclopentasiloxane[6]). The activation energies of reactions which lead to the formation of rearranged ions are evidently lower than those for reactions which can be purely dissociative[61]; many rearrangements of excited ions may occur without any activation energy.

There is no strict classification of ionic rearrangements but our compounds can be conveniently divided according to the observed effects into: (1) those leading to the migration of organic groups, and (2) those which are "skeletal". This division is provisional since the two types of process are often closely related (they may occur simultaneously), and in small molecules essentially the same, so that several rearrangements can be formally assigned to both "types" (for example, see Kuivila and coworkers[62]); however, such a classification is frequently sufficiently unambiguous. The rearrangements or migrations of organic groups is extremely widespread in the mass spectra of organometallic compounds; they play the same part in these compounds as hydrogen rearrangements in the mass spectrometry of organic compounds and accordingly, on the same basis can be regarded as distinct from "skeletal" rearrangements. It is noteworthy that hydrogen rearrangements are frequently indissolubly linked with "skeletal" ones[63].



Migration of Groups

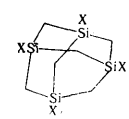
It would be difficult to list all the many examples of the migration of organic groups in the ions of Si, Ge, Sn, and Pb derivatives. From the results of recent years we will mention only certain observations of the migration of methyl[59], methoxy-[64], phenyl[65], and other organic[16,19] groups. We emphasise that the frequently observed ion of type R_3E^+ (E = Si, Ge, Sn, or Pb) which gives an intense, and in many instances the base peak, is rearranged to a considerable extent or completely, although frequently it could formally be formed also by simple breaking of a single bond (removal of a terminal group). The rearranged ions R_3E^+ are intense for cyclic compounds of the type $[R_2E]_n$ (where R = Me, Ph, Tol; E = Si, Ge, Sn [35,40,41,43]), $[R_2EO]_n$ (R = Me, E = Si [6] and at $n = 5$ the Me_3Si^+ ion gives a base peak and R = Pr^i, E = Ge; in the last instance the investigators[15] assigned the intense peak of the $Pr^i_3Ge^+$ ion to impurities!). Among ions of the R_3E^+ type are compounds $^1R^1_3E.^2E^2R_3$, where ^1R and ^2R are alkyl or aryl, and ^1E or ^2E are Si, Ge, or Sn, which contain all possible combinations of R and E.[66-69]. Investigation of rearranged ions in methylsiloxanes with trideuteromethyl terminal groups[70] showed complete rearrangement of the methyl groups at all the ions so that the mass spectrum in this instance is insensitive to the sites of the isotopic label (CD_3). This phenomenon is observed irrespective of the conditions of ionisation both in the decrease in the energy of the electrons up to a threshold, and in the ionisation of the molecules in collisions with metastable excited argon atoms. What has been said relates to all the most intense ions of the siloxanes, the formation of which does not require the breaking of C—H bonds; here the CD_3 groups migrate as a whole. However, for ions the formation of which requires the breaking of C—H bonds (the peaks of these ions are weaker in these mass spectra), a complete set of all possible combinations of H and D is observed, that is, hydrogen rearrangement also takes place‡. In this manner the breaking of one bond or another is indistinguishable from the corresponding rearrangements.



The migration of larger groups such as trimethylsilyl (TMS) has been observed for more complex molecules; here, however, the possibility of skeletal rearrangements, in particular, cyclisation, is usually considered simultaneously[72-76].

Skeletal Rearrangements

Such skeletal rearrangements as the contraction or enlargement of rings or the formation of a new ring are well known in the mass spectrometry of organic compounds, especially heteroatomic compounds[63,77]. The role of these processes in the mass spectrometry of organometallic compounds, especially rather complex ones, increases appreciably. The possibility of the enlargement of a four-membered to a five-membered ring was advanced as an explanation of the similarity in the mass spectra of dimethylsilacyclobutane and methylsilacyclopentane[27]; ideas about the contraction of the ring were used for the interpretation of intense fragment ions in the mass spectra of cyclic siloxanes, carbosiloxanes and tetra-azadisilacyclohexanes[6,34,47]. For cyclosiloxanes, in particular, the formation of bicyclic structures for both positively charged and neutral fragments is possible; the decomposition scheme of, for example, decamethylcyclopentasiloxane, can be represented as follows:



The cyclic structure of the ion $(SiO)_2$ (m/e 133) in the decomposition

is confirmed indirectly by its possessing (judging from the width of the corresponding metastable peak) an appreciable kinetic energy (~1 eV), which shows the considerable stability of the fragments formed.

Cyclisation of acyclic structures is often advanced as an explanation of observed rearrangements[71-73], etc. Especially convincing results which support the existence of this phenomenon can be found in the mass spectra of linear siloxane and carbosilane chains[6,45]. Almost all the fragment ions of sufficiently long siloxanes are formed in the cyclisation of either charged or neutral fragments. The mass spectra of the linear siloxanes contain all the elements of the mass-spectra of the corresponding cyclic molecules, including all the fragment and metastable ions and they could easily be taken for impurity ions if the corresponding multiply-charged ions were not absent. This phenomenon is analogous to the cyclisation of linear polysiloxanes on heating. The formation of an m/e 207 peak in the mass spectra of R_3AsO_3, R_3AsO_4, and R_3PO_3, where R = TMS (this is the base peak for R_3AsO_3) is undoubtedly connected with the cyclisation of ions[75].

There is evidently a connection between the skeletal rearrangement of tetrasila-adamantanes

where X = H, D, or Cl and of the cage polysilanes $Me_{2n-2}Si_n$ (n = 8, 9, or 10), and the appearance in their mass spectra of intense peaks of $[M-CH_3]^+$ (hydrogen rearrangement)[54] and $[M-Me_3Si]^+$ [55] ions; $[M-Me_3Ge]^+$ ions are typical for permethylcyclopolygermanes[48].

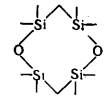
Geometrical factors are essential in the formation of new bonds[78]. In sufficiently rigid molecules rearranged ions are formed only when the interacting groups are

‡ A similar conclusion follows from the results obtained in the investigation of rearrangements in tetraphenylsilanes labelled with deuterium[71].

favourably situated. The migration of TMS groups, which gives intense peaks or rearranged ions in the mass spectra of TMS-derivatives of steroid phosphates does not occur when there is a considerable spatial separation of the corresponding groups; in this instance a hydrogen rearrangement prevails[79]. The mass spectra of TMS diethers of the type $Me_3SiO[CH_2]_nOSiMe_3$ (n = 10, 22) are characterised by the presence of the rearranged $Me_3SiOCH_2O_3SiMe_2$ ion, formed by the elimination of the central part of the molecule—almost all of the hydrocarbon chain, but, as the spectra of molecules labelled at one end with CD_3 groups show, there is no exchange of methyls between the TMS groups[80].

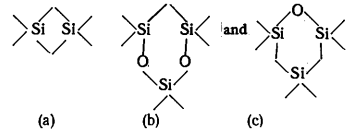
The examples of reactions (1a) and (1b) clearly show the connection between the skeletal rearrangements and the migration of the organic groups. Essentially, there is a single process of bond rearrangements (in this instance two bonds are broken, Si—O and Si—C and two such bonds are formed anew). Evidently, the rapid single-stage electronic process of bond migration in an electronically excited ion plays at least a significant part if not the determining one; after it follows the migration of the newly connected parts of the molecular ion.

However, it is possible that the comparatively high intensity of the rearranged ions in the mass spectra of organometallic compounds could be linked with the general retardation of the decomposition (see below); both are characteristic of the same compounds. Then the vibrational excitation of the ion facilitates the rearrangements which are dependent upon the necessary approach of the interacting parts of the molecular ion.



PRODUCTS OF IONIC MOLECULAR REACTIONS

In the mass spectrometric investigation of either individual organometallic compounds or of their mixtures with other substances it is necessary to take into account the possibility of distortion of the mass spectra by the products of ion-molecule reactions. The reactions of intense fragments of metal-containing ions with the molecules of a gas proper or of other compounds, leading to the intermolecular transfer of complex groups, are characterised by large effective profiles and proceed with appreciable yields at elevated or ordinary pressures in the ion source of the mass spectrometer.



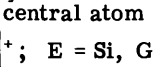
Heavy ions of the type $[M + 73]^+$, $[M + 147]^+$, etc. up to the very weak $[2M - 15]^+$ are recorded in the mass spectra of individual compounds, such as the TMS derivatives of glycerophosphates and other biologically active substances[81,82]. In the mass spectra of mixtures of compounds of the R_4E type (R = Me, Pr, or Bu; E = Si, Ge, or Sn) and Me_3SiR_1 (R_1 = OTMS, NHTMS, OMe) with a whole series of organic compounds which contain an electron-withdrawing group, ions of the $[M + A]^+$ type, where M is an organic molecule and A corresponds to R_3E^+, H_3E^+ and other intense fragment ions of these organometallic compounds, were observed[83]. The ratios of the intensities of the heavy ions for comparatively light A roughly follow the relations for fragment reagent ions; the intensity of $[M + A]^+$ falls with increase in the complexity of A.[82] (The peaks of the molecular ions R_4E^+ and $Me_3SiR_1^+$ are extremely weak.) The masses of the heavy ions (including the labelled ones) show that the heavy ions are formed by the simple addition of fragment ions A^+ to neutral molecules. Published results[83] reveal that the profiles of such reactions for even-electron fragment ions are much larger than those for the ion radicals.

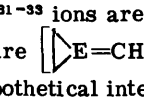
DISSOCIATIVE IONISATION AND THERMOLYSIS: MASS-SPECTRAL RESULTS ON UNSTABLE AND "NONEXISTENT" COMPOUNDS

An analogy between dissociative ionisation and the thermal decomposition of molecules has been noted repeatedly (it is naturally assumed that the last process proceeds under conditions of unimolecularity). Although these two processes differ in principle, due to the nature and magnitude of the excitation energy, with the properties of the charged species, the conditions of observation, etc., their comparison shows a series of common features connected with the combination of electron-vibrational processes of bond migrations in ions and molecules, above all the similarity of the sets of reaction products and also the correlation between the temperature dependence of the thermolysis and the appearance potentials of the corresponding ions[84]. A series of correlations of thermolysis and "electronolysis" was also noted for organometallic compounds. Thus on the one hand the thermal rearrangement of cyclocarboxyloxane (I)

(I)

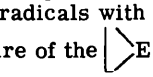
leads to the formation of smaller rings[85]:





and on the other in the mass spectrum (I) there are ions which correspond to the ions of the $[M - CH_3]^+$ type of molecules (a)—(c). The similarity in the thermolysis and dissociation of a molecular ion in electron bombardment was noted for dimethylsila- and mono-germa-cyclobutanes[86]; in both processes the initial species lose C_2H_4 and C_3H_6, and the relative probability of decomposition with loss of C_3H_6 is considerably greater for germacyclobutane both in electron bombardment and in thermolysis. A similarity in the ratios of the probabilities of removal of C_2H_4 and C_3H_6 in thermolysis and electron bombardment is also observed for the disila- and digerma-cyclopentanes[28].

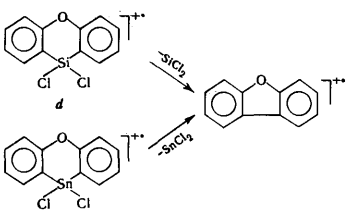
Comparison of thermolysis and dissociative ionisation is especially interesting in instances when the mass spectra allow the existence of unstable species postulated as intermediate reaction products to be guessed or confirmed to a certain extent. Among such substances there is considerable interest in the compounds of the bivalent elements of Group IVb§, including derivatives of silicon(II).[87] Compounds with multiple bonds are another type of unstable derivatives of these elements. The interest in these derivatives is due, on the one hand, to the fact that there is yet no satisfactory theoretical explanation of the inability of the Group IVb elements to form stable multiple bonds similar to the bonds in alkenes and carbonyls[89] (the calculations show the possibility of synthesis and separation of compounds with a double bond, in



§ The oxides SiO, GeO, SnO, and PbO and their oligomers were separated by matrix isolation[88].

particular, Si=Si.[90] On the other hand, the assumption of the existence of intermediate compounds with a double $(p-p)\pi$-bond allows the mechanism of such reactions as the thermocondensation of monosilacyclobutanes[91,92], thermal changes in the gas phase of cyclocarboxyloxanes and cyclosiloxanes[93-95] to be explained easily; in this species such as $Me_2Si{=}CH_2$ and $Me_2Si{=}O$ are postulated. Indirect experimental confirmation of the existence of the unstable product $Me_2Si{=}CH_2$ was obtained recently[96]. The thermal removal of ethylene by germacyclobutane evidently proceeds just as for silacyclobutane and the thermocondensation to digermacyclopentane probably includes the formation of carbenoid species of the Me_2Ge: type[86]. In connection with this it is desirable to consider the mass spectral results about species of this type. Under the conditions of observation in the mass spectrometer they can be either ion-radicals or even-electron neutral molecular groupings.

The first report of the observation in the mass spectra of siloxanes of species of the dialkylsilanone type, made more than 20 years ago by Andrianov and Sokolov[97], must be regarded above all as the prediction of the existence of such species, since the investigators, using the comparatively imperfect mass spectral technique of that time, evidently took for the hypothetical silanones the even-electron fragment ions (mainly rearranged ones) usual for these compounds[6].



When the ionised species have sufficient energy the mass spectrum includes ions so deeply dissociated including ion-radicals formally corresponding to the bivalent metal. The appearance potentials of such ions are usually higher than those of the neighbouring odd-electron ones. Therefore it is interesting here to consider only those instances when the intensity of such ions is sufficiently high. As an example there is the ion $[R_2Si{:}]^+$ in the mass-spectra of the phenoxasilins[50], $[C_2H_4E]^+$ in the mass spectra of spiro-compounds with a metal central atom (the possible structure is  ; E = Si, Ge, Sn, Pb [29,31-33]). Among the ions for which the presence of an E=X double bond (X = C or O) can be postulated are ions of the type $[R_2E{=}CH_2]^+$, which give extremely intense (or maximal) peaks in the mass spectra of the dialkylsila- and dialkylgerma-cyclobutanes[27-29]. In the mass spectra of the spiro-compounds[31-33] ions are released which can be assigned the structure  , which agree with the structure of the hypothetical intermediate product of the thermolysis of silaspiroheptane[98].

Ion radicals of the silanone type were not observed in the mass spectra of siloxanes.

Ion radicals with a composition which corresponds to a structure of the  type (significant but not exceeding in intensity the neighbouring even-electron ions) were observed in the mass spectra of 1,2-disila- and 1,2-digerma-cyclopentanes[28]. However, in other instances the peak of the $[Me_4Si_2]^+$ ion is maximal[53]. Ions of this type are also intense in the mass spectra of 1,4-digermahexadienes[48,99].

The mass spectral results on the formation of neutral fragments of this type may be of great interest for comparison with chemical results. Since the information about neutral fragments is confirmed or is obtained on the basis of an examination of the decomposition of metastable ions, which proceeds in times of the order of more than 1 μs, it can be presumed that neutral species live for at least as long. This corresponds closely to the non-excited state. The composition of the neutral metal-containing fragments, found as the difference in the composition of the initial metastable ions and fragment ions, obtained as a result of a single-step change, usually corresponds to the composition of the molecules—both those known and often those unknown in the free form.

Bivalent metals correspond to neutral fragments of the R_2E type—Me_2Si, MePhSi, eliminated in the decomposition of the disilanes[69], Me_2Ge in the decomposition of methylpolygermanes[19,43] $(p\text{-Tol})_2E$ (where E = Si or Ge) in the decomposition of tolylcyclo-silanes and -germanes[35], $SiCl_2$ and $SnCl_2$ in the decompositions[10,51]:

10,10-Dimethyl- and 10,10-diphenyl-phenoxysilin eliminate the lower oxide of silicon, SiO.[50] The same group is lost in the last stages of the decomposition of the cyclosiloxanes and also certain linear siloxanes after the loss of a large part of the organic framework[6].

The species, the composition of which corresponds to the formula R_2EX (X = CH_2, O, etc.) can be assigned structures such as REXR, which corresponds to a bivalent metal, or structures with the $R_2E{=}X$ double bond. The latter may be stable. They correspond in particular to the hypothetical dialkylsilanones. Information is available on the formation of the neutral fragments H_2SiO,[50,51] Me_2SiCH_2,[34] Me_2SiO,[6] Cl_2SiO,[51] Me_2GeO [15,16] (including instances when this species is not a unit of the molecule investigated—cyclo-$[Pr^i_2\,GeO]_3$ [15]). In siloxanes neutral fragments of the Me_2SiO type are eliminated, evidently solely when the formation of the usual oligomers $[Me_2SiO]_{3,4}$ is impossible.

INTENSITY OF METASTABLE IONS AND GENERAL RETARDATION OF THE DECOMPOSITION OF THE IONS OF ORGANOMETALLIC COMPOUNDS

Interest in metastable ions is usually restricted to the information which they can give about paths and distinct steps in the decomposition, allowing a scheme of successive decompositions to be drawn up (in general, however, insufficiently well founded, as shown above). Here the intensity of the metastable ions is usually not measured and its magnitude is not taken into account at all. Furthermore the relative intensity of the metastable ions in the mass spectra of the organometallic compounds is usually quite significant in even an approximate calculation of the breadth of the corresponding peaks¶. Thus the ratio I_m/I_0 of the sizes of the "metastable" peak and the "ordinary" peak of the decomposition product reaches ~0.1 for the reaction

$$Me_{13}Si_6O_5^+ \rightarrow Me_7Si_3O_2^+ + (Me_2SiO)_3$$

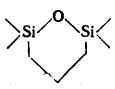
¶ Precise calculation is difficult because of the differing effectiveness of the collection of ions which decompose in the ion source and in the analyser.

in tetradecamethylhexasiloxane and 0.2 for reaction (1b) in decamethylcyclopentasiloxane[6]. Hence these are significantly retarded on the average.

The lifetime of metastable ions of derivatives of the Group IVb elements was not measured specially; it was noted that in a mass spectrometer with double focussing the number of recorded metastable ions which decompose between the ion source and the first (electrostatic analyser, is several times greater than the number of ions which decompose between the first and second (magnetic) analysers. The number of metastable ions of the last type falls from Si to Ge and Sn (6—3—1).[20] Evidently, the total retardation of the decompositions which are characterised by the total relative intensity of the metastable ions increases from C to Si and then falls again from Si to Sn and Pb.

The ratio I_m/I_0, which characterises the relative probability of the metastable breakdown, can vary strongly for different paths of dissociation; for siloxanes the lower value of the ratio corresponds to a path leading to the formation of a lighter ion. For example, for reaction (1b) (formation of the ion m/e 267) $I_m/I_0 = 0.2$ and for (1a) (ion with m/e 73) $I_m/I_0 = 0.02$.

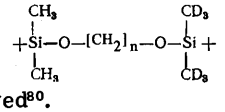
MULTIPLY-CHARGED IONS



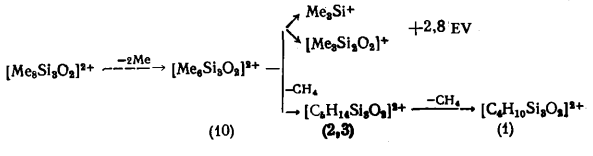
As noted in a recent study[100], the factors which determine the intensity of the doubly-charged ions and the path for their decomposition are "extremely complex and do not support widely used generalisations". In this connection a brief review of the empirical results on multiply-charged ions in the mass spectra of the organometallic compounds should be of interest.

The presence of multiply-charged ions in the mass spectrum of a complex molecule can be regarded as the appearance of its resistance towards dissociation or the retardation of the latter. The role of stabilising features in organic molecules usually brings about stable aromatic structures—this is so in particular for all the organic compounds for which triply-charged ions are observed. However, doubly- and triply-charged ions are characterised for the mass-spectra of organometallic compounds which contain respectively not less than two or three metal atoms in the molecule†. Intense peaks of multicharged ions are recorded in the mass spectra of methylsiloxanes[4,101,102] paraffins substituted with two TMS groups[5], silazanes[46], and other compounds which contain more than one metal atom[58,59,103]. Evidently the charges of multicharged ions are localised on different metal atoms.

For the heaviest of the observed multicharged ions usually $m/e = \frac{M}{n} - R$, which corresponds to the loss from the molecule M of a number of radicals R equal to the ionisation multiplicity n. Evidently these radicals are removed from the metal atoms on which the charge is localised, as is shown by the loss of valence electrons by these atoms. The stability of the multicharged ions is much greater when the metal atoms are separated by atoms or groups: O, CH_2, NH, etc.[104] and the effect of the oxygen atoms on the stabilisation of the multicharged ions is stronger than that of CH_2 groups. Thus the intensity[28,58] of the doubly-charged ions of the type $[M - 30]^{2+}$ is 1% in



and 4% in



for cyclocarboxyloxanes it increases twofold when all the CH_2 groups are replaced by oxygen atoms in the Si_3 molecules and threefold in Si_4 molecules[34]. Oxygen has the same effect in germanium compounds: the intensity of the doubly-charged ions from digermoxanes is higher than for the analogous digermanes[16]. The role of connecting groups in the stabilisation of multicharged ions can be determined by factors such as the increase in the distance between the charges and their delocalisation at the electronic orbitals of the connecting atom, strengthening the effect of $p_\pi - d_\pi$ conjugation for N or O. In individual instances, for the especially stable six-membered cyclic molecules it is possible to observe doubly-charged ions of the $[M-R]^{2+}$, obtainable in the breaking away of only one radical (considerably less intense, however, than ions of the $[M - 2R]^{2+}$ type)[34,58,103]. The intensity of the $[M - 30]^{2+}$ ions of the bistrimethylsilyl derivatives of the amino-oxynaphthalenes depends on the position of the substituent[105].

Multiple ionisation with localisation of charges on various metal atoms is evidently linked with the migration of charges (excitation) to these atoms. Charge migration in a hydrocarbon chain proceeds with minimal barriers[106] and is controlled by the ionisation potentials of the various parts of the molecules[107,108]. For chains with two Me_3SiO groups at the ends, one of which is completely deuteriated, the doubly-charged ions formed in the loss of two methyl groups from different silicon atoms

are readily observed[80].

Multiply-charged ions decompose according to two paths—with and without sharing of charges. The peaks of corresponding metastable ions are often observed; their form shows the nature of the process—in decomposition with charge sharing, which is accompanied by the release of a considerable kinetic energy, broad peaks with flat tops are obtained. The width of the peak allows the energy of the decomposition process to be estimated[109,110]; on taking into account that it is determined by the coulombic repulsion of the charges, the position of the latter in a multicharged ion and its configuration can be found. For example, doubly-charged octamethyltrisiloxane ions decompose according to the scheme:

(the numbers in parentheses give the relative intensity in percentages of the main singly-charged ion $[M - 15]^+$; the continuous arrows show the changes confirmable by metastable ions). The total energy of 2.8 eV of the singly-charged fragments of a doubly-charged ion corresponds to a charge separation of ~5 Å, which is close to the distance between the extreme silicon atoms in this molecule (5—6 Å, depending upon the conformation)[102].

The other path for the decomposition of multiply-charged ions (including triply-charged ones) is the splitting, usual for singly-charged ions, of neutral fragments,

† Doubly-charged ions GeH_2^{2+}, GeH^{2+}, and Ge^{2+} have been recorded for GeH_4.[16]

including those associated with rearrangements. Thus for the doubly- and triply-charged ions of the linear methylsiloxanes a series of fragment ions obtained by successive removal of two or three methane molecules formed from the organic framework of the molecule[94,102]. Since such a process is energetically less favourable than decomposition with charge division it shows the considerable stability of the siloxane skeleton of the multiply-charged ions. The slow decompositions of this type, which are observed, for example, for the Si_2 and Si_3 linear siloxanes[102], are especially remarkable[102]. In organic mass spectrometry similar results are known only for stable aromatic compounds[111].

NEGATIVE IONS

There have been only a few mass spectrographic studies of the negative ions of the organometallic compounds of Group IVb. An intense molecular anion-radical with a resonance maximum at electron energies not exceeding a few eV was observed for dodecamethylcyclohexasilane; for Me_6Si_2 the molecular anion was two orders of magnitude weaker and for Me_6Si_2O it was not observed at all[112]‡. A molecular anion was also not recorded in the negative mass-spectra of the tetramethyl derivatives Me_4E (E = Si, Ge, or Sn); however, for E = Si or Sn the intense ions $[M - 1]^-$ with resonance maxima at 4 and 7.8 eV and at 8 eV respectively, stabilised with $p_\pi - d_\pi$ interaction with the vacant orbitals of the central metal atom[114]. For E = Ge or Sn, Me_3E^- ions are characteristic; lighter fragment ions were also observed[114,115]. The main process for the decomposition of the negative ions of the tetraphenyl derivatives (E = Si, Ge, Sn, Pb) is the loss of phenyl or diphenyl; hydrogen rearrangement also plays some part in the subsequent decomposition[71].

Phosphorylated Aldehydes†

A.I.Razumov, B.G.Liorber, V.V.Moskva, and M.P.Sokolov

The review presents systematic data on the methods of synthesis and chemical properties of phosphorylated aldehydes. Attention has been concentrated on organophosphorus compounds containing the formyl group in the alkyl substituent linked to the phosphorus atom by a C-P bond. The phenomena of keto-enol tautomerism of phosphorylated aldehydes are described in greater detail, the influence of various factors on the position of the keto-enol equilibrium is assessed, and the geometrical structure of the enols formed is considered.
The bibliography includes 120 references.

IV. The keto-enol tautomerism of phosphorylated aldehydes 543

I. INTRODUCTION

Aldehydes occupy one of the central positions in organic chemistry both as regards their reactivities and synthetic possibilities. Presumably phosphorylated aldehydes will in time occupy just as important a place in the chemistry of organophosphorus compounds. In view of the high reactivity of the aldehyde group, they may be considered as the starting materials for the synthesis of a wide variety of other organophosphorus compounds. On the other hand, compounds of this class are convenient for the investigation of many general theoretical problems in organic chemistry and the chemistry of organophosphorus compounds.

Although from the time of the publication of the first study [1] which laid the foundations of the research on phosphorylated aldehydes twenty years have elapsed, the accumulation of factual data in this field has been extremely slow. This is probably due to the lack of convenient methods of synthesis for compounds of this kind. However, in recent years the number of published investigations of this problem increased sharply. Together with the development of synthetic methods, studies have been made on the structures and reactivities of phosphorylated aldehydes.

Hitherto there have been no reviews in the literature dealing with phosphorylated aldehydes. This paper is a first attempt at a general and systematic account of the available data on this question. At the same time, we feel it would be useful to draw the attention of investigators to this interesting branch of organophosphorus chemistry.

The review is devoted to derivatives containing the formyl group in the alkyl substituent linked to phosphorus via C-P bonds but other formyl-containing organophosphorus compounds are also briefly considered.

II. METHODS OF SYNTHESIS OF PHOSPHORYLATED ALDEHYDES

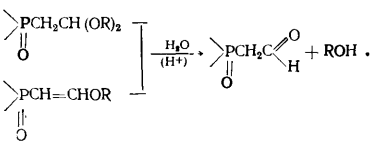
The vast majority of methods for the preparation of compounds with a C-P bond are based on the interaction of phosphorus(III) acid esters with electrophilic agents. However, the high reactivity of the aldehyde group in relation to such esters hinders the direct introduction of the formyl-containing substituent at the phosphorus atom. Organometallic synthesis, frequently used to form C-P bonds, also cannot be used. Therefore the formyl group must be introduced or regenerated from derivatives after the formation of the C-P bond.

In 1952, Dawson and Burger [1] suggested for the first time that the fundamental method for the synthesis of organophosphorus compounds—the Arbuzov reaction—be used to synthesise phosphorylated aldehydes with a halogenoacetal as the electrophilic agent. The reaction of the diethylacetal of bromoacetaldehyde with triethyl phosphate yielded the diethylacetal of diethylphosphonoacetaldehyde, the acid hydrolysis of which led to diethoxyphosphonoacetaldehyde:

$$(EtO)_3P + BrCH_2CH(OEt)_2 \rightarrow (EtO)_2P(O)CH_2CH(OEt)_2 + EtBr$$

$$(EtO)_2P(O)CH_2CH(OEt)_2 \xrightarrow{H_2O(H^+)} (EtO)_2P(O)CH_2C(O)H + 2EtOH .$$

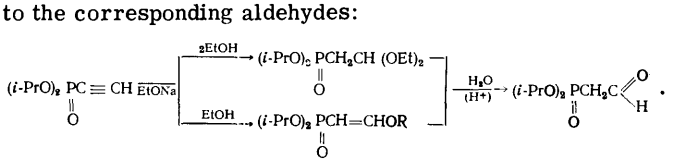
The authors failed to develop further this method (neither the phosphorylated acetal nor the aldehyde were isolated in a pure form; the latter was only identified in the form of its 2,4-dinitrophenylhydrazone), but their idea concerning the protection of the aldehyde group undoubtedly merited attention.



Detailed studies were made in our laboratory [2-8] of the reactions of halogenoacetals with phosphorus(III) acid esters followed by hydrolysis of the phosphorylated acetals to aldehydes up to the development of preparative procedures. Various phosphorus(III) acid esters (phosphites, aliphatic and aromatic phosphonites and phosphinites) together with a wide range of halogenoacetals were employed in the reactions. It was found that the influence of various factors [the nature of the phosphorus(III) acid ester and of the halogen in the halogenoacetals as well as the structure of the halogenoacetal] is determined by familiar relations typical for the Arbuzov reaction [9]. The temperature conditions in the reaction play a very significant role. At elevated temperatures phosphorylated aldehydes are degraded to the corresponding phosphorylated vinyl ethers:

$$>PCH_2CH(OR)_2 \xrightarrow[-ROH]{t^\circ} >PCH{=}CHOR$$

† Phosphonylated aldehydes (Editor of Translation).



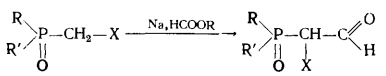
This type of degradation has also been noted in studies by other workers [10-12]. Probably the tendency of phosphorylated acetals to undergo reactions of this type is influenced, apart from the temperature factor, by the nature of the substituents at the phosphorus atom and the composition of the second component in the reaction mixture. Thus the reaction of tri-isopropyl phosphite with a chloroacetal (170°C) leads to the formation of a mixture of the phosphorylated acetal and alkoxyvinylphosphonate [10], while the interaction of a bromoacetal with trimethyl phosphite [11] and ethyl diphenylphosphinite [12] leads to the exclusive formation of the corresponding phosphorylated enolic ethers. It has been noted [11] that mainly ethoxyvinylphosphonate was formed in the study by Dawson and Burger [1].

The fact that phosphorylated acetals as a rule contain a mixture of the corresponding phosphorylated vinyl ethers is hardly a serious obstacle to the synthesis of phosphorylated aldehydes from them, since the hydrolysis of both the aldehydes and the vinyl ethers [10] leads to the formation of the same aldehydes:

In the hydrolysis of the phosphorylated acetal, a high concentration and a large excess of the acid should not be employed (to avoid the hydrolysis of the ester groups at the phosphorus atom). It is quite sufficient to use 5–7% HCl (80–90°C, hydroquinone). Naturally, as the electron-accepting phosphorus-containing group is removed further from the acetal group, the ease of hydrolysis increases. The excess acid and the volatile hydrolysis products should be removed *in vacuo* at relatively low temperatures. In the milder hydrolysis of phosphorylated acetals in the presence of ion exchangers, the yield of aldehydes increases [13].

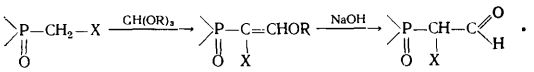
The Michaelis–Bekker reaction can also be used to synthesise phosphorylated acetals [14]. Moreover, ethynylphosphonates react with alcohols in the presence of alkoxides with formation of a mixture of phosphorylated enolic ethers and acetals [10], the hydrolysis of which leads to the corresponding aldehydes:

The applicability of the method is limited by the availability of the ethynylphosphonate.



On the whole, one may say that the method of synthesising phosphorylated aldehydes via the corresponding acetals is general and has the advantage over the methods described below that it can be used to obtain products with various relative positions of the phosphorus atoms and the aldehyde groups as a function of the structure of the initial halogenoacetals and phosphorus(III) acid esters.

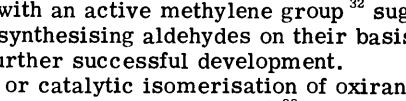
The genetic relation between vinylphosphonates and the corresponding phosphorylated acetals and the possibility of synthesising phosphorylated aldehydes on their basis was already noted above. The synthesis of vinylphosphonates was developed on the basis of the phosphorylation with phosphorus pentachloride of enolic [15] and dialkyl [16] ethers and acetals [17,18] as well as a number of other methods. It is clear that this method of synthesising phosphorylated aldehydes is based on the use of a fairly readily available class of compounds. The synthesis of phosphorylated aldehydes from the corresponding vinylphosphonates has also been thoroughly developed. Phosphorylated aldehydes belonging to the class of phosphonates [19-21], phosphonothionates [22,23], and phosphonothiolates [23,24] have been obtained by this procedure.



The hydrolysis of the corresponding alkoxyvinylphosphonates proceeds similarly to that of phosphorylated acetals but requires more severe conditions (particularly for phosphorothioic acid derivatives). This must be taken into account in the hydrolysis of acetals containing an admixture of a phosphorylated enolic ether. In practice the method is applicable only to the synthesis of α-phosphorylated aldehydes of the phosphonate series (in view of the availability of the initial enolic ethers).

In the synthesis of aldehydes with different relative positions of the formyl group and the phosphorus-containing substituent and also aldehydes belonging to the series of phosphinates and phosphine oxides, other procedures must be resorted to.

Many phosphorylated aldehydes have been obtained by the formylation of organophosphorus compounds with an active methylene group. The aldehydes synthesised include, together with the phosphorus-containing groups, other electron-accepting substituents in the α-position. Here one employs either direct formylation of the methylene group via the mechanism



or the alkoxymethylene fragment is introduced by the initial interaction of the organophosphorus compound with orthoformic ester, this being followed by the alkaline hydrolysis of the condensation product:

The active methylene group in phosphonoethylacetate [1,25,26], phosphonoacetone [25], benzylphosphonate [27], cyanomethylphosphonate [28], chloro- and bromo-methylphosphonates [29], diphenylbenzylphosphine oxide [12], and dibutylethoxycarbonylmethylphosphine oxide [30] was formylated by the first procedure. The formylation of dibenzylphosphinous acid proceeds at only one methylene group [31]. The synthesis of phosphorylated aldehydes with the preliminary introduction of the alkoxymethylene group has been achieved from cyanomethylphosphonate [26], phosphonoacetone [29], and dibutylphosphinylacetone [30]. The above reactions yielded phosphorylated aldehydes containing phenyl, chloro-, bromo-, cyano-, alkoxycarbonyl, and acyl groups next to the formyl group. Aldehydes of the above series proved suitable for the investigation of keto-enol tautomerism, which will be described below. The wide variety and large number of organophosphorus compounds with an active methylene group [32] suggest that methods of synthesising aldehydes on their basis will undergo a further successful development.

Thermal or catalytic isomerisation of oxiranylphosphonates ("epoxyvinylphosphonates") [33] leads to phosphorylated aldehydes in fairly high yields:

Both aliphatic [34] and cyclic [34,35] phosphorylated aldehydes can be obtained in this way. Oxiranylphosphonates without substituents in the oxiranyl group show little tendency to isomerisation of this kind [35]. Thus diethyl oxiranylphosphonate cannot be isomerised to phosphonoacetaldehyde either by heating or by treating with boron trifluoride-ether. However, phosphonoacetaldehyde is formed in a yield of up to 10% during the epoxidation of vinylphosphonate in methanol with hydrogen peroxide. It remains obscure whether this is a result of a rearrangement of the epoxide or of some other reaction between vinylphosphonate and hydrogen peroxide. Another method for the preparation of oxiranylphosphonate is dehydrochlorination of β-chloro-α-hydroxyethylphosphonate; here small amounts of phosphonoacetaldehyde are also formed together with the main reaction product—oxiranylphosphonate [36]:

$$(EtO)_2P(O)CH(OH)CH_2Cl \xrightarrow[\text{(in alcohol)}]{KOH} (EtO)_2P(O)CH\text{-}CH_2 + (EtO)_2P(O)CH_2C(O)H .$$

Dehydrobromination of β-bromo-α-hydroxypropylphosphonic acid with sodium bicarbonate yields α-phosphonopropionaldehyde as the main reaction product [37]:

$$CH_3CH(Br)CH(OH)P(O)(OH)_2 \xrightarrow{NaHCO_3} (HO)_2P(O)CH(CH_3)C(O)H .$$

Thus oxiranylphosphonates or phosphorylated halogenohydrins can also be used to synthesise substituted phosphorylated aldehydes.

Apart from the methods of synthesis of phosphorylated aldehydes dealt with above, methods which have not hitherto found much application have been described in the literature. Of the studies of this series, the synthesis of aldehydes from compounds of the oxaphosphorane type [38,39] obtained as the result of the interaction of trialkyl phosphites with $\alpha\beta$-unsaturated carbonyl compounds should be mentioned:

$$(RO)_3P + CH_2{=}CH{-}C(O)H \rightarrow \text{oxaphosphorane} \xrightarrow{HOH} (RO)_2P(O)CH_2CH_2C(O)H .$$

Treatment of the phosphorane with acetic acid also yields phosphonopropionaldehyde. The interaction of phosphoranes with alcohols leads to the acetals of the corresponding β-phosphonopropionaldehyde [40]. When crotonaldehyde reacts with triethyl phosphite in the presence of ethanol, the corresponding acetal is formed mixed with the enolic ether [41,42]. Phosphonoacetaldehydes have been obtained by the hydrolysis of β-acyloxy-β-chloroethylphosphonates [43-45]. The required starting materials were obtained by the low-temperature reaction of vinyl acetate with phosphorus pentachloride:

$$CH_3COOCH{=}CH_2 + 2PCl_5 \rightarrow CH_3COOCHClCH_2PCl_4 \cdot PCl_5 \xrightarrow{SO_2} \rightarrow CH_3COOCHClCH_2P(O)Cl_2 \xrightarrow[\text{pyridine}]{2ROH} CH_3COOCHClCH_2P(O)(OR)_2 \xrightarrow{H_2O} (RO)_2P(O)CH_2C(O)H .$$

The ambiguous interaction between phosphorus pentachloride and enolic esters, shown by the studies of the same investigators, does not allow the synthesis of a wide variety of aldehydes by this procedure.

Unsaturated phosphorylated aldehydes have been obtained via the corresponding acetals [46]. The latter were synthesised from the products of the phosphorylation with phosphorus pentachloride of allyl ethers in accordance with the following scheme:

$$CH_2{=}CHCH_2OR + 2PCl_5 \rightarrow [\text{complex}] \xrightarrow{SO_2} Cl_2P(O)CH{=}CH{-}CH(OR)Cl \rightarrow \xrightarrow{R'ONa} (R'O)_2P(O)CH{=}CH{-}CH(OR)OR' \xrightarrow[(H^+)]{H_2O} [(R'O)_2P(O)CH{=}CH{-}C(O)H]$$

$$\rightarrow (R'O)_2P(O)CH(CH_3)CH(CH_2)CH(O)H \xrightarrow{C_6H_6} (R'O)_2P(O)CH(CH_3)CH_2 \xrightarrow{H_2NNHC_6H_3(NO_2)_2} (R'O)_2P(O)CH{=}CHCH{=}NNHC_6H_3(NO_2)_2 .$$

In view of their instability, phosphonoacroleins were not isolated in a free state and were identified only as their 2,4-dinitrophenylhydrazones. If the hydrolysis of the corresponding acetal is carried out in the presence of a conjugated diene, the phosphonoacrolein formed is involved in a Diels–Alder synthesis [46,47]. This reaction not only confirms the structure of the phosphonoacrolein but also constitutes a method for the synthesis of phosphorylated alicyclic aldehydes. Phosphonomethacrolein was obtained from methylallyl ether via the scheme described above [48] and, in contrast to its unsubstituted analogue, proved to be more stable and was isolated in a free state.

A method of synthesising phosphorylated diacetals based on the following general scheme has been developed in our laboratory: the phosphorus(III) acid chloride reacts with the acetal of glycolaldehyde to form the corresponding phosphorus(III) acid ester containing the acetal group in the ester moiety; the interaction of the latter via the Arbuzov reaction with the acetal of bromoacetaldehyde leads to the corresponding diacetals [49]:

$$ROPCl_2 + 2HOCH_2CH(OR')_2 \xrightarrow{Et_3N} ROP[OCH_2CH(OR')_2]_2 \rightarrow \xrightarrow{BrCH_2CH(OEt)_2} ROP(O)(OCH_2CH(OR')_2)(CH_2CH(OR)_2) .$$

In the products synthesised, one of the acetal groups is contained in the alkyl substituent linked to the phosphorus atom and the other is in the ester moiety.

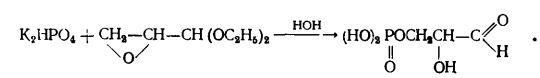
Compounds containing the formyl group attached directly to the phosphorus atom are still unknown. Possibly they cannot exist at all. We believe that the structure of the product quoted by Isamu [50] is unlikely. On the other hand, acetals of similar aldehydes are readily available and can be obtained in two ways: by the condensation of the partial esters of phosphorus(III) acid with orthoformic esters [51]:

$$>POH + HC(OR)_3 \xrightarrow{t^\circ} >P(O)CH(OR)_2 + ROH$$

or by the interaction of the latter with phosphorus(III) acid chlorides [52,53]:

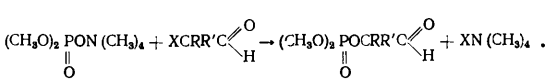
$$>PCl + HC(OR)_3 \rightarrow [>POR + ClCH(OR)_2] \rightarrow >P(O)CH(OR)_2 + RCl .$$

Satisfactory yields of phosphorylated formals are achieved by the first method only in the reaction with dialkyl phosphites; acid phosphonites and secondary phosphine oxides



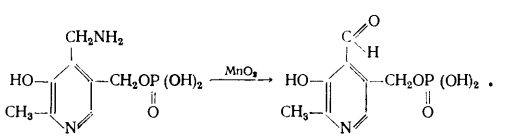
give extremely low yields of condensation products. The second method of synthesis—via phosphorus(III) acid chlorides—is more universal. The acetals of dimethylformamide (DMF) react with phosphorus(III) acid chlorides like orthoformic ester [54].

The hydrolysis of phosphonoformals does not lead to the corresponding aldehydes but involves the dissociation of the C–P bond [55] with formation of the initial dialkyl phosphite, alcohol, and alkyl formate.

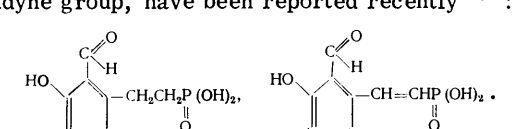


The structures of the phosphorylated aldehydes were confirmed in almost all cases by infrared spectroscopy and by the formation of 2,4-dinitrophenylhydrazones. In later investigations, NMR as well as infrared spectroscopy was employed.

Apart from the studies on phosphorylated aldehydes containing the formyl group in the substituent linked to the phosphorus atom by the C–P bond described above, mention has been made in the literature of compounds in which the formyl group is in the substituent linked to the phosphorus atom via a heteroatom (O, S, or N) and of phosphorus ylids and phosphonium salts. These studies on methods of synthesis cannot as yet be fitted into a definite system and therefore we shall confine ourselves to the enumeration of individual investigations in this field.

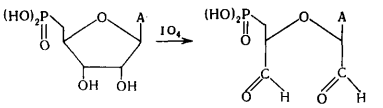


The interaction of the acetal of 2,3-epoxypropionaldehyde with dipotassium hydrogen phosphate followed by hydrolysis yielded glyceraldehyde phosphate [56]:

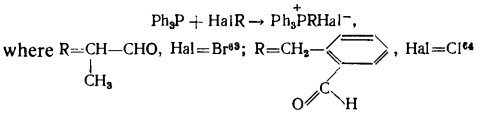


Another method of synthesising formyl-containing phosphates [57] consists in the interaction of the ammonium salts of phosphate esters with halogenoaldehydes:

Certain formyl-containing phosphates are interesting biologically active compounds. Pyridoxal phosphate [57-59], the synthesis of which involves the interaction of pyridoxamine with phosphoric acid followed by oxidation of the reaction product, is the most striking derivative of this kind:

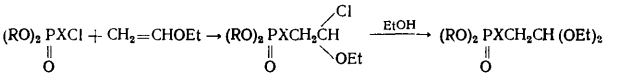


Phosphonic analogues of pyridoxal phosphate, in which the ester oxygen has been replaced by a methylene or methylidyne group, have been reported recently [60,61]:



Their synthesis is based on the interaction of the corresponding pyridinealdehyde with phosphonate Wittig reagents, in particular with tetraethylmethylenediphosphonate. Esters of vinyl- and ethyl-phosphonic acids have been obtained by the oxidation of the hydroxymethylene group to the formyl group under mild conditions. The esters are hydrolysed by concentrated hydrochloric acid and phosphonic acid analogues of pyridoxal phosphate are isolated.

When adenosine monophosphate is oxidised by periodate, dialdehydes of the following type are formed [62]:



A = adenine residue

A series of phosphonium salts containing the aldehyde group are known [63,64]. Their synthesis is based on the interaction of triphenylphosphine with halogenoaldehydes:

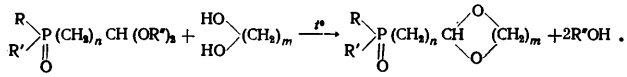
Kirsanov and coworkers began the study of phosphazo-compounds with the aldehyde group in the aromatic ring, which are synthesised by the interaction of azidoaldehydes [65] or their oximes [66] with triphenylphosphine. In the latter case, the aldehyde was isolated by hydrolysing the oxime.

Acetals with the general formula $(RO)_2PXCH_2CH(OR')_2$ [67,68] where X = S or Se, are obtained according to the scheme

Acid hydrolysis of the acetal of the thio-derivative [67] led to the isolation of the corresponding aldehydes.

Several methods of synthesising aldehydes of the phosphorane type have been described, namely by the formylation of phosphinoalkylenes $Ph_3P{=}CH_2$ by *N*-formylimidazole [69] or ethyl formate [70] and also by the interaction of bromonitroethylenes with triphenylphosphine [71].

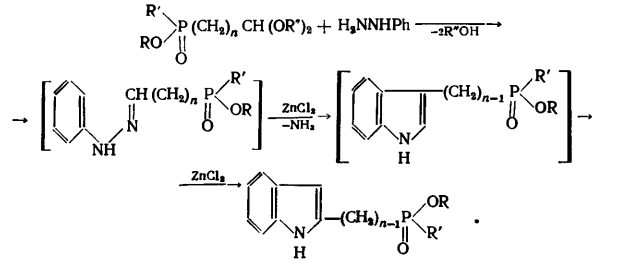
Compounds containing the formyl residue at a nitrogen atom linked to the phosphorus atom can be regarded as substituted formamides and are therefore not dealt with in the present review.



The foregoing discussion shows that many different types of synthesis of phosphorylated acetals and aldehydes have been described in the literature. The choice of a specific method for preparative purposes is determined mainly by the structure of the aldehyde to be synthesised and by the availability of the initial compounds. The advantages and disadvantages of individual methods have been stated in their discussion.

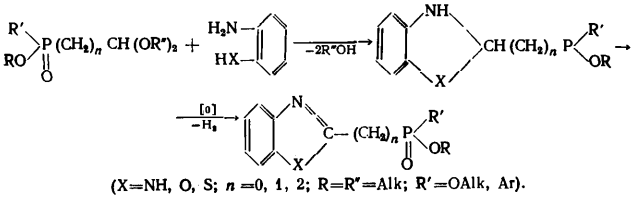
III. CHEMICAL PROPERTIES OF PHOSPHORYLATED ALDEHYDES

The chemical properties of phosphorylated aldehydes have been investigated much less than the methods of their synthesis. The limited number of studies in this field still precludes a broad general description of studies on the reactivity of compounds of this class and in the first place a description of the effects of electronic and steric factors on the course of nucleophilic addition reactions, which are most characteristic of the carbonyl group. Studies on keto-enol tautomerism of phosphorylated aldehydes, in which the mutual influence of the phosphorus-containing and formyl groups is clearly revealed, constitute an exception.



The first publications dealing with syntheses on the basis of phosphorylated aldehydes confirm their usefulness in this field. Certain reactions of phosphorylated aldehydes are described below. The most thoroughly investigated synthetic application of phosphorylated aldehydes is the synthesis of phosphorylated heterocyclic compounds with phosphorus in the side chain [72]. The first attempt to synthesise a phosphorylated aldehyde [1] was undertaken precisely with the aim of its subsequent employment to synthesise phosphorylated heterocycles. In many cases phosphorylated acetals were used successfully in the syntheses instead of phosphorylated aldehydes.

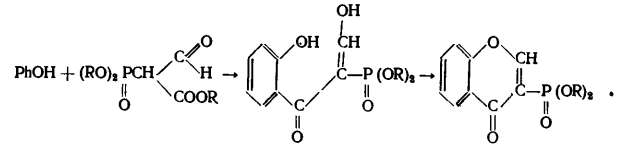
The reaction of phosphorylated acetals with diols yielded phosphorylated 1,3-dioxolanes [73], 1,3-dioxans [74], and polymethylene acetals [75]:



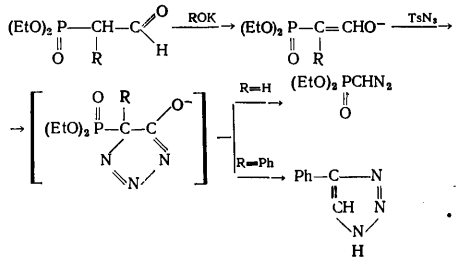
The reaction is carried out by heating equimolar amounts of the reactants with simultaneous distillation of the alcohol liberated. The phosphorylation of poly(vinyl alcohol) by phosphonoacetaldehyde can also be regarded as a transacetalisation reaction [76].

Phosphorylated acetals enter into a Fischer cyclisation reaction with arylhydrazines, forming phosphorylated indoles [5,77]:

It has been shown that the indoles phosphorylated in the 3-position, which are formed initially, isomerise to the 2-derivatives in the presence of an excess of zinc chloride.



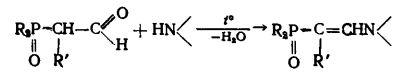
A wide range of phosphorylated heterocycles can also be obtained by the condensation of phosphorylated acetals with aromatic *ortho*-disubstituted compounds containing mobile hydrogen atoms, such as *o*-phenylenediamine, *o*-aminophenol, *o*-aminothiophenol, and others:



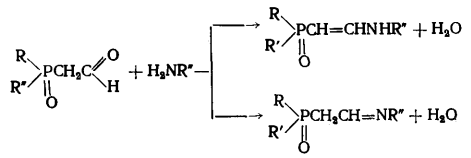
(X=NH, O, S; n =0, 1, 2; R=R″=Alk; R′=OAlk, Ar).

These reactions, which are common to the given classes of compounds, yielded respectively phosphorylated benzimidazoles [77,78], benzoxazoles [79], and benzothiazoles [80]. 2-Phosphorylated benzazoles are synthesised via a stage involving the formation of azolines [81]. The interaction of phosphorylated acetals with *o*-dihydroxy-derivatives of benzene and naphthalene resulting in the corresponding phosphorylated dioxoles takes place similarly [82]. Thus acetals of real phosphorylated aldehydes and derivatives known only in the acetal form (phosphorylated formals) have been used in the condensation reactions [77-82]. It has been found that, as the phosphorus-containing substituent moves further away from the acetal group, the rate of reaction increases, which can be accounted for by the decrease of the effect of the electron-accepting substituent on the mobility of the alkoxy-groups in the acetal moiety.

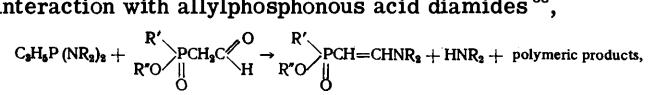
Substituted phosphorylated aldehydes also enter into a condensation reaction with monohydric phenols to form phosphorylated heterocycles [25]:



The ability of phosphorylated aldehydes to be converted comparatively readily into phosphorylated diazo-compounds greatly extends their synthetic possibilities, including the synthesis of heterocycles [83,84]:

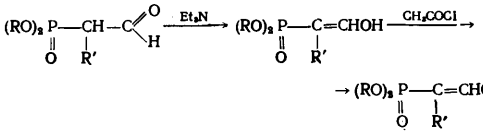


The free phosphonodiazomethane isolated [84] can be used for various organophosphorus syntheses.

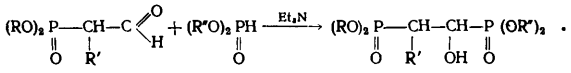


Phosphorylated enamines—a little known class of organophosphorus compounds—can also be obtained successfully from phosphorylated aldehydes. The interaction of equimolar amounts of the latter with cyclohexylamine in methanol [85] or with secondary aliphatic amines in toluene in the presence of catalytic amounts of toluene-*p*-sulphonic acid, accompanied by azeotropic distillation of water [86], gave satisfactory yields of phosphorylated enamines:

The interaction of phosphorylated aldehydes with primary amines leads to phosphorylated enamines, imines, or their mixtures depending on the structure of the amine employed [87]:

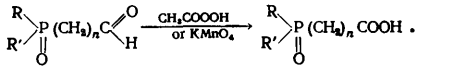


Virtually only enamines are formed when there is an electron-donating substituent at the nitrogen atom. When an electron-accepting substituent is present at the nitrogen atom, either a pure imine or a mixture of both products with the imine form predominating is formed. Whereas the direct interaction of secondary amines with phosphorylated aldehydes can involve either the keto- or the enolic form of the latter, the synthesis of phosphorylated enamines from the corresponding aldehydes via their interaction with allylphosphonous acid diamides [88],



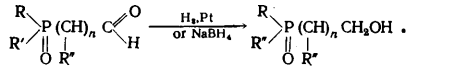
apparently involves the enolic form of the aldehydes.

Acylation of the enolic form of phosphorylated aldehydes by acetyl chloride in the presence of bases leads to β-acyloxyalkenylphosphonates [89]:



^{1}H NMR spectra have shown that the β-acyloxyvinylphosphonates, like the β-dialkylaminovinylphosphonates discussed above, have exclusively (or at least within the limits of the sensitivity of the ^{1}H NMR method) the *trans*-(P, O, or P, N) form. There are no specific data which would provide an answer to the question concerning the reason for the formation of only one geometrical isomer: either by the involvement in the reaction of only the *trans*-enolic form of the phosphorylated aldehyde or by the capacity of the *cis*-form of the corresponding derivative to isomerise readily under the reaction conditions to the energetically more favourable *trans*-form.

The extension of the familiar reactions of partial phosphorus(III) acid esters with aldehydes and ketones [90] to phosphorylated aldehydes leads to new possibilities in the synthesis of substituted ethylenediphosphonates [13,20]:



The reaction in the presence of a tertiary amine [13] or directly with dicyclohexyl phosphite salt [20] proceeds vigorously and reaches completion rapidly. On this basis, one may conclude that the aldehyde groups influenced by the electron-accepting phosphorus-containing substituent exhibit a fairly high electrophilic activity.

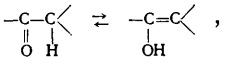
Phosphorylated aldehydes are oxidised by peracids [91] or by alkaline potassium permanganate [92] to the corresponding phosphorylated carboxylic acids:

The reduction of phosphorylated aldehydes over a platinum catalyst [27] or by sodium borohydride [93] leads to the corresponding hydroxy-derivatives in fairly high yields:

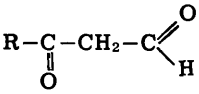
β-Aminoethylphosphonate has been obtained by the reduction of phosphonoacetaldehyde oxime in acetic anhydride [92].

Thus the data described show that the oxidation and reduction reactions of phosphorylated aldehydes and their derivatives can be used for preparative syntheses of organophosphorus compounds with functional groups.

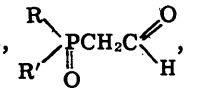
The capacity of phosphorylated acroleins to undergo the Diels–Alder reaction [46,47] was mentioned above. The absence of a similar reaction involving phosphonomethacrolein has been explained [48] by the increased steric hindrance and by the electron-donating properties of the methyl groups, which reduce the electrophilicity of the C=C bond.



The diethylacetal of diethoxyphosphonoacetaldehyde has been used to synthesis olefins (via phosphonate carbanions). This acetal has been used successfully to synthesise cinnamaldehyde from benzaldehyde [94], but it did not react with steroid ketones [95].



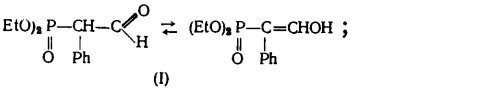
It has been noted [92] that, in an acid medium at an elevated temperature (90°C), phosphonoacetaldehyde decomposes with formation of acetaldehyde and inorganic phosphate. Possibly this constitutes one of the explanations of our earlier observation [2] that in the hydrolysis of phosphorylated acetals a high yield of aldehyde is achieved when volatile products and the excess volatile acid are removed from the hydrolysis product *in vacuo* before distillation. The high sensitivity of phosphorylated aldehydes to acids was also pointed out by Tavs [13]. On the other hand, a considerable excess of acid has been employed in many studies [19,20,23] involving the hydrolysis of phosphorylated enolic ethers without a significant decrease of the yield of the phosphorylated aldehyde.



It follows from the data discussed that the properties characteristic of the aldehyde group are largely retained in phosphorylated aldehydes. This suggests that in future all the potentialities of the aldehyde group will be widely employed in organophosphorus synthesis.

IV. THE KETO–ENOL TAUTOMERISM OF PHOSPHORYLATED ALDEHYDES

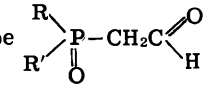
The keto–enol tautomerism, involving the characteristic irreversible interconversion



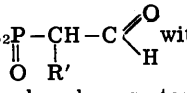
is very common and has been thoroughly investigated in organic chemistry. Mainly substances with two carbonyl groups separated by a methylene link were investigated in this field: β-diketones and β-ketoacid and malonic acid esters (β-dicarbonyl compounds) [96]. β-Ketoaldehydes with an unsubstituted methylene group,  , have not been investigated in this connection in view of their low stability [97]. There are only isolated data [98,99] showing a somewhat higher stability of their keto-enol form. For further investigation of such tautomerism, it was of great interest to study other chemical series with structures close to that of β-ketoaldehydes.

Phosphorylated aldehydes are one such class of compounds. These include primarily phosphorus analogues of β-dicarbonyl compounds,  , in which the C=O group has been replaced by the P=O group. The considerable similarity between the structures and properties of the two classes of compounds has been established for a long time and has been the subject of numerous investigations [32,100–102].

On the basis of these considerations, it was to be expected that α-phosphorylated aldehydes should exhibit keto–enol tautomerism. Presumably, apart from the principal external and structural factors determining the tautomeric equilibrium of β-dicarbonyl compounds, the P=O group also plays a significant role in phosphorylated aldehydes. It can exert an influence via the formation of hydrogen-bonded complexes with the hydrogen atom of the OH group of the enolic forms (which are more stable than in the case of the C=O group [103]) and via the involvement of the 3*d* orbitals of phosphorus in conjugation with the double bond of the enolic forms. Moreover, one cannot fail to

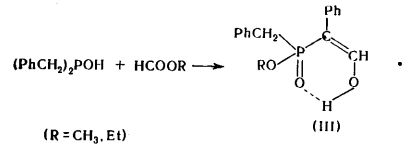


take into account the possible steric factors due to the larger bulk of the P=O group compared with that of the C=O group.



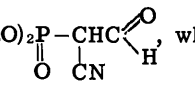
Indeed, in 1960 Tammelin and Fagalind [27] described the tautomeric properties of 2-diethoxyphosphonyl-2-phenylacetaldehyde (I), which they obtained,

(I)

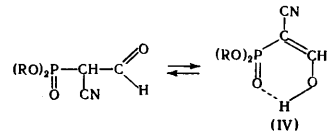


they resemble those of ethyl phenylformylacetate (II). Comparison of the infrared spectra and the dissociation constants of compounds (I) and (II) and also the spectrophotometric determination [on the basis of the colour of the complex with iron(III) chloride] of the keto–enol equilibrium constant and the rate of enolisation of compound (I) led the authors [104] to the conclusion that compounds (I) and (II) exist only in the keto- and *cis*-enolic forms in carbon tetrachloride and isopropyl alcohol solutions and that the *trans*-form is absent from such solutions. The infrared spectra of compound (I) showed the absorption bands of the OH group involved in an intramolecular hydrogen bond. At the same time the vibration frequency of the P=O group was displaced towards longer wavelengths, which indicated the formation of a hydrogen bond between them, while the enolisation of the phosphoryl group was not observed. The dissociation constants of compounds (I) and (II) were found to be very similar (pK_a = 7.09 and 7.21 respectively).

In subsequent studies dealing with the keto–enol tautomerism of α-phosphorylated aldehydes, two main trends were established. On the one hand, aldehydes without a second substituent at the α-carbon atom of the type  were investigated and the influence of substituents at the phosphorus atom on the position of the keto–enol equilibrium was elucidated. These investigations make it possible to estimate the intrinsic effect of the  groups, since in these cases it is not masked by the superposition of any other effect of substituents in the methylene group.

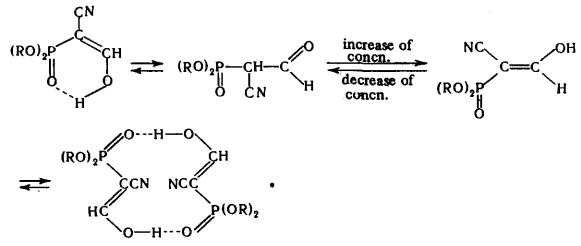


On the other hand, a study was made of the effect of substituents at the carbon atom in α-substituted aldehydes of the type  with retention of the same groups at the phosphorus atom. The substituents R′ were chosen mainly so that they could enter into conjugation with the π-electrons of the double bonds of the enols. At the same time, the introduction of the α-substituent can alter the molecular geometry, hindering the reverse transition into the keto-form, and hence can increase the general tendency towards enolisation. With this aim in view, groups possessing a considerable resonance component σ_R (CN, CH_3CO, COOR), together with a high negative inductive effect ($-I$), were employed as substituents in the first place. They make it possible to shift the equilibrium almost completely towards the enolic form. Next, substituents with lower values of σ^* (C_6H_5, Cl, Br) were introduced, and finally substituents exhibiting a positive inductive effect. In all these cases, the equilibrium was displaced towards the enolic form. The fact that substituents with opposite inductive effects (halogens [29] and alkyl groups [21]) caused an unambiguous shift of the equilibrium towards the enol cannot as yet be satisfactorily accounted for without additional investigations.



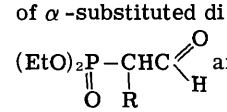
Thus, in studies of the second type, a decisive influence is attributed to the nature of the substituents at the α-carbon atom. The phosphoryl group influences the nature of the enolisation reaction (*cis*–*trans*-enolisation) and causes a slight shift of the equilibria. Naturally, particular investigations cannot always be definitely assigned to a particular type, since the data accumulated suggest quite clearly that the effect of the substituents at both the α-carbon atom and at the phosphorus atom is fairly important. In view of these findings, in later studies investigators attempted to take into account the overall effect of all the substituents present in the molecule. Chronologically, it is more convenient to consider initially the keto–enol tautomerism of substituted phosphorylated acetaldehydes.

In a further development of studies mentioned above [27,104], Arbuzov and coworkers [31] attempted to synthesise phosphorus-containing dialdehydes. However, they isolated alkoxybenzylphosphinylphenylacetaldehydes in the crystalline enolic forms (III) with stable cisoid configurations, which are sparingly soluble in organic solvents:



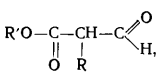
(III)

Kirilov and Petrov [28] investigated the tautomerisms of cyanoaldehydes of the type  , where R = C_2H_5, n-C_3H_7, or n-C_4H_9, by infrared spectroscopy and by titration. However, the classical bromometric method proved to be unsuitable in view of the sensitivity of the aldehyde groups to bromine. A method involving the acidimetric titration of aqueous solutions of aldehydes with 0.01 M NaOH revealed the presence of up to 98% of the enolic form. On the basis of the literature data and the frequency shift of the OH and P=O groups in the infrared spectra, the authors suggest that a cisoid structure (IV) with an intramolecular hydrogen bond is characteristic of the enolic form and they explain the high stability of this bond by the considerable polarity of the P=O group:

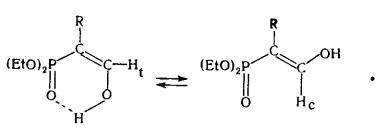


(IV)

The study of the infrared spectra of solutions of the aldehydes in carbon tetrachloride (at concentrations of 0.4 and 3.63%) led to the hypothesis that new enolic forms, namely the dimeric forms (V) and polymeric forms with an intermolecular hydrogen bond and involving *trans*-enols, appear in more concentrated solutions:

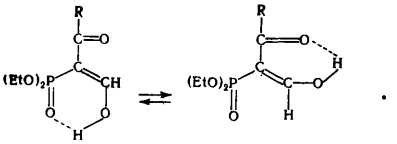


The dimeric structure is thought to be confirmed by the characteristic increase of the intensity of the absorption bands associated with the deformation vibrations of the bound OH group, with the concentration of the solution.



In a series of interesting studies, Kabachnik, Ioffe, and others [26,29,30,105-109] investigated by ^{1}H NMR the enolisation of α-substituted diethoxyphosphonoacetaldehydes

and compared it with the tendency towards enolisation in the corresponding substituted formylacetic esters:



where R = CN, COOEt,[26] Ph, Cl, Br, or CH_3CO.[29] Particular attention was devoted to the elucidation of the nature of the hydrogen bonds. One should bear in mind that, owing to the lower thermodynamic stability of the *trans*-enolic form compared with the *cis*-enolic form [110], the *trans*-enolisation of open-chain formyl derivatives takes place extremely rarely and only under conditions such that structural factors or the solvent cause an additional stabilisation of the *trans*-form. One should also mention that hitherto there have been no reliably established instances of the *trans*-enolisation of open-chain β-dicarbonyl compounds with the exception of a small number of formyl derivatives [111,112]. The assignment of the tautomeric enolic forms to the *cis*-(VI) or *trans*-series (VII) was based on the vinyl proton signals in the ^{1}H NMR spectra. Integration of the signals made it possible to estimate the contents of the *cis*- and *trans*-isomers of the enolic forms relative to the P=O and OH groups:

cis (VI) *trans* (VII)

In addition, in acetyl- and ethoxycarbonyl derivatives there is a possibility of competition between two *cis*-enolic forms with chelation in different directions. Thus an intramolecular hydrogen bond can be formed with both C=O [formula (VIII)] and P=O groups [formula (IX)]:

P-*cis* (VIII) C-*cis* (VIII)

(R = CH_3, OEt)

The results of the investigations showed that, in the case of the ethoxycarbonyl derivative, the P-*cis*-form (VIII) is mainly involved in the equilibrium owing to the higher basicity of the P=O group compared with that of the carbonyl group. On the other hand, in the acetyl derivative the C-*cis*-form is dominant, probably due to the opposite changes in the basicities of the P=O and C=O groups. This enabled the authors to arrange the hydrogen bond acceptors in the following series in terms of their capacity for chelate-formation with the hydroxy-methylene group:

$$CH_3CO > (EtO)_2P(O) > COOEt$$

Determination of the proportions of the tautomeric forms in solvents of different polarities (carbon tetrachloride, dioxan, acetonitrile, and nitromethane) showed that, in solutions of phosphonic and carboxylic acids containing the CN, CH_3CO, and COOEt groups as α-substituents, the keto-form is absent (Table 1). This finding is probably related to the high acidity of the CH protons (Table 2) due to the appreciable inductive and mesomeric effect of the α-substituents.

According to the authors, the capacity for *trans*-enolisation is determined not so much by the steric effects as by the polar effects of the α-substituents. Thus, in acetonitrile esters containing chlorine and bromine exist in the *trans*-enolic and keto-forms but not in the *cis*-form. This phenomenon has been attributed to the inductive effect of the halogen atoms. The latter decrease the basicity of the P=O and C=O groups and reduce the energy of the hydrogen bond with a corresponding destabilisation of the pseudoaromatic ring of the *cis*-enolic form. On the other hand, in both acetonitrile and nitromethane the enolisation of carboxylic and phosphonic acids is similar, while in

carbon tetrachloride and in dioxan differences are observed. For example, all three forms of chloroformylacetic ester are present in equilibrium, while the *cis*-enolic form of its phosphonic analogue is absent. Moreover, it has been shown that the *trans*-enolic form which predominates in the equilibrium is stabilised by intermolecular hydrogen bonds. In order to find the degree of association of the molecules, their molecular weights in benzene, dioxan, and acetonitrile were determined. It was discovered that carboxylic acid derivatives are monomeric, while phosphonic acid derivatives are associated in benzene but are converted into monomers during ebullioscopic determinations in acetonitrile. In the latter case, intermolecular hydrogen bonds are ruptured at the boiling point of the solvent. The results provide additional evidence in support of the above hypothesis concerning the intermolecular association of the enolic forms in solution, which stabilises them. The observations are also supported by infrared spectroscopic data [108].

Table 2. The pK_a values in water at 20°C. [29,109]

Compound	pK_a	Compound	pK_a

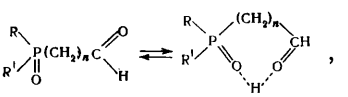
BrCH (CHO) P (O) $(OEt)_2$	6.14	EtOOCCH (CHO) P (O) *n*-Bu_2	6.40

To confirm the dependence of the nature of the enolisation on the basicity of the C=O and P=O groups, a study was made [30] of the compounds n-Bu_2P(O)CH(R)CHO (R = COOEt or $COCH_3$). In contrast to the diethoxyphosphono-derivatives with the general formula $(EtO)_2$P(O)CH(R)CHO discussed previously, in the present case the enolic forms present in the equilibrium solution in acetonitrile have only the *cis*-configuration. They are stabilised by an intramolecular hydrogen bond, since the n-Bu_2P(O) group becomes a more basic chelating centre. It is extremely difficult to generalise these results and to find general relations governing the enolisation of phosphonoacetaldehydes, since in this case the overall effects of the α-substituents and the R(R′)P(O) groups operates. A characteristic pattern may be observed for each substituent and one of the above effects may become of primary importance if it is sufficiently powerful, as can be seen from halogeno- and cyano-derivatives. On the other hand, the interaction of all the effects enumerated creates different nuances in the type of enolisation which is a highly refined phenomenon [109].



Therefore the study of unsubstituted phosphorylated aldehydes, where the complicating effect of α-substituents is removed and it is possible to follow the effect of the R(R′)P(O) group alone, is of special interest. The keto–enol tautomerism of unsubstituted phosphorylated aldehydes has been studied in a number of investigations [6-8,113-115]. In their approach to the solution of the problem of the relative amounts of tautomers in aldehydes of different classes of organophosphorus compounds (phosphonates, phosphinates, and phosphine oxides), Razumov and coworkers employed infrared, ^{1}H NMR, and ^{31}P NMR spectroscopic methods and to some extent polarography [6-8,113-115]. The following keto–enol equilibrium is observed in series of unsubstituted phosphorylated aldehydes:

(B) (A) (C)

where R = OAlk, C_2H_5, C_3H_5, or C_6H_5 and R′ = OAlk, C_2H_5, or C_6H_5.

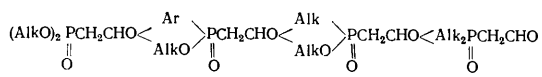
Apart from the usual external factors (medium, temperature, and concentration), the equilibrium depends directly on the nature of the R(R′)P(O) group. In polarographic studies of the behaviour of phosphorylated acetaldehydes and propionaldehydes in neutral, alkaline, and acid aqueous solutions, it was found in the first place that their polarographic activity is due to the aldehyde group and not the phosphoryl group, since the latter is not reduced at the dropping mercury electrode. It was discovered that in a neutral aqueous medium aldehydes exist in the keto-form in equilibrium with the hydrated form:

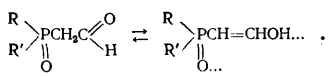
where R = C_2H_5, C_6H_5, p-ClC_6H_4, p-$CH_3C_6H_4$, or OC_2H_5 and R′ = OC_2H_5.

The polarographically active form amounts to 11–12% for phosphinylacetaldehydes and 20–22% for phosphinylpropionaldehydes. In acid solutions, the equilibrium is displaced towards the enol and in alkaline solutions the enolic form is not detected, since it probably exists in the form of a polarographically non-reducible anion. A study was also made of the influence of the group R on the capacity of the aldehyde group to be hydrated and on the tendency towards enolisation. In phosphinylacetaldehydes, the effect is shown to a much greater extent than in phosphinylpropionaldehydes, but the effect is of the same type [113,114].

The employment of infrared and NMR spectroscopic methods in the study of the keto–enol equilibrium led to the discovery of many interesting relations governing the processes. Experiments were performed for many compounds of the series mentioned above. In each series ethoxy- and isopropoxy-groups were always present, which made it possible to follow the effect of only one substituent at the phosphorus atom. The study of the dependence of the position of the keto–enol equilibrium on the nature of the substituent showed that it is determined mainly by the basicity of the P=O group, which limits its capacity to form hydrogen bonds stabilising the enolic forms, and to a lesser extent by steric factors.

The basicity of the P=O group as a function of the nature of the substituent can be assessed from the chemical shifts $\delta^{31}P$ of the phosphorus nuclei, the energy of the π bond, and the shifts of the OH frequencies of the enolic forms in the infrared spectra. The latter also make it possible to establish that the acidity of the enolic forms is constant ($pK_a = 7.5 \pm 0.03$)‡ within the limits of the accuracy with which $\Delta\nu$(OH) is measured for the series investigated. The authors observed that, with increase of the basicity of the P=O group and the consequent increase of the hydrogen bond energy, there is a successive shift of the position of the keto–enol equilibrium towards the enol (Table 3). The aldehydes investigated can be arranged in the following sequence in terms of increasing amounts of the enolic form:





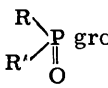


Table 3. The keto–enol equilibrium constants, free energies, π-bond energies, hydroxy-group frequency shifts, and the chemical shifts of the phosphorus nuclei of phosphorylated acetaldehydes[8]:

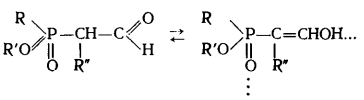
Table 3 shows that the keto–enol equilibrium constant, the basicity of the P=O group, and the charge on the phosphorus atom increase and the free energy and the π-bond energy decrease with increase of the positive inductive effect of the substituents and with decrease of the p_π–d_π conjugation of the phosphorus atom with the surrounding atoms. The experimental ΔF are satisfactorily correlated with Kabachnik's constants for the substituents[116] (Fig. 1), i.e. the keto–enol equilibrium constant is directly related to the basicity of the P=O group and thereby demonstrates unambiguously the role of the latter as the decisive factor in this equilibrium.

‡ pK_a was determined from the $\Delta\nu$(OH) shift in triethylamine.

It follows from the foregoing that the transmission of the influence of the  group takes place via a hydrogen-bonded complex and not via the system

Variation of ΔF with $\Sigma\sigma_{ph}$ after Kabachnik; the numbers of the points in the graph correspond to the numbers of the compound in Table 3.



Structures with intramolecular (*cis*-) and intermolecular (*trans*-) hydrogen bonds (structures B and C) are characteristic of the enolic forms of phosphorylated acetaldehydes. The study of the nature of the hydrogen bonds by infrared spectroscopy showed that the undiluted compounds have structures with both configurations (B and C). For all the aldehydes investigated and the substances with the isopropoxy-group, the intramolecular hydrogen bond is stronger and the equilibrium constant is higher than for ethoxy derivatives. These findings can probably be accounted for not only by the higher basicity of the P=O group in the former compounds but also by the steric effect of the isopropoxy-residue, which leads to the proximity of the P=O and OH groups in the *cis*-positions of the enolic form (which can be seen also from the Stuart–Briegleb models).

To elucidate the type of enolisation of aldehydes, a study was made of their behaviour both in solvents with different polarities and basicities and as a function of temperature. Interesting observations were made. In non-polar solvents (carbon tetrachloride, dioxan, and hexane; in the last solvent only the aldehydes with high molecular weights are soluble), the equilibrium is displaced towards the keto-form, i.e. in a direction opposite to that for β-dicarbonyl compounds and phosphorylated ketones. Examination of the concentration variation in carbon tetrachloride (0.5, 0.05, and 0.005 M solutions) indicated a stabilisation of the enolic forms mainly by intermolecular association. On the other hand, in solutions the intermolecular hydrogen bonds present in the undiluted compounds and in more concentrated solutions are ruptured. Hence the presence of only one keto-form in 0.005 M solutions (Table 3, compounds 3, 4, 7, 10, 15, and 16) and of an insignificant amount of the *cis*-enolic form in certain cases become understandable.

When aldehydes are dissolved in a highly basic solvent (triethylamine), the situation changes. Here the equilibrium is displaced in the opposite direction—towards the enol with formation of a chelated structure involving powerful hydrogen bonds.

The study of the temperature variation of the keto–enol equilibrium showed that a change in temperature has a significant influence on the relative amounts of the forms [115]. With increase of temperature from 11° to 100°C, there is initially a transition from the *trans*-enol to the keto-form. This shift of the equilibrium is accompanied by a decrease of the content of the *trans*-enolic form and takes place up to temperatures in the range 50–75°C depending on the nature of the substituent at the phosphorus atom. A further increase of temperature to 95–100°C causes a shift towards the *cis*-enolic form.

Table 4. Keto–enol equilibrium constants, enthalpies, and entropies of phosphorylated aldehydes [115]:

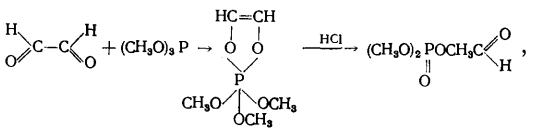
The study of the concentration and temperature variation of phosphorylated aldehydes containing an alkyl substituent in the methylene unit, $(C_2H_5O)_2P(O)CHRCHO$ ($R = CH_3$ or C_2H_5), showed that their enolisation has other characteristics (Table 4). Then, whereas in the undiluted state at 20°C they exist in the keto- and *trans*-enolic form (33 and 67% respectively for $R = CH_3$ and 25 and 75% respectively for $R = C_2H_5$), on dilution with carbon tetrachloride (0.05 and 0.005 M solutions) as well as on raising the temperature to 100°C, they are converted from the *trans*-enolic form into the keto-form alone (75 and 25% for $R = CH_3$ and 80 and 20% for $R = C_2H_5$).



Thus the study of the tautomerism of phosphorylated aldehydes has led to the discovery of definite characteristics in their behaviour, which distinguish them from β-dicarbonyl compounds. These are as follows: firstly, α-phosphorylated aldehydes unsubstituted in the methylene group are stable keto–enol systems whose keto–enol equilibrium may be investigated; secondly, phosphorylated aldehydes are some of the few open-chain compounds capable of both *cis*- and *trans*-enolisation.

ADDENDUM

To make the review complete, mention must be made of a number of studies published recently when the manuscript of the review was with the editors. In addition to studies on the interaction of phosphorus(III) acid esters with the acetals of halogenoaldehydes, considered at the beginning of the review, Reichel and Jahns [117] examined the interaction of triethyl phosphite with the acetal of α-bromopropionaldehyde followed by hydrolysis of the Arbuzov reaction product to α-phosphonopropionaldehyde. In a continuation of the study reported previously [63], Reichel and Jahns [117] carried out a detailed synthesis of an aldehyde with a phosphonium structure.

Continuing their earlier investigations [54,55], Gross and Costisella [118] obtained data for the reactivities of phosphonoformals.

In addition to the earlier study by Ramirez et al. [119], who described the synthesis of aldophosphates according to the scheme

Kraus and Stürtz [120] extended the range of α-aldophosphates obtained by the method described above [57].

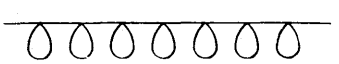
Cardopolymers (Loop Polymers)

S.V.Vinogradova and Ya.S.Vygodskii



Polymers containing bulky side groups linked in ring form to the main chain are distinguished by a specific set of properties (cardopolymers). The review deals with the characteristics of the synthesis and with the physicochemical properties of cardopolycarbonates, cardopolyarylates, cardopolyamides, cardopolyimides, cardopoly-1,3,4-oxadiazoles, carbonchain cardopolymers, etc. The bibliography includes 232 references.

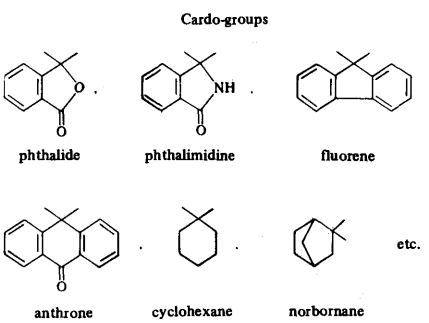
IV. Applications 565

I. INTRODUCTION

The set of physicochemical properties of polymers is in many ways determined by their chemical structure. Recently studies have been made in the field of polymers containing in the repeat units of the chain at least one element entering into the composition of a cyclic side group. It has been suggested[1] that such polymers be called cardopolymers from the latin word "cardo" (loop), since such groups can be regarded as loops in relation to the main chain of the macromolecule:

Naturally the properties of cardopolymers are influenced also by the structure of the main polymer chain. However, the presence in various types of heterochain and carbonchain polymers of cardo-groups imparts to them specific properties: a combination of enhanced heat resistance with excellent solubility, which is particularly important for rigid-chain aromatic heterocyclic polymers.



As early as the 1930's, Wagner[2] mentioned in his list of different initial compounds (diols) the possibility of employing phenolphthalein for the synthesis of polyesters. Data concerning the synthesis of resin-like products of complex composition from phenolphthalein were published in a number of reports[3-5].

A few of the early studies dealt with the products of the condensation of formaldehyde and phenolphthalein[6-10]. In 1946 a report was published on the synthesis of alkyd polymers of fluorescein and phenolphthalein[11] and two years later polymers were obtained by the polymerisation of diallylphenolphthalein dicarbonate[12]. Later data were published on the semiconductor properties of polymers prepared by heating phenolphthalein with $ZnCl_2$ at 256° and 306°C[13] and also on the epoxy-polymers based on phenolphthalein[14-18].

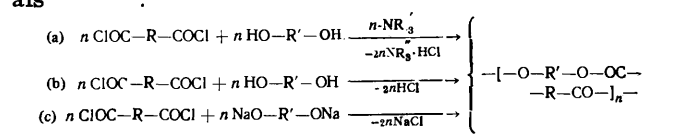
A characteristic feature of the above investigations is that phenolphthalein—the starting material for the synthesis of particular polymers—was used as a member of the enormous class of diols without taking into account its specific contribution to the properties of the polymer.

Systematic studies on cardopolymers as such probably began with the synthesis of high-molecular-weight polyarylates from phenolphthalein and various dicarboxylic acids in 1961 when, essentially for the first time, attention was turned to the specific contribution of the phthalide cardo-group to the formation of the set of properties of heterochain polymers[19,20].

So far numerous cardopolymers with ester, amide, imide, 1,3,4-oxadiazole, ether, etc. groups have been synthesised:

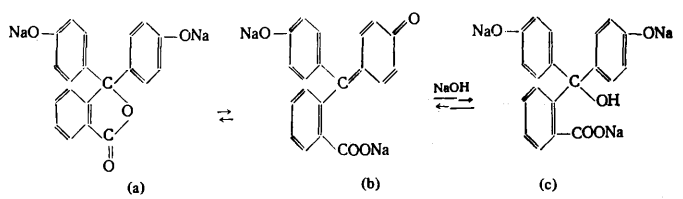
The introduction of cardo-groups into polyesters, polyethers, aromatic polyamides, heterocyclic polymers[21-25], and carbonchain polymers imparted to them many specific properties and made it possible to investigate characteristics which could not be estimated using polymers without such groups. In recent years the manufacture of first examples of cardopolymers (cardopolyarylates) has begun in the USSR on an experimental industrial scale.

Among the monomers with cardo-groups, perhaps only phenolphthalein [3,3-bis-(*p*-hydroxyphenyl)phthalide] is an industrial product employed in analytical chemistry and as a medicinal preparation. Other bi- or poly-functional compounds of the cardo-type have been studied much less, and frequently the information about them (before their employment in the synthesis of polymers) was restricted to one or two reports. Many cardomonomers were altogether unknown previously and were synthesised specially for the preparation of cardopolymers, for example 9,9-bis-(*p*-carboxyphenyl)-10-anthrone[26], the dianhydride of 3,3-bis-(3′,4′-dicarboxyphenyl)phthalide[27], and 2-(β-hydroxyethyl)-3,3-bis-(*p*-hydroxyphenyl)phthalimidine[28].



II. SYNTHESIS

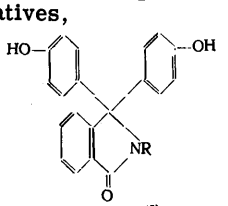
The usual methods for the formation of polymers of a particular type are used as a rule to synthesise cardopolymers. Therefore in the present review attention has been



concentrated on those characteristics of the synthesis which are due to the specific features of the structure and behaviour of cardomonomers and cardopolymers. In addition certain general characteristics of the synthesis of the polymers of various classes have been traced using cardopolymers as an example and phenomena useful for the understanding of the reaction mechanism have been discovered; these findings have also been reflected in the review.

1. Bisphenol Polyesters

Bisphenol polyesters are obtained nowadays with the aid of different types of non-equilibrium polycondensations such as (a) low-temperature (acceptor-catalytic) polycondensation, (b) high-temperature polycondensation in solution, and (c) interfacial polycondensation using dicarboxylic acid chlorides and bisphenols as the starting materials[2,25,29-32]:



All these methods are also applicable to the preparation of cardopolyarylates. In many cases, when these polymers are synthesised by interfacial polycondensation, account must be taken of the specific features of the behaviour of cardomonomers such as phenolphthalein in aqueous alkaline media. The structure of phenolphthalein in an aqueous alkaline solution is known to depend on the amount of alkali present:

The formation of polyarylates without quinonoid structures in the interfacial polycondensation of phenolphthalein and dicarboxylic acid chlorides shows that a rearrangement or a shift of equilibrium between forms (B) and (A) takes place during the reaction and leads to the retention of the lactone ring in phenolphthalein[25,33,34].

The phthalide structure is characteristic of the glycidyl ether of phenolphthalein[35], which is formed in an alkaline medium, and of aromatic phenolphthalein polyethers obtained by the nucleophilic substitution of activated halogen-containing aromatic compounds[36,37]. The existence of cardobisphenols such as fluorescein or phenolsulphophthalein in the form of a mixture of isomers (in the quinonoid and lactone forms) even in a neutral medium hinders the synthesis of high-molecular-weight polymers based on them.

The replacement of phthalide derivatives by phthalimidine derivatives,

(R=H; Ph, ETOH etc.).

(I)

which do not undergo changes in an alkaline medium associated with formation of a quinonoid structure, makes it possible to synthesise high-molecular-weight polyarylates by interfacial polycondensation under the usual conditions[38]. One should only note that in the interfacial polycondensation of 2-(β-hydroxyethyl)-3,3-bis-(*p*-hydroxyphenyl)phthalimidine and isophthalic or terephthalic acid chlorides[39] in the presence of more than two moles of alkali, not only the phenolic but also the alcoholic hydroxyl is acylated, which leads to the formation of a cross-linked polymer.

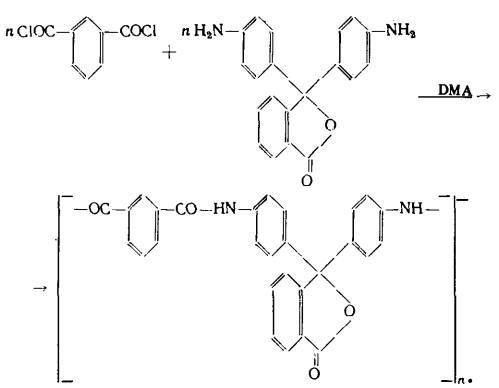
Cardopolyarylates are usually synthesised by acceptor-catalytic polycondensation whereby it is possible to obtain high-molecular-weight polymers under mild conditions in a short time[25,39,40,41]. Much attention has been devoted to the study of the mechanism and characteristics of this process[31,32,40-47]. In contrast to interfacial polycondensation, where the behaviour of phenolphthalein is unusual, in acceptor-catalytic polycondensation in anhydrous solvents the structure of phenolphthalein does not change even in the presence of highly basic tertiary amines.

The greatest number of cardopolyarylates have been synthesised by the high-temperature polycondensation of dicarboxylic acid chlorides and bisphenols in organic solvents. The kinetics of this reaction have been investigated for the interaction of terephthalic acid chloride and 9,9-bis-(*p*-hydroxyphenyl)fluorene and other polycyclic bisphenols, which led to the suggestion of an ionic mechanism for this reaction, including the formation of an acylium ion[48,49]. Cardopolyarylates are synthesised in ditolylmethane[19,20], sovol[50-56] (a mixture of tetra- and pentachlorobiphenyls), α-chloronaphthalene[56], *o*-dichlorobenzene[57], 1,2,4-trichlorobenzene[57], nitrobenzene[57], etc. at a concentration of the starting materials in the range 0.6–5.0 M in the temperature range 180–220°C for several hours and in many cases also at higher temperatures (see below).

It is noteworthy that, whereas in the polycondensation of phenolphthalein and aromatic dicarboxylic acid chlorides in ditolylmethane the polyarylate precipitates from the reaction medium during its formation in the form of a thick sparingly soluble mass, in the synthesis of polyarylates in a medium which dissolves the polymer unfolded rigid macromolecular conformations are produced preferentially which results in the formation of fibrous structures, while the polymer synthesised in ditolylmethane is made up of not altogether regular globular ~ 1000 Å particles, which in turn consist of still smaller also nearly spherical 30–40 Å particles[57].

Thus in the synthesis of polymers with rigid macromolecular chains, it is necessary to make a correct choice of the reaction medium bearing in mind its influence on the selection of particular macromolecular conformations during the synthesis.

In the synthesis of crystallisable cardopolyarylates[59,60], particularly the polyarylate produced from 9,9-bis-(*p*-hydroxyphenyl)-10-anthrone and terephthalic acid, the process conditions affect not only the molecular weight but also the structure of the polymer. It is most crystalline when the polycondensation is carried out at 220°C in Sovol, 1,2,4-trichlorobenzene, and similar solvents; the polymer is obtained in amorphous form on rapid heating of a 0.6 M solution of the starting materials in Sovol at 330°C, the solution being kept at this temperature for 1 h with subsequent rapid cooling of the reaction mass to room temperature[60].



High-molecular-weight thermoreactive mixed polyarylates based on phenolphthalein, aromatic dicarboxylic acid chlorides, trihydric alcohols (for example trishydroxymethylpropane), the chlorides of unsaturated dicarboxylic

acids, for example fumaric acid, or 2,2-di-(3-allyl-4-hydroxyphenyl)propane[61,62] have been synthesised.

2. Aromatic Polyamides

The low basicity of aromatic diamines, including cardodiamines, and the high softening temperatures of cardopolyamides rule out the possibility of their successful formation by polycondensation in the melt. The method of interfacial polycondensation is also relatively unsuitable owing to the low solubility of cardodiamines and even their hydrochlorides in water. Cardopolyamides have been obtained by interfacial polycondensation only on the basis of 3,3-bis-(*p*-carboxyphenyl)phthalide and aliphatic diamines[63,64].

