Covalent Tetrahydroborates

K.N.Semenenko, O.V.Kravchenko, and V.B.Polyakova

The properties, structure, and methods of preparation of the tetrahydroborates of beryllium, aluminium, and certain heavy metals (zirconium, hafnium, thorium, and uranium) are reviewed.
These compounds, which can provisionally be grouped together as the so-called covalent complex hydroborates, have much in common both as regards physical properties and high reactivity and as regards the nature of the chemical bond and the character of the chemical changes in which the $M(BH_4)_n$ molecules participate. The main types of chemical reactions of the covalent tetrahydroborates, the structural principles lying at the basis of their molecular and crystal structures, and also the possibility of using covalent tetrahydroborates in various fields of inorganic synthesis are examined. 114 references.

I. INTRODUCTION

For the last 15—20 years the saltlike alkali metal tetrahydroborates, the crystal lattices of which contain isolated tetrahedral BH_4^- ions, have been the subject of an intensive investigation, which has shown the possibility of their use in preparative inorganic chemistry and chemical technology.

Considerably less attention has been paid to the tetrahydroborates of metals, the "cations" of which show high reduced moments z/r (beryllium, aluminium, and the heavy metals zirconium, hafnium, thorium, and uranium), where z is the charge and r the radius of the ion.

Evidently, the main reason for ignoring the experimental chemistry of the complex covalent tetrahydroborates of the $M(BH_4)_n$ type was the difficulties associated with the preparation and investigation of these extremely reactive and volatile compounds.

Actually, aluminium tetrahydroborate $Al(BH_4)_3$, for example, reacts explosively in the solid, liquid, and gaseous states with atmospheric oxygen and moisture, beryllium tetrahydroborate $Be(BH_4)_2$ and uranium tetrahydroborate $U(BH_4)_4$ are spontaneously inflammable in air, and so forth.

The relatively low thermal stability of the covalent tetrahydroborates (they all decompose rapidly and irreversibly in the range 130—150°C) gives rise to additional difficulties in their preparation.

Nevertheless the chemistry of the complex covalent hydroborates is much richer and more interesting than that of the saltlike tetrahydroborates. The $M(BH_4)_n$ molecules exhibit a dual reactivity: the BH_4 group in them is simultaneously a carrier of the functions of both a tetrahedral BH_4^- "ion" and an H_2BH_2 bridging group, close in structure and properties to the H_2BH_2 group in the diborane molecule.

The saltlike nature of the tetrahydroborates $M(BH_4)_n$ increases in the sequence:

	$Be(BH_4)_2$	$Al(BH_4)_3$	$U(BH_4)_4$	$Zr(Hf)(BH_4)_4$	$U(BH_4)_3$	$Ca(BH_4)_2$
z/r	4.4	4.3	3.8	3.7	2.8	2.0

It is interesting to trace how the structure of the BH_4 group situated in the field of the "cation" M and the type of the M—H—B chemical bond vary as the reduced moment z/r is increased.

In the most saltlike tetrahydroborate (that of U^{III}) the proper symmetry of the BH_4 group is evidently the same as in the tetrahydroborates of univalent cations, T_d. On going to molecular structures with $z/r > 3$ the nature of the bonding of the BH_4 group with the cation is more complicated. In the M^{IV} tetrahydroborates the symmetry of the BH_4 group is decreased to C_{3v} and a new type of multicentre bridging bond MH_3B, unknown in the chemistry of the boron hydrides, is formed.

The $Al(BH_4)_3$ molecule contains AlH_2B bridges close in structure to the BH_2B fragments in the B_2H_6 molecule (symmetry of the BH_4 group C_{2v}) and from the nature of the chemical bond in it is a complete analogue of diborane.