Cardopolyamides are usually synthesised by the low-temperature polycondensation of dicarboxylic acid chlorides and primary diamines in aprotic dipolar solvents, for example *NN*-dimethylacetamide (DMA) and *N*-methylpyrrolidinone (NMP) which function both as solvents for the starting materials and the polymers and as acceptors for the hydrogen chloride liberated[63-67], for example:

Polymers with the highest molecular weight are obtained by adding the solid acid chloride to a solution of the diamine between −10° and −30°C and stirring the reaction mixture at this temperature for 15–60 min. Although the high solubility of cardoamides makes it unnecessary to introduce into the reaction medium inorganic salts (LiCl), which are often used in the synthesis of other aromatic polyamides and when they are extruded as fibres from solutions.

3. Polyimides

Cardopolypyromellitimides obtained from anilinephthalein [3,3-bis-(*p*-aminophenyl)phthalide] and its imide were the first soluble examples of these extremely heat-resistant polymers[68,69]. Like other polyimides, they are synthesised by two-stage polycondensation with thermal cyclodehydration of the high-molecular-weight polyaminoacid obtained beforehand[68,69]. In the synthesis of cardopolyimides, it was shown that the heat treatment of polyaminoacids entails, together with intramolecular cyclisation, also solid-phase polycyclisation involving the terminal anhydride and amino-groups, leading to an increase of the molecular weight of the polyimide[70].

Single-stage high-temperature polycyclisation in an organic solvent (nitrobenzene, benzonitrile, α-chloronaphthalene, sulpholane, cresol, etc.) has been used successfully to synthesise high-molecular-weight soluble cardopolyimides[71-74]. The difference of this method from the two-stage version is that in the single-stage polycyclisation the growth of the polymer chain (the polymerisation reaction proper) takes place simultaneously with ring closure. This has been demonstrated both by kinetic studies (the rate of reaction is limited by the formation of the amidoacid and not by its cyclodehydration[75,76]) and by the discovery that the molecular weight of the polyimide increases slowly and gradually with duration of the reaction[73,74]. It has been shown for the reaction of anilinephthalein with pyromellitic anhydride and also of anilinephthalein and 9,9-bis-(*p*-aminophenyl)fluorene with the dianhydride of di-(3,4-dicarboxyphenyl) ether in nitrobenzene at 180°C that the rate of reaction is more sensitive to the change in the nature of the tetracarboxylic acid dianhydride than in the diamine[75,76].

It is noteworthy that single-stage high-temperature polycyclisation is applicable also to the synthesis of other high-molecular-weight soluble or insoluble and fusible or infusible polyimides[77,78].

The formation of polyimides from tetracarboxylic dianhydrides and primary diamines is a reversible reaction[72,73,76]. Therefore, in order to obtain high-molecular-weight polyimides, it is necessary to remove from the reaction medium as far as possible the water formed on cyclisation, which is achieved in high-temperature cyclisation by raising the reaction temperature and by carrying out the process in a stream of an inert gas, by binding the water with chemical agents (acid anhydrides and chlorides, carbodi-imides, etc.), and by employing a vacuum in the two-stage process.

High-molecular-weight cardopolyimides are also obtained by the cyclisation in solution of high-molecular-weight polyamidoacids in the presence of a mixture of carboxylic acid anhydrides and tertiary amines at 20–100°C without the intermediate formation of the final moulded objects from the polyamidoacids[79].

Cardopolyimides have also been successfully synthesised[80,81] by two-stage polycyclisation of the dichlorides of tetracarboxylic acid diesters and primary diamines. Cyclisation of the intermediates (polyamidoesters) which are much more resistant to hydrolysis than polyamidoacids, leads to the formation of carbopolyimides with higher molecular weight than those obtained by the cyclodehydration of the corresponding polyamidoacids, best results being obtained by the cyclisation of polyamidoesters in nitrobenzene at 210°C or by treatment in solution in amide-type solvents with a mixture of acetic anhydride and pyridine. The cyclisation of polyamidoesters is also a reversible process[80] since polyimides readily undergo methanolysis.

The study of the kinetics of the solid-phase polycyclisation of cardopolyamidoesters in films showed that the process follows first-order kinetics in the initial stage, the rate of cyclisation increasing with the basicity of the diamine used to prepare the polyamidoester ($k_c = 7.10 \times 10^{-2}$ and 3.10×10^{-2} min^{-1} at 200°C for the polypyromellitamidoesters derived from 9,9-bis-(*p*-aminophenyl)fluorene and anilinephthalein respectively[82]).

4. Poly-1,3,4-oxadiazoles

Cardopoly-1,3,4-oxadiazoles have been synthesised using 3,3-bis-(*p*-carboxyphenyl)phthalide and its derivatives (the dichloride and the dihydrazide) as the starting materials[83-86]. Two methods were chosen for its synthesis and investigated: a two-stage method designed to

prepare high-molecular-weight polyhydrazides with subsequent cyclodehydration and single-stage polycyclisation in polyphosphoric acid (PPA).

The characteristics of the low-temperature polycondensation of the dihydrazide and the dichloride of 3,3-bis-(*p*-carboxyphenyl)phthalide and also of either of these compounds coupled with the corresponding derivatives of other dicarboxylic acids are similar to those of the formation of other polyhydrazides with the sole difference that the high solubility of cardopolyhydrazides makes it possible to carry out the reaction not only in hexamethylphosphoramide but also in solvents such as NMP and DMA. It is also noteworthy that in the synthesis of mixed polyhydrazides the reaction takes place more successfully when one of the initial dihydrazides is that of 3,3-bis-(*p*-carboxyphenyl)phthalide coupled with the chloride of another acid. This is probably due to the higher solubility of the dihydrazide compared with the dihydrazides of many other aromatic dicarboxylic acids, the higher rate of the main process, and the consequent decrease of the contribution by side reactions.

Apart from the thermal cyclisation of polyhydrazides, which requires extremely high temperatures, the chemical cyclisation method for the conversion of cardopolyhydrazides into poly-1,3,4-oxadiazoles has become possible and has proved extremely effective. It consists in the treatment of the polyhydrazide in solution at 100°C for 5 h with the dimethylformamide (DMF)–sulphur trioxide complex[86]. The resulting polymer is identical in structure to the poly-1,3,4-oxadiazole obtained by the thermal cyclodehydration of the polyhydrazide at 300°C for 35 h in a vacuum of 10^{-3} mmHg.

A particularly successful method of synthesising solid cardopoly-1,3,4-oxadiazoles is single-stage polycyclisation in PPA at 140–150°C for 5 h.[86] An unusual feature of the synthesis of cardopoly-1,3,4-oxadiazoles in PPA consists in the fact that soluble linear polymers are formed only when equimolar amounts of 3,3-bis-(*p*-carboxyphenyl)phthalide and its dihydrazide interact. This is because in the reactions according to other generally adopted schemes, based on the acid and hydrazinium sulphate or the acid dihydrazide alone, there are side reactions between the lactone ring and hydrazine or the dihydrazide[86]. The molecular weight of the polymer depends on the concentration of phosphorus pentoxide in PPA, increasing markedly with the latter, starting from about 82%.

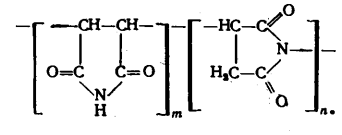
The study of the formation of poly-1,3,4-oxadiazoles also shows that the method of synthesis affects the structure of the polymer[87]. Thus, in contrast to the insoluble crystalline poly(1,3,4-oxadiazole-2,5-diyl-1,4-phenyleneoxy-1,4-phenylene) obtained by the thermal cyclisation of the corresponding polyhydrazide, in the single-stage polycyclisation in PPA the product is an amorphous polymer soluble in a *sym*-tetrachloroethane–phenol mixture (3 : 1, w/w).[87]

5. Other Polymers

Aromatic cardopolyethers derived from phenolphthalein, obtained by the nucleophilic substitution of activated aromatic dihalogeno-compounds and alkali metal bisphenoxides in dimethyl sulphoxide (DMSO)[36], were already mentioned above. The formation of polyethers from cardobisphenols (phenolphthalein, 9,9-bis-(*p*-hydroxyphenyl)fluorene proceeds less vigorously than the reaction with bisphenols such as 2,2-di-(*p*-hydroxyphenyl)propane, which may be due both to the reduced reactivity of the former owing to the high acidity of cardobisphenols and to the heterogeneity of the reaction medium owing to the low solubility of such alkali metal bisphenoxides. High-molecular-weight polyethers based on cardobisphenols have been obtained using as the initial dihalogeno-compound di-(*p*-fluorophenyl) sulphone and 4,4′-difluorobenzophenone, which are more reactive than their chlorinated analogues, and at higher temperatures (170–185°C) than other polyethers[36].

Despite the opening of the lactone ring of phenolphthalein in alkaline media (see above), aromatic polyethers based on it are soluble, have high molecular weights, and their lactone rings remain unaffected, which rules out the possibility of reaction between the dihalogeno-compound and the carboxy anion of the open-chain form of phenolphthalein [(B) and (C), see p.552]. Owing to the reactivity of the NH-group of the lactim ring of 3,3-bis-(*p*-hydroxyphenyl)phthalimidine in the formation of the polyester from it and di-(4-fluorophenyl) sulphone, the NH group is also involved in the reaction, which results in the formation of an insoluble and probably structured polymer.

The preparation of soluble and fusible aromatic homo- and mixed cardopolyanhydrides from 3,3-bis-(*p*-carboxyphenyl)phthalide by low-temperature polycondensation in solution has been described[88]. The chloride of 3,3-bis-(*p*-carboxyphenyl)phthalide or a mixture of this chloride with 3,3-bis-(*p*-carboxyphenyl)phthalide are employed for the synthesis of homopolyanhydrides. In the first case, the polycondensation is achieved in the presence of water.



Cardobisphenols [phenolphthalein, fluoroscein, *o*-cresolphthalein, 1,1-bis-(*p*-hydroxyphenyl)cyclohexane, etc.] have been used successfully to synthesise thermoreactive polymers of the phenol-formaldehyde type[89–92]. Owing to the insolubility of such bisphenols in water, the polymers were formed in solvents such as DMF and n-propyl alcohol[89] in the presence of aqueous ammonia as a catalyst. The polymers become infusible and insoluble on heating at 160–180°C.

Many high-molecular-weight (with M_W up to 100 000 and above) carbon chain cardopolymers have also been synthesised: polymethylenephthalide, polymethylenephthalimidine, polyacenaphthene, etc.[92–98] They are synthesised by the usual polymerisation methods: the high melting point of the monomers hinders polymerisation in bulk, since such polymerisation requires the initial fusion of the monomer.

It has been shown that the resistance of methylenephthalimidines to polymerisation is lower than that of methylenephthalide, which is probably due to the greater steric hindrance in the former monomer.

An unusual monomer of the cardo-type is maleic anhydride the capacity of which for homopolymerisation was clearly demonstrated as late as 1961–1963.[99–103] It was established that maleic anhydride polymerises via a radical mechanism under the influence of γ-radiation or in the presence of a high sensitiser concentration (for example 5% benzoyl peroxide).

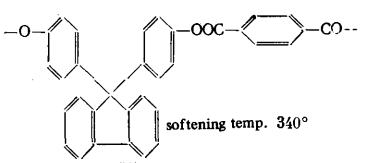
Maleimide, the nitrogen analogue of maleic anhydride, polymerises via radical and ionic mechanisms[104,105], the ionic polymerisation proceeding partly with migration of hydrogen atoms and the formation of a polymer with the following structure[105]:

III. PROPERTIES

We shall consider initially the effect of the chemical structure of the polymer on its heat resistance and solubility. The joint examination of such seemingly different properties is not fortuitous, since the effect of cardo-groups has the greatest influence precisely on these polymer characteristics.

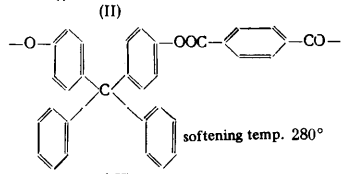
One of the ways of obtaining heat resistant polymers is the synthesis of rigid-chain macromolecules with large segments, which leads to high glass temperatures. In many cases the glass temperature of rigid-chain polymers may be above the temperature of the onset of their vigorous decomposition and the latter then determines the temperature range in which the polymer may be used.

Thus there is a serious contradiction between the attempt to create the most heat resistant polymer and the possibility of moulding it into finished articles: the higher the heat resistance of the polymer the more difficult it is to mould its melt by the usual methods. One of the ways of overcoming this difficulty involves the formation of articles from highly heat-resistant polymers in solution, which requires the creation of polymers combining a high rigidity of its component macromolecules and a high solubility†.



The introduction of various rings into the main macromolecular chain, the enhancement of the intermolecular interaction owing to polar groups and hydrogen bonds, the introduction of cyclic side groups, the crystallisation of the polymer, an increase in the degree of order in the supermolecular structure, the employment of starting compounds with a symmetrical structure (for example the replacement of isophthalic acid by terephthalic acid), the formation of chemical cross-links between linear macromolecules, a regular distribution of chain units, conversion into stereoregular polymers, etc. lead to an increase of the heat resistance of linear polymers.

Solubility is improved mainly by the conversion of the polymer into an amorphous form, an increase of the rigidity of the macromolecular chain, the introduction of polar groups with an affinity for the solvent (i.e. leading to a positive heat of mixing), the introduction of various substituents "loosening" the polymer structure, the introduction of cyclic side groups containing polar groups with an affinity for the solvent, the breakdown in the order of alternation of chain units and the introduction of units of different kinds, etc. In many cases one of these factors is insufficient for a significant improvement of the solubility—a combination of various factors is necessary.



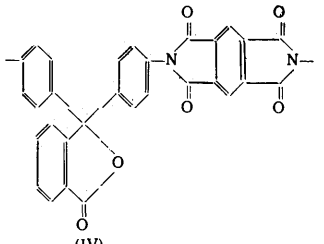
Comparison of the factors leading to an improvement of heat resistance and of solubility shows that some of these improve one property and impair the other (for example a decrease of rigidity improves solubility but lowers heat resistance, etc.) It would be most interesting to achieve a simultaneous increase of the heat resistance of polymers and of their solubility. This can be done by introducing cyclic side groups into the macromolecule. An appreciable effect is obtained when cardo-groups are introduced.

† Therefore infusible and insoluble, as a rule heterocyclic, polymers are moulded mainly at an intermediate stage of their synthesis—the soluble pre-polymers (polyamidoacids, polyhydrazides, etc.)—which has its disadvantages relating to the removal of water and the solvent, which impairs the integrity of the finished article, and a number of other unfavourable complications[72,106].

The superior heat resistance of the polyterephthalate of 9,9-bis-(*p*-hydroxyphenyl)fluorene (II) compared with the polyterephthalate of 4,4′-dihydroxytetraphenylmethane (III) is instructive in this sense:

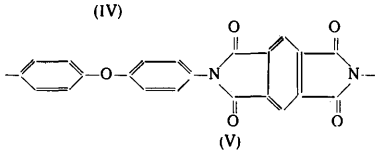
(II)

(III)



As already stated, one of the ways of increasing heat resistance is crystallisation of the polymer. Since many cardopolymers have an amorphous structure, it has come to be believed that the increase of the rigidity of the polymer chain as a result of the introduction of cardo-groups and crystallisation are largely mutually exclusive factors, since crystallisation requires the presence of chains with a symmetrical structure and a powerful interaction between the chains, while bulky substituents, such as cardo-groups in particular, hinder it[106]. That this is a mistaken view was demonstrated subsequently by the synthesis of crystallisable polyarylates derived from 9,9-bis-(*p*-hydroxyphenyl)-10-anthrone, the structure of which may be varied both by the conditions of synthesis and by the conditions in the subsequent treatment of the polymer[59,60]. Other cardopolymers in different structural forms can also be obtained, for example polyarylates derived from 9,9-bis-(*p*-hydroxyphenyl)fluorene and 1,1-bis-(*p*-hydroxyphenyl)-cyclohexane[107]. These factors, in conjunction with the finding that polyarylates from phenolphthalein as well as other cardopolyheteroarylenes containing phthalide groups are amorphous non-crystallisable polymers lead to the hypothesis, based on the asymmetric structure of the phthalide group, that the structure of such polymers resembles that of atactic polymers. Like atactic polymers, cardopolymers with phthalide groups in the chain contain an asymmetric substituent distributed at random.

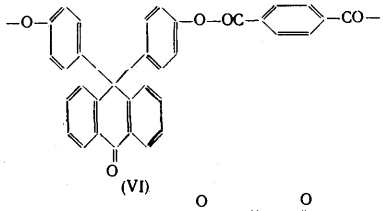
Presumably under certain conditions it is possible to achieve a stereoregular distribution of the phthalide groups and the formation of a crystalline polymer is then possible.



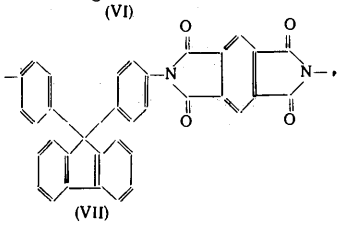
The crystallinity of cardopolymers and others must be taken into account when their properties are compared, since it affects[107] the heat resistance and the thermal stability of the polymers, their solubility, etc. Therefore, in order to compare polymers with different chemical structures, it is best to employ data for amorphous polymers.

As already stated, cardo-groups increase the rigidity of the main chain and loosen the polymer, which improves the solubility. The solubilisation of rigid-chain polymers such as polypyromellitimides due to cardo-groups appears particularly striking. Thus the polypyromellitimide derived from anilinephthalein (IV), which has a glass temperature of 485°C, is readily soluble in DMF, DMA, nitrobenzene, *sym*-tetrachloroethane, cresol, hexafluoroacetone sesquihydrate, etc., in contrast to the familiar

polyoxydiphenylenepyromellitimide (V), which is insoluble in known organic solvents:



(IV)



(V)

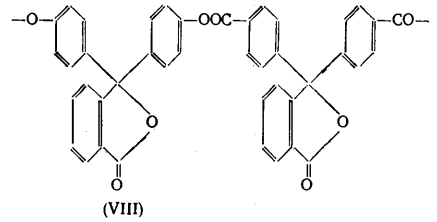
The solubility of cardopolymers with polar groups is much higher than that of polymers with less polar cardo-groups while their heat resistance is approximately the same. Thus the 9,9-bis-(*p*-hydroxyphenyl)-10-anthrone polyarylate (VI) are more soluble than the 9,9-bis-(*p*-hydroxyphenyl)-fluorene polyarylate (II) despite their higher tendency towards crystallisation while the polypyromellitimide derived 9,9-bis-(*p*-aminophenyl)fluorene (VII) does not dissolve in any of the known organic solvents in contrast to the polyimide (IV):

(VI)

(VII)

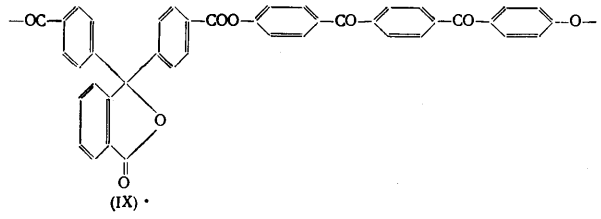
1. Polycarbonates

The properties of cardopolycarbonates derived from bisphenols and based on 2-norbornanone and analogous ketones, cyclohexanone, etc. have been investigated in greatest detail[108-114]. Such polycarbonates have an amorphous structure and dissolve in chlorinated and saturated aliphatic hydrocarbons: CH_2Cl_2, $CHCl_3$, 1,2-dichloroethane, aromatic hydrocarbons (benzene and toluene), cyclohexanone, and dioxan; they swell in aliphatic ketones. Their enhanced solubility is probably associated with the large size of the non-planar cardo-group, which leads to an appreciable loosening of the polymer. At the same time, the presence of cardo-groups leads to an increase of the heat resistance of the polymers and it is interesting that the glass temperature increases with the dimensions of the cardo-group of the norbornane type. The high glass temperatures of such polycarbonates are due to the fact that the non-coplanar groups of the norbornane type, which are very bulky in various directions, cannot be oriented in any particular direction and therefore cannot "migrate" in the small space between the molecular chains to the same extent as, for example, alkyl or phenyl groups[108].



Polycarbonates derived from phenolphthalein and its derivatives show an even higher heat resistance while retaining a high solubility. The somewhat greater range of solvents for the polycarbonate from phenolphthalein compared with the polycarbonate from 3,3-bis-(*p*-hydroxyphenyl)phthalimidine is striking; this is probably due to intermolecular hydrogen bonds in the second polymer. At the same time it dissolves in chloroform, while the corresponding polyterephthalate is insoluble in chlorinated solvents owing to hydrogen bonding[115].

2. Polyarylates

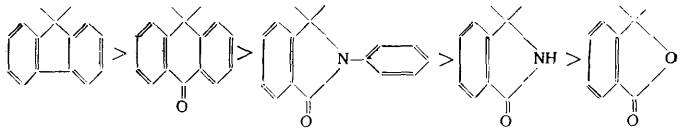


As already stated, the characteristics of cardopolymers were discovered for the first time for polyarylates; it is therefore natural that their properties have been investigated in greatest detail, which in turn required the synthesis of a wide variety of examples of this class of polymers differing in the nature of the cardo-group and other moieties of the macromolecule. They include polyarylates derived from phenolphthalein[19,20,34,54,116-127], 4,5,6,7-tetrachlorophenolphthalein[128], 3,3-bis-(*p*-hydroxyphenyl)phthalimidine[34,129-131], 3,3-bis-(*p*-hydroxyphenyl)-2-phenylphthalimidine[37,52,53,132], 2-ethyl-3,3-bis-(*p*-hydroxyphenyl)-phthalimidine[133], 2-(β-chloroethyl)-3,3-bis-(*p*-hydroxyphenyl)phthalimidine[134], phenolsulphophthalein[135], 9,9-bis-(*p*-hydroxyphenyl)fluorene[113,136-139], 9,9-bis-(*p*-hydroxyphenyl)-10-anthrone[59,95,113,114,132], and many other cardobisphenols and dicarboxylic acids[56,140-149].

The main characteristic feature of these polymers is heat resistance, greatly exceeding the heat resistance of polyarylates which have a similar structure but do not contain cardo-groups. The polyarylates devised from 9,9-bis-(*p*-hydroxyphenyl)fluorene and 4,4'-dihydroxytetraphenylmethane were already compared above in this sense.

Another clear example is provided by the much higher heat resistance of polyarylate (VIII) (softening temperature 340°C)[150] compared with the isomeric polyarylate (IX) (270°C)[142]:

(VIII)



(IX)

The influence of the cardo-group on the softening temperature is shown particularly clearly in polyarylates synthesised from aliphatic dicarboxylic acids. Thus the softening temperatures of polyarylates from phenolphthalein

and 2,2-di-(*p*-hydroxyphenyl)propane on the one hand and sebacic acid on the other are 100° and 36°C respectively.

Estimation of the "intrinsic" contribution of various cardo-groups to a heat resistance of polyarylates showed that they can be arranged in the following series in terms of the decrease of their contribution[114]:

K_i/M 1.58 1.56 1.55 1.43 1.40

where K_i/M is the ratio of the "reduced" volume of the ring to its molecular weight[151]. Above it was stated that, depending on the nature of the solvent in which the polyarylates are synthesised, coiled or uncoiled conformations are produced, which entails the formation of globular (synthesis in a non-solvent medium) or fibrous (synthesis in a medium dissolving the polymer) forms of supermolecular structures respectively[50,51,57,152]. The supermolecular structure of polyarylates has a significant influence on the entire set of their physical properties. Table 1 shows that, for identical molecular weights, the specific impact strength of a polyarylate synthesised in "good" solvents (Sovol, α-chloronaphthalene, nitrobenzene) is higher by a factor of 4–10 than that of the same polyarylate synthesised in ditolylmethane. The elongation on rupture also increases severalfold.

Table 1. Properties of the polyarylates synthesised from phenolphthalein and isophthalic acid by high-temperature polycondensation in various media[51].

Property	Medium used in synthesis				
	ditolylmethane	Sovol	α-chloronaphthalene		nitrobenzene
Structure	globular	← fibrous →			
Molecular weight M_w	28000	33000	28000	48000	26000
Softening temperature, °C*	270	280	290	300	275
Tensile strength (film), kgf cm^{-2}	640	640	740	780	650
Elongation on rupture (film), %	10—20	85	80	100	40—70
Specific impact strength (monolithic specimen), kgf cm^{-2}	2—3	11	10	20	14

* The temperature at which the strain in the monolithic specimen relaxes to zero was adopted[150].

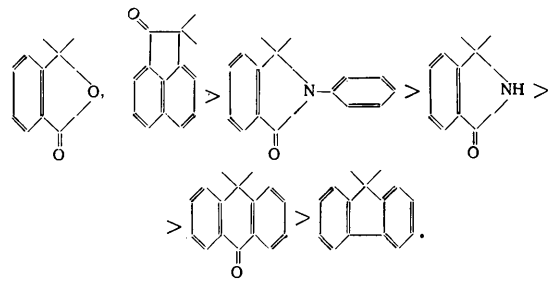
The more satisfactory physicomechanical parameters of the fibrous polyarylate obtained from 3,3-bis-(*p*-hydroxyphenyl)-2-phenylphthalimidine by high-temperature polycondensation in a medium dissolving the polymer compared with the corresponding polyarylate having a globular supermolecular structure and obtained by interfacial polycondensation (Table 2) suggests that high-temperature polycondensation is perhaps a more successful method of synthesising polyarylates[51].

Although the majority of cardopolyarylates are amorphous, many of them have a distinct tendency to become ordered. Among the latter, the polyarylate obtained from 9,9-bis-(*p*-hydroxyphenyl)-10-anthrone and terephthalic acid, which can be synthesised with a high degree of crystallinity[60], is outstanding. The structure and hence the properties of this polymer can be regulated both by varying the conditions of synthesis and by appropriate treatment of the finished polymer. The polymer is obtained in the most crystalline form on polycondensation at 220°C in solvents such as Sovol, 1,2,4-trichlorobenzene, nitrobenzene, and α-chloronaphthalene.

Table 2. Properties of the polyarylates synthesised from 3,3-bis-(*p*-hydroxyphenyl)-2-phenylphthalimidine and terephthalic acid[51].

Property	Method of synthesis	
	interfacial	high-temperature, in solution
Softening temperature, °C	280–285	315–320
Tensile strength (film), kgf cm^{-2}	960	1000
Elongation on rupture (film), %	13	40–50
Specific impact strength (monolithic specimen), kgf cm^{-2}	1	7–9

By successive treatment of such a polymer by various solvents, it is possible to crystallise the amorphous polyarylate and conversely to obtain the amorphous polymer from a crystalline specimen. For example, when amorphous polyarylate is treated with chloroform in a swollen state, it crystallises, while reprecipitation of crystalline polyarylate with the same chemical structure from solution in a 3 : 1 (by weight) tetrachloroethane (TCE)–phenol mixture results in the formation of an amorphous polymer[107]. The crystalline polyarylate does not soften up to the onset of its decomposition and dissolves only in a 3 : 1 (by weight) tetrachloroethane–phenol mixture, while in the amorphous form it softens at 325–365°C and dissolves readily in various organic solvents[107,118]. Polyarylates obtained from 9,9-bis-(*p*-hydroxyphenyl)fluorene also show a tendency to crystallise, albeit to a smaller extent[107,118].



The crystallisability of cardopolyarylates depends not only on the nature of the cardo-group but also on the component in which it is introduced into the macromolecule. Thus the polyarylate obtained from hydroquinone and 9,9-bis-(*p*-carboxyphenyl)-10-anthrone, which is isomeric with the polyarylate 9,9-bis-(*p*-hydroxyphenyl)-10-anthrone and terephthalic acid, has an amorphous structure, in contrast to the latter[132]. Cardopolyarylates derived from phenolphthalein have a certain degree of order only when an acid with a cardo-group in the molecule is employed as the initial component[119], for example polyarylate (VIII), which may be due to the fact that, while the phthalide group itself is asymmetric, the macromolecule as a whole becomes more symmetrical.

Certain cardopolyarylates derived from 3,3-bis-(*p*-hydroxyphenyl)phthalimidine and 2-(β-hydroxyethyl)-3,3-bis-(*p*-hydroxyphenyl)phthalimidine also show some tendency towards becoming ordered, which may be consequence of hydrogen bonds influencing also the solubility of such polymers[129–131].

The presence in the polymer chain of cardo-groups results in a high solubility of such polyarylates in many organic solvents. Polyarylates from phenolphthalein and aromatic dicarboxylic acids are soluble in methylene chloride, chloroform, 1,2-dichloroethane, *sym*-tetrachloroethane, tetrahydrofuran (THF), cyclohexanone, DMF, and others with formation of highly concentrated solutions

(> 25%).[19,20] The increase of solubility as a result of the introduction of cardo-groups (for example the phthalide group) is also achieved when they are present at a very low concentration in the macromolecules of copolymers. For example, the mixed polyarylate obtained from terephthalic acid, phenolphthalein, and 2,2-di-(*p*-hydroxyphenyl)propane (in molar proportions of 1.0 : 0.15 : 0.85) is readily soluble in chloroform[20]. An analogous enhancement of solubility is achieved by the introduction of the phthalide group into the polymer chain as part of the acid component[56,119].

Comparison of the contributions of various cardo-groups to the increase of the solubility of polyarylates suggests that they can be arranged in the following sequence:

The highest solubility of polymers with phthalide and phthalimidine groups is probably due to the greater dimensions, polarity, and asymmetry of the structure of such groups. The somewhat lower solubility of polyarylates containing fluorene and anthrone cardo-groups is probably due to their greater symmetry, which leads to the crystallisation of such polymers.

The solubility of polymers containing phthalimidine cardo-groups is due to the presence or absence of mobile hydrogen atoms. Thus polyarylates from 3,3-bis-(*p*-hydroxyphenyl)phthalimidine or 2-(β-hydroxyethyl)-3,3-bis-(*p*-hydroxyphenyl)phthalimidine dissolve only in solvents which rupture intermolecular hydrogen bonds[39,129-131], while polyarylates from 3,3-bis-(*p*-hydroxyphenyl)-2-phenylphthalimidine in which the mobile hydrogen atom is replaced by the phenyl group, dissolve even in chloroform and methylene chloride[38,52,53].

The solubility of cardopolyarylates makes it possible to determine their molecular weight and to establish the relation between the intrinsic viscosity of their solutions and the molecular weight (Table 3). The properties of solutions of cardopolyarylates have been described in dissertations and in a monograph[152-155]. The method of synthesis affects not only the physicochemical properties of polyarylates but also their molecular-weight characteristics (Table 3).

The study of thermal and thermo-oxidative degradation of polyarylates showed[162-172] that, according to dynamic thermogravimetric (TG) data (in an atmosphere of helium at a heating rate of 5 deg min^{-1}), the onset of the decrease of the weight of various polyterephthalates occurs at 350–360°C and their vigorous decomposition takes place at 460–470°C.[172] The polyarylate obtained from terephthalic acid and 9,9-bis-(*p*-hydroxyphenyl)fluorene begins to decompose at a temperature higher by 10–15 deg than the other polymers. Cardopolyarylates differ from one another mainly in the amount of carbon residue at 900°C. Polyarylates from 9,9-bis-(*p*-hydroxyphenyl)-10-anthrone, 9,9-bis-(*p*-hydroxyphenyl)fluorene, and 2,2-bis-(*p*-hydroxyphenyl)-1-acenaphthenone, in which there are two aromatic rings in the cardo-group, decompose in an inert atmosphere to the extent of 43–44% regardless of the presence of absence of a carbonyl group, while the polyterephthalate synthesised from phenolphthalein loses 50% of its weight.

The study of the ageing processes of polyarylates for low degrees of conversion (250–350°C) showed that structure-formation processes predominate on heat treatment alone and on thermo-oxidation[166,168,170]. Degradation of the polymers takes place at 300–350°C together with structure formation, as shown by the splitting of the maximum on the molecular-weight distribution curve[166-168]. At higher temperatures (350–500°C), more far-reaching changes take place, accompanied by the formation of solid and gaseous low-molecular-weight products and of a solid carbonised residue[165-170].

The resistance of cardopolyarylate based on phenolphthalein and 9,9-bis-(*p*-hydroxyphenyl)fluorene to the action of ionising and ultraviolet radiation in films and solutions has been studied[121,173-176].

3. Aromatic Polyamides

Another type of cardopolymers which exhibit all the specific features are aromatic polyamides (Table 4). In contrast to many aromatic polyamides, cardopolyamides have an amorphous structure. A tendency has been noted towards the ordering of polyamides derived from 9,9-bis-(*p*-aminophenyl)fluorene and terephthalic acid (when the solution of the polymer in DMF is allowed to stand) and from 9,9-bis-(*p*-aminophenyl)fluorene and isophthalic acid (when its solution in cyclohexanone is allowed to stand). Despite their amorphous structure, the heat resistance of cardopolyamides is much higher than that of other polyamides. Thus the polyamide from 9,9-bis-(*p*-aminophenyl)fluorene and isophthalic acid softens at 385°C,[65] while the widely familiar poly-*m*-phenyleneisophthalamide has a glass temperature of 270°C. The softening temperature of the cardopolyamide is always higher than that of the corresponding cardopolyarylate[186].

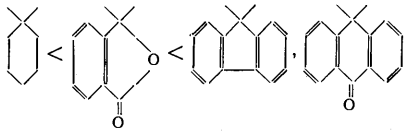
f. In *N*-methylpyrrolidinone.
g. In sulphuric acid.

The activation energy for the relaxation process in polyamides is always higher than in the analogous polyarylates[178] (Table 5). This suggests that the rearrangement processes in polyamide superstructures and their elements are more difficult than in polyarylates. It has been suggested[186] that this is mainly due to the presence of hydrogen bonds between the polyamide macromolecules and to some extent also to a change in the mobility of the elements of the macromolecule caused by the replacement of the ester linkage by the amide linkage.



In contrast to the majority of aromatic polyamides, which are sparingly soluble in organic solvents and are mainly soluble in solutions of inorganic salts in amide

solvents, cardopolyamides are highly soluble in various amide solvents, DMSO, and cresol with formation of highly concentrated solutions (25–35%).[177] The somewhat lower solubility of polyamides with fluorene cardo-groups compared with polyamides from 9,9-bis-(*p*-aminophenyl)-10-anthrone is shown by the fact that the polyterephthalamide derived from 9,9-bis-(*p*-aminophenyl)-10-anthrone is soluble in cyclohexanone while the polyterephthalamide from 9,9-bis-(*p* -aminophenyl)fluorene does not dissolve in this solvent.

Table 5. Activation energies for the relaxation process (U_0) and molar structural constants (γ) cardopolyamides and cardopolyarylates[178].

Parameter	Polyamides from 9,9-bis-(*p*-aminophenyl) fluorene and various acids				Polyarylates from phenolphthalein and various acids	
	sebacic	isophthalic	terephthalic	diphenyl-4,4′-dicarboxylic	isophthalic	terephthalic

γ, kcal mm^2 mole^{-1} kg^{-1}	1.300	0.834	1.290	1.286	1.13	1.74

A detailed study of the thermal and thermo-oxidative degradation of many cardopolyamides showed that their thermal stability depends to a high degree on the nature of the cardo-group[180,187,188], while that of polyarylates is limited mainly by the stability of the ester linkage. Cardo-groups can be arranged in the following series in terms of increasing thermal stability of polyterephthalamides[180]:

It has been shown for the highly soluble polyterephthalamides derived from anilinephthalein and 9,9-bis-(*p*-aminophenyl)fluorene[189] that branching and structure-formation processes develop at temperatures preceding the decrease in their weight (up to 350°C).

4. Aromatic Polyimides

Aromatic polyimides (Table 6) are the first examples of heterocyclic cardopolymers. The characteristics of the structure of rigid-chain cardopolymers such as polyimides affect in the first place their solubility. The only example of such polymers with the most rigid chains (polypyromellitimides), which are soluble in organic solvents while retaining their high heat resistance, are the polypyromellitimides derived from anilinephthalein and 3,3-bis-(*p*-aminophenyl)phthalimidine[68,69,72]. It is noteworthy that in the series of cardopolyimides solubility is determined not only by the chemical structure of the cardo-group but to a considerable degree also by the nature of the bridging group between the phenyl groups of the second component. Thus, in contrast to cardopolypyromellitimides, the cardopolyimides derived from biphenyl-3,3′,4,4′-tetracarboxylic acid do not dissolve in amide solvents. On the other hand, the introduction of a

a. Concentration of polymer solution 0.5 g/100 ml.
b. The softening temperature was determined in the useful operating range[150].
c. The softening temperature was assumed to be the point of intersection of tangents to the thermomechanical curve in the region of polymer flow (load 100 g, disc diameter 4 mm).
d. In sulphuric acid.
e. In *sym*-tetrachloroethane.
f. In tricresol.

carboxylic acid residue, on either group, or a carbonyl group between the phenyl rings restores the solubility of the polyimides in DMF, DMA, DMSO, and NMP and makes them soluble in methylene chloride and chloroform, while retaining their solubility in TCE.[190] An unusual feature of cardopolyimides from aliphatic diamines is that they do not dissolve in DMF but do dissolve in DMA and many chlorinated solvents[78]. The presence of two cardo-groups (phthalide or phthalide and fluorene) in the elementary unit of polyimides promotes an even greater increase of solubility, making them soluble in cyclohexanone, in which other known polyimides do not dissolve[194].

An antagonistic effect in mixtures of a number of solvents[190] has been observed for cardopolyimides obtained from di-(3,4-dicarboxyphenyl) ether, of the type which has been noted also for the polyarylate from phenolphthalein and terephthalic acid[34]. Certain cardopolyimides have a lower consolute in DMF and chloroform.

The molecular weight distribution for the polypyromellitimide obtained from anilinephthalein has been estimated and the relation between $[\eta]$ of its solution in DMF and M_w has been found[72,197,198]:

$$[\eta]^{20^\circ} = 32.83 \cdot 10^{-4}\,\bar{M}_w^{0.516}$$

together with the analogous characteristics for the polyimide from di-(3,4-dicarboxyphenyl) ether and 9,9-bis-(*p*-aminophenyl)fluorene[199]:

$$[\eta]^{20^\circ}_{DMF} = 8.91 \cdot 10^{-4}\,\bar{M}_w^{0.56},$$
$$[\eta]^{20^\circ}_{DMA} = 3.33 \cdot 10^{-4}\,\bar{M}_w^{0.65}.$$

Electron microscope and viscometric studies have shown[198] a relatively higher rigidity of the macromolecules of the polypyromellitimide obtained from anilinephthalein, which exist in solution in a coiled form. The diphenylphthalide group, where the rotation about the

linkage is hindered, is responsible for the rigid coiling of the chain[198].

Cardopolyimides can be arbitrarily divided into several groups on the basis of their heat resistance[190,200]. Polyimides from pyromellitic and naphthalenetetracarboxylic acids exhibit the highest heat resistance. An unusual feature of these polymers is that their elementary units are made up of 3–4 condensed rings. As regards this feature, they occupy an intermediate position between the usual polycondensation systems, such as aromatic polyesters and polyamides, and ladder-type polymers. As a result of this feature, these polyimides have higher softening temperatures, which are sometimes not attained owing to degradation. Monolithic specimens of cardopolyimides[200] have operating characteristics at high temperatures and stresses which are unusual for organic polymers. Thus at 300°C polypyromellitimide devised from 9,9-bis-(*p*-aminophenyl)fluorene withstands a load of 500 kgf cm^{-2}, while at 400°C it withstands a load of 200 kgf cm^{-2}.

Polyimides obtained from dinuclear and polynuclear tetracarboxylic acids with phthalimide groups (Table 6, polymers Nos. 6–20) have a high heat resistance (although lower than that of polypyromellitimides), and their softening temperature can be regulated within wide limits by varying the nature of the bridging group between the phenyl rings of the tetracarboxylic acid or diamine residues[190,194].

Polyimides from aliphatic diamines show the lowest heat resistance among cardopolyimides but, even when the polymer chain contains long aliphatic fragments [$(CH_2)_6$ or $(CH_2)_8$], the softening temperature of the polymers reaches about 200°C.[78]

Like other polyimides, cardopolyimides have a high thermal stability[72,190] and in a series of polyimides thermal stability depends to an even greater extent on the nature of the cardo-group than among polyamides. Polyimides with fluorene and anthrone cardo-groups show the highest thermal stability[190,192]; on heating to 1000°C in an inert atmosphere (under the conditions of dynamic thermogravimetric measurements, the heating rate was 5 deg min^{-1}), they retain 68–70% of the weight of the initial specimen and the decrease in weight begins at 480–500°C.[72] The lowest thermal stability is characteristic of cardopolyimides with cyclohexyl groups[190,191], which, like aliphatic polyimides, begin to decompose in air at about 400°C. This has been explained by the initial degradation of the cyclohexyl groups. Polyimides with phthalide groups[72,190,191,201], the thermal stability of which is lower than that of the imide rings, occupy an intermediate position.

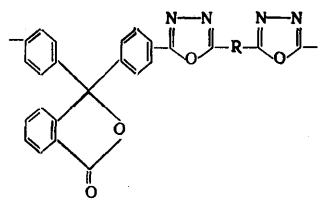
It has been shown that, at temperatures (300–350°C) preceding the onset of decrease in weight, processes leading to a change of molecular weight characteristics and solubility develop in polyimides[202].

Certain chemical properties of cardopolyimides (the data obtained are probably valid also for other polyimides) have been estimated. On heating, polyimides are resistant to acidolysis and exchange reactions involving the imide ring but decompose under the influence of amines and other bases[203,204]. Compared with the corresponding aromatic polyamides, polyimides are less resistant to hydrolysis[73,74]; their hydrolysis is accelerated in the presence of DMF, DMA, and DMSO[73,74] and depends on the chemical structure of the polymer and on its physical structure[196,205,206].

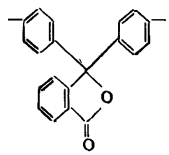
5. Poly-1,3,4-Oxadiazoles

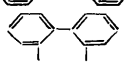
Another class of heterocyclic cardopolymers are poly-1,3,4-oxadiazoles (Table 7). The use of aromatic dicarboxylic acids and their derivatives containing cardo-groups in the molecule for the synthesis of such polymers made it possible to obtain highly soluble amorphous polymers[71,73,86], poly[1,3,4-oxadiazole-2,5-diyl-1,4-phenylene-(3,3-phthalidylene)-1,4-phenylene] among which contains two phthalide groups per elementary polymer unit, shows the highest solubility; it is soluble in methylene chloride, TCE, DMA, HMP, NMP, pyridine, benzyl alcohol, etc.

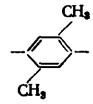
The polydispersity of cardopoly-1,3,4-oxadiazoles synthesised in polyphosphoric acid has been estimated[208,209]. The polydispersity coefficient ($\bar{M}_w/\bar{M}_n$) of the linear poly-1,3,4-oxadiazole based on 3,3-bis-(*p*-carboxyphenyl)phthalide and its dihydrazide is 3.0–3.1. The variation of the viscosity of solutions of this polymer with molecular weight is of the following type[208]:

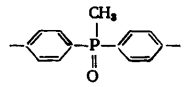


$$[\eta]^{25^\circ}_{DMA} = 7.74 \cdot 10^{-4}\,\bar{M}_w^{0.57},$$
$$[\eta]^{25^\circ}_{TCE} = 4.00 \cdot 10^{-4}\,\bar{M}_w^{0.66}.$$









As in other cases, the introduction of phthalide cardo-groups into poly-1,3,4-oxadiazoles increases significantly the thermal stability of the polymer. Thus poly[1,3,4-oxadiazole-2,5-diyl-1,4-phenylene-(3,3-phthalidylene)-1,4-phenylene] softens at a temperature approximately 150 deg above that of amorphous poly(1,3,4-oxadiazole-2,5-diyl-1,4-phenyleneoxy-1,4-phenylene).[86]

Cardopoly-1,3,4-oxadiazoles are resistant at room temperature to the action of organic solvents, water, and

corrosive media; they are slightly degraded at elevated temperatures in amide solvents[210]. Poly-1,3,4-oxadiazoles are degraded at room temperature in 98% sulphuric acid[210]. The polymers have been found to be stable in water at 100°C; poly-1,3,4-oxadiazoles are hydrolysed at higher temperatures, the hydrolysis being accelerated in acid and basic media.

Table 7. Properties of cardopoly-1,3,4-oxadiazoles

a. Concentration of polymer solution 0.5 g per 100 ml of TCE–phenol mixture (3 : 1 by weight).
b. See footnote b to Table 6.

Poly-1,3,4-oxadiazoles do not enter into exchange reactions involving the oxadiazole ring up to 200°C but decompose under the influence of carboxylic acids and their hydrazides.

Cardopoly-1,3,4-oxadiazoles obtained from 3,3-bis-(*p*-carboxyphenyl)phthalide begin to decompose in air according to dynamic thermogravimetric data obtained at a heating rate of 5 deg min^{-1} at 400–430°C, i.e. the thermal stabilities of the 1,3,4-oxadiazole and phthalide rings are approximately the same[194].

6. Carbon Chain Cardopolymers

Cardopolymers of the polymerisation type have been investigated in less detail, although the number of known examples of such polymers is very large. These include polyacenaphthylene[95,211–219], polyindene[85,220], polybiindenyl[221], poly(vinylene carbonate), poly(maleic anhydride)[100], polymaleimide[222], poly-*N*-phenylmaleimide[223,224], and polymethylenefluorene[225]. Systematic studies on carbon chain cardopolymers of methylenephthalide[93] and many methylenephthalimidines[94] and their copolymers with monomers of the vinyl type[1,226] have shown that such polymers are amorphous highly heat-resistant substances soluble in polar solvents. Thus polymethylenephthalide softens at about 300°C and dissolves in trifluoroacetic acid, formic acid, DMSO, the monohydrate of 1,3-dichloro-1,1,3,3-tetrafluoroacetone, trifluoroethanol, sulpholane, NMP, DMF, tricresol, etc., the solvent depending appreciably on the molecular weight of the polymer. It is distinguished from the majority of carbon chain polymers by a high density (d = 1.3462 g cm^{-3}). In a study of the glass temperatures of the copolymers of methylenephthalide with styrene, methyl methacrylate, and methyl acrylate, it was shown experimentally and by calculation[226] that the glass temperature of polymethylenephthalide should be 370–380°C, but is not attained owing to the depolymerisation process at temperatures in excess of 300°C.[1] Consequently the heat resistance of polymethylene phthalide

(X)

surpasses that of the majority of other carbon chain polymers and many heterochain polymers (polyarylates and aromatic polyamides).

The heat resistance of the carbon chain cardopolymers polymethylenephthalide, polymethylenefluorene, and polymethylenephthalimidine is independent of the chemical structures of the cyclic groups and is determined in this instance by the nature of the bonds in the main polymer chain[1,94]. All these polymers are depolymerised at temperatures in the range 250–300°C, while heterochain cardopolymers with similar groups remain thermally stable up to 350–450°C, the thermal stability of the latter depending on the nature of the cardo-groups (see above).

Comparison of the cardopolymers and other carbon chain polymers showed that the presence in the macromolecule of phthalide or phthalimidine groups improves the solubility of the polymer (for example, compared with polyethylene) in highly polar solvents[93]. However, the above carbon chain polymers do not dissolve in many polar solvents incapable of intense intermolecular association (for example in *sym*-tetrachloroethane) in which polystyrene dissolves readily, although it is insoluble in highly polar solvents such as trifluoroacetic and formic acids and DMSO. Such differences between the solubilities are probably due to the greater rigidity of the cardopolymers compared with polystyrene and the presence in the former of highly polar groups capable of intermolecular interaction.

Polymethylenephthalimidine and also copolymers of methylenephthalide and methylenephthalimidine dissolve in formic and trifluoroacetic acids, i.e. in solvents capable of rupturing intermolecular hydrogen bonds, but are insoluble in amide and chlorinated solvents[94].

In contrast to the cardopolymers mentioned above, polymethylenefluorene does not involve in the known organic solvents, which may be due to a definite albeit slight ordering of the structure of this rigid-chain polymer.

IV. APPLICATIONS

Films of various cardopolymers have been obtained by casting from solution in various organic solvents. The high heat resistance and thermal stability of such polymers ensures the stability of the physicomechanical and particularly the dielectric characteristics of such films up to 300°C.[21,86,138,152,193,227,228] Highly heat-resistant fibres of cardopolyarylates and certain other cardopolymers, which have an isotropic amorphous structure with traces of crystallinity, have been obtained by extrusion from solutions[113,180]. The use of cardopolymers as varnish coatings for plastics, as binders for fibreglass, as antifriction self-lubricating materials, and other products is also promising[229-232].

Structure and Properties of Polymer Mixtures in Solution

V.N.Kuleznev and L.S.Krokhina

Modern views on the solubility of two polymers in a common solvent are discussed, and the possibility of controlling the properties of polymer mixtures is examined. A list of 125 references is included.

I. INTRODUCTION

Mixtures of polymers are attracting increasing attention not only for the solution of applied problems but also in connection with the theory of the compatibility (mutual dissolution) of polymers, which in the amorphous state have the structure of highly viscous liquids. The high viscosity of polymeric liquids impedes the establishment of equilibrium, and macroscopic phase separation does not take place in mixtures of polymers even if the mixture actually comprises two phases, whose separation is determined thermodynamically. This fact is very useful for applied purposes, as it has led to the manufacture of materials from polymer mixtures. Nevertheless, the considerable difficulties involved in determining the phase constitution of a mixture of polymers have been responsible for broadening investigations of their properties in solution, where the phase composition can be easily established, and also means may be available for examining the structure of each phase separately and of the mixture as a whole. Many generalisations have already been made on polymer mixtures in solution, although they have been investigated systematically in effect during the past two decades.

The convenience of the rapid establishment of equilibrium in work with solutions is complicated by many difficulties, resulting from the presence of the solvent, in assessing interaction between the polymers themselves. For this reason results for polymer–polymer interaction in a polymer–polymer–solvent system cannot at present be confidently transferred to the polymer mixture in the absence of solvent or even to a solution of the polymers in a different solvent. Determining the interaction parameters of polymers and the structural parameters of their binary mixture from results obtained for their solutions constitutes a most important task for the future.

The present Review is concerned mainly to summarise work on solutions of polymer mixtures whose macromolecules contain neither ionogenic nor strongly polar groups. Reviews on this topic are lacking both in the Soviet and in the foreign literature.

II. THERMODYNAMICS OF THE MIXING OF POLYMERS AND THEIR SOLUTIONS

1. Polymer–Polymer System

The spontaneous mixing of two liquids leads to the formation of a true, single-phase solution of one component in the other, provided that the process is accompanied by a decrease in the Gibbs function, i.e. that

$$\Delta G = \Delta H - T\Delta S$$

is negative. The spontaneous process ceases when $\Delta G = 0$, and the liquids then have limited miscibility. The direction of the change and the magnitude of ΔG are governed by the relation between ΔH and $T\Delta S$, the enthalpy of mixing ΔH being determined by the magnitude and sign of the heat of mixing, while the entropy of mixing ΔS represents the change in order of the system resulting from the intermingling of the molecules.

The change in the parameters can be calculated most easily for an idealised system. If the structure of the miscible liquids and that of the mixtures are regarded as completely similar, so that neither the volume nor the short-range order is affected by mixing, the change in entropy is determined by the increase in the number of ways in which the two kinds of molecules can be distributed in space. Calculation based on the lattice theory of solutions[1-3] yields the formula

$$\Delta S = -kn_1 \ln \frac{n_1}{n_1+n_2} - kn_2 \ln \frac{n_2}{n_1+n_2} \qquad (2)$$

where k is Boltzmann's constant, for the change in entropy accompanying the mixing of n_1 molecules of one liquid with n_2 molecules of another liquid. According to this equation the entropy of mixing of the liquids decreases with increase in molecular weight. In fact, the higher the molecular weight the smaller the number of molecules (n_1 and n_2) in unit volume. Decrease in the number of molecules involves a decrease also in the number of combinations in which the molecules can be arranged: i.e. the entropy of mixing decreases.

If the molar volume of an ordinary liquid of low molecular weight is taken to be 100 cm³, and the molar volume of a polymer as 100 000 cm³, calculation using (2) for the mixing of 1 cm³ of one simple liquid with 1 cm³ of another gives[4] $T\Delta S$ = 8.3 cal/2 cm³; the corresponding value for the mixing of 1 cm³ of a polymer with 1 cm³ of the simple liquid is 4.5 cal/2 cm³, and for the mixing of the same quantities of two polymers $T\Delta S$ = 0.0083 cal/2 cm³. We are concerned here with the formation of an ideal mixture, in which molecules of one polymer are surrounded by those of the other, to give a molecularly disperse system, in which fluctuations of concentration are absent. These results show clearly that the entropy of mixing of polymers is so small that it can be disregarded in the calculation of ΔG. The quantity $T\Delta S$ cannot affect the sign of ΔG, so that the change in the Gibbs function is determined by the sign of the change in enthalpy (heat effect).

The same lattice model of a solution will yield a formula for the enthalpy of the mixing of n_1 solvent molecules with a volume fraction φ_2 of a polymer

$$\Delta H = kT\chi_1 n_1 \varphi_2 , \tag{3}$$

in which

$$\chi_1 = \frac{z\,\Delta\omega_{12} x_2}{kT} \tag{4}$$

is a dimensionless parameter representing the excess energy of interaction in the solution, where $\Delta\omega_{12}$ is the energy of interaction of a solvent molecule with a polymer segment of the same size, z is the coordination number of the model lattice, and $x_2 = v_2/v_1$ (the molar volumes of polymer and solvent being v_2 and v_1).

On the basis of the Flory–Huggins theory[1-3] presented here, Flory[5], as well as Scott and Magat[6], obtained almost the same expression for the chemical potentials of the mixing of two polymers (2 and 3), which can be written

$$(\mu_2 - \mu_2^0) = \ln\varphi_2 + \left(1 - \frac{x_2}{x_3}\right)\varphi_3 + x_2\chi_{23}\varphi_3^2 , \tag{5}$$

$$(\mu_3 - \mu_3^0) = \ln\varphi_3 \left(1 - \frac{x_3}{x_2}\right)\varphi_2 + x_3\chi_{23}\varphi_2^2 , \tag{6}$$

where χ_{23} is a parameter of interaction of the polymers, μ the chemical potential of one polymer surrounded by the other, and μ^0 the chemical potential of the same polymer surrounded by like molecules. The critical conditions for the mixing of two polymers (i.e. the concentration and the interaction parameter at which phase separation ensues) were determined by Scott[7], who obtained expressions for these critical values:

$$\chi_{23c} = \frac{1}{2}\left(\frac{1}{\sqrt{x_2}} + \frac{1}{\sqrt{x_3}}\right)^2 , \tag{7}$$

$$\varphi_{2c} = \sqrt{x_3}/(\sqrt{x_2} + \sqrt{x_3}) , \tag{8}$$

$$\varphi_{3c} = \sqrt{x_2}/(\sqrt{x_2} + \sqrt{x_3}) . \tag{9}$$

In the particular case of a mixture of polymers having molecules of the same length ($x_2 = x_3 = x$) we find that $\varphi_{2c} = \varphi_{3c} = \frac{1}{2}$ and $\chi_{23c} = 2$. Substituting $\chi_{23c} = 2$ in Eqn. (4) yields the condition

$$z\,\Delta\omega_{23}/kT = \frac{2}{x} \tag{10}$$

for a mixture of polymers at the consolute point. When x is large, $\Delta\omega_{23}$ is small. With the high molecular weights of polymers, their already negligible interaction energy, i.e. negligible absorption of heat on mixing, will lead to phase separation. Thus in an ideal mixture of polymers phase separation occurs with the slightest endothermic change, and the insignificant positive change in entropy is unable to balance the increase in enthalpy. The mixing of polymers can take place only with considerable evolution of heat.

A systematic investigation of the heats of mixing of polymers was first undertaken by Slonimskii and his coworkers[8,9]. In only two of the twenty-one pairs of polymers that they examined (polybutadiene rubber mixed with polystyrene and with butadiene–styrene rubber) was the sign of the thermal effect inconsistent with the behaviour of the polymers on mixing. The evolution of heat on the mixing of these two segregating pairs of polymers was attributed to a change in volume accompanying mixing.

Subsequent work has shown that segregation of a mixture of solutions or melts occurs even when the polymers are closely similar[10-14]. Two-phase systems appear in a mixture of melts of linear and branched polyethylene[15], in a mixture of solutions of the butadiene–nitrile copolymers SKN-18 and SKN-40,[16] in a mixture of melts of copolymers of methyl methacrylate and butyl acrylate whose macromolecules differ by more than 10% in their content of the former monomer[17], and also in a mixture of butadiene–styrene copolymers differing in composition by ~20%.[18] Two-phase systems appear even in a solution of a mixture of isotactic and atactic poly(methyl methacrylate) (so called stereocomplexes)[19]. There are grounds for expecting incompatibility of fractions of the same polymer differing significantly in molecular weight, which has already been shown for a solution of fractions of polyethylene[20].

Allen et al.[21] determined several thermodynamic functions of the mixing of oligomeric polyisobutylene and polymethylsiloxane. They measured the heat of mixing of the polymers experimentally, and calculated the interaction parameter per segment $\alpha_{23} = \chi_{23}/v$ (where v is the molar volume of the polymer) from the Flory–Huggins theory by means of Eqn. (3). The result was comparable in order of magnitude with that calculated on the basis of Hildebrand's theory from the difference between the solubility parameters δ_2 and δ_3 of the polymers. Since the latter theory assumes a random distribution of molecules, the result would correspond to a similar structure of the mixture. The value of α_{23} was equated to α_{23c}, which according to Eqn. (7) defines the condition of critical separation of the mixture into two phases. This permitted the critical temperature of mixing of the polymers to be calculated. If the heat of mixing had alone been responsible for the phase separation of this mixture, separation would have occurred at a temperature almost 300 deg below the observed consolute temperature. It was concluded[21] that the entropy contribution to the term $\chi_{23}kTn_1\varphi_2$ in Eqn. (3) is quite large. The entropy of mixing which they calculated from the experimental results differed considerably from the theoretical value. This discrepancy, a consequence of some ordering of the system, was regarded as responsible for the deviation of calculated values from experimental data.

Flory[22] has recently used Prigogine's theory of solutions[23] to calculate the changes in thermodynamic parameters accompanying the mixing of polymers. The equilibrium properties of a liquid—its thermodynamic functions—depend on the fluctuation of its density: i.e. they are determined by its internal structure. Mixing may involve changes in structure, which influence the thermodynamic functions. The structure of a liquid was characterised in terms of the density, the free volume, and also the coefficient of thermal expansion. Experimental values of the thermodynamic functions for polyisobutylene and polymethylene were used to calculate the

thermodynamic parameters of the mixing of these polymers at temperatures above the melting point. Thus $\Delta H = 2.5$ cal/100 g mixture at 150°C, while $T\Delta S$ is negative (−5.4). Therefore ΔG is large and positive (7.9), which indicates that the polymers are incompatible. Flory did not indicate reasons for the decrease in entropy on mixing. A possible increase in the degree of order of the system—an increase in short-range order—probably increases the non-combinatorial component of the entropy[24], which will be discussed in Section III.

The considerable decrease in entropy observed when polymers are mixed above the glass point shows that phase separation can occur even with a small exothermic effect, as has been found experimentally[8,9]. From the above it is obviously illegitimate to estimate the mutual solubility (compatibility) of polymers from the difference in their cohesion energies[25], for this disregards the important part played by the entropy factor in the expression for the free energy of mixing of polymers.

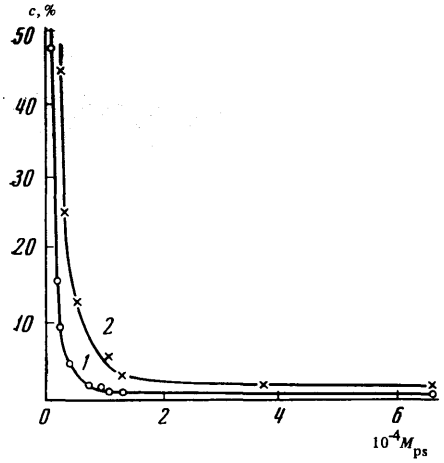

Figure 1. Solubility limit c (%) as function of molecular weight of polystyrene (ps) in: 1) polyisoprene ($\overline{M}_W = 10^6$); 2) poly(methyl methacrylate) (0.87×10^5).

The difficulty of the direct experimental measurement of the free energy of mixing demonstrates the importance of the direct determination of the mutual solubility of polymers[26,27] as a measure of their affinity. Fig. 1 shows that at high molecular weights the solubility of polymers is small (fractions of 1%) independently of their chemical nature: only at low molecular weights does the solubility increase. Polystyrene dissolves completely in polyisoprene of high molecular weight only when $M_W \leq 600$, and in poly(methyl methacrylate) when $M_W \leq 1500$.

These results are qualitatively consistent with those of other investigators. Thus Berek[28], while determining the variation in the critical separation concentration of polystyrene and atactic polypropylene in solution with polymers of different molecular weights, found by extrapolation that, in the absence of a solvent, complete miscibility was exhibited by polymers having molecular weights in the range 330—660. Kuhn and Cantow[29] found that poly(methyl methacrylate) of degree of polymerisation 17 ($M_W \simeq 1500$) should be a θ-solvent for polystyrene. Oligomeric acrylates of various structures display considerable solubility in poly(methyl methacrylate)[30].

The above work together with that of Paxton[31], who established the limited miscibility of oligomers, disproves predictions[32] that polymers having $M_W \simeq 10^4$ are completely miscible. Fig. 1 indicates that $M_W = 10^4$ is the molecular-weight limit below which solubility increases rapidly with decrease in molecular weight.

Poly(vinyl chloride) and the butadiene—nitrile rubber SKN-40, which interact strongly owing to the polarity of their groups, probably constitute the only pair of polymers of high molecular weight that differ in chemical nature but yet are completely miscible[33].

Since mutual solubility increases markedly (up to complete miscibility) as the molecular weight of polymers falls below $M_W = 10^4$, segmental solubility of polymers was postulated[34] at their interface. This phenomenon is due to the dual nature of the macromolecules: they actually consist of segments, which accomplish the elementary act of thermal motion (displacement of the macromolecule). Mutual dissolution of the segments of unlike macromolecules can be assumed to occur[34] at the boundary of block polymers and especially in solution. Mutual solubility of the segments is well supported by the complete miscibility of the monomers (even when hydrogenated) of most polymers. Further confirmation is provided by the good miscibility of oligomers (Fig. 1). Hence most polymers are macromolecularly incompatible, but segmentally compatible in the interfacial layer[34]. The presence of such a transition layer, resulting from segmental solubility, is evidently responsible for the quite intense interaction of polymers in two-phase mixtures, i.e. when they are incompatible. Experimental determinations of the free energy of polymer mixtures, recently begun by Tager[35], show that ΔG is quite large and negative even for a mixture of incompatible polymers.

2. Solvent—Polymer—Polymer (1—2—3) System

Under certain conditions solutions of mixtures of two polymers in a common solvent, completely miscible with each of the polymers, separate into two phases each containing predominantly one polymer. Experience has shown that separation occurs not only in mixtures of polymers differing markedly in nature and structure, whose mutual insolubility is self-evident, but also in mixtures of polymers which are very similar in nature, such as polymeric *o*- and *p*-methylstyrenes[36], linear and branched polystyrenes[10], poly(methyl acrylate) and poly(ethyl acrylate)[11], poly(methyl acrylate) and poly(methyl methacrylate)[11], etc.

At infinite dilution, when the solution contains isolated macromolecules, the polymer—polymer—solvent system forms a single phase. Like any critical phenomenon, phase separation results from the interaction of macromolecules of the same kind and the consequent change in the supermolecular structure of the system. On increasing the concentration of solutions of polymer mixtures, therefore, we may expect phase separation only at a sufficiently high concentration, as follows from Eqns. (7)—(9), depending primarily on the interaction parameter of the polymers χ_{23} and on their degrees of polymerisation x_2 and x_3.

The conditions for the transition of a single-phase solution into two phases have been analysed thermodynamically mainly by Scott[7], Tompa[37], and Maron[38]. The calculations by Scott and by Tompa, which are complementary, are based on the Flory—Huggins theory, and have

been reported in detail in the books by Flory[39] and by Tompa[40].

If we assume that the polymers have the same degree of polymerisation and the same affinity for the solvent ($x_2 = x_3 = x$ and $\chi_{12} = \chi_{13} < 0.5$), the equality of the chemical potentials of the polymers and the solvent in the two phases of the separated solution will yield (Eqn. 5) the formula

$$\ln \varphi_2 + \chi_{23}(1-v_1)\varphi_3^2 = \ln \varphi_2' + \chi_{23}(1-v_1)\varphi_3'^2 \qquad (11)$$

where the volume fraction of polymer 2 in one phase is $\varphi_2 = v_2/(v_2 + v_3)$ and its volume fraction in the other phase

$$\varphi_2' = \frac{v_2'}{v_2' + v_3'} = \frac{v_2}{v_2 + v_3} = 1 - \varphi_2$$

so that $\varphi_3 = 1 - \varphi_2$ and $\varphi_3' = 1 - \varphi_2'$. Equation (11) is fundamental, giving the composition of the coexisting phases of the separated polymer–polymer–solvent (2–3–1) system.

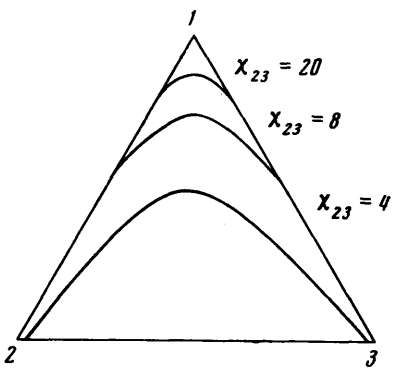

Figure 2. Diagram of solvent–polymer–polymer (1–2–3) ternary system with $x_2 = x_3 = x = 1000$ and the same interaction of the polymers with the solvent[7].

The "symmetry" of Eqn. (11) appears natural with the given initial conditions of equal degrees of polymerisation and the same affinity of the polymers for the solvent. Calculation of the phase diagram by means of Eqn. (11) yields symmetrical binodal curves separating the two-phase from the one-phase region (Fig. 2). In this case the position of the binodals is determined solely by χ_{23} and x.

By analogy with the binary system it is easy to determine the critical phase-separation concentration and the critical interaction parameter of the polymers in the ternary system:

$$\varphi_{2c} = \varphi_{3c} = (1 - \varphi_{1c})/2, \qquad (12)$$

$$\chi_{23c} = 2/(1 - \varphi_{1c}). \qquad (13)$$

Equation (13) shows that phase separation takes place only as a consequence of polymer–polymer interaction: the quantities χ_{12} and χ_{13}, representing the interaction of each polymer with the solvent, do not even occur in the equations for the critical conditions. Comparison of the critical interaction parameters of the polymers in ternary and binary systems (Eqns. 13 and 7 respectively) indicates that stronger interaction is tolerable between the polymers, without causing phase separation, in the presence of a solvent than in the binary system. As in the binary system, however, interaction between the polymers at the consolute point is small, as follows from an analysis of Eqn. (13). Equating χ_{23} from Eqn. (4) to the critical interaction parameter from Eqn. (13), we obtain

$$\chi_{23c} = xz\,\Delta\omega_{23}/kT = \frac{1}{1 - \varphi_{1c}},$$

which can be more conveniently written $\chi_{23c}(1 - \varphi_{1c}) = 1/x$. Hence χ_{23c} is very small for compounds of high molecular weight, corresponding to large values of x. It was therefor concluded that mutual insolubility of polymers in solution is the rule rather than the exception. The equation shows also that the larger the interaction parameter the lower the phase-separation concentration (Fig. 2). No phase separation takes place when $1 - \varphi_{1c} \ll 1/x$. Hence solutions of mixtures of polymers in which x is large should separate at very low concentrations, and the limit of separation should become lower with increase in the molecular weight of the polymers.

Scott showed[7] that a phase equilibrium diagram similar to Fig. 2 holds for a large class of ternary systems in which χ_{12} does not greatly differ from χ_{13}, while the length of the molecular chains satisfy the condition $x_2^{1/2} < x_3 < x_2^2$. Most systems encountered in practice conform to this condition, so that mutual insolubility of polymers in solution is general in character.

The symmetry of the phase diagram is destroyed if the equality $x_2 = x_3 = x$ does not hold. Unsymmetrical diagrams have been obtained[40-42] in which the consolute point was displaced in the ternary diagram (Fig. 2) along the axis of the polymers towards the polymer of lower molecular weight.

An unsymmetrical phase diagram is obtained also when $\chi_{12} \neq \chi_{13}$. The macromolecules are solvated to different extents, so that the actual sizes of the coils of macromolecules of different polymers differ even when they have the same molecular weight. No detailed thermodynamic analysis has been made of the effect of the nature of the solvent on the critical conditions of phase separation. However, Tompa showed[37] that, when there is no interaction between one of the polymers and the solvent, the phase diagram is completely unsymmetrical.

Thermodynamic analysis shows that polymers possess little affinity for one another. Thus from the solubility parameters of polystyrene and polybutadiene Scott[43] found that mixtures of two butadiene–styrene copolymers should segregate if their styrene contents differ by only 8%.[18] Tompa[40,42] predicted from his theory of phase equilibria that fractions of the same polymer might separate if they differ significantly in molecular weight and are placed in a poor solvent for the given homologous series of polymers. This deduction has since been confirmed experimentally[20,44].

According to theory[7] a completely incompatible system, i.e. a system in which one phase consists of solvent plus polymer 2, and the other of solvent plus polymer 3, is in principle possible only where χ_{23} is very large or at high concentrations of the polymers, which is quite well confirmed experimentally.

We now realise that the theories of the phase composition of a polymer mixture in solution are oversimplified, representing idealised views on the behaviour of polymers in solution. Nevertheless, the theory gives a correct view of the main features of phase separation in the polymer–polymer–solvent system, as is indicated by several experimental investigations reported below.

The main conclusions from the Flory—Huggins theory are supported qualitatively by the work of Dobry and Boyer-Kawenoki[45], who examined 78 combinations in solution. They studied the effect of the nature of the polymers, their molecular weights and proportions in the mixture, and also the type of solvent on the miscibility of the polymers in solution by determining the phase-separation limit and analysing the composition of the coexisting phases.

Theory has been confirmed also by investigations of a mixture of homologous polymers in a common solvent. Sieglaff[10] observed the separation into two phases of a mixture of a linear polystyrene with its microgel in benzene. The best quantitative support for the theory was provided by Koningsveld and Staverman[20], who calculated, in conformity with Tompa's predictions[40,42], that a third phase must be expected at 119.0—121.7°C in a solution of a mixture of two polyethylenes having molecular weights M_w of 1.2×10^4 and 5.4×10^5. Mixtures of these homologues in diphenyl ether actually separate into three phases in the range 120.4—121.6°C: the agreement with theory is entirely satisfactory. Shultz and Flory[46], who also investigated the phase separation of two polystyrene homologues ($x_2 = 770$ and $x_3 = 1100$) in cyclohexane, found that theoretical and experimental curves were of the same character, but the latter covered far wider ranges of composition and temperature. Koningsveld and Staverman[44] showed that the discrepancy was due to neglect, in Shulz and Flory's treatment of the experimental results, of the multimolecular character of the polymers.

Experimental work by Bristow[47] and by Berek et al.[28] provided quantitative confirmation of the theory. The former obtained symmetrical diagrams for the natural rubber—poly(methyl methacrylate)—benzene system and the latter for the polystyrene—polypropylene—toluene system; in both cases the polymers had the same molecular weights and a good solvent for both polymers was employed. The systems were analogous to the case examined by Scott[7] and characterised by the parameters $x_2 = x_3 = x$ and $\chi_{12} = \chi_{13}$. The consolute points calculated by Bristow did not lie on the experimental curves, which he attributed to inaccurate determination of molecular weights. The theoretical binoidal calculated by Berek by means of Scott's equation (11) coincided with the experimental curve. The symmetry was destroyed when polymers having different molecular weights were taken.

Allen et al.[32] made an interesting comparison of the Flory—Huggins and Hildebrand theories. They determined the interaction parameter $\alpha_{23} = \chi_{23}/v$ from the distribution of the polymers in the phases. The parameter found from the phase equilibrium was of comparable order of magnitude with the interaction parameters of other pairs of polymers, e.g. with that calculated by Scott[7] from Dobry and Boyer-Kawenoki's results and with that found by Stockmayer and Stanley[48] by light scattering. The interaction parameter was also calculated by means of Hildebrand's formula[49,50] $\alpha_{23} = (\delta_2 - \delta_3)/RT$. It is interesting to compare this work[32] with that of Paxton[31], who determined the interaction parameters of polymers by means of an equation, obtained by him on the basis of Maron's theory[38,51,52], for a mixture of two polymers of low molecular weight in a common solvent. This theory modifies the usual Flory—Huggins formula for the free energy by including a term representing the variation in the effective volume of the polymer in solution, as a consequence of which the interaction parameter varies with the concentration of the solution.

Table 1 assembles values of the interaction parameters, calculated on the basis of various theories, for polystyrene and polybutadiene in solution. The difference in the results given by the Flory—Huggins and Hildebrand theories is to some extent understandable. As already mentioned, Hildebrand assumed a completely random distribution of the molecules. The low results given by the Flory—Huggins theory indicate some ordering of the system and a decrease in entropy. This is confirmed by Flory's calculations for a binary system[22]. Nevertheless, the excessively high values of α_{23} obtained from Maron's theory, which already allows for some orientation of the molecules in the mixture, are completely incomprehensible, and Paxton's explanations of the discrepancies in α_{23} in terms of the polydispersity of the specimens are unconvincing.

Table 1. Polystyrene—polybutadiene interaction parameter calculated on basis of different theories.

Theory	α_{23}, litre^{-1}	Ref.
Flory-Huggins	0.1	32
Hildebrand	0.15	32
Maron	28—29	31

The results surveyed show that the Flory—Huggins theory provides the most complete description of the behaviour of ternary systems, although certain discrepancies are found, mostly concerning estimates of the interaction parameter of polymers in solution. According to the theory χ_{23} represents the energy of contact between segments of the two polymers, and is constant for a given pair of polymers, independently of the composition of the mixture and the temperature. Experiment shows that the interaction parameter depends on the mixture composition[32] and on the total concentration of polymers in solution[28]. Theory indicates also that χ_{23} is independent of the solvent, although in several cases it has been found to vary with the nature of the latter[36,53].

A need has undoubtedly grown in this field for general papers that will show, on the basis of comprehensive experimental data, the dependence of the limit of phase separation, the composition of the layers after separation, and ultimately the dependence of the structure of the polymer mixture after removal of solvent on the interaction parameter calculated by any available method.

III. ONE-PHASE SOLUTIONS OF MIXTURES OF POLYMERS

Nuclei of a second phase appear in any system long before the phase transition takes place. This should apply also to solutions of polymer mixtures, where corresponding changes in the supermolecular structure of the solution must be expected at concentrations below the phase-separation limit.

Association complexes of the macromolecules appear in a polymer solution at a certain concentration[24,54]. In a solution of a polymer mixture there are two theoretical

possibilities: either molecules of polymer A and those of polymer B can associate separately; or mixed adducts, each containing macromolecules both of A and of B, can be formed. In the former case increase in size of the association complexes with increase in concentration can reasonably be expected, terminating in the formation of an interface between unlike aggregates and the separation of droplets of a new phase. In the latter case increase in size of adducts of unlike macromolecules can hardly lead to separation of the solution into two phases, since experiment shows that, after a solution has separated into layers, each phase contains predominantly one of the polymers, so that adducts of unlike molecules must have broken down at the instant of phase separation, after which separation into layers occurs with the formation of association complexes of like molecules in each phase. The second type of structural changes at the instant of phase separation is illogical to the extent that formation of adducts of unlike macromolecules can probably be assumed only in cases in which the polymer mixtures do not separate into layers at all (at least in solution).

Although these suggestions on the mechanism of structure formation appear convincing, they require experimental verification, and the present Section is devoted to the relevant results.

When the concentration of a very dilute solution of a polymer is increased, a point may be reached at which isolated coils of macromolecules come into mutual contact. This ensues at a critical concentration c_1, indicated by a break on the property—concentration curves for the polymer solution[55,56] or determinable, following Debye, from the reciprocal of the intrinsic viscosity, the latter having the dimensions of a specific volume and characterising the density with which the solution is filled with macromolecule segments[57].

A critical concentration has been detected experimentally in solutions of polymer mixtures[58-60]. Cragg and Bigelow[58,59] determined the intrinsic viscosity and the intrinsic asymmetry ($[\eta]_A$ and $[\varepsilon]_A$) of a polymer A from light-scattering data in a solvent—a solution of polymer B of concentration c_B—and observed at the critical concentration a discontinuity—a peak or a dip—in the dependence of $[\eta]_A$ and $[\varepsilon]_A$ on c_B. Kuleznev and his coworkers[60] compared the intensity of scattering $R_{90}{}^{\circ\prime}$ by a mixture of polystyrene and polyisobutylene in toluene with the scattering by polystyrene in pure toluene, and found that, up to a certain concentration c_1, polystyrene scatters with the same intensity in the mixture as in pure toluene, after which its scattering in the mixture increases sharply. Such comparison was made possible by the isorefractivity of polyisobutylene and toluene, as a consequence of which the former was optically invisible in the latter. The critical concentration c_1 was easily determined from the break in the linear dependence of $c/R_{90}{}^{\circ\prime}$ on c. The considerable increase in intensity of scattering by polystyrene in mixtures having $c > c_1$ is attributed by the Reviewers to the fact that, in the presence of another polymer, the polystyrene macromolecules are constrained to associate to a greater extent than in the pure solvent (excess association).

The results reveal at least two characteristic concentrations in solutions of polymer mixtures, separating concentration ranges differing in structure. The first and lowest concentration may be c_1, at which the macromolecules come into mutual contact; at the second concentration c_2, termed the phase-separation limit, the solution divides into two layers. The concentration range c_1—c_2 gives solutions with a definite extent of association of the macromolecules: association begins at c_1, and at c_2 the size of the aggregates reaches a limit at which an interface appears (Fig. 3). Let us examine the changes in structure undergone by solutions of polymer mixtures within these concentration ranges.

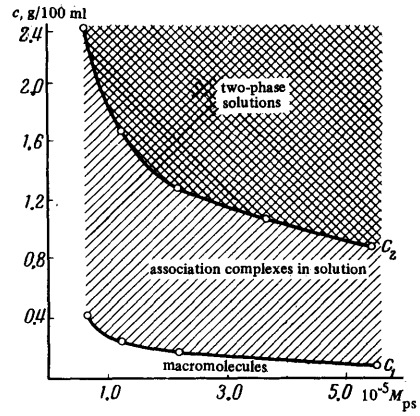

Figure 3. Concentration limits of solutions of polystyrene—polyisobutylene (7 : 3) mixtures in three structural states as function of molecular weight of polystyrene.

In 1964 we first proposed[61] the "polymeric" (isorefractive) solvent method for investigating such structures. The method consists essentially in choosing a solvent in which the increment of the refractive index of one polymer is zero, and a solution of this polymer of given concentration is used as the "polymeric" solvent, e.g. a solution of polyisobutylene in toluene. This permits the preparation of solutions of polymer mixtures, e.g. with different concentrations of polystyrene and a constant concentration of polyisobutylene. Such solution may be concentrated with respect to the polymer mixture, but dilute with respect to polystyrene, which permits the theory of dilute solutions and the usual methods of processing experimental results to be applied to the solution of polystyrene. The Debye or Zimm method can be used to determine the molecular weight of polystyrene, the size of its coil, and the second virial coefficient in a polymeric solvent at a different concentration. This principle has since been applied by several workers in investigating light scattering[29,62-65] and viscosity in solutions of polymer mixtures[53].

Using a very dilute polymeric solvent, Eskin[64] and Kuhn[62,63] observed a contraction of the polymer coil relative to its size in the pure solvent, but Kuhn noted that the coil is larger in a polymeric θ-solvent than in a θ-solvent of low molecular weight. Eskin[66] also remarked on the lack of identity between the two types of θ-solvents. The coil contracted with increase in concentration of the polymeric solvent, but, as already noted, the concentration remained low. Similar results were obtained in viscosimetric measurements[53], when a decrease in intrinsic viscosity with increase in the concentration of the polymeric solvent was established. However, these results are inconsistent with those of Hyde and Tanner[65], who found that the size of the polymer coil was independent of the concentration of the polymeric solvent, and attributed

this to the almost zero interaction parameter of the polymers. The Reviewers have shown[60] that the size of the coil of one polymer in a solution of another polymer remained constant over a certain concentration range of the polymeric solvent not exceeding the concentration at which association begins. At higher concentrations the coil size increases while the molecular weight remains constant. The Reviewers offer the explanation that, at solution concentrations below c_1, unlike macromolecules may be sufficiently far apart not to interact strongly enough to increase the extent of association or change the shape of the coil. If the concentration of the polymeric solvent comes to exceed c_1, the molecular coils of unlike macromolecules may interpenetrate. This is entirely possible, for the solution is a single phase at these concentrations, so that there is no physical boundary between coils of unlike molecules or their association complexes in contact. Thus a considerable concentration of segments of one polymer may be produced within a coil of the other polymer in a single-phase solution of a polymer mixture. Because contacts between like segments are preferred, the interaction of unlike segments will be equivalent to repulsion. As a consequence of the presence of polyisobutylene segments both outside and inside the polystyrene coil, the latter may either uncoil or contract depending on whether the resultant effect is directed inside or outside the coil. In the present case the polystyrene coil unwinds, becoming larger, a prerequisite for the association of such an "uncoiled" molecule with similar molecules, as occurs at high polystyrene contents in the solution. In other cases[62-64] the polymer coil became smaller with increase in concentration of the "polymeric" solvent.

The partial straightening (uncoiling) of coils with increase in solution concentration is characteristic of all individual solutions of polymers (see e.g. Ref. 57, p. 102). If, however, a solution of one polymer is diluted with a fairly concentrated polymeric solvent (total solution concentration close to the phase-separation limit of the mixture), the solution of the first polymer will not break down into individual coils of macromolecules, as Kuhn and Cantow showed[62,63], but the polymeric solvent will contain aggregates of degree of association ~55. It is obvious that data on the variation in size of the coil give limited information on possible association processes, for almost all the experiments mentioned were made at high dilutions of the polymer whose molecular association was being investigated.

The 1964 paper already mentioned reported the determination of the second virial coefficient A_2 of polystyrene from light-scattering data in a polymeric solvent (a solution of polyisobutylene). It was found that A_2 for polystyrene dropped sharply, approaching zero, with increase in the polyisobutylene concentration[61]. Kuhn has since found[29] that A_2 may not only reach zero but even assume negative values. The higher the molecular weight of the polymer in the polymeric solvent, the lower its concentrations at which A_2 becomes zero.

A decrease in A_2 indicates deterioration of the solvent. Hence a solution of one polymer is a thermodynamically poor solvent for another polymer. In poor solvents the association of polymers is large, which sometimes may even lead to separation of the polymer as a new phase. It can reasonably be assumed that macromolecules of one polymer will show a greater tendency to associate in the presence of another.

The scattering of light has been used to investigate association phenomena[60]. With simple liquids the composition variation of the scattering is often non-additive. A positive deviation in the intensity of scattering above the additive value indicates[67] excess molecular association relative to the mean degree of association of the two liquids.

The polymer–polymer–solvent system is more complicated than a mixture of two liquids. It would have been completely unjustified to apply the additivity principle here, and therefore the investigation was made in the polystyrene–polyisobutylene–toluene system, in which the latter two compounds had almost the same refractive indices, so that scattering in the mixture was due mainly to polystyrene, whose scattering $R_{90°}''$ was compared with its scattering in toluene. The dependence of $R_{90°}''$ on the composition of the polymer mixture (Fig. 4) at constant solution concentrations in the range c_1–c_2 passes through a maximum. The increased scattering by polystyrene in the mixture, relative to its scattering in toluene, depends on the proportions of the polymers, the molecular weight, and the concentration of the solution. The excess scattering $\Delta R_{90°}''$, obtained by subtracting the intensity of scattering by polystyrene in toluene from the intensity of scattering by the mixture, increases linearly with the concentration of the solution (Fig. 5), which separates into layers at concentration c_2.

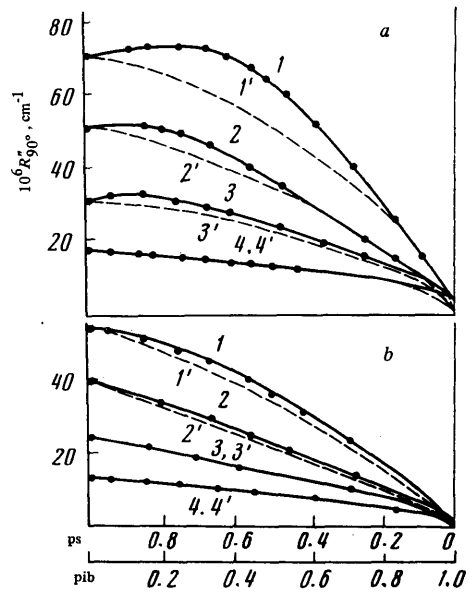

Figure 4. Dependence of $R_{90°}''$ ratio of polymers for polystyrene–polyisobutylene (ps–pib) mixtures in toluene solutions of constant concentration (g/100 ml): *a*) 0.5; *b*) 0.2 on molecular weight of polystyrene ($\times 10^{-5}$): 1) and 1') 5.5; 2) and 2') 2.2; 3) and 3') 1.2; 4) and 4') 0.65. The full (unprimed) curves represent solutions of mixtures, and the broken (primed) curves solutions of polystyrene.

The above results show that, in a solution of a mixture of polymers, like molecules begin to associate at a concentration c_1, and the association complexes reach their limiting size and density at point c_2, when the system separates into two phases. At the concentration c_2 the

density of association complexes of polymer A and polymer B is such that they acquire the properties inherent in particles of a new phase: in particular, a physical interface appears. It may be suggested that a polymer of given chemical nature will have a critical degree of association, independent of the molecular weight of the polymer, at which an interface is formed. This hypothesis was tested[80] by determining the excess scattering $\Delta R_{90°}$" by polystyrene of various molecular weights in mixtures having the same ratio of polymers (Fig. 5).

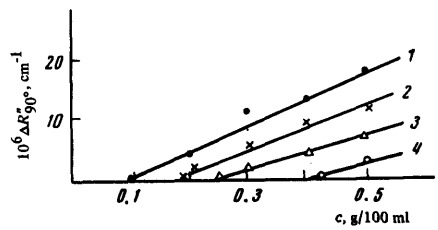

Figure 5. Concentration dependence of excess scattering $\Delta R_{90°}$" of polystyrene in mixture with polyisobutylene (7 : 3) in comparison with individual solution of polystyrene in toluene for different molecular weights ($\times 10^{-5}$) of polystyrene: 1) 5.5; 2) 2.2; 3) 1.2; 4) 0.65.

The excess light scattering can be regarded as the same in solutions of mixtures of polystyrene and polyisobutylene independently of the molecular weight of the former, provided that the solutions are in a corresponding state, i.e. that their concentrations are equidistant from c_1 and c_2. A dimensionless parameter—the reduced concentration $c^* = (c - c_1)/(c_2 - c_1)$, where c is the concentration of the solution of the polymer mixture in the usual weight units—was taken as measure of a corresponding state. The experiment showed that the dependence of $\Delta R_{90°}$" on c^* is represented by a single straight line for all solutions of mixtures of the two polymers in toluene, independently of the molecular weight of the polystyrene (Fig. 6). In the precritical range $\Delta R_{90°}$" is the same for all polystyrene fractions independently of their molecular weight.

It is hardly justifiable to assert that mixtures of different pairs of polymers will be represented by the same linear plot of $\Delta R_{90°}$" against c^*, since an interface is apparently formed at different densities of association complexes with different polymers. In any case, comparison of the tendency of polymers to associate in a mixture must obviously be made at equal values of c^*, whose calculation requires a knowledge of c_1 and c_2.

Thus a solution of a mixture of two polymers has a fairly specific "cellular" structure. Segments of polymer A are concentrated in individual microvolumes, and segments of polymer B in others; the intermediate spaces are filled with a mixture of segments of A and B in the absence of a physical interface. Light-scattering data show that microvolumes containing like segments (association complexes) are more densely packed than the corresponding homophase fluctuations in individual solutions of polymers A and B at the same concentrations by weight. Microvolumes containing a mixture of segments, on the other hand, would be loosened, for, in a system of incompatible polymers, the A—A and B—B segment interactions are more intense than the A—B interaction. Such a structure affects the properties of the solution, and also provides an explanation of certain aspects of the properties of polymer mixtures in bulk. Examples are given below.

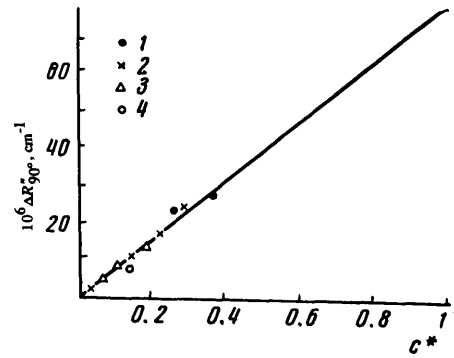

Figure 6. Dependence of excess scattering $\Delta R_{90°}$" by polystyrene in mixture with polyisobutylene on reduced concentration c^* for different molecular weights ($\times 10^{-5}$) of polystyrene: 1) 5.5; 2) 2.2; 3) 1.2; 4) 0.65.

The presence of microregions with a loosened structure leads to a considerable increase in solubility of a third polymer in a solution of a binary polymer mixture. If solutions are prepared of a mixture of polyisobutylene, polybutadiene, and polystyrene in chloroform having a total concentration of 4.0 g/100 ml but with different proportions of the polymers, the range of proportions in which the mixture is transparent defines the region of mutual solubility of the polymers. With the above total concentration of polymers in solution the solubility of polyisobutylene in polybutadiene and in polystyrene is ~1.4%, but its solubility in a 3 : 1 mixture of the latter polymers is 13%. Fig. 7 shows as example the solubility diagram for the polyisoprene—polyisobutylene—polystyrene system, where the effect is still more clearly evident.

A mixture of polyethylene and polypropylene illustrates the increase in order of arrangement of segments in each polymer phase when polymers are mixed in the melt[89]. The temperature range between the melting point and the crystallisation point in each polymer phase in the mixture is smaller than in the individual polymers. The fact that each molten polymer crystallises at higher temperatures in the mixture indicates a high degree of order in the molten mixture.

Research on solutions of polymer mixtures was first made by physicochemical methods, and the composition dependence of viscosity was studied initially. This approach was not altogether fruitful, for it was necessary to compare the viscosity—composition curve with the calculated or experimental curve for the same components forming an ideal mixture. The experimental curve then differs from the theoretical curve (ideal mixture), and the interaction of the components can be assessed from the magnitude and character of the deviations. Such approach is known to be fruitful for investigating the vapour pressure over mixtures of liquids of low molecular weight.

The situation is more complicated with polymer mixtures in solution, since in several cases the theoretical property—composition curve can be plotted only for very dilute solutions. For a long time the experimental curves were compared with straight lines connecting the properties of the individual components, which cannot be accepted as justified, since most properties—especially mechanical—are not represented by these lines even in ideal mixtures[70].

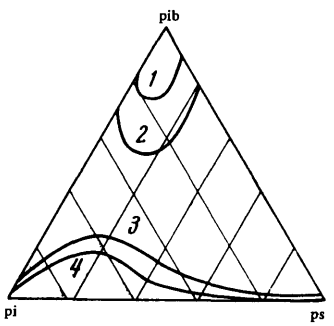

Figure 7. Miscibility diagram at 25°C for solutions of polyisobutylene (pib), polyisoprene (pi), and polystyrene (ps) in chloroform with different total concentrations (g/100 ml) of polymers in solution: 1) 2.5; 2) 2.25; 3) 2.25; 4) 2.5.[68]

It is very important here to examine the units in which the composition of the mixture is expressed and the quantity used to measure the given property. In fact Arrhenius long ago suggested, for the viscosity of binary liquid mixtures, the empirical formula[71]

$$\ln \eta = N_1 \ln \eta_1 + N_2 \ln \eta_2 \qquad (14)$$

where N_1 and N_2 are the mole fractions of the components, and η_1 and η_2 the corresponding viscosities. Although this formula is quite approximate, it nevertheless shows that viscosity is not an additive function of composition, but its logarithm varies linearly with mixture composition. For a polymer mixture this formula agrees with experiment only in the region of small concentrations[72].