The $Be(BH_4)_2$ molecule, the structure of which is considered in detail on p. 5, can be described as the result of "association" of a distorted B_2H_6 molecule and a BeH_2 molecule[1] or as a combination of two BH_4 tetrahedra with a common vertex and a planar BeH_3 group, which complete a six-membered ring $\{BeH_3B_2\}$.[2]

The dual reactivity of the tetrahydroborates $M(BH_4)_n$ connected with the intermediate nature of the bond between the BH_4 group and the M atoms, appears clearly in the chemistry of aluminium tetrahydroborate, which reacts with alkenes like diborane and with ammonia like the tetrahydroborate $[Al(NH_3)_6](BH_4)_3$.[3,4]

Since the covalent tetrahydroborates, like diborane, are electron-deficient compounds—the number of atomic orbitals in the $M(BH_4)_n$ molecules is greater than the number of valency electrons—a specific type of reaction, not characteristic of the saltlike tetrahydroborates, is inherent for them. This refers to the addition of molecules which are donors of electrons, with the formation of new molecular structures of the type $M(BH_4)_n.mL$ (I) or $[M(BH_4)_nX]^-$ (II), in which the atom M, which exhibits a coordination number anomalously high from the viewpoint of classical ideas, is at the centre of a coordination polyhedron with an unusual configuration.

Examples of such compounds are the complexes[4,5] of aluminium tetrahydroborate with trimethylamine, trimethylphosphine, and trimethylarsine, in the molecules of which the aluminium atom is surrounded by three boron atoms, six hydrogen atoms, and a nitrogen atom, situated at the vertices of greatly distorted $[H---AlH_5---N]$ pentagonal bipyramids.

The structures of compounds of types (I) and (II) are of exceptional interest in connection with the definition of the concepts of "valency" and "coordination" number, the classical treatment of which is inapplicable for the description of most light metal hydrides.

The prospects of the practical use of the tetrahydroborates $M(BH_4)_n$ is evidently linked with their use as starting materials in the preparation of new inorganic compounds containing an M—H—B bond and also with their high volatility and with the possibility of their use in this connection for separating elements with very similar properties, for example, Zr and Hf or the isotopes ^{235}U and ^{238}U.[6-10]

It has also been noted repeatedly[7,8] that the light metal tetrahydroborates, which have high heats of combustion, can be regarded as promising components of rocket fuels.

II. METHODS OF SYNTHESIS

1. DOUBLE DECOMPOSITION BETWEEN METAL HALIDES AND ALKALI METAL AND ALUMINIUM TETRAHYDROBORATES

Schlesinger[11,12] was the first to use the method of double decomposition for obtaining aluminium and beryllium tetrahydroborates from the corresponding chlorides and alkali metal tetrahydroborates by the reactions:

$$BeCl_2 + 2\,LiBH_4 \xrightarrow{140^\circ} Be(BH_4)_2 + 2\,LiCl\ , \quad (1)$$

$$AlCl_3 + 3MBH_4 \xrightarrow{100-130^\circ} Al(BH_4)_3 + 3\,MCl\ . \quad (2)$$

Reactions (1) and (2) take place in the solid phase at 100—130°C, the yield of the desired product depending on the ratio of the reagents and the nature of the tetrahydroborate used. It has been shown[12,13] that the greatest yield of aluminium and beryllium tetrahydroborates (90—95%) occurs when the metal chlorides react with lithium tetrahydroborate in ratios close to stoichiometric. When sodium tetrahydroborate is used the yield is considerably less (~50%), but the yield of aluminium tetrahydroborate can be increased by the introduction of a large excess of the metal chloride into the reaction mass[11,12]. When potassium tetrahydroborate is used, the yield of aluminium and beryllium tetrahydroborates by reactions (1) and (2) are reduced almost to zero.