Calculation of the composition dependence of a particular property can sometimes be usefully based on its dependence on molecular weight, since the molecular weight of a mixture is the mean of those of the components. Thus the calculation[73] of the dependence of the specific viscosity of a solution on the ratio of the polymers showed that mixtures of solutions of polyethylene fractions are not "ideal" even at low concentrations.

The intrinsic viscosity of solutions of polymer mixtures is given by the simple formula[74-78]

$$[\eta]_{m.} = x[\eta]_1 + (1-x)[\eta]_2 \qquad (15)$$

where x is the fraction of component 1 by volume[74-76] or by weight[77,78].

The specific interaction in solutions of polymer mixtures of finite concentration, at which unlike macromolecules interact, could be estimated if the ideal behaviour of the mixture were known. Thus several attempts were made to describe the theoretical specific viscosity η_{spm} of a solution of a mixture[73,79-81]. Krigbaum and Wall[79] suggested the formula

$$\eta_{spm} = [\eta]_1 c_1 + [\eta]_2 c_2 + b_{11} c_1^2 + 2\sqrt{b_{11} b_{22}}\, c_1 c_2 + b_{22} c_2^2 , \qquad (16)$$

$$b_{12} = \sqrt{b_{11} b_{22}} , \qquad (17)$$

where b_{11} and b_{22} are parameters of interaction between the like macromolecules, and b_{12} is the parameter of interaction between unlike macromolecules. An analogous equation, differing only in the expression for b_{12}, was proposed by Catsiff and Hewett[80]:

$$\eta_{spm} = [\eta]_1 c_1 + [\eta]_2 c_1 + b_{11} c_2^2 + (b_{11} + b_{22}) c_1 c_2 + b_{22} c_2^2 , \qquad (18)$$

where

$$b_{12} = \frac{b_{11} + b_{22}}{2} . \qquad (19)$$

Cragg and Bigelow[81] obtained a theoretical formula for the Huggins constant k' for a binary polymer mixture in solution and a theoretical value for the viscosity of the mixture:

$$\frac{\eta_{spm}}{c} = \frac{[\eta]_1 c_1 + [\eta]_2 c_2 + k_1' [\eta]_1^2 c_1^2 + k_2' [\eta]_2^2 c_2^2 + 2\sqrt{k_1' k_2'}\,[\eta]_1 [\eta]_2 c_1 c_2}{c_1 + c_2} . \qquad (20)$$

If the interaction parameter is taken to be $b = k'[\eta]^2$, this relation proves to be analogous to the Krigbaum—Wall equation.

These workers[79,80] propose that the difference between experimental and theoretical values of the parameter $\Delta b_{12} = b_{12,\,exp} - b_{12,\,theor}$ should be taken as a measure of the affinity of the polymers in solution.

Wright and Williamson[82] compared the two methods for calculating b_{12}, and considered that far better agreement between theory and experiment is obtained by substituting the arithmetic mean value of b_{12} in the appropriate equations.

The parameter Δb_{12} has recently been used to assess the compatibility of polymers in solution, and results have been obtained[41] coinciding with the estimate obtained from phase separation. Other workers[83] have shown that the range of compatibility of polymers can be established by means of Δb_{12}, but they regard the possibilities of the method as limited.

It is still impossible to calculate the composition dependence of viscosity (or a related quantity) at sufficiently high mixture concentrations. In some cases definite information can be obtained on the structure of a mixture of polymers in solution and on the intensity of their interaction by analysing the viscosity—composition curve itself, without comparing it with the curve for an ideal mixture[84,85].

Finally, it must be borne in mind, when plotting a property—composition graph, that the polymer macromolecules have different effective volumes in the solvent and in the mixed solutions. Mixing solutions of polymers in a common solvent usually involves an increase in the coil volume of that polymer which has the greater affinity for the solvent. It is then obvious that the true volume fraction of this polymer in the mixture will be larger than that calculated from the ratio of the initial volumes of solutions of equal concentration. The real volume ratio of polymers in a solution of their mixture has recently been allowed for[86].

IV. FACTORS INFLUENCING THE LIMIT OF PHASE SEPARATION

The more highly concentrated the solution of a polymer mixture at which it separates into layers, the broader the range of existence of thermodynamically stable single-phase systems. Although a polymer mixture is stable for an unlimited time in the absence of a solvent, and phase separation is prevented by the high viscosity of the components, the viscosity of solutions is usually sufficiently low for phase separation to occur quite rapidly and to be easily noticeable. Therefore study of the dependence of the phase-separation limit on various external and internal factors is an indirect method for assessing the effect of these factors on the compatibility of polymers in the block (in the absence of a solvent), where such estimates are very difficult. An investigation of this type is also of intrinsic scientific value in connection with the use of polymer mixtures as a common solution[87] for subsequent processing. The phase-separation limit of a solution of a polymer mixture can in principle be affected by the factors—(*a*) nature and structure of macromolecules, (*b*) proportions of polymers in mixture, (*c*) molecular weights of polymers and molecular-weight distribution, (*d*) type of solvent, (*e*) temperature, (*f*) shear stress, and (*g*) additives—which will be examined below.

(*a*) Nature and Structure of Macromolecules

A pair of polymers in solution can be regarded as compatible or incompatible depending on the concentration. The higher the phase-separation limit the higher the mutual affinity of the polymers, as is shown by experience, and the greater the compatibility of the polymers, it is usually supposed. However, the phase-separation limit of a mixture in solution is only a particular qualitative indication of the mutual solubility (compatibility) of the polymers. No comparison has been made of this limit or of its variation with the true solubility of the polymers in the absence of a solvent.

Analysis of published information shows[45,88,89] that solutions of polymers are usually mixed to establish the actual fact of their compatibility or incompatibility, without relating the phase-separation limit with their nature and structure. Polymers of apparently similar polarity, whether a mixture of two polar or two non-polar polymers, and also those differing strongly in polarity—a combination of polar and non-polar polymers—have been found to be incompatible[88,89]. Moreover, the incompatibility has been established of polymers of the same chemical nature, differing in the stereochemistry of the monomer units (the position of substituents[11,13]) or in the degree of chain branching[10,90]. Thus Kern[13] found that polymeric *o*- *p*-, and *m*-methylstyrenes were incompatible. Rylov and Karpov[12] observed mutual insolubility of natural rubber and gutta-percha, which are *cis*- and *trans*-isomers. Attempts were made to correlate the phase-separation limit with the structure of the polymers. Dobry and Boyer-Kawenoki[45] were unfortunately unsuccessful: no definite rule could be established.

In order to elucidate the effect just of the structure of the polymers, all factors influencing the phase-separation limit must be maintained constant, and only the chain structure of the macromolecules varied. This is an extraordinarily complicated task, since it is especially difficult to select polymers of the same molecular weight. Fuchs[11] was faced with this problem in studying the effect of the structure of polymethacrylates and polyacrylates on the limit. He determined the limit in benzene of solutions of mixtures of polyacrylates (methyl, ethyl, and n-butyl) with one another, mixtures of polymethacrylates differing in the length of the alkoxyl side-chain (methyl, ethyl, n-butyl, isobutyl, and hexyl), and also mixtures of polyacrylates with polymethacrylates, and compared the results with the difference in the number of carbon atoms in the monomer units of the mixed polymers. Unfortunately, the molecular weights were not always the same or even close, but nevertheless a general tendency could be established. A difference of one carbon atom, whether in the main chain or in a side-chain, was sufficient for the polymers to become incompatible. Thus poly(methyl acrylate) separated from poly(ethyl acrylate) and from poly(methyl methacrylate) in solution. Moreover, solutions of mixtures of poly(isobutyl methacrylate) with poly-(n-butyl methacrylate) separated into layers. The phase-separation limit fell with increase in the difference in the numbers of carbon atoms in the monomer units of the mixed polymers. Unfortunately, these rules were not verified on binary mixtures of two polymers in the absence of a solvent.

The effect of the degree of branching of the macromolecules on the phase-separation limit has also been studied[90].

(*b*) Proportions of Polymers in Mixture

The theoretically calculated binoidal separating the single-phase from the two-phase region in Fig. 2 shows that increasing the content of one of the components raises the phase-separation limit. This applies also to unsymmetrical diagrams. Regions having a low content of one of the polymeric components have in general been little investigated. Moreover, it has been noted several times[70,85,91] that phase separation does not take place when the mixture contains 10% of one of the polymers. This conclusion is probably due to the technique used to study the phase separation of solutions: solutions of the same concentration, deliberately exceeding the phase-separation limit for a 1 : 1 mixture, were always mixed in various proportions. But this concentration might be insufficient for the mixture to separate into layers when the content of one of the polymers is small.

A correct choice of technique enabled the Reviewers[92] to observe phase separation in a mixture of polyisobutylene with only 0.4% of polystyrene. It is quite obvious that the compatibility of a solution of one polymer with a solution of another depends on the total polymer concentration, and diminishes with increase in the total concentration of the solutions taken.

(*c*) Molecular Weights of Polymers

Dobry and Boyer-Kawenoki[45] were long ago able to establish qualitatively that the higher the molecular weight the lower the concentrations at which solutions separate into layers. Theory also predicts a decrease in mutual solubility with increase in the molecular weight of polymers.

The effect of molecular weight on the phase-separation limit has repeatedly been examined experimentally, and this usually ended in establishing empirical relations

unconnected with theory. Berek et al.[93] found the relation—later confirmed[94]—between the critical phase-separation concentration c_c and the molecular weights of the polymers

$$c_c = A(\bar{M}^+)^{-2/3} + c_\infty , \quad (21)$$

where $\bar{M}^+ = (M_i M_j)^{0.5}$ is the geometric mean of the molecular weights, M_i and M_j are the molecular weights of polymers i and j, and A and c_∞ are constants for a given pair of polymers. This equation applies in effect both to monodisperse and to relatively polydisperse polymers. Only when a combination of polymers is investigated whose molecular weights differ very markedly, and for which the conditions $\chi_{12} - \chi_{13} < 1$ and $x_2^{0.5} < x_3 < x_2^2$ are not satisfied, do the values of c_c depart from a linear dependence on $(\bar{M}^+)^{-2/3}$.

Berek's equation is similar to an equation proposed by Kuhn et al.[95]. Later results[29] indicate that the dependence of c_c on the molecular weight of polystyrene in the ternary system with poly(methyl methacrylate) and benzene is given by the equation

$$1/[\eta]_{nc} = a_1 \ln(c_c v_{av.}) + f(\bar{M}_{w_{nc}}) , \quad (22)$$

where v_{av} is the mean specific volume of the polymer, and a_1 and f are constants. An analogous equation can be written for the dependence of c_c on the molecular weight of the poly(methyl methacrylate).

On the assumption that the phase-separation limit should depend on the molecular weight and the type of solvent, Fuchs[96] suggested the empirical relation

$$\left(\frac{\eta_2}{P_2} + \frac{\eta_3}{P_3}\right) b = k c_3 , \quad (23)$$

where η_2 and η_3 are the specific viscosities of solutions of the polymers (c = 1 g/100 ml), P_2 and P_3 are the degrees of polymerisation of the polymers, and b and k are constants. The validity of this relation was confirmed on several pairs of polymers.

Analysis of the above results shows that decrease in molecular weight of the polymers (over the range investigated) was always accompanied by a rise in the phase-separation limit: i.e. the concentration range in which the solution consisted of a single phase increased.

(*d*) Type of Solvent

Theory regards the solvent as a simple diluent, which merely shifts the phase-separation limit.

Experimentally, Bristow's choice of solvents[47] was very unfortunate, one being a good solvent for both polymers, whereas the other was in our opinion a poor solvent, again for both polymers. He did not explain the effect of this quality on the symmetry of the phase diagrams, because he did not evaluate the quality, but simply started from the similarity in structure between solvent and polymers. At the present time no definite criterion of solvent quality is available, although certain properties of the solution have been correlated with solvent quality by Schulz[97] and by Tager[98,99]. As a consequence of the lack of a sensitive criterion for estimating the affinity of a solvent for a polymer, each worker has used his own criterion for assessing the quality of a solvent in investigating the effect of type of solvent on compatibility.

Kern[36] judged the quality of a solvent from its solubility parameter δ. He compared the parameters of various solvents with those of the mixed polymers, and observed maximum compatibility in solvents whose solubility parameters were closely similar to those of the polymers.

Fuchs[96] investigated the compatibility of polystyrene with poly(vinyl acetate) in eighteen solvents, in whose choice he was guided by the solvating power assessed from the viscosity of solutions of concentration 1 g/100 ml, which introduces some arbitrariness, as it would have been more reliable to base the comparison on the intrinsic viscosity. He determined the empirical relation (23), which indicates that the poorer the solvent (the lower the viscosity) the lower the concentration at which solutions separate into layers. This conclusion has been confirmed[27] on mixtures of widely varying composition, the quality of a solvent with respect to the polymers being judged from the intrinsic viscosity.

An explanation for the phase separation of a polymer mixture at lower solution concentrations the poorer the solvent is that polymer—solvent interaction is slight in poor solvents, so that polymer—polymer interaction increases. Deterioration in the quality of the solvent in the solvent—polymer—polymer (1—2—3) system involves an increase in the size of 2—2 and 3—3 polymeric association complexes. This size must probably reach a certain critical value for phase separation to ensue, and this occurs at a lower concentration in poor solvents because of the greater tendency of polymers to associate in such solvents.

Hugelin et al.[53] proposed that the affinity of a solvent for a polymer should be assessed by the constant α in the Kuhn—Mark—Houwink equation $[\eta] = kM^\alpha$, characterising the shape of the polymer coil, which varies with swelling. The phase-separation limit rises as the difference between the constants of the mixed polymers becomes smaller, except in poor solvents for both polymers. This is inconsistent with the results[27,96] indicating that the compatibility of polymers in solution diminishes as the quality of the solvent becomes worse. A poor solvent for both polymers should correspond to a small difference $\alpha_2 - \alpha_3$ and a low phase-separation concentration. Hugelin's equation evidently applies only to systems containing a good solvent for one or both polymers.

Sometimes homogeneous films can be obtained from a mixture of incompatible polymers by suitable choice of solvent. Thus Thies and his coworkers[100,101] obtained transparent and turbid films respectively of a mixture of polystyrene and poly(methyl vinyl ether) from solutions in toluene and in chloroform. The temperature dependence of the slope of the mechanical-loss curve indicates some microheterogeneity of the transparent films (one intermediate loss peak), but from the results there is no doubt about the strong effect of the nature of the solvent on the structure of the film.

(*e*) Temperature

Varied views have been published on the effect of temperature on phase separation. Several workers state that temperature has either almost no effect[62,63] or a very slight effect[28,45] on the phase-separation limit of solutions. Flory's theoretical calculation[22] of the thermodynamic functions of the mixing of polymers has also shown their independence of temperature. Other work[36,100] shows that temperature plays a considerable part, influencing the flexibility of the polymer molecules and also their solvation. Thus Kern[36] found that a mixture of polystyrene and poly(methyl methacrylate) in *o*-xylene separates into

layers at 25°C, and becomes a single phase at 85°C. In methoxybenzene, however, this mixture was homogeneous at 25°C, and separated at 85°C. A similar phenomenon was observed by Purcell[100] with a mixture of chlorinated rubber and an ethylene—vinyl acetate copolymer: the mixture was compatible at 25°C, but separated into layers with rise in temperature.

Available experimental results show that both lower and upper temperatures of mixing can exist in solutions of polymer mixtures, as in solutions of individual polymers. The more distant a solution from both consolute temperatures the less marked the effect of temperature on its phase constitution. Systems having a lower consolute temperature are evidently not a rarity among solutions of polymer mixtures. The desirability of further experimental investigation in this field is self-evident.

(*f*) Shear Stress

The phase-separation limit of solutions of polymer mixtures has been found experimentally to depend on the rate of stirring of the solution. Detailed studies have been made[86,102-104] of the effect of the rate of shear on the phase composition of a mixture of polymers in solution.

Silberberg and Kuhn showed[102] that, if the polystyrene—ethylcellulose—benzene system is subjected to shear, solubility of the phases equivalent to 15% dilution can be achieved at a certain rate of shear. The changes observed under the influence of a shearing force are completely reversible, in contrast to those occurring on dilution: the system again separates into layers immediately stirring ceases. Drops of an emulsion undergo deformation and breakdown in a field of mechanical shear stresses. Diminution in the size of the drops is associated with the accumulation of free energy in the system. The reverse phenomenon—coalescence and enlargement of the drops—accompanies the tendency of the free energy to decrease. Homogenisation depends on the relative rates of the two processes—destruction of the drops and their coalescence.

A more detailed investigation has shown[86,103] that, with increase in the shear stress, the phase-separation limit rises only to a certain limiting value, after which it ceases to depend on the shear stress. Thus c_2 in the polystyrene—polyisoprene—decalin system at 20°C increases from 10.5% to 12.5% with increase in the shearing stress ($\lg \tau$) from 1.2 to 2.9 dyn cm^{-2}, after which it ceases to depend on the stress.

Any pair of polymers can in principle be combined under shear, i.e. converted into a single-phase system, provided that the supermolecular structures in both polymers can be destroyed. Under these shear conditions in solutions of polystyrene and polyisoprene, however, the viscosity did not even reach that with limiting breakdown of the structure, which is indirect evidence of association of the macromolecules of each polymer in the system. This gave rise to the following explanation.

Previous Sections of the Review have mentioned that the macromolecules of polymers are incompatible, while their segments may be compatible, so that an intermediate layer is present at the boundary between the polymer phases. This layer is quite large in the absence of a solvent[105], and obviously becomes larger on addition of a solvent. As a consequence of the subdivision of droplets of a two-phase system under shear, their radius becomes close to the thickness of the transition layer even in the presence of comparatively coarse drops (according to Kuhn[102] amounting to micrometres or fractions of a micrometre). The system thus becomes a single phase while association of like macromolecules is preserved.

The above results must be taken into account in determining consolute temperatures and concentrations. Stirring the solution may lead to a change in the critical parameters, especially in very viscous systems.

(*g*) Additives

The compatibility of polymers in their mixed solutions can be influenced by additives of low molecular weight[84,91,106-108]. There is no generally accepted view on the mechanism of their action. Voyutskii et al.[84] attributed the action of polar additives—alcohol and acetone—on a mixture of solutions of poly(vinyl chloride) and a butadiene—styrene copolymer to the blocking of polar groups in the polymers by the additives. But this explanation did not fit the observed effect of methanol and acetone on a mixture of non-polar polymers[91]. Lipatov[106] explained the elimination of phase separation in solutions of polystyrene and poly(vinyl acetate) on the introduction of acetone by aggregation of the molecules and a change in their shape. However, Hunyar and Weisner[107], who investigated the effect of several simple substances on the poly(vinyl chloride)—cellulose nitrate—acetone system, found that phase separation was delayed by substances of higher surface tension than acetone or whose solutions in acetone possessed a higher surface tension than acetone itself. No quantitative relation was established between the concentration of additive eliminating phase separation and its surface tension.

Kuleznev and Igosheva[108] examined the effect of 23 additives representing various classes of chemical compounds on a polystyrene—poly(methyl methacrylate)—benzene mixture, and found that the phase separation of 9% solutions is completely eliminated by dimethylaniline, heptanol, and pentanol. There was no direct relation between the action of the additive and its surface tension, dipole moment, dielectric constant, or heat of evaporation.

We conclude by considering the action of copolymers and block copolymers on the phase separation of a mixture of the corresponding homopolymers[109,110]. There are no data to show that random copolymers or block copolymers raise the phase-separation limit of a mixture of homopolymers in solution. Block copolymers are stabilisers of the incipient emulsion of type "polymer A solution—polymer B solution". The size of the blocks controls that of the emulsion droplets[109,110]. Molau considers that a block copolymer acts as an emulsifier, forming a protective layer preventing adhesion of the drops of emulsion. We can hardly regard such explanation as satisfactory. Unlike blocks of the copolymer most probably form in a solution distinctive domains or, by analogy with soaps, micelles, in which the corresponding homopolymers undergo solubilisation, as is observed in the solubilisation of hydrocarbons in solutions of surface-active substances. Because the blocks are chemically combined in the block copolymer, and it is obviously impossible to separate the whole quantity of the latter into two macrophases, the emulsion remains stable. In our opinion it is also wrong to think that the effectiveness of a block copolymer is due merely to lowering the surface tension of drops of solutions of the homopolymers: the interfacial tension here by itself is negligible[111,112].

V. SOME ASPECTS OF THE TRANSITION OF A ONE-PHASE INTO A TWO-PHASE SOLUTION

The transition of a one-phase into a two-phase system has always been a central problem of colloid chemistry. Such a transition can conveniently be investigated on solutions of polymer mixtures, because the transition is produced by increasing the solution concentration: when a certain concentration c_2 is reached, the system separates into two layers—a solution of the less dense polymer above a solution of the denser polymer. The transition takes place here without change in chemical composition of the system, in particular without the addition of surface-active agents.

Very scanty data are at present available on the properties of a solution of a polymer mixture in the region of phase separation. In effect they relate only to the investigation of viscosity and light scattering[72,103,104,113].

The optical density of a system usually increases sharply in the vicinity of the phase-separation point, to reach a maximum at the instant of separation. After this the light scattering diminishes appreciably owing to the increase in size of the scattering particles and the non-monotonic variation in scattering with particle size.

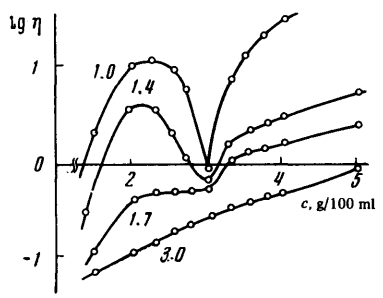

Figure 8. Dependence of viscosity on concentration of toluene solution of 1 : 1 polystyrene—polyisoprene mixture. The numerals on the curves indicate the shear stress ($\lg \tau$, dyn cm^{-2}) at which the solution was deformed.

The viscosity—concentration curve passes through a maximum before phase separation ensues. Fig. 8 shows such relations for different shear stresses[104]. Minimum viscosity corresponds to transition into a two-phase system. The minimum levels out with increase in shear stress, and at high stresses the viscosity increases monotonically with concentration: transition into a two-phase system is accomplished gradually over a wide concentration range.

The Reviewers accept the explanation that a polymer mixture may pass through a metastable region during the transition from a true solution into a rapidly separating two-phase system[57]. The region of metastable states may evidently be quite large in polymers, especially in view of their broad molecular-weight distribution. The structure of a polymer or its solution in the critical region has not yet been finally elucidated, and we can only make certain suggestions here. It is entirely possible that such compression of macromolecular coils or ordering of supermolecular structures occurs in this region that the viscosity decreases considerably. The possibility of such rearrangement is mentioned by Eskin[114], who calculated that the size of the macromolecular coils of a polymer is smaller by factors of 1.5—7 at the consolute point than at the θ-point.

Thus the most probable cause of the decrease in the viscosity of a solution of a polymer mixture in the region of phase separation is evidently the transition of the system into a special critical metastable state[115]. With increase in the variation in the shear stress, of course, fluctuating structures break, and separation of the solution into phases takes place gradually over a wider concentration range.

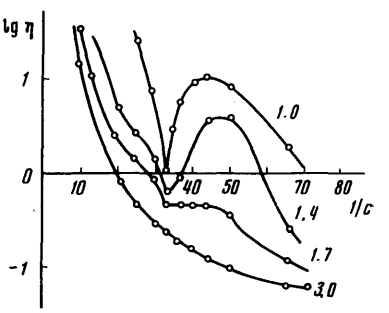

Figure 9. Dependence of viscosity of toluene solution of 1 : 1 polystyrene—polyisoprene mixture on the dilution $1/c$. The numerals on the curves indicate the logarithms of the shear stresses at which the solution was deformed.

It is interesting that the dependence of the logarithm of the effective viscosity on the dilution of the solution is represented by a family of curves (Fig. 9) resembling the isotherms of a real gas. The dilution axis expresses the volume occupied by 1 g of polymer, and the ln η axis can, though very arbitrarily, be compared with the pressure axis in a gas: like the pressure, the viscosity of a solution reflects the intensity of interaction of solute molecules. The function of different temperatures is filled here by different shear stresses, which, like the temperature in a gas, lead to the breakdown of association complexes. The greater the shear stress in a solution (or the temperature in a gas), the closer is the system to ideal. It is curious that the whole isostress line (line of equal shear stress), including the portion along which viscosity increases with dilution, can easily be obtained for a solution: the isotherm of a gas in the corresponding region (rise in pressure with increase in volume) cannot be obtained experimentally.

A decrease in the viscosity of a solution of a polymer mixture in the precritical region can be obtained also when the volume of one of the separating phases is very small. Thus the viscosity of a solution of a mixture of polystyrene and polyisoprene in decalin falls in the precritical range even when the quantity of polystyrene phase being formed is 2% of the total volume of the solution. This shows how specific is the interaction of polymers. This phenomenon can appropriately be compared with the effect of interstructural plasticisers on the viscosity of polymer melts[116]. It is significant that, in contrast to such plasticisers, the

addition of a solution of another polymer more viscous than the original solution may lower its viscosity. This is not due to a plasticising effect in the usual sense, but to the creation of conditions for transition into a special pre-critical state, in which the system as a whole has diminished viscosity.

VI. TWO-PHASE SOLUTIONS OF POLYMER MIXTURES

Insufficient study has been made of the structure and properties of solutions of polymer mixtures above the phase-separation concentration, which is easily understood from the instability of such systems with time. Two lines of information—the distribution of polymers and solvent in the separating phases and the rules of variation in interfacial tension between these solutions—are worthy of attention in this field.

Mixing solutions of different polymers in a common solvent, at a concentration above the phase-separation limit, produces a turbid emulsion of a solution of one polymer in a solution of the other polymer. The mixture is unstable: with time it gradually becomes clearer, and ultimately the mixture separates into two layers, between which a distinct boundary is visible. One of the layers is frequently more turbid than the other, and retains a cellular structure. The cause of the enhanced turbidity of one of the layers has not been studied. Each layer contains predominantly one polymer—the denser polymer in the lower layer, and the less dense in the upper layer.

The stability of a two-phase mixture of polymer solutions depends on the total concentration of polymers in solution, the composition of the mixture, and the temperature, as has been studied in detail by Mikhailov and his coworkers[117-119]. The stability was assessed visually from the appearance of an interface. The mixture became more stable with increase in concentration of the solutions, owing to the increase in viscosity. It had early been shown[45] that temperature has the opposite effect: it increases the rate of phase separation.

Theory predicts that each layer should contain predominantly one polymer, except in the vicinity of the critical phase-separation concentration. Each layer must contain a small amount of the second polymer. According to Scott's theory[7] complete incompatibility is possible only with very large interaction parameters or at high solution concentrations. At high concentrations, however, the kinetic stability, which is due to the high viscosity, increases strongly, and the establishment of equilibrium is retarded.

A detailed study of the composition of the layers was made on the polystyrene—atactic polypropylene—toluene system by Berek[28], who determined the concentration dependence of the polypropylene content of the mainly polystyrene lower layer, beginning from tenths percent above the critical concentration. Near the consolute concentration the polystyrene layer contained ~50% of polypropylene. With increase in concentration of the solutions the polypropylene content of the layer dropped sharply, to reach a value (4—5%) which remained almost unchanged with further variation in concentration. Calculation of the interaction parameter by means of Scott's equation showed that χ_{23} fell asymptotically with increase in concentration.

At first glance this contradicts Alekseenko's observation[120], on the system comprising polyethylene and a butadiene—styrene copolymer in a common solvent, that both polymers pass into the lower layer, only 4.8% of the copolymer remaining in the upper layer, whereas theoretically the latter should contain polyethylene. The probable reason is that polyethylene, which is sparingly soluble in the solvent at low temperatures, becomes insoluble in the presence of the second polymer, and is precipitated into the lower layer. The action of a second polymer in worsening the quality of a solvent for an initial polymer is well known[29,61-63].

On the basis that each layer contains predominantly one polymer, a method was proposed for determining the molecular weight of a polymer from the ratio of the volumes of the solutions resulting from separation of its mixture with a polymer of known molecular weight[45,106]. It was assumed that, when the two separated solutions are in equilibrium, the two phases have the same osmotic pressure. If each phase contains only one polymer, and the osmotic pressure is proportional to concentration, the molecular-weight ratios should approximate to the ratio of the concentrations of the polymers in the layers or to the ratio of the layer volumes. However, this method has not found application, since it does not allow for incomplete separation of the polymers, especially appreciable with polydisperse systems, and also disregards the effect of the nature of the solvent on the volume ratio. However, it may be of interest for a systematic estimation of molecular weight for a homologous series of polymers.

Lautout-Magat[121] made a general calculation of the partition coefficient of the solvent between the phases. The calculation was tested only on two polymer mixtures in solution.

Little study has been made of the establishment of equilibrium between the phases and of their composition. Available experimental results often concern only isolated aspects, and do not cover the phenomenon as a whole. For example, it was found[111] that, when solutions of the same concentration were mixed, the equilibrium concentration of the upper layer far exceeded those of the lower layer and of the initial solutions. However, no analysis was made of the composition of the polymer layers.

Hyde and Tanner[65] made an extremely interesting observation on the stability of the separated solutions resulting from mixing solutions of polystyrene and polyisobutylene in cyclohexane at 30°C, which is 4—5 deg below the θ-point of polystyrene in this solvent. Solutions of the mixtures were stable for several hours, and more concentrated solutions for several days. The polystyrene molecules were regarded as retaining the same ability to aggregate and be precipitated as in the absence of the other polymer, but their aggregation occurred extremely slowly in the mixture, as the solution contained polyisobutylene molecules.

The most important parameter characterising the properties of any two-phase system is its interfacial tension. As early as 1952 it was suggested[102] that a polymer—polymer—solvent system has a low value, because droplets of a solution of one polymer break down in a solution of another polymer at very low velocity gradients.

Among the first experimental determinations[111,112] were measurements of the interfacial tension between solutions of poly(vinyl acetate) and poly(vinyl chloride) in ethyl oxalate[111]. Two capillaries of different diameters were placed at the interface, and the tension was calculated from the difference in liquid levels in them. The extraordinarily low value of 10^{-3} dyn cm^{-1} was observed.

Interfacial tension has been determined also by the sessile drop method[112]. A drop of a solution of one polymer was forced out on to a solid support into a solution of

the other polymer. The interfacial tension could be calculated from the shape of the drop. At the interface between polystyrene and polyisobutylene solutions the tension was so small that the drop spread all over the support, and a considerable proportion was spontaneously dispersed in the surrounding solution of the other polymer.

Vrij[122] calculated the surface tension theoretically. The calculation of interfacial tension is formally similar to Debye's calculation of the scattering of light by polymer solutions near the consolute temperature. Vrij confirms directly that the two phenomena—separation of an individual solution of a polymer into layers at a critical temperature and phase separation of a mixture of solutions of incompatible polymers—are similar. The equation which he deduced is valid only for a symmetrical system, containing polymers of the same molecular weight. The calculated[122] interfacial tensions were of the same order of magnitude as the experimental values[111].

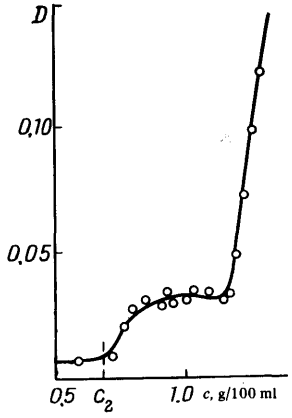

Figure 10. Dependence of optical density D on concentration c of toluene solution of polystyrene—polyisobutylene mixture.

The earlier work[112] was later continued[92] by measurements of the interfacial tension between solutions of polystyrene and polyisobutylene by means of two capillaries. With this pair of non-polar polymers, as with polar polymers[111], the interfacial tension tended to zero at c_2, and increased with increase in the concentration of the solution and in the molecular weight of the polymers. Values fluctuated within the range 0.01—0.001 dyn cm^{-1} depending on these two factors. Extrapolation to 100% concentration (absence of solvent) gave the interfacial tension between polystyrene and polyisobutylene as ~1 dyn cm^{-1}, the first experimental value of the interfacial tension between non-polar polymers of high molecular weight.

The low surface tensions can easily be explained by the presence of a considerable transition layer at the interface, resulting from the segmental solubility of polymers discussed in Section II.

Liquids of low interfacial tension are capable of spontaneous emulsification[123,124], when the increase in entropy of the system produced by dispersion exceeds the increase in surface [free] energy, so that the process occurs under the influence of the thermal motion and terminates in the formation of a thermodynamically stable two-phase system. This requires that the interfacial tension must have been <0.1—1.0 dyn cm^{-1}. Spontaneous mutual emulsification of polymers obviously cannot be observed in the absence of a solvent, owing to the high viscosity of the mixture. Nevertheless, the low polymer—polymer interfacial tension is one of the main reasons for the high operational compatibility of polymers[125].

Spontaneous emulsification of a drop of a solution of one polymer in another was observed as long ago as 1967,[112] and has since been studied in greater detail[92] on solutions of polystyrene and polyisobutylene. If a layer of a solution of the latter polymer is carefully placed on a solution of polystyrene, after a few weeks the upper layer will contain not only polyisobutylene but also 4.5—5% of polystyrene. The layer has become cloudy, and under a microscope drops of diameter 0.5—3 μm are visible. However, if the solutions are mixed, the concentration of the emulsion of the polystyrene solution in the upper layer is about 10% (weight of polystyrene to weight of polyisobutylene) after phase separation. Formation of a stable spontaneous emulsion in a polymer—polymer—solvent system can be observed also from the concentration dependence of optical density (Fig. 10), where the appearance of a stable emulsion corresponds to a horizontal portion on the curve.

The results explain the turbidity[45] of one layer after phase separation of a solution of a polymer mixture: it is due to formation of a stable emulsion of one solution in the other. It is interesting that, for a given pair of polymers in a common solvent, the cloudiness of the layer is determined by the viscosity ratio of the solutions: after phase separation the more viscous layer is turbid (Table 2).

Table 2. Phase separation of mixtures of solutions of polystyrene (ps) and poly(methyl methacrylate) (pmma) in a common solvent.

Mol. wt. M_w		Solvent	Parameters of true solutions			Cloudy layer
ps	pmma		c, g/100 ml	η, cP	η, cP	
$3.9 \cdot 10^5$	$0.87 \cdot 10^5$	benzene	20.0	604.4	37.5	upper
$3.9 \cdot 10^5$	$0.87 \cdot 10^5$	chloroform	20.0	536.8	33.0	upper
$3.9 \cdot 10^5$	$0.87 \cdot 10^5$	butyl acetate	20.0	495.2	27.2	upper
$3.9 \cdot 10^5$	$30.9 \cdot 10^5$	benzene	17.0	31.2	9 978	lower
$3.9 \cdot 10^5$	$30.9 \cdot 10^5$	chloroform	7.0	34.5	22 962	lower
$3.9 \cdot 10^5$	$30.9 \cdot 10^5$	butyl acetate	4.0	5.3	5 008	lower

The upper (polystyrene) layer is cloudy if its viscosity exceeds that of the poly(methyl methacrylate) solution; the lower layer becomes turbid if, owing to increase in molecular weight of the poly(methyl methacrylate), its viscosity exceeds that of the polystyrene solution. The effects of viscosity and the structural parameters of the polymers on the formation of stable emulsions is of great interest and requires further investigation.

Thus the vast majority of polymers are incapable of unlimited mutual dissolution, either in the presence or in the absence of a solvent. Segmental solubility occurs at the interface in their mixture, with a fall in interfacial tension to a negligible value. The low interfacial tension results in the spontaneous dispersion of a solution of one polymer in a solution of another; this is responsible for the high operational stability of a binary mixture of polymers. Within a certain concentration range below

the phase-separation limit, polymers in solution form a single-phase system generated by association complexes of macromolecules of the same chemical nature, the degree of association being greater than in a solution of the individual polymers of the same concentration. The association of macromolecules begins at the concentration c_1 and reaches a limit at the phase-separation point c_2; the degree of association is determined by the reduced concentration in the range c_1-c_2. The value of c_2 can be varied, and the concentration limits of single-phase mixtures increased, by varying the temperature, shear stress, nature of solvent, etc. The structural peculiarities of solutions of polymer mixtures lead to a sharp drop in viscosity in the concentration range directly preceding phase separation.

Further development of research on the theoretical and experimental thermodynamics of polymer mixtures is required, as a basis for comparing the interaction parameters of unlike polymers in solution and in the block.

Preparation of *N*-Substituted Thiourea

V.V.Mozolis and S.P.Iokubaitite

Results on the preparation of *N*-substituted thioureas by the reaction of organic isothiocyanates with compounds containing an amino-group, by the action of alkali-metal thiocyanates on amine hydrochlorides, and by the treatment of primary and secondary amines with thiocarbonyl chloride or carbon disulphide, published in the Soviet and foreign literature including 1972, are systematically discussed. The reactions of hydrogen sulphide with substituted cyanamides and of thiourea with compounds containing various functional groups are also examined. Certain views are presented on the mechanism of the formation of *N*-substituted thioureas, and the advantages and disadvantages of various methods for their preparation are compared. Practical applications of *N*-substituted thioureas are considered. A list of 247 references is included.

CONTENTS

I. Introduction 587
II. Methods of preparation of *N*-substituted thioureas 587
III. Some aspects of their practical application 591

I. INTRODUCTION

Thiourea is able to give both *S*-substituted and *N*-substituted derivatives. It was therefore thought possible that tautomeric transition into the thiol forms

$$-NH-\underset{|}{C}=S \rightleftarrows -N=\underset{|}{C}-SH$$

occurred in solutions of thiourea and its derivatives. However, the ultraviolet absorption spectra and Raman spectra of thiourea and its mono- and di-phenyl derivatives showed that the thione form was stable both in the crystalline state and in solutions, and no tautomerism was observed[1].

Since the time of the first syntheses of thiourea and its derivatives in the 1860s a vast literature has accumulated. The present Review is therefore restricted to methods of preparation and aspects of the practical application of *N*-substituted thioureas, and ignores metal-substituted derivatives and sulphothioureas. The literature up to 1954 is covered by specialised reviews on the chemistry of thiourea[2] and sulphonylthiourea[3], which emphasise specific aspects of individual methods of preparation and application of thiourea derivatives. The present Review has been guided by these surveys, and includes only a few of the literature sources cited. In every case, however, re-examination of these references has been dictated by a novel approach and the desire to preserve the integrity of the material reported.

The interest taken in thiourea and its derivatives can be explained by their wide applications: they have valuable pharmacological properties, exhibit insecticidal, fungicidal, and nematocidal activity, and are also widely employed as brighteners in the electrodeposition of metals.

II. METHODS OF PREPARATION OF *N*-SUBSTITUTED THIOUREAS

Methods of preparing *N*-substituted thioureas can be divided into six main groups.

1. Interaction of Organic Isothiocyanates with Compounds containing an Amino-group

The method consists in the direct interaction of organic isothiocyanates with compounds containing an amino-group, and can conveniently be used to obtain unsymmetrical thioureas. It can yield 1-monosubstituted derivatives[4-19]

$$RNCS + NH_3 \rightarrow RNHC(S)NH_2$$

1,3-disubstituted derivatives[4-9,11-13,17,18,20-167]

$$RNCS + R_1NH_2 \rightarrow RNHC(S)NHR_1$$

and 1,3,3-trisubstituted derivatives[7,10,17,18,34,35,37,42,49,58,68,77,79,89,105,145,160,168-178]

$$RNCS + R_1R_2NH \rightarrow RNHC(S)N\begin{matrix}R_1\\R_2\end{matrix}.$$

Various compounds containing an amino-group can be used for the preparation of thioureas by this method (Table 1), and various organic isothiocyanates can undergo this reaction (Table 2).

The condensation of organic isothiocyanates with amino-compounds is usually conducted in methanol or ethanol, but other solvents may also be used (Table 3). Papers have recently appeared on the possibility of carrying out the reaction in the absence of a solvent[49,71,83,106,116,140,141,153,164,170,171,176]. The process is

Table 1.

Amino-compounds	Ref.
Ammonia	4—6, 9, 11—19, 105, 154, 164
Chloral-ammonia	116
primary amines	
Saturated aliphatic	4—7, 11—13, 22, 34, 44, 47, 49, 54, 58, 59, 89, 105, 128, 135, 136, 140, 141, 144, 151, 154
Unsaturated aliphatic	16, 151
Aromatic	5, 6, 9—12, 17, 19—21, 23—28, 30—36, 38, 40, 41, 43, 50—57, 69—71, 89, 105, 108, 109, 134, 138—148, 150, 151, 154, 157, 159, 165—167
Heterocyclic	6, 8, 11, 12, 17, 18, 20, 21, 23, 25, 28, 32, 36, 50, 58, 74—80, 82—84, 86, 87, 90, 91, 94—107, 109—112, 115, 117—120, 123, 124, 138, 139, 144, 149—152, 155—158, 167, 171, 172, 177
Carbocyclic	6, 9, 46, 49, 59, 105, 109, 123, 124, 154
secondary amines	
Aliphatic	7, 10, 18, 34, 37, 49, 58, 89, 105, 145, 168, 169, 176
Aromatic	7, 17, 58, 105, 168, 176
Heterocyclic	9, 18, 37, 49, 72, 73, 77, 81, 85 86, 89, 92, 93, 104, 145, 168, 170, 178
Phenetidines	57, 62, 63, 88, 137

Unsaturated carbocyclic	11, 12
Acyl	13, 30, 32, 33, 36, 37, 39, 51, 56, 57, 60—66, 105, 157, 166
Aroyl	13, 57—59, 109, 123, 124, 126, 175
Carbamoyl	145
Cyanoalkyl	128

generally accomplished with cooling or at room temperature, sometimes with heating[4,6,8,9,12,15-17,20,21,23-26,28,30,34,36,38-41,43,44,51,52,55-57,60-63,65,66,70,71,72,74-80,82,83,85,86,88,90-108,111-113,115-117,120-122,125,127,129,134,135,137,140,141,143,144,147,149,151-153,157,158,160,163-165,167,169-171,173,175]. There are also exceptions to the usual equimolecular quantities of the reactants, when excess of the organic isothiocyanate[20,21,23-25,93,98,99,113,117,131] or excess of the amino-compound[5,7,29,48-50,96,104,105,117,170] is taken.

The usual products of the reaction of primary amines with isothiocyanates are unsymmetrical 1,3-disubstituted thioureas. However, there are indications[87,147,171] that the condensation of heterocyclic amines with aryl isothiocyanates gives ambiguous results on more prolonged heating: symmetrical 1,3-disubstituted thioureas are formed together with the unsymmetrical derivatives. Symmetrically substituted thioureas are probably products of secondary reactions of the initially formed unsymmetrical thioureas, cleavage of which leads to the accumulation

Table 3.

Solvent	Ref.	Solvent	Ref.
Acetone	9, 13, 17, 18, 30, 33, 43, 55, 56, 58, 61, 64—68, 109, 111, 117, 129, 130, 134, 135, 140, 157, 159, 164—166, 175	Toluene	32, 80, 92, 93, 131

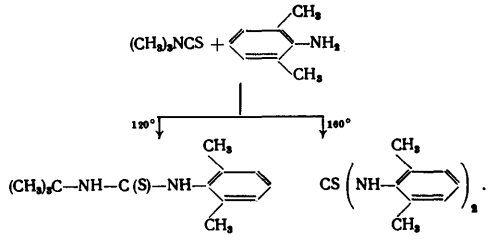
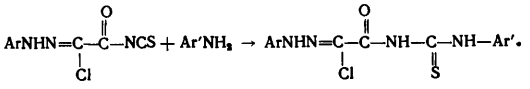
		Water	4, 11, 37, 59, 140

of two different amines and two different isothiocyanates in the mixture, which then yield two symmetrical thioureas:



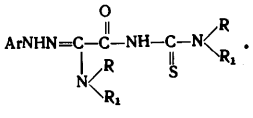
$$RNCS + R_1NH_2 \rightleftarrows \underset{(I)}{RNHC(S)NHR_1} \rightleftarrows RNH_2 + R_1NCS,$$

$$R_1NH_2 + R_1NCS \rightarrow I,$$



$$RNH_2 + RNCS \rightarrow RNHC(S)NHR,$$

The driving force of such changes is provided by differences between the basic strengths of the amines RNH_2 and R_1NH_2 and between the reactivities of amines and aryl isothiocyanates. The proportions of the products depend on the stability of the thiourea derivative formed initially.



Aliphatic isothiocyanates react very slowly with aromatic amines, to form symmetrical or unsymmetrical 1,3-disubstituted thioureas depending on the temperature[140]:

Isothiocyanates of arylazochloroacetic acids react very peculiarly with amines. The isothiocyanate group interacts with the formation of 1-aryl-3-arylazochloroacetylthioureas[67,68]:

Also the chlorine atom is replaced by the amine residue[68] to yield thioureas of the type

2. Reaction of Alkali-metal Thiocyanates with Amine Hydrochlorides

Heating mono- and di-substituted ammonium thiocyanates at 160°C for a few hours brings about rearrangement into thioureas:

$$\underset{(II)}{RR_1NH_2SCN} \rightarrow RR_1NHC(S)NH_2.$$

Such rearrangement is impossible with tri- and tetra-substituted ammonium cations.

This rearrangement is used for the preparation of 1-monosubstituted thioureas[91,179-190]:

$$RNH_2 + HCl + NH_4SCN \rightarrow RNHC(S)NH_2 + NH_4Cl$$

and also 1,1-disubstituted derivatives[191,192]

$$RR_1NH + HCl + NH_4SCN \rightarrow II + NH_4Cl.$$

The method is straightforward, and can be used for aliphatic, aromatic[179-183,185,186,191,192], and heterocyclic[91,186-188] amines, esters of amino-acids[184], and diamines[189,190]. An example of the reaction with a diamine is the preparation of *N*-2′-aminoethylthiourea:[190]

$$KSCN \xrightarrow{5} H_2NCH_2CH_2NH_2 + HCl \rightarrow H_2NCH_2CH_2NH_2^+SCN^- \rightarrow$$
$$\rightarrow H_2NCH_2CH_2NHC(S)NH_2.$$

The reaction of alkali-metal thiocyanates with amines is usually conducted in an inert organic solvent, most frequently chlorobenzene[179,180,182,184] or in aqueous medium[181,183,185,186,189,190]. Other solvents—glacial acetic acid[187,188], methanol[191], and ethanol[191,192]—may also be used. Chlorobenzene is saturated with hydrogen chloride, the appropriate amine and the alkali-metal thiocyanate are added, and the mixture is heated at 110–120°C for a time depending on the nature of the components. When the reaction is conducted in water, hydrochloric acid, the appropriate amine, and a small excess of the alkali-metal thiocyanate are added, and the solution is boiled and evaporated to dryness. The residue is dissolved in an appropriate solvent, and then precipitated with hydrochloric acid. The saturation of chlorobenzene with hydrogen

chloride or the addition of hydrochloric acid to water can be avoided by using the amine hydrochlorides[179,180,182,183,185-189,191,192] or sulphates[180].

The yield of thiourea increases slightly with increase in the concentration of the reactants, but it remains low, since side-reactions occur with the formation of an isothiocyanate

$$RNH_2 + 2HCl + NH_4SCN \rightarrow RNCS + 2NH_4Cl$$

and a symmetrical 1,3-disubstituted thiourea

$$RNCS + RNH_2 \rightarrow RNHC(S)NHR.$$

In the reaction of 1 mole of ammonium thiocyanate with 2 moles of tryptamine hydrochloride, for example, 1,3-di-[2-(5-methoxyindol-3-yl)ethyl]thiourea is obtained[107].

This method can be used to prepare arylthioureas having either electropositive or electronegative substituents, and is considerably more convenient and rapid than the preparation of arylthioureas from aryl isothiocyanates and amines.

3. Reaction of Thiocarbonyl Chloride with Primary and Secondary Amines

Primary amines react with thiocarbonyl chloride to form, depending on their quantity, either isothiocyanates[19,193]

$$RNH_2 + CSCl_2 \rightarrow RNCS + 2HCl$$

or symmetrical 1,3-disubstituted thioureas[193-195]

$$2RNH_2 + CSCl_2 \rightarrow RNHC(S)NHR + 2HCl.$$

Secondary amines form only symmetrical 1,1,3,3-tetrasubstituted thioureas[196]:

$$2RR_1NH + CSCl_2 \rightarrow RR_1NC(S)NRR_1 + 2HCl.$$

In order to prepare thioureas by this method, 1 mole of thiocarbonyl chloride is heated with 2 moles of the amine in an aqueous[193,194] or in an aqueous acetone[195] medium.

The course of the reaction may be

$$RR_1NH + CSCl_2 \rightarrow \underset{(III)}{(RR_1NHClCSCl)} \rightarrow RR_1NCSCl + HCl.$$

If the compound (III) is stable, the reaction

$$III + RR_1NH \rightarrow RR_1NC(S)NRR_1 + HCl \qquad (a)$$

takes place independently of the nature of the radical R_1. If, however, (III) is unstable ($R_1 = H$), a different reaction takes place:

$$III \rightarrow RNCS + HCl,$$
$$RNCS + H_2NR \rightarrow RNHC(S)NHR. \qquad (b)$$

Primary amines are able to react with thiocarbonyl chloride in conformity both with (*a*) and (*b*), but secondary amines can undergo only reaction (*a*). The correctness of this mechanism is supported by the fact that in some cases compound (III) has been isolated from the reaction mixture and identified[196].

Owing to the toxic properties of thiocarbonyl chloride this method is very rarely used—only when other methods do not give the results to be expected, e.g. for the preparation of symmetrically 1,3-disubstituted thioureas containing strongly electronegative substituents.

4. Reaction of Carbon Disulphide with Primary and Secondary Amines

This method is most simply and generally applied to the preparation of symmetrical 1,3-disubstituted thioureas[38,40,52,71,90,97,142,167,182,188,196-208].

$$2RNH_2 + CS_2 \rightarrow RNHC(S)NHR + H_2S$$

Because of the great volatility of carbon disulphide, excess is used over the 1 mole per 2 moles of the amine indicated by the equation. The reaction is complete when the evolution of hydrogen sulphide ceases.

This method can be employed for the preparation of 1-monosubstituted derivatives[182]

$$RNH_2 + CS_2 \rightarrow \underset{(IV)}{RNHC(S)SH},$$
$$RNHC(S)SH + NH_3 \rightarrow [RNHC(S)S]^-[NH_4]^+ \rightarrow RNHC(S)NH_2 + H_2S,$$

unsymmetrical 1,3-disubstituted derivatives[208-210]

$$IV + R_1NH_2 \rightarrow [RNHC(S)S]^-[NR_1H_2]^+ \rightarrow RNHC(S)NHR_1 + H_2S,$$

and 1,3,3-trisubstituted thioureas[142,169,211]

$$IV + (R_1)_2NH \rightarrow [RNHC(S)S]^-[N(R_1)_2H_2]^+ \rightarrow RNHC(S)N(R_1)_2 + H_2S.$$

Carbon disulphide reacts with primary amines—aliphatic[199,202,207], aromatic[38,40,52,71,167,169,182,196-198,200,207,208,211], heterocyclic[39,90,97,167,188,199,201,209,210], and hydroxylamines[208]—to form symmetrical and unsymmetrical 1,3-disubstituted thioureas and with secondary amines—aliphatic[142,169,211] and cyclic[142]—to form 1,3,3-trisubstituted thioureas.

This method is not advisable with arylamines having strongly electronegative substituents, since the latter greatly lower the yields of thioureas, nor with heterocyclic amines, which react with carbon disulphide with very great difficulty.

Carbon disulphide reacts not only with primary and secondary amines but also with amino-acids[142,203-205] esters of amino-acids[204], dicyclohexylcarbodi-imide[199,200], and *N*-benzylbis-*p*-methoxyphenylmethanimine[212]

The solvent used is normally ethanol[38-40,52,71,97,142,167,169,182,188,196,197,201,202,210,211] or benzene[167,182,197], but sometimes methanol[205], water[203,206], diethyl ether[90,199,200], oxolan[199], pyridine[197,200,204], or dimethylformamide[208].

A substantial disadvantage of this method is its duration. Catalysts for the reaction are sulphur[38,97,142,167,197,201], hydrogen peroxide[197,207], caustic potash[40,52,167,188,196], caustic soda[198,203,205,206,209,211], pyridine[197,200,204], pyridine together with iodine[197,204], and potassium ethyl xanthate[39]. Sulphur accelerates the reaction, but difficulties arise in separating it from the reaction products. Hydrogen peroxide is an efficient catalyst, but in this case free sulphur is formed (from the carbon disulphide), which is difficult to remove.

The most practicable catalysts are caustic potash and caustic soda, which involve the intermediate formation of thiuram disulphides and isothiocyanates:

$$RNH_2 + CS_2 + NaOH \rightarrow RNHC(S)SNa + H_2O \rightarrow$$
$$\rightarrow RNHC(S)S{-}SC(S)NHR \rightarrow 2RNCS + H_2S + S. \qquad (a)$$

Thioureas are formed in subsequent stages of the reaction:

$$RNCS + NH_2R \rightarrow RNHC(S)NHR,$$
$$RNHC(S)S{-}SC(S)NHR \rightarrow RNHC(S)NHR + S.$$

If R = Alk, thioureas can be formed only in conformity with Eqn. (*c*), for an aliphatic isothiocyanate rearranges

rapidly into the corresponding amine, without having time to react with the primary amine.

Pyridine can also be used to accelerate the reaction. It forms unstable products with hydrogen sulphide. Still better results are obtained by adding to the solution of pyridine the calculated quantity of iodine, which is easily removed as pyridinium iodide:

$$2RNHI_2 + CS_2 + I_2 + 2C_5H_5N \rightarrow RNHC(S)NHR + 2C_5H_5N \cdot HI + S.$$

During the reaction the solution becomes decolorised, and pyridinium iodide is precipitated. The quantity of iodine is measured out very carefully, for excess will lead to formation of the corresponding isothiocyanate:

$$RNH_2 + CS_2 + I_2 + 2C_5H_5N \rightarrow RNCS + 2C_5H_5N \cdot HI + S.$$

Small quantities of potassium ethyl xanthate catalyse this reaction. Although the acceleration is less than with sulphur, purer products are obtained.

5. Reaction of Hydrogen Sulphide with Substituted Cyanamides

Thioureas are formed by the reaction of cyanamides with hydrogen sulphide. Monosubstituted cyanamides yield 1-monosubstituted thioureas[213,214]:

$$RNHCN + H_2S \rightarrow RNHC(S)NH_2.$$

Disubstituted cyanamides yield 1,1-disubstituted thioureas[14]:

$$R_1R_2NCN + H_2S \rightarrow R_1R_2NC(S)NH_2.$$

The reaction is best accomplished by saturating an ethanolic solution with the corresponding cyanamide, ammonia, and hydrogen sulphide, used either as a saturated solution[214] or in the gaseous state[14,213]. Ammonia acts as catalyst in this reaction. The reaction mixture is then boiled[213] or heated in a sealed tube at 100°C.[214]

At high pressures hydrogen sulphide can add also to dicyanodiamide to form amidinothiourea[215]:

$$H_2NC(=NH)NHCN + H_2S \rightarrow H_2NC(=NH)NHC(S)NH_2.$$

6. Reaction of Thiourea with Compounds containing Various Functional Groups

Since thiourea contains mobile hydrogen atoms, it will react with compounds having various functional groups to form mono-, di-, tri-, and tetra-substituted derivatives.

Quite a few papers have been published on the condensation of thiourea with aldehydes[216-226]. Thiourea can condense with formaldehyde both in equimolecular proportions to form hydroxymethylthiourea[216-218,221,225] and at a molar ratio of 1 : 2 to form bishydroxymethylthiourea[216-225]. This reaction has been conducted with 36.4%[219] and 40%[216,218] solutions of formaldehyde made alkaline with caustic soda[219] or baryta[216,218].

Mono-, bis-, and tetrakis-hydroxyalkylthioureas have been obtained by the condensation of thiourea with other aliphatic, alicyclic, aromatic, and heterocyclic aldehydes in molar proportions of 1 : 1, 1 : 2, and 1 : 4 in ethanol at pH 9:[226]

$$RCHO + NH_2C(S)NH_2 \rightarrow RCHOHNHC(S)NH_2,$$

$$2RCHO + NH_2C(S)NH_2 \rightarrow RCHOHNHC(S)NHCHOHR,$$

$$4RCHO + NH_2C(S)NH_2 \rightarrow (RCHOH)_2NC(S)N(CHOHR)_2.$$

1-Monosubstituted thioureas can also undergo condensation with formaldehyde at pH 7, to form unsymmetrical 1,3-disubstituted thioureas[227]. The condensation of unsymmetrical substituted thioureas with aldehydes in acid media yields the thioureas $RR'C{:}CH.NH.CS.NR'R'''$.[228]

Thiourea and 1-monosubstituted thioureas will condense not only with aldehydes but also with ketones, forming 1-monosubstituted[229,230] or unsymmetrical 1,3-disubstituted[230] thioureas.

Thiourea reacts with alkylphenols in the presence of concentrated hydrochloric acid in 37% aqueous formaldehyde solution to form bishydroxyalkylbenzylthioureas[231,232].

Thiourea will react with amines to form 1-aminothioureas[57,234] and symmetrical 1,3-diaminothioureas[57,233,234] respectively below and above 150°C. At high temperatures equilibrium is established between thiourea and ammonium thiocyanate:

$$NH_2C(S)NH_2 \rightleftarrows NH_4SCN.$$

The latter reacts with amines to form aminothioureas. 1-Monosubstituted thioureas yield unsymmetrical 1,3-disubstituted thioureas with amines[235]. Thiourea reacts with organic acids[236-238] or esters[239,240] to yield symmetrical 1,3-disubstituted[236,237] and unsymmetrical 1,3-disubstituted[238-240] derivatives.

Thiourea will react with mono- and di-arylated cyanamides[241], chlorides of carboxylic acids[242], and substituted propiolactones[243] to give 1-monosubstituted[241,243], symmetrical[241], and unsymmetrical[242] 1,3-disubstituted thioureas.

III. SOME ASPECTS OF THEIR PRACTICAL APPLICATION

N-Substituted thioureas have great preparative value for the identification of organic compounds, e.g. amines and organic isothiocyanates[2,144]. They are also able to form complex compounds with several metal ions. In this connection *N*-substituted thioureas are used in analytical chemistry as complexing agents[6,17,65,172,244,245].

Certain unsymmetrically 1,3-disubstituted thioureas exhibit biological[20,21,23,131], physiological[20,27,77-79,227,243], bacteriostatic[63,178], and bactericidal[35,50,110,166] activity, and find application in medicine.

Most *N*-substituted thioureas possess pharmacological properties[15,25,41,138,155], and therefore find widespread application as tuberculostatic[28,38,39,47,50,52-54,60,62,64-68,70,72-76,80,82,85,86,93,96-98,104,108,111,112,117,118,123-125,129,137,143,149-152,157,160,185,194,195,209,235], antineoplastic[51], antispasmodic[69], antitrichomonad[95], antiviral[112,154], and other[84,92,166,214] therapeutically active substances.

Descriptions have recently appeared of 1,1-dimethyl-3-[2,3(2,4)-dimethylphenyl]-2-thiourea[110] and a 3-substituted 1-(1,2,3,4-tetrahydroisoquinol-2-yl)alkyl-2-thiourea[169], both possessing hypotensive activity and used for the treatment of high blood pressure, and of 1,3-bis-*p*-aminophenylimidazolylthiourea[195], which exhibits chemotherapeutic activity and is employed in the treatment of cancerous conditions, chiefly leukaemia.

Several derivatives of allylthiourea[23-27] and phenylthiourea[41,127,159] find application as plant-growth regulators; and 3-substituted 1-hydroxythioureas[161] exert an inhibiting effect on certain microbiological systems.

Several *N*-substituted thioureas possess herbicidal[44,116,196,211,238], fungicidal[52,63,139,166,170], nematocidal[10], and rodenticidal[42,186-188] activity, and are used in agriculture against soil nematodes[10], insects[174], rodents[42,186-188], and other pests.

Derivatives of *N*-substituted thioureas are employed as protective agents against radiation[246] and are capable of enhancing the resistance of the organism to X-rays[69].

N-Substituted thioureas are widely used in industry as starting materials for the production of polymers[16,31], stabilisers of copolymers in polyalkenes[222], vulcanisation accelerators in the manufacture of porous rubbers[136,166], agents for whitening wool[223] and for impregnation of acrylonitrile[224], corrosion inhibitors[166,232], antioxidants[166,231], and brighteners in sulphate copper-plating electrolytes[225,247].

Advances in the Chemistry of Inorganic Films and the Interference Indicator Method

E.S.Vorontsov, V.K.Altukhov, A.N.Korneeva, and N.P.Peksheva

The fast developing field of chemical methods of preparation of inorganic films is reviewed, and a new method of investigating heterogeneous reactions (based on recent advances in the chemistry of inorganic films) is formulated, and termed the "interference indicator method". Specific features of the method are discussed, and examples are given of its application to studies of mechanism, kinetics, and catalysis in heterogeneous reactions; the limitations of the method, and its advantages and disadvantages, are also discussed. 106 references.

I. INTRODUCTION

1. Inorganic Films on Solids

It has been known for a long time that the surface properties of solids can be improved by the application of inorganic coatings, which tend to prevent physical or chemical interactions between the solid and the surrounding medium and in this way extend the useful life-span of a large number of articles. Surface films on solids can also have decorative, protective, and complex physicochemical and electrophysical functions.

Interest in inorganic films has increased steadily during the last few years: for example, the publishing house "Mir" has produced the fifth (and almost certainly not the last) volume in the series "Physics of Thin Films" [1] during 1972. Whereas physicists are primarily interested in the physical and mechanical properties of thin layers of inorganic materials, chemists are concerned mainly with developing new and better methods of preparation of films having prescribed properties.

The increasing importance of thin films in science and technology stems not only from their decorative, protective, and mechanical properties when applied to everyday materials, but also from new developments in electrical and radio technology such as the microminiaturisation of integrated electronic circuits, which was made possible by the exploitation of thin films of metals, semiconductors, and insulators ("planar technology") [2,3].

The chemical composition of the films can be simple (single component) or complex (multi-component); their phase composition also can be simple (single-phase, homogeneous films) or complex (multi-phase, heterogeneous films). As regards electrical properties, we can distinguish metallic, semiconducting, and insulating (or dielectric) films. There is no generally accepted classification of the films in terms of thickness: for example, some workers [4] consider films between a monolayer and 100 Å in thickness as very thin, between 100 Å and 10 000 Å as thin, and above 1 μm as thick, whereas others [5] specify thin films (up to 400 Å), films of intermediate thickness (400–5000 Å), and thick films (over 5000 Å).

In this review we shall not be concerned with electroplated metal films, which are discussed systematically and in detail elsewhere [6]. The chemistry and technology of enamel films are also well known [7].

Chemical methods of preparation of thin films, relying on a wide range of reactions, have made considerable progress in the last few years. We have based our "interference indicator method" for the physicochemical study of heterogeneous chemical reactions [8-10] on these recent advances in the chemistry of thin films.

2. Chemical Methods of Preparation of Inorganic Films

The application of chemical reactions to the preparation of inorganic films is developing in the following directions.

1. The reaction between a solid and its gaseous or liquid environment, leading to the formation of a layer of product in whose composition the original solid is included. Oxide, sulphide, halide, and other films are produced on metals and semiconductors by this reaction. The method can be described schematically by the equations

$$A_{(s)} + B_{(g)} = AB_{(\text{film on A})}, \quad (1)$$

$$A_{(s)} + B_{(\text{soln.})} = AB_{(\text{film on A})}, \quad (2)$$

where $B_{(\text{soln.})}$ denotes a solution of B in any solvent.

For example, the oxidation of iron and its alloys in alkaline solutions and in water vapour is now widely used [11]. A salt-like film having strongly protective properties is formed when metals are phosphated [12].

The formation of oxide films on metals is described in detail in a number of monographs [13-18].

As a result of the development of semiconductor microelectronics, several papers on the growth of oxide films on Si and Ge have appeared in recent years. The preparation of films on silicon by oxidation in water vapour, in

dry or in wet oxygen, and also by anodic oxidation has been discussed by many workers[19-24].

2. The deposition of a film on a substrate, followed by chemical treatment to produce the desired properties. This method can be described schematically by the equations

$$A_{(film)} + B_{(g)} = AB_{(film)}, \quad (3)$$
$$A_{(film)} + B_{(soln.)} = AB_{(film)}, \quad (4)$$
$$AB_{(film)} + C_{(g)} = A_{(film)} + BC_{(g)}, \quad (5)$$
$$AB_{(film)} + C_{(soln.)} = A_{(film)} + BC_{(soln.)}. \quad (6)$$

For example, a metal film is deposited on a plastic, ceramic, alloy, or semiconductor, and it is allowed to react with a gas or a liquid to give an oxide, sulphide, selenide, telluride, halide, or more complex film.

On the other hand, one can deposit a layer of a compound on the substrate and convert it into a coating of simpler chemical composition by decomposing it or by allowing it to react with the surrounding medium. Copper–nickel coatings have been prepared[25-27] by reduction with hydrogen or carbon monoxide of mixed layers of Cu_2O and NiO, previously deposited on a ceramic or metallic substrate. This chemical procedure is interesting because it enables "hot" metallic coatings to be prepared without using molten alloy baths. Furthermore, the method is superior to electro-plating, which cannot provide complex metallic and metal-ceramic layers.

3. The most rapid progress has been made in the preparation of films by chemical deposition from the vapour phase. Reduction of a compound of the desired element, followed by condensation of the element on a substrate, is one important variant of this method:

$$AC + B = A_{(g)} + BC, \quad (7)$$
$$A_{(g)} = A_{(film)}, \quad (8)$$

where B is a reducing agent.

The growth of monocrystalline films of silicon on sapphire and on spinel ($MgO.Al_2O_3$) by reduction of $SiCl_4$ or decomposition of SiH_4, and the epitaxial relationships of the layer and the substrate, have been adequately discussed[28-37]. Silicon films offering the best crystallographic and electrical properties are obtained on sapphire previously heated to a high temperature in a hydrogen atmosphere.

Films of metals having a relatively high vapour pressure have been obtained[38] by chemical reduction followed by distillation and condensation at normal pressures, avoiding the need for relatively expensive vacuum equipment. The process can be described by the following equations:

$$MO_{(s)} + B_{(g)} = M_{(s)} + BO_{(g)}, \quad (9)$$
$$M_{(s)} = M_{(g)}, \quad (10)$$
$$M_{(g)} = M_{(film)}. \quad (11)$$

Many compounds (including oxides, sulphides, carbides, borides, silicides, and various intermetallic compounds) can be prepared by chemical vapour deposition. The reaction is usually carried out at atmospheric pressure. The growth conditions and the properties of the following films have been described: Si_3N_4,[39-47] rutile (TiO_2),[48,49] Ta_2O_5,[50] Nb_2O_5,[51] and Al_2O_3.[52-57]

We may consider the following reactions as typical of the chemical deposition of compounds from the vapour phase:

$$3SiCl_{4(g)} + 4NH_{3(g)} = Si_3N_{4(s)} + 12HCl_{(g)}, \quad (12)$$
$$2AlCl_{3(g)} + 3H_2O_{(g)} = Al_2O_{3(s)} + 6HCl_{(g)}, \quad (13)$$
$$2SiO_{(g)} + O_{2(g)} = 2SiO_{2(s)}. \quad (14)$$

In addition to reduction and oxidation, decomposition reactions can be used for chemical vapour deposition. Typical examples are:

$$Ni(CO)_{4(g)} \xrightarrow{200-300^\circ} Ni_{(s)} + 4CO_{(g)}, \quad (15)$$
$$SiH_{4(g)} \xrightarrow{800-1300^\circ} Si_{(s)} + 2H_{2(g)}, \quad (16)$$
$$CH_{4(g)} \xrightarrow{1000-2000^\circ} C_{(s)} + 2H_{2(g)}. \quad (17)$$

Involatile materials are commonly deposited by the procedure known as chemical transport. The term "chemical transport" denotes a process in which an involatile material is transported (in the form of a volatile compound) from one region of the system (called the source region) to another region (called the deposition or substrate region). The process consists of three steps: 1) conversion of the source material into a volatile compound by a chemical reaction; 2) transport of the compound to the substrate; 3) decomposition of the compound close to or directly on the substrate, and deposition of the source material on the substrate. For example[58]:

$$Ti_{(s)} + 2NaCl_{(g)} \rightarrow TiCl_{2(g)} + 2Na_{(g)} \quad (18)$$
$$TiCl_{2(g)} \rightarrow Ti_{(s)} + Cl_{2(g)} \quad (19)$$

Disproportionation reactions (in particular, of metal halides) are among the most widely used for chemical transport. They rely on the fact that many involatile metals can form an unstable, volatile, lower halide at high temperatures. Hence, when such a metal reacts with the higher halide at relatively high temperatures, the lower halide is formed, and the latter disproportionates to the metal and the higher halide when it reaches the lower-temperature region of the system. The metal is deposited on the substrate, and the higher halide is returned to the vapour phase, and can be transported back to the source region. This transport cycle can continue until the whole of the source material has been transported to the substrate. A known example of this process is the transport of silicon in the iodide system[59]:

$$Si_{(s)} + 2I_{2(g)} \rightarrow SiI_{4(g)}, \quad (20)$$
$$Si_{(s)} + SiI_{4(g)} \rightarrow 2SiI_{2(g)}, \quad (21)$$
$$2SiI_{2(g)} \rightarrow Si_{(s)} + SiI_{4(g)}. \quad (22)$$

Chemical transport by halide disproportionation reactions has been demonstrated for B, Al, Si, Ge, Ti, Cr, Ga, In, Zr.[60-62] The theory of transport reactions was developed by Schaefer and by Mandel and coworkers[63-66].

The preparation of metal, semiconductor, and oxide films by the thermal decomposition of metal–organic compounds has been actively developed during the last few years[67]. The method, which can call upon an enormous range of initial compounds, is best illustrated by the following reactions:

$$[(CH_3)_2CH-CH_2]_3Al \xrightarrow{\sim 250^\circ} Al + 3(CH_3)_2C=CH_2 + \frac{3}{2}H_2, \quad (23)$$
$$(C_6H_6)_2Cr \xrightarrow{\sim 350^\circ} Cr + 2C_6H_6, \quad (24)$$
$$(C_2H_5O)_4Si \xrightarrow{\sim 800^\circ} SiO_2 + 4C_2H_4 + 2H_2O. \quad (25)$$

The preparation of thin transparent films, of great importance to the optical industry, has been discussed by Suikovskaya[68]. Transparent films deposited on dense, opaque substrates produce a coloration due to the interference of light. In this way, heterogeneous chemical reactions accompanied by a change in the thickness (and hence in the colour) of a film can be made "visible".

II. THE INTERFERENCE INDICATOR METHOD

1. Indicators of Chemical Reactions

We shall use the Russian term "indikator", derived from the Latin "indicator", which means a pointer [69].

All chemical reactions are accompanied by physical effects: heat absorption or evolution, transport of elementary particles (including electrons), changes in weight, volume, and pressure of the reactants, etc. Explosions also produce light and sound effects.

We can often monitor the progress of a chemical reaction by observing changes in some physical property of the reaction system: this property acts as an indicator of (or a pointer to) the state of the reaction. For example, in potentiometric titrations the measured e.m.f. of the system is the indicator property of the system. In the dissociation of a carbonate in a vacuum the indicator property is the increasing pressure of CO_2, which grows to a constant value corresponding to the establishment of a dynamic equilibrium in the system. The inversion of cane sugar can be followed with a polarimeter by observing the rotation of the plane of polarisation of a beam of light passing through the optically active solution.

Often, however, reactions take place without visible change, and the choice of a physical property as an indicator of the path or of the extent of the reaction becomes difficult. Homogeneous reactions in solutions are of this type. In this case one adds to the reaction mixture special substances (indicators) having a property (such as colour) which can be easily monitored and which is sufficiently sensitive to the extent of the reaction.

In the chemistry of aqueous (including some non-aqueous) solutions the indicators are usually organic or inorganic compounds, capable of detecting the end-point of a titration by a colour change, by the appearance or disappearance of a turbidity, by luminescence, etc., or of giving an indication of the value of some physicochemical property of the system such as pH or redox potential. Indicators are usually added to the solution under study in small amounts [70].

During the last 15–20 years the isotopic (including radioactive) indicator method has become very popular: it is based on the "labelled atom" method proposed by Hevesy and Paneth in 1913. Isotopic indicators are substances in which the isotopic composition is different from the natural isotopic composition. They can therefore be used as tracers to study a wide variety of processes. Both stable and radioactive isotopes of the elements can be used as isotopic tracers, since both types of isotope can easily be detected and quantitatively determined [70].

The isotopic indicator method is extremely sensitive; the specificity of these indicators is so high that they can be used in processes involving mixing, migration, and chemical reaction in the most complex systems, including living organisms. The method has therefore been used in studies of the thermodynamics, kinetics, and mechanism of chemical reactions [71–73].

Of course, any indicator has advantages, disadvantages, and limitations. For example, many organic indicators in aqueous solutions are suitable only for identifying the equivalence point in titrations. Radioactive isotopes with very short half-lives have a very limited field of application as indicators; indicators which emit penetrating radiation are dangerous to life and require elaborate screening arrangements.

2. The Interference Colour of Films

One of the most characteristic physical effects of heterogeneous reactions such as oxidation on the surface of a compact monocrystalline or polycrystalline metal is the formation of iridescence (or "temper" colours). This phenomenon has been described in detail [13–18]; a brief discussion of its essential features is given below.

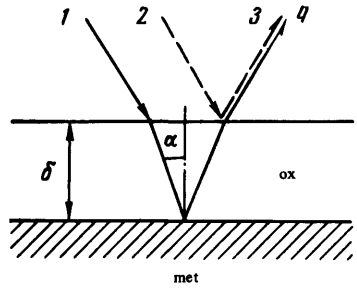

Figure 1. Formation of interference colours in films on metal substrates: *1*) and *2*) incident beams, *3*) and *4*) reflected beams.

When a metal is oxidised by a gaseous reagent (oxygen, chlorine, carbon dioxide, or sulphur, iodine, or water vapour) a transparent, invisible film of product is initially formed on the surface. As the films grows, its thickness becomes comparable with the wave length of visible light, and at this stage interference colours begin to appear.

If a beam of monochromatic light is allowed to strike at right angles the surface of a metal covered by a film, part of the radiant energy is reflected at the film–air interface, and the remainder is refracted into the film and reflected at the metal surface. The condition for destructive interference of the two beams is a phase lag by an odd number of half-waves (Fig. 1); in other words, colours will appear when

$$2\delta = \frac{\lambda}{2n}, \frac{3\lambda}{2n}, \frac{5\lambda}{2n} \ldots \quad (26)$$

where δ is the thickness of the layer of products, λ is the wave length of the light in air, and n is the refractive index of the film.

If a phase change occurs as a result of the double reflection, it can be treated as a correction (c) to the optical path difference:

$$\delta = \frac{\lambda}{4n} - c; \frac{3\lambda}{4n} - c; \frac{5\lambda}{4n} - c \ldots \quad (27)$$

Extinction of part of the visible spectrum by the film produces the complementary colour. As the reaction proceeds, and the film becomes thicker, the colour changes from yellow to blue, as shown by the data on the oxidation of iron [13] given in Table 1.

It follows from the condition for destructive interference that this colour sequence can be repeated as the film continues to grow, giving rise to a second-order spectrum. On some metals it is possible to observe spectra of order three, four, or even five. For example, the book by Bai and coworkers [18] on the oxidation of

titanium and its alloys quotes four distinct interference spectra for oxide films on this metal. Five iridescence spectra were recorded (Table 2) in our continuous observations [74] of the oxidation of titanium in air at 600°†.

Table 1. Interference colours on iron.

Heated in air at 400°		Film thickness, A
time, min	film colour	
1.0	Yellow	460
1.5	Orange	520
2.0	Red	580
2.5	Violet	680
3.0	Blue	720

On titanium, the first-order iridescence spectrum is much more intensely coloured than the higher-order spectra; the spectra of order two, three, and four have pinkish tones, and grey tones are observed at the end of the fifth-order spectrum, indicating a change from interference colours to the genuine colour of the oxide (rutile).

Table 2. Interference colours on titanium heated in air at 600°. (Roman numerals in brackets denote the order of the spectrum.)

Oxidation time	Film colour	Oxidation time	Film colour
0 min 45 s	Dark yellow (I)	63 min 40 s	Crimson
1 min 00 s	Brown	82 min 00 s	Violet
1 min 25 s	Violet	84 min 00 s	Violet-blue
2 min 25 s	Dark blue	88 min 10 s	Green
6 min 30 s	Light blue	113 min	Greenish yellow (IV)
17 min 00 s	Dark yellow (II)	116	Yellowish pink (IV)
22 min 05 s	Crimson	134	Crimson
30 min 00 s	Violet	158	Violet
32 min 30 s	Blue	160	Dark green
38 min 00 s	Dark green	183	Yellowish green (V)
49 min 40 s	Yellow (III)	210	Pink (V)

Because of the development of micro-electronics technology, which relies on thin films of semiconductors and of oxides (insulators), there is a growing awareness of the importance of films showing interference colours. Thin, coloured films on semiconductors such as silicon and germanium are used in practice in structures known as MOS (metal–oxide–semiconductor). [For all practical purposes, MOS technology relies on silicon, not germanium, as the substrate. (Ed. of Translation).]

3. Interference Colour as an Indicator of Heterogeneous Reactions

The colour of thin films on metals and on some semiconductors is a physical effect directly related to a heterogeneous reaction between the solid and its surrounding medium.

The interference colours of thin films have been discussed in depth in the scientific literature. However, most of the published work is concerned with the oxidation of metals by gaseous reagents (see, for example, Refs. 13–18), i.e. with only one type of chemical interaction.

† The temperatures are expressed throughout in degrees Celsius.

Von Wartenberg and Aoyama [75] used the tarnishing of the metal as an indicator in their study of the equilibrium composition of the gas phase in the Cr–O–H system. The interference colour of the oxide film could not be used as a reaction indicator in this work, because it was masked by radiation from the hot metal at the relatively high temperatures used by the authors.

A series of experiments carried out in 1965 by one of us and Agapova [76] demonstrated a reversible colour change when Fe, Ni, and Cu are reduced by hydrogen from their coloured films at relatively low temperatures:

Colour changes during oxidation →

Film colour: yellow brown violet blue

← Colour changes during reduction

That work [76] marked the beginning of a more general use of interference colours as indicators of heterogeneous chemical reactions. It became obvious that interference colours can give valuable information not only on the oxidation of metals, but also on their reduction from the oxides. Reduction reactions can therefore be made "visible", as well as oxidation reactions, by monitoring the colour changes of oxide films in a reducing medium.

Changes in the colour of the films can be seen also during thinning by chemical or electrochemical etching. This information is of fundamental importance in studies of the kinetics and mechanism of the interaction between oxides and electrolyte solutions, and should lead to better control of technological processes for the production of semiconductor and insulator films as well as yielding additional information on the nature of passivating films on metals.

Thus, the change of interference colour during the course of a reaction can be used as an indicator of the extent of reaction in the following systems:

solid–coloured film–gas,
solid–coloured film–liquid,
solid–coloured film–solid.

It is important to remember that a semiconductor, e.g. Si or Ge, can be used in place of the metal, and any other oxidation product, e.g. chloride or bromide, in place of the oxide. Thus, the range of heterogeneous systems in which interference colour can be used as an indicator is very wide indeed.

Several papers in which interference colours are used as indicators of chemical reactions have already been published, and we can therefore state that a new method of physicochemical research has been proposed and validated: the "interference indicator method".

We shall now consider some specific aspects of this method and some concrete results of its application.

III. REACTIONS IN THE METAL–OXIDE–GAS SYSTEM

1. Mechanism

Studies of reactions in the metal–oxide–gas system are very important in clarifying the mechanism of oxidation and reduction reactions of metals: this is particularly true of the theory of heterogeneous chemical reactions in general, and of the theory of metallurgical processes and of the rapidly developing micro-electronics technology in

particular. The use of the interference colours of oxide films as reaction indicators can lead to valuable practical results in these fields of technology.

The generalised equations for the oxidation and the reduction of metals

$$mM_{(s)} + \frac{n}{2}O_{2(g)} \rightleftharpoons M_mO_{n(s)}, \quad (28)$$

$$M_mO_{n(s)} + nB_{(g)} \rightleftharpoons mM_{(s)} + nBO_{(g)}, \quad (29)$$

describe only the quantitative relationships between the reactants, and give no indication whatever of the mechanism of the reaction. The mechanism consists of a series of simple acts and steps, such as diffusion of the reactants in the gas medium and in the layer of products, adsorption and desorption, the chemical act itself, and electron transfer.

The oxidation of metals begins with chemisorption of the oxidising gas, e.g. oxygen, on the metal surface. Oxygen atoms, being electron acceptors, extract electrons from the metal: all the subsequent events on the metal surface stem basically from this cause.

One of the consequences of oxygen chemisorption on a metal surface is the creation of an electric field [15,16] whose value can be as high as 10^7 V cm^{-1}. The electric field can pull cations from the metal lattice into the adsorption layer even at room temperature; its influence was first pointed out by Mott and Cabrera [77,78], whose theory gave the first convincing explanation of the formation of oxide films on metals at low temperatures (i.e. under conditions in which the transport of atoms by diffusion is negligibly small).

Interference colours are observed if a metal is heated after the formation of the primary (low-temperature) oxide film. The theory of Cabrera and Mott, as developed and refined by Wagner, Hauffe, Il'shner, and others [15], can account also for the formation of layers showing interference colours.

Thus, the formation and growth of coloured films is discussed in adequate detail in the theory of the oxidation of metals. However, nothing appears to have been published on the thermodynamics, kinetics, mechanism, and other physicochemical aspects of the reduction of these films to the metal. Some preliminary work in that direction has been done in our laboratory [9,76,79] by observing changes in the interference colours on Fe, Ni, and Cu in a reducing atmosphere.

We found that the reduction of Fe, Ni, and Cu from their coloured films in hydrogen or in carbon monoxide at relatively low temperatures gives colour changes in the opposite sequence to that observed during oxidation. Hence, heterogeneous reactions of the type

$$MO_{(s)} + H_{2(g)} = M_{(s)} + H_2O_{(g)}, \quad (30)$$

$$MO_{(s)} + CO_{(g)} = M_{(s)} + CO_{2(g)}, \quad (31)$$

do not lead to the formation of the product (M) at the oxide–gas interface. Reduction is accompanied by a decrease in film thickness from the direction of the metal substrate.

Our experimental results, combined with the main propositions of the Mott–Cabrera theory, lead to the mechanism shown in Fig. 2 for the reduction of a metal from thin oxide layers. This scheme differs from Richardson and Dancy's [80] in two respects:

1. It emphasises the role of disorder in the oxygen sublattice and of migration of oxygen anions under the influence of the electric field.

2. The disordering of the cation and the anion sublattice, and therefore the generation of the appropriate vacancies, is ascribed to the chemical (reduction) reaction itself.

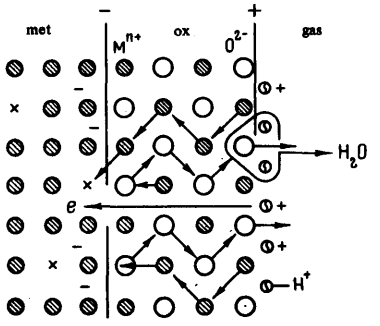

Figure 2. Reduction mechanism of thin metal oxide layers.

The relevance of our experiments, using the colour of the films as a reaction indicator to investigate the mechanism of the reduction of oxide films, is not confined to a reconsideration of the role of oxygen migration in these reactions [81]. The experimental results were used also to identify the site of reactions of the type

$$MO_{(s)} + B_{(g)} = M_{(s)} + BO_{(g)}. \quad (32)$$

Recent publications on the physical chemistry of pyrometallurgical reactions [82,83] attach great importance to the metal–oxide interface, which is assumed to be the reaction surface, i.e. the site of reactions of the type of reaction (32). Once the metal–oxide interface has been formed, reaction (32) is localised at this interface.

Our experimental results on the reduction of coloured oxide films, and the reaction mechanism shown in Fig. 2, are not consistent with the view that the surface-chemical reaction (32) occurs exclusively at the metal–oxide interface. After formation of a metallic phase the reaction is not completely localised at the interface, but it splits up into a series of simpler steps in three-dimensional space, for example:

$$B_{(g)} \rightarrow B^{n+}_{(ads)} + ne_{(ads)}, \quad (33)$$

$$ne_{(ads)} \rightarrow ne_{(m)}, \quad (34)$$

$$M^{n+}_{(ox)} \rightarrow M^{n+}_{(m-ox)}, \quad (35)$$

$$M^{n+}_{(m-ox)} + ne_{(m)} \rightarrow M_{(s)}, \quad (36)$$

$$O^{n-}_{(ox)} \rightarrow O^{n-}_{(ox-g)}, \quad (37)$$

$$O^{n-}_{(ox-g)} \rightarrow O^{n-}_{(ads)}, \quad (38)$$

$$O^{n-}_{(ads)} + B^{n+}_{(ads)} \rightarrow BO_{(ads)}, \quad (39)$$

$$BO_{(ads)} \rightarrow BO_{(g)}, \quad (40)$$

$$MO_{(s)} + B_{(g)} \rightarrow M_{(s)} + BO_{(g)}. \quad (32)$$

The above scheme is justified in our earlier papers [84,85]. Without claiming to be universally applicable, it does illustrate the complexity of the reduction of metal oxides with gaseous reagents, and in particular it shows how spatially separate steps can be combined in the overall mechanism.

One of the theoretical arguments in support of the role of the MO–M interface in surface-chemical reactions of type (32) rests on the application of the law of mass action [82]. We have removed some misconceptions in the application of the law of mass actions to these reactions [86,87].

We have dwelt at length on the mechanism of reactions (28)–(32) because of its relevance to the discussion to follow.

Table 3. Relative increase in the mean rate of oxidation of titanium with increase of temperature during the formation of a first-order coloured film. Mean rate at 500° taken as unity.

Temperature, °C	500	600	700	800
Time for the colour to change over the whole of the first-order spectrum, s	6000	390	70	30
Relative value of the mean rate of oxidation	1	15.4	85.7	200

2. Kinetics

Reaction rates can be inferred from the time for a given change in the colour of the film. For an oxidation reaction we can construct the kinetic curve (film thickness against time) by comparing the colours of films obtained by heating the metal in air or in oxygen for different times with the colours of standard samples.

Tamman [88] described the first experiment of this type. He measured approximate film thicknesses by comparing (in reflected light) the colour of the metal with that of a layer of air between glass plases. The interference colours of a layer of air of variable thickness are given in a table compiled by Rollet. The thickness of the film on the metal was calculated by dividing the thickness of the air gap showing the same colour by the refractive index n of the oxide (or other compound).

Useful kinetic data on the initial stages of oxidation of a metal can be obtained by simple visual observation of colour changes with time, using a stop-clock or a watch. Thus, we have shown [74] that the increase in the mean rate of the initial stage of oxidation of titanium with temperature can be estimated by comparing the times needed to develop the colour corresponding to the completion of the first-order spectrum at different temperatures (Table 3).

A quantitative indication of the retardation of the oxidation of titanium by the increasing thickness of the film of products can be obtained by noting the times needed for the completion of successive spectral orders (Fig. 3).

Depending on the nature of the reactants, on the oxidation temperature, on the range of thicknesses observed, and on other factors, film formation in an oxidising atmosphere is found to obey different kinetic laws (linear, parabolic, or logarithmic) [13–16]. For small changes in thickness (in the range 200–400 Å) the rate of growth is linear to a first approximation, and the mean rate of oxidation is close to the true rate.

Other conditions being equal, the mean rate of oxidation $\bar{V}$ of a metal can be expressed as an exponential function of temperature

$$\bar{V} = \frac{\delta}{\tau} = ke^{-E/RT}, \qquad (41)$$

where δ is the film thickness, τ is time, k is a pre-exponential factor, E is an apparent activation energy, R is the gas constant, and T is the absolute temperature.

For δ = const,

$$\lg\tau = \frac{E}{2.3RT} + C, \qquad (42)$$

and τ and E become the main kinetic parameters of the reaction.

Eqn. (42) suggests a new method of kinetic investigation, which avoids the need for measurements of the film thickness. By choosing a standard interference colour, the time needed to reach a prescribed thickness at different temperatures can be determined visually.

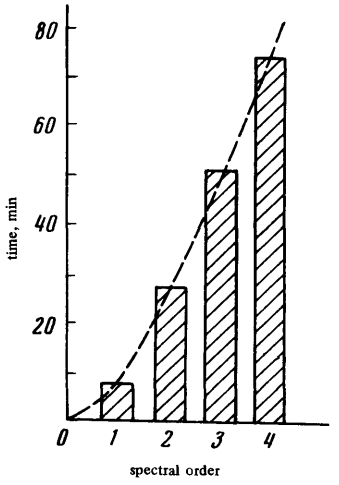

Figure 3. Inhibition of the oxidation of titanium in air at 600° by the increasing thickness of the oxide film.

Using previously published results [9,89], we have made a comparative study of the rates and apparent activation energies for the oxidation of Fe, Ni, and Cu. In the early stages of the reaction, we find that copper oxidises more easily than iron, and the latter more easily than nickel: the colour of the film begins to change appreciably at 200° on copper, at ~300° on iron, and above 400° on nickel.

The interference colour of oxide films has been used also to study the relative rates of oxidation and of Fe, Ni, and Cu [and reduction of their oxides], and also to compare the kinetic efficiencies of two gaseous reducing agents (hydrogen and carbon monoxide) [9,79]. We found that oxidised copper is reduced more easily than oxidised nickel, and the latter more easily than oxidised iron; of the two reducing gases, hydrogen was found to be the more effective.

3. Catalysis

The catalytic effect of the resulting metal on the reduction of an oxide with a gaseous reducing agent is well known: detailed discussions are given in Refs. 90 and 91.

However, the mechanism of the catalytic action is far from perfectly understood. Thus, some workers believe that acceleration of the reaction by the product is possible only when the metal and the oxide are in intimate contact: they assume that the catalytic properties are confined to the metal which is produced by the reaction as a new phase [92]. Other workers [93] report long-range catalytic effects by the product. Further study of these problems is desirable.

Our work with films showing interference colours suggests that it should be possible to observe very much more rapid colour changes in the presence of any agency (such as a catalytically active metal) capable of accelerating the reaction.

As a first step, we examined [10] the catalytic effect of platinum on the reduction of oxidised copper by hydrogen. The catalytic effect of platinum on a wide range of oxidation–reduction reactions is well known [94]. Plates of the electrolytic metal (99.9% Cu), 2 × 1 × 0.2 cm in size, were lapped, polished, and de-greased, and then oxidised in the air at 500° to give a thin, pale-yellow (almost white) film. This interference colour was taken as the standard for the experiment (~950 Å).

The films were then reduced in a hydrogen atmosphere until the interference colour disappeared and the natural colour of copper was restored. The reduction times of the standard film thickness at different temperatures and in the absence of the catalyst are listed in Table 4.

Table 4. Reduction time of a pale yellow film on copper as a function of temperature.

t, °C	200	250	300	350	400	Remark
τ, min	97	25	6	2	0.9	Mean value

The apparent activation energy corresponding to the data of Table 4 is 11.5 kcal mole^{-1}.

The experiment was repeated in the presence of the catalyst, consisting of platinum wires (bright, or coated with platinum black), placed in contact or out of contact with the film surface.

A catalytic effect of platinum on the reduction of oxidised copper was detectable in all the variants of the experiment. The strongest (and most localised) catalytic effect was noted in the experiments in which the wire was platinised and in contact with the sample (Table 5).

The powerful catalytic effect of platinised platinum on the reduction of oxidised copper is evident by simple inspection of Tables 4 and 5. Thus, 97 min were needed to reduce the film at 200° in the absence of the catalyst, whereas the natural colour of copper became visible in less than 7 s in the region adjacent to the contacting surface of Pt black. The acceleration factor for the reduction in the vicinity of the catalyst was 800 or more!

Two observations concerning the action of the platinum catalyst are noteworthy:

1. In the region 40–250° the temperature coefficient of the reaction rate is positive. In the presence of the catalyst the reaction proceeds at a measurable rate even at 40°.

2. At higher temperatures the catalytic activity of the platinum black is substantially lower. Hence, the temperature coefficient of the reaction rate in the presence of the catalyst shows two opposing effects: on the one hand, increase of temperature accelerates the reaction, and on the other hand it lowers the efficiency of the catalyst and thus it inhibits the reaction. We can therefore expect to find an optimum temperature, corresponding to maximum reaction rate. For the range of temperatures of our experiment (40–350°) the optimum is close to 250°.

Table 5. Reduction time of a standard film on Cu in the presence of a freshly platinised wire in contact with the sample.

t, °C	40	50	100	150	200	250	300	350
τ, min	12	3.5	0.75	0.25	0.116	0.0334	0.25	0.33

We have also found [95] that copper has a definite catalytic effect on the reduction of coloured films on copper by carbon monoxide as well as by hydrogen. The largest catalytic effect was obtained with hydrogen, using electrolytic copper as the catalyst.

We have also reported [96,97] a catalytic effect of Pt on the hydrogen reduction of coloured oxide films on Fe. The results are summarised in Table 6.

Table 6. Reduction time of a blue film on iron (to disappearance of colour).

τ, min \ t, °C	250	350	400
Without catalyst	>360	30	3
With catalyst, near contact area	0.333	0.256	0.067

It is evident from Table 6 that the reaction is accelerated by Pt: at 400° the acceleration factor is about 44, at 350° it is 110, and at 250° it is even greater.

In the region close to the platinum contact the reduction proceeds even at temperatures too low to give a significant reaction rate in the absence of the catalyst. Incipient reduction (corresponding to a barely visible colour change) was noted after 10 min at 25°, after 80 s at 50°, and after 35 s at 100°.

Further discussion of the mechanisms of the catalytic action of platinum on the reduction of an oxidised metal, based on observations of changes in the interference colours of the films, can be found in our earlier papers [8,10,97].

IV. REACTIONS IN THE METAL–OXIDE–LIQUID SYSTEM

1. Chemical Etching of Coloured Films on Iron

Uniform dissolution of the films on metals showing interference colours should be accompanied by a sequence of colour changes opposite to the colour changes observed during the growth of the films. This expectation has been confirmed experimentally.

Oxide films often need to be removed from metal articles as the first step in a series of technological operations. Hence, an understanding of the behaviour of films during dissolution has practical as well as theoretical importance.

Experiments with films showing interference colours can be expected to give more reliable results than experiments with thick films, which are liable to contain a greater number of defects such as pores, cracks, bubbles, chemical and structural inhomogeneities.

We believe that all the following questions can be answered by using films showing interference colours to study reactions in the metal–oxide–liquid system:

1. Is a given reagent a suitable etchant for the oxide film on a particular metal? If the etching rate is acceptable, colour changes will be noted in a relatively short time, otherwise the colour will remain unchanged for hours or days.
2. Is the etching action uniform? If the colour changes uniformly, the answer is in the affirmative. Selective etching is indicated by a spotty appearance of the interference colour.
3. Whis is the effect of the nature, concentration, and temperature of the acid?
4. Whis is the effect of convection, ultrasonic irradiation, electric field, etc. on the etching process?

We have used[98] interference colours as a reaction indicator to study the dissolution of oxide films on iron, the commonest of all industrial metals. Polished and de-greased plates of Armco-iron were oxidised in air to a standard interference colour (dark blue) corresponding to a thickness of 720–725 Å.[13] Etching of this film to the disappearance of the interference colour corresponds to a decrease in thickness by about 350 Å, which is of the same order as the thickness of the colourless natural film.

The samples were immersed in solutions of hydrochloric or sulphuric acid, and the colour of the film was continuously noted. The kinetic curves obtained are shown in Fig. 4.

It can be seen that coloured films on iron dissolve at approximately the same rate in hydrochloric and in sulphuric acid over our range of temperatures (20–60°) and concentrations (0.1–1.0 N). Increase of temperature from 20 to 60° increases the rate of the reaction by a factor of 5–6.

For a constant concentration of the etching solution, the etching time is an exponential function of temperature:

$$\tau = Be^{\frac{E}{RT}}, \qquad (43)$$

where B is a constant and E is the apparent activation energy of the dissolution process. The experimental results are satisfactorily described by a linear plot of $\lg\tau$ against $1/T$, which corresponds to the logarithmic form of Eqn. (43):

$$\lg\tau = \lg B + \frac{E}{2.3RT}. \qquad (44)$$

Plots of Eqn. (44) for etching in hydrochloric acid are shown in Fig. 5. The plots for dissolution of the films in sulphuric acid are very similar.

The apparent activation energy E calculated from these plots is 7500–8000 cal mole^{-1}.

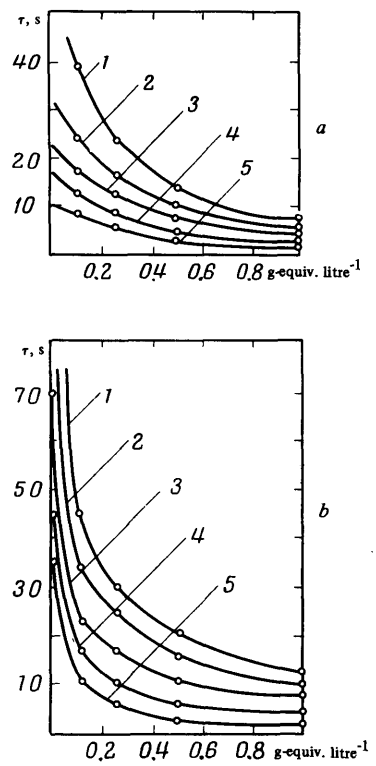

Figure 4. Time for disappearance of interference colour against acid concentration during etching in (*a*) HCl and (*b*) H_2SO_4 at different temperatures: *1*) 20°, *2*) 30°, *3*) 40°, *4*) 50°, *5*) 60°.

2. Behaviour of the Yellow Film on Titanium in Various Inorganic Acid Solutions

The high chemical stability of rutile (TiO_2) towards solutions of inorganic acids has been stressed in the literature[99,100]. Hence it is interesting to study the corrosion behaviour of titanium covered with a thin film of oxide, whose crystal structure is known[18] to be that of rutile.

We have examined the behaviour of titanium samples (OT4-O grade) with a dark yellow oxide film (first-order spectrum) in solutions of HCl, H_2SO_4, HNO_3, H_3PO_4, and CH_3COOH of various concentrations[74]. The samples were immersed in the solutions and monitored visually and gravimetrically.

The behaviour of the interference colours and of the metal in these solutions was somewhat unexpected: as long as a coloured film remained on the metal, the weight of the sample did not change. In these reactions the colour of the film can be used as an accurate indicator of the onset of dissolution.

The beginning of corrosive attack on titanium covered with a yellow oxide film is marked by the appearance of gas bubbles on the metal surface and by the loss of integrity and of uniform coloration of the film: these conclusions are made from visual and gravimetric observations.

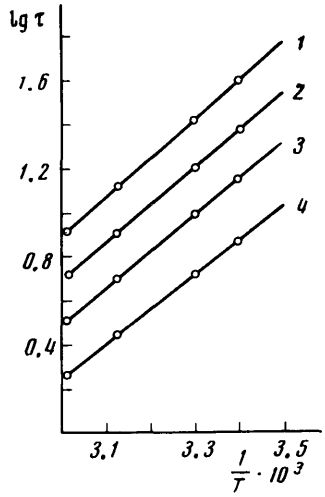

Figure 5. Plots of $\lg\tau = \varphi(1/T)$ for etching in hydrochloric acid solutions of different concentrations: *1*) 0.1 *N*, *2*) 0.25 *N*, *3*) 0.5 *N*, *4*) 1.0 *N*.

The presence of a yellow film on titanium ensures a relatively high corrosion resistance. Thus, in 22% HCl the weight loss of titanium was 2.395 g m^{-2} in 4 h without the yellow film, whereas in the filmed samples the loss was not measurable after 400 h.

In H_2SO_4 solutions of 20–45% concentration the corrosion of samples of the polished metal is slow at first, but it becomes quite fast after an induction period. At 55–96.5% concentrations corrosive attack begins as soon as the sample is immersed in the solution. A peculiar behaviour is observed when Ti is immersed in 75% H_2SO_4: a yellow film is formed on the surface in 20–25 h, and protects the sample for a further 200 h.

The yellow film is highly protective also towards solutions of H_2SO_4. Thus, in 60% H_2SO_4 the loss of unprotected Ti during 4 h is 3.25 g m^{-2}, whereas in the presence of the yellow film the loss is immeasurably small over 320 h.

When samples covered with a yellow interference film are stored in H_2SO_4 solutions of the concentrations used in this work (except 90 and 96.5%) a colour change is observed (Table 7), no doubt due to further oxidation of the metal.

In nitric acid solutions titanium exhibits self-passivation, and hence it is very resistant to corrosion in this medium[99]. Nevertheless, we have detected weight losses with samples of the polished metal in 5–55 wt.% solutions of HNO_3 after 720 h. For example, the loss amounted to 1.026 g m^{-2} in a 25% solution, and to 0.513 g m^{-2} in a 40% solution. In similar experiments with filmed samples, weight losses could be detected only after 1500–1700 h, and amounted to 0.171 and 0.342 g m^{-2} respectively.

Hence, the yellow interference film on titanium offers increased corrosion resistance even in solutions of nitric acid. This conclusion is confirmed by the observation that on storage in HNO_3 solutions of various concentrations the colour of the film changes from yellow towards blue in the same sequence as during the thermal oxidation of titanium to produce films showing a first-order interference spectrum.

Table 7. Colour changes of an oxide film on Ti exposed to H_2SO_4 solutions. (The film was initially yellow.)

Concentration of acid, %	Time of exposure, h	Colour of film after exposure
10	792	Yellow-violet
	960	Violet-blue
	1056	Light blue
25	168	Yellow-violet
	216	Violet-blue
	336	Blue
	480	Light blue
30	144	Yellow-violet
	168	Violet-blue
	216	Blue
	480	Light blue
40	408	Violet-blue
	960	Blue
	1056	Light blue
45	168	Violet
	216	Blue
	240	Light blue

Our experiments with H_3PO_4 showed that in this medium the titanium samples covered with a yellow film are least stable in the concentration range 55–75%, corrosive attack beginning after 365–412 h in these solutions. At concentrations above 75% the corrosion resistance increases appreciably, reaching 892 h in 85% H_3PO_4. Even greater stability, in excess of 1000 h, was found in H_3PO_4 solutions of concentration below 40%.

For comparison, we studied the chemical behaviour of polished titanium (free from interference colours) in H_3PO_4 solutions of the same concentrations. In 35–85% solutions of H_3PO_4 the reaction between the metal and the acid was quite rapid: thus, in a 60% solution the weight loss of titanium in 19 h was 1.539 g m^{-2}. In solutions below 30% concentration the attack on the titanium was very slight at first, and this initial stage was followed by an increase in weight and by the formation of a yellow film, indicating self-passivation of the metal under these conditions.

In acetic acid solutions of 5–45% concentration, titanium covered with a yellow film is extremely stable. Zero weight loss was recorded after 4800 h in acetic acid. On the other hand, samples of polished titanium gave measurable losses after 450–500 h in the same solutions. Thus, oxidised titanium is much more resistant to corrosion than the bright metal even in acetic acid.

The enhanced corrosion resistance of titanium covered with a yellow film, and the mechanism of its corrosion in solutions of HCl, H_2SO_4, and H_3PO_4, may be explained as follows.

During the induction period, when the colour of the film remains unchanged and no gas bubbles are evolved, defects in the film are being slowly eroded. Ultimately the film is punctured at the defective sites, and a "metal–solution" contact is established, leading to the formation of micro-corrosion galvanic couples of the "film–pore" type [13]. Evolution of gas bubbles can then begin, accompanied by disruption of the film, which is lifted from its metallic substrate and loses its protective properties.

V. REACTIONS IN THE METAL–OXIDE–SOLID SYSTEM. CARBO-THERMIC REDUCTION

We have recently extended our study of the possible applications of the "interference indicator method" to reactions between solid phases by investigating the iron–iron oxide–solid carbon system [101,102]. An analysis of this system offers particular interest from the standpoint of metallothermic and carbo-thermic reduction processes.

In order to stress the importance of these results, and the role of interference colours as reaction indicators in this work, we shall dwell briefly on some details of the mechanism of carbothermic reduction reactions, which is discussed in detail in a number of monographs [82,83,103].

In accordance with Baikov's principle of consecutive reactions [82], the final step in the carbo-thermic reduction of iron is usually expressed in the form

$$FeO_{(s)} + C_{(gr.)} = Fe_{(s)} + CO_{(g)}\,. \qquad (45)$$

By combining this equation with the equation for the gasification reaction

$$C_{(gr.)} + CO_{2(g)} = 2CO_{(g)} \qquad (46)$$

we conclude that iron is thermodynamically stable in this system only at temperatures of at least 700°. [82]

Current views on the mechanism of the carbo-thermal reduction of metals from their oxides, depending on the properties of the oxide {stability, volatility [dissociation pressure? (Ed. of Translation)]} and on the experimental conditions (temperature and pressure), are summarised in the following schemes [104]:

Scheme 1
$$MO_{(s)} = M_{(s)} + \tfrac{1}{2}O_{2(g)} \qquad (47)$$
$$\tfrac{1}{2}O_{2(g)} + C_{(gr.)} = CO_{(g)} \qquad (48)$$
$$MO_{(s)} + C_{(gr.)} = M_{(s)} + CO_{(g)} \qquad (49)$$

Scheme 2
$$MO_{(s)} + CO_{(g)} = M_{(s)} + CO_{2(g)} \qquad (50)$$
$$C_{(gr.)} + CO_{2(g)} = 2CO_{(g)} \qquad (51)$$
$$MO_{(s)} + C_{(gr.)} = M_{(s)} + CO_{(g)} \qquad (49)$$

Scheme 3
$$MO_{(s)} = MO_{(g)} \qquad (52)$$
$$MO_{(g)} + C_{(gr.)} = M_{(soln.\ in\ C)} + CO_{(g)} \qquad (53)$$
$$MO_{(s)} + C_{(gr.)} = M_{(soln.\ in\ C)} + CO_{(g)} \qquad (54)$$

All three schemes have one feature in common: gasification of the solid reducing agent. This highlights their common weakness, since it is well known that many different products can be formed when carbon is heated in air: gaseous monoxide and dioxide, and surface oxygen complexes. For example, it has been shown that oxygen becomes chemisorbed on purified carbon at temperatures below 300°, when the formation of gaseous products is negligibly small [105]. Nor should the absorption or occlusion of oxygen by the carbon be ignored.

Thus, there are reasons to suggest that at relatively low temperatures ($t < 500°$) the initial stage of the reaction between metal oxides and carbon does not involve the gasification of the solid reducing agent. But in this case a thermodynamic analysis of the M–O–C system based on Eqn. (45) cannot give a meaningful answer since it does not reflect the real nature of the reaction.

If the reduction gives rise to a metallic phase without the intervention of a gaseous product (CO or CO_2), the process can be tentatively expressed in the form

$$MO_{(s)} + C_{(gr.)} = M_{(s)} + CO_{(s)} \qquad (55)$$

where $CO_{(s)}$ denotes a solid solution of oxygen in graphite, or oxygen chemisorbed on the carbon.

Clearly, the thermodynamic driving force of reaction (55) is not determined by the quantity p_{CO}, but by the activity of oxygen in carbon, in accordance with the reaction isotherm

$$\Delta G = RT\,(\ln a_0' - \ln K_a) \qquad (56)$$

where ΔG is the change in Gibbs free energy of the system attending reaction (55), T is the absolute temperature, a_0' is the non-equilibrium (initial) activity of the oxygen sorbed by the carbon, and K_a is the equilibrium constant of reaction (55): $K_a = a_0$, where a_0 is the equilibrium activity of oxygen.

These considerations raise two important questions:

1. What is the practical importance of reaction (55)?
2. By what method can the reality of reaction (55) be demonstrated?

We shall try to answer both questions.

1. Reaction (55) is undoubtedly vitally important from the viewpoint of the theory of metallurgical processes, but it also has definite practical connotations.

Non-equilibrium structures of the metal–oxide–semiconductor (MOS) type are widely used in modern semiconductor technology. Chemical reactions at the interfacial boundaries of these structures can occur at low temperatures (and, even more so, at high temperatures), and they produce a very undesirable drift in the electrical characteristics of the semiconductor devices made from these structures [2].

In view of the very rapid development of semiconductor technology, the possibility of contact interaction between a conductor (graphite) and a semiconductor (the oxide) is a highly topical problem.

2. Experimental demonstration of the reality of the contact reaction (55) is a very difficult problem, which is the subject of continuing debate (see, for example, Ref. 103).

The very sensitive radioactive indicator method [106], used to detect the temperature at which direct reduction sets in, is inappropriate in this case because it relies on the gasification of "labelled" solid carbon.

We have used the "interference indicator method" to demonstrate the reality of reaction (55). [102] Reduction of a coloured oxide layer should be accompanied by a change in colour, and therefore the chemical interaction should be detectable from the colour change even if the reduction proceeds by the contact mechanism.

A few experiments were made to test this proposition. Samples of Armco-iron were heated in air after being polished and de-greased. When the surface had attained a stable temperature (measured by a Chromel–Alumel thermocouple), and a blue oxide film had appeared, the samples were placed in contact with a pellet of activated charcoal of "Karbolen" grade.

The pellets were pushed aside after various time intervals, and changes in interference colours in the reverse sequence to those corresponding to film growth were observed on the contact surface.

In another series of experiments the pellets were fixed to the specimens with special clamps, and the whole assembly was quenched in water to preserve the colour change. Contact reduction was again observed (see Table 8).

The phenomenon can be observed repeatedly, indicating that the contact reduction is satisfactorily reproducible.

In subsequent experiments by the interference indicator method we observed the contact reduction by carbon of oxide films on Ni at temperatures up to 250°, and on Cu up to 150°.

Table 8. Change of interference colour with time during the contact reduction of oxide films by graphite.

$t = 250°$		$t = 350°$	
Reaction time, s	Film colour	Reaction time, s	Film colour
0	Blue	0	Blue
180	Violet	30	Blue-violet
360	Yellow	60	Brown
630	Colour disappears	90	Yellow

Our results can be interpreted as follows. Oxide films on iron showing the colours of the first-order spectrum consist mainly of the phase α-Fe_2O_3. The temperature at which Fe_2O_3 begins to react with graphite is stated[104] to be 490°, but in our experiments with "interference indicators" chemical reaction between iron oxide and graphite was unmistakably detected at much lower temperature (up to 250°).

All the experiments were carried out in air. It is evident from our results that the presence of an oxidising atmosphere does not inhibit the contact reduction of the oxide film. This may be because the samples had been carefully polished and gave a good contact to the graphite pellet, which also had been polished. Under these conditions the access of air to the contact region was practically excluded.

Low-temperature chemical reactions between solid phases are usually thought to be hindered by the low diffusion rates under these conditions. This view is probably correct for the final stages of a reaction, striving to go to completion, but it cannot be applied to the initial stages. The oxide film on most technical metals (except the noble metals) is formed in the air, at room temperature, in a fraction of a second[6]. The main achievement of the theory of Cabrera and Mott[15] was to provide an explanation of this phenomenon.

In our experiments, too, the contact reaction between solids (oxide and carbon) takes place at an appreciable rate at relatively low temperatures. These results are inexplicable in terms of the standard reaction mechanisms quoted above. They can be explained, however, by the following scheme (Fig. 6). If the contact between the sample and the graphite surface is sufficiently perfect, many points and areas of contact are produced. Carbon, being a reducing agent and therefore an electron donor, can transfer electrons to the metal (an acceptor) through the oxide layer, which is a mixed (electronic–ionic) but predominantly electronic conductor.

This electron transfer generates an electric field across the metal–oxide–graphite system, which produces a kind of electrolysis in the oxide layer: cations migrate towards the metal–oxide interface, and cause the metallic substrate to grow, and oxygen anions migrate towards the graphite, where they are absorbed by the active solid. This process leads to a decrease in thickness of the oxide film, and therefore to a colour change.

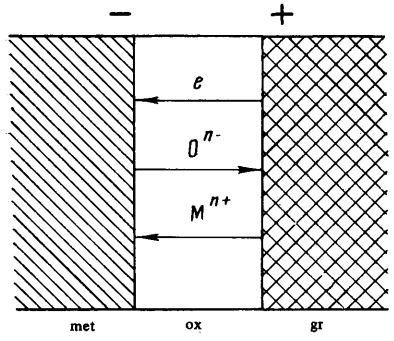

Figure 6. Mechanism of reduction to the metal by contact reaction between an oxide film and graphite.

Thus, by using the interference colour of oxide films on Fe, Ni, and Cu as an indicator of their contact reduction by graphite we have been able to demonstrate a low-temperature chemical reaction between solids and qualify the mechanism of this reaction.

VI. LIMITATIONS, ADVANTAGES, AND DISADVANTAGES OF THE METHOD

It may be concluded from the previous sections that a new method of studying the thermodynamics, kinetics, catalysis, mechanism, and other physicochemical aspects of heterogeneous reactions now exists: the use of the interference colours of thin films as indicators of the extent of reaction. In some cases the colour results from the formation of a thin layer of condensed products, in other cases the coloured layer itself is one of the reactants.

Of course, any method of experimental investigation has a limited region of applications. What are the limitations of interference colour as a reaction indicator?

Firstly (and in contrast to many of the organic indicators used for homogeneous reactions in aqueous solutions) interference colours can be used as indicators of heterogeneous reactions only. The temperature range over which they can be applied extends from room temperature or below to a few hundred degrees: the upper limit of temperature is determined by the stability of the coloured layer itself or by the stability of the underlying substrate.

In principle, the method can be applied whenever a condensed phase is present as a thin film showing interference colours which vary in the course of the reaction.

In this review we have relied mainly on metal–oxide systems to provide illustrations of the interference indicator method. This is partly because these systems are among the commonest and most easily accessible, and partly because of their extreme importance in industrial processes involving the oxidation and reduction of metals (metallurgy, machine construction, micro-electronics, chemical technology). However, the results obtained so

far justify the belief that the method should be equally applicable to systems in which the metal is replaced by a semiconductor and the oxygen by any other non-metal (e.g. S, Se, Te, F, Cl, Br, I). It is well known [3,14] that interference colours can appear on semiconductors as well as on metals, and that many gaseous or liquid reagents can be used instead of oxygen as the film-forming agent.

In summary, the interference indicator method can be recommended for the following specific investigations:

1. Comparing the rates of the initial stage of oxidation of a metal, semiconductor, or alloy at different temperatures with a single oxidising agent, or at a given temperature with different oxidising agents, and also the initial rates of oxidation of different metals and alloys with a given oxidising agent and at a fixed temperature.

2. Determining the rates of reduction of various oxidised metals, and comparing them under different sets of conditions. Quantifying the reducing power of various reagents, i.e. comparing their effectiveness.

3. Studies of heterogeneous catalysis, and comparing the effectiveness of different catalysts.

4. Studies of the solubility of oxides, sulphides, halides, and other compounds which can be prepared as interference-coloured films, in different solvents. Characterisation of the dissolution process, and of its dependence on the nature of the solvent, on temperature, convection, ultra-sonic irradiation, and electric field. In particular, we could study the dissolution of oxygen in a metal, a problem of fundamental importance in the theory and practice of welding, since oxide films are invariably present on the surface of metals being welded.

5. Studies of electrochemical processes in the metal–oxide–electrolyte system, and further investigation of the nature of metal passivity.

6. The contact interaction of solid phases, a problem of over-riding urgency in the rapidly developing technology of micro-electronic devices. The method seems particularly adapted to the very systems of interest in micro-electronics.

The range of applications of the method is not, of course, limited to the above recommendations, and is likely to be further extended by the results of future work.

We shall now discuss the advantages and disadvantages of interference colour as an indicator of chemical reactions.

In the present review, certain aspects of the method have been specially stressed in order to demonstrate its simplicity and attractiveness. It requires no specialised or dedicated equipment, such as is used in the isotopic and radioactive indicator methods. In most cases the experiment can be easily arranged for convenient observation of the colour of the film. The temperature and pressure regions over which the method can be applied are sufficiently wide.

The method is entirely free from hazards, and does not require the special safety precautions and apparatus screening arrangements inherent in the use of radioactive indicators.

The main shortcoming of interference indicators is the fact that coloured films cannot be obtained in all systems. The method is not suitable for heterogeneous reactions in which the condensed phase is in a finely divided state.

Of course, any experimental method must have some weaknesses. However, new procedures should always be welcomed because they offer new possibilities to the experimenter. The present review aims to bring to the attention of its readers a new and (we believe) powerful method of studying heterogeneous reactions.

In conclusion, we offer some additional comments on the concept of a reaction indicator. The use of interference colour as an indicator of heterogeneous chemical reactions is an extension of the concept, and gives a new slant to the theory of chemical reaction indicators.

In contrast to homogeneous reactions in solutions, for which whole systems of special indicators have been developed, heterogeneous reactions have lacked special indicators of the extent of reaction. In some systems, stable or radioactive isotopes have been used as heterogeneous reaction indicators, but their complexity, limitations, and practical disadvantages are well known, and are mentioned in this review.

Our experiments with various interference indicators of heterogeneous reactions have shown that, as in the case of homogeneous reactions in aqueous solutions, the indicator produces a definite colour in the medium, varying with the extent of reaction or at a predetermined stage in the reaction. This clear analogy justifies the use of interference colour as a chemical reaction indicator, and we propose the term "interference indicator method" for the use of interference colours in this context.

As commonly used, the term indicator denotes a substance specially added to the reaction system to make visible the progress of the reaction. The increasing use of interference colours and of other criteria and properties of the reactants as indicators in heterogeneous reactions creates a need to reconsider and to extend the concept and the definition of a chemical indicator [2].

We propose the following comprehensive definition: a chemical reaction indicator is any easily observed criterion or property of the reaction system, or of the reactants, which changes during the course of the reaction, thus allowing the course of the reaction and its extent to be monitored. The property may be inherent in one of the reacting phases, or it may be contributed by a specially added substance.

In accordance with this definition, all indicators can be divided into two classes.

1. Intrinsic indicators. These include the criteria and properties which are fundamental to the reaction system or to the reactants. If they are easily observable, and if they change during the reaction, they allow the course of the reaction to be monitored: for example, changes in weight, volume, or pressure of the reactants. Other indicators belonging to this class are the varying e.m.f. of the system during a potentiometric titration, and the angle of rotation of plane polarised light during the inversion of cane sugar. Films showing interference colours can also be classified as intrinsic indicators.

2. Impurity indicators. These include all organic and inorganic substances added to reaction mixtures to produce a colour, luminescence, or other physical property varying during the reaction. Isotopic indicators belong to this class.

Alternatively, indicators could be classified according to the type of chemical reaction as *homogeneous* or *heterogeneous*.

Vibrations of the Ethynyl Group (C≡C-H), the Hydrogen Bond, and Intramolecular Interactions in Monosubstituted Acetylenes

E.A.Gastilovich and D.N.Shigorin

The problem of whether or not the vibrations of the ethynyl group are characteristic has been examined and data are presented for the vibration modes, the potential fields, and the electro-optical parameters. Much attention has been devoted to the spectroscopic model of the hydrogen bond. Various methods of investigating intramolecular interactions in acetylene derivatives (containing halogen, Si, Sn, and N atoms as well as groups with π-electrons) by vibrational (infrared) spectroscopy have been considered.
The bibliography includes 94 references.

I. INTRODUCTION

Acetylene and its derivatives are extensively used to synthesise a wide variety of compounds employed in industry. The physical and chemical properties of compounds of the acetylene series are largely determined (owing to the characteristics of the electronic structure of the C≡CH group) by intramolecular and intermolecular electronic interactions. The changes in the electronic structure of the molecules are clearly reflected in the vibration spectra. At the end of the 1950's and in the 1960's, there was an appreciable increase of interest by

spectroscopists in the study of acetylenic compounds. The simple linear structure of the ethynyl groups $-C\equiv C-H$ provided a convenient model for the investigation of the nature of the hydrogen bond and its manifestations, a problem which has been discussed for a long time. On the other hand, in order to create new polymers, new derivatives of acetylene containing various heteroatoms, particularly those of elements of Group VI and others, were synthesised. It was necessary to investigate the intramolecular interactions of these compounds of these compounds. However, the application of vibration spectroscopy to the study of electronic interactions in molecules is impossible without the knowledge of the spectroscopic characteristics of the vibrations considered. At present there is no complete review in the literature devoted to closely related problems such as the characteristics of the vibrations of the ethynyl group and the manifestation of intramolecular and intermolecular interactions in the vibration spectra of acetylene derivatives. Therefore we hope that the present review will be of interest to specialists working in the field of the chemistry and spectroscopy of acetylene and its derivatives.

II. VIBRATIONS OF THE ETHYNYL GROUP

The principle data on the vibration frequencies of the ethynyl group $C\equiv C-H$ have been presented, for example, in Bellamy's monograph [1], which contains information about the influence of various substituents in the molecule on the vibration frequencies of this group. Luneva's review [2] is devoted to acetylene derivatives containing Group IV elements, but it gives little space to spectroscopic studies on these compounds. We may note that the study of intramolecular interactions by infrared absorption (i.r) and Raman spectroscopy must be based on the knowledge whether or not the vibrations of a particular group of atoms are characteristic as regards frequency, mode, and intensity. When these vibrational characteristics are ignored, those conclusions concerning the mutual influence of individual groups of atoms in the molecule which are based only on experimental vibration frequencies and intensities of the corresponding bands and lines in infrared and Raman spectra become baseless.

1. Vibration Mode and Frequency

The stretching vibration frequencies of the $C\equiv C$ and $\equiv CH$ groups in acetylenic compounds ($\nu C\equiv C$ and $\nu\equiv CH$) occur in a part of the spectrum which is free from the vibrations of most other polyatomic molecular groups (2250–1950 cm^{-1} and 3300 cm^{-1} respectively).

In the simplest example of compounds of this class, i.e. acetylene ($HC\equiv CH$), the sharp change in the vibration frequency of the $C\equiv C$ group following the substitution of the hydrogen atom by deuterium is associated with the mechanics of the vibrations [3]. The problem of whether or not the vibrations of the ethynyl group show characteristic frequencies and modes in acetylene derivatives of different structures has been considered by Gastilovich, Shigorin, and coworkers [4–8], Popov and coworkers [9–11], Duncan [12], and Zerbi and Gussoni [13].

Calculations on the vibrations in acetylene derivatives such as methylacetylene, t-butylacetylene, trimethylsilylacetylene, and halogenoacetylenes led to the conclusion that the $\nu C\equiv C$ vibration mode is not determined by the $C\equiv C$ group alone [4,12]. Having considered the $\nu C\equiv C$ and $\nu\equiv CH$ stretching vibrations in monoalkyl-, monosilyl-, monostannyl- and monovinyl-acetylenes, the present authors and their coworkers [4–8] concluded that the modes of these vibrations do not change and are characteristic for the $\nu C\equiv C$ vibrations of the entire $X-C\equiv C-H$ group and for the $\nu\equiv CH$ vibrations of the $C\equiv C-H$ group. Data concerning the mode of the stretching vibrations of the $X-C\equiv CH$ group in molecules with a very wide variety of structures—alkyl-, vinyl-, and phenyl-derivatives as well as derivatives containing Group IV atoms in the α-positions —are presented in Table 1†. The data in Table 1 show that the $\nu\equiv CH$ and $\nu C\equiv C$ vibrations are localised in the $X-C\equiv C-H$ group and their mode remains unchanged. An exception is the $\nu C\equiv C$ vibration in methylacetylene according to the data of Lubuzh and Popov, whose calculations showed that the C–H bonds of the methyl group are involved in this vibration [9]. Duncan's calculation for the same molecule, according to which the $\nu C\equiv C$ vibration is localised at the $C-C\equiv C-H$ group, is inconsistent with this conclusion [12].

Table 1. Modes of the stretching vibrations of the $X-C\equiv C-H$ group in certain monosubstituted acetylenes.

Compound	Vibration frequency ν, cm^{-1} (expt.)	Vibration modes: q	Q	Q_1	Q_2	β	explanation	References

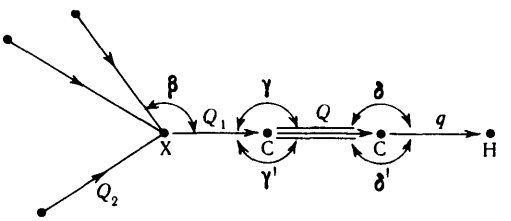
The knowledge of the vibration mode is necessary to decide whether or not the vibrations have characteristic intensities. On the other hand, the knowledge of the modes of the $\nu\equiv CH$ and the $\nu C\equiv C$ vibrations makes it

†The vibration modes have been recalculated in terms of a single system of units (see text); the designations of the coordinates are indicated in the Figure.



possible to calculate the dependence of these vibration frequencies on the changes of the dynamic (force) constants of the X—C≡C—H group. Thus the familiar expression for the derivative of the square root of the vibration frequencies with respect to the force constant K as a function of the vibration mode [17] yields the following relations:

$$\begin{array}{c|c|c} \Delta K_q = +1.0 & \Delta H_q^Q = +1.0 & \Delta H_{Q_1}^Q = +1.0 \\ \Delta\nu_{\equiv CH} = +136\ cm^{-1} & \Delta\nu_{\equiv CH} = -32\ cm^{-1} & \Delta\nu_{\equiv CH} = +2\ cm^{-1}; \end{array} \quad (1)$$

for the ≡C—H group ($\nu_{\equiv CH}$ = 3310 cm^{-1}) and

$$\begin{array}{c|c|c} \Delta K_Q = +1.0 & \Delta K_{Q_1} = +1.0 & \Delta H_{Q_1}^Q = +1.0 \\ \Delta\nu_{C\equiv C} = +34\ cm^{-1} & \Delta\nu_{C\equiv C} = +14\ cm^{-1} & \Delta\nu_{C\equiv C} = -43\ cm^{-1} \\ \Delta K_q = +1.0 & \Delta H_q^Q = +1.0 & \\ \Delta\nu_{C\equiv C} = +3\ cm^{-1} & \Delta\nu_{C\equiv C} = +22\ cm^{-1} & \end{array} \quad (2)$$

for the C≡C group (νC≡C = 2100 cm^{-1}). The generally accepted notation for force constants is employed here [17] (in units of 10^6 cm^{-2}). The designations of the normal coordinates are shown in the Figure. The relations show clearly the characteristic nature of the $\nu_{\equiv CH}$ and νC≡C vibrations as regards frequency. On the other hand, they make it possible to explain the differences between the force constants calculated by a different investigators from the experimental vibration frequencies of the same molecule.

Designation of the natural coordinates.

Certain dynamic constants of the X—C≡CH group in molecules of different structures, calculated by different investigators, are listed in Table 2. In the studies under consideration, the dynamic constants were expressed in different units. In Table 2 and throughout the text, all the constants are given in units of 10^6 cm^{-2}; 1 Å and one atomic mass unit (1/16 of the mass of the oxygen atom) being adopted as unit length and unit mass respectively.

The $\nu_{\equiv CH}$ vibration frequency is determined by only two constants: K_q and to some extent H_q^Q. Table 2 shows [5,9,12,14] that the large differences between the K_q in various studies can be accounted for by the fact that some investigators introduced the spectroscopic mass of the hydrogen atom (1.088 a.m.u.) when $K_q \simeq 10.88$–10.55 cm^{-2} while others assume that the mass of the hydrogen atom is 1.008 a.m.u. ($K_q \simeq 10.1$–9.83) (in this case the conversion factor for K_q is approximately 1.07. The coefficient H_q^Q plays a relatively small role and probably cannot be determined reliably from vibration frequencies in infrared spectra. Thus significantly different H_q^Q values are quoted by Duncan [12], by Popov and Gribov [19], and by Lubuzh and Popov [9] for almost the same set of molecules (Table 2 does not list all the data).

The νC≡C vibration is characteristic as regards mode and frequency for the X—C≡C—H group. Table 2 shows that the constants K_Q, K_{Q_1}, H_q^Q, and $H_{Q_1}^Q$ which determines the frequency of this vibration, are extremely different for the same or similar compounds (Table 2) [6,10,12,13,16]. Firstly, this difference is due to the fact that the νC≡C vibration frequencies were calculated by the authors with different accuracies ($\nu_{C\equiv C}^{exp} - \nu_{C\equiv C}^{calc}$). Secondly, since the vibration frequency depends to an almost equal extent on the four force constants, the uniqueness of this set of constants depends on the accuracy of the calculation for other vibrations too ($\nu_{\equiv C\text{-}X}$, ν_p). Otherwise the set of constants K_Q, K_{Q_1}, H_q^Q, and $H_{Q_1}^Q$ becomes arbitrary (Table 2) [6,10,16]. The variation of their values in each set obeys Eqns. (2). The sets quoted by Lubuzh and Popov for methylacetylene and by Zerbi and Gussoni [13] for the compounds H_2XC—C≡CH constitute an exception. This is probably because the νC≡C vibration mode differs from that used in the remaining calculations. We noted above that this was the case in Lubuzh and Popov's study [9]. In contrast to the remaining investigations, Zerbi and Gussoni [13] employed a potential field of a mixed type: a valence force field for the C≡C—H group and a Urey–Bradley field for the H_2XC-group, which probably affected the vibration mode (data for the mode are not quoted).

The absorption bands for the deformation vibrations of the ≡C—H group lie in the range 610–680 cm^{-1}. [1] The stretching and deformation vibration in the ethynyl group are fully separated [19]. According to the data of Duncan [12], Lubuzh and Popov [9], Epshtein and Popov [11] and others, the amplitudes of the changes in the angles δ and γ (see Figure) in the δ≡CH vibration differ by a power of ten. From the form of this vibration mode, it is possible to obtain relations between the changes in the dynamic constants for the —C≡C—H group and the changes in the δ≡CH vibration analogous to Eqns. (1) and (2):

$$\begin{array}{c} \Delta K_\delta = \pm 0.1\ (\times 10^6\ cm^{-2})\ \ \Delta K_\gamma = \pm 0.1\ \ \Delta l_\gamma^\delta = \pm 0.1 \\ \Delta\delta_{\equiv CH} = \pm 90\ cm^{-1}\ \ \Delta\delta_{\equiv CH} = \pm 1\ \ \Delta\delta_{\equiv CH} = -18 \end{array} \quad (3)$$

The δ≡CH vibration in acetylene is doubly degenerate. In monosubstituted acetylenes, this degeneracy is removed and two bands ($\delta_{\equiv CH}^{(1)}$ and $\delta_{\equiv CH}^{(2)}$) are observed in the spectrum. The different possible mechanisms of the intramolecular interactions, which leads to a splitting of the δ≡CH band, have been considered by Nyquist and Potts [23]. The splitting can reach several units. Thus, in vinylacetylenes with a heteroatom Y = S, O, or N in the —RYCH=CH—C≡CH conjugated chain, $\delta_{\equiv CH}^{\perp} - \delta_{\equiv CH}^{\parallel} = 48$, 50 and 107 cm^{-1} respectively [15], which corresponds to a change in $K_\delta^\perp - K_\delta^\parallel$ of about $(0.05$–$0.12) \times 10^6$ cm^{-1}. This is a considerable difference bearing in mind that the force constant K_δ is itself small ($K_\delta = 0.375 \times 10^6$ cm^{-2}, $\delta_{\equiv CH}$ = 633 cm^{-1}) [9].

2. Electro-optical Characteristics from Infrared Spectra

The problem of whether or not the vibrations of the ethynyl group show characteristic intensities can be treated on the basis of the valence-optical theory of intensity [24]. As a result of its development by Gribov, a computational scheme was put forward where the electro-optical parameters (EP) μ_i, $\partial\mu_i/\partial q_i$, and $\partial\mu_i/\partial\alpha_j$ (μ_i is the dipole moment of the ith bond and q and α are the normal coordinates of the bond and angle) were introduced as the

characteristics of the bonds and angles in the molecule[25]. Adopting further reasonable approximations (the zeroth approximation when only the diagonal elements are non-zero as well as higher degrees of approximation), it is possible to assess from the electro-optical parameters (and not from the intensities of the infrared absorption bands) for molecules of similar structures the mutual influence of the individual groups of atoms in the molecule. This treatment is analogous to the consideration of force constants instead of vibration frequencies in the study of the effect of intramolecular interactions on vibration frequencies.

The electro-optical parameters for acetylene[19,26], t-butylacetylene[5], vinylacetylene and diacetylene[27], trimethylsilylacetylene[5], and organotin derivatives of acetylene with several ethynyl groups[14,21] have now been

calculated from experimental intensities of infrared absorption bands and are listed in Table 3. Popov et al.[27] also determined the dipole moments of the C≡C bonds ($|\mu_Q| = 1.0$ D) for diacetylene and vinylacetylene and the C=C bond ($|\mu_{Q_2}| = 0.70$ D) for the latter.

Table 3. The electro-optical parameters $\partial\mu_i/\partial q_i$ [D/Å] and μ[D] of the CXC≡CH groups and the experimental absolute intensities B (in units of 10^4 cm^{-2} litre mole^{-1}) of the absorption bands associated with the C≡C—H groups in the infrared spectra.

Note. The values listed in the Table correspond to the following combinations of electro-optical parameters in the publications quoted: [a] $\partial\mu_q/\partial q - \partial\mu_q/\partial q'$; [b] $\partial\mu_Q/\partial Q - \partial\mu_Q/\partial Q'$; [c] for all the R_3X—C≡CH, $\partial\mu_q/\partial Q + \partial\mu_Q/\partial Q + \partial\mu_{Q_1}/\partial Q$; [d] $\partial\mu_{Q_1}/\partial Q_1'$ (the prime indicates an equivalent but "foreign" coordinate).

It has been shown[5,7,14] that the ν≡CH vibration in molecules of different structures is characteristic as regards intensity. In other words, the intensity of the corresponding absorption band in the infrared spectrum is determined mainly by the electro-optical parameters for this bond ($\partial\mu_q/\partial q$). On the other hand, the intensity of the νC≡C vibration band is characterised by the set of electro-optical parameters of the entire X—C≡C—H group and $\partial\mu_Q/\partial Q$ does not play a decisive role. Thus, in compounds with a heteroatom (X = Si and Sn), both the direction of the dipole moment of the transition $\partial\vec{M}/\partial Q_{C\equiv C}$ ($\vec{M}$ is the dipole moment of the entire molecule and $Q_{C\equiv C}$ the normal coordinate of the νC≡C vibration) and the intensity of the νC≡C band are determined by the parameters of the X—C≡ bond and not the C≡C bond. A similar phenomenon has been observed for another class of compounds—ethylene derivatives, for which it has been shown that the intensity of the C=C absorption band ($\nu_{C=C}$) is not determined by the parameters of this bond[28]. The low contribution of the electro-optical parameters of carbon chains to the intensity of the absorption bands associated with the skeletal vibrations of the molecule was noted previously by Gribov and Popov[29]. Thus theoretical calculation of the absorption band intensities in the infrared spectrum of dimethylacetylene using only the electro-optical parameters of the C—H bonds in the ethane molecule[30] gave satisfactory agreement between the calculated and experimental values for all these vibrations. Hence it was found that the electro-optical parameters of the C—C≡C—C group in the dimethylacetylene molecule may be neglected. However, in the vinylacetylene and diacetylene molecules[27] as well as in other monosubstituted acetylenes (Table 3), the electro-optical parameters of the multiple bonds are fairly large.

In a study of the intensities of the νC≡C absorption bands in the spectra of compounds with a complex molecular structure, RYCH=CH—C≡CH and RYCH=CH—C≡C—Si$(CH_3)_3$ (R = alkyl; Y = S, O, or N atom), Gastilovich, Shigorin et al. concluded that the νC≡C intensity depends on the electro-optical parameters of the Y—C= group[7,15]. They also concluded that in molecules with conjugated bonds and with a heteroatom, the νC≡C vibration remains characteristic as regards frequency and mode for the C—C≡C—H group but cease to be characteristic as regards intensity for this group. The νC≡C intensity is determined by the electro-optical parameters of the entire YCH=CH—C≡CH group; this corresponds, within the framework of the valence-optical theory of intensity, to the employment of high degrees of approximation, which is probably impossible in practice.

The results of studies on intermolecular interaction (the hydrogen bond in acetylene derivatives), such as the electron-donating and electron-accepting properties of the —C≡C—H group and changes in the absorption band intensities in electron-donating solvents, can also be very useful for the solution of the problem of intramolecular interactions. Therefore, having considered the problem of whether or not the vibrations are characteristic, we proceed to the problem of the hydrogen bond in acetylene derivatives.

III. THE HYDROGEN BOND

As early as 1939, the anomalously high solubility of acetylene in electron-donating solvents (EDS) and the experimental heats of solution in such solvents led Copley and Holley to the conclusion that there is a specific intermolecular interaction in such solutions between the acetylene and solvent molecules[31]. In 1941 Standford and Gordy observed in the infrared spectra of phenylacetylene solutions in EDS a bathochromic shift of the absorption band due to the stretching vibration of the ≡C—H group. The shift was of the same order of magnitude as that observed for the OD group in deuteriated alcohols. The authors concluded that a hydrogen bond is formed in phenylacetylene solution in EDS.[32] In 1958, Shigorin and coworkers suggested, on the basis of a study of the spectra of vapours and liquids, the formation of a specific hydrogen bond between the molecules of acetylene derivatives involving the π-electrons of the C≡C group (electron-donating group) and the orbitals of the hydrogen atom (in the ≡C—H electron-accepting group), i.e. in the formation of π-complexes[33,34]:

The structure of the π-complex was subsequently refined by other investigators.

The existence of both π-complexes of acetylenic hydrocarbons and of a hydrogen bond between such hydrocarbons and the solvent has now been demonstrated. Hyong's studies[35] on hydrogen bonds in acetylenic compounds were published in 1963 in the form of a review. The review gives a detailed bibliography (153 references). A paragraph in Bellamy's familiar monograph (1968)[1] is devoted to the hydrogen bond in acetylenic hydrocarbons.

However, recently new data have appeared on the hydrogen bond in acetylenic compounds which are not quoted in the earlier publications. For example, the data of Iogansen and coworkers[36-38] concerning the nature and spectroscopic manifestations of the hydrogen bond,

data for the hydrogen bond in acetylenic compounds containing Group IV atoms, and others. In his treatment of studies on the hydrogen bond, Bellamy [1] devoted insufficient attention to investigations published in Russian. We should like to fill this gap.

1. Effect of Molecular Structure on the Vibration Frequency Shift in the Formation of the Hydrogen Bond

The first infrared spectroscopic evidence for the existence of a specific interaction in acetylenic hydrocarbons was obtained by Shuvalova [41], Murash et al. [42], Gastilovich et al. [43], Hyong and Lastondi [44], and Iogansen and Kurkchi [36,37]. They observed, using infrared spectra, a shift in the equilibrium between free and associated molecules of acetylenic hydrocarbons as a function of temperature and concentration of the solution.

Many studies have been made on the dependence of the band shift $\Delta\nu_{\equiv CH}$ following the formation of a hydrogen bond by acetylenic compounds on the structure of the R—C≡CH and solvent molecules [1,4,35,45-49].

Table 4 gives a compilation of certain data concerning the changes in the vibration frequency of the ≡CH group in acetylenes R—C≡CH of different structures dissolved in electron-donating solvents. Experimental studies have shown that an increase of conjugation in R—C≡CH molecules increases the $\Delta\nu_{\equiv CH}$ shift. Shigorin [52] explains this phenomenon by the fact that charge transfer on hydrogen bond formation is not localised at the A—H---⨯B- group but induces an additional change of electron density in all the rest of the electron-acceptor molecule. Electrons in the donor molecule ⨯B—R occupy the vacant p orbitals of the hydrogen atom and are therefore capable of participating in conjugation. Thus the increase of the $\Delta\nu_{\equiv CH}$ shift in both silyl- and arylacetylenes compared with the alkyl and stannyl derivatives can be accounted for by this type of conjugation:

Iogansen [39,53] has developed logically the concept of the additive influence of the acidity and basicity of the A—H and ⨯B—R components in the formation of a hydrogen bond. A somewhat different approach to the treatment of electron-donating properties of the solvent has been proposed by Plotnikov and Shigorin [54]. They suggested that the involvement in conjugation of the unshared electron pair of the donor in "its" molecule decreases the electron-donating capacity of the latter. For example, in nitrogen-containing electron-donating solvents, the $\Delta\nu_{\equiv CH}$ shift increases in the series R_2N-  ,  N, and $(C_2H_5)_3N$, while in oxygen-containing solvents it increases from acetone to dioxan [50].

The vibration frequency of the C≡C group changes little on formation of a hydrogen bond [35,55]. Molecules where the C≡C—H group is involved in conjugation constitute an exception. For example, in the spectrum of phenylacetylene and trimethylsilylacetylene dissolved in electron-donating solvents, two $\nu C\equiv C$ bands are observed ($\Delta\nu C\equiv C \simeq 7-12$ cm^{-1}), the intensity ratio of which changes with concentration [55]. These bands correspond to "free" and associated molecules in the R—C≡C—H—⨯B—R′ complex. The appearance in the spectrum of the solution of two $\nu C\equiv C$ bands makes it possible to calculate the degree of association in the hydrogen-bonded complexes from the intensity of the $\nu C\equiv C$ absorption band of the "free" molecule, as has been done on the basis of the $\nu_{\equiv CH}$ absorption band [48]. However, the splitting of the $\nu C\equiv C$ bands is not observed for all types of conjugation but only when the conjugation promotes further charge transfer from the  group to the R group of the acetylene. Otherwise, the splitting of $\nu C\equiv C$ is not observed. For example, spectroscopic data suggest a π-electronic interaction between the $R_2NCH=CH-$ and $-C\equiv C-H$ groups in the compound $R_2NCH=CH-C\equiv CH$ (Gastilovich et al. [15]); chemical data demonstrate a high reactivity of the C≡C group in this compound [56]. However, the $\Delta\nu_{\equiv CH}$ shift in the spectra of solutions of this compound in electron-donating solvents is the same as in alkylacetylenes (or smaller) and the $\nu C\equiv C$ band is not split (a different type of conjugation is postulated here: ) [57].

2. π-Complexes

The hypothesis of the formation of π-complexes between acetylenic compounds has been confirmed experimentally by Murash et al. [42], Shuvalova [58], and others [1,35]. When π-complexes are formed, the $\nu_{\equiv CH}$ vibration frequency changes very little, by approximately 20 cm^{-1} (Table 4), while the change in the vibration frequency of the C≡C group [35,55] is even smaller (1–2 cm^{-1}). However, as for the hydrogen bond of the type R—C≡C—H---⨯B—R′, two $\nu_{\equiv CH}$ bands are observed in the spectrum of the solution, corresponding to free and associated molecules. It has been shown [59] that the π-complex is T-shaped and that not one but two $\nu_{\equiv CH}$ frequencies are due to the bound molecules.

The electron-donating properties of the C≡C groups in various acetylenic compounds were studied by West and Kreihancel [60] and Hyong [35] using changes in the vibration frequency of the O—H groups of phenol and p-chlorophenol respectively. Similarly the electron-donating properties of the C≡C groups in certain silyl- and stannyl-acetylenes [8] have been determined from the changes in the vibration frequency of the O—H group of ethanol in the complex

Table 5 presents some data for the electron-donating properties of the C≡C groups of various ethynyl compounds. Hyong [35] determined the energy of formation of the π-complex with p-dichlorophenol from the temperature variation of the degree of association. It varies in the range 2–3 kcal mole^{-1} for different acetylenes. Hyong showed that the π-electron-donating properties increase in the series alkenes < aromatic hydrocarbons < alkynes. According to the data of West and Kreihancel [60], the electron-donating properties of the C≡C group are more marked in disubstituted acetylenes compared with monosubstituted derivatives, and in the latter they decrease when the triple bond is conjugated with a ring. In disubstituted tin and silicon-containing acetylene derivatives (RXC≡CXR′), the electron-donating properties weaken in the series with X = Sn, C, and Si (Table 5).

3. The Lateral Band

In all ethynyl compounds, a weak ν_X band, which does not disappear on dilution of the solution, is observed on the long-wavelength side of the absorption band of the ≡CH group. Its nature has been investigated in numerous studies[1,35]. The appearance of the ν_X band is explained in Bellamy's monograph by Fermi resonance. Kreihancel and West[61] and Hyong[35] interpret this band as due to a hot transition in alkylacetylenes: $\nu_X = \nu_{\equiv CH} + \delta_{\equiv CH} - \delta_{\equiv CH}$. The ν_X band has a low intensity (the optical density ratio $D_X/D_{\equiv CH} \simeq 0.10$), is displaced relative to $\nu_{\equiv CH}$ towards longer wavelengths by about 20 cm^{-1}, and persists in the spectra of deuteriated compounds. At different temperatures, the intensity ratio of the $\nu_{\equiv CH}$ and ν_X bands varies in accordance with the calculated population of the "hot" $\delta_{\equiv CH}$ vibration level. In the spectrum of phenylacetylene, this additional band on the long-wavelength side (ν_C) is very intense ($D_C/D_{\equiv CH} \simeq 0.70$). Hyong[35] interprets its appearance by the Fermi resonance of the $\nu_{\equiv CH}$ and ν_C vibrations in a manner analogous to the interpretation of the ν_X band by Evans and Nyquist in the spectra of alkyl-substituted derivatives[62]. The latter postulate that $\nu_X = \nu_{C\equiv C} + 2\delta_{\equiv CH}$ or $\nu_{C\equiv C} + \delta_{\equiv CD}$ in deuteriated derivatives of acetylene. In a recent study, Bagdanskii et al.[51] studied the infrared spectra of acetylene in matrices at low temperatures. The band with a maximum at 3312 cm^{-1} (argon matrix) was interpreted as due to the $\nu_{C\equiv C} + \delta_{\equiv CH}$(i.r) + $\delta_{\equiv CH}$(Raman) = 1973.5 + 737 + 612 cm^{-1} transition intensified by Fermi resonance with the $\nu_{\equiv CH}$(i.r) = 3289 cm^{-1} vibration. The longer-wavelength band with a maximum at 3276 cm^{-1} was assigned to the $\nu_{\equiv CH}$ vibration (i.r) of the $^{12}C^{13}CH_2$ molecule. However, the authors noted that in this region there is a possibility of absorption by acetylene polymers.

The weak lateral bands ν_X are also observed in the spectra of dilute solutions of acetylenic compounds containing silicon and tin. In the latter [$(C_2H_5)_3Sn-C\equiv CH$], there are weak bands on the long-wavelength and short-wavelength sides of the main band (Table 6).

4. Spectroscopic Three-Atom Model of the Hydrogen Bond

The intensities of the absorption bands due to the ≡CH and C≡C groups in hydrogen-bonded complexes have been determined in a few studies. Brand et al.[63] observed a change (in different directions) of the stretching ($\nu_{\equiv CH}$) and deformation ($\delta_{\equiv CH}$) vibrations in hydrogen-bonded complexes as well as of the intensities of the corresponding absorption bands. Systematic studies of the $\nu_{\equiv CH}$ and $\delta_{\equiv CH}$ vibration frequencies and of the intensities of the absorption bands in different electron-donating solvents have been made by Iogansen and Kurkchi for acetylene and its alkyl-substituted derivatives[36-38,64]. Table 7 presents data for the changes in the intensity of the C≡C—H absorption band intensities on formation of a hydrogen-bonded complex with a solvent by certain acetylenic compounds of different structures.

On the basis of data showing that the $\nu_{\equiv CH}$ and $\delta_{\equiv CH}$ bands vary regularly in opposition and that $\Delta\nu_{\equiv CH}$ and $\Delta\delta_{\equiv CH}$ shift in opposite directions on formation of the hydrogen bonds, it was concluded [36-38,64] that the hydrogen bond is covalent. Using these concepts, Iogansen proposed a three-atom model for the formation of the hydrogen bond [39]. The model is based on the hypothesis that the charge transferred from the atom of the electron donor $\overset{\times}{}$B to the R—AH molecule is not delocalised over the latter. As a result, the change in the intensity of the absorption bands in the infrared spectra of the hydrogen-bonded complexes is caused by a change of the dipole moment of the H---B hydrogen bond itself during the vibration of the hydrogen atom and not due to a change in the dipole moment of the A–H bond.

Table 6. Positions of the absorption bands of the ≡CH group ($\nu_{\equiv CH}$) and the lateral ν_X bands (cm^{-1}) and their relative intensities (at the absorption maximum) $D_X/D_{\equiv CH}$ in the infrared spectra of compounds of the type R—C≡C–H (D) in carbon tetrachloride solutions [35].

*The compound R—C≡C—D.
**Solution in hexane.

In the $\nu_{\equiv CH}$ stretching vibration in the "free" R–C≡CH molecule, only the hydrogen atom is displaced from the equilibrium position (the displacements of the C atoms may be neglected). Then, in accordance with the valence-optical scheme [25], the absolute intensity of the $\nu_{\equiv CH}$ absorption band ($B^{(0)}_{\nu CH}$) is related to the amplitude of the vibration of the ≡CH—H bond (q) and the derivative of the dipole moment of the molecule M with respect to the normal coordinate q by the expression const. $(B^{(0)}_{\nu CH})^{1/2} \simeq -(\partial M/\partial q)q$. When the C≡C—H---$\overset{\times}{}$B—R complex is formed, one can assume that the ≡C and B atoms are stationary and that hydrogen vibrates between them. Then the vibration amplitude q_{H---B} is equal to q but with the sign reversed, i.e. $q_{H---B} = -q$. The dipole moment changes in the –H--$\overset{\times}{}$B– bond vibration:

$$(\partial\mu_{H---B}/\partial q_{H---B})q_{H---B}.$$

The intensity of the absorption band of the hydrogen-bonded complex ($B^{(C)}_{\nu CH}$) is in this case determined by the two components: const. $(B^{(C)}_{\nu CH})^{1/2} = (\partial M/\partial q)q + e(\partial\mu_{H---B}/\partial q_{H---B})(q_{H---B})$. It is readily seen that the difference $(B^{(C)}_{\nu CH})^{1/2} - (B^{(0)}_{\nu CH})^{1/2} = \Delta(B^{1/2}_{\nu CH})$ for such a model depends only on the change in the dipole moment of the H---B bond during the vibration: $\Delta(B^{1/2}_{\nu CH}) \simeq (\partial\mu_{H---B}/\partial q_{H---B})q_{H---B}$.

Similarly, for deformation vibrations, $(B^{(C)}_{\delta})^{1/2} - (B^{(0)}_{\delta})^{1/2} = \Delta(B^{1/2}_{\delta}) \simeq (\mu_{H---B}/\rho_{H---B})\Delta e_{\equiv CH}$ (according to the valence-optical theory [24,25]), where ρ_{H---B} is the length of the H---B bond and Δe is the change of direction of the unit vector of the ≡C—H bond in the $\delta_{\equiv CH}$ vibration. Data for the changes in the frequency and intensity of the absorption bands of the C≡CH group led to the conclusion [64] that the derivatives $\partial M/\partial q$ and $\partial\mu_{H---B}/\partial q_{H---B}$ are of the opposite sign, while the dipole moments μ_q and μ_{H---B} have the same direction.

Table 7. The frequencies (cm^{-1}) and intensities B (in units of 10^4 cm^{-2} litre $mole^{-1}$) of the absorption bands of the stretching and deformation vibrations of the C≡C—H group in the spectra of compounds of the type R—C≡C—H in solutions in an inert solvent (O) and an electron-donating solvent (C).

Note. Kurkchi and Iogansen [38] used iso-octane and carbon tetrachloride (distinguished by an asterisk) as the inert solvent (IS) and methylpyrrolidone or pyridine (asterisk) as the electron-donating solvent (EDS) and the corresponding values of B are quoted without taking into account the degree of association: Hyong [35] used carbon tetrachloride as IS and pyridine as EDS and the B are quoted without taking into account the degree of association; Gastilovich and coworkers [47,48] used carbon tetrachloride as IS and pyridine as EDS and the B are quoted with allowance for the degree of association.

The three-atom model of the covalent hydrogen bond discussed above have been confirmed by certain experiments. Thus the experimental intensities of the absorption bands corresponding to the vibrations of other bonds and the values calculated using the parameter $\partial\mu_{H---B}/\partial q_{H---B}$ agreed satisfactorily. For example, $(B^{(C)}_{\nu C\equiv C}) = 0.02 \times 10^4$ cm^{-1} litre $mole^{-1}$ was calculated for the $\nu_{C\equiv C}$ vibration frequencies of acetylene in the complex with acetone, the measured value being $B^{(C)}_{\nu C\equiv C} = 0.08 \times 10^4$ cm^{-1} litre $mole^{-1}$. [65]

5. Limitations of the Three-Atom Model

However, certain experimental data show that the three-atom model is apparently valid only to a first approximation and holds for A–H molecules in which the degree of conjugation of the donor electrons with the remainder of the A molecule is low. In molecules where there is such conjugation (R–C≡C–H---B), one cannot neglect the change in electron density in the remainder of the molecule on formation of the hydrogen bond. For example, an observation such as that of the appearance of two $\nu C{\equiv}C$ absorption bands in the spectra of the hydrogen-bonded complexes of certain acetylenic compounds contradicts the three-atom model discussed above. A numerical estimate shows that the vibration frequency of the C≡C group in the hydrogen-bonded complex may change only as a result of a change in the force constant K_Q. On the other hand, a change in the force constant of the ≡CH bond on formation of the hydrogen-bonded complex ($\Delta K_q \simeq -1.0 \times 10^6$ cm^{-2}) cannot change the $\nu C{\equiv}C$ vibration frequency[47] to such an extent (by about 10 cm^{-1}), despite the fact that the vibration mode of the latter is characteristic of the entire X–C≡C–H group.

The inadequacy of the three-atom model has been pointed out by Gastilovich et al.[47], who measured the intensities of the absorption bands due to the ≡CH and C≡C groups in certain acetylene derivatives in various solvents. Taking into account the $\nu{\equiv}CH$ and $\nu C{\equiv}C$ vibration modes and using the parameter $\partial\mu H\text{---}B/\partial q H\text{---}B$, the intensities of the C≡C absorption bands were calculated[47,48] from the relations

$$\left(\frac{\partial M}{\partial Q_{\equiv CH}}\right)_c = \left(\frac{\partial M}{\partial Q_{\equiv CH}}\right)_0 - 0.90\frac{\partial \mu_{H\text{---}B}}{\partial q_{H\text{---}B}} e_{\equiv CH},$$
$$\left(\frac{\partial M}{\partial Q_{C\equiv C}}\right)_c = \left(\frac{\partial M}{\partial Q_{C\equiv C}}\right)_0 - 0.24\frac{\partial \mu_{H\text{---}B}}{\partial q_{H\text{---}B}} e_{\equiv CH}, \quad (4)$$

where $Q{\equiv}CH$ and $QC{\equiv}C$ are the normal coordinates of the $\nu{\equiv}CH$ and $\nu C{\equiv}C$ vibrations respectively; $(\partial M/\partial q{\equiv}CH)[D/Å] = 1.6 \times 10^{-2} (E\nu CH)^{1/2}$, and a similar expression holds for $B\nu C{\equiv}C$, E being measured in cm^{-2} litre mole^{-1}. A discrepancy has been found between the calculated and experimental intensities of the $\nu C{\equiv}C$ bands in the spectra of the hydrogen-bonded complexes of phenylacetylene and trimethylsilylacetylene. The discrepancy has been attributed to a change in the electro-optical parameter of the C≡C bond ($\partial\mu X\text{–}C{\equiv}C\text{–}H/\partial Q$) on formation of the hydrogen bond, which is inconsistent with the three-atom model. However, for alkylacetylenes and certain silyl- and stannyl-acetylenes, the calculated and experimental intensities agree within the limits of experimental error. This finding can be explained by the weak conjugation in molecules with this structure[48].

The intensity of the C≡C absorption band decreases on formation of the hydrogen bond in aryl- and alkyl-acetylenes[35,47,55] and increases in silyl- and stannyl-acetylenes[47,48] (Table 7). It has been shown[5,14] that the dipole moments for the transition of the $\nu{\equiv}CH$ and the $\nu C{\equiv}C$ vibrations have opposite directions in alkylacetylenes and the same directions in silyl and stannyl derivatives ($R_3X\text{–}C{\equiv}CH$). On this basis, the opposite sign for the change in the intensity of the $\nu C{\equiv}C$ band in the spectra of these compounds on hydrogen bond formation has been explained from the standpoint of Iogansen's three-atom model (zeroth approximation) and on the hypothesis of conjugation in the C≡C–H models involving the electrons of the donor B (next approximation)[49]. Thus the parameter $\partial\mu X\text{–}C{\equiv}C\text{–}H/\partial Q$ for phenylacetylene and trimethylsilylacetylene dissolved in an inert solvent has the same sign. The change of this parameter for substances dissolved in an electron-donating solvent is also of the same sign. For example, $\Delta(\partial\mu X\text{–}C{\equiv}C\text{–}H/\partial Q) \simeq -0.9$ for pyridine.

Table 8. The dipole moments μ_q of the ≡C–H bond and their derivatives $\partial\mu_q/\partial q$ based on the infrared spectroscopic data for solutions of compounds of the type R–C≡CH in carbon tetrachloride and the changes in vibration frequencies (wave-numbers) $\Delta\nu{\equiv}CH = \nu{\equiv}CH$ (solution in CCl_4) – $\nu{\equiv}CH$ (solution in pyridine).

$(C_2H_5)_3Sn\text{–}C{\equiv}CH$	1.3±0.2	0.85	—74

The stretching and deformation vibrations of the ≡C–H group in acetylene derivatives are characteristic as regards mode. Therefore the intensity of the absorption bands associated with these vibrations in the spectra of solutions in an inert solvent is proportional to the derivative of the dipole moment of the ≡C–H group with respect to the coordinate q, i.e. $\partial\mu_q/\partial q$, and to the dipole moment μ_q of the ≡CH bond respectively. Thus information about the distribution of electron density in the ≡C–H group may be obtained from the infrared spectrum. Table 8 lists the values of $\partial\mu_q/\partial q$ and μ_q for various compounds R–C≡CH,[8] obtained from measurements of the intensity in the spectrum of the solution in an inert solvent. These parameters have been compared with the shift of the $\nu{\equiv}CH$ band in the spectrum of the solution in pyridine. The data in Table 8 demonstrate the absence of a monotonic relation between the dipole moment, its derivative, and the capacity of the compounds R≡C–CH to form a hydrogen bond ($\Delta\nu{\equiv}CH$), which apparently indicates a limitation of the three-atom model.

6. Energy of the Hydrogen Bond

The spectroscopic determination of the energy of the hydrogen bond from the change in the degree of association with temperature yielded a fairly low value (1.5–2 kcal mole^{-1}).[35] The energy ΔH of the hydrogen bond between acetylene and its simplest alkyl derivatives on the one hand and an electron-donating solvent on the other has been determined[64] from the heat of solution. For example, $\Delta H = 1.4$ kcal mole^{-1} for the hydrogen-bonded complex with acetone and $\Delta H = 2.4$ kcal mole^{-1} for the complex with hexamethylphosphoramide.

Iogansen proposed a method for the determination of the hydrogen bond energy on the basis of the three-atom model of the hydrogen bond[40]:

$$\Delta H \text{ (kcal mole}^{-1}) = g\,[(B^{(c)}_{\nu CH})^{1/2} - (B^{(0)}_{\nu CH})^{1/2}] \qquad (5)$$

where the coefficient $g = 2.9$ hardly differs for different classes of A—H compounds. This method is very simple, since it does not require measurements at different temperatures. Only the intensity of the A—H(≡C—H) absorption band in the spectrum of the hydrogen-bonded complex and in the spectrum of the solution in an inert solvent is measured. According to the valence-optical scheme, the above relation presupposes a direct dependence of the hydrogen bond energy on the derivative of the dipole moment of the hydrogen bond itself with respect to the coordinate $q_{H\cdots B}$: $\Delta H \propto \partial\mu_{H\cdots B}/\partial q_{H\cdots B}$.

The energies of the hydrogen bond between acetylene and its alkyl derivatives on the one hand and the solvent on the other, determined from the absorption intensity and from the heat of solution, agree satisfactorily: $\Delta h = 1.1$ and 2.4 kcal mole^{-1} from the intensities in the infrared spectra in acetone and hexamethylphosphoramide solutions respectively (the data based on the heat of solution were given above). The hydrogen bond energies in alkyl-, stannyl-, and certain silyl-acetylenes ($R_3X—C\equiv CH$, X = C, Si, or Sn) in hydrogen-bonded complexes with pyridine have been determined from Eqn. (5)[48]. The hydrogen bond energy increases in the sequence X = C < X = Sn < X = Si: 1.2, 2.0, and 3.6 kcal mole^{-1}. However, in the light of the hypothesis concerning the hydrogen bond[52], discrepancies should be observed in certain systems between the hydrogen bond energies measured directly and those determined from the equation [Eqn. (5)] proposed by Iogansen. Such discrepancies may be expected for R—C≡C—H derivatives where the π electrons of the C≡C bond interact with the π electrons of the R—C≡C—H group, for example in $R_3Si—C\equiv CH$ and phenylacetylene.

IV. VIBRATIONAL (INFRARED) SPECTROSCOPIC STUDY OF INTRAMOLECULAR ELECTRONIC INTERACTION

As already mentioned in the introduction, conclusions concerning the mutual influence of various groups in the molecule cannot be reached solely on the basis of the experimental vibration frequencies and band and line intensities in the vibration spectra. The problem of applying vibration spectra in the study of polyatomic molecular structures is considered in the review of Gribov and Popov[66]. However, in the majority of spectroscopic studies where the problems of structures were examined this finding was ignored. For example, in the section dealing with spectroscopic studies in Luneva's review[2], the conclusions of the investigators quoted on the spectroscopic manifestation of π–d conjugation in molecules are discussed uncritically in this sense. Since the $\nu C\equiv C$ vibration does not show characteristic intensities and its frequency may vary within fairly wide limits [see Eqn. (2)] when the atom X in the X—C≡C—H group is varied, we shall not discuss here purely experimental studies devoted to the investigation of intramolecular interaction.

Certain conclusions about the mutual interaction of individual groups of atoms in the molecule can be reached by examining the force constants and electro-optical parameters of various molecules. However, we may note that these quantities may vary in different molecules both as a result of intramolecular interactions and as a result of a change of the hybridisation of the electrons forming the bonds under consideration. Moreover, since in the calculations on the vibrations the choice of the non-zero non-diagonal elements of the molecular force field is to some extent arbitrary, one cannot simply compare the force constant obtained by different investigators and arrive at conclusions concerning the change in the molecular force field on the basis of the differences between them. This is indicated by the data in Table 2. Finally the force constant itself and its changes in one direction or another for different molecules still cannot provide any information about the nature of the intramolecular interaction. A conclusion about the specific type of mutual interaction of groups in the molecule can be usually reached by considering data obtained in studies on the molecule by other methods. The problems of intramolecular interaction in acetylenic compounds have been discussed in a number of studies.[5,9–11,14,15,20–22,27,47,48,68]

1. Interaction with a Halogen and π–π Interaction

Lubuzh and Popov studied the effect of a halogen on the potential field of the ethynyl group[9]. Calculation on molecular vibrations showed that the replacement of hydrogen atoms in acetylene by the CH_3 group (methylacetylene) or Cl does not have an appreciable influence on the force (dynamic) constant of the C≡C—H group (Table 2).[9] In contrast to these groups, the remaining halogens (F, Br, and I) influence the ethynyl group. Thus in fluoroacetylene there is a sharp increase of the force constant of the C≡C bond ($K_Q = 27.2$) and of the dynamic interaction between the F—C≡ and C≡CH groups ($H^Q_{Q_1} = 1.09$). On the other hand, in bromo- and iodoacetylenes, $H^Q_{Q_1}$ decreases ($K_Q \simeq 25.5$) but the halogen does affect the ≡CH group: K_q decreases ($K_q = 10.4$). The results of this study are consistent with Duncan's data[12] for analogous compounds. Zerbi and Gussoni[13] showed that the halogen X separated from the C≡C—H group by a carbon atom ($H_2X—C—C\equiv CH$) does not alter the force constant of this group. However, the influence of the halogen distorts the cylindrical symmetry of the force field of the C≡C—H group and the spectra of these compounds show two bands corresponding to the δ≡CH deformation vibrations. Iodine has the greatest effect; the difference $K^{(1)}_\delta - K^{(2)}_\delta$ for this compound is high (about 0.09×10^6 cm^{-2}).

It has been shown[9,10,68] that the force constant of the C—C bond changes little (approximately by 10–15%) when the state of hybridisation of the electrons forming it alters: sp^3–sp^3, sp^3–sp^2, and sp^3–sp. The force constant is greatly influenced by the change in π-electron density: with increase of bond order K also increases. A considerable asymmetry of the force constants in the ≡C—O—C group was noted by Tenisheva et al.[20]: $K(\equiv C—O) = 13.6 \times 10^6$ cm^{-2} and $K(O—C) = 8.0 \times 10^6$ cm^{-2}. A similar phenomenon has been observed for silyl and stannyl derivatives of acetylene: $K(\equiv C—Si) = 5.7 \times 10^6$ cm^{-2} and $K(Si—C) = 5.1 \times 10^6$ cm^{-2} for the silyl derivative and $K(\equiv C—Sn) = 4.1 \times 10^6$ cm^{-2} and $K(Sn—C) = 3.60 \times 10^6$ cm^{-2} for the stannyl derivative[5,21]. However, in the latter the change in K can probably be accounted for mainly by a change in hybridisation.

Popov and coworkers carried out an interesting series of studies in which they established a definite correspondence between the type of force field and the nature of the intramolecular electronic interaction (conjugation). Popov and Lubuzh[22] determined the force field for diacetylene and dimethyldiacetylene. The force constant of the $\overset{Q}{C}\equiv\overset{q_0}{C}-\overset{Q'}{C}\equiv C$ groups (the designation of the normal coordinate is indicated above the bonds) for these molecules differ considerably from the corresponding values for the acetylene and methylacetylene molecules. Thus K_Q is appreciably reduced (24.1×10^6 cm^{-2}), K_{q_0} increases (12.8×10^6 cm^{-2}), and the dynamic constant for the interaction of triple bonds is also higher ($H^{Q}_{Q_1} = -1.64 \times 10^6$ cm^{-2}); $H^{Q}_{Q_0} = 0.54 \times 10^6$ cm^{-2}. The authors concluded that such a characteristic force field in the molecules investigated can be accounted for by electron delocalisation. They showed that the proposed set of force constants describes satisfactorily the vibration spectra of the polyacetylenes $R-(C\equiv C)_n-R$ with $n = 2-6$ in contrast to the set obtained by other workers. The form of the force field of polyacetylenes led the authors[22] to the conclusion that the interaction between the triple bonds in the $(C\equiv C)_n$ chain decays rapidly and that the phenomenon of bond order equalisation does not occur. Having examined the force fields of molecules with different types of intramolecular electronic interaction, Popov and Kogan[67] proposed a classification of molecular force fields, involving a subdivision into four types depending on the diagonal and non-diagonal elements, so that each type of force field corresponds to a definite type of distribution of electron density in the molecule. Popov and coworkers carried out calculations on the vibrations of vinylacetylene and its methyl-substituted derivatives[10] on the basis of the force field classification and quantum-mechanical calculations which showed a delocalisation of electron density in the molecules under consideration. The authors concluded that the satisfactory agreement among more than 120 calculated and experimental vibration frequencies confirms the data showing a delocalisation of electron density in such a molecule and the initial postulates that the type of force field and the electronic structure of the molecule correspond.

Epshtein and Popov[11] obtained a distinctive type of force field for the propynal molecule ($\overset{O}{\underset{H}{\diagdown\!\!\diagup}}C-C\equiv CH$): K_Q and $K(O=C)$ are reduced compared with acetylene and acetaldehyde, while K_{Q_1} is higher. The authors concluded that the type of force field of this molecule is consistent with quantum-mechanical calculations, which demonstrate a delocalisation of π electrons in this molecule.

Popov et al.[27] pointed out the similarity of the force constants and electro-optical parameters for the $C=C-C\equiv C$, $C=C-C=C$, and $C\equiv C-C\equiv C$ carbon chains, which they explained by the same cause in each molecule—a partial delocalisation of electron density. Thus the calculated electro-optical parameters of the carbon chain in the vinylacetylene molecule are non-zero and large, in contrast to the data for dimethylacetylene[29]. The authors concluded that these results indicate a polarisation of the $C=C-C\equiv C$ bonds in the molecule ($\underset{\sim}{C}=\underset{\sim}{C}-\underset{\sim}{C}\equiv\underset{\sim}{C}$). Calculation of the absorption band intensities in the spectrum of another substance (diacetylene) using the electro-optical parameters of vinylacetylene resulted in a satisfactory agreement between the calculated and experimental data.

2. Interaction Involving Groups Containing Si, Sn, N, O, and S Atoms

Gastilovich, Shigorin, and coworkers studied the mutual interaction of groups in acetylene derivatives containing silicon and tin as the X atom. The suggested electronic effects—the inductive effect and π–d conjugation–lead to the opposite changes in the distribution of electron density in the $Si-C\equiv CH$ and $Sn-C\equiv CH$ groups: $\begin{matrix}C\\ \downarrow\\ C\rightarrow X\rightarrow C\equiv C-H\\ C\end{matrix}$.

Calculations on the vibrations of the $C_3X-C\equiv CH$ groups in the $(CH_3)_3Si-C\equiv CH$ (Gastilovich et al.[5]) and $(C_2H_5)_3Sn-C\equiv CH$ (Gastilovich et al.[14]) groups showed that the dynamic constants K_Q and K_q for the compounds are smaller than for t-butylacetylene[5] $(CH_3)_3C-C\equiv CH$ (Table 2). The changes in the electro-optical parameters of these compounds can be seen from Table 3. The changes in the electro-optical parameters of the $X-C\equiv C-H$ groups and the almost constant value of the electro-optical parameter of the C_3-X group led the authors to the conclusion that the degrees of π-d conjugation in the silicon- and tin-containing compounds investigated are different[14]. The study of hydrogen bonding in these compounds showed that the electron-donating properties of the groups decrease in the sequence $Sn-C\equiv C-Sn > C-C\equiv C-C > Si-C\equiv C-Si$ and the electron-accepting properties of $R_3SiC\equiv CH$ are more pronounced than those of $R_3C-C\equiv CH$ and $R_3Sn-C\equiv CH$ (Tables 4 and 5). The authors concluded that the above findings indicate a shift of π-electron density in silylacetylenes from the $C\equiv C$ group to $\equiv C-Si$ (π-d conjugation) and an appreciably smaller degree of such interaction in stannylacetylenes.

Another approach has been proposed[47] for the study of the problem of conjugation, which is based on the hypothesis that the three-atom model of the hydrogen bond is inadequate for molecules where the intramolecular interaction takes the form of conjugation (see Section III, 5). Calculation of the absorption band intensities associated with the $\nu C\equiv C$ vibrations on formation of an intermolecular hydrogen bond with an electron-donating solvent showed that the calculation based on an additive scheme (three-atom model) yields satisfactory results for the stannylacetylene[48] $(C_2H_5)_3Sn-C\equiv CH$. However, the assumption of additivity for trimethylsilylacetylene[47] $(CH_3)_3SiC\equiv CH$ and also for phenylacetylene leads to a discrepancy between the calculated and experimental quantities owing to the neglect of conjugation. A similar experiment and calculation led the authors to the conclusion that in silyl derivatives with several ethynyl groups π-d conjugation diminishes. Shakhovskii et al.[69] believe that the shift of the electron cloud towards the silicon atom (which they explained by π-d conjugation) is indicated by the magnitude and the direction of the dipole moments of substances of the type $R_3SiC\equiv C-C\equiv CH$.

On the basis of NMR data and measurements of the molecular dipole moments, Petrov et al. concluded that there is intramolecular charge transfer from the nitrogen atom to the ethynyl group in the compound $R_2NCH=CH-C\equiv C-Si(CH_3)_3$.[70] Considerable changes in the intensities of the absorption bands associated with the $\nu C\equiv C$ and $\nu C=C$ vibrations are observed in the spectra of compounds of the type $RYCH=CH-C\equiv CH$ (Y = S, O, or N) as a function of the atom Y.[15,71,72] However, these changes arise mainly because the above vibrations do not have characteristic intensities[6,15]. It is suggested that there is an intramolecular interaction between

YCH=CH and −C≡C−H groups in such compounds on the basis of data showing that there is discrepancy between the experimental intensities and the values calculated assuming additivity [15]. Calculation of the intensities of the $\nu C{\equiv}C$ absorption bands in the spectra of the compounds $RYCH{=}CH{-}C{\equiv}C{-}Si(CH_3)_3$ from the $\nu C{\equiv}C$ band intensities in the spectra of the compounds $RYCH{=}CH{-}C{\equiv}CH$ and the electro-optical parameters of the $\equiv C{-}Si(CH_3)_3$ group showed a deviation from additivity only for compounds containing nitrogen. The authors concluded that other heteroatoms (S and O) have only a weak influence on the dynamic and electro-optical characteristics of the $=C{-}C{\equiv}C{-}H$ group.

Table 9. Vibration frequencies (wave-numbers) ν (cm^{-1}) and intensities B (in units of 10^4 cm^{-2} litre $mole^{-1}$) of the infrared absorption bands and I of the Raman lines [in relative units: $I_{313}(CCl_4) = 100$] in the spectra of compounds with several ethynyl groups.

*Solution in CS_2.

A considerable mutual influence of the C≡C and ≡C−Sn groups (in contrast to CAlk−Sn) was also detected by calculating the electro-optical parameters of tin-containing compounds with several ethynyl groups [21]. However, we may note that a similar interaction has been observed also for H−C bonds in the methyl group [25].

Among purely experimental studies, mention should be made of those of Buchert, Zeil, and Haals [73-75], Sacher, and coworkers [76,77], and Miller and Lemmon [78], who quote the vibration frequencies of the molecules investigated and give their interpretation [for the compound $R_3SiC{\equiv}C{-}X$ with X = H, $Si(CH_3)_3$, or Hal, $H_3C{-}X(C{\equiv}C{-}H)_3$ and $X(C{\equiv}CH)_4$ with X = Si, Ge, or Sn, and $Y(C{\equiv}CH)_3$ with Y = P, As, or Sb]. The characteristic frequencies of compounds containing Group IV and V elements can be found in the reviews by Chumaevskii and coworkers [79,80]. In the majority of other experimental studies, certain vibration frequencies and absorption bands or line intensities were considered and the specific changes in these quantities for various molecules were explained by changes in the distribution of electron density in the XC≡CX′ group (see, for example, Refs. 71-72 and 81-88). However, examination of the vibrations of the ethynyl group (Section I of the present review) shows that the authors' conclusion concerning the electronegativities of various atomic groups, conjugation, vacant orbitals, and the activity of the lone electron pairs of various atoms are in the majority of cases groundless. However, these studies contain rich and remarkable experimental data. For example, there is an interesting variation of the absorption and line intensities in the infrared and Raman spectra corresponding to the $\nu C{\equiv}C$ vibration (Table 9) with the number of ethynyl groups. Thus in the Raman spectra the intensity increases in proportion to the number of these groups, which is not the case in the infrared spectra.

Table 10. Effect of molecular structure on the $\nu C{\equiv}C$ vibration frequency and the intensity B (in units of 10^4 cm^{-2} litre $mole^{-1}$) of the infrared absorption bands or I of the Raman lines (in relative units*).

*$I_{C\equiv C}$ in monoalkylacetylene was taken to be 100 units.

We shall complete the present review by a Table (Table 10) providing a clear illustration (together with Table 9) of the changes, which are sometimes enormous, in the frequency and particularly the intensity of the absorption band associated with the $\nu C{\equiv}C$ vibrations as a function of molecular structure. Unfortunately, these changes in the infrared spectra and apparently to an even greater extent in the Raman spectra do not characterise the changes in the distribution of electron density directly in the C≡C group.

The Determination of the Position of Double Bond in Unsaturated Steroids by Mass Spectrometry

N.S.Vul'fson and V.G.Zaikin

The possibilities and limitations of the mass-spectrometric method in the solution of problems concerning the location of the double bond in steroids have been demonstrated for a large number of such compounds containing the double bond in various positions in the polycyclic system and in the side chain. The mass spectra of Δ^1-, Δ^2-, Δ^4-, Δ^5-, Δ^7-, Δ^{13}-, Δ^{16}-, Δ^{22}-, Δ^{23}-, and Δ^{24}-steroids, in which the diagnostic fragments are due to the dissociation of at least one allylic bond, are the most characteristic. The double bonds in other positions in the steroid skeleton either do not initiate specific decomposition processes at all, or inhibit processes characteristic of the corresponding saturated analogues, or cause the appearance of fragments the driving force responsible for the formation of which is obscure. A separate section of the review deals with aromatic and diene steroids. The bibliography includes 86 references.

I. INTRODUCTION

The determination of the position of the double bond in natural unsaturated steroids does not present much difficulty at present, since the steroids from hormones encountered in nature contain double bonds in a limited number of positions in the polycyclic system and in the side chain at $C_{(17)}$. However, this problem constantly faces investigators working in the field of the synthetic chemistry of steroids and also chemists dealing with the determination of the structure of various functional derivatives of natural steroids. In the latter case, when the positions of certain substituents, for example hydroxy-, alkoxy-, or acyloxy-groups, are determined, the problem is significantly facilitated when the location of the double bond formed as a result of the *trans*-elimination of these groups is known. Recently, mass spectrometry has been successfully employed to establish the position of the bond together with other physicochemical methods. The advantage of this method over others consists in its speed and extremely small amounts of substance required for analysis.

Attempts to employ mass spectrometry in order to establish the position of the double bond in aliphatic compounds were unsuccessful. As a rule, owing to the migration of the double bond under the influence of electron impact, peaks of the characteristic ions, the formation of which could be related to the position of the double bond, cannot be observed in the mass spectra of the corresponding compounds. The study of the mass spectra of the products of a transformation of unsaturated aliphatic compounds which fixes the position of the double bond, for example of the corresponding epoxides, is more promising. In cyclic compounds, including steroids, the double bond shows less tendency towards migration under the conditions of mass-spectrometric measurements and frequently initiates specific decompositions which can be used to determine its position. The formation of the majority of fragments arising under the influence of the double bond includes the dissociation of at least one allylic C—C bond. A special case of this process is the decomposition of the type of the retro-diene reaction (RDR) (or the "Diels—Alder retro-reaction"), which takes place with the dissociation of two allylic C—C bonds, and the charge may be located at the diene and or the so called dienophile fragment. Sometimes the process is accompanied by the migration of the hydrogen atom to the charged fragment or away from it. The relative intensities of the peaks corresponding to RDR depend on the stability of the ions formed. Decomposition of the RDR type was first described by Reed[1] and was subsequently analysed in detail by Biemann[2] and Djerassi and coworkers[3] for different types of unsaturated cyclic compounds. This type of fragmentation is interesting because, apart from the determination of the position of the double bond, the mass number of the corresponding ion frequently yields information about the nature of the substituent in the ring.

Among unsaturated steroids, compounds without functional substituents, such as keto-, hydroxy-, alkoxy-, and acyloxy-groups, or additional double bonds, are comparatively rarely encountered. Each of these functional groups can influence the decomposition of the molecular ion under electron impact and the problem of the determination of the double bond position in such cases is closely related to the determination of the nature and position of the substituent.

Numerous studies in which mass-spectrometric data for unsaturated steroids are given and discussed in different degrees of detail have now accumulated. However, there are comparatively few systematic studies in this field and many published investigations suffer from lack of a detailed analysis of the mass spectra quoted.

In the present review an attempt is made to give a systematic account of the accumulated mass-spectrometric determinations of the position of the double bond in unsaturated steroids. Studies in which the mass-spectrometric data quoted are insufficient to infer the influence of the

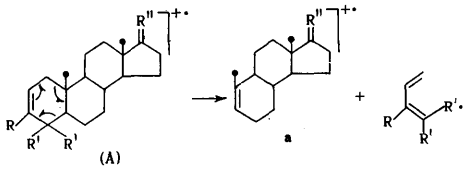
double bond on fragmentation under electron impact have been excluded from consideration.

One must stipulate beforehand that many of the decomposition mechanisms and ionic structures quoted in the review are of a formal kind and frequently have not been confirmed experimentally. However, such representation of mass-spectrometric processes is now generally adopted in the literature. On the other hand, the proposed mechanisms of decompositions under electron impact frequently find analogies in photochemistry, radiation chemistry, plasma chemistry, electrochemistry of organic compounds, and even solution chemistry. In representing the bond dissociations, we have employed three types of notation: homolytic dissociation is represented by a "hook", an arrow represented heterolytic dissociation, and a wavy line represents any of these dissociations when it is impossible to postulate a reasonably well founded mechanism.

II. STEROIDS WITH A DOUBLE BOND IN RING *A*

1. Δ^2-Steroids

One of the first studies dealing with the effect of the position of the double bond in steroids on the pathways in the decomposition of the molecular ion under electron impact was that by Audier et al.[4], who showed that decomposition via an RDR mechanism is characteristic of the type (A) Δ^2-steroid which they investigated (Table 1):



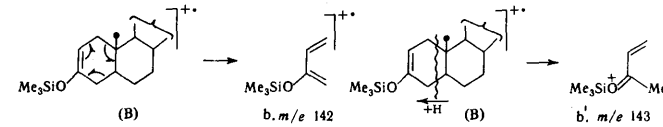


Table 1. The values of *m/e* (intensity expressed as a percentage of the maximum) for the ion a in the mass spectra of type (A) Δ^2-steroids[4]. *

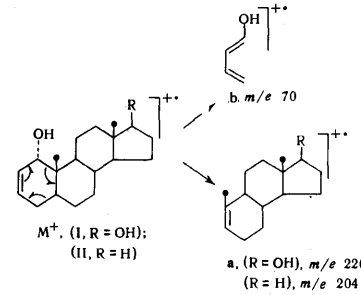
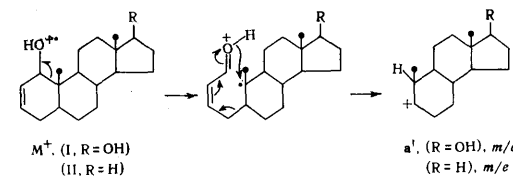


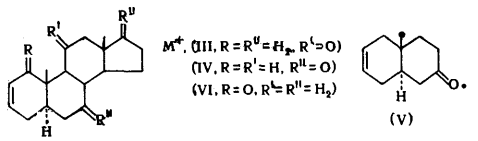
Compound	R	R′	R″	Diene eliminated	*m/e* for ion a
Androst-2-ene	H	H	H_2	Butadiene	$(M-54)^{+\cdot}$,204(91)
Cholest-2-ene	H	H	H, C_8H_{17}	Butadiene	$(M-54)^{+\cdot}$,316(65)
Androst-2-en-17-one	H	H	0	Butadiene	$(M-54)^{+\cdot}$,218(100)
3-Methylcholest-3-ene	Me	H	H, C_8H_{17}	2-Methylbutadiene	$(M-68)^{+\cdot}$,316(81)
Cholest-2-en-3-yl acetate	MeCOO	H	H, C_8H_{17}	2-Acetoxybutadiene	$(M-112)^{+\cdot}$,316(68)
3-Methoxycholest-2-ene	MeO	H	H, C_8H_{17}	2-Methoxybutadiene	$(M-84)^{+\cdot}$,316(38)
4,4-Dimethylcholest-3-ene	H	CH_3	H, C_8H_{17}	2-Methylpenta-2,4-diene	$(M-82)^{+\cdot}$,316(3)

* Audier et al.[4] do not quote the peak intensities of the type b diene ions.