However, when potassium tetrahydroborates reacts with aluminium chloride in the presence of lithium chloride the yield of aluminium tetrahydroborate is increased to 40—50%.[14] In addition to the main products from reactions (1) and (2), side-products are formed: diborane, hydrogen, and chloro-substituted derivatives of tetrahydroborates of composition $MCl_x(BH_4)_{n-x}$.[11,15]

Reaction (2) can also be effected in the presence of inert organic substances: petroleum, mineral oil, heavy mineral oil with graphite flakes, benzene; this facilitates the charging of the reagents, the mixing of the reaction mass, and the discharge of the product[16-20].

Lithium tetrahydroborate reacts with zirconium(IV) chloride in a manner similar to reactions (1) and (2):

$$ZrCl_4 + 4\,LiBH_4 \rightarrow Zr(BH_4)_4 + 4\,LiCl\ . \quad (3)$$

The yield of zirconium tetrahydroborate by reaction (3) is 77%; when sodium or potassium tetrahydroborate replaced the lithium salt zirconium tetrahydroborate could not be obtained by this method[21].

For uranium tetrahydroborate the "dry" method of synthesis—heating mixtures of alkali metal tetrahydroborates with uranium(IV) fluoride up to 200°C—did not give results. Uranium and thorium tetrahydroborates were obtained by the reaction of uranium(IV) and thorium(IV) fluorides with aluminium tetrahydroborate[22-24]:

$$MF_4 + 2\,Al(BH_4)_3 \rightarrow 2\,AlF_2BH_4 + M(BH_4)_4\ . \quad (4)$$

When there is an excess of aluminium tetrahydroborate the yield of uranium tetrahydroborate reaches 80%.[22,23] The method can also be used for the preparation of zirconium tetrahydroborate:

$$ZrCl_4 + 2Al(BH_4)_3 \rightarrow 2\,AlCl_2BH_4 + Zr(BH_4)_4\ . \quad (5)$$

However, in this instance there are additional difficulties associated with the separation of the reaction products, the volatilities of which are very similar. Zirconium and hafnium tetrahydroborates can be obtained from aluminium tetrahydroborate and fluoro-complexes[24,25]:

$$NaMF_5 + 2Al(BH_4)_3 \rightarrow NaF + 2AlF_2BH_4 + M(BH_4)_4\ . \quad (6)$$

Fluoro-complexes are used because zirconium(IV) and hafnium(IV) fluorides do not react directly with aluminium tetrahydroborates[26].

2. REACTION OF METAL ALKYLS OR METAL HYDRIDES WITH DIBORANE

The first covalent tetrahydroborate obtained by the reaction of a metal alkyl with diborane was that of aluminium[27,28]:

$$Al(CH_3)_3 + 2B_2H_6 \rightarrow Al(BH_4)_3 + B(CH_3)_3 . \quad (7)$$

The yield of the reaction was 70—80%. This method is also applicable for the preparation of beryllium tetrahydroborate[29].

Reaction (7) is inconvenient preparatively since it is slow, with the formation of intermediate products of the $Al(BH_4)_x(CH_3)_{3-x}$ type, which are difficult to separate.

Beryllium tetrahydroborate can also be obtained by the action of diborane on beryllium hydride[30]. There is a report of the possibility of obtaining aluminium tetrahydroborate in yields of up to 90% by the action of diborane on crystalline lithium tetrahydroaluminate at 70—80°C:[31]

$$LiAlH_4 + 2B_2H_6 \rightarrow LiBH_4 + Al(BH_4)_3 . \quad (8)$$

3. PREPARATION IN THE PRESENCE OF SOLVATING SOLVENTS

Fuchs and Kollonitsch[32,33] described the preparation of aluminium tetrahydroborate from calcium tetrahydroborate and aluminium chloride in tetrahydrofuran (THF) solution:

$$3Ca(BH_4)_2 + 2AlCl_3 \cdot C_4H_8O \xrightarrow{C_4H_8O} 3CaCl_2 + 2Al(BH_4)_3 \cdot C_4H_8O . \quad (9)$$

When the solution is cooled to −60°C a complex of aluminium tetrahydroborate and tetrahydrofuran crystallises from it.