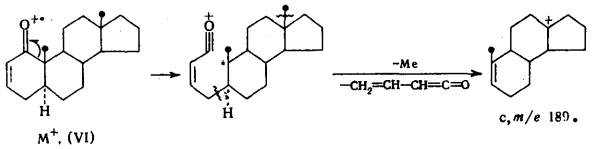


Peaks due to ions caused by the elimination of a diene as a rule predominate in the mass spectra of these compounds, while the ionic peaks of the dienes themselves are low. In the mass spectrum of 4,4-dimethyl-5α-cholest-2-ene the peaks of the dienophile fragment a amounts to only 3% of the maximum peak in the spectrum, while the intensity of the peak corresponding to the diene ion (*m/e* 82) is much higher. A similar situation is observed also in the spectrum of lanost-2-ene (4,4,14α-trimethyl-5α-cholest-2-ene).[5] Thus the introduction of a *gem*-dimethyl group in the 4-position partly stabilises the diene fragment. Table 1 shows that the RDR type of decomposition is characteristic also of enol acetates and enolic ethers. In type (B) 3-trimethylsilyloxy-Δ^2-steroids[6], this process leads to the preferential formation of the diene ion b with *m/e* 142 to which corresponds a rearranged ion with *m/e* 143 (b′).

In the mass spectra of androst-2-ene-1α,17β-diol (I) [7] and androst-2-en-1α-ol (II),[8,9] there are intense peaks due to ions **b** with *m/e* 70 (in both cases) and also of ions **a** with *m/e* 220 and 204 respectively due to the RDR type of decomposition:



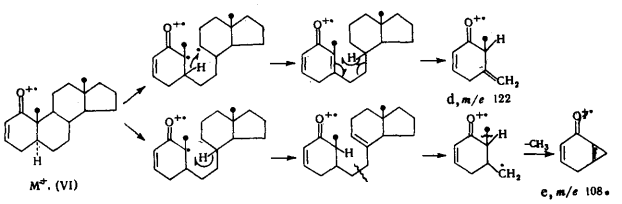
An important characteristic of spectra (I) and (II) is also the presence of peaks with *m/e* 221 and 205 (due to ions a′) respectively, which are much more intense than the peaks due to ions a and are formed with migration of a hydrogen atom to the charged fragment. The mechanism suggested[8,9] for the formation of ions a′,



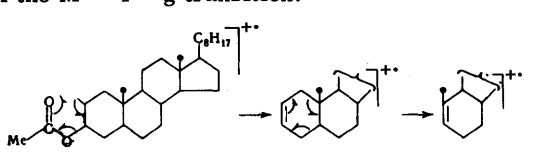
has not been confirmed experimentally.

It is interesting to follow the influence of the number and positions of carbonyl groups in Δ^2-steroids on their capacity to decompose via an RDR mechanism. The effect of carbonyl groups remote from the double bond may be considered for the following two examples. An intense peak due to an ion with *m/e* 218, $(M-54)^+$ formed by RDR in ring *A* accompanied by the ejection of a butadiene molecule, was observed by Djerassi and coworkers[10] in the mass spectrum of 5α-androst-2-en-11-one (III). In contrast there is no peak corresponding to RDR in the spectrum of 5α-androst-2-ene-7,17-dione (IV),[4] while in the spectrum of *trans*-10-methyl-2-octalone (V), which has a similar structure, the peak of the ion due to RDR is present[11]. We believe that this unusual behaviour of (IV) is associated with the possibility of the location of the charge at carbonyl groups remote from the double bond. This factor must be always borne in mind in the interpretation of the mass spectra, since ionisation of molecules "far" from the double bond can either greatly stabilise the molecular ion or can facilitate the occurrence of

competing reactions and thereby inhibit the processes initiated by the double bond:



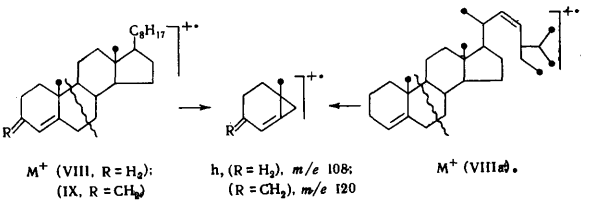
In the study of the decomposition of 5α-androst-2-en-1-one (VI) and its deutero-analogue (labelled at $C_{(2)}$, $C_{(4)}$, $C_{(5)}$, $C_{(6)}$, $C_{(7)}$, and $C_{(16)}$) under electron impact, Djerassi and coworkers[12] showed that the $C_{(2)}$ and $C_{(4)}$ atoms are eliminated from the neutral molecule on formation of an ion with *m/e* 189 (c) from the molecular ion. They proposed the following mechanism for the formation of the ion c:



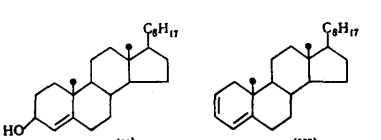
We suggest that the formation of the ion c can be due to an RDR type of decomposition with simultaneous elimination of one of the angular methyl groups.

Moreover, the spectrum of compound (VI) has peaks due to ions with *m/e* 122 (d) and 108 (e) the formation of which is interpreted as follows[12]:

The peak of the ion d with *m/e* 108 is accompanied by the peak of an ion with *m/e* 909 which is formed with migration of two hydrogen atoms, in contrast to the former.



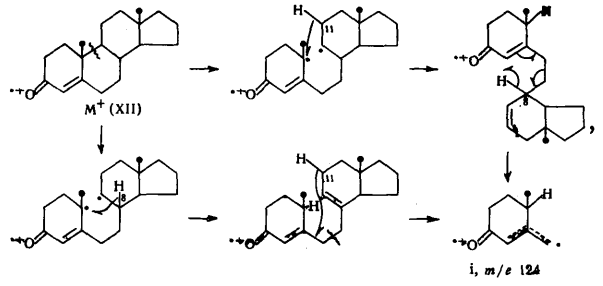
In connection with the discussion of the retro-diene reaction, which is characteristic of Δ^2-steroids, mention should be made of the capacity of such related 3-hydroxysteroids and particularly their acetates to undergo a type RDR decomposition after the elimination of the 3-OH or 3-$OCOCH_3$ groups in the form of water or acetic acid. In most cases the 1,2-elimination of these substituents is associated with a thermal process which leads to the formation of a Δ^2-steroid even before electron impact. Indeed in the spectrum of 5α-cholestan-3β-yl acetate (VII), recorded when the specimen was introduced at 250°C,[13] the peak of the M^+ ion is absent and the peak of the $(M - CH_3COOH)^+$ ion (e), which splits off butadiene as a result of RDR with formation of an *m/e* 316 ion (g), predominates in the mass spectrum. One cannot rule out the possibility that the ion f is formed to some extent also under electron impact. Thus the spectrum of compound (VII), recorded at 80°C,[14] shows all the peaks characteristic of the $M^+ \rightarrow f \rightarrow g$ transition:



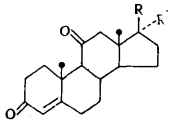
A similar sequence is observed also in the decomposition of the molecular ions from 5α-cholestan-3β-ol, coprostan-3β-ol, its acetate, and 4,4-dimethyl-5α-cholestan-3β-ol.[15] This feature of the fragmentation of saturated 3β-acetoxysteroids has been used[16] to establish the composition of a mixture of plant sterols subjected to preliminary hydrogenation and then acetylated. Butadiene is not split off from Δ^5-hydroxysteroids and their acetates[14], which also form readily $(M - 18)^+$ and $(M - 60)^+$ ions. This phenomenon is associated with the preferential formation of a conjugated 3,5-diene and not its 2,5-isomer.

2. Δ^4-Steroids

Among the simplest Δ^4-steroids without additional functional groups, cholest-4-ene (VIII) [17,18] and stigmasta-4,22-diene (VIIIa) [1] have been investigated. The peak of the ion with *m/e* 108 (h), which is the second most intense in the mass spectrum of compound (VIII), is due to the simple dissociation of the 6—7 and 9—10 allylic bonds[18]. An intense peak due to the ion h is observed also in the spectrum of compound (VIII).[1] A similar dissociation of 6—7 and 9—10 allylic bonds in 3-methylenecholest-4-ene (IX) [18] leads to an ion with *m/e* 120. The peak of this ion in the spectrum of compound (IX) is accompanied by equally intense peaks due to ions with *m/e* 106 and 94 the first of which may be formed as a result of the dissociation of 5—6 and 9—10 bonds:



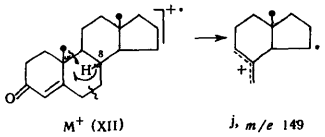
Proceeding now to steroids containing functional groups, we must consider in the first place the mass spectrum of allocholesterol (X).[17-19] The allocholesterol molecule shows an exceptional tendency towards thermal dehydration and therefore its spectrum, recorded using a hot glass inlet system at 200°C, does not contain the peak of the molecular ion and is absolutely identical with the spectrum of cholesta-2,4-diene (XI) (see section VII, 2). When the specimen is introduced directly into the ion source, which makes it possible to reduce the experimental temperature to 90—100°C, a large peak due to the molecular ion and the fragments resulting from its subsequent decomposition appears in the spectrum of compound (X), but a very significant feature of this spectrum is still the decomposition characteristic of compound (XI).



The most extensive and interesting data have been obtained in mass-spectrometric studies on Δ^4-3-ketosteroids. Shapiro and Djerassi[20] were the first to demonstrate for androst-4-en-3-one (XII) an important characteristic of the decomposition of such systems. It was found that the main peak in the mass spectrum of compound (XII) corresponds to the ion i with *m/e* 124. It was shown with the aid of the mass spectra of 2,2,4,6,6-D_5-, 8-D_1, 11,11-D_2-, and 19-D_1-analogues of compound (XII), its 7β-D_1-17β-OH-analogue, and also the

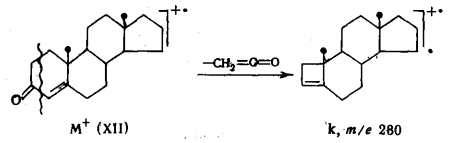
spectrum of cholest-4-en-3-one (XIII) that the ion i contains the *A* ring, the 19-CH_3 group, and a $C_{(6)}$ atom, being formed as a result of the dissociation of 6—7 and 9—10 allylic bonds with transfer of two hydrogen atoms from $C_{(8)}$ and $C_{(11)}$ to the charged fragment, as shown in the mechanism below[20,21]:

An additional piece of evidence of the validity of the mechanism proposed to account for the formation of the ion i is also the finding that in the mass spectra of androst-4-ene-3,11-dione (XIV),[20,22] cortisone (XV),[2,20,23-25], and androst-4-ene-3,11,17-trione (XVI) [24] a peak with *m/e* 122 due to the simple dissociation of the 6—7 and 9—10 bonds without the migration of hydrogen atoms appears instead of the ion i. This can be explained by the absence of hydrogen atoms at $C_{(11)}$ in compounds (XIV)—(XVI).



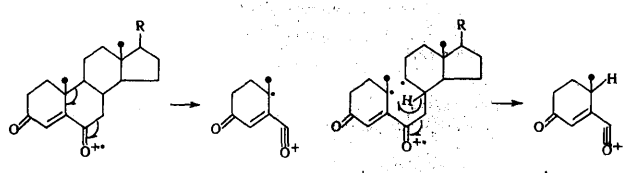
(XIV, R = R' = H);
(XV, R = $COCH_2OH$, R = OH);
(XVI, R + R' = O)

The presence of the peak due to the ion i and its analogues, the mass number of which depends on the substituents in ring *A* and at $C_{(6)}$ and $C_{(19)}$ is common to the mass spectra of all steroid Δ^4-3-ketones and can be used for their identification (Table 2).

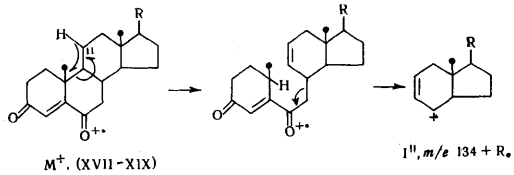


The ion i and its analogues are formed directly from the molecular ion and therefore their peak intensities are related. In the spectra of compounds containing, for example, functional groups which are readily eliminated by electron impact, the molecular ion peaks are small or altogether absent. At the same time there is a significant decrease of the peak due to the ions i. However, the peaks of these ions and their analogues with even mass numbers, can be as a rule reliably detected in the spectrum, since groups of peaks in which odd peaks are much more intense than even peaks are characteristic of this part of the mass scale for steroids and other carbocyclic compounds and one can readily observe even a slight increase in the intensity of the even peaks in the region where the peaks of the ion or its analogues is presumed to be.

Another characteristic of the mass spectra of steroid Δ^4-3-ketones is the presence of peaks due to the dissociation of the same 6—7 and 9—10 bonds but with fixation of the charge on the fragment containing the *C* and *D* rings. It has been shown for androst-4-en-3-one (XII) with the aid of its 8-D_1-analogue[20] that the formation of the corresponding ion j is accompanied by the migration of the hydrogen atom from $C_{(8)}$ to a neutral fragment:

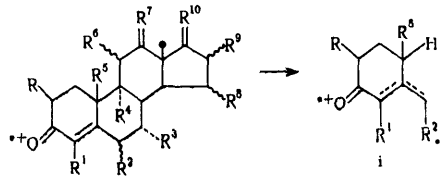


Peaks due to analogous ions have been detected also in the mass spectra of substituted progesterones[9,34]. Although this is a decomposition pathway which in general leads to low-intensity peaks and is not discussed for other Δ^4-3-ketones listed in Table 2, it is also evidently common to all Δ^4-3-ketosteroids.



The third specific pathway in the fragmentation of Δ^4-3-ketosteroids is associated with the formation of an $(M - 42)^+$ ion (k). The probable mechanism of its formation involves the ejection of $C_{(2)}$ and $C_{(3)}$ atoms in the form of keten:

The situation changes somewhat in Δ^4-3,6-diketosteroids. Djerassi and coworkers[41] investigated the mass spectra of androst-4-ene-3,6-dione (XVII), pregn-4-ene-2,6-dione (XVIII), and cholest-4-ene-3,6-dione (XIX) and observed in them an intense double peak with *m/e* 136 and 137. The spectrum of compound (XVII) also contains an intense *m/e* 135 peak, the peaks in the triplet decreasing in the sequence 135 < 136 < 137. The peaks of the ions with *m/e* 136 (l) and 137 (l') in the mass spectrum of 2,2,7,7-D_4-(XIX) shift by 2 a.m.u., which indicates the retention of ring *A* in their structures. The involvement of the hydrogen atom at $C_{(8)}$ in the formation of the ion l' is postulated by analogy with Δ^4-3-ketones:



The *m/e* 135 peak (ion l''), which is characteristic of the mass spectrum of compound (XVII), shifts to *m/e* 163 and 247 in the spectra of compounds (XVIII) and (XIX) respectively. The authors suggest that the corresponding ion is formed as a result of a rearrangement involving the hydrogen atom at $C_{(7)}$ similar to the rearrangement described above for Δ^4-3-ketosteroids:

The mass spectra of the Δ^4-3,6-diketones under consideration also contain peaks of $(M - CH_2CO)^+$ ions, the formation of which may be due to both the 3-oxo-and the 6-oxo-group.

In conclusion of the section dealing with Δ^4-steroids, mention may be made also of studies on the mass-spectrometry of Δ^4-6-aza-7-ketosteroids (XX) [42,43] the spectra of which contain, despite the presence of a heteroatom in ring *B*, peaks of m, m', and m'' ions, whose intensity

Table 2. The values of *m/e* (intensity expressed as a percentage of the maximum) for the ion i in the mass spectra of Δ^4-3-ketosteroids.

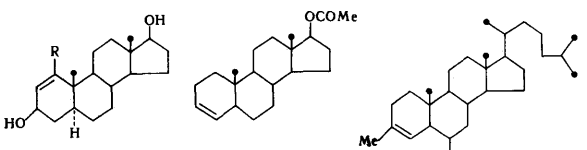
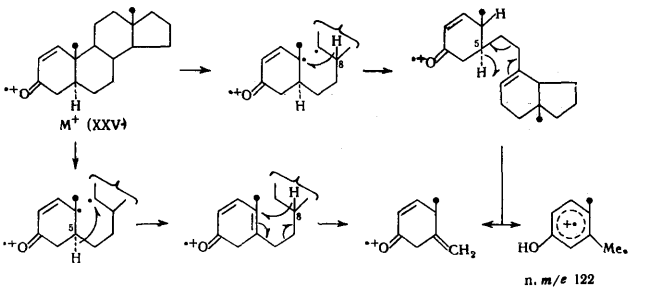
* Intensity expressed as a percentage of the total ionic current.

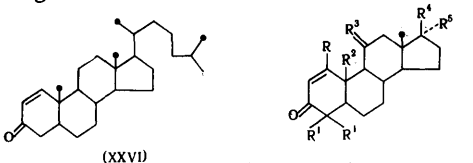


is highest, which are also due to the dissociation of the 6—7 and 9—10 bonds:

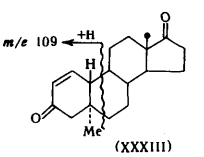


3. Δ^1- and Δ^3-Steroids

Specific fragmentation pathways have not been observed in Δ^1- and Δ^3-steroids without functional groups near the double bond. Thus the most intense peak in the mass spectrum of 1-methyl-5α-androst-1-ene-3β,17β-diol (XXI) [7] is that with *m/e* 220, the structure of the corresponding ion being most probably similar to that of the ion a. Probably the fragmentation of the molecular ion of compound (XXI) resembles the decomposition of Δ^2-steroids, which hinders their identification. Spitteller and coworkers[8,9] noted that fragments typical of Δ^4-steroids can be detected in the spectrum of compound (XXII), the 1-desmethyl analogue of compound (XXI).



One of the main peaks in the spectrum of androst-3-en-17β-yl acetate (XXIII) [9] is one with *m/e* 108 (ion h, $C_8H_{12}^+$), which is also characteristic of 4-cholestene (VIII). In the spectrum of 3-methylcholest-3-en-6β-yl acetate (XXIV), [18] there is no molecular ion peak, the dominant intensity being that of the peak due to the $(M - CH_3COOH)^+$ ion, which corresponds to the maximum mass number. The latter subsequently splits off part of ring *A* with formation of an $(M - 60 - 68)^+$ ion corresponding to *m/e* 314; its formation is a result of the RDR ejection of an isoprene molecule (68 a.m.u.), which is more likely to be typical for the corresponding Δ^2-steroid:



The mass spectra of Δ^1-3-ketosteroids are significantly more characteristic. The decomposition of these compounds resembles that of their Δ^4-3-keto-isomers. The most intense peak in the mass-spectrum of 5α-androst-1-en-3-one (XXV) [20] is that of the *m/e* 122 ion n. Judging from its mass number, this ion should form as a result of a simple dissociation of the 6—7 and 9—10 bonds without the migration of a hydrogen atom. However, analysis of the mass spectra of the 5α- and 8β-D_1 analogues of compound (XXV) showed that in the formation of the ion n hydrogen atoms move towards each other, that from $C_{(5)}$ migrating to the neutral fragment and that from $C_{(8)}$ to the charged fragment. The following possible mechanism for the formation of the ion n has been proposed on the basis of these results[20,21]:

Intense peaks due to the ions n (*m/e* 122) are present also in the mass spectra of cholest-1-en-3-one (XXVI), [22] 5α-androst-1-ene-3,11-dione (XXVII), 17β-hydroxy-5α(and 5β)-androst-1-en-3-ones (XXVIII), and 5α(and 5β)-androst-1-ene-3,17-diones (XXIX) [44] and the peaks of the homologous ions with *m/e* 136, 150, and 108 are present in the spectra of 17β-hydroxy-1-methyl-5α-androst-1-ene-3-one (XXX), 4,4-dimethyl-5α-cholest-1-en-3-one (XXXI), [22] and 19-nor-Δ^1-3-ketosteroids (XXXIIa, b) respectively. In connection with the different behaviour of Δ^1- and Δ^4-3-ketosteroids, it has been suggested[14] that the reason why the ion n cannot be formed from the latter is the absence of a hydrogen atom at $C_{(5)}$, which is necessary for the migration of the two hydrogen atoms towards one another described above. This hypothesis is confirmed by the finding that the mass spectrum of 5α-methyl-19-norandrost-1-ene-3,17-dione (XXXIII), [18] which also lacks a hydrogen atom at $C_{(5)}$, contains virtually no peak with *m/e* 122, the main peak being one with *m/e* 109, which probably arises on dissociation of the 5—6 and 9—10 bonds with migration of a hydrogen atom to the charged fragment.

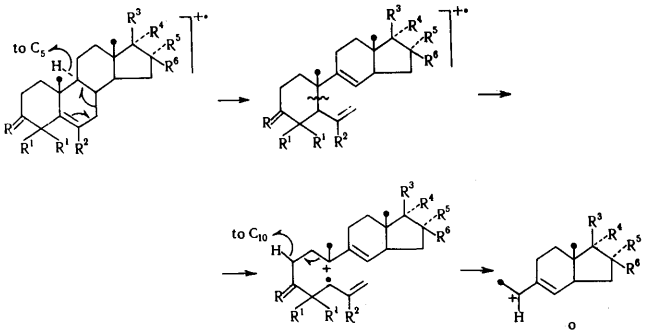
(XXVII, R = R1 = R4 = R5 = H, R2 = Me, R3 = O);
(XXVIII, R = R1 = R5 = H, R2 = Me, R3 = H2, R4 = OH, 5α- and 5β-);
(XXIX, R = R1 = H, R2 = Me, R3 = H2, R4 + R5 = O);
(XXX, R = R2 = Me, R1 = R5 = H, R3 = H2, R4 = OH);
(XXXI, R = R5 = H, R1 = R2 = Me, R3 = H2, R4 = C8H17);
(XXXIIa, R = R1 = R2 = R5 = H, R3 = H2, R4 = OCOMe, 5α- and 5β-);
(XXXIIб, R = R1 = R2 = H, R3 = H2, R4 = COMe R5 = OH).

Thus, in contrast to Δ^4-3-ketosteroids, the dissociation of the 6—7 and 9—10 bonds in Δ^1-3-ketosteroids is accompanied only by the migration of hydrogen atoms towards one another and the corresponding characteristic peak of the ion n is smaller by 2 a.m.u. than the peak of the ion i, which is characteristic of Δ^4-3-ketosteroids.

It is striking that the intensity of the peak due to the ion n depends on the configuration at $C_{(5)}$ and is always greater in the 5β-series[44,45].

The presence in the Δ^1-3-ketosteroid molecule of an $\alpha\beta$-unsaturated keto-chromophore is the reason for the elimination of keten from M^+. This process has been noted for the majority of the Δ^1-3-ketones described above and in this respect their decomposition is analogous to that of their Δ^4-3-keto-isomers, which leads to ions of type k. Egger[44] suggested that the absence of the peak of the $(M - 42)^+$ ion from the mass spectrum of the 5β-isomer (XXVIII) be employed to determine the configuration of the

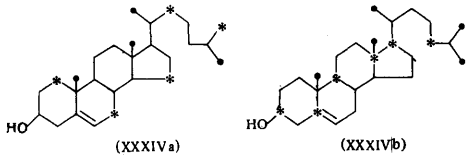
5th centre in steroids of the Δ^1-3-keto-series. However, Schulz[45] did not find a similar difference in the 5α- and 5β-Δ^1-3-ketones which he investigated, and noted the presence of the peak of the $(M - 42)^+$ ion in the spectra of the 5α- and 5β-isomers of compound (XXXIIa) and its absence from the spectra of the 5α- and 5β-isomers of compound (XXXIIb).



III. STEROIDS WITH A DOUBLE BOND IN RING *B*

1. Δ^5-Steroids

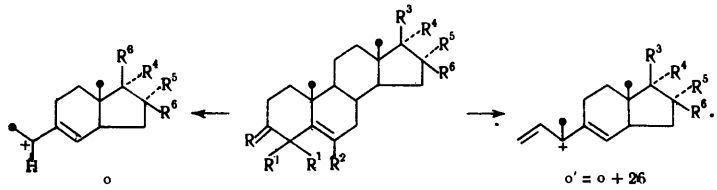
A large number of natural steroids, particularly of plant origin, contain a double bond in the 5—6 position. A combined gas—liquid chromatographic and mass-spectrometric method has been widely used recently to investigate natural steroid mixtures. As a rule, volatile steroid derivatives—acetates and especially trimethylsilyl ethers—are used in such investigations. In many studies of this kind, no data were obtained whereby one could infer the influence of the position of the double bond on the nature of the decomposition of the molecular ion under electron impact. Naturally, these investigations are not considered here.



In one of the first mass-spectrometric studies on Δ^5-steroids, Friedland et al.[46] were the first to draw attention to the intense peak due to ions with *m/e* 275, 303, and 177, among the many peaks characteristic of the majority of steroids, in the spectra of cholesterol (XXXIV), β-sitosterol (XXXV), and dehydroepiandrosterone (XXXVI) respectively. They attributed the formation of these ions to the dissociation of the 9—10 bond and of the 5—6 vinylic bond. Somewhat later Ryhage and Stenhagen[15] also published the spectrum of cholesterol but failed to interpret many of the peaks in it, including the *m/e* 275 peak. We undertook a systematic study of the effect of the Δ^5-bond [17,19] in numerous Δ^5-3-hydroxy- and Δ^5-3-keto-steroids. Regardless of the conditions employed during its recording (a heated glass filling system or direct introduction into the ion source), the mass spectrum of cholesterol (XXXIV) shows an intense *m/e* 275 peak, the intensity of which depends on that of the peak due to the molecular ion: in experiments with a hot glass inlet system at 200°C, the intensity of the *m/e* 275 peak decreases together with decrease of that of the molecular ion peak; under milder conditions, when the specimen is introduced directly into the ion source, the size of the *m/e* 275 peak differs little from the molecular ion peak, which predominates in the spectrum.

The mass spectrum of cholest-5-en-3-one (XXXVII),[17,19] recorded on an apparatus with a heated glass filling system at 200°C, is identical with the spectrum of cholest-4-en-3-one (XIII), which indicates the ease of the thermal isomerisation of Δ^5-3-ketones under the conditions of mass-spectrometric measurements. However, when the apparatus with direct introduction of the specimen into the ion source is employed, the mass spectrum of compound (XXXVII) differs significantly from that of compound (XIII), since it contains an intense *m/e* 275 peak (ion o). The *m/e* 275 peak of the ion o is observed also in the spectrum of cholest-5-ene (XXXVIII).[8,9,17] Similarly the spectra of pregn-5-en-3,20-dione (XXXIX) and androst-5-ene-3,17-dione (XL) show intense peaks with *m/e* 205 and 177 respectively, which are absent from the spectra of the isomeric Δ^4-3-ketones. However, it is noteworthy that the spectra of the Δ^5-3-ketones as a rule also show peaks with *m/e* 124 (ion i) and M − 42, which are characteristic of Δ^4-3-ketones. This indicates a partial isomerisation of Δ^5-3-ketones to Δ^4-3-ketones even under mild experimental conditions. Thus one may conclude that the ions o are characteristic of Δ^5-steroids. Since the mass number of the ion o depends on the size of the side chain at $C_{(17)}$, it must contain rings *C* and *D* together with the side chain (Table 3). In view of the fact that the mass number of the ion o does not vary with substitution in ring *A*, the latter must be absent (or only a small portion of it remains at the junction with ring *B*). On the other hand, the $C_{(6)}$ atom does not enter into the composition of the ion o, since in the spectrum of 6-methylcholesterol (XLI) [18,19] its mass number remains unchanged compared with the spectrum of compound (XXXIV). Thus the mechanism of the formation of the *m/e* 275 ion, proposed previously[46], is erroneous and the following mechanism may be proposed for the formation of the ion o:[8,18]

The mechanism shows that the ion o is probably formed directly from the molecular ion, although the corresponding metastable peak was not observed. This hypothesis is confirmed indirectly by the fact that in the spectra of compounds which do not contain the peak of the molecular ion, or its intensity is low, the intensity of the peak due to the ion o is greatly reduced, sometimes to such an extent that it cannot be reliably identified. For example, in the spectra of the acetate (XLII), trifluoroacetate (XLIII), and trimethylsilyl ether of cholesterol (XLIV), of which the first two altogether fail to give rise to the molecular ion peak and the third contains a low-intensity M^+ peak, the peaks of the ion o are small (Table 3).



The final proof of the origin of the ion o can be obtained by studying the spectra of labelled compounds. In this connection, Knights[47] put forward an interesting idea. He suggested that one should investigate the mass spectra of cholesterols labelled with ^{13}C in various positions of the steroid skeleton, namely the spectra of compounds (XXXIVa) and (XXXIVb), which may be obtained by biosynthesis from [2-^{13}C]- and [4-^{13}C]-mevalonic acids respectively. However, this has not been achieved experimentally.

(XXXIVa) (XXXIVb)

The mass spectra of Δ^5-3-hydroxysteroids contain, together with peaks of the ions o, peaks with an intensity higher by 26 a.m.u. (o + 26, ion o′), which are not observed in the spectra of Δ^5-3-ketones (Table 3). As a rule, the intensity of these peaks is of the same order of

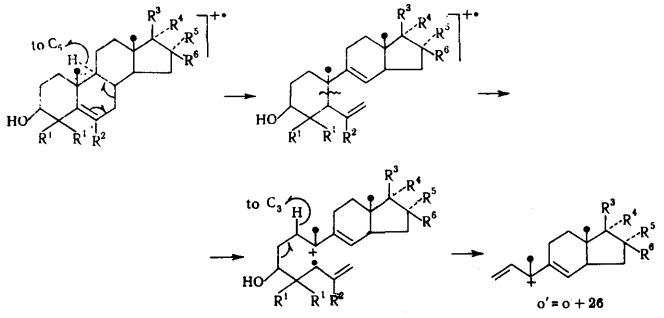


Table 3. The values of *m/e* (intensity expressed as a percentage of the M^+ peak) for the ions o and o′ in the mass spectra of Δ^5-steroids.

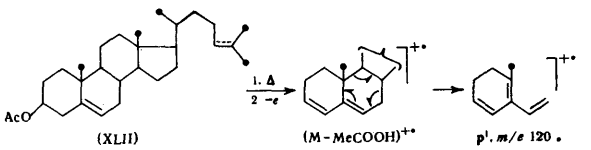
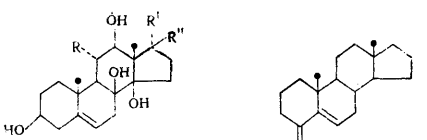
magnitude as that of peaks due to the ions o. The data in Table 3 lead to the conclusion that the ions o′ contain rings *C* and *D* and do not contain the $C_{(4)}$ atom. However, they also incorporate the $C_{(1)}$ and $C_{(2)}$ atoms. A formal mechanism has been proposed for the formation of both the o and o′ ions assuming the retention in the latter of the most probable carbon atoms[8,18]:

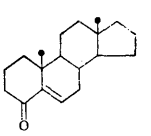


In principle one may expect that Δ^5-steroids should decompose via a type RDR mechanism. One cannot rule out the possibility that in the cases described above this process does occur but only to such a slight extent that the corresponding peaks are difficult to observe against the background of the surrounding peaks. This applies particularly to the peaks of the diene fragments, since their mass numbers are usually smaller than 100 and this region contains fairly intense uncharacteristic peaks typical for all carbocyclic compounds. Nevertheless in the case of certain Δ^5-steroids containing labile functional groups, the spectra of which show low-intensity peaks due to molecular ions (this precludes an unambiguous identification of the peaks due to the ions o and o′), peaks caused by RDR in ring *B* frequently appear. Reichstein and coworkers[51] observed in the spectrum of stapelogenin (XLV) a medium-intensity *m/e* 138 peak (ion p) due to a type RDR decomposition. This ion is accompanied by one formed as a result of dehydration (the ion p′). The origin of the ions has been confirmed by comparison with the spectrum of the di-OD-analogue of compound (XLV):

Later Galli and Maroni[52] observed *m/e* 120 peaks of the ion p′ in the mass spectra of cholesteryl acetate (XLII) and cholesta-5,24-dien-3β-yl acetate (XLVI) (with intensities of 30 and 15% respectively), which arise as a result of RDR in the $(M - CH_3COOH)^+$ ion. Probably the latter is formed by the thermal elimination of CH_3COOH, since these spectra do not contain M^+ peaks and the peaks



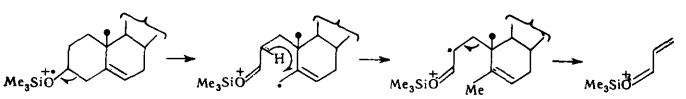
of the $(M - CH_3COOH)^+$ ions have the highest mass number.



(XLII) (XLVI. Δ^{24})

The mass spectra of compounds (XLII) and (XLVI) contain also the peaks of *m/e* 247 and 245 ions, which are probably formed on dissociation of the same bonds (7—8 and 9—10) but with migration of hydrogen and location of the charge on the dienophile fragment.

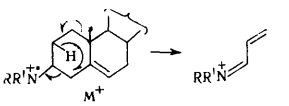
In a recent mass-spectrometric study of a large number of polyols of the 5-pregnene series, of the type of marsdenin (XLVII) and sarcostin (XLIII), Fukuoka et al.[53] also observed peaks of ions p and p'. They likewise interpreted a series of other peaks produced by a mechanism similar to that of the formation of the ions p and p' but involving a rearrangement of the hydrogen atoms. The presence of peaks due to ions formed by the dissociation of the same bonds (7—8 and 9—10), but involving the fixation of the charge on the dienophile fragment with $m/e = M^+ - 138$ ($M^+ - 180$ for 3-acetoxy-derivatives), was noted in the same investigation.



(XLVII, R=OH, R'=COMe, R''=H);
(XLVIII, R=H, R'=CHOHMe, R''=OH)

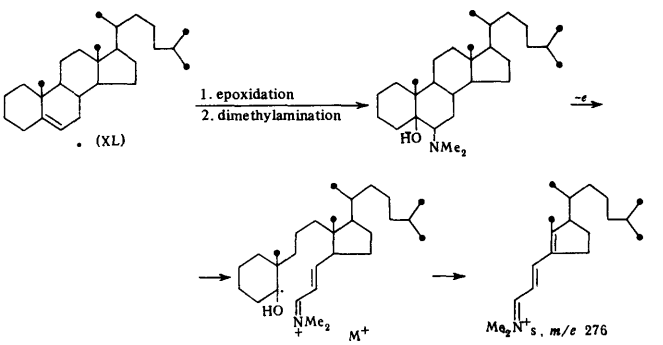
(XLIX).

Thus the peaks of the ions p and p' or o and o' are diagnostic in the series of Δ^5-steroids, depending on the stability of the molecular ion and the presence of labile functional groups. It is interesting to note that the mass spectrum of androst-5-en-4-one (XLIX) [54] also contains the peaks of the ion o with *m/e* 163. Von Unruh and Spiteller[55] believe that the peaks of *m/e* 135, 147, and 149 ions are characteristic of compound (XLIX). The first two probably arise in a type RDR decomposition in ring *B* with migration of the hydrogen atom to or away from the charged fragment; it is not clear which half of the molecule is charged under these conditions.



Certain data concerning the capacity of trimethylsilyl ethers of Δ^5-3-hydroxysteroids to give rise to ions of types o and o' in decomposition under electron impact are presented in Table 3. Another characteristic of the decomposition of these derivatives is the ease of formation of the ion with *m/e* 129 (r) whose peak is the most intense in their spectra[50,56-58] (in the spectra of the corresponding saturated analogues, the peak of this ion is insignificant). The ease of formation of the ion r on decomposition of Δ^5-steroids is due to the dissociation of two allylic bonds (3—4 and 1—10), which is confirmed by their comparison with the spectra of deutero-analogues[57]:

r, *m/e* 129

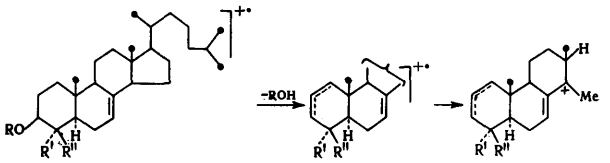


It is noteworthy that the presence of the Δ^5-bond greatly intensifies the elimination of $(CH_3)_3SiOH$ from the molecular ion[57,58], which in all probability results in the formation of the ion of the conjugated 3,5-diene.

In a manner similar to the increase of the intensity of the peak of the ion r on passing from saturated to Δ^5-3-trimethylsilyloxy-derivatives, there is a sharp increase of the intensity of the peak due to the ion r' in the mass spectra of 3-amino-Δ^5-steroids compared with their saturated analogues[59-65]. The mechanism of the formation of the ion r' is evidently similar to that of the formation of the ion r, the dissociation of two allylic bonds (3—4 and 1—10), which intensifies the formation of the ion r', also being responsible for the occurrence of this process:

r', (R=R'=H), *m/e* 56;
(R=H, R'=Me), *m/e* 70;
(R=R'=Me), *m/e* 84;.

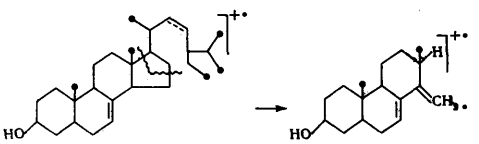
In conclusion of the discussion of Δ^5-steroids, attention should be drawn to the interesting method of determining the position of the double bond in these compounds, proposed by Reed[66]. Although the principle of this method has been demonstrated only for 5-cholestene (XL), it is presumably of more general validity. Its essential feature is that the test compound is epoxidised, the epoxide treated with dimethylamine, and the resulting α-aminoalcohol analysed mass-spectrometrically. The presence in the mass spectrum of the peak due to the ion s serves as evidence of the presence of a Δ^5-bond in the olefin investigated:



(XL)

2. Δ^7-Steroids

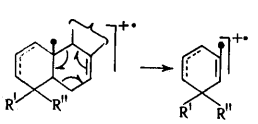
Compounds containing the double bond in the 7—8 position occupy an important place among plant sterols. A number of mass-spectrometric studies have been made on hydroxysteroids of this type, particularly their ethers, trimethylsilyl ethers, and acetates. Gustavsson et al.[58], who considered the mass spectra of the trimethylsilyl ethers of 5α-cholest-7-en-3β-ol (L) and 4α-methyl-5α-cholest-7-en-3β-ol (LI), noted the insignificant intensity of the peaks of the ions r. In addition, they pointed out the presence in the spectra of these compounds of peaks due to ions with *m/e* 229 and 243, the nature of which they failed to establish. Galli and Maroni[52] also observed peaks due to ions with *m/e* 229, 243, and 257 in 5α-cholest-7-en-3β-yl (LII), 4α-methyl-5α-cholest-7-en-3β-yl (LIII), and 4,4-dimethyl-5α-cholest-7-en-3β-yl (LIV) acetates respectively. Having investigated a large number of acetate and trifluoroacetate esters and trimethylsilyl ethers of Δ^7-3-hydroxysteroids, Knights[47] concluded that the formation of the ions t as a result of the elimination of the substituents at $C_{(3)}$ together with a hydrogen atom from the side chain and part of ring *D* is most characteristic of these compounds.



The formation of the ion t can be represented in a general form as follows:

M^+, (L, R = Me_3Si, R' = R'' = H);
(LI, R = Me_3Si, R' = Me, R'' = H);
(LII, R = COMe, R' = R'' = H);
(LIII, R = COMe, R' = Me, R'' = H);
(LIV, R = COMe, R' = R'' = Me)

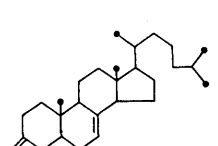
t, (R' = R'' = H), *m/e* 229;
(R' = Me, R'' = H), *m/e* 243;
(R' = R'' = Me), *m/e* 257.



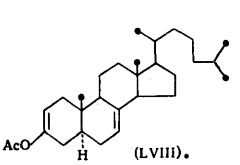
In a study of the mass spectra of stigmast-7-en-3β-ol (LV) and stigmasta-7,22-dien-3β-ol (LVI), Clark-Lewis and Dainis[67] drew attention to the *m/e* 246 fragment (t') which they also regard as characteristic of Δ^7-steroids:

M^+ (LV)
(LVI: Δ^{22})

t, *m/e* 246



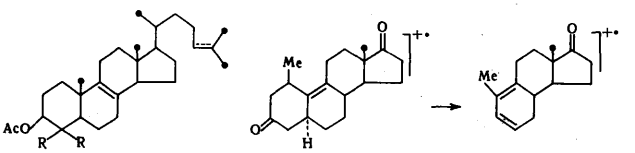
Without denying that the formation of the ions p is characteristic of the decomposition of Δ^7-steroids under electron impact, Galli and Maroni[52] nevertheless believe that type RDR decomposition in ring *B* is more important. They detected peaks with *m/e* 94, 108, and 122 (the ions u) in the mass spectra of compounds (LII), (LIII), and (LIV) respectively, which are probably formed as a result of RDR after the elimination of the functional group at $C_{(3)}$ with an additional hydrogen atom:



$(M-ROH)^{+\cdot}$ (LII-LIV)

u, (R' = R'' = H), *m/e* 94;
(R' = Me, R'' = H), *m/e* 108;
(R' = R'' = Me), *m/e* 122.

We believe that the ion u is difficult to employ for the identification of the Δ^7-bond, since the spectra of all steroids contain groups of peaks of approximately equal intensity with *m/e* 91—96, 105—110, and 119—124 against the background of which it is not always possible to isolate the required peak with certainty. Moreover, the process cannot be regarded in principle as specific to the steroid olefins under consideration. For example, in the spectrum of cholest-7-en-3-one (LVII) [18] there is no peak corresponding to the ion u, but there are peaks due to ions of types t and t' (both contain the C=O group). In 5α-cholesta-2,7-dien-3β-yl acetate (LVIII),[68] RDR in ring *B* is not observed either but the peak due to the fragment caused by type RDR decomposition in ring *A*, characteristic of Δ^2-steroids, is very intense (75% of the maximum peak in the spectrum).



(LVII)

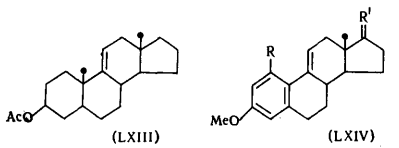
(LVIII).

3. Δ^8- and Δ^9-Steroids

In a study of the mass spectra of cholesta-8,24-dien-3β-yl (LIX), cholest-8-en-3β-yl (LX), and 4,4-dimethylcholest-8-en-3β-yl (LXI) acetates, Galli and Maroni[52] failed to observe the peaks of characteristic ions the formation of which might have been due to the Δ^8-bond.

(LIX, R = H, Δ^{24});
(LX, R = H);
(LXI, R = Me)

M^+ (LXII)

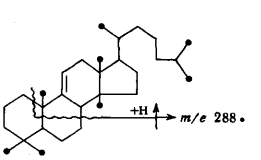


v, *m/e* 216.

The mass spectrum of 1β-methyl-19-norandrost-9-en-3,17-dione (LXII) [18] is fairly characteristic, but on the basis of this single example it is hardly possible to conclude that the decomposition pathways considered are typical for all Δ^9-steroids. After the molecular ion peak, the most intense peak in the spectrum of compound (LXII) is that of the ion with *m/e* 216 (v), which is most probably formed as a result of the ejection of the 1-CH_3 group and the cyclopropanone moiety (atoms $C_{(2)}$ – $C_{(4)}$) from ring *A*, although one cannot rule out the possibility that this ion can be formed from the $(M-15)^+$ ion with scission of part of ring *D* (atoms $C_{(15)}$ – $C_{(17)}$).

IV. STEROIDS WITH A DOUBLE BOND IN RING *C*

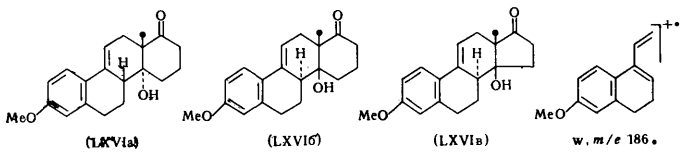
1. $\Delta^{9(11)}$-Steroids



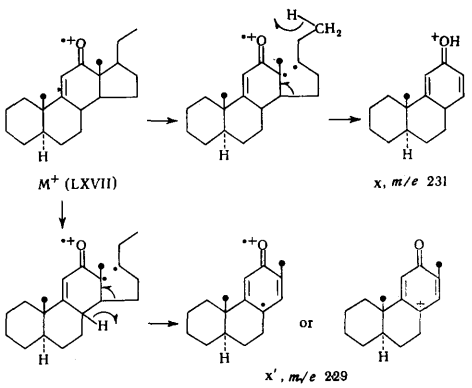
Despite the fact that the double bond in the 9—11 position might initiate type RDR decomposition, the mass spectra of androst-9(11)-en-3β-ol (LXIII) and derivatives of $\Delta^{9(11)}$-dehydro-oestrone (LXIV, a—c) [3,69] do not contain the corresponding peaks:

(LXIII) (LXIV)

(a, R = H, R' = H, OH);
(b, R = OMe, R' = O);
(c, R = Me, R' = O)

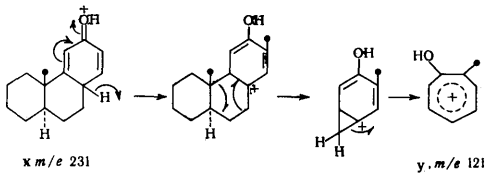


This is in full agreement with Reed's observation[11] that the peak of the *m/e* 204 ion (produced as a result of a type RDR decomposition) has only a slight intensity in the spectrum of lanost-9(11)-ene, while the peak of the $(M-15)^+$ ion (evidently produced by the ejection of the 19-CH_3 group) and the peak of the *m/e* 288 ion formed as a result of the dissociation of three allylic bonds (1—10, 5—10, and 7—8) with transfer of a hydrogen atom to the charged fragment, are very intense:

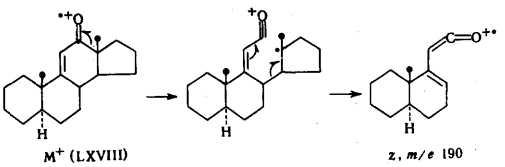


(LXV)

In contrast, in the mass spectra of the methyl ethers of $\Delta^{9(11)}$-dehydro-14α-hydroxy-D-homo-oestrone (LXVIa), $\Delta^{9(11)}$-14β-hydroxy-8α-D-homoiso-oestrone (LXVIb), and $\Delta^{9(11)}$-dehydro-14β-hydroxy-8α-iso-oestrone (LXVIc) the dominant peaks correspond to ions with *m/e* 186 (w).[70,71]

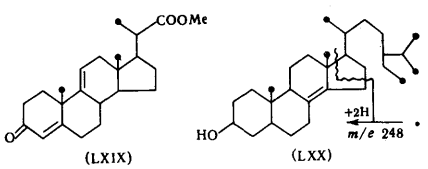


Although medium-intensity peaks with the same value of m/e are present in the mass spectra of almost all oestrone derivatives without the 9—11 double bond, their sharp increase in the spectra of compounds (LXVI, a—c) is apparently evidence that in this case the ions w are formed via a type RDR mechanism:



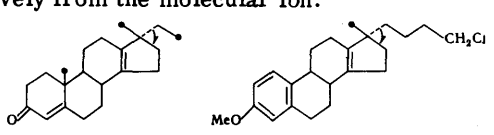
Tökes and Djerassi[72] made a mass-spectrometric study of $\Delta^{9(11)}$-12-keto-steroids and found that the mass spectrum of 5α-pregn-9(11)-en-12-one (LXVII) contains, together with the intense m/e 231 peak (the ion x), due to the elimination of ring D and the migration of a hydrogen atom to the charged moiety (the composition typical for 12-ketosteroids), there is also a peak due to an ion with m/e 229 (x′) formed as a result of an analogous process with migration of a hydrogen atom from the 8β-position in the charged species:

The maximum peak in the spectrum of compound (LXVII) with m/e 121 (the ion y) is due to further decomposition of the ion x:



In contrast to compound (LXVII), in the mass spectrum of 5α-androst-9(11)-en-12-one (LXVIII) there are virtually no peaks due to the ions x and y. It was also suggested[72] that this is due to the absence from compound (LXVIII) of a substituent at $C_{(17)}$, which initiates the dissociation of the 13—17 bond and serves as a donor of a hydrogen atom from the 20-position in the course of the formation of the ion x. The peak of the m/e 147 ion ($C_{10}H_{11}O^+$), which contains, according to the mass-spectrometric data for the 8,11-dideutero-analogue of compound (LXVIII), the $C_{(8)}$ and $C_{(11)}$ atoms, predominates in the spectrum of compound (LXVIII). Moreover, the spectrum of this compound contains a medium-intensity peak due to an ion with m/e 190 (z) caused by the dissociation of the 8—14 and 12—13 bonds. In compound (LXVII) this process is less characteristic:

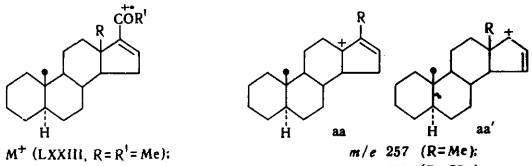
Ions of types x, y, and z are also present in the mass spectrum of the ester of 3,12-dioxobisnorchola-4,9(11)-dienoic acid (LXIX).[18]



2. $\Delta^{8(14)}$-Steroids

The mass spectra of only two examples of compounds of this type have been described, namely of stigmast-8(14)-enol (LXX) and its acetate. Clark-Lewis and Dainis[57] believe that the peaks of ions with m/e 248 and 234, are characteristic of both compounds; the first is evidently formed as a result of the dissociation of the 13—17 and 15—16 bonds accompanied by the migration of two hydrogen atoms to the charged fragment. Naturally this one example is insufficient to assess whether or not this process is characteristic of all $\Delta^{8(14)}$-steroids.

V. STEROIDS WITH A DOUBLE BOND IN RING D



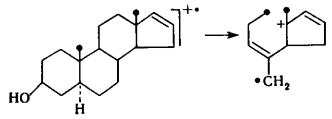
The presence of a double bond in the 13—14 position in the steroid molecule stimulates the dissociation of the allylic 17—20 bond with elimination of the substituent at $C_{(17)}$ and therefore the mass spectra of 17α-ethyl-17β-methyl-18-norandrosta-4,13-dien-3-one (LXXI) and 17α-(γ-chloropropyl)-3-methoxy-17β-methyl-18-norоestra-1,3,5(10),13-tetraene (LXXII) show[73] very intense peaks associated with the elimination of C_2H_5 and C_3H_6Cl respectively from the molecular ion:

Peterson[32] quotes mass-spectrometric data for a group of Δ^{16}-steroids of the pregnane series, a characteristic feature of which is the absence of peaks due to the elimination of ring D from the molecular ion with formation of the so called "tricyclic fragment" containing rings A, B, and C. Generally speaking, this process should be inhibited in all compounds containing a double bond in any position in ring D, since its occurrence requires the dissociation of at least one double bond.

Tökes and Djerassi[72] confirmed the absence of the peak due to the "tricyclic fragment" from the spectrum of 5α-pregn-16-en-20-one (LXXIII) and noted that the most intense peaks in the spectrum are those of the $(CH_3CO)^+$ and $(M - CH_3CO)^+$ ions with m/e 43 and 257 respectively, due to the dissociation of the 17—20 double bond, i.e. a

process which is extremely unfavourable on energy grounds. To account for this anomaly, the authors suggested that this process involves a rearrangement accompanied by the migration of the CH_3 group from the 13-position to the 17-position and the formation of a stable allyl carbonium ion **aa**. On the basis of this single instance, the authors conclude that the dissociation of the double bond may be facilitated if it is associated with a simultaneous rearrangement. From our point of view, the formation of the $(M - CH_3CO)^+$ ion may be due to a preliminary migration in the molecular ion of the double bond to the 15—16 position followed by the dissociation of the 17—20 bond, which has become allylic, and the formation of the ion aa′:

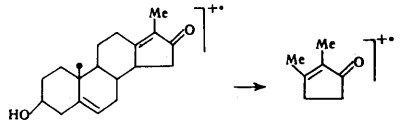
M^+ (LXXIII, R = R′ = Me); (LXXIIIa, R = CD_3, R′ = Me); (LXXIIIб, R = Me, R′ = CD_3)



aa aa′

m/e 257 (R = Me); *m/e* 260 (R = CD_3); *m/e* 257 (R = Me).

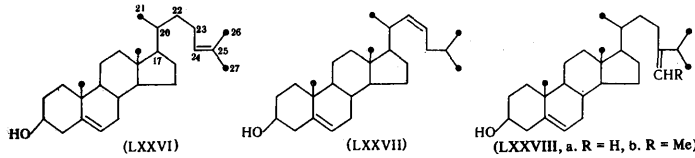
Studies of the mass spectra of trideuteromethyl analogues of compounds (LXXIIIa and b) showed[72] that, in contrast to saturated pregnanes, in which the elimination of the CH_3 group from the 13-position does not occur, in the mass spectrum of compound (LXXIII) the peak of the $(M - 15)^+$ ion has been generated to the extent of 82% as a result of the loss of this particular methyl group.



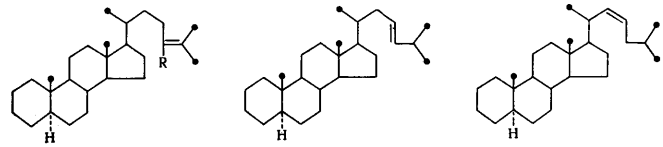
It is noteworthy that the elimination of the side chain from the $C_{(17)}$ atom is believed by many investigators[74-76] to be typical also for $\Delta^{13(17)}$-steroids, although they did not consider the mechanism of this process. Probably in the present case too there is a preliminary migration of the double bond to the 13—14 position with subsequent dissociation of the 17—20 bond, which has become allylic.

The peak of the ion with *m/e* 148, to which structure bb was ascribed, was detected in the mass spectrum of 5α-androst-16-en-3β-ol (LXXIV).[9] Von Unruh and Spiteller[55] believe that this ion is common to all steroids in which the structures of rings *B*, *C*, and *D* are analogous to those of compound (LXXIV):

M^+ (LXXIV) bb, *m/e* 148.



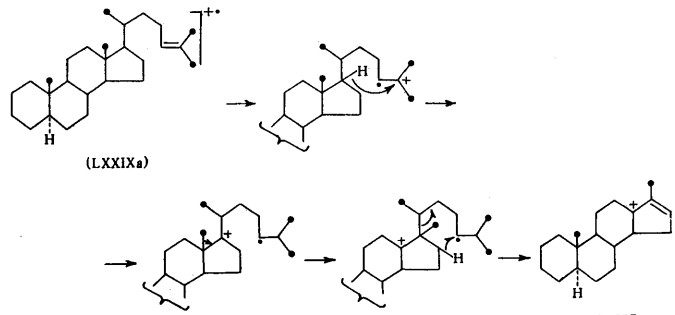
An interesting example of the effect of the double bond in ring *D* on decomposition under electron impact is provided by the mass spectrum of 3β-hydroxy-17-methyl-18-norandrosta-5,13(17)-dien-16-one (LXXV),[18] which shows a medium-intensity peak with *m/e* 110 (the ion bb) due to the dissociation of two allylic bonds 8—14 and 11—12 with migration of two hydrogen atoms to the charged fragment. Probably, as in the formation of the ion i (section II, 2), the driving force of this process in compound (LXXV) is provided by the αβ-unsaturated ketone grouping in ring *D*:



M^+ (LXXV) u, *m/e* 110.

VI. STEROIDS WITH A DOUBLE BOND IN THE SIDE CHAIN AT $C_{(17)}$

Wyllie and Djerassi[77] demonstrated for a large number of steroids with a double bond in different positions in the side chain at $C_{(17)}$ that the scission of the side chain is accompanied by the migration of two hydrogen atoms from the charged fragment. This distinguishes the above type of steroids from their saturated analogues which lose the side chain as a result of simple dissociation of the 17—20 bond. Thus the spectra of cholesta-5,24-dien-3β-ol (LXXVI), cholesta-5,22-dien-3β-ol (LXXVII), 24-methylenecholesterol (LXXVIIIa), and 24-ethylidenecholesterol (LXXVIIIb) show peaks with *m/e* 271, while in those of 5α-cholest-24-ene (LXXIXa), 5α-ergost-24-ene (LXXIXb), 5α-cholest-23-ene (LXXX), and 5α-cholest-22-ene (LXXXI) the mass numbers of the above peaks are displaced to *m/e* 257.



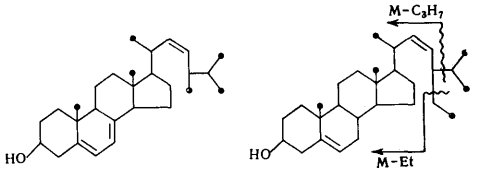
(LXXVI) (LXXVII) (LXXVIII, a. R = H, b. R = Me)

(LXXIX, a. R = H, b. R = Me) (LXXX) (LXXXI).

Analysis of the mass spectra of 17,22,22-D_3-, 15,15,17-D_3-, 12,12-D_2-, 14-D_1, and 16,16-D_2-analogues of (LXXIXa) showed that the rearrangement leading to the formation of the *m/e* 257 ion (dd) involves the hydrogen atom at $C_{(17)}$ to the extent of 100%, while the second hydrogen atom migrates from $C_{(12)}$ (35%), $C_{(14)}$ (10%), and $C_{(16)}$ (25%). The mechanism proposed[77] for the formation of the ion dd includes also the migration of the 18-CH_3 group to the $C_{(17)}$ atom, which leads to an allylically stabilised ion:

(LXXIXa)

dd, *m/e* 257.

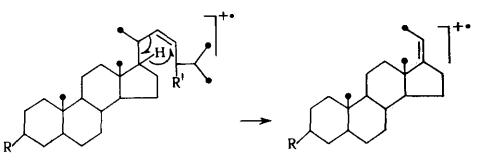


In Δ^{22}-steroids, the hydrogen atoms at $C_{(17)}$ (100%) and $C_{(14)}$ (55%) are involved in the formation of the ion dd, which has also been confirmed by the corresponding shifts in the mass spectra of the deutero-analogues[77].

The presence in the mass spectrum of the steroid of the peak due to the ion dd is evidence that it contains an unsaturated side chain at $C_{(17)}$ but does not provide information about the location of the double bond in it. As the position of the double bond is altered, the intensity of the peak due to the ion dd changes too, which has been recommended[77] as a feature suitable for diagnostic purposes. However, the mass spectra of steroids with

an unsaturated side chain contain many characteristic peaks, which reflect more rigorously the location of the double bond.

1. Δ^{22}-Steroids

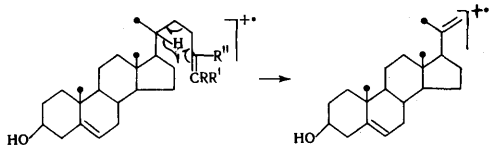


A characteristic feature of this group of steroids, together with the peaks of the ion dd, is the presence in the mass spectra of intense peaks caused by the elimination of the side chain at $C_{(17)}$ from the molecular ion without the migration of hydrogen atoms. The driving force of this process is provided by the dissociation of the 17—20 allylic bond. Thus the most intense peaks correspond to *m/e* 271 in the spectrum of ergosterol (LXXXII),[23,78] *m/e* 273 in the spectra of stigmasterol (LXXXIII)[47,77] and 7,8-dihydroergosterol (24-methylcholesta-5,22-diene-3β-ol),[77] and *m/e* 259 in the spectrum of 5α-cholest-22-ene (LXXXI).[77] In the mass spectra of the above compounds, all the peaks are present as doublets with those due to the ions dd differing from the peaks described above by 2 a.m.u.

(LXXXII) (LXXXIII).

In addition, the spectra of stigmast-22-en-3β-yl acetates (LXXXIV)[79] and (LXXXIII)[77] contain peaks due to the $(M - C_2H_5)^+$ and $(M - C_3H_7)^+$ ions produced as a result of the elimination of part of the side chain owing to the dissociation of other allylic bonds.

The mass-spectra of compounds (LXXXI)[77] and (LXXXIV)[79] also show peaks due to ions with *m/e* 344 and 286 (ee), caused respectively by the dissociation of the 20—22 double bond with transfer of a hydrogen atom from the charged species. It has been noted that for low ionisation energies the *m/e* 286 peak in the spectrum of compound (LXXXIV) becomes a maximum. Naturally when the molecule contains an acetoxy-group [for example, as in compound (LXXXIV)] the peak of the ion ee is accompanied by that of the $(ee - CH_3COOH)^+$ ion:



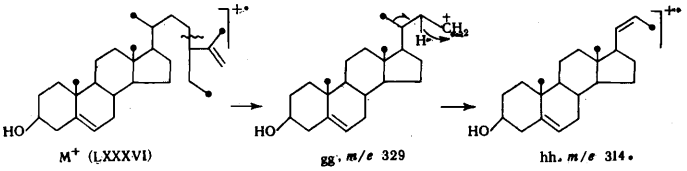
M^+ (LXXXI, R = R' = H); (LXXXIV, R = OCOMe, R' = Et) ee (R = H), *m/e* 286; (R = OCOMe), *m/e* 344

2. Δ^{23}-Steroids

The mass spectrum of 5α-cholest-23-ene (LXXX)[77] contains, together with the intense peak of the ion dd (*m/e* 257), an appreciable peak due to the ion with *m/e* 287 produced by the dissociation of the allylic 20—22 bond. When the ionising potential is reduced, the peak of the ion dd becomes dominant in the spectrum.

3. Δ^{24}- and 24-Alkylidene-derivatives of Steroids

In the mass spectra of compounds of this type, the peak of the ion dd is one of the most intense. On the other hand, the presence of very intense peaks of ions of type ff, generated by the dissociation of the allylic bond 22—23 with the elimination of a hydrogen atom, probably from the 20-position, is frequently characteristic of such compounds, for example (LXXVIIIa and b),[77] (LXXIXa and b),[77] desmosterol (LXXXV),[47] and many other 24-alkylidene-derivatives discussed by Knights and coworkers[47,80,81] and Benveniste et al.[82] Peaks of ions of type ff are characteristic only of the spectra of Δ^{24}- and 24-alkylidene-derivatives of steroids:



M^+ (LXXVIIIa, R = R' = H, R'' = C_3H_7); (LXXV, R = R' = Me, R'' = H) ff, *m/e* 314.

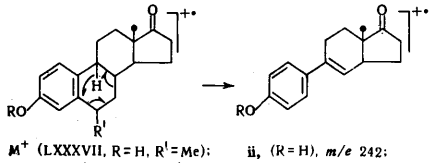
Galli and Maroni[52] noted that the most intense peaks in the spectra of cholesta-5,24-dien-3β-yl (XLVI) and cholesta-8,24-dien-3β-yl (LIX) acetates are those of the $(CH_3)_2C{=}\overset{+}{C}HCH_2$ ion with *m/e* 69, produced by the dissociation of the allylic 22—23 bond.

4. Δ^{25}-Steroids

The only example of a Δ^{25}-steroid, namely stigmasta-5,25-dien-3β-ol (LXXXVI), has been described by Wolfgang[83], who pointed out the presence in the spectrum of *m/e* 329 and 314 peaks, but did not discuss the question of their origin. We believe that the first (the ion gg) is due to the dissociation of the allylic 23—24 bond, while the second (the ion hh) may be formed as a result of the subsequent loss by the ion gg of one of the methyl groups, for example at $C_{(20)}$:[18]

M^+ (LXXXVI) gg, *m/e* 329 hh, *m/e* 314.

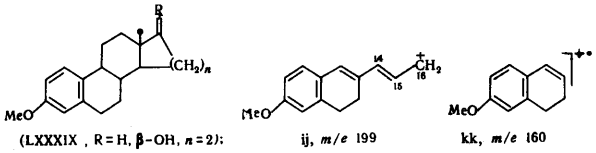
In conclusion of this section, we may note that in the majority of the studies quoted the decrease of the intensities of the characteristic peaks following the introduction of additional double bonds into the nucleus was considered. On the other hand, according to the observations of Knights[47], the appearance of a double bond in the side chain hinders certain processes characteristic of the decomposition of Δ^5- and Δ^7-steroids.



VII. AROMATIC AND DIENE STEROIDS

Certain aromatic and diene steroids were frequently mentioned in the previous sections but as a rule these were compounds with unsaturated centres fairly remote from one another which have little mutual influence and do not alter the fundamental decomposition pathways characteristic of each (see sections II, 2; III, 3; IV, 1; VI; VI, 1, 3, and 4). Aromatic and diene steroids containing conjugated or very close unsaturated centres, which

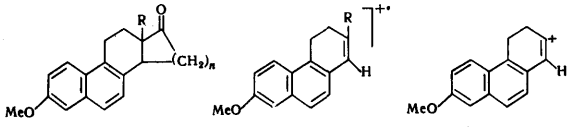
sometimes alters radically the fragmentation pattern characteristic of the corresponding monoenes, constitute a special group.



1. Aromatic Steroids

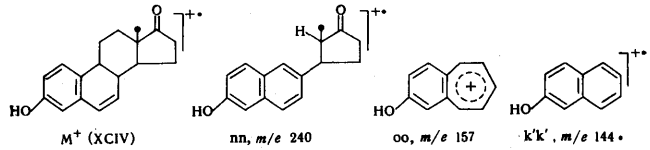
Djerassi et al.[69] investigated the mass spectra of many steroids with one and two aromatic rings, belonging to the group of oestrone and equilenin. The presence of the aromatic ring in these compounds greatly stabilises the molecular ion, the peak of which is as a rule dominant in the spectrum. In the high-molecular-weight region of the spectrum of 6-methyloestrone (LXXXVII) and the methyl ether of oestrone (LXXXVIII), there are intense peaks due to the $(M - C_2H_4)^+$ and $(M - C_3H_6)^+$ ions caused respectively by the elimination of the $C_{(6)}$ and $C_{(7)}$ atoms with formation of the ion ii:

M^+ (LXXXVII, R = H, R' = Me); (LXXXVIII, R = Me; R' = H) ii, (R = H), *m/e* 242; (R = Me), *m/e* 256



The peak of the *m/e* 199 ion (jj), for the formation of which a complex mechanism has been proposed involving the loss of the $C_{(11)}$–$C_{(13)}$ and $C_{(17)}$ atoms, is one of the most characteristic in the spectra of compound (LXXXVIII) and its stereoisomers. The peak is observed also in the spectra of the stereoisomers of the methyl ether of oestradiol (LXXXIX) [27,70] and the methyl ether of D-homo-oestrone (XC).[84]

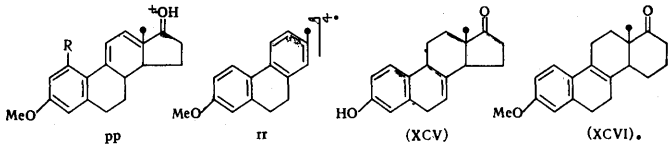
(LXXXIX, R = H, β-OH, *n* = 2); (XC, R = O, *n* = 3) ij, *m/e* 199 kk, *m/e* 160



The mass spectra of all the compounds considered above, and also of their 14-hydroxy-derivatives (LXVI, a–c) [71] contain intense peaks due to *m/e* 160 ions (kk) formed as a result of the dissociation of the 8–14 and 9–11 bonds and the ion w with *m/e* 186 (see section IV, 1).

In the mass spectra of the methyl ether of equilenin (XCI),[69] its 18-nor-13-ethyl-analogue (XCII),[69] and the methyl ether of D-homoequilenin (XCIII),[84] there are also intense peaks due to molecular ions. On the other hand, the characteristic peaks are those of the "tricyclic ions" ll and mm, the formation of which involves the dissociation of bonds in ring *D*:

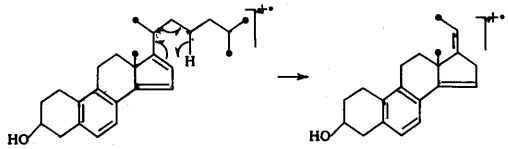
(XCI, R = Me, *n* = 2); (XCII, R = Et, *n* = 2); (XCIII, R = Me, *n* = 3) ll, (R = Me), *m/e* 224; (R = Et), *m/e* 238 mm, *m/e* 209



In the spectrum of Δ^6-dehydro-oestrone (XCIV) [69] there is an intense M – 28 peak (the ion mm), the formation of which probably involves the elimination of an ethylene molecule from ring *C*. The most intense peaks in the spectrum of compound (XCIV) with *m/e* 157 and 144 most probably correspond to the ions oo and k'k' respectively:

M^+ (XCIV) nn, *m/e* 240 oo, *m/e* 157 k'k', *m/e* 144.

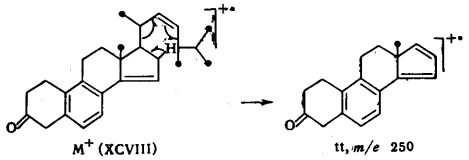
The mass spectrum of equilin (XCV) [69] differs from that of compound (XCIV) only by a lower intensity of the peak due to the ion oo.



The peaks due to $(M - 15)^+$ ions, which may have the structure pp, are dominant in the mass spectra of the methyl ether of $\Delta^{9(11)}$-dehydro-oestrone and its 1-methyl analogue (LXIVc) (see section IV, 1).[69] Another characteristic feature of the spectra of these compounds is the presence of an M – 57 and M – 58 double peak (the ion rr) due to the loss of ring *D*:

pp rr (XCV) (XCVI).

The characteristic ions derived from the methyl ether of Δ^8-dehydro-D-homo-oestrone (XCVI),[27] as for the methyl ether of equilenin (XCI), are those formed as a result of the dissociation of bonds in ring *D*, namely the 6,7-di-hydro-analogues of the ions ll and mm.

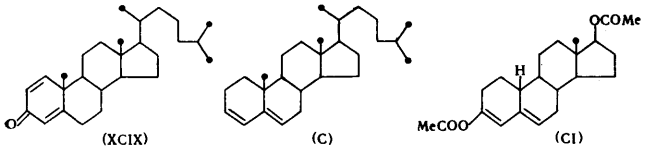


The peak of the ion corresponding to the loss of part of the side chain at $C_{(17)}$ with migration of a hydrogen atom to the charged species ss has been detected by Brown and Turner[85] in the mass spectrum of cholesta-5(10),6,8,14,16-pentaen-3β-ol (XCVII). Presumably the driving force in this process comes from the dissociation of the allylic 20–22 bond accompanied by the migration of the double bond and the transfer of a hydrogen atom via a six-membered transition state:

M^+ (XCVII) ss, *m/e* 280.

However, on the basis of this one example, it is impossible to say whether the process is determined by the Δ^{16}-bond alone or whether it can occur only in the presence of a conjugated system of double bonds.

In ergosta-5(10),6,8,14,22-pentaen-3-one (XCVIII),[85] the side chain is eliminated as a result of the rupture of the allylic 17–20 bond accompanied by the elimination of a hydrogen atom from the charged species (the ion tt).

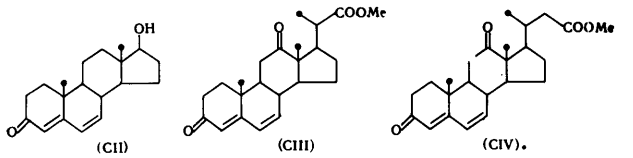


M^+ (XCVIII) tt, *m/e* 250

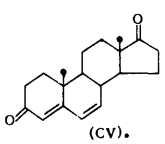
Apparently the elongation of the conjugation chain provides the driving force for the formation of the ion tt.

2. Diene Steroids

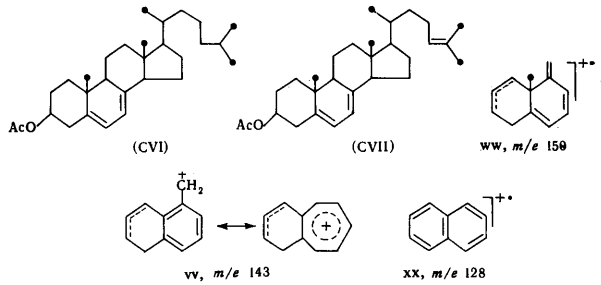
The intense peak of the ion with m/e 122 is the most characteristic of the mass spectrum of cholesta-1,4-dien-3-one (XCIX).[22] It is probably formed via a mechanism similar to that of the formation of the ion 1 (see section II, 2) from which it differs by two mass units, as expected.



Galli and Maroni[52] believe that the most characteristic type of fragmentation of cholesta-3,5-diene (C) involves the formation of the ion p' with m/e 120 (see section III, 1) as a result of type RDR decomposition in ring B. The peak of an analogous ion with m/e 122 is observed also in the spectrum of 19-norandrosta-3,5-diene-3,17β-diyl diacetate (CI).[18] When the molecular ion of compound (CI) decomposes, a molecule of keten is initally eliminated from the 3-CH_3COO group (a process characteristic of enol acetates) and the resulting radical-ion undergoes a further type RDR decomposition). Moreover, ions with m/e 147 (tt) and 161 (uu) are formed from the $(M-CH_2=C=O)^+$ ion.



The mass spectrum of cholesta-2,4-diene (XI) (see section II, 2) is not very characteristic[18] but in the region of low mass numbers it contains a very specific triplet of peaks with m/e 105–107. The formation of ions responsible for these peaks probably involves the dissociation of the 6–7 and 9–10 bonds and the location of the charge on ring A.



In the mass spectrum of 17β-hydroxyandrosta-4,6-dien-3-one (CII),[9,23] there are intense peaks due to ions with m/e 136 and 157, the origin of which has not, however, been elucidated. These peaks are also observed in the mass spectra of the methyl esters of 3,12-dioxobisnorchola-4,6-dienoic (CIII)[38,39] and 3,12-dioxonorchola-4,6-dienoic (CIV)[38] acids:

Recently Orr and Broughton[86] also observed the peak of the m/e 136 ion in the mass spectrum of androsta-4,6-diene-3,17-dione (CV) and explained its origin by the dissociation of the 9–10 and 7–8 bonds and the migration of two hydrogen atoms to the charged fragment containing ring A and part of ring B. When the charge is located in the other part of the molecule with migration of a hydrogen atom away from it, an ion with m/e 149 is formed with the dissociation of the same bonds, its peaks being approximately three times less intense than that of the first ion:

Galli and Maroni[52] have analysed the mass spectra of cholesta-5,7-di-en-3β-yl (CVI) and cholesta-5,7,24-trien-3β-yl (CVII) acetates. The authors noted intense peaks due to ions with m/e 143 (vv) and 158 (ww) and a small peak with m/e 128 (xx).

---o0o---

Thus the entire data analysed above demonstrate that the mass spectra of steroids with double bonds in the 1–2, 2–3, 4–5, 5–6, 7–8, 13–14, 16–17, 22–23, 23–24, and 24–25 positions are very characteristic which as a rule makes it possible to infer unambiguously the location of the double bond in the steroid nucleus or in the side chain by analysing the mass spectra. The double bonds in other positions either do not initiate specific decomposition pathways of the molecular ions or give rise to processes which are difficult to interpret from the standpoint of the current hypothesis of the preferential dissociation of the weakest bonds. In certain cases the insufficient number of examples investigated precludes a generalisation. Steroids with several double bonds remote from one another decompose via pathways initiated by each separately. The inclusion of double bonds in the conjugated system gives rise to special decomposition pathways which are not characteristic of compounds with the corresponding isolated double bonds, and the stability of the molecular ion increases appreciably.

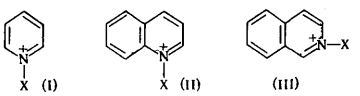
N-Acylpyridinium Salts and Corresponding Fused Benzo-derivatives

A.K.Sheinkman, S.I.Suminov, and A.N.Kost



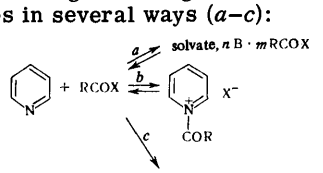
Published information on the preparation, structure, and reactions of *N*-acylpyridinium salts and the corresponding benzo-derivatives is summarised. They comprise purely ionic structures with the acyl group attached to the nitrogen atom, which bears a positive charge (partly delocalised through the ring), and a halide counter-ion. In individual cases (quinolinium and isoquinolinium) the electron of the anion may be transferred to a non-bonding orbital of the heterocycle with formation of a charge-transfer complex. *N*-Acylated heterocyclic cations contain more than one reaction centre, and are capable of *trans*-acylation, ring opening, hetarylation, one-electron reduction, etc. Processes involving hetarylation are especially interesting, and permit the preparation of various difficultly accessible derivatives of pyridine, quinoline, isoquinoline, and acridine. A list of 419 references is included.

CONTENTS

I. Introduction 642
II. Preparation and structure of *N*-acylpyridinium salts and corresponding fused benzo-derivatives 642
III. Reactivity of *N*-acylpyridinium salts and corresponding fused benzo-derivatives 645

I. INTRODUCTION

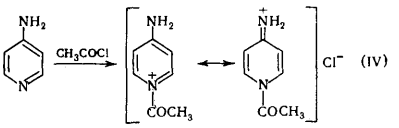
A systematic survey is made of published data on the preparation, structure, and chemical reactions of *N*-acyl derivatives of six-membered nitrogen heterocycles—pyridine and its benzologues



as well as their analogues—where X represents an electron-accepting group—RCO, $CONR_2$, COOR, sometimes CN, phosphoryl groups PO_3^-, PO_3R, $NH_3PO_2^-$, etc.

Although several reviews and monographs have been devoted to quaternary pyridinium, quinolinium, and isoquinolinium salts[1-4], the general aspects of *N*-acylated heterocyclic cations have not been considered: there are only brief summaries of already obsolete literature on *N*-acylpyridinium salts in papers on other topics[2,5,6]. During the past 10–15 years development of the acylation and phosphorylation of various nucleophilic compounds by salts of *N*-acylated heterocyclic cations (sometimes formed *in situ*) has been accompanied by elaboration of a method for introducing a heterocyclic ring into compounds containing an acidic methine group (ketones, dialkylanilines, pyrrole, furan, etc.), and several new reactions have been discovered. All this demands our attention.

II. PREPARATION AND STRUCTURE OF *N*-ACYL-PYRIDINIUM SALTS AND CORRESPONDING FUSED BENZO-DERIVATIVES

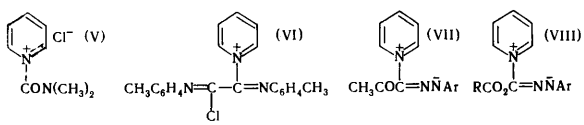


Pyridine and analogous nitrogen bases are able to react with acid halides in several ways (*a–c*):

When pyridine is carefully mixed with acetyl chloride in ether or petroleum ether, heat is evolved, and after cooling solid acetylpyridinium chloride is precipitated[7-9]. Other workers[10-12], however, were able to isolate only pyridine hydrochloride and keten, with part of the latter polymerising to dehydracetic acid[11,13,14]. Quinoline, 2-methylquinoline, and 2,6-dimethylpyridine under these conditions form mixtures of their hydrochlorides and the corresponding adducts with acetyl chloride[10,15]. If the reaction is conducted in chloroform, which dissolves pyridine hydrochloride, especially at low temperatures, *N*-acetylpyridinium chloride of greater purity can be obtained[12].

N-Acylpyridinium chlorides are prepared by adding pyridine to an equivalent quantity of the acyl chloride in anhydrous ether, benzene, petroleum ether, or dry nitrogen in the absence of a solvent[16-26]. Only pyridine hydrochloride is formed when the reactants are added in the opposite sequence. The method can be used to prepare quinoline and 2-methylquinoline salts[27,28]. Methylpyridines react with acetyl chloride in the cold to form compounds of variable composition, which are unstable on keeping[9,29].

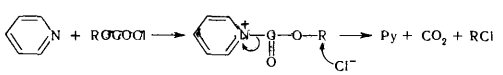
The stability of *N*-acetylpyridinium salts is increased by the presence of substituents capable of helping to delocalise the positive charge[25,30,31]. Treatment of 4-aminopyridine in ether with acetyl chloride (as well as with benzoyl and toluenesulphonyl chlorides) produces salts of the type (IV):



1-Acetyl-4-dimethylaminopyridinium chloride is evidently still more stable[25,30], but a very unstable quaternary salt is obtained by the action of acetyl chloride an 4-acetamidopyridine in oxolan[30].

Benzoyl chloride and quinoline form the adduct $C_9H_7N.2C_6H_5COCl$,[32] but equivalent quantities of the reactants generally yield a mixture of an *N*-benzoylquinolinium chloride and the hydrochloride of the base[33]†. It has not

†Reissert[34,35] was unable to isolate a product from the reaction of benzoyl chloride with quinoline, but obtained the corresponding "pseudobase" on attempting the Schotten–Baumann synthesis (with aqueous alkali).

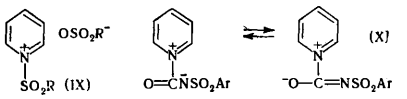


hitherto proved possible to isolate pure *N*-benzoylpyridinium chloride [8,12,17,32], but aroyl chlorides containing electron-accepting substituents in the ring form stable *N*-acylpyridinium salts [7,16]. Olah [36] has recently reported the preparation of *N*-acetyl-, *N*-propionyl-, and *N*-benzoylpyridinium hexafluoroantimonates by acylating pyridine with solutions of carboxonium salts in sulphur dioxide. *N*-Nitro- and *N*-nitroso-pyridinium fluoroborates have been prepared similarly [37]. Information on salts of pyridinium bases, benzoyl chloride, and Lewis acids will be found in Ref. 31.

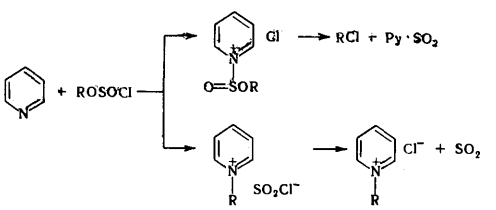
The adducts formed by pyridine, quinoline, and isoquinoline with carbamoyl chlorides, e.g. (V), are very stable [38-43]. Similar salts have been obtained also with 4-methylpyridine, 3,5-dimethylpyridine, and nicotinamide [42,44,45].

Pyridine and its homologous react with imidoyl chlorides of the type (o-$CH_3C_6H_4N$: $CCl)_2$, CH_3COCCl: : NNHAr, [46,47] and ArNHN : CClCOOR [48] to form stable compounds (VI)–(VIII).

According to the patent literature [49-56] adding carbonyl chloride, perchlorocarbonates, or alkyl chlorocarbonates to pyridine or 2-methylpyridine in benzene results in the rapid formation of precipitates containing 2 moles of base per mole of acylating agent, which react smoothly with water and aliphatic alcohols to produce symmetrical or unsymmetrical carbonates [57]. Repeated observations have since been made of the formation of adducts of pyridine, 2-methylpyridine, and quinoline with ethyl chlorocarbonate [58-63], but the products could not be isolated in a pure form. The adducts decompose when the temperature is raised. Carré has studied the breakdown of various chlorocarbonates in pyridine and quinoline [60,64,65], and demonstrated the high catalytic activity of the first of them:



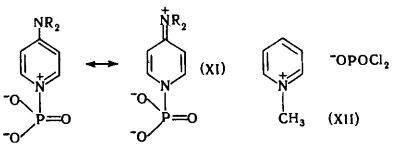
Information is available [66,67] on the reaction of carbonyl chloride with quinoline and 4,4′-bipyridyl.



Similarly to the above example with acetyl chloride, treating 4-dimethylaminopyridine with t-butoxycarbonyl chloride in dry ether at 0°C yields the corresponding *N*-acyl salt [68].

Pyridine, quinoline, isoquinoline, and 4-methylpyridine readily form adducts with various substituted arenesulphonyl chlorides $RC_6H_4SO_2Cl$. [69-72] The stability of such salts diminishes in the sequence—isoquinoline, pyridine, quinoline [70]—and 2-methylpyridine probably does not react at all [69,74]. With polysulphonyl chlorides the reaction may cease on the replacement of one chlorosulphonyl group [71]. It has also been reported that *p*-acetamidobenzenesulphonyl chloride does not react with triethylamine and pyridine in anhydrous acetone [74,75]. The enhanced stability of *N*-arenesulphonylpyridinium salts in comparison with the *N*-acyl salts is shown in the possibility of obtaining adducts (IX) from anhydrides of methane- and benzene-sulphonic acids [73,76].

It is interesting that the condensation of isocyanatosulphonyl chloride $OCNSO_2Cl$ with pyridine involves only the sulphonyl group [78]. Yet the reaction of nitrogen bases with arenesulphonyl isocyanates usually leads to betaines of the type (X): [77,79]



The reactions of pyridine and other tertiary amines with chlorosulphates $ROSO_2Cl$ have been surveyed in detail [80]. The normal products are alkyl halides and the complex $C_5H_5N.SO_3$, formed by breakdown of intermediate quaternary salts $ROSO_2\overset{+}{N}C_5H_5 + Cl^-$. [80,81] Pyridine reacts with alkyl chlorosulphinates to form mixtures of *N*-acyl and *N*-alkyl salts [82,83]:

The reactions of pyridine and its derivatives with thionyl chloride, sulphuryl chloride, chlorosulphuric acid, phosphoryl chloride, and other inorganic chlorides have also been studied [35,84,85].

Several quaternary pyridinium salts have been prepared containing a phosphoric-acid residue attached to the nitrogen atom. Treatment of 4-dimethylamino- and 4-morpholino-pyridines in benzene solution with excess of phosphoryl chloride and triethylamine followed by alkaline hydrolysis gave the salts (XI) as amorphous white powders [25,86]:

Analogous salts of 4-amino-, 4-isopropylamino-, and 4-dimethylamino-pyridines have been obtained by exchange with an *N*-phosphoryl salt of *N*-methylimidazole [25,87].

The possible formation of *N*-acyl derivatives also in the preparation of organophosphorus compounds by the reactions of acid chlorides and chloro-esters of phosphorus in the presence of pyridine and quinoline has been discussed [83,88], but few adducts have been isolated [84,89,90], and information on their structure is frequently lacking. The reaction may involve the O–R bond, not the phosphorus atom: thus the salt (XII) alone is formed from methyl phosphorodichloridate and pyridine [91].

A saltlike structure for the 1 : 1 adducts of pyridine with acyl chlorides was already suggested in the earliest papers [12,92]. Such a structure is indicated by the insolubility of the adducts in most non-polar solvents, the possibility of recrystallising the most stable compounds, the relatively high melting points, the reactions involving exchange of the anion, and the rapid and unambiguous acylations involving such adducts. Alternatively it was postulated that these adducts were complexes or even molecular compounds. It can now be accepted that the adducts are ionic structures with the acyl group attached to the nitrogen atom of the pyridinium ring and the halogen acting as counter-ion. This is based on the results of electrical conductivity measurements, polarography, heats of mixing, acid–base titrations, kinetic methods,

and ultraviolet, infrared, and nuclear magnetic resonance spectroscopy.

Paul and his coworkers [9,15,29,32,38,93] made visual and conductometric titrations of pyridine, methylpyridines, quinoline, and dimethylaniline in acetyl and benzoyl chlorides with titanium tetrachloride, tin tetrachloride, or arsenic pentachloride. The nitrogen heterocycles reacted with the Lewis acids (acceptors of the chloride ion) completely, giving one or two neutralisation points corresponding to the formation of "normal" and "acid" salts [15,29,93,94]. The same workers found appreciable electrical conductivity in solutions of the three methylpyridines and quinoline in acetyl chloride, although rather less than with benzyltrimethylammonium chloride. A mixture of pyridine and acetyl chloride in liquid sulphur dioxide at −30°C exhibited a complicated conductance corresponding in magnitude to the purely ionic salts $(C_2H_5)_3NH^+SbCl_6^-$ and $R_3O^+SbCl_6^-$. The strongly ionising solvent plays a definite part in this, of course.

Holeček [96] studied the electrical conductivity of solutions of pyridine, isoquinoline, quinoline, and acridine in acetyl bromide, and showed that they form adducts $[B.CH_3CO]^+Br^-$, which behaved as univalent electrolytes. The ionisation constants were 0.7×10^{-4} for the pyridine salt and $1.8–1.9 \times 10^{-4}$ for the quinoline, isoquinoline, and acridine salts. Korshak et al. [97] have recently determined potentiometrically the thermodynamic equilibrium constants for the reaction of benzoyl chloride with pyridine and triethylamine in acetonitrile. The higher value for pyridine than for triethylamine (1.2×10^{-4} and 2×10^{-5}), in spite of the less basic character of the former, was attributed to resonance factors enhancing the stability of the *N*-benzoylpyridinium salt.

The possibility of mesomerism is slight with unsubstituted *N*-acylpyridinium salts [95,98], and this is responsible for their relative instability.

1-Dimethylcarbamoylpyridinium chloride (V) behaves in aqueous solution as a strong electrolyte. This applies also to acetonitrile solutions, but the picture is then complicated by partial breakdown of the salt into its components as a result of solvolysis [42]. The conductance of solutions of *N*-diphenylcarbamoylisoquinolinium chloride in nitrobenzene has been studied recently [43]. A solution of benzoyl chloride and pyridine in 89% aqueous acetone conducts electricity and is able to benzoylate butylamine [99]. Although arenesulphonyl chlorides do not conduct electricity in nitromethane or liquid sulphur dioxide, considerable conductance is observed in the presence of pyridine and quinoline.

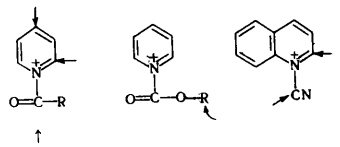
Paul [100,101] determined calorimetrically the heats of dissolution of 2-methylpyridine, quinoline, and dimethylaniline in acetyl and benzoyl chlorides, and also their heats of neutralisation by Lewis acids. The dependence of the enthalpy change on the concentration of the base showed in all cases a characteristic break at low concentrations, indicating increased dissociation of the solvates under these conditions.

On polarography in pyridine, acylpyridinium salts exhibit a typical reduction curve with two waves (half-wave potentials 0.1–0.7 and 1.3–1.7 V). [16,17,102] Similar results were obtained with mixtures of benzoyl or *p*-methoxybenzoyl chloride with pyridine, which suggests in these cases also the formation of acylpyridinium salts *in situ* [16,17].

Detailed studies have been made of the infrared spectra of *N*-acetyl- and *N*-propionyl-pyridinium chlorides [16–18], acetyl-pyridinium, -quinolinium, -isoquinolinium, and -acridinium bromides [103], and adducts of acetyl and benzoyl chlorides with pyridine and 3- and 3-methylpyridines [104]. Several papers mention the positions of individual bands in the infrared spectra of other salts [30,31,42,66,105,106].

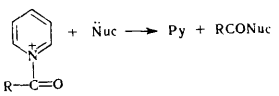
Most workers note a shift in the carbonyl-stretching band (1760–1800 cm^{-1}) to higher frequencies (1790 to 1804 cm^{-1}) with *N*-acylpyridinium chlorides derived from aliphatic and aromatic acids. Such displacement indicates the presence of a positively charged cyclic nitrogen atom beside the carbonyl group. Although a larger shift is to be expected from the difference in values of the Taft constants for NR_3^+ and Cl, the replacement of Cl in the acyl chloride by NR_3^+ has the opposite effect by increasing the C—C—N angle [18]. This has been found also with aliphatic acylammonium salts [95,107–109].