Complexes of aluminium tetrahydroborate with diethyl ether are formed by the reactions[31,34]:

$$4AlH_3 \cdot Et_2O + 3BCl_3 \xrightarrow{Et_2O} Al(BH_4)_3 \cdot Et_2O + 3AlCl_3 \cdot Et_2O , \quad (10)$$

$$3LiAlH_4 + 3BCl_3 \xrightarrow{Et_2O} Al(BH_4)_3 \cdot Et_2O + LiCl + 2AlCl_3 \cdot Et_2O , \quad (11)$$

$$2AlH_3 \cdot Et_2O + nB_2H_6 \xrightarrow{Et_2O} 2H_{3-2n}Al(BH_4)_{2n} \cdot Et_2O . \quad (12)$$

The reaction of uranium(IV) fluoride with lithium tetrahydroborate in diethyl ether gives a complex of uranium tetrahydroborate with the ligand-solvent[22]. It is noteworthy, however, that the oxonium complexes of the covalent tetrahydroborates are stable compounds from which the non-solvated tetrahydroborates cannot be separated.

The methods of synthesis considered in sections II. 2 and II. 3 are preparatively inconvenient or associated with the impossibility of using difficulty available and costly initial substances. The most promising methods of preparation of the covalent tetrahydroborates are those based on double decomposition between metal halides and alkali metal or aluminium tetrahydroborates.

III. PHYSICOCHEMICAL PROPERTIES AND REACTIVITY

Under normal conditions the covalent tetrahydroborates $M(BH_4)_n$ are crystalline, except for aluminium tetrahydroborate, which is a colourless, mobile, low-boiling liquid.

Table 1 gives some physicochemical properties of the tetrahydroborates $M(BH_4)_n$.

In addition, the following quantities have been determined for liquid aluminium tetrahydroborate[35-37]: (a) coefficient of viscosity 2.0 mP (25°C); (b) free energy of formation ΔG_i° 36.2 kcal mole^{-1}; (c) specific heat capacity C_p° = 46.8 cal deg^{-1} mole^{-1}; (d) entropy of vaporisation ΔS_e = 22.6 e.u.

Table 1. Physicochemical properties of the covalent tetrahydroborates.

Compound	M.p., °C	B.p., °C	Coefficients A and B in the equation $\lg P = A - B/T$	ΔH_f (1) ΔH_e^f (2)	ΔH_{rev}	Density, g cm^{-3}
$Al(BH_4)_3$	−64.5[28]	44.5[28]	A B 7.808 1565[35] 9.56796 1789.1[36]	1.68[27] (1) 7.2 (2)	−72.1[37] −26.4[38] −74.7[7]	0.544 (20°)[28] 0.7866— 0.0007937[36]
$Be(BH_4)_2$		91.3 sublimation temp. (Ref.29)	11.772 3240[29]	14.81 (2)[29]	−25.8[7]	9.604 (20°)[7]

$Hf(BH_4)_4$	29[24]	118[24]	10.719 2983[24]	3 (1) 9.7 (2)[24]		1.85 (20°) 1.60 (30°)[39]
$Th(BH_4)_4$[24]	203 with decomposition	—	P=0.05 mmHg at 130° P=0.20 mmHg at 150°	—	—	—

As Table 1 shows, there has not yet been any serious investigation of the thermodynamic characteristics of covalent tetrahydroborates except for the melting and boiling points. For example, several values have been given for the heats of formation of aluminium tetrahydroborate, the reliability of these being equally doubtful. The difficulties in the determination of the thermodynamic characteristics of covalent tetrahydroborates are connected with their extremely high reactivity. For aluminium tetrahydroborate, for example, it is almost impossible to select an oxidant with which this compound will not react explosively during simple mixing under normal conditions.