Data on the ultraviolet spectra of solid *N*-acylpyridinium salts are restricted to examples of 1-acetyl-4-dialkylaminopyridinium chlorides [30,31], 1-dimethylcarbamoylpyridinium chloride [42,68], and 4-alkylamino-1-phosphorylpyridinium salts [25,86]. Conversion of a nitrogen base into an *N*-acyl salt is accompanied by a considerable bathochromic shift, while the absorption characteristic of the aromatic ring is maintained. Kinetic studies of the hydrolysis of acetic anhydride and reactions involving the transfer of acyl [20,110] have recorded the ultraviolet spectra of *N*-acyl derivatives of alkylpyridines obtained *in situ*, the differential spectra corrected for absorption by pyridine and its salt giving for acetylpyridinium λ_{max} = 272 and 255 nm (ϵ = 4300 and 7000).



Data on the proton magnetic resonance spectra of these compounds are also fragmentary [25,30,36,37,42,68,86]. The chemical shifts of the 2-, 3-, and 4-protons of 1-acetyl-, 1-propionyl-, and 1-benzoyl-pyridinium fluoroantimonates in liquid sulphur dioxide (at −60°C) increase with increase in the accepting properties of the acyl group in this sequence [36] (cf. spectra of quaternary pyridinium salts [111]), which correlates with hetarylation experiments on these salts [112]. The chemical shifts also agree well with the expected values for pyridinium, *N*-nitrosopyridinium, and *N*-nitropyridinium fluoroborates [37].

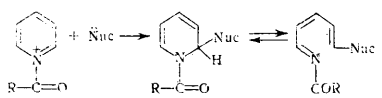
On passing from 1-acetyl-4-dimethylaminopyridinium chloride to its analogue containing the less strongly electron-accepting 1-t-butoxycarbonyl group we observe the same decrease in chemical shift for both 2- and 3-protons [30,68], although the infrared spectra indicate that the charge on the former is more strongly delocalised (νCO = 1755 and 1770 cm^{-1}). It is more difficult to analyse the nuclear magnetic resonance spectra of 4-amino-1-phosphorylpyridinium [25,86]. The contribution of immonium forms to resonance stabilisation would probably be greater for the dimethylamino- than for the isopropylamino-group (cf. XI). This diminishes appreciably the deshielding of the 2-protons in the former case, which is shown in the chemical shifts (8.2 and 8.6 ppm). The opposite relation is found for the 3-protons.



In view of the possible involvement of *N*-acylpyridinium salts in acylation by acid anhydrides, many attempts have been made to detect by infrared and n.m.r. spectroscopy their presence in solutions of pyridine and an anhydride [19,112–116]. In non-polar solvents such as carbon tetrachloride no significant changes are observed in the spectra when pyridine is mixed with acetic and trifluoroacetylacetic anhydrides [113,114,116]. Similarly, the ultraviolet spectra of pyridine–acetic anhydride mixtures in cyclohexane are additive [113]. In the acetic anhydride–1,4-diazabicyclo[2,2,2]octane system, however, formation of the corresponding *N*-acyl salt can be established from the infrared and n.m.r. spectra or refractometrically [114].

III. REACTIVITY OF *N*-ACYLPYRIDINIUM SALTS AND CORRESPONDING FUSED BENZO-DERIVATIVES

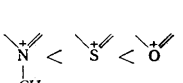
N-Acylpyridinium salts and the corresponding fused benzo-analogues contain more than one reaction centre both in the ring system and in the acyl group. In conformity with this their reactions can be divided into six main types.



1. Attack by nucleophilic reagents on the exocyclic carbon atom attached to the heteroatom leads to elimination of the nitrogen base and transfer of the acylating group to a component of the medium (acylation of water, alcohols, amines, acids, etc.) or to the gegenion (solvolysis)[42,102]:

We must include here reactions in which the acyl group is transformed—hydrolysis of nitrile to amide[106], decomposition of acyl salts of chlorocarbonates, chlorosulphates, etc. effected by attack by the gegenion (Cl^-) on the C–O–R bond[55,65,80], formation of ketens (attack by the pyridine ring on an α-proton relative to the carbonyl group)[117,118].

2. Attack by a nucleophilic reagent at the 2-carbon atom of the heterocycle, yielding so called "pseudobases" or more often opening the ring (Zincke–König reaction)[3,119]:



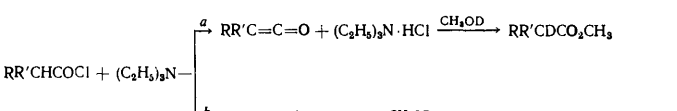
3. Addition of nucleophilic reagents at the 2- and 4-positions of the heterocyclic ring results in the formation of 1-acyl-1,2(or 4)-dihydro-derivatives or, if these are unstable, to substituted heterocycles (after detachment of the acyl groups and aromatisation). These reactions, which can be combined under the name "hetarylation", are of the greatest interest, since they permit the preparation of various compounds, including naturally occurring substances, that are often inaccessible by other methods.

4. Reactions involving one-electron transfer to the *N*-acyl salts followed by dimerisation of the radicals (Dimroth reduction)—or radical hetarylation.

5. Reactions involving methyl or methylene side-groups activated by the presence of the *N*-acyl group[17,28,120,121].

6. Electrophilic substitution in salts of *N*-acylated heterocyclic cations[122,123].

Reactions of types 3–5 are known for various aromatic and heterocyclic cations—tropylium, cyclopropenylium, pyrylium, thiapyrylium, etc.—which is evidence of the similarity of their π-electron systems. The effect of substituents is transmitted through the positively charged nitrogen atom[111,124], although probably not by conjugation but purely by induction. In this connection the sequence of increasingly strong electron-accepting properties of the heteroatoms



found for pyrylium, thiapyrylium, and pyridinium salts[125] should change significantly if a strongly electron-accepting substituent is attached to the cyclic nitrogen atom. By comparing values of pK_{ROH} for a series of pseudobases Johnson has shown[126] that the acceptor effect of the  group in *N*-cyanoquinolinium approaches that of the  group in benzopyrylium and exceeds the effect of  .

1. Acylation in the presence of Pyridine Bases

Examples of the use of pyridine in the acylation of alcohols and phenols date from the 1890s (bibliography in Ref. 127), but pyridine was regarded initially merely as a substitute for alkali. The advantages and limitations of this method were studied on many hydroxy-compounds and acylating agents by Einhorn and Hollandt[127], and hence the term "Einhorn acylation" is encountered in the literature[128,129a–131a].

Acylation in pyridine is effective for alkali-sensitive compounds. Pyridine is a good solvent, and therefore acid chlorides can be replaced by acids with subsequent addition of chlorinating agents (e.g. carbonyl, thionyl, and benzoyl chlorides) or the experimentally more convenient acid anhydrides (especially acetic anhydride). Acylation in the presence of pyridine takes place also in acid media. Even under these conditions the acylpyridinium chloride is evidently formed[127]. The use of acetic formic anhydride or a mixture of formic acid with acetic anhydride and pyridine has recently been recommended for the formylation of aliphatic and cycloaliphatic alcohols[132]. Pyridine compounds also play an important part in the preparation of chlorocarbonic esters, carbonates, chlorosulphates, and several other compounds having mixed functions[51,55,80,133]. If the hydroxy-compounds are replaced by their alkoxides, only traces of pyridine are required, since it is regenerated in the course of the exchange reaction.

The high acylating power of individual *N*-acylpyridinium salts towards alcohols and phenols is confirmed by direct experiments[23,51,53,57]. Addition products of carbonyl chloride and pyridine bases[53,54,86] effectively phosgenate alcohols, phenols, naphthols, anilines, and cyclic imines. Although *N*-nitropyridinium fluoroborate is unsuitable for the nitration of aromatic compounds, it does *o*-nitrate water and alcohols[37]. There is indirect confirmation of the involvement of acylammonium salts in acylations[134,135]. Aliphatic acid chlorides react with CH_3OD in triethylamine to form a mixture of $RR'CDCOOCH_3$ and $RR'CHCOOCH_3$, produced by two competitive reactions[136]:

Path (*a*) predominates or is the sole reaction with acid chlorides that are sterically hindered at the reaction centre, since they have less effect at the stage of elimination of the α-hydrogen atom (acid–base equilibrium) than on formation of the quaternary acyl salt. The percentage inclusion of deuterium in acetyl halides falls in the sequence Cl > Br > I > CH_3COO, i.e. with improvement in the so called "leaving group"[137–139].

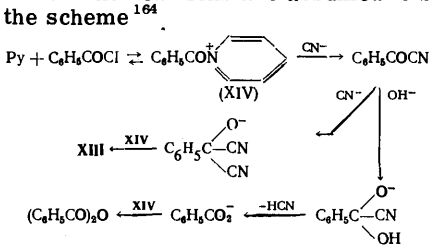
Such data are lacking for esterification in pyridine, but the weakness of pyridine bases compared with triethylamine, together with the greater resonance stabilisation

of *N*-benzoylpyridinium than of benzoyltriethylammonium [95,97,98], leads us to expect reaction (*b*) alone, at least with sterically unhindered acid chlorides. Individual monographs, however, have hitherto assigned to pyridine bases the role merely of participation in acid–base equilibria (proton acceptor) [140].

The preparation of arenesulphonates of alcohols and phenols is also often conducted in pyridine [6,129b,130a,131b,141,142], again with intermediate formation of arenesulphonylammonium salts [70,71,73,75,76]. In most cases higher yields are obtained than with aqueous sodium hydroxide. Sometimes, however, the resulting esters (especially of lower alcohols) alkylate the pyridine to form alkylpyridinium salts, which lowers the yield. It has therefore been recommended that pyridine should be replaced by 2,6-dimethylpyridine, although this slows down the process significantly [143]. In the arenesulphonylation of 1,4- and 1,5-diols, certain amino-alcohols, and γ-hydroxy-amides the intermediate monosulphonate may be cyclised with the formation of various oxygen and nitrogen heterocycles (see Refs. 131b, 144, and 145 and the bibliography given there). Kröhnke has prepared aldehydes via quaternary pyridinium salts [6,141].

Systems comprising a carboxylic acid and pyridine with benzenesulphonyl or toluene-*p*-sulphonyl chloride have an acylating, not an arenesulphonylating, action [145]. They yield esters with primary and secondary alcohols, phenols, and polyphenols. This method is mostly used for the acylation of tertiary alcohols liable to dehydration. The reaction is assumed to involve the formation of acid anhydrides *in situ*, with regeneration of the arenesulphonyl chloride:

$$(RCO)_2O \xrightarrow[\text{TosCl + Py}]{R'OH} RCO_2H + RCO_2R'$$



For the analytical application of acylations see Refs. 114, 128, 140, and 146–150.

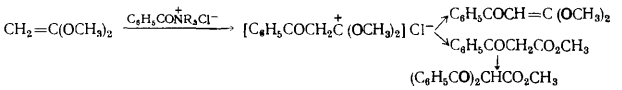
Similarly, *N*-acylpyridinium salts react with carboxylic acids to form anhydrides or mixed anhydrides:

$$\left[RCO\text{-}\langle\text{pyridinium}\rangle\right] Cl^- + R'CO_2H \rightarrow RCOOCOR' + Py \cdot HCl$$

This reaction, discovered as early as 1892, [92,151–153] has not lost its importance for the preparation of anhydrides even at the present time. To obtain symmetrical anhydrides it is sufficient to act with water on a mixture of the acid chloride and pyridine (better in an inert organic solvent). No advantage is generally obtained by using a mixture of the acid chloride and the carboxylic acid or alkaline additives (sodium carbonate, barium carbonate, sodium hydrogen carbonate) to combine with the hydrogen chloride. At various times this method has been used to obtain anhydrides of substituted benzoic acids [8,92,151,154–157], cinnamic acid [151], several aliphatic acids [8,40,151,154,156] including α-chloro-acids, and certain heterocyclic acids [8]. Acid chlorides can also be employed *in situ*, by introducing into a solution of pyridine and the acid either carbonyl chloride or thionyl chloride [53,158,159] or a mixture of an arenesulphonyl chloride and an acid [145]. The possibility that solid adducts of acyl chlorides and pyridine are involved in these condensations has been demonstrated many times [8,22,23,40,53,160]. Mixed anhydrides are usually prepared by adding acetyl and benzoyl chlorides or chloroformic esters to a mixture of a relatively unreactive acid and pyridine in ether or benzene, and then treating with ice [153,161,162].

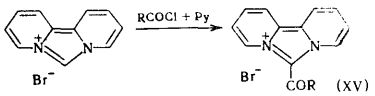
Still greater simplifications have recently been introduced into the preparation of anhydrides [163]. If the acid halide and the reaction product are comparatively stable towards water, the chloride can simply be added to an aqueous solution of an equivalent quantity of the sodium salt of the acid in the presence of catalytic quantities of pyridine, 3-aminopyridine, or pyridine *N*-oxide. Some decrease in yield occurs with methylpyridines, while the reaction is not catalysed by 2- and 4-aminopyridines, 2-fluoropyridine, or any pyridinecarboxylic acid. Aqueous *N*-benzoylpyridinium chloride acylates also salts of certain inorganic acids: e.g. benzoyl azide is obtained in 85% yield with sodium azide. An analogous reaction was described [8] with hydrogen sulphide in petroleum ether at −20°C. When benzoyl chloride is shaken with aqueous potassium cyanide and pyridine (1 : 1 : 1), however, the resulting benzoic anhydride is accompanied by the so called "dimer of benzoyl cyanide" $R.C_6H_4CO.O.C(CN)_2.C_6H_4.R$ (XIII); with chlorides of substituted benzoic acids dimeric products are formed as byproducts or as the main products [163,164]. The reactions are assumed to be represented by the scheme [164].

The controlled hydrolysis of acid chlorides in the presence of pyridine has been employed also in the preparation of tetra-alkyl pyrophosphates and mixed anhydrides of phosphoric acid [88,165–167]. Pyridine can be replaced by isoquinoline; both the yield and the quality of the products diminish with 2-methylpyridine; and no reaction occurs with quinoline.



Acyl salts of pyridine and other tertiary amines are able to split off the acyl group under the influence of ethers [168], which resembles the process occurring in alkylpyridinium salts. Thus veratrole, anisole, and diphenyl ether are smoothly decomposed when heated with acylpyridinium chlorides to 220°C, with the formation of esters of the phenols [7]. An interesting preparation of an acyloin has been described, from benzothiazol-2-aldehyde in the presence of acetic anhydride and pyridine, which evidently involves the intermediate *O*-acylation of the *N*-acetylpyridinium ion. Under these conditions chloral forms chloral hydrate diacetate in quantitative yield [169]. The reaction of benzoyl halides with aldehydes in the presence of pyridine has been described [170].

The acylation of amines by acylpyridinium salts is of no great preparative interest, since reactions with acid anhydrides usually proceed satisfactorily even in the absence of a catalyst, but aroylation in pyridine is applicable to amines of enhanced NH acidity [128,129c,130b]. Acylation by acetic anhydride in pyridine is used more widely in the analysis of amines [128,147,150,171,172]. Application of the method to the preparation of sulphonamides has been discussed [173,174]. Both pyridine and triethylamine have an unfavourable effect on the molecular weight of the products in the preparation of polyamides from isophthaloyl and terephthaloyl chlorides and diaminodiphenols [175], which was attributed to catalysis of *NO*-transacylations. The part played by individual *N*-acyl- and *N*-arenesulphonyl-pyridinium salts in the acylation of amines has been discussed [22,39,53,68,76].



The considerable acylating power of acylpyridinium chlorides is especially clearly developed in reactions

with amides of carboxylic acids: mono- and di-acylation of the amide or dehydration to the nitrile takes place depending on the nature of the acyl halide and the amide [176]. Chlorides of weak acids usually form monoacyl derivatives, those of stronger acids diacylate the amide, and chlorides of strong acids exert only a dehydrating action. For example, 3,5-dinitrobenzoyl chloride in pyridine has been proposed for the quantitative dehydration and hence analysis of amides [128,177]. The reaction goes especially smoothly with benzenesulphonyl and toluenesulphonyl chlorides [145,178]. Sulphonamides can be acylated similarly [179].

Organic compounds can undergo *C*-acylation by acid chlorides in the presence of pyridine, although in most cases the reaction is not regarded as involving initial formation of *N*-acylpyridinium derivatives‡. The action of benzoyl chloride on 1,1-dimethoxyethylene in triethylamine or pyridine, for example, yields a mixture of three products [181]:

Certain nucleophilic heterocyclic nitrogen compounds readily undergo acylation at a carbon atom [182,183]:

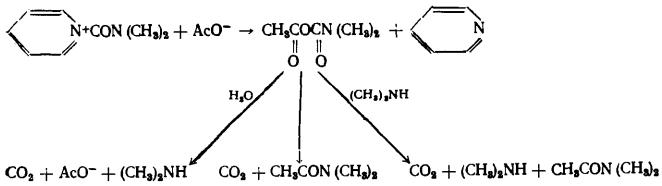
The product (XV: R = C_6H_5) can also be obtained by cyclising 1-phenacyl-2-pyrid-2′-ylpyridinium bromide by the action of toluene-*p*-sulphonyl chloride in boiling pyridine [182]. Information has been published on the possible acylation of alkyl groups by certain heterocycles [184,185].

Various β-dioxo-compounds and ketones capable of keto–enol tautomerism generally give *O*-esters—not the *C*-acyl derivatives usually obtained by the acylation of sodium enolates—by the action of *N*-acylpyridinium salts *in situ* [186,187]. Reaction takes place under very mild conditions, sometimes at room temperature or even in the cold. However, Dieckmann et al. [188,189] observed that a *C*-derivative was also present in the acylation of cyanoacetic ester and dihydroresorcinol in pyridine. β-Aminocrotonic ester and its analogues yield *N*-acylated and/or *C*-acylated products depending on the acyl chloride [190]. The use of other tertiary amines generally leads to the formation predominantly of *C*-acylated products [98,181,191,192].

The first attempts to explain the role of pyridine in such reactions were made by Doering and McEwen [98,192,193]. The interaction of benzoyl chloride, pyridine, and acetophenone yielded 1-benzoyl-1,4-dihydro-4-phenacylpyridine (XVI) and *O*-benzoylacetophenone. It was suggested that the *N*-benzoylpyridinium salt attacks acetophenone simultaneously at $C_{(2)}$ and $C_{(4)}$, forming the stable (XVI) and 1-benzoyl-1,2-dihydro-2-phenacylpyridine, which rearranges to the *O*-adduct via a geometrically favourable quasi-six-membered transition state [98,193]. Results of a kinetic investigation of this system were interpreted similarly [194].

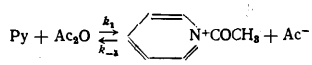
Recent results indicate [195,196] that the reaction of acetoacetic ester with benzoyl chloride in pyridine, triethylamine, 2-methylpyridine, and 2,6-dimethylpyridine gives only the *O*-benzoate (but the yield decreases in the above sequence). The reaction is of the first order with respect to both components with inverse proportionality to the chloride-ion concentration. All reactions are slower in non-polar solvents. Acylation is assumed to proceed via the keto-form of acetoacetic ester without involving intermediate products of addition to the pyridine ring; in the case of benzoylation the slow stage is formation of a benzoylammonium salt, which is hindered when the nitrogen atom is shielded. Further research is obviously necessary before a final solution will be obtained to the problem of the mechanism of the *O*-acylation of β-keto-enols.

2. Nucleophilic and General Base Catalysis by Pyridine Bases



The study of reactions involving the migration of an acyl or a phosphoryl group in systems comprising an *N*-acylpyridinium ion and a nucleophile not only has enabled the kinetic and thermodynamic factors governing the stability of salts of *N*-acylated heterocyclic cations to be estimated (although such data are still too few), and the influence of structural and steric factors in nucleophilic reagents on their reactivity to be assessed, but has also introduced some clarity into our understanding of the mechanisms of nucleophilic reactions and certain problems of nucleophilic catalysis [137–139]. Furthermore, *trans*-acylations and *trans*-phosphorylations are directly involved in problems of biochemistry and bio-organic chemistry [137,138,197].

Nucleophilic catalysis implies attack by a nucleophile on a substrate (ester, anhydride, acid chloride), leading to the formation of an unstable intermediate structure, which then breaks down either spontaneously, catalytically, or under the influence of a weaker nucleophile to give the final product and regenerate the catalyst. General base catalysis covers the exchange of a proton between a base and a substrate at the rate-determining stage of a reaction. The former type of catalysis is regarded as typical of acid derivatives having a "good" leaving group (halide, acetate, radical of an alcohol of high pK_a) [198–200], and the latter of so called inactivated esters [198]. Among tertiary amines nucleophilic catalysis is typical of pyridine, its 3- and 4-methyl (polymethyl) derivatives, and isoquinoline; 2-methyl derivatives of these heterocycles and often quinoline itself are weak catalysts, despite their high basicity, because of steric hindrance of the nitrogen atom. The applicability of Brønsted's relation between lg k_B and pK_a to pyridines substituted at all positions in the ring is usually interpreted as evidence of general base catalysis [139]. The isotope effect on passing from water to deuterium oxide as solvent is $k_H/k_D = 2–3$ for most reactions, including acid–base equilibrium, and is close to unity for the nucleophilic hydrolysis of derivatives of organic acids [201–204].



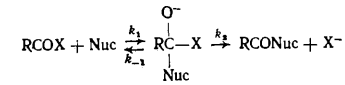
N-Dimethylcarbamoylpyridinium chloride (V) is stable in acidified aqueous solutions (pH 1–5), but undergoes rapid decomposition catalysed by the hydroxide ion when the solution is made alkaline [102]. On the addition of hydroxylamine hydrochloride, imidazole, sodium azide, sodium fluoride, or the formate ion, direct nucleophilic

‡The Dakin–West reaction involves *C*-acylation at an intermediate stage [180].

substitution occurs at the nitrogen atom. Hydrolysis of (V) is accelerated also by components of the buffer solution (e.g. the acetate ion):

Comparing the behaviour in aqueous solutions of solid *N*-acetylpyridinium chloride and of systems formed by acetic anhydride with pyridine bases, Jencks and Fersht [20,110,205] conclude that appreciable quantities of the *N*-acylpyridinium and its homologues may accumulate in aqueous buffer solutions. Increasing the concentration of the acetate ion lowers the quantity of acetylpyridinium formed by raising the rate k_{-1} of the reverse reaction. Pyridine has the opposite effect:

4-Substituted pyridines show a dependence on the basicity of the nitrogen atom (Table): the quantities lg k_1 and lg K_{eq} correlate satisfactorily with pK_a of the base.

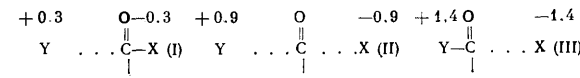


Relations between structure and reactivity in *N*-acetylpyridinium ions [20].

Base	pK_a of base	k_1, mole^{-1} s^{-1}	K_{eq}	Hydrolysis rate const. k_2, mole^{-1} s^{-1}		$-\Delta F^{\neq}$ of hydrolysis
				water	acetate ion	
Pyridine	5.51	84	0.092	6.9	910	18.31
4-Methylpyridine	6.33	490	1.86	2.3	262	17.67
3,4-Dimethylpyridine	6.79	1160	9.67	1.5	120	17.33
4-Methoxypyridine	6.82	935	31.2	0.4	30	16.65
Imidazole	—	—	2950	—	—	14.05

The acetylation of anisidine and *p*-toluidine by acetic anhydride in the presence of pyridine in aqueous solution is pseudo-unimolecular, with a rate constant independent of the type or concentration of arylamine. Hence the migration of an acyl group passes through a limiting stage in which the acetylpyridinium ion is formed, followed by rapid reaction with the nucleophile [20,110]. Thus these amines at concentrations of $(5–10) \times 10^{-4}$ M compete successfully with water, which illustrates the high selectivity of acetylpyridinium ions for the type of nucleophilic agent [20,206–208]. Corresponding comparative data for water and acetate ions (Table) are well correlated by Brønsted's equation ($\beta = -0.5$ and 0.68 respectively).

Values of k_2 for the nucleophilic substitution of the four *N*-acetylpyridinium ions in the Table with thirteen *O*- and *N*-nucleophiles (alkoxide and phenoxide ions, aliphatic amines, cyclic amines, and hydrazines) reveal a decrease in sensitivity ("levelling") of the acetylpyridinium ions to the basicity of the attacking nucleophile as this quantity increases [205]. The Brønsted constants fall in a series of *O*-nucleophilic reagents, from 0.9 for the acetate ion to 0.2 in alkoxides. For amines of moderate strength $\beta = 0.9$, after which it drops sharply. "Levelling" is absent in the less reactive acetylimidazolium ion.



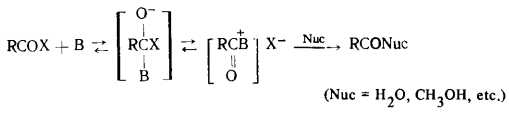
The scheme which has now been worked out for reactions at the carbonyl group in derivatives of carboxylic acids postulates the equilibrium formation of a tetrahedral addition product, which then breaks down:

(Nuc = neutral molecule or anion)

With strongly basic nucleophiles the intermediate adduct is rapidly converted into the final products, and when $k_2 \gg k_1$ the addition stage (k_1) is rate-determining. The dependence of the reactivity of the acid derivative RCOX on the basicity of the leaving group X will then be minimal. With weaker nucleophiles k_{-1} is relatively larger, and cleavage of the adduct begins to limit the overall rate of the process. Bender demonstrated that the second stage could rightly be chosen as determining the rates of reactions involving inactivated esters [137,138]. These concepts are often used also to explain the regular features of nucleophilic substitution at a quinquevalent phosphorus atom. However, isolated reactions may occur at the carbonyl group and at the phosphorus atom without necessarily involving intermediate formation of addition products.

Jencks [205,208] has proposed a new classification of acyl migrations, which depends on the strength of the nucleophile and on the values of β for the nucleophile and for the leaving group:

(the numbers denote the change in the charge on the attacking or leaving group of atoms compared with the change of 1.7 for the complete reaction). The first class comprises reactions of strongly basic nucleophilic reagents with acylating compounds having good leaving groups (i.e. with *N*-acetylpyridinium ions); they have an unsymmetrical transition state with relatively little formation of new bonds and destruction of old bonds (termed an early transition state). These reactions bear a definite resemblance to S_N2 substitutions at a saturated carbon atom.



The third class, on the other hand, includes reactions of feebly basic nucleophilic reagents and compounds with poor component groups. If the existence of an intermediate tetrahedral adduct is assumed, its cleavage determines the overall rate of the reaction. The second class covers many reactions where the transition state is more or less symmetrical with respect to the attacking and leaving groups ($\beta = 0.7–1.0$). It includes also reactions of acetylpyridinium ions with amines where the two groups have closely similar pK_a values. Formation of a tetrahedral intermediate structure is difficult to predict here.

The aminolysis of 4-substituted *N*-phosphorylpyridinium ions (XI) in aqueous solution by aliphatic and heterocyclic amines and imines having pK_a = 2.6–10.8 shows slight sensitivity to the basicity of the attacking group (Brønsted nucleophilic constant in the range 0.2–0.3) [86]. The value of k_2 for the nucleophilic reagent is strongly dependent on the nature of the leaving group in (XI).

Information has been published on the hydrolytic stability of several other solid *N*-phosphorylpyridinium salts and their *N*-acyl analogues [25,30,31,68,86,110]. In both series

the rate of hydrolysis decreases with increase in the basicity of the 4-substituent, as a consequence of delocalisation of the positive charge through the longer conjugated chain. The contribution of onium or immonium forms should, of course, increase in the sequence $\overset{+}{H}O=$, $\overset{+}{N}H_2=$, $R\overset{+}{N}H=$, $R_2\overset{+}{N}=$. In conformity with this the resonance-stabilised 1-acetyl-4-dimethylaminopyridinium chloride is hydrolysed more slowly than the unsubstituted *N*-acetylpyridinium chloride with a rate ratio of 1/2000.

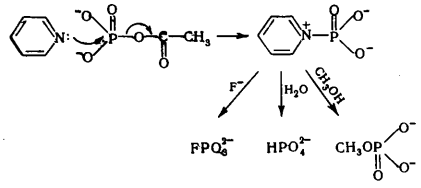
Nucleophilic catalysis by pyridine bases has been proved for the hydrolysis of acetic anhydride (in water [113,209], an acetate buffer [206,210,211], and aqueous-organic mixtures [199,212,213]), several mixed anhydrides [113,214], various acid chlorides in 89% aqueous acetone [99], acetyl fluoride [207], and arenesulphonyl chlorides in water [215]. Another model in kinetic investigations of hydrolysis is provided by *p*-nitro- and 2,4-dinitro-phenyl acetates [216-218], and certain sulphonic esters [219-221]. Nucleophilic catalysis by various pyridine derivatives of the methanolysis of 2,4-dinitrophenyl acetate, picryl acetate, and picryl benzoate, certain enol acetates, and arenesulphonyl chlorides has been investigated [222-227]. In all cases the results agree satisfactorily with the general scheme of catalysis

(Nuc = H_2O, CH_3OH, etc.)

The hydrolysis of acetic anhydride is highly sensitive to the acetate-ion concentration [206,210,211,213]: e.g. the catalytic effect of pyridine is completely inhibited in the presence of a buffer comprising 1.06 M acetate plus 0.54 M acetic acid in 40% dioxan [206]. On the other hand, the extraordinarily high isotope effect of $k_{H_2O}/k_{D_2O} = 5 \pm 1$ has been found for hydrolysis in acetate buffers [210,211]. This could be explained theoretically on the assumption of solvolysis of the acetylpyridinium ion as the rate-determining stage [201-203].

Transfer from water to methanol as solvent slows down the solvolysis of acetic anhydride by a factor of 10^5 [219], and in the latter solvent pyridine is only slightly more active than the acetate ion as a catalyst. Hydrolysis catalysed by pyridine is retarded with increase in the concentration of dioxan in mixtures with water [206,213]; it is supposed that decrease in the polarity of the solvent is accompanied by a significant fall in the equilibrium constant K_{eq} of the stage of formation of the *N*-acetylpyridinium ion (decrease in k_1 with simultaneous increase in k_{-1}).

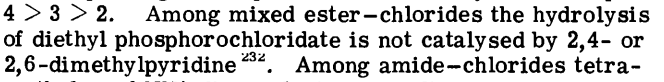
Study of the hydrolysis of several chlorides of carboxylic acids in 89% acetone in the presence of butylamine, trimethylamine, triethylamine, pyridine, and trimethylpyridine distinguished [99] those reacting by an S_N2 mechanism (through formation of *N*-acyl salts) from those reacting by unimolecular ionisation (S_N1). The rates of hydrolysis of piperidinocarbonyl, *NN*-di-isopropylcarbamoyl, and 2,4,6-trimethylbenzoyl chlorides remained almost unchanged in the presence of any of the amines, but acetyl, pivaloyl, benzoyl, and 2,4,6-trimethyl-3,5-dinitrobenzoyl chlorides showed a 10^5–10^7-fold acceleration in the presence of pyridine. The sequence of catalytic activity obtained for the tertiary amines



pyridine > trimethylamine > triethylamine > trimethylpyridine

is typical of nucleophilic catalysis.

The hydrolysis of benzenesulphonyl chloride in aqueous solution in the presence of ten pyridine derivatives having donor and acceptor substituents at positions 3 and 4 in the ring is well represented by the first-order equation $k_{obs} = k_w + k_b[B]$ [215,227]. The reaction is accelerated by the presence of donor substituents, and slowed down by acceptor substituents. Its sensitivity to the basicity of the nucleophiles is intermediate between the above cases of carbonyl compounds and phosphoric acids. It is postulated that, because of the greater polarisability of the sulphur atom, the bond may be formed in the transition state at a greater distance than for the carbon atom.



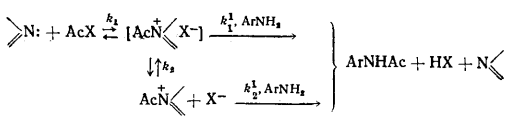
Various acid derivatives of phosphorus are of considerable interest in connection with the factors governing the possibility that hydrolysis may occur by mechanisms of general base and nucleophilic catalysis [197,228]. The relative reactivity of substrates may be affected not only by structural features but also by the pH of the solution (neutral molecule, mono- and di-anion).

In 1952 Koshland discovered that pyridine catalyses the hydrolysis of an acetyl phosphate in buffer solutions [19]. The list of nucleophilic catalysts was later extended when it was established that pyridine, 4-methylpyridine, triethylenediamine, and probably triethylamine attack the phosphorus atom preferentially, ensuring rupture of the phosphorus–oxygen bond, whereas trimethylamine, imidazole, and *N*-methylimidazole cause rupture of the carbon–oxygen bond [229,230]. The reactions were not catalysed by 2-methylpyridine, 2,6-dimethylpyridine, or 2,4,6-trimethylpyridine, which is consistent with the scheme

In the case of acetyl phenyl phosphate all the amines mentioned attack only the carbon atom, being catalysts of acyl migration.

Di-isopropyl and diethyl phosphorofluoridates are hydrolysed in a bicarbonate buffer 5–20 times as rapidly in the presence of 10 mole % of imidazole and pyridine derivatives [231]; with picolines the catalytic activity diminishes depending on the position of the methyl in the sequence 4 > 3 > 2. Among mixed ester–chlorides the hydrolysis of diethyl phosphorochloridate is not catalysed by 2,4- or 2,6-dimethylpyridine [232]. Among amide–chlorides tetramethyl- and *NN'*-dipropyl-phosphorodiamidic chlorides are hydrolysed at comparable rates in neutral or weakly acid aqueous solutions, the reactions being catalysed by 3,5-dimethylpyridine, pyridine, and 4-methylpyridine, but not by their 2-methyl analogues [200]. On the other hand, some catalysis by 2,6-dimethylpyridine has been found with *NN'*-diethylphosphorodiamidic chloride (XVII), obviously by the general base mechanism [232]:

Nucleophilic catalysis has been established for hydrolysis of the phosphorus-nitrogen bond in phosphoramidic [233-235] and *p*-chlorophenylphosphoramidic [236] acids. In neither case did 2-methylpyridine, 2,6-dimethylpyridine, or pyridine-2-carboxylic acid show appreciable activity. A test of six pyridine bases having $pK_a = 2.8$–6.0 gave satisfactory correlation of the Brønsted k_2 values ($\beta = 0.22$) [235]: i.e. the anions of these amides exhibit the same



diminished sensitivity to the basicity of the nucleophile as does N-phosphorylpyridinium (XI)[86]. It was proved that intermediate N-phosphorylated pyridines may accumulate during the reaction.

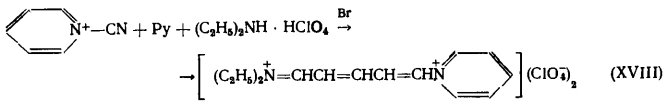
A similar pattern of nucleophilic catalysis is exhibited by the hydrolysis of the dianions of *o*- and *p*-nitrophenyl phosphates substituted in the ring by hydrogen, chlorine, acetyl, and nitro[237-239]. In the last case the reaction with pyridine is highly sensitive to the leaving group ($\rho = -1.03$), and almost completely insensitive to the basicity of the attacking group. This probably belongs to the first type of nucleophilic reactions in the Jencks classification[205], with almost complete absence of a phosphorus–nucleophile bond in the transition state. Pyridine bases and other nitrogen nucleophiles do not catalyse the hydrolysis of monoanions of phenyl, *p*-nitrophenyl, and *o*-nitrophenyl phosphates[236,238], but acceleration has been found with *para*-substituted *o*-nitrophenyl phosphates[238]. The reaction mechanism is assumed to approximate to the classical $S_N2(F)$, with formation of new bonds and rupture of old bonds in the transition state (type II in the Jencks classification).

Among neutral phosphoric esters appreciable catalysis by pyridine derivatives and imidazole has been found with ethylene methyl phosphate[240]. In buffer solutions ring-opening takes place preferentially, and to a less extent hydrolysis of the P–OCH_3 bond. The reaction is only slightly affected by steric hindrance in the catalyst molecule (4-methylpyridine > 3-methylpyridine > 2,4-dimethylpyridine > pyridine > 2,6-dimethylpyridine) and has $k_{H_2O}/k_{D_2O} \simeq 2$. Hence it is an example of general base catalysis. Tetrabenzyl pyrophosphate has also been investigated[241,242].

Litvinenko and his coworkers[243-253] have made a long series of kinetic investigations on the benzoylation of arylamines in the presence of tertiary amines in aprotic solvents. Various substituted pyridines exhibit high catalytic activity, considerably exceeding those of triethylamine and dimethylaniline[243,244]. The sequence of relative efficiencies follows the increase in basicity (pK_a in water) of the pyridine base: 3-NO_2 < 3-Cl < H < 3-CH_3 < < 4-CH_3 < 4-$(CH_3)_2N$. The Hammett correlation gives $\rho = -3.74$, indicating that the catalytic effect is highly sensitive to structural changes in the catalyst; 2-methylpyridine and 2,6-dimethylpyridine are relatively ineffective. A similar correlation was made of the constants of the non-catalytic reaction k_0 and of the catalytic reaction k_B with respect to the structure of the arylamine $RC_6H_4NH_2$ ($\rho = -2.67$, -1.35): this corresponds to an increase in the effective charge on the reaction centre in the transition state for catalysis by pyridines. The ratio k_B/k_0 increases as the amine to be acylated becomes less strongly basic, which is typical of nucleophilic reactions. The influence of *meta*- and *para*-substituents in the benzoyl chlorides is less marked, and *p*-chloro-, *p*-methoxy-, and *p*-dimethylamino-benzoyl chlorides are appreciably less reactive than would be expected from the σ-values. It has been explained by postulating the possibility of direct polar conjugation of the substituents with the reaction centre, which is more strongly developed than in Hammett's standard series (dissociation of carboxylic acids[248]).

Kinetic confirmation has recently been obtained of the formation of N-acyl salts during the acylation of *p*-anisidine by *m*-toluene- and *p*-nitrobenzene-sulphonyl chlorides in nitrobenzene in the presence of pyridine[252,253]. Values of $k_{eff} = k_0 + k_{Py}[Py]$ fell as the reaction proceeded. This is possible if the intermediate adduct of pyridine with the arenesulphonyl halide (acyl halide) dissociates into ions, either partly or completely, in the strongly ionising solvent, so that two catalytic paths—interaction of the arylamine with an ion-pair or with an acylpyridinium cation—are available for the reaction. Accumulation of the gegenion (Br^-, Cl^-) will displace the dissociation equilibrium and then formation of the primary adduct, similarly to the hydrolysis of acetic anhydride and phenyl acetates[206,208]:

(for cases of acylation by means of acid anhydrides see Refs. 245 and 250).



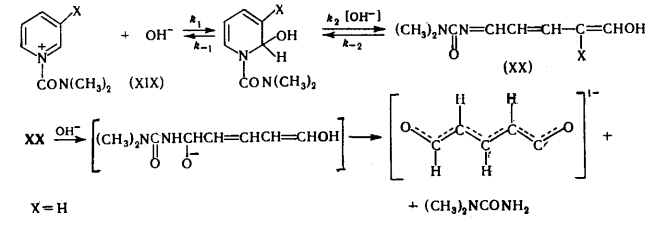
Bonner and his coworkers[116,254,255] have recently studied the kinetics of the trifluoroacetylation and the acetylation of several phenols and alcohols by trifluoroacetic, acetic, and trifluoroacetylacetic anhydrides in the presence of pyridine and its homologues in carbon-tetrachloride solution. The pyridines are assumed to have a dual function: they form hydrogen-bonded solvates with phenols, which makes the oxygen atom more strongly nucleophilic; and they solvate the leaving acetoxy-group in the transition state[116]. Calculation showed[254] that the hydrogen bonding of *p*-cresol and *p*-chlorophenol makes them more strongly nucleophilic by factors of 300 and 700 respectively. The degree of association of aliphatic alcohols with pyridines is small, which explains the slight catalytic effect (at 25°C). The isotope effects $k_H/k_D = 1.51$ and 1.40 obtained with deuterophenol and duetero-*p*-chlorophenol indicate that heterolysis of the oxygen–hydrogen bond is of some importance in acetylations[255].

Korshak et al.[105,256-259], in an investigation of low-temperature polyesterification in the presence of tertiary amines, also conclude that two mechanisms of catalysis—nucleophilic and general base—operate in the acylation of monohydric and dihydric phenols by acid chlorides. The latter mechanism is especially important with highly basic aliphatic amines (e.g. triethylamine) and highly acidic phenols[256]. Nucleophilic catalysis evidently predominates with sterically unhindered pyridine bases[257]. Thus the degree of conversion of phenol in the competitive benzoylation of phenol and methanol fell rapidly as pK_a decreased in the series of bases—tributylamine, triethylamine, ethyldimethylamine, 2,4,6-trimethylpyridine, 2-methylquinoline, 2-methylpyridine, isoquinoline, 3-methylpyridine, pyridine, and quinoline[258]. The solvent—its tendency to solvate the reactants physically and chemically—has an appreciable effect on the relative contributions of nucleophilic and general base catalysis. The quantity $q = (1 - x)/x$, where x is the conversion of phenol, has maximum values in dioxan, acetone, and nitrobenzene, and minimum values in benzene and dichloroethane.

3. Reactions of N-Acylpyridinium Cations with Opening of the Ring

Cleavage of the pyridine ring (the Zincke–König reaction[3,119-141]) with the formation of glutaconaldehyde or its anils or enamines is characteristic of quaternary pyridinium and benzopyridinium salts containing an electron-accepting substituent attached to the nitrogen atom. N-(2,4-Dinitrophenyl)- and N-cyano-pyridinium salts are cleaved in this way in the presence of alkali and various

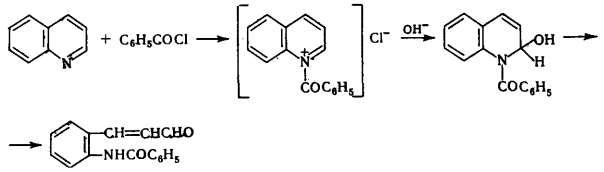
aromatic amines and *N*-alkylanilines[260–265]. 4-Methylpyridine and 4,4'-bipyridyl have also been used successfully (but not 2-methylpyridine). Besides the use of cyanogen chloride and bromide, the König reaction has been accomplished by the action of sulphur trioxide and ethyl chlorosulphate[226], carbonyl chloride, phosphoryl chloride, phosphorus pentachloride, thiocarbonyl chloride, and other thio-acid chlorides[262,267]. The combined action of cyanogen bromide and triethylamine perchlorate on pyridine yields the simplest polymethine dye (XVIII)[268]:



(XVIII)

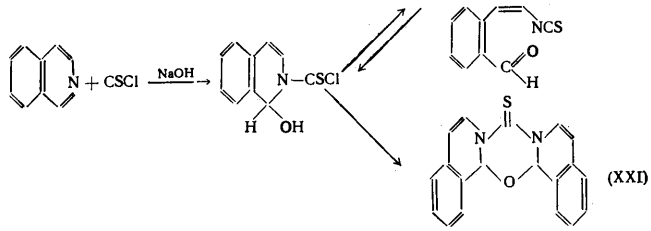
The view arose (probably because of the predominance of acylation processes) that acyl chlorides were incapable of initiating cleavage of the pyridine ring[262,269]. However, such a process was observed on the interaction of diphenylcarbamoyl chloride with pyridine in the presence of alkali[40] and when adducts of pyridine with di-*o*-tolyloxalimidoyl chloride and with *N*-phenylbenzimidoyl chloride were treated with various aromatic amines in alcoholic solution[45]. A case in which alkaline benzoyl chloride was used was also reported[270], but the yield of glutaconaldehyde was not indicated. Derivatives of this aldehyde are obtained in almost theoretical yield when *N*-nitro- and *N*-nitroso-pyridinium ions are cleaved under alkaline conditions[119,270]. This reaction is a sensitive test for pyridine[74,271]. Other analytical applications of the König reaction will be found in Refs. 272–276.

The cleavage of *N*-acylpyridinium salts is facilitated by the presence of compounds containing active methyl or methylene groups. They condense with the cleavage product to give polymethine dyes. Thus aroyl chlorides and pyridine react comparatively readily with 2,3-dihydro-2-oxobenzofuran, oxindole, or 3-hydroxy-1-methylindole[63,277]. With cyanoacetic esters initial nucleophilic addition to acylpyridinium salts is followed by opening of the pyridine ring at $C_{(2)}$[278].



Kinetic investigation of the cleavage of *N*-dimethylcarbamoylpyridinium cations (XIX: X = H, $CONH_2$) under alkaline conditions[44,279,280] shows that the equilibrium formation of pseudobases when the hydroxide ion attacks the ring at $C_{(2)}$ is more rapid than opening of the ring. The rate of the latter is proportional to $[OH^-]^2$ or $[B][OH^-]$, where B is a base (e.g. CO_3^{2-}). The resulting 5-dimethylureidopenta-2,4-dienals (XX)

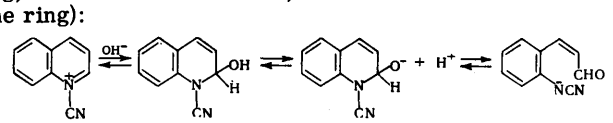
X = H



are relatively stable, and can be isolated from the solution. The strong "acidifying" action of the 3-carbamoyl group in (XIX) on the relative ease of formation of the pseudobase is significant: the pH of equilibrium between cyclic and open-chain forms is shifted to 8.6 from 10.64 for X = H; the constants $k_2(CONH_2)$ and $k_2(H)$ differ by factors of 10^5, although for reactions involving migration of the acyl group (Section III, 2) they increase only 3 to 14 times[44].

N-Alkyl-quinolinium and -isoquinolinium pseudobases are very stable and exist only in the cyclic form[4]. For this reason Reissert assigned a pseudobase structure to the product of the reaction of quinoline with benzoyl chloride in the presence of 10% alkali[34], but later he suggested the "open" benzamidocinnamaldehyde structure[281]:

The open structure (with the *trans*-configuration) has now been proved by various spectral methods[282,283].



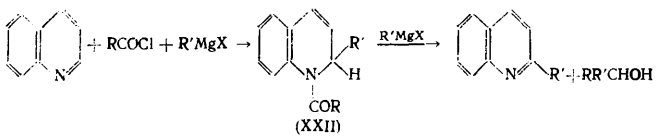
Reissert's method is of applied significance for the preparation of various polyfunctional compounds[282]. Pseudobases can be prepared by means of cyanogen bromide[284–287]. Reaction of isoquinoline with thiocarbonyl chloride in alkaline medium yields a ring-cleavage product together with a compound (XXI) formed by dehydration of the pseudobase[288]:

(XXI)

A stable pseudobase has been obtained from an *N*-benzoyl salt of 5-nitroquinoline; in this case its cyclic structure and the absence of tautomeric conversion to an acyclic form have been proved[283].

A series of studies by Johnson and his coworkers[106,123,126,283,287–290] on *N*-cyano-quinolinium and -isoquinolinium ions have revealed the great importance of pseudobases in the occurrence of most reactions of such compounds (acid–base equilibria of two types, hydrolysis, ring-opening, formation of *O*-ethers, bromination and nitration in the ring):

The formation of pseudobases and opening of the pyridine ring are two stages of a general process of attack by the nucleophilic reagent (hydroxide ions, arylamines) at the α-carbon atom of the heterocyclic ring. This process frequently competes with reactions involving migration of the acyl group to other nucleophiles.

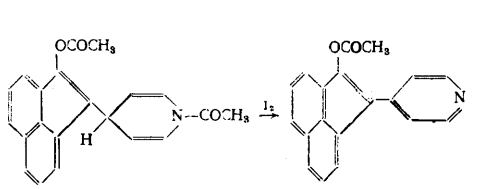


4. Hetarylation

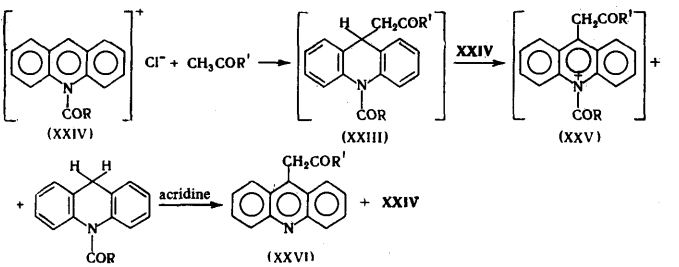
The reaction of *N*-acyl-quinolinium and -isoquinolinium salts with the cyanide ion is of great importance for synthetic organic chemistry. In contrast to the hydroxide ion, the cyanide ion does not cleave the heterocyclic ring and, with few exceptions, does not detach the acyl group. Attack at $C_{(2)}$ leads in this case to the formation of extremely stable 1-acyl-2-cyano-1,2-dihydroquinolines or 2-acyl-1-cyano-1,2-dihydroisoquinolines (so called

Reissert compounds). *N*-Acyl-pyridinium and -acridinium salts do not undergo this reaction[34,281]—see, however, Ref. 291. In view of the appearance of two reviews on the Reissert reaction[292,293], we shall merely give references to the most important papers published during the past three years on the subject of the present paper[294-310]. The interaction of *N*-cyanoquinolinium with anhydrous hydrogen cyanide has been discussed[283,284].

Pyridine undergoes the Grignard reaction with difficulty, while its *N*-alkyl salts are sparingly soluble in most of the solvents used in this synthesis[1]. When pyridine interacts with a Grignard reagent in the presence of acylating agents, the corresponding 1,4-dihydropyridines are formed[292], and easily pass into 4-substituted pyridines. With 4-substituted pyridines, however, Grignard reagents attack position 2, not 4, in the *N*-acylpyridinium ions[311].



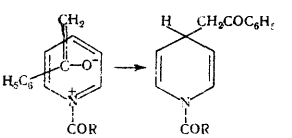
The addition of Grignard reagents to a mixture of quinoline and an acyl halide gives compounds of type (XXII), but with the reactants mixed in the opposite sequence, i.e. in excess of the organomagnesium compound, the 1,2-dihydro-derivative loses a proton, and is converted into a 2-substituted quinoline[312,313], the acyl group giving the corresponding tertiary alcohol:



(XXII)

Similarly, *N*-acylpyridinium salts react *in situ* with silver acetylides at position 2[314].

In the early work Claisen and Haase[315], in a study of the reaction of acetophenone with benzoyl chloride in the presence of pyridine, isolated a compound $C_{20}H_{17}NO_2$ as well as the expected *O*-benzoyl derivative of the enol. Much later a compound containing a pyridine group was also obtained by the acylation of acenaphthenone with acetic anhydride in pyridine[316]. McEwen[98] showed that 4-substituted 1-acyl-1,4-dihydropyridines had been obtained in both cases: e.g. Ghigi's product[316] was 2-(1-acetyl-1,4-dihydropyrid-4-yl)acenaphthylen-1-yl acetate. Oxidation by iodine gives the 4-substituted pyridine:

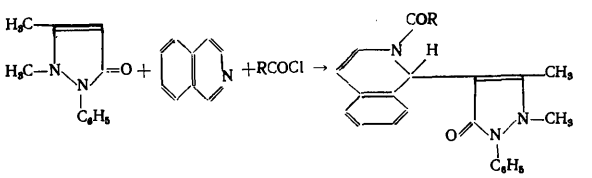


Under similar conditions *N*-acylquinolinium salts usually "quinolinate" both monocarbonyl and β-dicarbonyl compounds to form 2-substituted 1-acyl-1,2-dihydroquinolines[192,278]. Hetarylation—not acylation—products also constitute the main yield of the reactions of *N*-acylated isoquinolinium, phenanthridinium, and acridinium salts with various keto-compounds[317,318]. In this way preparative yields of ketones of the acridine series have been obtained directly from acridine and acyl halides with acetophenone. The probable mechanism of the latter reaction is that the initially formed 10-acyl-9,10-dihydro-9-phenacylacridine (XXIII) is converted, by detachment of a hydride ion on attack by an *N*-acylacridinium cation, into an unstable *N*-acyl salt (XXV), which is decomposed by excess of acridine with regeneration of the salt (XXIV) and formation of the product (XXVI)[319]:

(XXIV) (XXIII) (XXV) (XXVI)

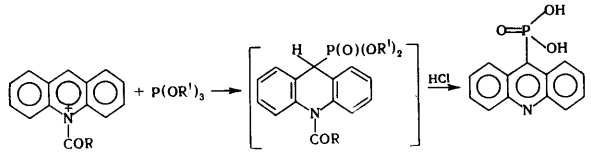
The distribution of electron density can be used to explain preferential attack by a nucleophile at position 2 or 4 in the pyridine ring[320]. Other approaches have tried to take into account both the electronic nature of the two reactants and the character of the transition state (Kosower–Klopman theory[321,322] and Pearson's general acid–base principle[323]).

Kosower[324] suggested that substitution occurs at the $C_{(4)}$ atom of the pyridine ring if the reagents (electron donors) form charge-transfer complexes with pyridinium cations; if, however, the formation of such complexes is hindered, position 2 is substituted. For example[321], the benzoylpyridinium cation reacts with the enolate anion of acetophenone to form initially an adduct (XXVII), in which the nucleophilic atom of the ambident group is situated near position 4, and the anionic centre near the positively charged nitrogen atom:



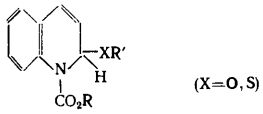
(XXVII)

Nevertheless, Kosower himself stresses that his ideas do not apply to the behaviour of the cyanide ion, which attacks *N*-alkylpyridinium salts solely at $C_{(4)}$, although no absorption band corresponding to charge transfer has yet been detected.

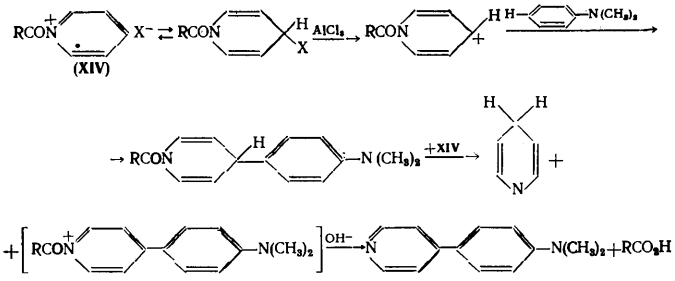


In terms of Pearson's generalised acid–base principle[323] the character of the attack by the nucleophilic agent (a generalised Lewis base) on *N*-acylated heteroaromatic cations, which are ambident ions, will be determined by the relative "hardness" or "softness" of individual positions in the ring. Hence position 4 is attacked in pyridinium salts, but the orientation in quinoline and isoquinoline remains obscure as before. The thermodynamic factor is probably decisive[122,325]. Comparison of the 1,2- and 1,4-dihydroquinoline structures shows the former to be thermodynamically preferred, with the $C_{(3)}=C_{(4)}$ double bond conjugated with the benzene ring, and the necessary conditions established for production of a homoaromatic structure (in terms of Winstein's ideas[326]).

The reactions of *N*-acylated heterocyclic cations *in situ* with pyrazolones, thiazolidine-2,4-diones, rhodanine, thio- and iso-rhodanines, azalactones, and other azolidones are of the same type (interaction with ambident methine anions)[327-331]:

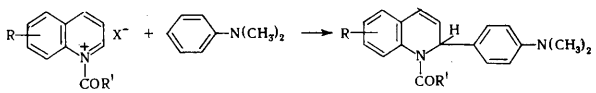


It has recently been established that the Dakin–West synthesis involves the intermediate pyridylation of oxazolones by *N*-acetylpyridinium cations [332,333] (for greater detail see Ref. 180). The cyclopentadienyl ring has also been hetarylated (by the reaction of *N*-acylated pyridinium and benzopyridinium salts with azulenes) [334]. The reaction of *N*-acylpyridinium salts with nitroalkanes [335] yields anomalous products not containing a pyridine ring, but quinolinium salts form hetarylation products containing two quinoline ring systems.



Interaction between *N*-acylated heteroaromatic cations and compounds having a heteroatom with a lone pair of electrons mostly involves attack on the carbonyl carbon atom, as stated above, with elimination of the heterocycle and migration of the acyl (acylation of amines, alcohols, thiols, etc.). However, there are several examples of reactions occurring by a mechanism of hetarylation. Thus the well known synthesis of *N*-pyrid-4′-ylpyridinium chloride by chlorinating pyridine with thionyl chloride [336–338] probably involves attack by pyridine as a nucleophile on $C_{(4)}$ in the *N*-acyl salt. Among the very few cases of intramolecular hetarylation is the formation of dyes by interaction between quinoline-2-carboxylic acid and acetic anhydride or between quinoline-2-carbonyl chloride and quinoline [339–341]. Another example is the successful accomplishment of the Arbuzov rearrangement for trialkyl phosphites by the action of *N*-acyl-pyridinium, -quinolinium, and -acridinium salts [342,343]:

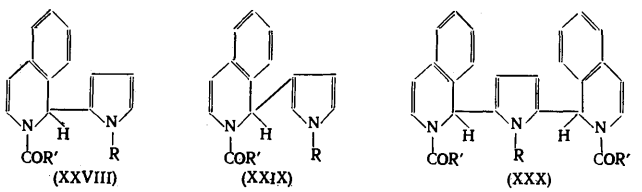
It has recently been shown [344] that, in the presence of acylating agents (ethyl chlorocarbonate, acetyl and benzoyl chlorides), quinoline readily adds alkoxide and thiolate ions at position 2. This method has been used to prepare high yields of 1,2-dihydro-derivatives of general formula



During recent years the chemistry of *N*-acylpyridinium salts has been developed most widely in the hetarylation of the aromatic ring. Like the usual inorganic cations and the widely studied carbonium ions, acylpyridinium ions and their benzo-analogues have proved convenient reagents for the introduction of a heteroaromatic substituent into an aromatic ring§. *N*-Benzoylpyridinium chloride is mostly used in the presence of aluminium chloride or copper powder [112,345,347], when there is no need to isolate the *N*-acylpyridinium salt. The mechanism of the reaction is apparently that the positive charge on the pyridine cation, as a result of the action of the aluminium chloride, becomes concentrated on the 4-carbon atom to form a carbonium ion:

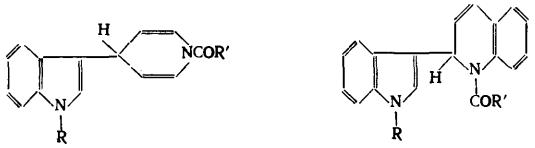
It may also be supposed that *N*-acylpyridinium halides are present in solution either as charge-transfer complexes or as ion-pairs, in which donor–acceptor interaction occurs between the pyridinium cation and the anion [324]. Such systems are less strongly electrophilic than the "purer" cations present in salts with weakly nucleophilic anions like perchlorate, tetrachloroaluminate, etc. This is another explanation of the action of Lewis acids. In a comparative series of experiments on the pyridylation of dimethylaniline with various aliphatic acid chlorides the yield of 4-*p*-dimethylaminophenylpyridine increased as the alkyl chain became longer, which is evidently connected with the strengthening of the electron-accepting effect of the *N*-substituent in the intermediate *N*-acyl salt [37].

N-Acylquinolinium salts, which are most strongly electrophilic, react with dialkylanilines and their analogues in the absence of catalysts [351,352]:



The nature of the anion in *N*-acylquinolinium salts has a significant effect on the yield of quinolination products. Thus the yield of 1-benzoyl-2-*p*-dimethylaminophenyl-1,2-dihydroquinoline increased regularly in the reactions of dimethylaniline with quinoline and a benzoyl halide (fluoride, chloride, bromide, iodide), which may be attributed simply to the increasing reactivity of the benzoyl halides in this sequence. On the other hand, this effect can also be explained by the formation of charge-transfer complexes (with transfer of the electron of the anion to a non-bonding orbital of the heterocycle), which facilitates occurrence of the reaction by a radical mechanism. The possibility of a radical scheme is seen still more clearly in the hetarylation of dialkylanilines by *N*-acylisoquinolinium salts [353,354], since the yields of reaction products were increased by exposure to ultraviolet radiation. The reaction between dialkylanilines and phenanthridinium salts proceeds similarly, but with smaller yields [355].

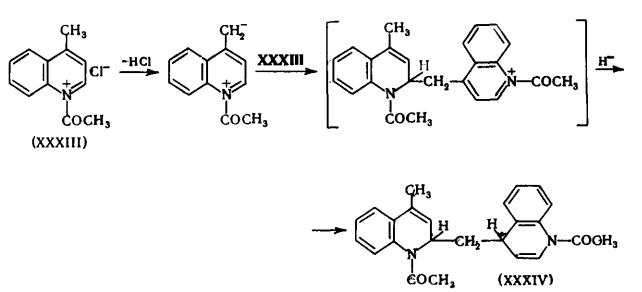
Acridine reacts more vigorously than other benzopyridines with dialkylanilines in the presence of acylating agents, but it forms 9-arylacridines and *N*-acylacridans [356], not 10-acyl-9-aryl-9,10-dihydroacridines. Hetarylation by acylpyridinium or acylbenzopyridinium salts has been described also with 1-alkyl-2,3-dihydroindoles, *N*-alkyltetrahydroquinolines, *N*-phenylmorpholine, *N*-phenylpyrrolidine, etc. [354,355,357–364]. Similarly to the benzene ring, acylpyridinium cations readily attack the electron-excess rings of such heterocycles as pyrrole, furan, and indole.



§Some 10–15 years ago there were only isolated publications on this topic [17,345,346]. After pyridylation had been developed [112,347], however, many papers appeared on hetarylation by quinolinium [348], pyrylium [348–350], etc. salts.

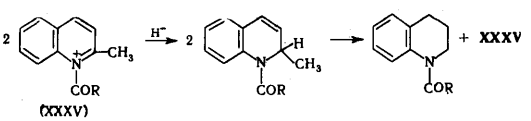
Fischer [365] long ago isolated a pyridine-containing substance from the action of pyridine and cyanogen bromide on ethyl 2,4-dimethylpyrrole-3-carboxylate. Much later pyrrolylpyridine derivatives of undetermined structure were obtained.[366,367] by the acylation of pyrroles with acyl chlorides in pyridine solution. However, a more detailed study of the reactions of *N*-acylpyridinium salts and the corresponding benzo-analogues with pyrroles has been made only comparatively recently[368-377], and has shown the formation of both monoadducts (of types XXVIII and XXIX) and bisadducts (XXX).

(XXVIII) (XXIX) (XXX)



The hetarylation of indoles by *N*-acyl salts of six-membered nitrogen heterocycles [21,278,372,378-384] produces compounds of types

(XXXI) (XXXII)

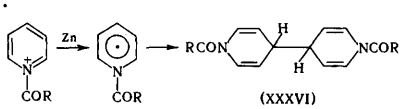


Thus 1-benzoyl-1,4-dihydro-4-indol-3'-ylpyridine has been obtained from pyridine, benzoyl chloride, and indole [178,378,380]. The yield is considerably lower when acetyl chloride is used, and with toluene-*p*-sulphonyl chloride the corresponding compound, formed in small quantities passed very readily into indolylpyridine. Under analogous conditions the reaction with *N*-acylacridinium salts gives only 3-acridin-9'-ylindoles [383,384]. The reaction of pyridine with indole in the presence of trichloroacetyl chloride involves the acylation (not the pyridylation) of indole, but in the presence of cyanogen bromide the pyridine ring is cleaved with formation of a pentadienal derivative of indole [379]. Isoindoles, in contrast to indoles, form 1,3-dipyridylisoindoles on interaction with pyridine and benzoyl chloride [385].

Many authors have pointed out that 1-acyl-2(and 4)-methylquinolinium salts cannot be used in hetarylations. Depending on the reaction conditions 1-acyl-4-methylquinolinium cations (XXXIII) are converted [386] either into 1-acyl-1,2-dihydro-4-methylquinolines or into "dimers" (at 50° and 100°C respectively). Detailed analysis of the mass spectrum of the "dimer" obtained with acetyl chloride indicates the structure (XXXIV). Its formation can be represented by the scheme (based on the dimerisation of 1-alkyl-4-methylquinolinium salts) [387]

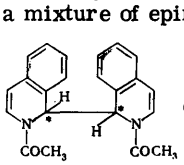
(XXXIII) (XXXIV)

Formation of dimers has not been observed with 2-methylquinoline, probably because the methyl group is less strongly activated than in the 1-acyl-4-methylquinolinium ion [120]. 1-Acyl-1,2,3,4-tetrahydro-2-methylquinolines were always obtained when the reaction was conducted under various conditions, probably as a result of the disproportionation (with migration of hydrogen) of intermediate 1-acyl-1,2-dihydro-2-methylquinolines [380]:



(XXXV)

5. One-electron Reduction of *N*-Acylated Heteroaromatic Cations

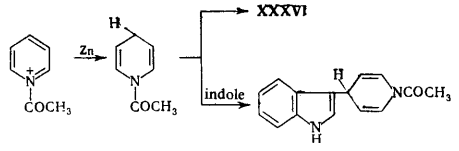


The strongly electrophilic character of *N*-acylated heteroaromatic cations is shown not only by their addition to reaction centres of high electron density or by their formation of charge-transfer complexes: reactions involving electron transfer and formation of the corresponding radicals are also facilitated in this series, since the one-electron reduction potentials of pyridinium cations fall when the electron-accepting properties of substituents attached to the heteroatom become stronger [388], and should be especially low with *N*-acylpyridinium salts and their benzologues. In fact, whereas *N*-alkylpyridinium salts are reduced only by sodium amalgam [389], zinc dust at room temperature or slightly above (30°C) is sufficient to reduce *N*-acylpyridinium salts; furthermore [74], a vigorous reaction with liberation of iodine is observed when potassium iodide is added to pyridine–arenesulphonyl chloride systems.

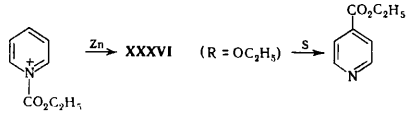
The formation of radicals by the action of benzoyl chloride and zinc dust on pyridine was first observed by Weitz et al. [390] Almost simultaneously Dimroth [391,392] observed the formation of a compound of type (XXXVI) in the reaction of acetic anhydride, pyridine, and zinc dust (more detailed information on its structure will be found in Ref. 393):

(XXXVI)

This reaction is characteristic of various *N*-acylpyridinium salts and their benzologues [394-400]. For example, isoquinoline forms a mixture of epimers of



(XXXVII)



in equal proportions [397]. Acridine, however, does not yield a dimer but *N*-acetylacridan [401], which is probably explained by the greater stability of the *N*-acetylacridinyl radical: the latter does not recombine, but is reduced to the anion and then adds a proton.

For a long time the reaction could not be conducted with 2- and 4-methylpyridines [402,403], but the use of chloroformic esters as acylating agents enabled dimers of *N*-acylmethylpyridines and even of *N*-acyl-trimethylpyridine to be obtained [398-400]. With 4-substituted pyridines, however, 1,4-diacyl-1,4-dihydropyridine derivatives were isolated [399].

The *N*-acylpyridyl radicals formed in Dimroth's reaction are able not only to recombine but also to hetarylate nucleophilic aromatic or heteroaromatic compounds added to the reaction medium [28,404,405]:

4-Ethylpyridine has been prepared by the further reduction of pyridine with zinc in acetic acid (by Wibaut's method) [338,396,406-410], and the process has been exploited on an industrial scale [411-417]. The mechanism of the reaction has been discussed [338,408]. In spite of many unsuccessful attempts initially, it proved possible to obtain in this way 4-ethyl-2(and 3)-methylpyridines from 2- and 3-methylpyridines [418]. The use of chloroformic ester in this reaction yielded isonicotinic ester [419]:

---o0o---

Thus the chemistry of *N*-acylpyridinium salts and their benzo-analogues has already developed far enough to solve major theoretical and practical problems. From the point of view of synthetic organic chemistry several analogous compounds can be obtained by a different process, via the corresponding *N*-oxides. This line of attack, which has been especially broadly developed by Japanese chemists, is substantially different in its theoretical aspects, and therefore we have not dealt with it in the present paper.

Silicon-containing Isocyanates

V.P.Kozyukov, V.D.Sheludyakov, and V.F.Mironov

Methods of preparation, properties, and prospects for the application of silicon-containing isocyanates are surveyed. In the Review these compounds are divided into two classes—isocyanatosilanes and "*C*-functional" organosilicon isocyanates—because of the substantial differences in their properties and methods of preparation. Not only monomeric compounds but also oligomeric and polymeric products containing silicon and one or more isocyanato-groups are considered. The Review covers papers that appeared up to the end of 1971 and to some extent at the beginning of 1972. A list of 304 references is included.

CONTENTS

I. Introduction 662
II. Compounds containing an isocyanato-group attached to the silicon atom 662
III. "*C*-Functional" organosilicon isocyanates 666

I. INTRODUCTION

The importance of organic isocyanates in theoretical and applied chemistry is well known, and progress in this field has been surveyed repeatedly [1-5]. The chemistry of organosilicon isocyanates began to be developed intensively only during the past decade, and their applied importance is continually increasing. Organosilicon isocyanates can be divided into two fundamentally different classes: the first comprises compounds containing the isocyanato-group directly attached to the silicon atom; and the second class includes isocyanato-alkyl, -aryl, -alkoxyl and other derivatives of silicon in which the isocyanato-group is separated from the silicon atom by some other group of atoms. Isolated data on the first type of compounds will be found in a review [6] on the pseudohalides of elements of Groups IIIb and IVb and in two papers [7,8]. However, most of the information on either type of silicon isocyanates has not been specially summarised. The present Review is an attempt to fill this gap.

II. COMPOUNDS CONTAINING AN ISOCYANATO-GROUP ATTACHED TO THE SILICON ATOM

1. Methods of Preparation

(*a*) Exchange between halogenosilanes and metal cyanates

A general method for the preparation of isocyanatosilanes is the double decomposition of halogenosilanes and metal cyanates [9-58]. This reaction has been used to prepare isocyanatosilanes of general formula $R_nSi(NCO)_{4-n}$, where $n = 1-3$ and R = Alk, Ar, OAlk, Hal, etc.

Although isocyanatosilanes are best obtained from bromosilanes, the more readily available chlorosilanes are often used. With iodosilanes yields are lower and the final products are less pure. Fluorosilanes do not undergo this reaction [27]. Replacement of the halogen by an isocyanato-group is effected by passing the vapour of the halogenosilane over the cyanate salt [29,30], in the melt [32], in an aprotic liquid organic solvent, or in the absence of a solvent [27,56].

The silver, mercury, lead, copper, tin, zinc, antimony, and thallium salts are generally employed for the double decompositions [27,33,34,43,44,47]. The use of freshly prepared salts taken in excess normally improves the yield [19,42,43,47]. The reaction of halogenosilanes with potassium and sodium cyanates is considerably more difficult. For example, silicon tetraiodide has not reacted with potassium cyanate at 20°C after twelve days [30], and the prolonged heating of silicon tetrachloride with potassium and sodium cyanates gives a low yield of silicon tetraisocyanate [9,45]. Satisfactory yields of this product are obtained when silicon tetrachloride vapour is passed over the finely ground or molten salts of alkali or alkaline-earth metals at temperatures above 200°C. [45] Trimethylsilyl isocyanate has been obtained under similar conditions [34,57].

Isocyanatosilanes have recently been obtained in high yields by the reactions of chlorosilanes with potassium and sodium cyanates in liquid sulphur dioxide [35], and also with the lithium salt in benzene [36]. The most complete series of compounds $R_nSi(NCO)_{4-n}$ have been obtained with R = Alk and C_6H_5. [12,18,19] Isocyanatosilanes having a vinyl, phthalocyanine, alkoxyl, aroxyl, or organosilyl group attached to the silicon atom are obtained by the same scheme as are alkyl and aryl derivatives [14,18,31,35,37,38,41,49].

In the preparation of silicon tetraisocyanate from the tetrachloride and silver cyanate the reaction takes place step by step and is accompanied by partial hydrolysis of the reaction products [10,17]. In this way the compounds

$$Cl_3SiNCO,\quad Cl_2Si(NCO)_2,$$

$$Si(NCO)_4;\ (OCN)_3SiOSi(NCO)_3 \text{ and } (OCN)_3SiOSi(NCO)_2OSi(NCO)_3$$

were isolated.

Partly halogenated silanes are also used for the preparation of isocyanatosilanes [13,59]: e.g.

$$2SiHCl_3 + 8AgOCN \rightarrow 2Si(NCO)_4 + 6AgCl + 2Ag + H_2$$

Finally, it is noteworthy that isothiocyanato- and mercapto-groups can also be replaced by the isocyanato-group [11,27]:

$$Cl_3SiSH + 4AgNCO \rightarrow Si(NCO)_4 + AgSH + 3\,AgCl$$

$$Me_2Si(NCS)_2 + 2AgNCO \rightarrow Me_2Si(NCO)_2 + 2AgSCN$$

(*b*) Aspects of exchange reactions

Eaborn arranged organosilicon compounds in what he termed "conversion series", characterising their capacity for irreversible transformation on reaction with metal

salts. With the triethylsilyl derivatives, for example, the series is (R = C_2H_5) [26,27,60]

$$R_3SiI \xrightarrow{Ag_2S} (R_3Si)_2S \xrightarrow{AgBr} R_3SiBr \xrightarrow{NaH} R_3SiH \xrightarrow{AgCN} R_3SiNC \rightarrow$$
$$\xrightarrow{AgCl} R_3SiCl \xrightarrow{AgSCN} R_3SiNCS \xrightarrow{AgNCO} R_3SiNCO \xrightarrow{KOAc} R_3SiOC(O)Me \rightarrow$$
$$\xrightarrow{H_2O} (R_3Si)_2O \xrightarrow{\text{heavy-metal fluorides}} R_3SiF$$

Hence it follows that isocyanatosilanes cannot be obtained from acyloxysilanes, siloxanes, and fluorosilanes. Analogous conversion series have been established for methylsilanes $(CH_3)_3SiX$, dialkyl(and aryl)silanes R_2SiX_2 [23,27], and salts of other metals—mercury, tin, antimony, cadmium, zinc, and copper.

Under the conditions of a heterolytic reaction mechanism the factor determining the sequence of compounds in conversion series is probably the affinity of the various functional groups for the silicon atom, although other factors are also important. This conclusion is supported by the coincidence of the conversion series with the sequence of compounds in order of increasing energy of the ionic Si–X bonds (X = I, S, Br, etc.) [27].

On the other hand, Anderson showed [24,60-66] that silicon; germanium, and phosphorus isocyanates undergo exchange reactions with compounds of elements in the middle of the Periodic System provided that the most volatile component is removed from the reaction mixture. Such sequences of conversion of some compounds into others were termed "volatility series". Examples of such reactions are

$$Me_2Si(NHPh)_2 + Ph_2Si(NCO)_2 \rightarrow Me_2Si(NCO)_2 + Ph_2Si(NHPh)_2$$
$$Et_3GeOSO_2R + Ph_3SiNCO \rightarrow Et_3GeNCO + Ph_3SiOSO_2R$$

In the triethylsilyl series the conversions

$$Et_3SiNHPh \rightarrow Et_3SiNCS \rightarrow Et_3SiI \rightarrow Et_3SiNCO \rightarrow Et_3SiBr \rightarrow Et_3SiCl$$

are possible. It must be noted that the sequences of exchange reactions in "conversion series" and "volatility series" often do not coincide.

(*c*) Reactions of organosilicon compounds with isocyanic acid

The original attempts to use isocyanic acid to replace chlorine atoms in chlorosilanes by the isocyanato-group were unsuccessful, in spite of the use of aluminium, zinc, iron, and mercury chlorides as catalysts [11,34]. It was found, however, that isocyanatosilanes are easily formed if the hydrogen chloride liberated is bound by tertiary amines or by amides of carboxylic acids [37,67,68]:

$$R_nSiCl_{4-n} + (4-n)\,HNCO + (4-n)\,R'_3N \rightarrow R_nSi(NCO)_{4-n} + (4-n)\,R'_3N \cdot HCl$$

The reaction must be conducted in the presence of a slight excess of chlorosilanes, which stabilise isocyanic acid and isocyanatosilanes [68]. Alkoxy- and aryloxy-isocyanatosilanes have been obtained by this method [69]. According to patent claims [70] silanols, e.g. triphenylsilanol, can be used as initial compounds in the reaction with isocyanic acid. In view of the ready availability of isocyanic acid, obtained by the pyrolysis of cyanuric acid or urea, its use for the preparation of isocyanatosilanes is extremely promising.

(*d*) Disproportionation

Many observations have been made of the formation of isocyanatosilanes by disproportionation [10,71-79]:

$$Si(NCO)_4 + Si(NCS)_4 \rightarrow SCNSi(NCO)_3$$
$$Si(NCO)_4 + SiCl_4 \rightarrow Cl_3SiNCO + Cl_2Si(NCO)_2 + ClSi(NCO)_3$$
$$Si(NCO)_4 + SbF_3 \rightarrow F_3SiNCO + F_2Si(NCO)_2 + FSi(NCO)_3$$

However, isolation of the reaction products is extremely difficult owing to their tendency to symmetrisation. This applies especially to compounds of the type $XSi(NCO)_3$ (where X = Cl, OCH_3, F) [10]. Compounds of types $(CH_3)_nSi(NCO)_{4-n}$ and $(CH_3)_nSiCl_{4-n}$ ($n \geq 1$) exhibit a tendency to disproportionate only about one-thousandth of that shown by silicon tetraisocyanate and the tetrachloride or tetrabromide [10,72-74].

A quantitative study by means of proton magnetic resonance spectroscopy of the exchange of isocyano, isocyanato, and isothiocyanato for chloro, bromo, alkoxyl, alkylthio, etc. in mono- and di-methylsilanes [75-77] showed that, with rare exceptions [75], the position of equilibrium conforms to a random distribution. Equilibrium constants have been determined for several exchange reactions [75-77,80].

Disproportionation has found application only in the preparation of fluoroisocyanatosilanes.

(*e*) Other methods of preparation of isocyanatosilanes

Besides the above general methods there are several specific reactions one of whose products is a compound containing an Si–NCO fragment. Gilman et al. [46] obtained triphenylsilyl isocyanate by the reactions

$$Ph_3SiCl + \begin{matrix} Na \\ \diagdown \\ NCOOEt \\ \diagup \\ H \end{matrix} \rightarrow Ph_3SiNCO + EtOH + NaCl$$
$$Ph_3SiCl + NH_2CONH_2 \xrightarrow{Cu} Ph_3SiNCO + NH_4Cl$$

Goubeau and Paulin [34] prepared trimethylsilyl isocyanate and dimethylsilylene di-isocyanate by the reaction of urea at 240–320°C with trimethylchlorosilane and dimethyldichlorosilane respectively, the yield in the latter case being 5–10%.

Pump and Rochow [81] showed that trimethylsilyl isocyanate is formed in the thermal decomposition of silicon derivatives of carbamic acid:

$$ROC(O)Cl + NaN(SiMe_3)_2 \rightarrow RO-\overset{\overset{N-SiMe_3}{\|}}{C}-OSiMe_3 \rightarrow Me_3SiNCO + Me_3SiOR$$

The reaction of carbon dioxide with bistrimethylsilylsodamide obviously has a similar mechanism, via trimethylsilyl isocyanate as an intermediate product [82]. The formation of this isocyanate has been observed also in the reaction of carbonyl chloride with hexamethyldisilazane [83-85] and in the interaction of technical calcium or barium cyanamide with trimethylchlorosilane in a lithium chloride–sodium chloride melt at 400°C [86].

Zhinkin and his coworkers [87-92] suggested an interesting route for the preparation of isocyanatosilanes:

$$(Me_3Si)_2NH + PhNCO \rightarrow PhNHC(O)N(Ph)SiMe_3 + Me_3SiNCO$$
$$Me_3SiNHC(O)N(Ph)SiMe_3 \xrightarrow{120°C} Me_3SiNCO + Me_3SiNHPh$$

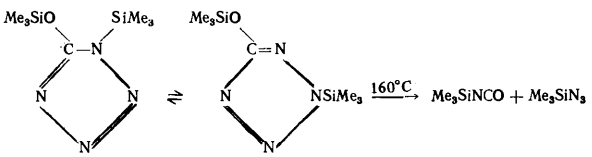
Unsymmetrical organodisilazanes yield two isocyanatosilanes and two aminosilanes in this reaction [92]. Mono-, di-, and tri-isocyanatomethylsilanes, as well as isocyanatosilanes containing unsubstituted hydrogen, have been obtained by the pyrolysis of *N*-silylated ureas [94-96]:

$$Me_nSi(NHCONPh_2)_{4-n} \rightarrow Me_nSi(NCO)_{4-n} + (4-n)\,Ph_2NH$$

$$NH_2CONH_2 + (HSiMe_2)_2NH \rightarrow HSiMe_2NCO + NH_3$$

$$NH_2CONH_2 + (Me_3Si)_2NH \rightarrow Me_3SiNCO + NH_3$$

$$(PhNH)_2CO + (Me_3Si)_2NH \rightarrow Me_3SiNCO + Ph_2NH$$



Silyl isothiocyanates are readily formed by the action of sulphur on silicon isocyanides [97,98]. Nevertheless, mild oxidation of the latter with mercury(II) oxide or silver(I) oxide does not yield isocyanatosilanes but products in which the silicon–nitrogen bond has been ruptured [7,56,98]. Strong oxidants (lead dioxide, manganese dioxide, and sodium peroxide) react with trialkylsilyl isocyanides only on heating, but formation of isocyanatosilanes has not been reported at all [52,99,100].

Heating trimethylsilyl isoselenocyanate in dry air gives selenium, trimethylsilyl isocyanate, and trimethylsilyl cyanide [52].

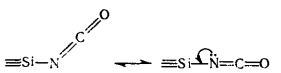
A peculiar type of exchange occurs in the reaction between chlorosilanes and chlorine isocyanate [95]:

$$R_3SiCl + ClNCO \rightarrow R_3SiNCO + Cl_2$$

Finally, trimethylsilyl isocyanate has been obtained by the pyrolysis of a mixture of tautomeric forms of 1-hydroxy-*NO*-bistrimethylsilyltetrazole [101]:

2. Structure and Properties of Isocyanatosilanes

(*a*) Physical properties



Pseudohalide groups are polyatomic, linear, electronegative, and able to develop a negative inductive effect along a bond with a metal. All these properties are exhibited by isocyanato-groups in silanes. Nevertheless, in contrast to organic isocyanates, the proximity of the isocyanato-group to a silicon atom having vacant *d*-orbitals may produce special structural features connected with the ability of the isocyanato-group to be conjugated by means of its π-system or its donor atoms (nitrogen or oxygen). These peculiarities may be represented by the structural isomerism

$$\underset{\text{isocyanate form}}{Si{-}N{=}C{=}O} \rightleftharpoons \underset{\text{siloxynitrile form}}{Si{-}O{-}C{\equiv}N}$$

and by the partly double-bond character of the silicon–nitrogen bond, as a consequence of which the Si–N=C=O unit should be spatially linear.

The isocyanate form is generally accepted, although problems of the three-dimensional structure of the molecules, and in particular linearity of the Si.N : C : O system, have still been inadequately studied. Preference has been given to the iso-structure on the basis of molecular refractions, infrared, Raman, nuclear magnetic resonance, and mass spectra, and also the observed analogy in properties between isocyanatosilanes and the thermodynamically more stable (relative to the isomeric cyanic esters) organic isocyanic esters.

Spectral data for trimethylsilyl isocyanate [99], compounds $(C_6H_5O)_nSi(NCO)_{4-n}$ (n = 1–3) [103,104], trichlorosilyl isocyanate [104], and several other isocyanates and isothiocyanatosilanes [37,49,105-115] confirm their iso-structure. The infrared spectra of isocyanatosilanes contain bands corresponding to the characteristic stretching vibrations ν_{sym}^{NCO} = 1475–1325, ν_{asym}^{NCO} = 2290–2190, and δ_{Si-NCO} = 616, 606 cm^{-1}. [37,99,102-105,116-118] Vibrations of the Si–NCO bond are probably responsible also for bands around 2381 and 1972–2000 cm^{-1} [117,118]. In the series of compounds $(CH_3)_nSi(NCO)_{4-n}$, moreover, the ν_{sym}^{NCO} frequency increases with n; the intensity and the width of the infrared bands remain typical of organic isocyanates [99,116,119-121]. The probable reason is $p \rightarrow d$ interaction between silicon and nitrogen atoms, which governs the multiplicity of the Si–NCO bond and the appearance of the resonance structures [116]

The infrared and Raman spectra of silyl isocyanate [122], trichlorosilyl isocyanate, and chlorosilylidyne tri-isocyanate are consistent with this hypothesis, and agree well with the formal charge distribution in silyl isocyanate and the octet rule [123].

The carbon-13 nuclear magnetic resonance spectra show that all the carbon atoms in silicon tetraisocyanate are of the same type [119]. According to the proton magnetic resonance spectra protons of only one type are present in silyl isocyanate and isothiocyanate and in disilylcarbodiimide [48]. The infrared and Raman spectra of the tetraisocyanate in the range 4000–80 cm^{-1} are very simple, which indicates that the molecule is highly symmetrical, and corresponds to a tetrahedral model [116,119,120].

Electron diffraction examination of silyl isocyanate [124], trimethylsilyl isocyanate [125], silicon tetraisocyanate [126], chlorosilylidyne tri-isocyanate, dichlorosilylene di-isocyanate, trichlorosilyl isocyanate [127], and trifluorosilyl isocyanate [128] shows that the Si–N–C angles are smaller than 180°, being respectively 151.7 ± 1.2°, 154 ± 2° (150 ± 3°), 146.4°, 145.0°, 136.0°, 138.0°, and 160.7 ± 1.2°. The results no longer correspond to a rigid model (of symmetry D_{2d}) but to a model with free rotation about the silicon–nitrogen bond (symmetry C_{3v} [125]), and indicate the absence of appreciable double-bond character. In the Reviewers' opinion, however, a final conclusion on this matter is premature.

Mass-spectroscopic investigation of the tetraisocyanate reveals the formation of a molecular ion $Si(NCO)_4^+$. [129]

Isocyanatosilanes, other than the gaseous silyl and trifluorosilyl isocyanates, are colourless liquids or solids with an acrid smell. The odour of triethylsilyl isocyanate recalls that of camphor [12].

The boiling points of compounds R_3SiX vary with the nature of X in the sequence [61] Cl < Br = NCO < I < NCS < < NHC_6H_5.

Several alkyl- and aryl-isocyanatosilanes exhibit a tendency to supercooling [11]. Members of the series $(CH_3)_nSi(NCO)_{4-n}$ (n = 1–3), on the other hand, have sharp melting points. Isocyanatosilanes burn readily in air, dissolve well in organic solvents [17,71], and are mostly thermostable compounds [16]. Their stability is greater the lower the electronegativity of other substituents attached to the silicon atom [130], and is sharply diminished by contamination with silver cyanate, cyanic acid, diborane, or triethyl phosphine [29].

The values of the Trouton constant suggest that there is little or no association of isocyanatosilanes in the liquid state [18,19,29].

(v) Chemical properties

The pseudohalide character of the NCO group in isocyanatosilanes is shown in their ability to react with proton-containing compounds, either with replacement of the isocyanato-group [6]

$$R_3SiNCO + H{-}X \rightarrow R_3SiX + HNCO$$

or with addition of the elements of H–X at the double bond in the isocyanato-group

$$R_3SiNCO + H{-}X \rightarrow R_3SiNHC(O)X$$

Hydrolysis. All isocyanatosilanes, on treatment with water, are hydrolysed to silanols and isocyanic acid. Qualitative observations show that the rates and the heats of hydrolysis of the compounds $Alk_nSi(NCO)_{4-n}$ fall with increase in n [12,19]. The stability of triphenylsilyl and triethylsilyl isocyanates towards water is due to their poor solubility, since they are rapidly hydrolysed on the addition of alcohol, acetone, or dioxan [12,20,27,46]. The isocyanatosilanes $Cl_nSi(NCO)_{4-n}$, $F_nSi(NCO)_{4-n}$, and $(OCN)_3Si.O.Si(NCO)_3$ undergo vigorous hydrolysis with the evolution of heat [12,71,73]. Silicon tetraisocyanate forms products of partial hydrolysis when insufficient water is used [17]. Methoxy- and phenoxy-isocyanatosilanes hydrolyse at a moderate rate. The ease of hydrolysis of isocyanatosilanes in comparison with silicon pseudohalides of the same type places them in the sequence—$R_3SiNCO < R_3SiNCS < R_3SiNC$ [27].

The reaction of isocyanatosilanes with water is used for the quantitative determination of the isocyanato-group [12,16,27,71]. However, more reliable results are obtained by the Dumas determination of nitrogen [12,17–19].

Reactions with alcohols. A detailed study of the alcoholysis of isocyanatosilanes was made in work [34] which confirmed earlier results obtained by Forbes and Anderson [11,18,71] on the formation of alkoxysilanes and the corresponding urethanes. This showed that increase in the size and in the degree of branching of the radical, either in the silane or in the alcohol, leads to a fall in the rate of alcoholysis [34,46]. The two schemes

$$R_3SiNCO + R'OH \begin{cases} \xrightarrow{1} R_3SiOR' + HNCO \xrightarrow{R'OH} H_2NC(O)OR' \\ \xrightarrow{2} R_3SiNHC(O)OR' \xrightarrow{R'OH} R_3SiOR' + H_2NC(O)OR' \end{cases}$$

were suggested [34] to explain the course of the reaction. In the first stage of interaction with an aqueous alcohol, isocyanic acid is formed, and can be titrated [12]. Nevertheless, its presence was not detected in the reaction with an anhydrous alcohol [34].

Considerable doubt must attach to the reported [131] preparation of urethanes containing a silicon–nitrogen bond by heating dibutylsilylene di-isocyanate with higher alcohols and glycols, in view of the lack of adequate characterisation of the products. This applies equally to the synthesis of a polyurethane based on diphenylsilanediol and dimethylsilylene di-isocyanate [132], since, in contrast to alcohols, silanols and silanediols are inert towards e.g. trimethylsilyl isocyanate [133]. The claimed formation [134] of polysilylurethanes containing $\gtrless$Si.NH.CO.OR'– by the reaction of $R_nSi(NCO)_{4-n}$ and $(RO)_nSi(NCO)_{4-n}$ ($n = 0–2$) with glycols $R'(OH)_2$ and a polyethylene glycol ether is just as improbable.

Reactions with amines. In early studies of the reaction of isocyanatosilanes with amines it was erroneously concluded that the isocyanato-group was eliminated [62,135,136]. By the use of ammonia and primary and secondary aliphatic and aromatic amines with a variety of isocyanatosilanes Goubeau and Heubach as well as other workers were able to show [38,65,84,133] that the amines add at the C=N bond to form N-silylureas:

$$Me_nSi(NCO)_{4-n} + R_mNH_{3-m} \rightarrow Me_nSi(NHCONH_{2-m}R_m)_{4-n}$$

The reactivity of amines towards silicon isocyanates fell in precisely the same sequence as their reactivity towards organic isocyanates [43]:

$$AlkNH_2 > Alk_2NH > ArNH_2 \gg ArNHR > Ar_2NH$$

Silicon tetraisocyanate was found to be more reactive than its alkyl and aryl derivatives [62,133]: with trimethylsilyl isocyanate, for example, addition was observed only with amines of basicity $pK > 10$ [137]. The steric factor plays an important part, besides the basicity of the amine: 2,6-dibromoaniline reacts slowly even with silicon tetraisocyanate [43].

Symmetrical di-isocyanatodisilanes form disilylureas in conformity with the general scheme [38]. Tertiary amines do not react with isocyanatosilanes [133]. Hydrazines and silylhydrazines give silylsemicarbazides with trimethylsilyl isocyanate; the isocyanatosilane acts more selectively in these reactions than do organic isocyanates [137]. Free hydrazine undergoes exchange with trimethylsilyl isocyanate, and adds at the isocyanato-group [84,137].

Other reactions. The isocyanato-group in triethylsilyl isocyanate does not react with methylmagnesium iodide, nor do those in the tetraisocyanate interact with dimethylmercury [19]. Triphenylsilyl isocyanate adds phenyl-lithium and phenylmagnesium bromide with difficulty at the carbonyl bond to form after hydrolysis triphenylsilanol and benzamide [46]. With bistrimethylsilylsodamide isocyanatosilanes are converted into disilylcarbodi-imides [138–141].

In the reaction of oxirans with isocyanatosilanes $R_nSi(NCO)_{4-n}$ ($n = 0–3$) the ring is opened [142–144]:

$$R_nSi(NCO)_{4-n} + CH_2{-}CH_2 \overset{O}{\diagup\diagdown} \xrightarrow[R_3N]{P \geq 1\ atm} R_n(OCN)_m Si(OCH_2CH_2NCO)_{4-m-n}$$

Use in the reaction of aldehydes [145] or of ketones containing an α-hydrogen atom [146] gives polymeric products of undetermined structure.

Sulphur tetrafluoride [147] and carbonyl fluoride [148] rupture the silicon–nitrogen bond in isocyanatosilanes:

$$Si(NCO)_4 + 4SF_4 \rightarrow SiF_4 + 4F_2S{=}N{-}C(O)F$$
$$Me_nSi(NCO)_{4-n} + (4-n)COF_2 \rightarrow (4-n)Me_nSiF_{4-n} + (4-n)FC(O)NCO$$

The reactions of isocyanatosilanes containing unsubstituted hydrogen are illustrated by the examples [29]

$$H_3SiNCO + NaOH \rightarrow NaOCN + H_2 + SiO_2$$
$$H_3SiNCO + H_2CO_3 \rightarrow H_2 + SiO_2 + CO_2 + HNCO$$
$$H_3SiNCO + MeOH \rightarrow SiH_4 + (MeO)_3SiH + (MeO)_4Si + MeOC(O)NH_2$$
$$H_3SiNCO + HCl \rightarrow H_3SiCl + {}^1/_3(HNCO)_3$$
$$H_3SiNCO + BF_3 \rightarrow H_3SiF + F_3BNCO \rightarrow BF_3 + [B(NCO)_3]_n$$

In this case addition products are not formed with diborane either at 20° or at –78°C, although the isocyanates are

decomposed in the presence of diborane at room temperature.

In conclusion, tri-isocyanatosilanes $XSi(NCO)_3$ (X = Cl, F, CH_3O, etc.) exhibit a strong tendency to disproportionate, which is greatly hindered by isolation of the compounds in pure form [10].

Isocyanatosilanes containing unsubstituted hydrogen can take part in hydrosilylation in conformity with the generally accepted scheme. They undergo neither di-, tri-, and poly-merisation nor decarboxylation when boiled for a long time with such catalysts as metal carbonyls, dimethyl tolyl phosphate, methylphosphafluorene oxide, and bis-*P*-methyl-*P*-phenyl-thiophosphoryl [94].

3. Prospects for the Application of Isocyanatosilanes

The great reactivity of isocyanatosilanes enables them to be used in the manufacture of various polymeric materials. Thus they have been proposed for the production of plastics [45], insulating materials, dielectrics [79], and pesticides [70,79], and as textile finishes [149], hydraulic fluids, components of self-setting compositions [150,151], and catalysts in the synthesis of polyurethanes, for the water-repellent treatment of glass, porcelain, and cloth, and for other purposes [33,44,57,68]. Polymers obtained by the reaction of dialkylsilylene di-isocyanates with amines or alcohols [134,142-144], aldehydes [145], and ketones [146] are suitable for the production of moulded articles and glass—plastic laminates, as additives to rigid foam plastics, and as adhesives for wood, metals, and other materials. Products of the interaction of silanediols† with isocyanatosilanes have been recommended for coating the internal surfaces of fuel tanks [132].

Compounds of type $(OCN)_nSi(OCH_2CH_2NCO)_{4-n}$ are capable of spontaneous polymerisation with the formation of resins or flexible films possessing good adhesion to glass [142-144]. Several materials based on isocyanatosilanes exhibit short-term fire-resistance and high thermal stability [68]. Modification with isocyanatosilanes sharply increases the adhesion of silicone rubbers to copper or brass [152]. Fillers treated with isocyanatosilanes improve the stability of polyurethane coatings for wood, metals, glass, concrete, and other materials [153].

A second promising usage of isocyanatosilanes is as ancillaries in organic synthesis. For example, the quantitative formation of silylureas by the reaction of isocyanatosilanes with amines and the ready hydrolysis of the products have been used to develop a general method for the preparation of ureas [43] which dispenses with the difficultly available alkyl isocyanates and alkyl(aryl, dialkyl, diaryl)carbamoyl chlorides.

III. "C-FUNCTIONAL" ORGANOSILICON ISOCYANATES

1. Methods of Preparation

(*a*) From derivatives of carboxylic acids

In contrast to isocyanatosilanes, carbofunctional organosilicon isocyanates (primarily compounds having isocyanato-alkyl and -aryl groups attached to the silicon atom) were little studied until quite recently. The first such compound was obtained in 1959 from *p*-trimethylsilylbenzoyl azide [154]:

$$p\text{-}Me_3SiC_6H_4COCl \xrightarrow{NaN_3} p\text{-}Me_3SiC_6H_4CON_3 \xrightarrow[-N_2]{t^\circ} p\text{-}Me_3SiC_6H_4NCO$$

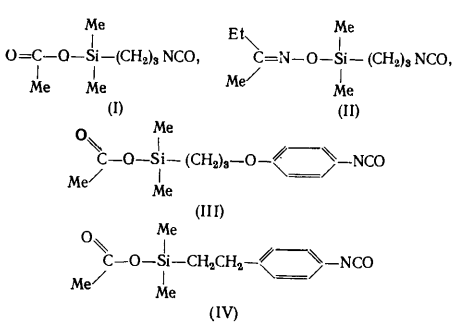
Intermediate formation of isocyanates has been observed also in the decomposition of azides of silylated aliphatic acids [93,94].

The intermediate formation of 3-ethyldimethylsilylpropyl isocyanate has been noted during oxidation of the corresponding amide by lead tetra-acetate [93,94]:

$$RC(O)NH_2 \xrightarrow[HCON(CH_3)_2]{Pb(OAc)_4} [R{-}N{=}C{=}O] \xrightarrow{C_5H_5NH_2} RNHC(O)NHC_5H_5,$$

(R = Et—Si(Me)(Me)—$(CH_2)_3$—)

(*b*) Hydrosilylation of alkenyl isocyanates



A convenient route for the preparation of monomeric, oligomeric, and polymeric organosilicon *C*-isocyanates consists in the catalytic addition of silanes containing unsubstituted hydrogen to unsaturated organic isocyanates. Monomers containing one, two, or three hydrolysable groups attached to the silicon atom can be obtained by this reaction [94,155-163].

Replacement of the chlorine atoms in trichlorosilane by alkyl groups leads to an appreciable decrease in the rate of addition to allyl isocyanate [94,156]:

$$MeCl_2SiH + CH_2{=}CHCH_2NCO \xrightarrow[3\ h]{H_2PtCl_6} Me{-}Si(Cl)(Cl)(CH_2)_3NCO \quad (80\%)$$

$$Me_2ClSiH + CH_2{=}CHCH_2NCO \xrightarrow[40\ h]{H_2PtCl_6} Cl{-}Si(Me)(Me)(CH_2)_3NCO \quad (40\%)$$

This reaction does not take place with methyldiethylsilane and triethylsilane. Several isocyanates, e.g. of the types

have been obtained by the addition of incompletely substituted silanes containing acyloxy- or hydroxyamino-groups to allyl, *p*-allyloxyphenyl, or *p*-vinylphenyl isocyanate in the presence of catalytic quantities of an ethylene–platinum complex [157]. Silicon-containing urethano-isocyanates have been prepared by the action of siloxanes and incompletely substituted silanes on urethano-isocyanates (products of the interaction of allyl and methylallyl alcohols with tolylene di-isocyanate) [158,159].

In contrast to silyl acetates, tetramethyldisiloxane does not add to allyl isocyanate [94,155]. However, a di-isocyanate could be obtained from another partly substituted silane, *p*-bisdimethylsilylbenzene [94,155], where addition takes place in steps.

†The products formed with alcohols and silanediols obviously do not possess a polysilylurethane structure (Subsection 2*b*), but comprise a mixture of polyoxasilaalkylenes or polysiloxanes with organic urethanes and polymeric forms of isocyanic acid.

The catalysts used have included, not only hexachloroplatinic acid and the ethylene–platinum complex, but also other platinum derivatives, palladium compounds, and certain catalysts of ionic and free-radical reactions [96,156–162].

In contrast to allyl isocyanate, isopropenyl isocyanate exhibits surprising inertness towards not only trialkylsilanes and tetramethyldisiloxane but also partly substituted alkoxy- and chloro-silanes [94].

The isocyanato-group, like the isoelectronic keten grouping [164,165], remains unchanged during hydrosilylation. Moreover, incompletely substituted silanes (especially those containing silicon–chlorine bonds) have a stabilising effect on the initial and the final isocyanates, diminishing their tendency to polymerise when heated.

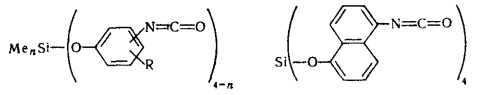
Examination of the addition products of incompletely substituted silanes to allyl isocyanate by means of proton magnetic resonance spectroscopy has shown [94] that they all contain the isocyanato-group in the γ-position relative to the silicon atom.

(*c*) Reaction of silylated amines with carbonyl chloride

Another convenient method for obtaining organosilicon *C*-isocyanates is the action of carbonyl chloride on the corresponding primary amines. Aliphatic isocyanates were first obtained in this way [93,163,166]:

$$2R_3Si(CH_2)_nNH_2 + COCl_2 \xrightarrow{20^\circ C} R_3Si(CH_2)_nNHCOCl + R_3Si(CH_2)_nNH_2 \cdot HCl$$
$$R_3Si(CH_2)_nNHCOCl \xrightarrow{110-150^\circ C} R_3Si(CH_2)_nNCO + HCl$$
$$R_3Si(CH_2)_nNH_2 \cdot HCl + COCl_2 \xrightarrow{110-150^\circ C} R_3Si(CH_2)_nNCO + 3HCl$$
$$2R_3Si(CH_2)_nNH_2 + 2COCl_2 \rightarrow 2R_3Si(CH_2)_nNCO + 4HCl$$
(R=Alk, Ar; $n = 1; 3$)

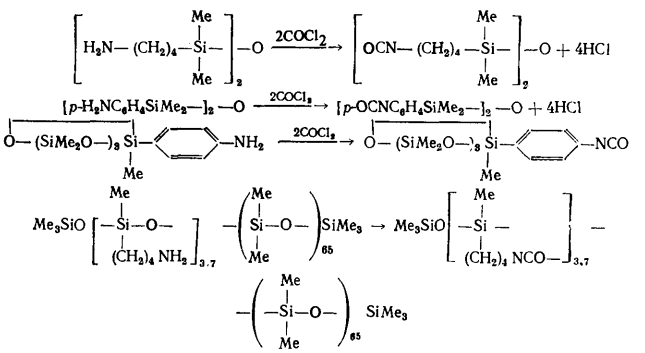
Dimeric compounds having a dioxouretidine structure are formed by a side-reaction [166]. 3-Trimethylsilylpropyl isocyanate isolated in pure form was completely stable, and did not dimerise either on storage or when distilled.



With amines containing alkoxy- or siloxy-groups attached to silicon, carbonyl chloride may act also on the silicon–oxygen bonds [94,163,167–169]:

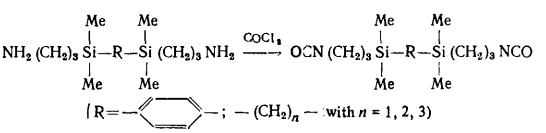
$$(EtO)_3Si(CH_2)_3NH_2 \xrightarrow[110-120^\circ C]{COCl_2} Cl_n(EtO)_{3-n}Si(CH_2)_3NCO + EtOC(O)Cl + HCl$$

$$NH_2(CH_2)_3\underset{\underset{Me\ Me}{|\ \ |}}{SiOSi}(CH_2)_3NH_2 \xrightarrow[-4HCl]{COCl_2} 2Cl\underset{\underset{Me}{|}}{Si}(CH_3)_3NCO + CO_2$$



$$NH_2(CH_2)_4\underset{\underset{Me\ Me}{|\ \ |}}{SiOSi}(CH_2)_4NH_2 \xrightarrow{COCl_2} Cl\underset{\underset{Me}{|}}{Si}(CH_2)_4NCO + OCN(CH_2)_4\underset{\underset{Me\ Me}{|\ \ |}}{SiOSi}(CH_2)_4NCO$$

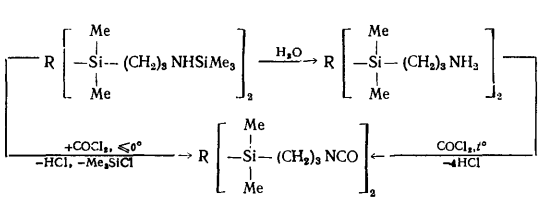
Silyl ethers of amino-alcohols of type $R_2Si(OCH_2CH_2NH_2)_2$ are completely cleaved at the silicon–oxygen bond on reaction with carbonyl chloride, but the final products were not identified [168]. Nevertheless, the analogous aminophenol and aminonaphthol derivatives, whether as the free bases or as the hydrochlorides, form the corresponding isocyanates [168,170]:



($n = 1-3$; R = H, Me)

Organic mono- and di-isocyanates containing silicon have been obtained by treating aminoalkyl and aminoaryl derivatives of di-, tetra-, and oligo-siloxanes with carbonyl chloride in toluene [169]:

A striking feature of this work is that the siloxane bonds remain unchanged under the severe conditions of treatment with carbonyl chloride and hydrogen chloride.



A new type of difunctional organosilicon monomers was obtained by the action of carbonyl chloride on diamines containing alkylene or phenylene bridges between the silicon atoms [94,171]:

Whether in a diamine with an arylene bridge or in 3-phenyldimethylsilylpropylamine the Si–Ar bond is stable towards the chlorinating action of carbonyl chloride, hydrogen chloride, and the chloroformamido-group [94,171].

(*d*) Action of carbonyl chloride on *N*-silylamines

It was discovered in 1969 that organosilicon di-isocyanates of the above type can be obtained in high yields and under milder conditions by the action of carbonyl chloride on the *N*-trimethylsilyl derivatives of the amines [94,172–176]:

Monoisocyanates have been obtained similarly [94,174–176]:

$$MeEt_2SiH + CH_2{=}CHCH_2NHSiMe_3 \rightarrow MeEt_2Si(CH_2)_3NHSiMe_3$$
$$MeEt_2Si(CH_2)_3NHSiMe_3 \xrightarrow[\leqslant 0^\circ]{COCl_2} MeEt_2Si(CH_2)_3NCO + Me_3SiCl$$

These observations provided an extraordinarily simple method for preparing 3-dimethylchlorosilylpropyl isocyanate [173,177]:

$$Me_2SiHCl + CH_2{=}CHCH_2NH_2 \rightarrow CH_2{=}CHCH_2NHSiMe_2H \xrightarrow{H_2PtCl_6} \rightarrow \left[-CH_2CH_2CH_2NH\underset{\underset{Me}{|}}{Si}-\right]_x \xrightarrow[-xHCl]{xCOCl_2} xClMe_2Si(CH_2)_3NCO$$

It was subsequently established[173-176] that the reaction of carbonyl chloride with *N*-silylated primary amines is general in character, and can be used to obtain not only organosilicon but any other isocyanates containing groups sensitive to heating and to the action of hydrogen chloride, carbonyl chloride, and the chloroformamido-grouping. For example, saturating the reaction mass with carbonyl chloride at a low temperature removes hydrogen chloride rapidly, which has enabled the previously difficultly accessible disiloxane di-isocyanates to be obtained:

$$[Me_3SiNH(CH_2)_3-SiMe_2-]_2-O \xrightarrow[-2HCl]{2COCl_2} OCN(CH_2)_3-\underset{\underset{Me}{|}}{\overset{\overset{Me}{|}}{SiO}}-\underset{\underset{Me}{|}}{\overset{\overset{Me}{|}}{Si}}-(CH_2)_3NCO + 2Me_3SiCl$$

N-Silylated amines react with carbonyl chloride under very mild conditions (−60° to 0°C). The yields of isocyanates reach 90–99%.

The pattern observed might have been quite different if the reaction had involved initial cleavage of the silicon–nitrogen bond in the silylamine. In fact the intermediate carbamoyl chlorides are quite stable under the reaction conditions, and decompose into hydrogen chloride and the isocyanate only when heated to ~100°C and above:

$$R-\underset{\underset{H}{|}}{N}-SiMe_3 \xrightarrow[-Me_3SiCl]{COCl_2} R-\underset{\underset{H}{|}}{N}-\underset{\underset{Cl}{|}}{C}=O \underset{\leftarrow}{\overset{\sim 100^\circ}{\rightarrow}} RNCO + HCl$$

To explain the formation of hydrogen chloride with such a reaction scheme it was necessary to assume that trimethylsilyl chloride already reacts with the carbamoyl chloride under the mild conditions, yielding ultimately the isocyanate:

$$R-\underset{\underset{H}{|}}{N}-\overset{\overset{O}{\|}}{C}-Cl + Me_3SiCl \xrightarrow{-HCl} R-\underset{\underset{SiMe_3}{|}}{N}-\overset{\overset{O}{\|}}{C}-Cl \rightarrow RNCO + Me_3SiCl$$

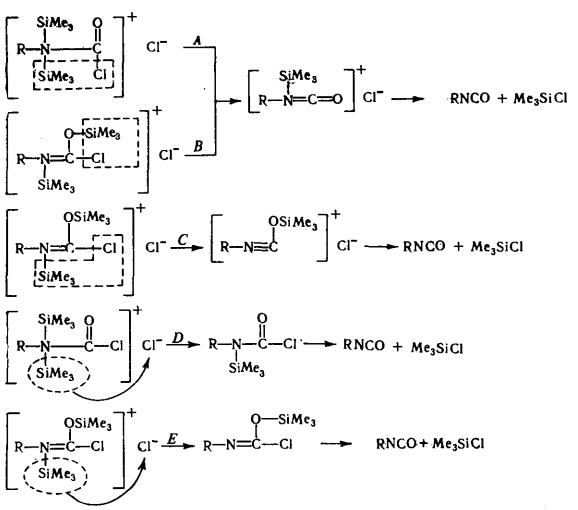
Actually it was found, however, that little or no substitution at the nitrogen–hydrogen bond with evolution of gaseous hydrogen chloride takes place even when trimethylsilyl chloride, triethylsilyl chloride, silicon tetrachloride, etc. are heated with methylcarbamoyl chloride at 90°C for a long time. It was thus established that carbonyl chloride attacks $RNHSiR'_3$ by rupturing the N–H bond, not the Si–N bond, and by forming *N*-trialkylsilylcarbamoyl chlorides as intermediate products:

$$R-\underset{\underset{H}{|}}{N}-SiMe_3 \xrightarrow[-HCl]{COCl_2} R-\underset{\underset{SiMe_3}{|}}{N}-\overset{\overset{O}{\|}}{C}-Cl \xrightarrow{-Me_3SiCl} R-N=C=O$$

The high yields of isocyanates at low temperatures of treatment with carbonyl chloride are explained by the thermal instability of the silylated carbamoyl chlorides due to the σσ-conjugated bond system Si–N–C–Cl for even below room temperature they undergo β-elimination with separation of isocyanate and trialkylchlorosilane molecules. A similar tendency to β-elimination is exhibited[178] by the well studied systems of the type Si–C–C–Y (where Y = Hal, OH, etc.).

The ease of thermal cleavage of *N*-silylcarbamoyl chlorides is especially marked in comparison with related compounds containing an analogous Si–N–C–X bond system but with different X substituents (X = OR, where R = Alk, Ar). In the case of *N*-silylurethanes, for example, containing the $\gtrdot$Si–NR′–CO–OR fragment, the tendency to β-elimination becomes much stronger on passing from alkoxy- to aryloxy-derivatives[94,179]. Replacement of OR by the more electronegative Cl intensifies σσ-conjugation still more, and enhances the thermal instability of *N*-silylcarbamoyl chlorides in comparison with *N*-silylurethanes. Furthermore, since chlorosilanes do not react with isocyanates, breakdown of the *N*-silylcarbamoyl chlorides is an irreversible stage, which is another important reason for the high yield of isocyanates at low temperatures of treatment with carbonyl chloride.

The method of preparing organic and organosilicon isocyanates by treating silylamines with carbonyl chloride was extended to *NN*-disilylamines of type $R.N(SiR'_3)_2$. The silicon–nitrogen bonds in these compounds are easily broken even at temperatures below 0°C with formation of an isocyanate and a chlorosilane[94,173-176]:



$$RN(SiR'_3)_2 + COCl_2 \rightarrow RNCO + 2R'_3SiCl$$

In this case the yield of saturated and unsaturated aliphatic, aliphatic–aromatic, and purely aromatic isocyanates, including those containing organosilyl substituents, approaches theoretical.

The mechanism of the reaction of silylamines with carbonyl chloride probably involves initial formation of an adduct resembling the complexes of tertiary organic amines with carbonyl chloride[180] and having the structure of an imidate with two equivalent and equally polarised silicon–nitrogen bonds. In considering the mechanism of the breakdown of such a salt we must take into account its possible existence in the tautomeric *O*-form (by analogy with *NN*-bistrimethylsilylamides of carboxylic acids[81])

$$\left[\begin{array}{l} Me_3Si \\ R-N \\ Me_3Si \end{array}\!\!-\!\!\overset{\overset{O}{\|}}{C}\!\!<_{Cl}\right]^+ Cl^- \rightleftharpoons \left[\begin{array}{l} OSiMe_3 \\ R-N=C-Cl \\ Me_3Si \end{array}\right]^+ Cl^-$$

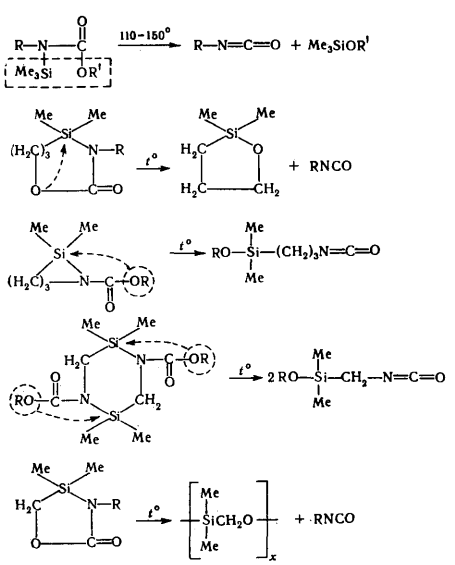
and also the possibility that the first stage of breakdown may involve a chlorine atom either in the inner sphere of the molecule (reactions *A*–*C*) or in the outer sphere (reactions *D* and *E*):

At present it is difficult to say what is the true course of the reaction. In view of the greater tendency of the Si–N–C–X bond system than of Si–N=C–X to undergo β-elimination, however, mechanism *C* can be regarded as the least probable. The other four paths are equally probable, although ionic chlorine is probably more active.

Small quantities of carbamoyl chlorides and amine hydrochlorides are formed as side-products in the reaction of *N*-monosilylamines with carbonyl chloride. Formation of the carbamoyl chlorides is due either to some reaction at the silicon–nitrogen bond or to the addition of incompletely removed hydrogen chloride to the isocyanate. Amine hydrochlorides result from cleavage of the initial silylamine or the silylated carbamoyl chloride by hydrogen

chloride. The formation of secondary products can be reduced to a minimum by conducting the reactions in solvents which only weakly retain hydrogen chloride or in the absence of a solvent, by adding the silylamine to the carbonyl chloride, and by keeping the temperature conditions as mild as possible. The action of carbonyl chloride on disilylated organic and organosilicon amines is unambiguous.

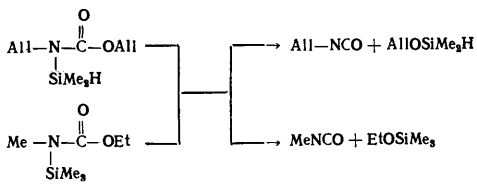
The amino-group can be protected not only with trialkylsilyl groups R_3Si- but also with other groups such as $R_2Si=$, $RSi\equiv$, and $=S=$, as well as incompletely substituted silyl groups.



Thus the method of treating *N*-mono- and *NN*-di-silylamines not only simplifies the preparation of organosilicon isocyanates but also enables compounds to be obtained whose preparation is difficult or impossible without silyl protection. For example, it has recently been shown that this method is extremely convenient for preparing esters of *N*-carbonyl-α-amino-acids [181]. Since the production of silylamines is a simple operation, and the silicon-containing fragment is completely regenerated during treatment with carbonyl chloride, this method of obtaining isocyanates shows great industrial promise.

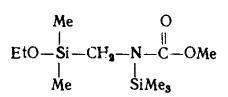
(*e*) Pyrolysis of esters of silicon-containing carbamic acids

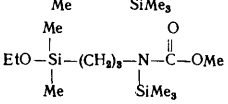
The characteristic thermal decomposition of carbamic esters to isocyanates has proved entirely suitable for the preparation of organosilicon isocyanates, including those with alkoxy-groups attached to the silicon atom. The reaction is reversible, and the alcohol must be removed from the reaction mixture for complete conversion of the urethane into the isocyanate [94,182]:



$$R_n(R'O)_{3-n}Si(CH_2)_mNHC(O)OR'' \xrightarrow{t^\circ} R_n(R'O)_{3-n}Si(CH_2)_mNCO + R''OH$$

N-Silylated urethanes show a greater tendency than the unsubstituted compounds to decompose. This is probably due to the irreversibility of cleavage of the σσ-conjugated bond system $\geqslant$Si–N–C–OR. This is a general reaction [94,179,183–189] and can be successfully used for the preparation of various organic and organosilicon isocyanates: e.g.





where R is an organic or organosilicon group.

When two urethanes having different *N*-silyl substituents and different alkoxy-groups undergo pyrolysis together, no alkoxysilanes of mixed structure are present among the decomposition products [190]:

This shows that no exchange of silyl groups between the urethanes occurs before the β-decomposition, which takes place by an intramolecular mechanism.

Proportions of products of trans-silylation and of β-decomposition from *N*-silyl-*N*-silylalkylurethanes.

N-Silyl-*N*-silylalkylurethane	Alkoxysilane (%) formed by	
	trans-silylation	β-elimination
	Me_3SiOEt 30	Me_3SiOMe 70
	Me_3SiOEt 87	Me_3SiOMe 13

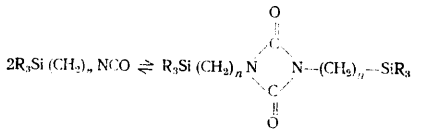
The composition of the pyrolysis products from specially prepared compounds indicates that the β-elimination of *N*-silylurethanes containing also an *N*-alkoxysilylalkyl group is preceded by trans-silylation [191] (see Table). In contrast to the intramolecular process of β-elimination, trans-silylation can probably occur by both intramolecular and intermolecular mechanisms. The latter mechanism probably predominates in the first example, in view of the difficulty of formation of an azasilacyclobutane derivative, and intramolecular trans-silylation in the second example. The complicating effect of trans-silylation should be taken into account when examining kinetic data on the β-elimination of *N*-alkoxysilylalkyl-*N*-silylcarbamic esters [94,188,192,193].

(*f*) Reaction of silylalkyl halides with metal cyanates

The first attempts to obtain isocyanates by exchange between silylmethyl halides and metal cyanates were unsuccessful [195–197]. Silylalkyl isocyanates have recently been obtained (though in moderate yield) [198–202] by the use of dimethylformamide as solvent:

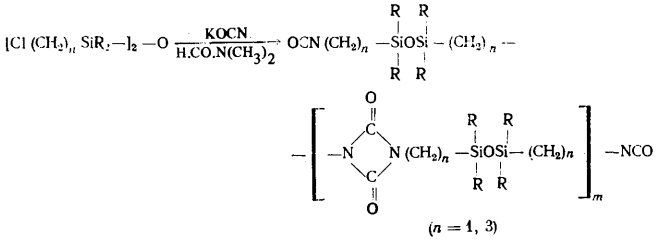
$$R_3Si(CH_2)_nCl + MOCN \xrightarrow[H.CON(CH_3)_2]{140-150^\circ C} R_3Si(CH_2)_nNCO + MCl\ .$$

($n = 1.3$; M=K, Na)



The effects of temperature, nature of solvent, and reactant and catalyst concentrations on the rate and the direction of the exchange between trialkylsilylalkyl chlorides and potassium cyanate have been examined [182,203–206]. This indicated that the optimum conditions for the preparation of silylalkyl isocyanates in dimethylformamide involve equimolecular proportions of 0.6 M silylalkyl

chloride and potassium cyanate with 5% (on weight of salt) of tetra-alkylammonium iodide as catalyst at 150°C for 20 min, when the yield of isocyanate reaches 60–70%.

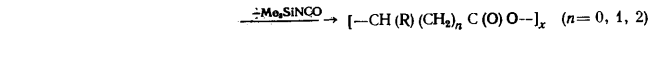


When the time of contact between the reactants is increased to 2–3 h, only dimeric products are formed [94,203–206]. The alkali-metal (sodium or potassium) cyanates used catalyse the dimerisation. Pyridine, triethylamine, and phenyldiethylphosphine also catalyse this reaction. Salts such as potassium, sodium, and tetra-alkylammonium chlorides and tetra-alkylammonium iodides present in the reaction mixture have no catalytic effect.

Replacement of potassium cyanate by the sodium salt has no significant effect on the yield of silylalkyl isocyanate although the duration of the preparation is increased [205]. Silylalkyl isocyanates are not formed in the absence of a solvent, in such solvents as benzene, acetone, and acetonitrile (probably because of the sparing solubility of potassium cyanate), nor in the presence of excess of the initial silylalkyl halide. 3-Chloropropylsilanes are rather less reactive than the chloromethyl derivatives in the exchanges, which is explained by the possible participation of *d*-orbitals of the silicon atom in formation of the intermediate complex in the case of α-derivatives [203].

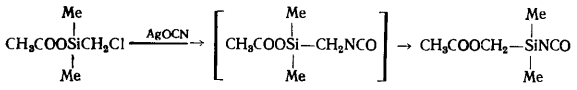
A dioxouretidine structure was assigned to the dimeric form of the silylalkyl isocyanates, at first conjecturally [166] and then on the basis of infrared spectra [204]. Dimeric and monomeric forms are present in equilibrium [94,204]:

Bishalogenoalkyldisiloxane derivatives form with potassium cyanate in dimethylformamide mainly oligomeric and polymeric products having terminal isocyanato-groups (together with small quantities of the monomeric di-isocyanates) [182,202–205,207]:



($n = 1, 3$)

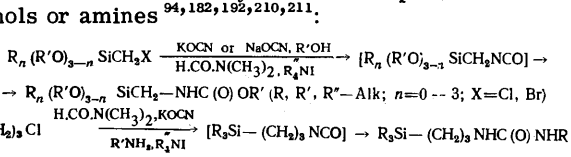
When the initial mixture of reactants is heated for 20–30 min, di-isocyanates cannot be isolated at all, since only polymeric products are formed.



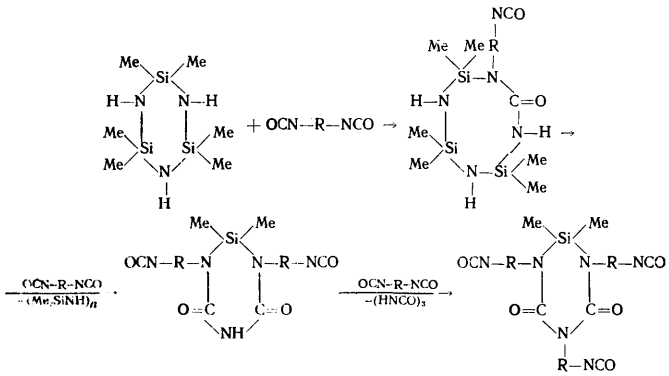
(*g*) Other reactions

A number of other chemical reactions of organosilicon compounds have been described, in which isocyanates are quite often formed only as intermediate products. These reactions can be briefly illustrated by the following schemes.

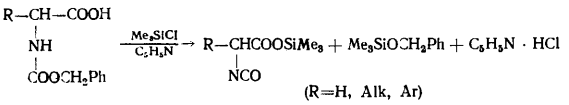
1. Decomposition of products of the reaction of trimethylsilyl α-, β-, and γ-bromo-carboxylates with silver cyanate [208]:



2. Isomerisation of an isocyanatomethylsilane into an isocyanatosilane [208]:

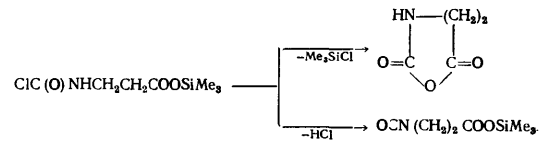


3. δ-Elimination from 4-siloxybutyl isocyanates [208] (in contrast to the stable tetrakisisocyanatomethoxysilane [209]):

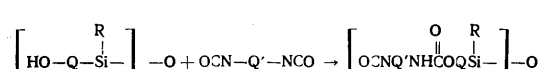


4. Formation of urethanes and ureas when silylalkyl halides react with metal cyanates in the presence of alcohols or amines [94,182,192,210,211]:

5. Interaction of hexamethylcyclosilazanes with excess of a di-isocyanate [212]:

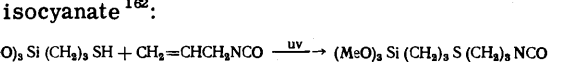


6. Decomposition of derivatives of organic amino-acids with strong silyl protection [185,186]:

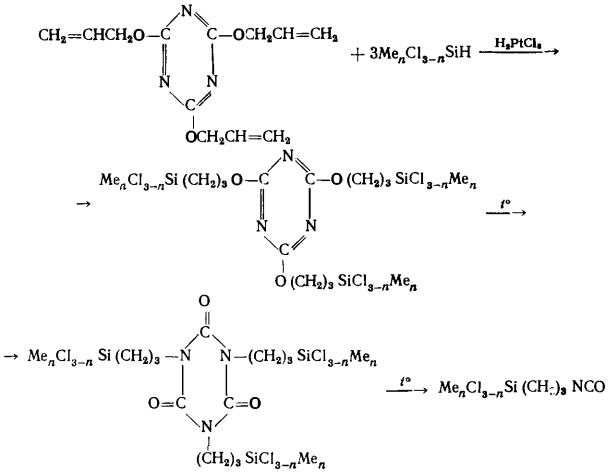


(R=H, Alk, Ar)

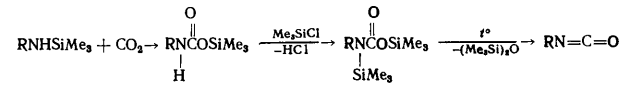
7. Interaction of bistrimethylsilyl α-azaglutarates with thionyl chloride, carbonyl chloride, or a phosphorus trihalide [213]. Isocyanates are formed as side-products in this reaction, which yields predominantly amino-acid anhydrides:



8. Addition of silicon-containing organic diols to di-isocyanates [214]:



(R=Me, R'=Ph; Q=—$(CH_2)_4$—, Q'=—$(CH_2)_6$—, —MeC_6H_3—)



9. Addition of silylalkanethiols at the double bond of allyl isocyanate [162]:

10. Pyrolysis of products of the hydrosilylation of triallyl cyanurate [94]:

11. An interesting method for obtaining organic and organosilicon isocyanates avoids the use of carbonyl chloride [215]:

(*h*) Oligomeric and polymeric silylalkyl and silylaryl isocyanates

A great deal of information has been published on oligomeric and polymeric organosilicon *C*-isocyanates, chiefly in the patent literature. These compounds can be formed in principle by the following processes—(i) hydrosilylation of alkenyl isocyanates with oligo(or poly)siloxanes having terminal Si–H bonds [159], (ii) chain termination in polysiloxanes by ω-isocyanatoalkylsilanes [216], (iii) treatment of siloxanes having terminal hydroxyalkyl and other groups with excess of an organic di-isocyanate [217–221], (iv) reaction of excess of an organic di-isocyanate with hydroxyl containing unsaturated compounds followed by addition of incompletely substituted silanes at ethylemic bonds [158,159], (v) action of excess of an organic di-isocyanate on silocanes having terminal aminoalkyl groups [218], (vi) condensation of organosilicon alcohols with organic or organosilicon di- or tri-isocyanates [167,214,217,220], (vii) pyrolysis of adducts of oligosiloxanes (having terminal aminoalkyl groups) with phenyl chloroformate [159], (viii) interaction of excess of an organosilicon di-isocyanate with silazanes and cyclosilazanes [212,222], (ix) stepwise action of carbonyl chloride on oligosiloxanes containing terminal amino-groups [169,223–225], and (x) synthesis of polyisocyanates from 1,3-bis-ω-chloroalkyldialkyldisiloxanes and alkali-metal cyanates [206].

2. Physical Properties

Monomeric and oligomeric organosilicon *C*-isocyanates are colourless or slightly yellowish liquids, indefinitely stable in the absence of moisture but easily hydrolysed in moist air [94,159,170,207]. When heated to 150–200°C, monomeric di-isocyanates form oligomeric products having terminal isocyanato-groups [207].

The infrared spectra of monoisocyanates [94,162,185,186,204,214,226] contain an intense absorption band due to the isocyanato-group in the range 2267–2243 cm^{-1}. A similarly intense bond has been observed with di-isocyanates (2270–2243 cm^{-1}).

The nuclear magnetic resonance spectra of several mono- and di-isocyanates have been discussed in Ref. 94.

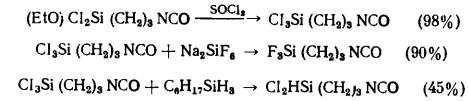
3. Chemical Properties

Like their carbon analogues, silicon-containing isocyanates react vigorously with ammonia and with primary and secondary amines to form silicon-containing ureas [94,154,163,203,227], and with hydrazides and amides of carboxylic acids to give the corresponding semicarbazides [203,226] and acylureas [203]. Urethanes and symmetrical ureas respectively are obtained with alcohols and with water [94,154,203,228].

Silicon-containing di-isocyanates on treatment with ammonia and with primary and secondary amines can be converted into the corresponding bisureas, and by the action of *NN'*-dialkylhydrazines into the bis-semicarbazides [94,173,207,229–234]. Reaction of the di-isocyanates with organic diamines or hydrazines yields polysilylalkylureas or polysilylalkylsemicarbazides [235–237].

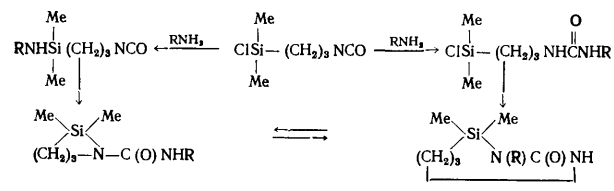
Various reagents containing a mobile hydrogen atom form the sequence

amines > hydrazides ≫ water > alcohol > amides



according to their reactivity towards 3-triethylsilylpropyl isocyanate [226]. The reactivity of an isocyanate of type $R_3Si.[CH_2]_nNCO$ with $n = 3$ exceeds that of the compound having $n = 1$ about twentyfold [226].

Heating converts silicon-containing aromatic isocyanates into carbodi-imides:



This reaction is catalysed by phosphorus compounds such as phosphafluorene. The aliphatic isocyanates do not undergo this reaction. In the presence of amines, amides, sodium benzoate, and other basic catalysts they form isocyanurates [238,239].

Several reactions of silylalkyl isocyanates have been described that do not involve the isocyanato-group [169,240]:

Chloro- and alkoxy-silylalkyl isocyanates exhibit dual reactivity. With water, for example, they give siloxane di-isocyanates [94,177], but with more active reagents (amines) with functional groups are involved [241]:

The isocyanato-group is also extraordinarily reactive in oligomeric compounds of silicon, and reacts with all types of reagents containing active hydrogen atoms [159].

4. Prospects for the Application of Silicon-containing C-Isocyanates

The enhanced interest taken in silylalkyl isocyanates is due primarily to the possibility of obtaining from them cold-self-vulcanising polysiloxane rubbers and polyurethanes with improved resistance to heat, moisture, and frost[159,218,221]. Cold vulcanisation takes place under normal conditions; the only byproduct is carbon dioxide, which readily diffuses through the vulcanised product. These rubbers contain carbamide cross-links, and surpass in mechanical strength and resistance to oils and benzene their alkoxylated and acyloxylated organosilicon analogues. They differ advantageously from ordinary polyurethane rubbers in high moisture resistance and in low-temperature elasticity[135,136,142,159,218,219].

Polymeric materials based on silicon-containing organic isocyanates can be used for the manufacture of various articles by moulding and casting, as insulating materials, for coating electrical goods, and for other purposes. The ability to set at low temperatures enables them to be employed e.g. for treating sensitive materials such as leather, paper, and cloth, in the printing industry, as sealants, etc.[159,169,218]

Silicon-containing organic di-isocyanates have been proposed for the production of polyurethane, polyurea, polyamide, etc. materials[159,207,218,220,221] and also for the synthesis of polysiloxane polymers containing free isocyanato-groups. The latter have been used to obtain plastics, rubbers, resins, liquids, and films[159,170,218,242]. Information has been published on the use of silanes and siloxanes with isocyanato-groups in the radical as hydraulic fluids, rubbers, elastomers, and adhesives[169,243] and for conferring wear resistance on polyamide and polyester fibres, and water resistance and adhesion on coatings[244].

Silicon-containing organic polyisocyanates improve the adhesion to substrates of hardenable compositions such as as silicones, polyacrylates, polyurethanes, and polysulphides[167,245,246]. Silanes and siloxanes modified with isocyanate fragments can be employed to obtain film coatings[156,162,202,246], rubbers, and resins[246], for impregnating various materials in order to confer water-repellent properties[158,182,224,247], as glues[248], surface-active agents[248], foam stabilisers in the production of polyurethane foams[223,249], for cementing glass[162,174], and for other purposes[159,160,167,212,216,242,243,249-253].

Research is probably widely developed on the application of organosilicon compounds mixed with organic isocyanates (with the components chemically uncombined in the initial mixtures). Combinations of organopolysiloxanes with organic di-isocyanates have already been suggested as coatings for electrical goods, distinguished by high heat resistance, elasticity, good adhesion to metals, and improved insulating properties compared with the usual polysiloxane varnishes[254].

Combining polysiloxanes with a mixture of polyesters and di-isocyanates yields compositions which foam at relatively low temperatures without the use of blowing agents[255] and are stable when heated to 200–250°C.

Rubberlike polymers based on silanediols and organic polyesters with terminal isocyanato-groups are elastic, durable, and heat-resistant[256].

Treating fillers for silicone rubber with organic polyisocyanates tends to reinforce them[257,258], and the application of mixtures of organosiloxanes or hydrolysable organosilanes with organic isocyanates to natural or synthetic materials confers hydrophobic properties on them[259].

Organic and organosilicon compounds mixed with isocyanates either individually or as components of more complicated compositions have been proposed for the preparation of water-repellent lubricating greases[260,261], elastic fibres[262], and adhesives[263], as well as for many other purposes[264-268].

Organic isocyanates have been patented as quick-setting agents for liquid organosilicon oligomers, polymers, and copolymers[269,270]. Compositions based on silicones containing isocyanato-groups and purely organic di- and polyfunctional compounds will apparently be identical in properties with materials based on organic di- and polyisocyanates and carbofunctional polysiloxanes. Since polymers of the latter type are unrelated to the topic of the present Review, we will merely list references to this work[271-293]. Investigations have been made also on polymeric materials based on organic isocyanates in which the organosilicon component has a subordinate role (surface-active agents, fillers, pore-regulators, stabilisers, catalysts, adhesion additives, etc.[294-304]).

Stereochemical Non-rigidity (Internal Rotation and Metallotropy) of Organic Derivatives of Transition Metals Investigated by Nuclear Magnetic Resonance Spectroscopy

L.A.Fedorov

Types of stereochemical non-rigidity of organic derivatives of transition metals, which have been widely studied by nuclear magnetic resonance during recent years, are classified. Two types of process—internal rotation in complexes of transition metals and intramolecular transfers of metal-containing groups (metallotropy)—are examined in greater detail. The discussion of the most characteristic structural situations met in π-complexes of transition metals covers not only the dynamic processes already observed by the n.m.r. method but also examples of compounds for which such processes have not yet been observed but may in principle be found. A list of 256 references is included.

I. INTRODUCTION

With many organometallic structures two aspects—static and dynamic—must be considered. The dynamic aspect implies possible activation of molecular rearrangements which cannot be classified as oscillations. Although this problem has been posed and solved for organic chemistry during the past few decades, for organometallic and inorganic chemistry it has become urgent only during recent years.

Many of the known types of dynamic processes can be examined by nuclear magnetic resonance. Some of them are intermolecular, and n.m.r. is widely used for their study (see e.g. reviews on intermolecular dynamics† in organometallic derivatives [1-6]). Other types of processes are intramolecular, and are a kind of manifestation of the "stereochemical non-rigidity" of the compounds (this term was proposed by Muetterties [7]). In several organometallic compounds transitions occur between non-equilibrium states of the system (non-degenerate conversions). In other compounds the intramolecular conversions are degenerate, so that the final state is indistinguishable from the initial state of the system. Nuclear magnetic resonance is an especially fertile approach to such systems, since the actual fact of conversion and also its mechanism cannot always be detected and studied by other methods.

† In the papers under discussion the word "dynamics" is applied to any processes which either lead to or are accompanied by a change in the relative equilibrium arrangement of the atoms in the molecule.

1. Types of Intramolecular Transitions

Nuclear magnetic resonance has been used to study many types of intramolecular processes in organic derivatives of transition metals. However, certain especially characteristic and quite frequent processes—internal rotation, tautomeric transitions, allogonic rearrangements (pseudorotation), reconstruction of organometallic rings, etc.—can be distinguished. Nevertheless, "purely" intramolecular processes are almost impossible under the actual conditions of an n.m.r. experiment, owing to the effect of the solvent and similar factors. It is therefore necessary to determine which processes can be regarded as intramolecular. We shall apply the term *intramolecular* to processes which do not involve breakdown of the compound into two or more kinetically independent species or entry of the compound into other kinetically independent species (stable solvates, complexes.

With internal rotation a change in the orientation of one fragment relative to another in a compound is accomplished by turning about an axis coinciding in direction with a chemical bond. In contrast to traditional organic compounds, internal rotation in transition-metal complexes can occur not only about a localised (σ or coordinate) bond but also about delocalised π-bonds, including bonds of order exceeding unity.

Tautomeric processes in organometallic compounds of transition metals involving intramolecular rearrangements

of metal-containing groups (metallotropic transitions) are fundamentally novel and therefore especially interesting. Metallotropic transitions occur in any change in the relative positions of two fragments of the compound—the metal (or metal-containing group) and the remainder of the molecule—which is accompanied by a redistribution of its bond system. Metallotropy was first studied by Nesmeyanov and Kravtsov on the intramolecular migration of a transition metal between σ-bonds in a compound [8]. Since then examples have also been found of various migrations of metal-containing groups on π-complexes of transition metals. The richness and variety of the structural possibilities characteristic of transition-metal complexes result in a multiplicity of types of metallotropic transitions.

Allogonic rearrangements (pseudorotation) cover all processes occuring in coordination polyhedra (including square planar complexes and complexes containing *inter alia* different kinds of π-bonds). They include also rearrangements of the skeleton of coordination compounds in which a polyhedron different from the original is formed as transition state (pseudorotation, a term proposed by Berry [9]) or intermediate (allogonic rearrangements, a term proposed by Bennett et al. [10]).

The stereochemical non-rigidity of organometallic rings containing the metal in the main skeleton of the ring may involve both the dynamic aspects that are investigated on the usual organic rings and several questions specific to organometallic compounds, such as the possibility of intermediate opening of the ring, etc.

The history of the problem is comparatively brief. During the "preparatory" decade 1956–1966 the efforts of various workers [7-27] led to the discovery and the investigation of several types of intramolecular conversions in organometallic compounds, and also in a series of compounds which can be regarded as models for organometallic structures. Thus the main outlines of the problem were revealed, and certain hypotheses formulated on the mechanisms of the molecular reorientations. A period of "attack and charge" began in 1967, characterised by an avalanche of fresh information. No tendency is yet evident for this process to level off on a plateau.

Thus, in spite of the relative novelty of the problem, the literature on the stereochemical non-rigidity of organometallic compounds is so large that it is already quite difficult to cover in a short survey (Cotton's review was published in 1968, [28] and that of Vrieze et al. in 1969 [5]). Only the first two types of intramolecular dynamics—internal rotation and tautomerism—will therefore be discussed in the present Review. However, we must not ignore the formality of any such (including the suggested) classification of these processes and hence the difficulty of deciding in several cases what type of transition takes place in a particular molecular system.

2. Equivalence of Nuclei in Static Molecule

Following Abragam's suggestion [29] comparable nuclei are termed *isochronous* if they have the same shielding, and *anisochronous* if their shielding differs. Nuclei may be either regularly or accidentally isochronous. Isochronous nuclei are equivalent only if their equivalence is due to considerations of symmetry (static or dynamic). Otherwise they are non-equivalent even if a spectroscopic experiment indicates identity of shielding (accidentally isochronous).

Depending on their relative arrangement in the molecule any comparable groups—by which we shall henceforward imply comparable nuclei or groups of nuclei in some fragment—may be either chemically equivalent, enantiotopic, or diastereotopic. Groups which are coupled by a simple axis of rotation C_n ($1 < n < \infty$) are chemically equivalent [30]. Groups that are defined as chemically equivalent, and hence isochronous "from the viewpoint" of nuclear magnetic resonance spectroscopy, are in fact equivalent in chemical terms: i.e. they cannot be distinguished by their behaviour in any chemical reaction [31] and they cannot become spectroscopically distinguishable in a chiral medium. Enantiotopic groups possess an enantiomeric environment and hence are coupled by a reflection–rotation axis S_n (rotation about axis C_n followed by reflection in the plane of symmetry, $1 \leq n < \infty$). [32] Enantiotopic groups are isochronous in achiral (optically inactive) solvents, but may become anisochronous in chiral media. Finally, diastereotopic groups cannot be interchanged by any symmetry operation, and thus are geometrically non-equivalent [32]. As a consequence, diastereotopic groups should in principle be anisochronous in any solvent. Although the diastereotopy (geometrical non-equivalence) of groups is in principle a necessary condition for the spectroscopic non-equivalence of their nuclei, this condition is not sufficient. Differences in the shielding of diastereotopic nuclei depend on the structure of the molecules, the solvent, and several other factors. In individual cases these differences may become so small that they cannot be observed, and the groups can then be regarded as accidentally isochronous (but not equivalent).

3. Dynamic Equivalence of Nuclei—Dynamic n.m.r. (d.n.m.r.)

The above definitions apply to molecular statics, in which molecules are considered in fixed structural situations with the mutual arrangement of their atoms and bonds unchanged. Actually the investigator is usually dealing not with static but with dynamic stereochemistry. Various intramolecular movements in compounds produce an averaging of the shielding and other spectral parameters of the groups. The symmetry of the molecule seems to improve, and hence the spectrum to degenerate. As a consequence of the degeneracy diastereotopic groups may become "dynamically chemically equivalent" or "dynamically enantiotopic". Several factors—temperature, nature of solvent, concentration of compound, etc.—may in principle be the averaging agent, introducing dynamic equivalence (in the n.m.r. sense) into the molecular system, but the temperature has the greatest importance for intramolecular processes.

The relative character of the "dynamic" behaviour of molecular systems must be emphasised: particular groups may be diastereotopic for some methods, but chemically equivalent or enantiotopic (dynamically) for others. Thus a spectroscopic examination of a compound usually yields not its absolute but its effective (average) symmetry, and hence the effective equivalence of its groups—equivalence "in terms of" the method of investigation used.

The relative character of the boundary between the static and the dynamic behaviour of a molecular system is governed also by the individual features of the compound (or process) and by the possibilities—the time scale—of the physical method used. A compound may "appear" static, immobile for some methods and dynamic for

others, and the process may correspondingly be "slow" for some methods and "rapid" for others.

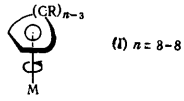
The time scale of a spectroscopic method (the time necessary for the observation of discrete spectra) is directly related to the energy of the transitions observed: the smaller the energy of transitions between states of the system, the slower the processes "visible" by this method. A comparison made by Muetterties [7] shows that microwave spectroscopy, particularly high-resolution nuclear magnetic resonance, is substantially "slower" than diffraction methods of analysis, or electronic and vibrational spectroscopy. With processes so rapid that the system remains for $10^{-13}-10^{-15}$ s in each state vibrational spectroscopy, for example, enables the spectrum of each state to be observed, whereas n.m.r. spectroscopy reveals only spectra averaged over several states of the molecular system. On the other hand, n.m.r. spectroscopy enables processes having a lifetime of $10^{-1}-10^{-9}$ s to be observed, and is quite rapid in comparison with any method involving direct isolation of molecular systems in any discrete states (if these states are non-degenerate, and such separation is feasible).

Thus n.m.r. spectroscopy is a fortunate method of investigation for chemistry, since it is able to cover a range of processes and problems which are often inaccessible to other methods. These include various states of organometallic compounds and their reactions having activation energies of 5–25 kcal mole^{-1}. This is especially important because the molecular structure of these compounds in the liquid phase may differ from their structure in the crystal [7]. The branch of n.m.r. spectroscopy used to investigate the inter- and intra-molecular dynamics of molecules is termed dynamic nuclear magnetic resonance (d.n.m.r.). Beginning with the classic work of Gutowsky and his collaborators [33-35], this branch underwent serious theoretical development and has found many applications (see reviews [36,37]).

Information on the dynamics of a molecule can in principle be obtained also by examining a "frozen" spectrum ("slow dynamics", the indicator groups being dynamically chemically non-equivalent or enantiotopic). However, investigation of a compound is especially fruitful and informative in a critical region, in which a small perturbation (change in temperature, introduction of a somewhat different substituent, etc.) will reveal the whole sequence of changes in the spectrum—from the "frozen" spectrum, through a series of intermediate spectra, to the degenerate spectrum.

Several d.n.m.r. approaches, including the stereochemical non-rigidity of compounds, have been worked out in the investigation of dynamic phenomena. The simplest approach is to study the merging of the signals. The kinetic and thermodynamic parameters are obtained by finding experimentally the coalescence temperature T_c. However, this approach will give acceptable results only for the simplest systems, in particular for a two-centre exchange without spin–spin interaction between the nuclei of diastereotopic groups.

However, complete analysis (usually by means of an electric computer) of the changes in spectral line form accompanying effective averaging of the environments of the diastereotopic groups is required for accurate investigation. Importance attaches both to the "limiting" spectra (the discrete, "static" spectrum, and also the averaged, "dynamic" spectrum) and to all intermediate spectra produced as the averaging process gradually becomes more intense. With intramolecular processes, as already mentioned, only changes in the temperature of the solution can act as such an averaging agent.



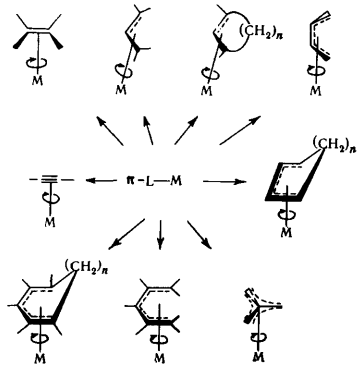
II. INTERNAL ROTATION IN COMPLEXES OF TRANSITION METALS

Rotation about σ-bonds has been relatively well studied on various organic models (e.g. review [38]). This type of dynamics applied to coordinate bonds and metal–ligand σ-bonds has also become the object of n.m.r. investigations during recent years [39-46], although it evidently possesses no special theoretical features.

Studies of two "new" types of rotation—about metal–ligand π-bonds and also in the ligands themselves having a π-type of coordination to a transition-metal atom—give especially interesting structural information. Investigation of this type of dynamics enables the problem of the electronic structure of π-bonds to be discussed from a fresh point of view [47].

1. Rotation about Metal–Ligand π-Bonds

Internal rotation about the n-fold axis in complexes in which a π-C_nR_n–M bond is formed (where C_nR_n is a cyclic ligand in which the multiple bonds are all equivalent and all involved in complex formation, $n = 3-8$, and R = H or R ≠ H—structure I)

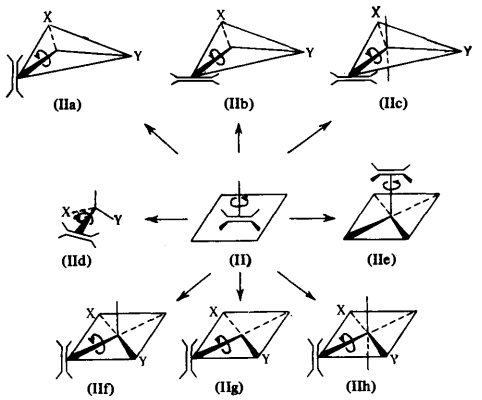


(I) n = 3-8

is opposed by such low barriers that its rate evidently cannot be measured by high-resolution n.m.r. in solution (see e.g. Refs. 48–51 for $n = 5$ and 6). With complexes in which the multiple-bond system coordinated with the transition-metal atom is not continuous, or else is continuous but non-uniform, on the other hand, examination of internal rotation is in many cases "permitted" by the high-resolution n.m.r. time scale. The first study of this kind was made by Cramer [15].

Scheme 1

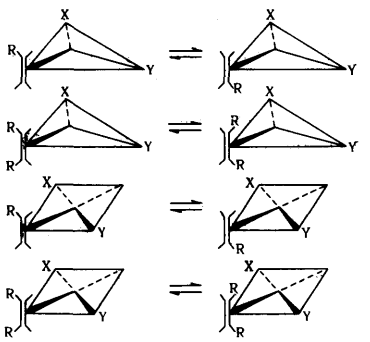
Some possible types of internal rotation about metal–ligand π-bonds



Among the main types of structures (Scheme 1) that can be examined in connection with the problem of internal rotation about a metal–ligand π-bond, π-ethylenic and π-allylic derivatives have been most studied.

(*a*) Internal rotation in π-ethylenic complexes

Various criteria can be used in examining internal rotation about a π-alkene–metal bond in π-ethylenic derivatives (structure II), the choice of which depends on the symmetry of the whole complex (i.e. on whether its rotational isomers are equivalent or non-equivalent). Scheme 2 assembles several types of π-ethylenic complexes, on which the problem of internal rotation can conveniently be considered.



Scheme 2

Some types of structures in which internal rotation about a π-alkene–M bond is possible

Complexes containing highly symmetrical ethylenic ligands [C_2H_4, C_2F_4, $C_2(CH_3)_4$, etc.] and different groups X and Y (structures II—a, g, h), for example, form equivalent rotational isomers. Changes in the rate of degenerate internal rotation in derivatives of this type can conveniently be assessed from the temperature dependence of the ^1H and ^{19}F n.m.r. spectra of the olefinic ligand. At sufficiently low temperatures with "slow" rotation the indicator groups of this ligand (the ^1H and ^{19}F nuclei) separate into two types of diastereotopic nuclei according to their environment and hence shielding. Thus the low-temperature limiting spectrum of the ethylenic ligand does not exhibit a solitary signal (as in the spectrum of the uncomplexed unsaturated compound—the spin system A_4 for ethylene and tetrafluoroethylene, and A_{12} for 2,3-dimethylbut-2-ene) but a set of signals of the system AA'BB' or AA'KK' for the first two compounds, and also the doublet $A_6 + K_6$ for the third compound. Rise in temperature and acceleration of rotation are accompanied by more rapid exchange of the environments of the diastereotopic nuclei and degeneration of the n.m.r. spectrum of the ethylenic ligand ($AA'KK' \rightarrow A_4$, $A_6 + K_6 \rightarrow A_{12}$, etc.).

Rotational isomers of compounds having a ligand of low degree of symmetry (monosubstituted or *cis*-disubstituted ethylene and X = Y are non-equivalent, and each has its own low-temperature boundary n.m.r. spectrum of corresponding intensity. Examination of the temperature dependence of the spectra of such complexes may reveal the interconversion of rotational isomers throughout the range of possible rates—from "slow" to "rapid" dynamics—processes (1)–(4), etc.

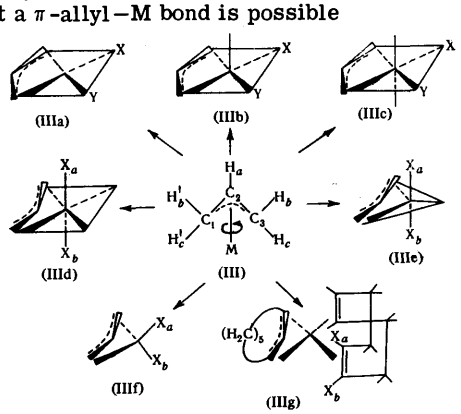
The largest number of papers have appeared on internal rotation in complexes of types (IIa) [15,52–58] and (IIg).[59–61] Very few data have yet been obtained on intramolecular dynamics in the other π-ethylenic derivatives—tetrahedral (IId), octahedral (IIh), trigonal bipyramidal (IIc), etc.—included in Scheme 2.[62–67] Low-resolution n.m.r. has also been used for this purpose[68,69].

Application of n.m.r. to rhodium and iridium derivatives of type (IIa) with highly symmetrical π-ethylenic ligands (X = C_5H_5, C_6H_6, etc. and Y = C_2H_4, C_2F_4, SO_2, etc.) shows that the rate of degenerate rotation of the alkene depends significantly on the nature of the metal and on the structure of the rest of the complex. Rotation is appreciably more rapid with M = Rh and Y = SO_2 or C_2F_4 than when Y = C_2H_4. An ethylene ligand (Y = C_2H_4) rotates more slowly in an iridium than in a rhodium complex. A tetrafluoroethylene group rotates much more slowly than does ethylene.

Study of degenerate rotation in platinum complexes PtXAlkeneChelate (X = Cl, Br) of type (IIg) reveals a slight dependence of the rate of rotation of ethylene on the structure of the remainder of the compound. Derivatives of this type also show non-degenerate rotation in the interconversion of isomers obtained from monosubstituted and *cis*-disubstituted ethylenes (reactions (3) and (4) respectively). It is significant that neither substitution of the *cis*-substituent X (Cl by Br) nor replacement of an acetylacetonate by a hexafluoroacetylacetonate ligand produces a definite change in the rate of rotation of the alkene. The very fact of observing geometrical isomers of (IIa) and (IIg) is an unambiguous n.m.r. proof that the axis of the alkene is oriented perpendicular to the plane of the complex both in solution and in the crystal[70,71].

The choice of transition state in the discussion of internal rotation about an alkene–metal π-bond is directly connected with the structure of the complexes. Diffraction data show that in several compounds an ethylenic ligand is oriented perpendicular to the plane of the molecule if such can be distinguished (IIa,[70] IIg,[71] etc.). In these complexes the state in which the ligand lies in the plane of the complex is obviously more favourable energetically, and is observed in the n.m.r. spectrum with slow dynamics, whereas the less favourable transition state is almost unobservable, since its contribution to the spectral parameters is negligible because of its short lifetime. The given dynamics applied to the complexes (IIg) can than be represented by[59]

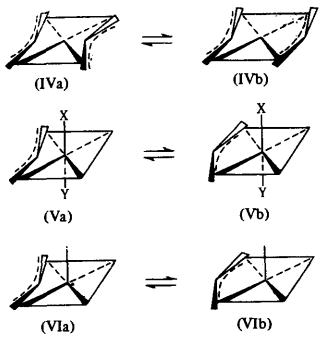
An attempt was made[59] to assess the effect of electronic and structural factors on the rate of this process and on the stability of its transition state. Since, however, the axis of an ethylenic ligand in a π-complex may be not only perpendicular to but also coplanar with the complex (IIb),[72] the transition state in process (5) may actually be an intermediate complex having an appreciable lifetime and hence making an appreciable contribution to the special parameters.



The observation of intramolecular rotation in ethylenic π-complexes by d.n.m.r. may in principle be complicated by a contribution from intermolecular dynamics, connected with the lability of certain alkene–metal π-bonds[73–83]. In several cases, however, experimental conditions can be distinguished which eliminate almost completely the intermolecular component of the process. Criteria of this are, for instance, that the parameters of the n.m.r. spectrum should be independent of the concentration of the compound, additions of the free ligand, etc.[53,76] The observation of spin–spin interaction between nuclei of the ethylenic ligand (hydrogen-1, fluorine-19, carbon-13, etc.) and nuclei of the metal (rhodium-103, platinum-195, etc.) or other ligands (phosphorus-31, etc.) in the π-alkene–metal fragment throughout the range of rates is convincing evidence that the process is intramolecular[15,54,59].

(*b*) Internal rotation in π-allylic complexes

Internal rotation about a π-allyl–metal axis (structure III) can in principle occur quite slowly (on the n.m.r. time scale) in a wide range of compounds in which the metal is attached to a three-electron ligand. Several examples are combined in Scheme 3.



Scheme 3

Some types of structures in which internal rotation about a π-allyl–M bond is possible

Asymmetry in π-allylic complexes with a non-degenerate ligand spectrum of type AGKPX [square planar (IIIa),[84,85] octahedral (IIIc),[86–93] etc.—for terminology see Refs. 91 and 94] originates in the inequality between the substituents X and Y. Slowness of internal rotation in complexes of this type is indicated by the anisochronous behaviour of the terminal methylene groups (structure III)—of the $C_{(1)}$ and $C_{(3)}$ nuclei in the ^{13}C n.m.r. spectrum, and of the *cis*-protons H(b) and H(b′) and also the *trans*-protons H(c) and H(c′) in the ^1H n.m.r. spectrum. With symmetrical complexes (IIId–g), possessing a degenerate spectrum AK_2X_2, slowness of internal rotation is evidenced by anisochronous behaviour of the structurally identical indicator substituents $X_{(a)}$ and $X_{(b)}$, e.g. in the niobium complex (IIIf) [$X_{(a)} = X_{(b)} = \pi\text{-}C_5H_5$ [95]], in the cobalt and rhodium complexes (IIIg),[96,97] etc. [the non-equivalence of the groups $X_{(a)}$ and $X_{(b)}$ is due to the non-coplanarity of the $C_{(1)}–C_{(2)}–C_{(3)}$ and $C_{(1)}–M–C_{(3)}$ planes of the π-allyl–metal bond].

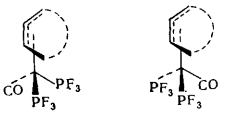
Slowness of rotation about a π-allyl–metal bond may be indicated also by the spectral observation in an appropriate temperature range (and the theoretical possibility of physical separation) of rotational isomers in those types of compounds whose rotamers are non-equivalent from considerations of symmetry. In particular, the isomeric pairs (IV)–(VI) (processes 6–8)

(6)

(7)

(8)

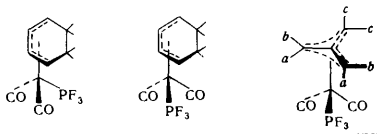
have been observed by ^1H n.m.r. Investigation of the temperature dependence of the ^1H n.m.r. spectrum for several π-allyl compounds of transition metals has shown that internal rotation about the π-allyl–metal bond may occur at rates that can be conveniently recorded by n.m.r. methods. The effect has been examined in greatest detail in a study of molecules of two types—asymmetric π-allylic compounds (IIIc), and also symmetrical compounds forming isomeric pairs (IV)–(VI).



With rise in temperature (dynamic) symmetry appears in the spectrum of the asymmetric complexes (IIIc) (AGKPX → AK_2X_2): anisochronicity of the two terminal methylene groups is replaced by their isochronicity and hence dynamic equivalence. This effect is observed between −20° and 90°C with $[RhCl(\pi\text{-}C_3H_5)_2]_2$,[91] from −67° to 20°C with $Fe(CO)_2(\pi\text{-}C_3H_5)_2$,[88,89] from 60° to 120°C with $Ru(CO)_2(\pi\text{-}C_3H_5)_2$,[93] etc. In the spectra of compounds (IV)–(VI) forming isomeric pairs, interconversion of the rotational isomers (a) and (b) begins to become more rapid with rise in temperature. As a result, the two spin systems AK_2X_2 coalesce into a single system (and the rotational isomers thus become indistinguishable by n.m.r. spectroscopy) or the ratio of the isomers changes[98–102].

With both types of compounds the observed spectral changes are satisfactorily explained on the assumption that the allyl group swings at an appropriate frequency about the metal–ligand axis (process III). The π-allyl ligand thus occupies successively first one and then another orientation relative to the remainder of the molecule, so that the terminal methylene groups exchange their environments [$C_{(1)} \rightleftharpoons C_{(3)}$, H(b) ⇌ H(b′), H(c) ⇌ H(c′)]. A similar explanation applies to the temperature dependence of the spectrum of tri-π-allylrhodium, which probably has a trigonal prism structure[21,22,90]. Becconsall and O'Brien first described intramolecular rotation of type (III) in this particular compound[22]. It must be stressed, however, that the observed spectral changes can in principle be

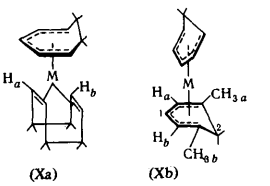
explained, not by transitions between rotational isomers, but by some other intermolecular (e.g. exchange) or intramolecular (pseudorotation) mechanisms [103]. Thus the most informative spectroscopic methods must be employed to elucidate the true mechanism of stereochemical non-rigidity in these compounds.



(*c*) Internal rotation in derivatives having four- and five-electron ligands

Internal rotation about the π-C_4H_6–M bond in compounds having four-electron ligands has been investigated on π-butadiene, π-cyclohexadiene, and π-trimethylenemethane complexes of the type π-L–$Fe(CO)_n(PF_3)_{3-n}$. [104-108] The π-butadiene and π-cyclohexadiene derivatives π-$C_4H_6Fe(CO)(PF_3)_2$ and π-$C_6H_8Fe(CO)(PF_3)_2$ can be most conveniently investigated by ^{19}F n.m.r. because of their low degree of symmetry. At sufficiently low temperatures the two trifluorophosphine groups are diastereotopic, but become dynamically equivalent with rise in temperature. These results are consistent with the hypothesis that, of the two non-equivalent rotational isomers

(VIIa) (VIIb)



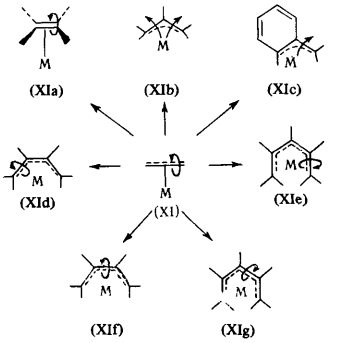
the energetically more favourable isomer (VIIa) is stabilised at low temperatures [104,107]. Investigation of the analogous complex π-$C_6H_8Fe(CO)_2PF_3$ has shown, however, that at low temperatures both rotational isomers—(VIIIa) and (VIIIb)—may exist with closely similar probabilities [107].

(VIIIa) (VIIIb) (IX)

The highly symmetrical π-trimethylenemethane ligand enables the interconversion of rotational isomers to be investigated by proton magnetic resonance. The spectrum of π-$C_4H_6Fe(CO)_2PF_3$ below $-73°C$ contains three equally intense groups of signals corresponding to three types of ligand protons—$H_{(a)}$, $H_{(b)}$, and $H_{(c)}$—in each of the three equivalent rotational isomers (IX). At sufficiently high temperatures, however, the spectrum is a doublet, which indicates the appearance of dynamic equivalence among these protons and the intramolecular character of the dynamics ($^{31}P-{}^{1}H$ spin–spin interaction is observed throughout the temperature range). These spectral changes are attributed [108] to acceleration of rotation about the π-C_4H_6–Fe bond, as a result of which the rotational isomers undergo more rapid interconversion, while the protons $H_{(a)}$, $H_{(b)}$, and $H_{(c)}$ interchange their environments.

A few papers have appeared on intramolecular rotation in complexes containing five-electron ligands. In the cobalt complex which according to n.m.r. data [106] has the "transverse" structure (Xa), the diene protons $H_{(a)}$ and $H_{(b)}$ of the π-cyclo-octa-1,5-diene ligand are diastereotopic owing to the low degree of symmetry of the π-cycloheptadienyl ligand. The temperature dependence of the n.m.r. spectrum shows that these protons are anisochronous at $-25°C$, but become isochronous at $70°C$, obviously as a consequence of dynamic equivalence. These changes in the spectrum were attributed [106] to acceleration of internal rotation about the π-1,5-diene–cobalt bond. However, this is not the only hypothesis, for similar spectral changes should be observed with more rapid rotation about the π-cycloheptadienyl–cobalt bond:

(Xa) (Xb)



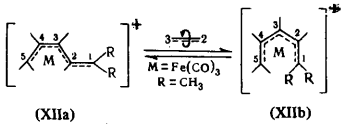
This latter explanation is supported by the temperature dependence of the spectrum of the biscyclohexadienyliron derivative [105]. The low-temperature spectrum of this compound is consistent with the transverse structure (Xb): groups lying outside the plane passing through positions 1, 2, and Fe [$H_{(a)}$ and $H_{(b)}$, $CH_{3(a)}$ and $CH_{3(b)}$] are diastereotopic and anisochronous in the n.m.r. spectrum (the authors [105] interpreted their results somewhat differently). With rise in temperature the shielding of the (*a*) and (*b*) groups averages out, and this is obviously an effect of internal rotation about the metal–pentadienyl π-bond.

2. Rotation about Multiple π-Bonds

In most organic compounds rotation about ethylenic bonds is opposed by considerable barriers, so that n.m.r. has not usually been employed to investigate this type of dynamics (see e.g. review [38]). However, several examples of compounds are known in which these barriers were lowered by certain structural changes, so that internal rotation could be observed by the n.m.r. method [109-118]. Nor is the dynamics associated with rotation about π-bonds with barriers accessible to n.m.r. investigation fundamentally impossible in organic derivatives of transition metals. However, whether or not such dynamics is observable may be determined not only by the structure of the organic ligand but also in considerable measure by the "electronic requirements" of the transition metal. Scheme 4 assembles examples of several structures in which dynamics of type (XI) is theoretically possible.

Scheme 4

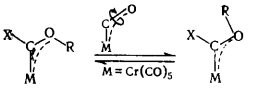
Some possible types of internal rotation about multiple bonds in π-complexes of transition metals



(XIa) (XIb) (XIc) (XId) (XI) (XIe) (XIf) (XIg)

Rotation of type (XIa–e), involving the terminal fragment of a system of multiple bonds, has so far been discussed in connection with n.m.r. data on certain π-allyl (XIb) and π-benzyl (XIc) derivatives. Thus examination of the spectrum of tetra-allylzirconium reveals that the diastereotopic (and anisochronous) *cis*- and *trans*-protons $H_{(b)}$ and $H_{(c)}$, added to each of the terminal carbon atoms (structure III), become isochronous with rise in temperature: whereas the spectrum is of AK_2X_2 type at −74°, it degenerates to AX_4 when the temperature rises to −10°C.[20,98,99,119] A similar spectral pattern is found with tetra-allylthorium (AK_2X_2 at 10° and AX_4 at 80°C).[119] A reversible change in the allylic portion of the spectrum has been found also with π-benzyl derivatives of molybdenum, tungsten, and palladium[19,120,121].

Even in the π-allyl derivatives, however, dynamic equivalence of *cis*- and *trans*-protons has so far been observed only in a limited number of examples. Attempts to detect it in several other π-allylic complexes have proved unsuccessful[91,122,123]. Nor have publications appeared on the dynamics (XI—a, d, e) in other types of π-complexes.



King and Fronzaglia[19], who were the first to observe process (XI) in a π-benzyl compound of molybdenum, suggested that the appearance of isochronicity of the methylene protons with rise in temperature was due to acceleration of rotation about a carbon–carbon bond of order 1.5 in the ligand. The temperature dependence of the spectrum of tetra-allylzirconium has been explained similarly[98]. However, the results obtained are consistent also with alternative mechanisms, including intermediate formation of a σ-type compound[120]:

(XIIa) (XIIb) (9)

The process (XIf, g), involving the central fragment of the system of multiple bonds in the ligand, has been observed only in the derivatives (XIg). Ionic π-pentadienyl complexes of iron exist as two isomers (XII), of which the *cis*-isomer (XIIb) is the more stable[124–127]. Nuclear magnetic resonance has revealed[125] *cis*- and *trans*-interconversions (9) of these isomers at all rates over the whole range, which confirms the possibility that rotation about the 1.5 bond $C_{(2)}–C_{(3)}$ may be accelerated. It is significant that the rate of rotation about the $C_{(1)}–C_{(2)}$ bond is much lower.

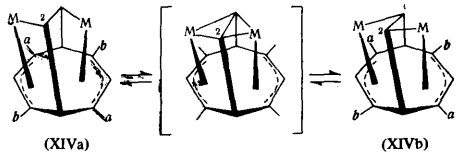
Internal rotation in carbene derivatives has been investigated on compounds of type (XIII). At sufficiently low temperatures they exist as two rotational isomers (*trans* and *cis*—XIIIa and XIIIb), each having its own n.m.r. spectrum, including the spectrum of the indicator groups OR (R = CH_3, C_2H_5) and X (X = CH_3, Ar). The relative intensities of the OR (or X) signals show that the mixture contains unequal amounts of the two isomers, which depend on the structure of the compound and the solvating power of the solvent. With rise in temperature the signals of both indicator groups gradually broaden, and then coalesce, at a temperature depending on the nature both of R and of X. An obvious explanation of the observed temperature dependence is that *cis*- and *trans*-isomers may be converted one into the other by internal rotation about the 1.5 bond C·····O:[128–131]

(XIIIa) (XIIIb)

III. INTRAMOLECULAR MIGRATIONS OF METAL-CONTAINING GROUPS (METALLOTROPY)

Processes of several kinds—transition of $\sigma–\sigma$, $\pi–\pi$, and $\sigma–\pi$ types—are included in metallotropy. Migrations of $\sigma–\sigma$ type (sigmatropic transitions) presuppose that the metal forms a localised coordinate or σ-bond with topologically distinguishable ligand atoms before and after the regrouping, during which its system of multiple bonds undergoes rearrangement. Metallotropic systems of this type reproduce formally the corresponding prototropic systems, and transitions can occur both between equivalent and between non-equivalent positions. Transitions of $\pi–\pi$ type consist in transfer of the metal from the system of multiple bonds with which the π-bond was originally formed to another—equivalent or non-equivalent—system. With $\sigma–\pi$ transitions the metal-containing group forms bonds of fundamentally different types with the ligand in initial and final states of the molecule. Transitions of $\pi–\pi$ and $\sigma–\pi$ types have no prototropic analogues.

Metallotropic transitions may be accompanied by either preservation of or change in the "connectedness"‡ of metal and ligand in the metal–ligand fragment of the molecule. The "connectedness" of this fragment is maintained in $\sigma–\sigma$ transitions, but changes during $\sigma–\pi$ transitions. Conversions of $\pi–\pi$ type are more varied: they can take place either with maintenance of or change in the "connectedness" of the given fragment.



Metallotropic transitions of all the above types will be discussed below with the use of several examples. It must be stressed, however, that there are many organometallic compounds, in particular cluster structures, in which the dynamics is so complicated that it is often difficult to assign to one of the simple types[133–145]. Furthermore, the term "metallotropy" merely indicates the final result of the process—migration of a metal-containing group in space—not its cause or mechanism. These may include the flexibility of the ligand, the ease of formation of the transition state, the spatial proximity of the two energy minima between which the metal-containing group migrates, etc.

1. $\sigma–\sigma$ Transitions

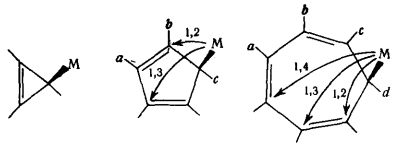
Intramolecular transitions of $\sigma–\sigma$ type, accompanied by rupture of an M–El σ-bond (El = N, O, S, etc.) and formation of a similar or some other σ-bond, have been little studied in the chemistry of transition metals. Only occasional examples are known[146,147]. Intramolecular

‡ The term "connectedness" is the [translation of] the Russian equivalent of *hapto* (proposed by Cotton[132])—the number h^n of the adjacent n atoms of the ligand involved in forming a bond with the metal. This term differs from "denticity" in sense and in range of use, and its application to π-complexes seems justified.

equilibrium $\sigma-\sigma$ transitions of metal-containing groups involving metal–carbon M–C bonds

(XIVa) (XIVb)

are obviously of fundamental interest.

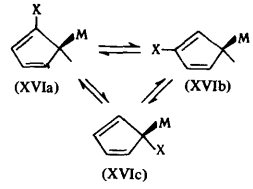


The transformations observed in the n.m.r. spectra of the derivative (XIV) with M = $Fe(CO)_3$ provide an example of such dynamics. Two types of bonds—π-allylic and σ—are formed by each metal atom in this compound. At 0°C the spectrum of the complex corresponds to the low-temperature limiting structure with diastereotopic (and anisochronous) protons $H_{(a)}$ and $H_{(b)}$ in both indicator π-allyl fragments. Gradual changes are observed with rise in temperature, and at 45°C the $H_{(a)}$ and $H_{(b)}$ protons become dynamically equivalent. The cause of these spectral changes is acceleration of the synchronous degenerate transitions of the metal atoms between two possible positions, as a result of which each atom forms a σ-bond alternately with the $C_{(1)}$ atom and with the $C_{(2)}$ atom [148].

In cyclic compounds $\sigma-\sigma$ transitions are most probable in derivatives of the type [28]

(XV) n: a) 1; b) 2; c) 3.

The position of the metal-containing group with respect to the system of double bonds in these compounds is favourable (though in different degrees) for both dynamic and static $\sigma-\pi$ conjugation. This may in principle promote significant activation of the M–C σ-bond, and hence facilitate its dynamics. Among specific examples with $n = 1-3$ σ-cyclopropenyl compounds (XVa) have so far remained completely unstudied, while the largest number of publications are concerned with σ-cyclopentadienyl compounds (XVb):



(XVa) (XVb) (XVc)

Dynamic n.m.r. investigation of σ-cyclopentadienyl derivatives of certain transition metals of the iron and chromium subgroups shows that at sufficiently low temperatures the spectrum of the cyclopentadienyl ligand contains a multiplet due to the five-spin system of protons AA'BB'X [10,149–154] (or ABCDX with compounds of lower symmetry [155]; a corresponding set of signals is observed in the ^{13}C n.m.r. spectrum [156]). Such spectra correspond to the presence in these compounds of a localised C_5H_5-M bond, and in several cases this has been confirmed independently by structural investigations by diffraction methods [10,157,158]. A series of patterns of intermediate type is observed with gradual rise in temperature, and at still higher temperatures a single signal representing a situation in which all five ring protons are isochronous owing to the time averaging of their shielding (or for some other reason).

Two main mechanisms have been suggested for the intramolecular migration of a metal-containing group resulting in such averaging: Piper and Wilkinson, the first to meet this phenomenon, pointed to the possibility of $\sigma-\sigma$ transfers of the metal-containing group along the perimeter of the cyclopentadienyl ligand [11]; more recently a mechanism involving a change in type of the C_5H_5-M bond ($\sigma-\pi$ transitions) has been proposed [159]. Either mechanism explains the main features of the ^1H n.m.r. spectra of these compounds. Study of the finer spectral changes shows that, depending on the structure of the compounds and several other factors, both the first [10,152,153] and the second [160–163] (Section III, 2) mechanisms may operate.

Certain features of the mechanisms of $\sigma-\sigma$ transitions in σ-cyclopentadienyl compounds ($\sigma-\pi$ transitions will be considered in Section III, 2) have been studied on derivatives of two types: in compounds containing C_5H_5M fragments (and C_5X_5M in general) migration of the metal-containing group reduces to the degenerate processes

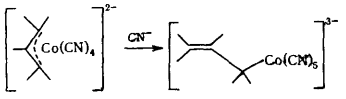
(XVIa) (XVIb) (XVIc) (10)

(where X = H); in derivatives having a substituted ligand (C_5H_4XM, etc.) degeneracy is eliminated, and the process reduces to the interconversion of the isomers (XVI) (X ≠ H). In both cases, however, the $\sigma-\sigma$ transition can in principle involve 1–2 and/or 1–3 migration of the metal-containing group within the cyclic fragment (structure XVb). [10]

The forms of the $H_{(a)}$ and $H_{(b)}$ signals in derivatives containing a C_5H_5M fragment are found to vary in different rates with rise in temperature (their assignment was based on analysis of the multiplicity of the main signals and their ^{13}C satellites, on the ^{13}C spectra, and also on the proton spectra of corresponding deuteriated derivatives [10,152,153]). The interconversion of isomers of (XVI) has been examined also on a σ-$C_5H_4CH_3$ derivative of ruthenium [153]. These spectral features agree best with 1–2 displacement. Thus a choice could be made in favour of one of the forms of sigmatropic rearrangement—that involving migration of the metal along the shortest path to the adjacent carbon atom (and representing a form of $\sigma-\pi$ conjugation—"counter" dynamics of electrons and metal-containing group). The Woodward–Hoffman rules have also been extended [164] to the mechanism of sigmatropic migration in the derivatives (XVb).

It must be emphasised that a C_5H_5-M σ-bond and hence a $\sigma-\sigma$ mechanism of migration have beem assumed also for many other derivatives—$C_5H_5AuP(C_6H_5)_3$, [165] $C_5H_5(CH_3)_2AuP(C_6H_5)_3$, [166] $C_5H_5(C_6H_5)Pt[P(C_2H_5)_3]_2$, [167] etc. The initial premise in all cases is that the "electronic requirements" of the transition or post-transition metal enable it in principle to form a metal–carbon σ-bond. However, such presuppositions are not sufficieintly convincing by themselves in the absence of other unambiguous confirmation. Such support could come from the detection of the AA'BB'X spin system in the low-temperature ^1H n.m.r. spectrum, the detection of a localised bond when the compounds are examined by diffraction, etc. In any specific case, moreover, additional investigations are

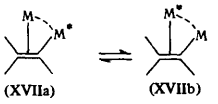
necessary which would reveal some disregarded factors—intermolecular dynamics involving the C_5H_5-M bond [168,169], change in character of this bond under the influence of strongly solvating solvents [169-172], bridge formation by the cyclopentadienyl ligand [173], maintenance of some form of dynamics in the crystal [174], etc.



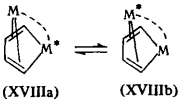
2. $\sigma-\pi$ Transitions

The $\sigma-\pi$ transitions often encountered in organometallic chemistry are investigated by various physicochemical methods, including nuclear magnetic resonance (available information on this topic has been reviewed [175]). $\sigma\pi$-Reactions are usually intermolecular. Thus n.m.r. observations have been reported on irreversible

(11)

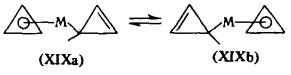


and reversible $\sigma-\pi$ transformations in ethylenic complexes of platinum [176,177]. Papers have appeared on irreversible and reversible $\sigma-\pi$ transitions in π-allylic complexes [178-181], in particular on the reversible reaction

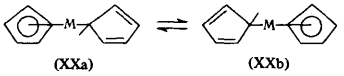


(12)

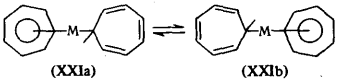
investigated by n.m.r. [182,183] (such transitions in π-allylic complexes gave rise to a lively controversy—see reviews [5,94] and subsequent communications [184,185]).



However, there are very few examples of $\sigma-\pi$ transitions that are actually intramolecular. Change in the valency state of the metal in the direction of the given ligand (change in the "connectedness" of the metal–ligand fragment) in compounds possessing stereochemical nonrigidity of this type should, of course, be balanced by the "internal resources" of the molecule. This condition can be realised (at least for degenerate $\sigma-\pi$ transitions) by e.g. combining in one molecule two formally identical metal–ligand fragments, two metals attached to a single ligand by different bonds (structures XVII and XVIII), or two ligands attached in different ways to one metal (structures XIX–XXI):

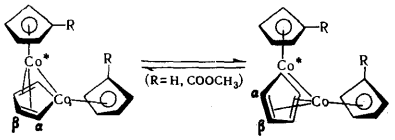


(XVIIa) (XVIIb) (13)



(XVIIIa) (XVIIIb) (14)

(XIXa) (XIXb) (15)



(XXa) (XXb) (16)

(XXIa) (XXIb) (17)

The two metals or ligands may be either structurally isolated or have some additional bond to form a kind of "cluster". Under appropriate temperature conditions the metal–ligand fragments may be expected to interchange functions, and the rates of certain of these degenerate processes may lie in a range suitable for n.m.r. observation.

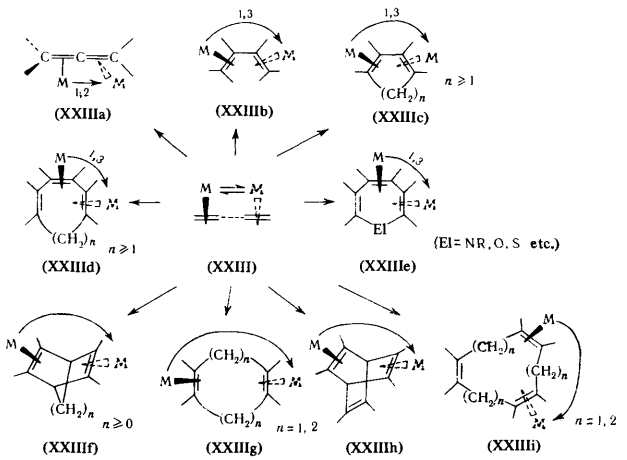
Examples are known of dimetal compounds of type (XVII), [186-190] but there are at present no reports of the observation of degenerate $\sigma-\pi$ reactions (13) in them. Among dimetal complexes (XVIII) [191,192] "dynamic" derivatives—the dicobalt compounds (XXII: R = H, $COOCH_3$)—are known [193,194]. In these compounds one metal atom is attached to the butadiene fragment by two metal–carbon σ-bonds, and the other by a π-C_4H_4-M π-bond. The two π-cyclopentadienyl ligands are then situated in different environments, and are therefore diastereotopic. Dynamic n.m.r. investigation of solutions of (XXII) indicates that the indicator groups (π-C_5H_5 and CH_3 respectively with R = H and $COOCH_3$) are anisochronous at room temperature, but become isochronous at higher temperatures. However, shielding of the diastereotopic α- and β-diene protons is maintained when dynamic equivalence of the indicator groups appears in the high-temperature spectra. These temperature changes correspond most probably to intramolecular reactions (18) (their rates are independent of concentration), in which each metal atom occupies alternately one of two nonequivalent positions—that in which it forms a π-butadiene bond or the position in which it is attached to the ends of the butadiene fragment by two σ-bonds:

(XXIIa) (XXIIb) (18)

Degenerate $\sigma-\pi$ transitions (15)–(17) are possible between the rings in compounds having $M(\pi\text{-}C_nH_n)(\sigma\text{-}C_nH_n)$ as principal fragment. Processes (15) and (17) for $n = 3$ and 7 respectively have not yet been investigated. With $n = 5$ process (16) has been observed in the n.m.r. examination of the compounds $(C_5H_5)_4M$, $(C_5H_5)_3MX$, $(C_5H_5)_2MXY$, etc. [150,151,154,155,160-163], and can be expected over a wider range of structures. In particular, the low-temperature n.m.r. spectra of certain $(C_5H_5)_4M$ derivatives [160-163] and $(C_5H_5)_3MoNO$, [150,151] together with X-ray examination of crystalline specimens [157,158,161,195,196], show that a C_5H_5-M bond occurs in two forms—delocalised π-bond (spectrum A_5) and localised M–C σ-bond (spectrum AA'BB'X)—within the same molecule. At higher temperatures the set of signals corresponding to the σ-C_5H_5 group degenerates into a single A_5 signal, so that two singlets can be observed, corresponding respectively to protons of the π-C_5H_5 group and the averaged signal due to protons of the σ-C_5H_5 group. At still higher temperatures further changes are observed in the spectrum, accompanied by coalescence of the two signals into one. Thus not only endocyclic $\sigma-\sigma$ transitions (10) take place in these compounds but also $\sigma-\pi$ conversions (16), in which the metal is attached to each cyclopentadienyl ligand alternately by a σ-bond and by a π-bond.

3. $\pi-\pi$ Transitions

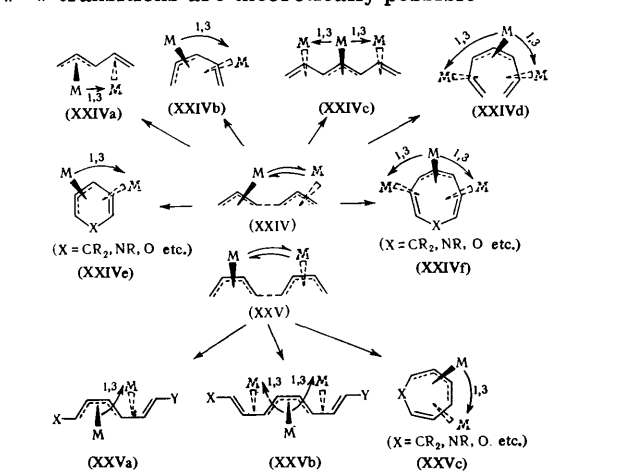
Dynamic n.m.r. spectral study of $\pi-\pi$ transitions—dynamic processes of a fundamentally novel type for chemistry—began only during 1966–1967. However, the



number of known examples is already fairly large, and research is extending to ever new classes of organometallic compounds.

(*a*) $\pi-\pi$ Transitions in derivatives with a ligand having an open system of π-electrons

Schemes 5 and 6 show several types of complexes in which $\pi-\pi$ migration of one metal-containing group is theoretically possible with maintenance of the "connectedness" of the π-metal–ligand fragment in the ground state. The main feature of these structures is the open chain of π-electrons in the carbon skeleton of the ligand.

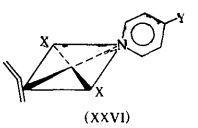


Scheme 5

Some types of ethylenic π-complexes in systems in which the ligand has an open chain of π-electrons and in which $\pi-\pi$ transitions are theoretically possible

Scheme 6

Some types of π-allylic and π-butadiene complexes in systems with an open chain of π-electrons, in which $\pi-\pi$ transitions are theoretically possible

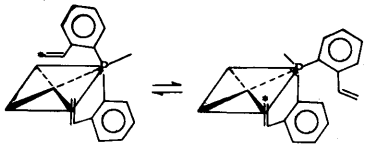


As a consequence, movements of the metal-containing group directed to one side along the perimeter of the unsaturated chain are excluded, and only "vibrational" transitions (degenerate or non-degenerate) between two or more centres are possible. The selection of systems assembled in Schemes 5 and 6 is obviously in considerable measure formal, so that each requires special examination of the conditions under which transitions can actually occur. 1,2-Transitions, involving migration of the metal-containing group to an adjacent C–C bond, are obviously possible only in a limited number of systems. The 1,3- and 1,4-types of migration, as well as more complicated transitions, are formally possible in a wider range of systems. It must be noted that not all the types of organometallic compounds in Schemes 5 and 6 are known at present. Even among those structures which have already been prepared [192,197–200], however, metallotropic $\pi-\pi$ transitions have been investigated so far in isolated cases.

The first investigation of metallotropic $\pi-\pi$ transitions in π-complexes having an open system of π-electrons was made by Ben-Shoshan and Pettit [201] on an allene derivative of iron (structure XXIIIa). In compounds of this type the metal is coordinated with only one multiple bond of the ligand [201–206]. Dynamic n.m.r. investigations have since been extended to compounds of other metals [204,205].

At sufficiently low temperatures the proton n.m.r. spectra of the tetramethylallene complexes π-$C_7H_{12}Fe(CO)_4$ and π-$C_7H_{12}PtCl_2py$ contain three singlet signals corresponding to the "frozen" structure of the compounds—two non-equivalent non-coordinated methyl groups and two equivalent coordinated groups—of relative intensities 1 : 1 : 2. With rise in temperature all the signals coalesce into a single signal, the effect being unaffected by the addition of free tetramethylallene and pyridine to the solution (at temperatures not exceeding $-40°C$). In the spectrum of $(\pi$-$C_7H_{12}PtCl_2)_2$, a compound of lower symmetry, four methyl singlets of equal intensity are observed at $-70°C$, which merge into one signal when the solution warms up to room temperature. Here $^{195}Pt-{}^1H$ spin–spin interaction is observed throughout the temperature range. The effect is independent of the concentration of the complex and of the addition of free tetramethylallene or another tetramethylallene complex [201,204,205].

These experimental facts are explained by intramolecular $\pi-\pi$ 1,2-transitions of the metal atom from one double bond to the other (XXIIIa). [201] The rate of migration of the metal depends significantly on the structure of the complex. Thus it varies appreciably in the compounds

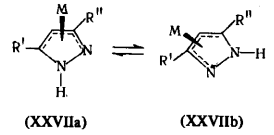


(where X = Cl and M = Pt) on such slight perturbations as changing the substituent Y. [204] The effect is still more striking with more profound structural changes: whereas the process is observed in the spectrum of tetramethylallene derivatives of iron and platinum, it has not yet been detected in allene and 1,1-dimethylallene derivatives of platinum, nor in the allene complex of nickel and the tetramethylallene complex of rhodium [201–206].

Investigation of the dynamic behaviour of other ethylenic π-complexes shown in Scheme 5 and also of other analogous systems awaits our research workers. We will mention certain specific types of $\pi-\pi$ migration studied in ethylenic complexes. Thus the dynamic behaviour of the compound

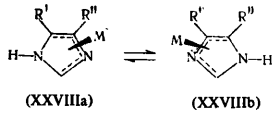
$Co(\pi\text{-}C_8H_8)\pi\text{-}C_5H_5$, in which the cyclo-octatetraene ligand has 1,5-attachment to the cobalt atom, has been examined[27]. Rise in temperature produces reversible spectral changes, confirming the occurrence of a $\pi-\pi$ transition in the system.

A peculiar example of a $\pi-\pi$ transition in an ethylenic system has been established[207] in an investigation of the proton n.m.r. spectra of tri-*o*-styrylphosphineplatinum and the corresponding arsine and stibine complexes. These compounds obviously have a square planar structure. A single ABX set of signals, corresponding to the two types of ethylenic groups—both uncomplexed and coordinated with the platinum atom—is observed in their n.m.r. spectra at room temperature. Signs of complex formation (displacement of the ethylenic signals towards higher fields relative to the initial ligands and decrease in the proton–proton interaction constants J_{cis} and J_{trans}) are appreciably less marked than in other known π-ethylenic derivatives of platinum[208-211]. The splitting constant $J_{^{195}Pt-^{1}H}$ with one of the protons in the given phosphine complex is about one-third of its value in the usual π-ethylenic complexes of bivalent platinum[208-211]. All these spectral peculiarities are consistent with quite rapid $\pi-\pi$ transitions



(19)

as a result of which all the spectral characteristics of coordinated and uncoordinated double bonds are averaged out. The process is assumed to be intramolecular with a five-coordinated transition stage.



Papers on migration in π-allylic systems (XXIV) have not yet appeared, whereas corresponding n.m.r. data are already known for several π-butadiene structures (XXV). It is found in particular that, in the open systems (XXVa) and (XXVb), $\pi-\pi$ transitions between isomers having somewhat different properties (X ≠ Y) are slow on the n.m.r. time scale. Because of the non-equilibrium character of the process, the n.m.r. recording of such transitions involves merely analytical measurement of the ratio of the isomers. The path of migration of the group M = $Fe(CO)_3$ in compounds (XXVa) and (XXVb) is more or less obvious: only 1,3-transitions, which require no rearrangement of the system of valency bonds, are possible. The "connectedness" of the fragment is assumed to diminish in the transition state, with formation of a π-ethylenic structure ($h^4 \rightarrow [h^2] \rightarrow h^4$).[212-214]

A unique route for intermolecular transformations—$\pi-\pi$ 1,3-transfers of the metal-containing group from one diene fragment to another—is possible also in carbocyclic and heterocyclic compounds (XXVc) having an acyclic system of multiple bonds. Among compounds (XXVc) that have been studied by n.m.r.,[192,200] however, this dynamics has hitherto been observed only in derivatives having X = NR.[215,216] At 0°C the spectrum of the ethylenic portion of the ^{1}H-azepine derivative corresponds to the instantaneous structure in which the tricarbonyliron group is coordinated with only one diene fragment; at room temperature the signals become blurred; and at 65–85°C the spectrum degenerates into a spin system corresponding to dynamic equivalence of the two diene fragments. These spectral changes were interpreted as evidence of the speeding up of transfers of the group M = $Fe(CO)_3$ between two structurally possible positions (another type of dynamics—acceleration of rotation about the N–R bond—is also possible, and appropriate spectral changes have been attributed to it; inversion of the nitrogen atom in this compound is probably quite rapid).

Tricarbonyliron derivatives of pyrazole and imidazole have been prepared[217], and most probably have a π-butadiene structure (XXVII and XXVIII). Their d.n.m.r. investigation showed significant differences between high- and low-temperature spectra: whereas at sufficiently low temperatures the indicator groups R′ and R″ (CH_3 or H) are anisochronous and hence diastereotopic, they become isochronous as the temperature gradually rises. The observed spectral changes might be explained by acceleration of the $\pi-\pi$ transitions a ⇌ b (1,2-transitions for the pyrazole derivatives (XXVII), and 1,3-transitions for the imidazole derivatives (XXVIII); a "counter" rearrangement of the system of double bonds is assumed in both cases) associated with intermolecular and/or intramolecular $\sigma-\sigma$ migration of NH protons:

(XXVIIIa) (XXVIIIb) (21)

Scheme 7

Some types of compounds with a cyclic system of π-electrons in the ligand, where $\pi-\pi$ transitions are possible

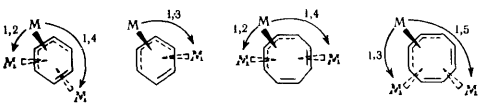
(XXIXa) (XXIXb) (XXIXc) (XXIXd) (XXIX) (XXIXe) (XXIXf) (XXIXg) (XXIXh) (XXIXi)

(*b*) $\pi-\pi$ Transitions in systems with a ligand having a closed chain of π-electrons

Scheme 7 assembles several types of organometallic π-complexes in which a carbocyclic ligand has a cyclic system of π-electrons. The transition metal, because of its "electronic requirements", is unable to coordinate with all the π-electrons simultaneously, but only with an individual segment of the carbon ring. In contrast to the

derivatives discussed in the preceding subsection, the complexes (XXIX) may in principle possess more intense and varied $\pi-\pi$ dynamics: not only "vibrational" but also unidirectional translational movements of metal-containing groups are possible in them; and the π-bond in the transition state of complexex (XXIX) can assume the energetically unforbidden form (I), which is formally similar to the structure of the ground state in many π-complexes. However, these features of the derivatives (XXIX) complicate substantially discussion of the mechanisms of their $\pi-\pi$ transformations because of the multiplicity of the latter.

Among the mono-olefinic π-complexes (XXIXa–c) $\pi-\pi$ transitions have so far been detected in the platinum derivative (XXIXb). The process is intramolecular, since spin–spin interaction between platinum-195 and the ring nuclei is observed throughout the temperature range. The n.m.r. spectrum of the compound in the "frozen" state is consistent with X-ray data [218].

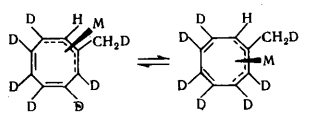


Information is available on the π-allylic complexes (XXIXd, e). The complex (XXIXd) has been prepared [219], and an aluminium derivative of this type has been studied by gas-phase electron diffraction [220]. Cycloheptatrienyl complexes of molybdenum, tungsten, cobalt, and iron of the type (XXIXe) have been described [19,221–229], and their stereochemical non-rigidity has been investigated by d.n.m.r. on several examples. Unfortunately, the structure (XXIXe) (based on the "electronic requirements" of the metal taking into account its bonds in the rest of the complex) is not uniquely possible. Low-temperature n.m.r. investigations of these complexes indicate the possibility not of a π-allylic but of a C_7H_7-M σ-bond [94,224], although in the fairly specific pyrazolylborate derivative of molybdenum the bond in the crystal is actually π-allylic [226]. Thus a more exact discussion of the mechanism of metallotropic transitions in the complexes (XXIXe) ($\pi-\pi$, $\sigma-\sigma$, or more complicated) will evidently be possible only after their "instantaneous" structure has been elucidated both in solution and in the crystal.

The preparation and the n.m.r. investigation of the derivatives $[C_7H_7Fe(CO)_3]^+$ and $C_7H_7Mn(CO)_3$ have been reported [16,219]. The low-temperature limiting spectrum of these compounds corresponds to the "frozen" structure (XXIXf) with anisochronous protons of the diastereotopic groups $a-d$. Degeneration of the spectrum into A_7 at higher temperatures indicates that the ligand nuclei become dynamically equivalent. The observed spectral changes are due to acceleration of $\pi-\pi$ transitions of the metal-containing group, but insufficient data are yet available for assessment of the more detailed mechanism of these transitions.

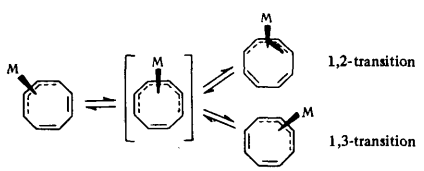
The largest number of papers are concerned with $\pi-\pi$ transitions in butadiene π-complexes (XXIXh) and (XXIXg), and much of the information on their dynamic behaviour has been obtained only during most recent years. The protons of the diastereotopic indicator groups ($a-d$ in XXIXg, and $a-c$ in XXIXh) are anisochronous at sufficiently low temperatures, but become isochronous at higher temperatures. The temperature dependence of the line form has been investigated experimentally, and the theoretical form of the line has been calculated for various lifetimes of the molecules in the "frozen" state.

The history of the d.n.m.r. study of the cyclo-octatetraene derivatives (XXIXg) is extremely dramatic. Originally it was known only that the protons of the cyclo-octatetraene ligand were isochronous in solutions of $\pi-C_8H_8Fe(CO)_3$ and similar compounds: the proton n.m.r. spectrum contained a narrow singlet independently of the choice of solvent or of solution temperature right down to $-60°C$. [230–232] As a result it was suggested that this ligand has a planar structure and that all its eight protons are equivalent (structure I: $n = 8$). [230,231,233] However, this hypothesis was not confirmed by a structural examination of $\pi-C_8H_8M(CO)_3$ molecules (M = Fe, [13] Ru [234]). Dickens and Lipscomb [13] found that, at least in the crystal, the $M(CO)_3$ group forms a π-bond with only one conjugated diene unit (structure XXIXg). These workers suggested that the equivalence of the protons of the $\pi-C_8H_8-M$ bond in a solution of the iron complex, in contrast to the crystal, was for the n.m.r. observer not static but dynamic in origin, and resulted from the rapid movement of the metal-containing group between several possible 1,3-diene positions. During 1966–1967 several groups of workers were able to reach sufficiently low temperatures to "freeze" the n.m.r. spectral pattern for both complexes and several related compounds [23,25,26,235–239]. The instantaneous structure of these compounds in solution was actually found to be identical with their structure in the crystal: as the temperature fell the spectrum of the π-cyclo-octatetraene ligand revealed four anisochronous indicator groups, corresponding to four types of diastereotopic nuclei in the ligand. Similar results have since been obtained in investigations of these and analogous derivatives of type (XXIXg) (M = Fe, Ru, Os) by proton [240–244] and carbon-13 [245] nuclear magnetic resonance. Evidence has also been obtained in support of the intramolecular character of the observed dynamics. For example, study of a solution of a mixture of cyclo-octatetraene and the complex $\pi-C_8H_8Fe(CO)_3$ at room temperature revealed no interaction between them: the ring protons of both compounds were anisochronous in the n.m.r. spectrum [231]. Finally, it has been found [246,247] that in these and related compounds $\pi-\pi$ dynamics is maintained even in the crystal. Only lowering the temperature of the crystal led to an (apparent) arrest of the process, i.e. to a decrease in the frequency of transitions to around 1 kHz (limit of sensitivity of the method employed).



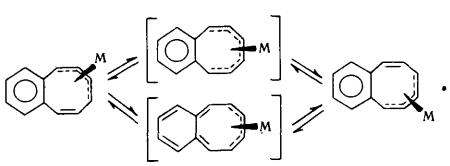
Consideration of the detailed mechanism of $\pi-\pi$ processes in π-cyclo-octatetraene derivatives (XXIXg) involves a choice [244] between several possibilities—1,2-, 1,3-, 1,4-, or 1,5-transitions (structures XXXc and XXXd)—with formation of a non-planar transition state or a $\pi-\pi$ transition via a planar transition state (I: $n = 8$) with a statistical distribution of products. Analogous mechanisms (XXXa, b) are suggested for the derivatives (XXIXh). [248] With 1,2- and 1,4-transitions (XXXa, c), of course, spatial displacement of the metal (if it occurs at all) must be accompanied by redistribution of the system of multiple bonds in the ligand (valency tautomerism), but with 1,3- and 1,5-transitions (XXXb, d) the bond system will be unchanged:

(XXXa) (XXXb) (XXXc) (XXXd)



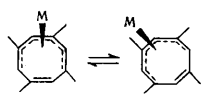
The experimental results are discussed on the basis of these possible mechanisms. Thus comparison of experimental and theoretical n.m.r. line forms indicates [244] that, in derivatives (XXIXg) of metals of the iron subgroup, both experimental and theoretical patterns are least consistent with 1,4- and 1,5-transitions, and also with the statistical mechanism involving the transition state (I: $n = 8$). The temperature dependence of the spectrum of $\pi-C_8H_8Ru(CO)_3$ led to the conclusion [237] that $\pi-\pi$ transitions

in systems such as (XXIXg) are effected by successive 1,2-shifts of the metal-containing group, and that a mechanism involving $\pi-\pi$ 1,3-transitions is unacceptable. A similar conclusion has been reached for compounds of type (XXIXh).[248] This is consistent with Anet's experimental results on the compound (XXXI),[236] which may in principle exist as very many structures, although contributions by structures other than (XXXIa, b) to the high-temperature spectrum are extremely small. Only two equivalent structures—(XXXIa) and (XXXIb)—are observed in the low-temperature boundary spectrum. Thus the intramolecular dynamics in this compound reduces to degenerate $\pi-\pi$ 1,2-transitions:



(XXXIa) (XXXIb) (22)

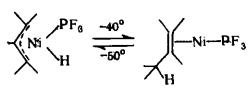
However, conclusions on 1,2-migration have since become somewhat less categorical. Thus the theoretical pattern of migration of the metal in π-$C_8H_8Ru(CO)_3$ agrees best with experiment only on the assumption of definite contamination of 1,2-transitions by a 1,3-type of mechanism[244]. On the other hand, study of the temperature dependence of the spectrum of π-$C_8H_8Os(CO)_3$ reveals several additional difficulties connected with the complexity of obtaining the theoretical n.m.r. line form for such multispin systems[243]:



(23)

It is probable that $\pi-\pi$ transitions in the derivatives (XXIXg) and (XXIXh) can be accomplished both by one of the suggested mechanisms (1,2-, 1,3-, 1,4-, and 1,5-transitions or the statistical mechanism) and by some other mechanism. For cyclo-octatetraene derivatives, in particular, mechanism (23) can be suggested as a hypothesis. Vibrations of the ring in the transition state would then be accompanied by an increase in the "connectedness" of the metal ($h^4 \rightarrow [h^6] \rightarrow h^4$), which allows for the objective result[244] that each step in the reaction involves formation of a mixture of 1,2- and 1,3-transition products. A mechanism with intermediate increase in the "connectedness" of the metal—as an alternative to a mechanism involving intermediate formation of a quinoid structure[249]—is useful in considering $\pi-\pi$ transitions of the tricarbonyliron group in benzo- and naphtho-cyclo-octatetraenes:

Stereochemical non-rigidity has been investigated[23,24,222,240,241,250,251] in the cyclo-octatetraene derivatives (XXIXi) of metals of the chromium and iron subgroups. However, the difficulties of interpreting the low-temperature boundary spectrum prevented sufficiently detailed information from being obtained on the mechanism of dynamics in the cyclo-octatetraene derivatives themselves[23,222]. These difficulties were overcome to a certain extent by using 1,3,5,7-tetramethylcyclo-octatetraene as ligand[24,251]. Over the range adjacent to the temperature at which the low-temperature boundary spectrum is observed the process is effected by 1,2-transitions:

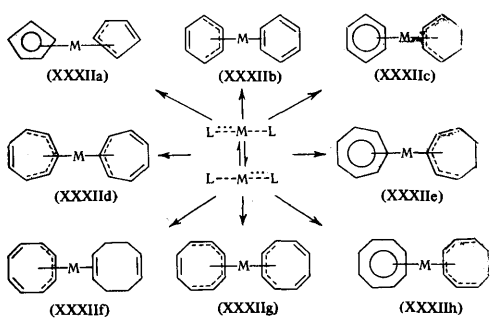


(24)

However, the spectral changes observed on further heating indicate that the process becomes more complicated. Under these conditions the stereochemical non-rigidity is probably due also to the formation in the transition state of the planar structure (I) with enhancement of "connectedness" ($h^6 \rightarrow [h^8] \rightarrow h^6$).

(*c*) $\pi-\pi$ Transitions accompanied by change in the "connectedness" of the metal in the metal–ligand fragment

Little study has yet been made of $\pi-\pi$ transitions of this type. An illustration is the reversible reaction



(25)

which has been investigated by n.m.r.[252] However, this reaction involves a $\sigma-\sigma$ transfer of a proton as well as a $\pi-\pi$ transfer of the metal, so that the composition of the metal–ligand fragment itself changes.

Scheme 8

Some types of π-complexes containing a $(\pi$-$C_nH_n)_2M$ fragment in which intercyclic $\pi-\pi$ transitions are fundamentally possible

(XXXIIa) (XXXIIb) (XXXIIc) (XXXIId) (XXXIIe) (XXXIIf) (XXXIIg) (XXXIIh)

A "purer" case of these processes is provided by degenerate intramolecular transitions of like ligands between non-equivalent states. Several types of complexes having $(\pi$-$C_nH_n)_2M$ as the main fragment are assembled systematically in Scheme 8. Dynamics of this kind can in principle occur in such compounds, provided that the variation in "connectedness" of each metal–ligand unit is produced by the "internal resources" of the other unit. Intercyclic $\pi-\pi$ exchanges are not yet known for rings containing an odd number of carbon atoms. Only one of the possible types of these reactions has been

investigated by n.m.r. for each of the "even" rings. Such reactions can in principle occur both in dicyclic compounds $(\pi\text{-}C_nH_n)_2M$ not containing any other ligands and in more complicated compounds—$(\pi\text{-}C_nH_n)_2MR$, $(\pi\text{-}C_nH_n)_2.MCO$, $(\pi\text{-}C_nH_n)_2MNO$, $(\pi\text{-}C_nH_n)_2M(CO)_2$, etc.

Structural data [253] indicate that one ring in the compound $(\pi\text{-}C_8H_8)_2Fe$ forms a diene π-bond, and the other a triene π-bond (structure XXXIIg). A d.n.m.r. investigation [240] suggests that, at temperatures below $-84°C$, the metal undergoes vigorous migration in the "diene" ring (all its protons are isochronous) and is "frozen" with respect to the triene ring (four types of protons are anisochronous). At higher temperatures the metal migrates rapidly inside both cyclo-octatetraene ligands—diene and triene (the protons in each of them become isochronous)— and above $-35°C$ the averaged signals due to the two rings coalesce into one. Thus cyclo-octatetraene ligands attached to an iron atom by unequal π-bonds exchange the types of bonds quite rapidly and entirely synchronously.

Similar conclusions follow from d.n.m.r. data on the ruthenium complex (XXXIIc). Two types of bonds—π-diene and π-arene—are present in the crystal [254]. Nevertheless, the temperature dependence of the n.m.r. spectrum of this complex reveals changes indicating the occurrence of quite rapid intercyclic $\pi-\pi$ transitions [255]. Finally, yet another type of dynamics, not shown in Scheme 8, has been observed in $(C_8H_8)_2M$ derivatives [256].

Molecular Complexes in the Liquid-phase Halogenation of Unsaturated Compounds

G.B.Sergeev, Yu.A.Serguchev, and V.V.Smirnov

Results on the halogenation of unsaturated compounds in the liquid phase are discussed. The possibility is examined that molecular complexes are involved in the polar, molecular, and radical mechanisms of addition. A list of 151 references is included.

I. INTRODUCTION

Reactions involving the addition of halogens at a multiple bond are important because of their wide distribution and their practical value. The electrophilic addition of halogens at a double bond was surveyed in a monograph[1]. A large amount of factual information has accumulated in recent years, and has been interpreted mainly on the basis of an ionic mechanism. Nevertheless, the existence of halogen–alkene molecular complexes and of complexes of halogens with several compounds used as solvents has been demonstrated experimentally. The role of such complexes in the mechanism of the halogenation of multiple bonds has not been finally established.

The Review analyses, mainly from an energetic point of view, the possibility that complexes are involved in polar, molecular, and radical mechanisms of the liquid-phase halogenation of unsaturated compounds.

The view that carbonium ions of varied structures were reaction intermediates was based on the work of Francis[2] and Roberts and Kimball[3]. The importance of the role of donor–acceptor interactions in reaction mechanisms was noted by Shilov[4,5]. Dewar developed the concept of π-complexes[6]. The theory of charge-transfer complexes was formulated by Mulliken[7].

The structure, physicochemical properties, and methods of studying molecular complexes in systems in which no appreciable chemical reaction is occurring have been

discussed in monographs [8-10]. The formation of halogen–alkene complexes is accompanied by a chemical change in the components, and therefore is especially interesting. The role of molecular complexes in the halogenation of unsaturated compounds has been partly considered in reviews [5,11-13].

II. MOLECULAR COMPLEXES OF HALOGENS WITH ALKENES

Molecular complexes of halogens with alkenes have been investigated mainly spectrophotometrically [14-18]. Charge-transfer bands appear in the spectra when halogens (acceptors) interact with alkenes (donors). The complexes absorb in the range 240–320 nm in the ultraviolet. The charge-transfer band $h\nu$ is related to the ionisation potential I_V of the alkenes by the equations [15] $h\nu(Br_2) = 0.69I_V - 2.09$ and $h\nu(Cl_2) = 0.51I_V + 0.03$.

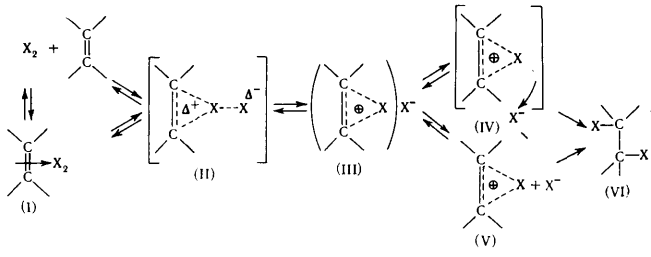
Inadequate study has been made of the complexes of halogens with alkenes, owing to the experimental difficulties involved in investigations in the reacting systems. Table 1 summarises experimental results on the thermodynamic functions of the complexes of reactive alkenes with halogens. Data have been published also on the complexes of cyclohexene with iodine bromide ($\Delta H = -7.5$ kcal mole^{-1} and $K_C^{298°} = 2.2$ M^{-1}) [16] and of hex-1-ene with iodine chloride (-1.5 kcal mole^{-1} and 2.0 M^{-1}) [19].

Table 1 shows that halogens form weak complexes with alkenes, characterised by low equilibrium constants ($K_C < 1$) and enthalpies of formation ($|\Delta H| < 5$ kcal mole^{-1}). The latter values are comparable with the activation energies of many halogenations of alkenes, and may make an appreciable contribution to the energetics of the process.

Table 2 lists data on the structural and physicochemical properties of the halogens.

Scheme 1 shows the mechanism of the reaction of halogens with alkenes [12]. Initially an internal ion-pair, analogous to Dewar's π-complexes [6] or to σ-complexes in aromatic substitution [23], is formed from a labile halogen–alkene π-complex or directly from the original molecules. This complex then rearranges into the reaction products or else breaks down into solvated ions, whose interaction results in formation of the product. In the termolecular reactions characteristic of the addition of bromine and iodine the anion X^- is replaced by X_3^-. The rate of the reaction is governed by the passage of the system through the transition states (II) (ionisation) and (IV) (separation or migration of the ions in the ion-pair).



Let us examine the rôle of halogen–alkene complexes (I) in formation of the transition state (II) under conditions such that the contribution by solvation effects can be neglected. This transition state (II) may be established both by collision of activated X_2 molecules with the unsaturated compound and by charge redistribution in the molecular complex (I). The latter follows from a comparison of structures (I) and (II).

Table 2. Some physicochemical properties of halogens [21,22].

Mol.	Internuclear distance, Å	Anionic radius, Å	Dissociation energy at 298°K, kcal mole^{-1}	Electron affinity	
				mol., eV	atom, eV
I_2	2.667	2.20	36.1	2.4	3.29
Br_2	2.283	1.81	46.1	2.6	3.54
Cl_2	1.998	1.06	57.9	1.70	3.76
ClI	2.321	—	50.5	—	—
BrI	—	—	42.5	—	—

Changes occur mainly in two distances—from the halogen molecule to the centre of the double bond r_{C-X} and between the nuclei in the halogen—as the molecule approaches the double bond with formation of an ion-pair.

Scheme 1.

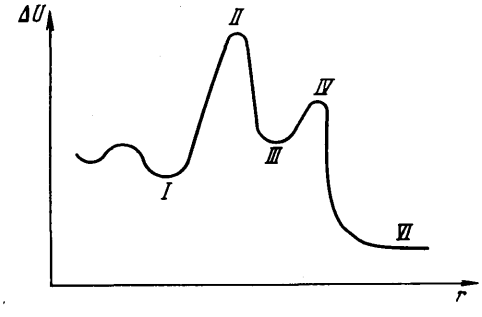


Figure 1. Variation in potential energy along reaction path of heterolytic halogenation.

The former distance r_{C-X} changes from infinity to the halogen–double bond distance in the carbonium ion. The internuclear distance X–X in the bromine molecule, for example, is < 2.3 Å. The X–X distance in the ion-pair can be estimated as the sum of the radii of the negative

ion and of the uncharged atom. For bromine this sum is 3.1 Å, which exceeds the internuclear distance in the molecule by 0.8 Å. Since these distances are the chief variables on formation of an ion-pair, the potential-energy surface of the system can be plotted with r_{C-X} and r_{X-X} as coordinates. The distance r_{C-X} is shorter in the complex than in the initial molecules. X-Ray diffraction has established that the formation of complexes involving halogens leads to some increase in the internuclear distances in the latter molecules[24,25]. Thus

$$(r_{X-X})_{init} < (r_{X-X})_{complex} < (r_{X-X})_{transn.\ state},$$

$$(r_{C-X})_{init} \gg (r_{C-X})_{complex} > (r_{C-X})_{transn.\ state}.$$

Hence the π-complex lies on the reaction path between the initial molecules and the transition state. It can be shown similarly that the σ-complex (internal ion-pair III) also lies on the reaction path between (II) and (IV).

Thus application of the transition-state theory to polar halogenation indicates that halogen-alkene complexes may be involved as intermediate species. Fig. 1 illustrates the variation in the potential energy along the reaction path.

III. POLAR MECHANISM

The energy barriers at individual stages in Scheme 1 can be estimated by means of a model involving electrostatic interactions.

The potential barrier (II) in Scheme 1 is connected with ionisation of the molecular complex. This process is analogous to complete electron transfer from donor to acceptor with energy equal to the difference between the ionisation potential of the donor and the electron affinity of the acceptor. The energy of Coulombic attraction between the oppositely charged ions is gained.

Formation of a bridging halogenonium cation of the type

is accompanied by partial dehybridisation of the double-bonded carbon atoms and the appearance of incompletely covalent C–X bonds. Quantum-mechanical calculation of the relative stabilities of ions differing in structure enables the contribution of these two factors to be estimated[26]. With ethylene, chloronium and bromonium bridges are more stable than the corresponding classical carbonium ions of type

by 28.4 and 26 kcal mole^{-1} respectively. The carbonium ion involves complete rupture of the double bond and formation of a C–X bond, and the heat of reaction can be estimated as the difference between the corresponding energy changes. Adding 28.4 or 26 kcal mole^{-1} to the result yields the stabilisation energy of the ion E_{st} due to formation of new bonds. Depending on the alkene E_{st} = 45–49 and 31–35 kcal mole^{-1} for chlorine and bromine respectively. On the assumption that an iodonium bridge is 20 kcal mole^{-1} more stable than the open system we obtain $E_{st} \simeq 7$–11 kcal mole^{-1}.

Thus the energy of the system during conversion of the π-complex into an ion-pair is described by the formula

$$U = e(I - E_x) - \sum_{ij} \frac{e_i e_j}{r_{ij}} - E_{st} \qquad (1)$$

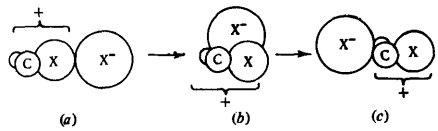
where I is the ionisation potential of the donor, E_X the electron affinity of the acceptor, r_{ij} the distance between the centres of i and j atoms bearing charges e_i and e_j respectively, $e = \Sigma e_i$ the total transferred charge, and E_{st} the stabilisation energy of the carbonium cation, which depends on the fraction of the charge transferred. Quantum-mechanical calculation of the structures of ethylene–chloronium and ethylene–bromonium cations shows that up to 30–40% of unit positive charge is concentrated on the halogen atom[26,27]. Hence the charge is uniformly distributed among all the vertices of the triangle. Calculations indicate[26] that the radius of the halogen atom in the cation can be regarded as equal to its covalent radius. Formula (1) can be used to estimate the heat of transition of the complex into the ionised state. In the series of complexes of chlorine, bromine, and iodine with ethylene, hex-1-ene, and cyclohexene the iodine–ethylene ion-pair had the largest heat of formation, and chlorine–cyclohexene the smallest (110 and 30 kcal mole^{-1} respectively).

The heat absorbed on complete charge transfer is not necessarily identical with the activation energy. The first term in Eqn. (1) varies linearly with the amount of charge transferred, and the second term is a quadratic function, so that $U(e_i, r_i)$ may reach a maximum even with incomplete charge transfer. This implies that partial transfer of the electronic charge may prove sufficient in the reactive systems, and further charge separation requires no further energy consumption, but occurs readily as a spontaneous process. The degree of charge transfer at which the potential energy reaches a maximum can be estimated by means of Eqn. (1). If we suppose that internuclear distances cease to depend on the degree of ionisation at charge transfers exceeding $0.5e$, we can then find the value of x corresponding to U_{max} from the condition for a maximum $dU/dx = 0$ (where x is the degree of transfer).

Table 3. Activation energies (kcal mole^{-1}) of formation of ion-pairs.

Alkene	Halogen		
	Cl	Br	I
Ethylene	69	73	110
Hex-1-ene	48	50	84
Cyclohexene	39	40	70

Specific values for I, E_X, E_{st}, and r_{ii} yield values for x_{max} from 0.6–0.7 (cyclohexene and hexene with chlorine) to 1.0 (systems containing iodine and ethylene–bromine). From the values of x_{max} we can calculate U_{max}, i.e. the activation energy of formation of ion-pairs. The results listed in Table 3 exceed those obtained on the basis of a four-membered transition state and the postulate that formation of a hemi-ionic pair is sufficient for reaction[28]. The values in Table 3 give the correct sequence of reactivity for the halogens $Cl_2 > Br_2 \gg I_2$,[1] whereas the opposite sequence was obtained in Ref. 28.



Considering now the probable structure and energetics of the σ-complex, we note that an ion-pair with a linear arrangement of the atoms

$$\overset{\oplus}{>}X....X^-$$

is in a state of unstable equilibrium. Any displacement of

the anion X^- from the plane of the cyclic cation in the direction of the double bond involves a gain in energy. In the stable state of the ion-pair the halide anion is situated above the plane of the carbonium cation, the C–X and X–X distances being minima (Scheme 2).

Scheme 2.

Structure (*b*) is also a σ-complex, the gain in energy on its formation from the unstable ion-pair (*a*) being the depth of the potential well (III) in Fig. 1). To estimate this gain we assume that the radii of atoms and ions in (*a*) and (*b*) are identical. Calculation of the energy of electrostatic attraction in (*b*) shows that (*a*) and (*b*) differ in energy by 38–42 kcal mole^{-1} for all the halogens.

In the last stage of the reaction the anion X^- again passes into the plane of the carbonium cation, but from the side opposite to the second atom (structure *c*). The height of the potential barrier to the transition (*b*) → (*c*) can be estimated as the difference between the Coulombic energies of attraction. Calculation shows it to be small, from 8 to 12 kcal mole^{-1} for iodine and chlorine respectively. Hence it may be expected that the σ-complex will pass readily into the product. The situation is different if this change is impeded, e.g. by steric hindrance. In fact stable complexes, having the character of internal ion-pairs, are formed by the interaction of bromine with sterically hindered alkenes at −78°C [29]. The above estimates show that the limiting step in the reaction is ionisation of the π-complex with formation of an ion-pair (σ-complex).

Table 4. Calculated activation energies (kcal mole^{-1}) in solutions.

Dielectric constant of solvent	Reactants								
	ethylene			hex-1-ene			cyclohexene		
	Cl_2	Br_2	I_2	Cl_2	Br_2	I_2	Cl_2	Br_2	I_2
2.2	39	40	64	28	28	47	22	22	38
4.5	33	35	54	24	25	38	19	20	33
8.0	31	31	51	22	23	36	16	18	30
20.0	28	28	49	18	20	34	15	16	28

1. Effect of Non-specific Solvation on Reaction Velocity

When a polar reaction takes place in a solvent of dielectric constant ε and incapable of specific solvation either of the starting materials or of the transition state, the ion-pair can be regarded as a dipole, and its energy of non-specific solvation can be estimated by means of Kirkwood's formula. We assume that the length of the dipole is the distance between the centre of the anion and the geometric centre in the carbonium cation. The radius of the dipole is the mean of the dimensions of the ion-pair parallel and perpendicular to the axis of the dipole. Solvation energies may reach several tens of kilocalories. Thus the consumption of energy required for ionisation should be appreciably smaller in the liquid phase than in the gas. The potential energy reaches its maximum value with incomplete charge transfer, as in the gas phase. We can find U_{max} by adding in Eqn. (1) a solvation term calculated by means of Kirkwood's formula. The estimated activation energies are given in Table 4.

In sufficiently polar solvents the difference between the activation energies of (*a*) and (*b*) (Scheme 2) plays no appreciable part, and the potential barrier (IV) should not be very high. Traversing the barrier, the reaction system forms the product by continuous passage of the halide anion to the side of the double bond opposite that on which the second X atom is located. Fig. 2 shows the change in the potential-energy profile on passing from the gas phase to a solvent having ε = 8 (for the reaction of chlorine with hex-1-ene). The activation energies for bimolecular polar reactions should be a few tens and 10–20 kcal mole^{-1} in media of low and high dielectric constant respectively.

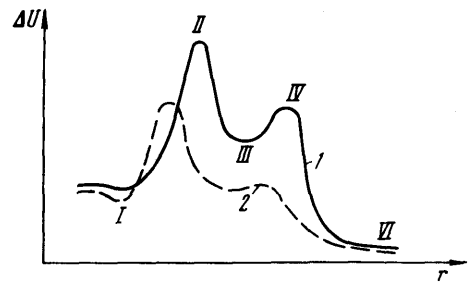


Figure 2. Variation of potential energy along reaction path of hex-1-ene with chlorine in: 1) gas phase; 2) solvent of dielectric constant 8.

The polar character of transition states and intermediate species in halogenation has been confirmed for several alkenes in various solvents by measuring the electrical conductivity during bromination [30]. The conductivity is determined by the degree of charge separation established in the alkene–halogen system. The effect of the solvent varies in parallel with its dielectric constant and its ability to solvate polar and ionic species. Alkenes form a sequence according to their reactivity towards bromination. The conductivity is small in carbon tetrachloride, phenyl bromide, and chloroform, which indicates the absence of ionic states.

The rate of bromination of pent-1-ene has been investigated in water, alcohols, acetic acid, dioxan, Freon, aqueous methanol, and other solvents [31,32]. The second-order rate constant varies widely, from 0.07 to 1.5×10^{-9} M^{-1} min^{-1} in Freon-113 and water respectively. It increases with the dielectric constant of the medium, and is given by the equation $\lg k = 5.40 - 1.164 \lg (k_S/k_0)$, where k_S and k_0 are the solvolysis rate constants for t-butyl chloride at 25°C in the given solvent and in 80% aqueous ethanol respectively.

A qualitative correspondence between the rate constant and the dielectric constant of the medium has been established[33] for the bromination of octene, vinyl acetate, and certain other unsaturated compounds. Direct proportionality of the rate constant to the dielectric constant of the medium was observed also in the chlorination of 3-chloro-1-phenylprop-1-ene in benzene to which more polar solvents had been added[34]. Rates of bromination in a 70:30 methanol–water mixture at 25°C may vary by factors of $\sim 10^4$ depending on the structure of the unsaturated molecule. On passing to methanol itself the rate falls roughly equally for all alkenes, in conformity with the equation $\lg k_{mixt} = 2.6 + 0.9 \lg k_{CH_3OH}$, which suggests that the reaction mechanism remains unchanged[35].

No systematic study has been made of the effect of the dielectric constant of the medium on the activation energy of halogenation. In the bromination of certain aliphatic alkenes in water E_{act} = 8–11 kcal mole^{-1}.[36] The activation energy for the bromination of 1,3-alkenynes in acetic acid varies from 3 to 8.5 kcal mole^{-1}.[37] The bromination of styrene in acetic acid has activation enthalpies of 8–11 kcal mole^{-1} and negative entropies of activation of 27–33 kcal mole^{-1} deg^{-1}.[38] The bimolecular bromination of cinnamic acid in methanol has an activation energy of 9.2 kcal mole^{-1},[39] and 6.1 kcal mole^{-1} is required for the bromination of allyl acetate in acetic acid[40]. The activation energy for the bromination of various alkenes in methanol varies from 7 to 11 kcal mole^{-1}.[41] The activation energies for the chlorination of allyltrimethylammonium perchlorate and 2,3-dichloropropene in acetic acid are 7.4 and 11.2 kcal mole^{-1} respectively[42].

Thus activation energies in polar media vary in the range 5–15 kcal mole^{-1}. This corresponds to the above estimates for a polar mechanism with the rate constant depending on the polarity of the medium.

The ionisation potential is a component of the activation energy and, according to the reaction mechanism assumed (Scheme 1), determines the reactivity of the alkene in the polar medium. A linear dependence of the logarithm of the rate constant on the ionisation potential may be expected in polar media.

2. Dependence of Reaction Velocity on Structure of Alkene

The dependence of the rate of bromination on the structure of the alkene is summarised in the form of correlation equations. Those containing the Taft σ^* [43] and Brown σ^+ [44] parameters are of the form (Table 5)

$$\lg k = \rho \sum \sigma + \text{const}. \qquad (2)$$

A term proportional to the sum of the steric parameters ΣE_S is sometimes detached from the constant in Eqn. (2)[46,47].

Table 5 shows that the parameters ρ have negative values typical of electrophilic reactions. These yield certain conclusions as to the structure of the transition state. Large negative values of ρ probably indicate considerable separation of charges in the transition state with polar solvents. The rate of bromination of tetrasubstituted alkenes correlates with the sum of the Taft σ^* parameters. This suggests that the positive charge in the transition state is uniformly distributed between the two carbon atoms, so that bromination of these compounds involves an intermediate structure of the bridged cation type[46]. As the agent becomes less electrophilic, e.g. on passing from Br_2 to Br_3^-, the value of ρ decreases. The corresponding values for the bromination of substituted stilbenes in acetic acid are −4.21 and −2.02.[52] Correlation equations for chlorination have been obtained only in Ref. 54.

Correlation equations have been published also linking the reaction velocity with parameters other than σ. A linear relation has been found between Γ, representing the electrostatic energy of the halogen–alkene complex in the excited state, and the rate constant for bromination in water: $\Gamma = b + a \lg k_2$.[15] The parameter Γ in turn correlates with the ionisation potential of the alkene: e.g. for bromine complexes $\Gamma = 0.31 I_V + b'$.

Table 5. Correlation equations for liquid-phase polar halogenations.

Alkenes	Halogenating agent	Solvent	Equation	Ref.
RCH = CHR′R″ (R, R′, R″ = alk)	Br_2	MeOH	$\lg k = -5.299\,\Sigma\sigma^* + 0.914\,\Sigma E_s + 7.414$	45
RR′C=CR″R‴ (R, R′, R″, R‴ — Alk)	Br_2	MeOH	$\lg k = -5.221\,\Sigma\sigma^* + 0.896\,\Sigma E_s + 7.381$	46
$CH_2 = CH - CH_2X$ (x = Alk, OH^-, Ph, Cl)	Br_2	MeOH	$\lg k = -3.10\,\Sigma\sigma^* + 8.8$	47
$CH_2 = CH - CHXX'$ (X,X′ = Alk)	Br_2	MeOH	$\lg k = -2.99\,\Sigma\sigma^* + 7.61$	48
(X,X′ — CH_2OH, CH_2Cl, CH_2OEt)	Br_2	0.2 M NaBr	$\lg k = -2.4\,\Sigma\sigma^* + \text{const}$	50
$X - C_6H_4 - CH = CH_2$ (X = Various solvents)	Br_2	ditto	$\lg k = -4.3\,\Sigma\sigma^* + \text{const}$	49
(X = Hal, NO_2)	Br_2	MeCOOH	$\lg k = -4.71\,\Sigma\sigma^* + \text{const}$	53
(X = Hal, NO_2)	Br_2	MeCOOH	$\lg k = -4.21\,\Sigma\sigma^* + \text{const}$	52
(X = Hal, NO_2)	Br_3^-	MeCOOH	$\lg k = -2.02\,\Sigma\sigma^* + \text{const}$	52
$R - C_6H_4 - CH = CH - Ph$ (R = Acceptor)	Br_2	MeOH 0.2 M NaBr	$\lg k = -1.53\,\Sigma\sigma^+ + \text{const}$	51
(R = Donor)	Br_2	ditto	$\lg k = -5.05\,\Sigma\sigma^+ + \text{const}$	51
$CH_2 = CH - C \equiv C - R$ (R = Alk)	Br_2	MeCOOH	$\lg k = -1.35\,\Sigma\sigma^* + \text{const}$	37
$X - C_6H_4 - C \equiv CH$	Br_2	MeCOOH	$\lg k = -5.17\,\Sigma\sigma^+ + \text{const}$	40
RR′C = CH — COOH	Cl_2	MeCOOH	$\lg k = -5.5\,\Sigma\sigma^+ + \text{const}$	54
$R - C_6H_4 - CH = CH -$ —COOH	Cl_2	MeCOOH	$\lg k = -3.9\,\Sigma\sigma^+ + \text{const}$	54

A linear relation has been established also between this parameter and $\Sigma\sigma^*$.[55] If two quantities are linearly related to a third, the relation between them is also linear. The application of this principle to the linear relationships involving free energy was discussed in Pal'm's monograph[56]. In the case of halogenation the principle implies that the above correlation equations represent the dependence of the rate of reaction on the ionisation potential of the alkene. The ionisation potential in turn determines the properties of the halogen–alkene molecular complexes. In this sense the correlation equations in Table 5 can be regarded as indicating a connection between reaction velocity and the properties of the complex.

3. Halogenating Agents in Polar Media

The reactivity of the halogens increases in the sequence $I_2 < Br_2 < Cl_2$. This differs from the sequence of increasing electron affinity (Table 2) and also from that of the increase in acid strength of the halogens ($I_2 > Br_2 > Cl_2$). Table 6 lists parameters representing the acidity of the halogens—free energies of formation of the corresponding trihalide ions ΔG, [57] the $X^- + X_2 \rightleftharpoons X_3^-$ equilibrium constants $K_{eq}(X_3^-)$ in sulpholan [58], and the equilibrium constants for forming the molecular complexes with benzene $K_{eq}(C_6H_6X_2)$. [59]

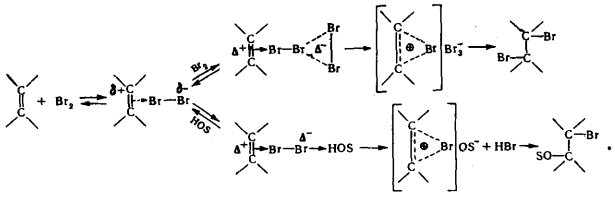

Table 6. Acidity parameters of halogens [57-59].

Hal	$-\Delta G$, kcal mole^{-1}	$K_{eq}(X_3^-)$ in sulpholan, M^{-1}	$K_{eq}(C_6H_6X_2)$, mole fractions
I_2	3.89	$10^{7.4}$	1.72
Br_2	1.67	$10^{3.8}$	1.04
Cl_2	−2.70	$10^{3.1}$	0.33

The reactivity sequence of the halogens can be explained by the participation of their cations in the reaction. The latter become more strongly electrophilic on passing from iodine to bromine and then to chlorine. The view has hitherto been held that X^+ ions act as halogenating agents in the reaction [60], but kinetic investigations have made the existence of such species improbable [61,62]. This conclusion is supported by a review on halogen cations [63]. Only cations of composition from X_2^+ to X_7^+ can exist in strongly acid media. Thus, in the absence of external additions, the only possible halogenating agents are the halogen molecules.

The reactivity of a halogen is determined by its electron affinity and molecular size. Increase in the latter weakens the Coulombic forces of attraction and prevents solvation of the transition state. The most favourable combination of these factors (Table 4) occurs with chlorine, and the least favourable with iodine. These conclusions are consistent with the observed reactivity sequence of the halogens.

The non-radical liquid-phase addition of chlorine is described by a second-order kinetic equation. Bromination in water and in methanol is also represented by a bimolecular equation, but in acetic acid third-order kinetics is observed. A termolecular equation applies in less polar media. Iodination in the absence of catalysts has a total order of three or four [1,64]. With chlorine reaction takes place readily in polar media by a simple bimolecular scheme, and does not require the action of a third particle. With bromine and especially iodine a second halogen molecule or a molecule of a hydroxylated solvent HOS is required. The gain in energy due to delocalisation of the negative charge on these particles lowers the activation energy and facilitates the reaction:

Addition of halide and other anions promotes the reactions in polar media [1]. Shilov's explanation [65] of anionic catalysis and of the action of nucleophilic solvent molecules is that the termolecular donor–acceptor mechanism involves halogenation via a transition complex in which the unsaturated molecule is subjected simultaneously to the action of electrophilic and nucleophilic reagents. The mechanism is represented by the general scheme $D \rightarrow (M \rightarrow A)$, where $(M \rightarrow A)$ is the donor–acceptor complex of unsaturated compound and acceptor (halogen) molecule, while D is an electron-donor. The transition state in the chlorination of ethylene in the presence of the chloride ion is

The simultaneous addition and removal of a chloride ion lowers the activation energy: the energy consumed in rupturing the Cl–Cl bond is balanced by the energy of formation of the C–Cl bond (Table 7).

Table 7. Activation energies for the chlorination and bromination of unsaturated compounds in acetic acid containing added lithium chloride.

Reactant	Trimethylammonium perchlorate with chlorine (Ref.42)		2,3-Dimethylpent-2-en-4-yne with bromine (Ref.66)		
LiCl, M	0	0.1	0	0.01	0.05
E_{act}, kcal mole^{-1}	7.3	4.9	7.16	6.69	5.53

The involvement of halide anions as component of the halogenating agent changes the rate law [42]. For chlorination in the presence of the chloride ion we have $W = k_3[Un][Cl_2][Cl^-]$ where Un is the unsaturated compound. Analogous equations have been established for bromination [1] and iodination [67].

Acceleration of the reaction in the presence of salts is a general feature of chlorination, and the catalytic strength of the anions is independent of their nucleophilic character [42]. The iodination of allyl alcohol in water exhibited the sequence $I^- > CNS^- > Br^- > Cl^-$. [67] Bromination is also accelerated by the addition of anions with the exception of the bromide ion, which sometimes accelerates but at other times slows down the reaction. The latter effect is explained by the binding of bromine into the tribromide anion, which is less strongly electrophilic than the free molecule. In the bromination of *trans*-stilbene in methanol the reactivity of free bromine exceeds that of the tribromide ion by a factor of 43 [68]. The ratio of their reactivities towards brominated alkenes under the same conditions varies from 5.7 to 25. [69] The activation energy for the bromination of 1,3-alkenynes is significantly higher with the tribromide ion than with molecular bromine [37]. Whereas the addition of bromide ions lowers the rate of the process with reactive alkenes, a catalytic effect is more characteristic of relatively unreactive alkenes [52,70,71]. In the bromination of several alkenes of reactivity varying by a factor of 10^7 correlations enabled anion catalysis by the bromide ion with unreactive alkenes to be separated

from inhibition of reaction due to formation of the tribromide ion with highly reactive unsaturated compounds [72]. Inhibition of chlorination by the chloride ion could not be observed because of the small equilibrium formation constant of the trichloride ion (Table 6). Thus a mechanism of polar halogenation allowing for termolecular donor–acceptor interaction provides a good explanation of the reactivities of different halogenating agents.

4. Products of Polar Halogenation

Three types of compounds—dihalides, mixed adducts (reaction involving the solvent), and monohalides (substitution)—are formed by the reaction of halogens with alkenes in polar media. Data on the composition and yields of substitution products obtained by halogenation, covering the period to 1965, were assembled in an exhaustive review by Bodrikov and Smolyan [73]. Bodrikov and his coworkers then studied the dependence of the yield and rate of formation of anomalous halogenation products on the nature of the alkene and the halogen, the temperature, the nature of the solvent, and other factors [74–77]. It was found in particular that the ratio of addition to substitution depended on the degree of charge separation in the polar transition state.

The tendency to form *trans*-dihalides falls in the sequence $I_2 > Br_2 > Cl_2$. The addition of bromine to *cis*-1-phenylpropene yields mainly the *trans*-dibromide, whereas chlorine forms a mixture of nearly equal quantities of *cis*- and *trans*-addition products [78]. The bromination of acenaphthene and phenanthrene produces the *trans*-dihalides [79,80]; chlorination gives a substantial quantity of the *cis*-adduct together with the *trans*-isomer [79,81]. Such variation is explained in terms of polar addition by the stronger tendency of bromine to form bridged structures in the cation [26]. Furthermore, the large size of iodine and bromine atoms may prevent formation of the *cis*-isomers.

Table 8. Effect of solvent on stereospecificity of bromination.

Solvnet	CCl_4	CS_2	MeCOOH	CH_2Cl_2	CCl_3COOMe	PhCN	CCl_3CN	$PhNO_2$	MeCN	H_2O
Dielectric constant ε	2.2	2.2	6.2	9.1	—	25.2	—	34.8	37.5	78.5
Percentage of *trans*-dibromide on bromination of *cis*-stilbene (Ref.88)	100	90	50	50	—	40	—	10	30	20
trans-stilbene (Ref.89)	77	31.4	—	—	51	34	34	29.5	—	—

The structure of intermediate species and of the transition state—and hence the stereochemistry of the products—depend on the nature of the unsaturated compound. Bridged structures and hence *trans*-dihalides are most probable with aliphatic alkenes. In fact the chlorination of butenes and allyl chloride in non-polar media [82] and in acetic acid [83] and the bromination of but-2-enes in acetic acid [84] are *trans*-stereospecific. Quantum-mechanical calculations show that an open carbonium ion structure is more probable for alkenes having aromatic substituents [27,85], in which stereospecificity may break down owing to stabilisation of the localised charge in the open carbonium ion. Mixtures of *cis*- and *trans*-dihalides are obtained in the chlorination of stilbenes in dichloroethane [86] and in chloroform [87], in the chlorination of 1-phenylpropenes [78], and in the bromination of substituted styrenes in acetic acid [84].

A polar mechanism provides an explanation also of the dependence of the stereochemistry of the halogenation products on the nature of the solvent. Table 8 shows that the *trans*-stereospecificity of bromination diminishes as the solvent becomes more polar. A polar solvent favours separation of charges and stabilisation of the open carbonium ion, since the energy of solvation of the latter is greater than that of the bridged structure. This leads to a decrease in the proportion of *trans*-addition.

Specific solvation may change the stereochemistry of the addition products. Thus the bromination of *cis*-β-methylstyrene in dioxan gives 80% of the *cis*-dibromide as a result of stabilisation of the unsymmetrical structure in the ion-pair by dioxan [90]. The chlorination of diphenylacetylene in benzene–pyridine mixtures yields solely *cis*-dichlorostilbene, which is explained by the cyclic structure of the transition state [91].

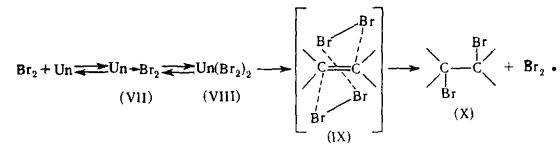
Table 9. Effect of solvent on relative yield of mixed chlorination products.

Solvent	ε	Ratio of yields of mixed products to dichlorides					
		pent-2-ene (Ref.92)		pent-1-ene (Ref.92)	1-phenylpropene (Ref.83)		methyl vinylacetate (Ref.93)
		cis	*trans*		*cis*	*trans*	
H_2O	78.5	—	—	—	—	—	Mixed product ∞ only
HCOOH	57.9	3.6	1.6	3.4	—	—	—
MeOH	32	10.7	5.4	11.2	4.9	4.9	—
EtOH	26.4	4.3	2.3	3.9	—	—	—
BuOH	12.3	1.0	0.45	1.4	—	—	—
CF_3COOH	8.2	0.2	0.095	0.2	—	—	0.25
MeCOOH	6.2	0.87	0.3	0.85	0.48	0.43	2.34

Halogenation results in mixed adducts when dissociated solvents (water, methanol, acetic acid) and anions of added salts are involved. Table 9 shows that the yield of mixed adducts is strongly dependent on the solvent. The quantity of mixed adducts does not correlate with the dielectric constant, and only qualitative dependence of the yield on the nucleophilic strength of the solvent is observed. It is difficult to interpret the combined effect of these two properties of the solvent. The yield of mixed products obtained by the chlorination of several unsaturated compounds [92,93] and substituted cinnamic esters [94] in acetic acid increases as the unsaturated component becomes less reactive.

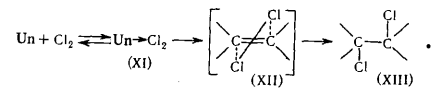
According Shilov's views [5] a third component (solvent or added anion) will have an insignificant effect on the reaction if the transition state approaches an ion-pair in character. On the other hand, the less ionised the transition state the more significant the effect of the third component. In polar halogenation energy is consumed mainly in converting the π-complex into an ionised state, and in this case the involvement of a donor component, e.g. an anion, is less significant. In conformity with this,

in the presence of 1 M lithium chloride the yield of *trans*-dichloride increases in parallel with the decrease in reactivity of the double bond[94]. The predominant formation of *trans*-isomers with mixed products is connected with the synchronous action of acceptor (halogen molecule) and donor (solvent or anion) on the multiple bond. Thus kinetic examination based on the effect of non-specific solvation, the structure of the alkene, the nature of halogenating agents and third components, and also the composition of the products shows that a mechanism involving molecular complexes provides a good description of aspects of the halogenation of unsaturated compounds in polar media.



IV. MOLECULAR MECHANISM

On passing from polar to non-polar solvents the composition of the products and the kinetics of the reaction change. We must therefore examine in greater detail the mechanism of halogenation in non-polar media.



If we assume that a polar mechanism is feasible even in media of low dielectric constant, we would then expect a similar strong dependence on the structure of the alkene, since the energy barrier to a polar reaction is a linear function of the ionisation potential of the alkene. However, the rates of bromination of cyclohexene and hex-1-ene differ by a factor of 27 in methanol methanol[42], but only 4 in carbon tetrachloride[19]. The weakening of the dependence of the rate on the structure of the unsaturated compound leads to a decrease in the values of ρ in the correlation equations for non-polar media: the slope is a few negative units (Table 5) for polar media, but −0.67 for carbon tetrachloride[95]. The observed difference is inconsistent with the view that the same mechanism operates in the two cases.

A wide range of reactions in non-polar media have negative activation energies[19,96-101]: the observed values for several alkenes vary from zero to −10 kcal mole^{-1}. On the assumption that the reaction has a polar mechanism the energy barrier should be higher in such solvents as hexane and carbon tetrachloride than in polar media, but this is contradicted by experiment.

It is supposed that the bromination of ethylenic compounds can take place without the intermediate formation of ionic or strongly polar compounds[102]. Two halogen molecules and one alkene molecule are assumed to form a 2:1 complex, which can rearrange into a non-polar six-membered ring containing 4 Br + 2 C. Constructing molecular models shows that such a ring can be formed without significant distortion of the C=C and Br—Br bond lengths. Carbon and bromine atoms approach one another until relatively close to the C—Br covalent bond length, and bromine atoms from different molecules to distances close to the Br—Br bond length in the Br_2 molecule. The dibromide is formed by simultaneous rupture of two Br—Br bonds and formation of two C—Br bonds together with a new Br—Br molecule. The energy of rupture of the bonds is immediately balanced by the energy evolved on formation of the new bonds. The overall process of bromination is exothermic, so that formation of the product does not require the consumption of energy. The free-energy barrier is determined by the entropy term. If the solvent is disregarded, the hypothetical transition state contains three oriented reactant molecules, and several degrees of freedom are eliminated, so that the transition state has a large negative entropy. The product is formed from the complex by simultaneous rupture and formation of bonds. Such a reaction mechanism can be termed molecular, and represented in general by the scheme

Such a mechanism is impossible for chlorination, and the size of the chlorine molecule does not ensure formation of a structure (IX): the Cl—Cl distances in a structure similar to (IX) are so large that formation of a new chlorine molecule simultaneously with the rupture of old bonds and the formation of C—Cl bonds is not feasible. However, direct rearrangement of the complex (XI) into the reaction product is possible during chlorination:

Since the suggested chlorination transition state contains only two molecules, and its structure is less rigid than that of (IX), a lower entropy of activation and a higher rate must be expected than with bromination.

The ultraviolet spectra of mixtures of bromine with cyclohexene indicate the existence of a 2:1 complex[103], which has been demonstrated also by low-temperature infrared spectroscopy[104]. When a mixture of bromine and cyclohexene vapours is sprayed as a molecular beam on to a surface cooled in liquid nitrogen, bands due to vibrations of the double bond in 1:1 and 2:1 complexes are observed on a background of a weak band due to deformation vibration of this bond. The composition of the complexes was proved by studying the dependence of absorption on the ratio of the reactants. The displacement of the band due to the double bond is greater in the 2:1 than in the 1:1 complex, and the former has a larger heat of formation. Solid-phase conversion of the 2:1 complex into a dibromoalkane was observed when the temperature rose to −160°C. Reactants not combined in the complex are not involved in the process. A 2:1 complex has been observed also when solutions of bromine and biadamantylidene in carbon tetrachloride are mixed[105].

Table 10 lists kinetic parameters for several halogenations in non-polar media. The data for stilbenes and several other alkenes containing aromatic substituents contrast sharply with results for the remaining reactions. This is probably due to stabilisation of the positive charge by the aryl substituents, which lowers the energy of formation of the ion-pair. Since the entropy of activation of the polar reaction is numerically smaller, a polar process having an activation energy of 5–15 kcal mole^{-1} is able to compete with the molecular process. Small and negative activation energies in non-polar media correlate with the occurrence of the reactions at very low temperatures[106]. The chlorination and the bromination of cyclohexene in the absence of a solvent takes place at −175°C.[107] The chlorination of ethylene in propane takes place with considerable velocities between −140° and −150°C.[108]

A negative temperature coefficient is a general feature of the addition of halogens to alkenes in non-polar media. It is not connected with the temperature dependence of the pre-exponential factor. The activation energy observed for an elementary termolecular reaction is given by the difference between the true height of the barrier and $4RT$, and the appearance of this difference is associated with

the pre-exponential factor. At 300°K we have $4RT \simeq 2.4$ kcal mole^{-1}, which does not explain the experimental values of the negative temperature coefficient.

Table 10. Kinetic parameters of some halogenations in carbon tetrachloride at 25°C.

Alkene	Hal	Overall order	Rate constant	Activation energy, kcal mole^{-1}	Ref.
Cyclohexene	Br_2	3	8 M^{-2} s^{-1}	-8.0	19
Hex-1-ene	Br_2	3	1.5 M^{-2} s^{-1}	-4.1	19
4-Methylpent-1-ene	Br_2	3	1.5 M^{-2} s^{-1}	-3.5	19
Diphenylalkenes	Br_2	3	20-150 M^{-2} s^{-1}	0--5	100
Hex-1-ene	Cl_2	2	0.013 M^{-1} s^{-1}	0	99
Cyclohexene	Cl_2	2	0.15 M^{-1} s^{-1}	-1.7	99
Cyclohexene	IBr	3	45 M^{-2} s^{-1}	-8.2	98
cis-Stilbene	Br_2	3	-	+6.5	12
trans-Stilbene	Br_2	3	0.032 M^{-2} s^{-1}	+13.9	12

The observation of negative activation energies may be evidence that molecular complexes are involved in the reaction mechanism. If the kinetic equations for a scheme of the type $Un + X_2 \rightleftharpoons \pi$, $Un + X_2 \rightarrow P$ (where π is the complex and P the product) with parallel formation of the complex are differentiated with respect to the reciprocal of the temperature, the resulting equation is

$$E_{obs} = -R\frac{\partial \ln k_{obs}}{\partial T^{-1}} = -R\frac{\partial \ln k_2}{\partial T^{-1}} + R\frac{\partial}{\partial T^{-1}}(1 + K_{eq}[Un] = \\ = E_2 + \frac{K_{eq}[Un]}{1+K_{eq}[Un]}|\Delta H| > 0 \quad (3)$$

where E_{obs} is the experimental activation energy, E_2 the true activation energy of the bimolecular reaction between halogen and alkene, $|\Delta H|$ the numerical value of the enthalpy, and K_{eq} the equilibrium constant of complex formation. Equation (3) shows that, at sufficiently high alkene concentrations [Un], the observed activation energy increases from E_2 to $E_2 + |\Delta H|$ with increase in this concentration. A similar increase is observed on passing from high temperatures ($K_{eq} \rightarrow 0$) to low temperatures ($K_{eq} \gg 1$). Thus increase in K_{eq}[Un] should be accompanied by a gradual increase in the activation energy, and

$$E_{obs}^{max} - E_{obs}^{min} = |\Delta H| \ . \quad (4)$$

For a termolecular scheme not involving the complex we have

$$E_{obs} = E_3 + \frac{2K_{eq}[Un]}{1+K_{eq}[Un]}|\Delta H| > 0 \\ \text{and } E_{obs}^{max} - E_{obs}^{min} = 2|\Delta H| \ . \quad (5)$$

For the simplest bimolecular scheme involving a π-complex we find that

$$E_{obs} = E_2 - |\Delta H| + \frac{K_{eq}[Un]}{1+K_{eq}[Un]}|\Delta H| \ . \quad (6)$$

If $E_2 > |\Delta H|$, this case is identical with the parallel scheme. But when $E_2 < |\Delta H|$, a negative temperature coefficient must be expected in the region of small values of the product K_{eq}[Un] (low concentrations and not too low temperatures). The numerical value of this coefficient will decrease at low temperatures and with increase in [Un], and at some point the coefficient will become positive. Here, as before, Eqn. (4) holds. Fig. 3 illustrates various forms of temperature dependence of the rate constant for the given scheme.

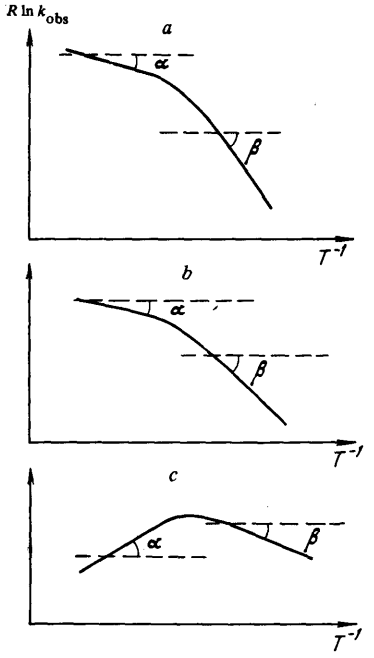


Figure 3. Possible forms of temperature dependence of the effective rate constant of bimolecular halogenation.

For the corresponding termolecular scheme we have

$$E_{obs} = E_3 - |\Delta H| + \frac{2K_{eq}[Un]}{1+K_{eq}[Un]}|\Delta H| \ . \quad (7)$$

With $E_3 < |\Delta H|$, low concentrations [Un], and sufficiently high temperatures a negative temperature coefficient may be expected even for termolecular reactions. Maximum and minimum values of the activation energy are connected by the relations (5).

The negative temperature coefficient may increase when two types of complexes (e.g. 1:1 and 2:1) are involved in the reaction. For a termolecular scheme and a steady state with respect to both complexes we have $E_{obs} = E_3 - (|\Delta H| + |\Delta H'|)$, where $|\Delta H'|$ is the enthalpy of formation of the 2:1 complex. The difference between maximum and minimum values of the observed activation energy is $2(|\Delta H| + |\Delta H'|)$. If a steady state with respect to the second complex is established slowly, the situation is more complicated. The product will accumulate in conformity with an autocatalytic law, and a negative temperature coefficient may not be observed under these conditions even when $E_3 < (|\Delta H| + |\Delta H'|)$.

Thus schemes that involve parallel formation of a molecular complex are unable to explain the appearance of a negative temperature coefficient. Such a possibility is feasible with a complex as a reaction intermediate. A negative activation energy therefore provides kinetic evidence that complexes are involved. Negative activation

energies indicate that the potential energy of the transition state during halogenation lies below that of the initial molecules. According to the theory of the activated complex maximum free and potential energy corresponds to the transition state. Fig. 4 shows possible changes in potential and free energy along the reaction path for the halogenation of alkenes in non-polar media. In the case illustrated the potential energy has a maximum in the transition state, but is lower than in the initial molecules. This means that the formal activation energy in the Arrhenius equation becomes less than zero for the effective rate constant. Observed activation energies close to zero can be expected for chlorination. Large negative values are possible for the entropy of activation, especially in the case of bromination, and reaction velocities will be low. All the above features are in fact confirmed by experimental data [19,102].

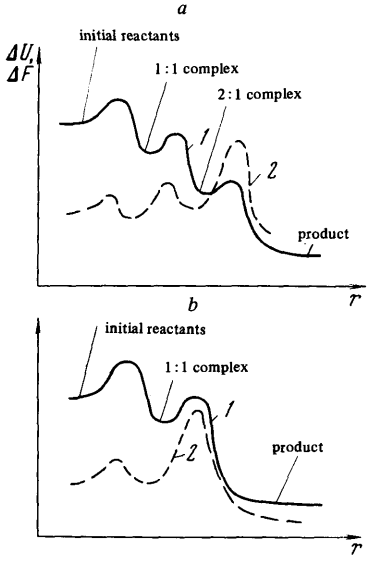

Figure 4. Variation of: 1) potential energy; 2) free energy along path of molecular reaction: *a*) bromination; *b*) chlorination.

Specific solvation of starting materials and transition state should play an important part in a molecular mechanism. The formation of complexes with halogens is typical of several compounds used as solvents (Table 11). Crystalline molecular compounds of carbon tetrachloride with chlorine are known [119]. A charge-transfer band between carbon tetrachloride and bromine in perfluoropentane solution has been detected spectrophotometrically [120].

The dissolution of any substance A in a solvent S is accompanied by solvation and the formation of a solvate complex of mean composition AS_n:

$$(A)_{S,L,G} + nS \rightleftarrows AS_n .$$

Strictly speaking, all the substance A is present in solution as such a solvate complex AS_n. The formation in solution of a complex of a halogen with a donor, e.g. an alkene, can be represented:

$$X_2S_n + D \overset{K_{eq}}{\rightleftarrows} X_2{\cdot}D + nS \qquad K_{eq} = \frac{[X_2D][S]^n}{[X_2S_n][D]} . \qquad (8)$$

Table 11. Enthalpies of formation ($-\Delta H$, kcal mole^{-1}) of molecular complexes of halogens with certain donor solvents.

Hal	Benzene	Toluene	Methanol	Dioxan	Dimethyl sulphoxide	Oxolan	Pyridine	Diethyl ether
I_2	1.3[109]	1.8[109]	1.9[110]	3.3[111]	3.7[114]	5.3[115]	7.8[116]	4.3[117]
Br_2	—	—	—	2.0[112]	—	3.5[112]	—	5.5[118]
Cl_2	—	—	—	2.1[113]	—	2.5[113]	4.3[113]	—

The applicability of Eqn. (8) has been shown [121] for the ternary systems formed by iodine and hexane with benzene, tetrachloroethylene, carbon tetrachloride, and allyl bromide and by iodine with benzene and carbon tetrachloride. In all cases 1 : 1 complexes are formed, which confirms the type of interaction between halogens and solvents.

Reaction may be prevented by formation of a halogen–solvent donor–acceptor bond. The acceptor and electrophilic properties of a halogen become weaker when it is bound into a complex. Formation of the complex X_2.Un by the exchange reaction (8) is impeded by the presence of a bond with the solvent. Increase in the donor strength of the solvent is accompanied by a rise in the potential barrier to complex formation: for example, the enthalpy of interaction of bromine with dimethyl sulphide is -9 kcal mole^{-1}, [112] and up to 10 kcal mole^{-1} is absorbed by reaction (8) in this case. In such solvents the formation of complexes may become the limiting stage, and the reaction velocity may be lower than in weakly complexing solvents such as carbon tetrachloride. In fact, hardly any bromination of alkenes occurs in dimethyl sulphide [118]. Donor solvents are able to solvate not only the halogens but also the transition state. The role of such solvation in effecting the reaction has been noted several times by Shilov [5,65]. Solvation of the transition state, like that of the initial molecules, depends on the donor strength of the solvents. Cases are probable in which solvation of the transition state will exceed that of the reactants. The reaction velocity may increase in such solvents. The relative strength of solvation effects in the reaction can be assessed from the enthalpy of the various processes involved in complex formation, and the reaction velocity may be expected to pass through a maximum depending on the stability of the halogen–solvent complex. This phenomenon has been observed in the bromination of cyclohexene and hex-1-ene in solvents that form complexes with bromine [118] (Fig. 5). The maximum rate of reaction is found in dioxan. A similar relation has been obtained for iodination–cyclisation [122], where the iodine–benzene complex exhibited the maximum rate.

A molecular mechanism should yield *trans*-addition products, which has been confirmed experimentally [99,102,123]. Breakdown of stereospecificity on passing to more polar media has been reported [78,88], and is probably due to a diminution in the contribution by the molecular mechanism.

In several cases specific solvation effects are as important as the dielectric constant of the medium. The concentration of added bromobenzene appears in the rate equation for the bromination of stilbenes in carbon tetrachloride, and the activation energy falls from 13.9 to 8 kcal mole^{-1} on the addition of 10% of bromobenzene [124].

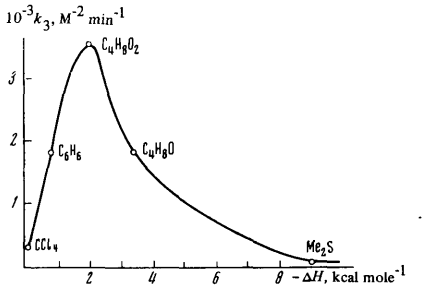

Figure 5. Dependence of rate constant for the bromination of hex-1-ene on enthalpy of formation of bromine–solvent molecular complex.

In mixtures of carbon tetrachloride and nitrobenzene the chlorination rate constant increases considerably more rapidly than might be expected from the variation in the dielectric constant of the medium [125]; this is explained by specific solvation of chlorine by nitrobenzene. This polarises the chlorine molecule, which facilitates electrophilic attack on the double bond. Catalysis of chlorination in carbon tetrachloride and benzene by carboxylic acids is also related to specific solvation [91], and becomes greater as the acid becomes stronger. Only the monomeric forms of the acids are active. A probable mechanism for the action of carboxylic acids is solvation of the anionoid part of the transition state by the proton.

Thus the halogenation of alkenes in non-polar media is characterised by negative effective activation energies and high kinetic orders. The reaction velocity depends on the specific solvation of the halogens. All these facts are consistent with the view that various donor–acceptor complexes are involved in the reaction, and are converted into the reaction products by a molecular mechanism.

V. RADICAL MECHANISM

The gas-phase halogenation of alkenes takes place by a radical–chain mechanism [126]. For a long time no attention was paid to radical halogenation in the liquid phase. The Review discusses radical halogenations taking place at normal temperatures in the absence of illumination and catalysts. Such a reaction (bromination) was first studied in 1951. [127] The process is sharply retarded by inhibitors and by contact with an extended glass surface. Toluene, which is stable towards the short-term action of bromine, reacts with the latter in the presence of an unsaturated compound. The *trans*-addition product is formed under conditions favouring a polar reaction. Nearly equimolecular proportions of *trans*- and *cis*-dibromides are obtained in carbon tetrachloride. Criteria enabling radical halogenations to be identified were formulated [127]—action of inhibitors, nature of products obtained under various reaction conditions, entry into reaction of reactants that are stable towards the halogen in the absence of an unsaturated compound.

The radical chlorination of alkenynes induces benzene and tetrachloroethylene to enter into reaction [128]. Poutsma demonstrated that the chlorination of cyclohexene proceeds partly by a radical mechanism [129]. The postulate of a radical mechanism explained the chlorination of aromatic and saturated hydrocarbons induced by alkenes [130–132]. Radical chlorination is not a consequence of chance external initiation but depends on the chemical nature of the reactants [133]. A radical mechanism is characteristic of the bromination of dienes [134,135], cyclohexene [103], hex-1-ene, and *p*-allylbromobenzene [101].

The proportion of radical processes is determined by the structure of the alkene. An unbranched chain confers the greatest tendency to radical chlorination, but branched alkenes—isobutene, tri- and tetra-methylethylenes, and also styrene—are not characterised by a radical reaction [123]. The reaction mechanism is affected also by the concentration of the alkene: the chlorination of cyclohexene becomes almost exclusively a radical reaction as the concentration of the hydrocarbon increases, and the proportion of the non-radical process increases with decrease in the concentration [133]. A similar phenomenon has been observed in the bromination of hex-1-ene [101], butadiene [135], and *cis*- and *trans*-penta-1,3-dienes [136]. Styrene, which is chlorinated and brominated in conformity with a non-radical scheme, reacts with iodine by a purely radical mechanism [137]. Oxygen inhibits radical chlorination [123], bromination [101,103], and iodination [137]. The scheme

$$StI^{\cdot} + O_2 \rightarrow StIO_2^{\cdot},$$

$$2StIO_2^{\cdot} \rightarrow IStOOStI + O_2,$$

$$StIO_2^{\cdot} + StI^{\cdot} \rightarrow IStOOStI,$$

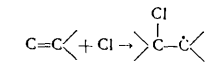
was suggested [137] for inhibition of the iodination of styrene (St). The action of oxygen is twofold: small additions of oxygen initiate the bromination of tetrachloroethylene, but excess slows it down [138]. Radical halogenation is inhibited also by quinones [137], substituted phenols [136], and cyclohexene oxide [139].

The radical bromination of cyclohexene gives the dibromide in yields exceeding 90%, [103] and hex-1-ene gives a 50% yield [19]. The dihalide is usually the *trans*-product contaminated with the *cis*-isomer. The chlorination of cyclohexene gives more than 95% of the *trans*-dichloride. The bromination of cyclohexene [102] and photochemical iodination of butenes [140] and pentenes [141] are *trans*-stereospecific. In several cases, however, stereospecificity is absent [127,136]. Radical halogenation also yields substitution products, whose proportion sometimes reaches 50%. Substitution products containing an allyl group

are most usual. Allylic compounds are formed in yields of 50%, 27%, and more than 40% in the isobutene–chlorine, cyclohexene–chlorine, and hexene–bromine systems respectively. Vinyl halides, containing halogen at the double bond, are always formed in small amounts (from fractions to 5%). Considerable quantities of the 4-halogeno-derivative are observed in the reaction of chlorine with but-1-ene [123] and in the bromination and chlorination of cyclohexene [103,133]. Products of the latter type are found only in radical halogenation.

Published kinetic data on radical halogenation are collected in Table 12, which shows such reactions to have low and negative effective activation energies, from −15 to 6.5 kcal mole^{-1}. The kinetic equations are extremely diverse. The quantity of data on radical liquid-phase halogenation is limited, and further investigation of these reactions is required.

Table 12. Radical-chain halogenation of alkenes in carbon tetrachloride.



Alkene	Hal	Kinetic equation	Activation energy	Ref
4-Methylpent-1-ene	Br_2	$k[Un][Br_2]^2$	−15	19
Hex-1-ene	Br_2	$k[Un]^2[Br_2]^{3/2}$	−8	19
Cyclohexene	Br_2	$\begin{cases} k[Un][Br_2]^2 \\ k[Un]^2[Br_2] \end{cases}$	−14	19
p-Allylbromobenzene	Br_2	$k[Un]^2[Br_2]$	0	101
Pentenes	I_2	$\frac{k_1[I_2]^{3/2}[Un]}{1+k_2[Un]}$	no data	141
Styrene	I_2	$k[Un]^{3/2}[I_2]$	+6.5	137

Halogenation in the dark is initiated by the alkene, not by thermal breakdown of the halogen molecule into two atoms. Aromatic and saturated hydrocarbons that are inert towards the halogen react in the presence of alkenes [130-132]. If the alkene were not involved in initiation, the rate of initiation would be independent of its presence, and the degree of halogenation of the aromatic or saturated compound would also have been constant. Actually, however, it differs by several orders of magnitude [128], which proves that more halogen atoms are formed in the presence than in the absence of alkenes. Comparison of possible rates of initiation with the observed reaction velocities also shows that the latter cannot be attained with actual chain lengths and with initiation by the dissociation of halogen molecules.

Table 13. Heats of initiation in halogen-alkene systems.

Initiation reaction		Heat of reaction, kcal mole^{-1}	
		bromine	chlorine
$-CH=CH- + X_2 \rightarrow -CHXC\dot{H} + X$	(9)	34	32
$2-CH=CH- + X_2 \rightarrow 2-CHX-C\dot{H}-$	(10)	22	6
$-CH=CH- + 2X_2 \rightarrow -CHX-CHX- + 2X$	(11)	14	8
$2-CH=CH- + 2X_2 \rightarrow -CHX-CHX- + X + +-CHX-C\dot{H}$	(12)	3	−18
$-CH=CH-CH_2- + X_2 \rightarrow HX + X + -CH= =CH-C\dot{H}-$	(13)	32 (35)	29 (32)
$2-CH=CH-CH_2- + X_2 \rightarrow 2HX + 2-CH= =CH-C\dot{H}-$	(14)	18 (24)	0 (+6)

With regard to possible schemes of initiation involving the alkene Table 13 gives several mechanisms of radical generation in the presence of bromine and chlorine, together with probable heats of reaction for these processes. The latter were estimated from the energies of rupture of bonds in the halogen molecules (Table 2). The thermal effect of the reaction

was equated to the heat evolved on attachment of a chlorine atom to ethylene, i.e. 26 kcal mole^{-1}. [133] In most compounds the C-Br bond is less stable than the C-Cl bond by 14 kcal mole^{-1}, and for the reaction

it was assumed that ΔH = 12 kcal mole^{-1}. The energies of formation of hydrogen chloride and hydrogen bromide are respectively 103 and 88 kcal mole^{-1}. [21] The heat of detachment of hydrogen in the allyl position was taken [133] to be 74 kcal mole^{-1}, but the values in parentheses in Table 13 are based on the more usual 77 kcal mole^{-1}. The C-Cl and C-Br bond energies are respectively 80 and 66 kcal mole^{-1}. [21]

The results for the heats of reaction enable reactions (10) and (14) to be eliminated for bromine, since both these routes are less favourable than (11). Bimolecular initiation according to (9) and (13) is energetically identical in the case of bromine. Thus three schemes of initiation—bimolecular with ΔH_{13} = 32-35 kcal mole^{-1}, termolecular with ΔH_{11} = 14 kcal mole^{-1}, and formally quadrimolecular with $\Delta H_{12} \simeq 3$ kcal mole^{-1}—can be considered for bromination. A similar analysis for chlorine gives corresponding values of 29-32, < 8, and −12 kcal mole^{-1}. [142] The pre-exponential factors of bimolecular and termolecular reactions can be taken to be 10^{10} M^{-1} s^{-1} and 10^4 M^{-2} s^{-1}. [142] With reactant concentrations each of 0.03 M at 25°C we find that the bimolecular reaction may generate radicals at rates of 10^{-17} and 10^{-14} M s^{-1} for bromine and chlorine respectively, the corresponding rates for the termolecular reaction being 10^{-13} and 10^{-5}. Stage (12) can be regarded as the collision of two molecules of the complex $\cdot X_2.Un$, when rates of initiation may be higher than in the remaining cases. In order that reaction (12) should occur four reactant molecules must be oriented in a certain way, which may lead to great steric hindrance.

The formation of radicals as a result of the interaction of valency-saturated molecules by bimolecular and termolecular mechanisms has been thoroughly studied in the liquid-phase oxidation of hydrocarbons [143]. A termolecular mechanism predominates with hydrocarbons having weak C-H bonds. It is very likely that termolecular and pseudo-quadrimolecular are more efficient than bimolecular reactions also in the halogenation of alkenes. A review has been devoted to the possible role of molecular complexes in the formation of radicals [144]. Complex formation may weaken the bond in the acceptor molecule. Such a mechanism has been proved for the formation of radicals from tetranitromethane complexes [145]. It has been accepted [133] that the first stage in chlorination is always formation of a complex $Cl_2.Un$, which then breaks down either by a homolytic or by a heterolytic mechanism. The involvement of complexes in the reaction has been assumed also for radical bromination [101,135] and iodination [137]. Hitherto, however, there has been no unambiguous experimental evidence in halogenation reactions that complex formation should precede the formation of radicals.

The participation of complexes in halogenation explains the parallel variation in the reactivity of alkenes in polar, molecular, and radical reactions. If a complex is an

intermediate species in all these processes, the rate constants should actually correlate with the properties of the complex and thus also among themselves. Pseudo-quadrimolecular initiation must be regarded as resulting from pair collisions of 1 : 1 complex molecules.

In radical halogenation chain propagation can be effected by the reactions

$$X + -CH=CH-CH_2- \rightleftarrows -CHX-C\dot{H}-CH_2- , \quad (15)$$

$$X + -CH=CH-CH_2- \rightleftarrows HX + -CH=CH-C\dot{H}- , \quad (15')$$

$$-CHX-C\dot{H}-CH_2- + X_2 \rightarrow -CHX-CHX-CH_2- + X , \quad (16)$$

$$-CH=CH-C\dot{H}- + X_2 \rightarrow -CH=CH-CHX- + X . \quad (16')$$

The activation energies of (15) and (15′) can be estimated by means of the formulae—$E_{act} = 4.3 - 0.1\Delta H$ in an exothermic reaction, and $E_{act} = 4.3 + 0.91\Delta H$ in an endothermic reaction [146]—and in the case of chlorine we have $E_{act} = 2$ kcal mole^{-1} for reaction (15). The pre-exponential factors of the gas-phase reactions of the atoms with the ethylenic compounds amount to 10^{12} M^{-1} s^{-1}, [147]† which gives $k_7 = 10^{10}$ M^{-1} s^{-1}, in good agreement with the experimental $10^{9.9}$ M^{-1} s^{-1}. [148] The heats of reaction of stages (15) and (15′) differ by 2–3 kcal mole^{-1}, and the corresponding rates differ little. As a consequence, the dihalide is accompanied by large quantities of substitution products. In the case of bromine we have $k_7 \simeq 10^8$–10^9 M^{-1} s^{-1} for reactions (15) and (15′). The estimated rates of reactions (16) are of the same order. The rate of (16) may be lower than the calculated value because of steric hindrance to reaction of the halogenalkyl radical with the molecule. The most feasible value in this case is 10^7–10^8 M^{-1} s^{-1}. The rate of reaction (16′) is lower, since its heat of reaction is 5 kcal mole^{-1}. The reversibility of stage (15) is a very important matter, and may affect the kinetics of the process. With chlorine this stage is irreversible, since the reverse reaction is strongly endothermic. With bromine, on the other hand, the decomposition constant of the halogenoalkyl radical is estimated to exceed 10^6 s^{-1}. At a halogen concentration of 0.01 M this decomposition is able to compete with reaction (16).

Halogen atoms, which possess high electron affinities, are very strong acceptors and form complexes with organic donors such as benzene [149]. The enthalpy of formation of such complexes is about double those of complexes of the corresponding molecular halogens [150]. Such complexes should be formed also with alkenes, and the enthalpy can be expected to be 6–12 kcal mole^{-1}. The intermediate species in halogenation may not be classical halogenoalkyl radicals but radical-like complexes

distinguished by the position of the atom and by delocalisation of the free valency over a three-membered ring [103,140]. In fact the heat evolved on formation of a classical radical is smaller with iodine, but with bromine is close to that evolved on formation of the complex. The latter does not require rupture of the double bond, so that formation of such a complex may not have an activation barrier, in contrast to the reaction yielding

A bridged structure for the halogenoalkyl radicals is supported by the *trans*-stereospecificity of the radical addition of bromine and iodine [140]. If the reaction involved the radical

it would not have been completely *trans*-stereospecific with iodine, and with bromine there would have been no advantage at all in formation of a *trans*-product, as is observed e.g. in ionic reactions of the geometrically entirely similar cation [1]

Thus the most probable structure with bromine is

The reversibility of stage (15) can be regarded as a consequence of complex formation between the bromine atom and the unsaturated compound. With chlorine, formation of the complex involves a smaller—and that of the radical a larger—heat of reaction than with bromine, so that the radicals

play the main part in the reaction.

Complex formation explains negative activation energies in radical bromination, since the enthalpy of formation of the radical–complex occurs in the activation energy with a negative sign [116]. A negative activation energy due to reversible formation of a bromoalkyl radical has been reported for the gas-phase hydrobromination of alkenes [151].

Chain termination takes place either by the recombination of atoms and radicals or by reaction with an inhibitor (In):

$$2X \rightarrow X_2 , \quad (17)$$

$$X^{\cdot} + \dot{C}-C(X) \rightarrow \text{Products} , \quad (17')$$

$$2\,\dot{C}-C(X) \rightarrow \text{Products} , \quad (17'')$$

$$\left.\begin{array}{l} X + In \rightarrow \text{Termination} \\ \dot{C}-C(X) + In \rightarrow \text{Termination} \end{array}\right\} . \quad (18)$$

Only the rate constants of reaction (17)—$10^{10.6}$ and $10^{10.3}$ M^{-1} s^{-1} for bromine and iodine [148] respectively—are known for the liquid phase. The rates of reactions (17′) and (17″) are apparently lower owing to steric hindrance. This is supported by data for the gas phase, where $k_{17} = 10^{16}$–10^{17} M^{-1} s^{-1} for chlorine‡, the reaction Cl + C_2H_4Cl gives only 10^{14}, and the recombination of two chloroethyl radicals only 10^{13}. [147] Mechanism (18) is more probable. Furthermore, chain termination may take place on oxygen, which is usually present in solution at concentrations of $\sim 10^{-3}$–10^{-4} M. Radical halogenation is complicated by liberation of the hydrogen halide, which influences the kinetics of the reaction.

†The pre-exponential factors given in Ref. 147 are $\sim 10^{12}$ cm^3 mole^{-1} s^{-1} (Ed. of Translation).

‡This value of k_{17} is in fact the third-order rate constant in cm^6 mole^{-2} s^{-1}, and the two subsequent rate constants are in cm^3 mole^{-1} s^{-1}, although the units are not stated in the Russian text (Ed. of Translation).