Beryllium, aluminium, zirconium, hafnium, and uranium tetrahydroborates are less stable thermally than saltlike tetrahydroborates of univalent cations. Aluminium tetrahydroborate decomposes even at room temperature, with the formation of hydrogen. The decomposition is faster in the gas phase than in the liquid. Certain substances, for example, alloys of aluminium and copper, catalyse the decomposition[40]. Solutions of aluminium tetrahydroborate in saturated hydrocarbons with up to 50% $Al(BH_4)_3$ decompose at the same rate as the pure substance[41].

According to Schlesinger[11,42], aluminium tetrahydroborate is stabilised during prolonged storage under normal conditions or when heated for several days at 40°C. It is suggested that the stabilisation is linked with the formation of decomposition products which are inhibitors of further decomposition reactions.

The NMR spectrum of aluminium tetrahydroborate that has been kept for some time at 80°C differs from the spectra of "ordinary" aluminium tetrahydroborate[43]. The artificial introduction of diborane reduced the difference in the spectra, which suggested a reversible change by the following mechanism:

$$2\,Al(BH_4)_3 \rightleftarrows Al_2H_2(BH_4)_4 + B_2H_6\ . \qquad (13)$$

The probable mechanism of deuterium exchange between deuteriated diborane and aluminium tetrahydroborate[44] agrees with this assumption. However, the existence of $Al_2H_2(BH_4)_4$ in the gas phase is not confirmed by investigations of the infrared spectra[44].

Raising the temperature facilitates the more rapid decomposition of $Al(BH_4)_3$, with release of hydrogen and formation of a mixture of a crystalline powder and an amorphous black substance, which reacts with water with the release of hydrogen[45,46].

Beryllium tetrahydroborate is stable at room temperature and starts to decompose at 123°C.

The rate of decomposition of uranium and zirconium tetrahydroborates at room temperature is low; these substances are completely stable at 50–60°C. Further heating greatly increases the rate of pyrolysis. Uranium(IV) tetrahydroborate decomposes at 100°C with the formation of a red-brown uranium(III) tetrahydroborate[22]:

$$2\,U(BH_4)_4 \xrightarrow{100^\circ} 2\,U(BH_4)_3 + B_2H_6 = H_2\ . \qquad (14)$$

The decomposition of $U(BH_4)_4$ at 150°C leads to the formation of a metallic mirror on the walls of the pyrolyser and the release of hydrogen. Unlike uranium(IV) tetrahydroborate, uranium(III) tetrahydroborate is pyrophoric and decomposes explosively when heated. The decomposition of $U(BH_4)_4$ proceeds mainly in the gas phase and is accelerated in the presence of Hg, Cu, Ni, and "Pyrex" glass[22].

Zirconium and hafnium tetrahydroborates start to decompose at an appreciable rate when heated to 60–70°C.[24] Thorium tetrahydroborate decomposes slowly at 150°C and rapidly at 300°C. Its pyrolysis at 300°C leads to the formation of a metallic mirror of composition ThB_4, together with hydrogen[24].

The high reactivity of covalent tetrahydroborates in relation to oxygen and to compounds which contain positively polarised hydrogen atoms is due to the low strength of the MH_nB bridging bonds in the $M(BH_4)_n$ molecules, the unsaturated nature of these compounds, and their high heats of combustion or hydrolysis. Actually, all the covalent tetrahydroborates react with water even at ~–80°C.[47] The products of the reaction are the hydroxides of the corresponding metals, boric acid, and hydrogen. The hydrolysis of aluminium tetrahydroborate, like, probably, that of other tetrahydroborates, proceeds in stages, with the formation in the first stage of diborane, which is subsequently hydrolysed to hydrogen and boric acid[47,48]:

$$Al(BH_4)_3 + 3H_2O \rightarrow Al(OH)_3 + {}^3/_2B_2H_6 + 3H_2\ , \qquad (15)$$

$${}^3/_2\,B_2H_6 + 9\,H_2O \rightarrow B(OH)_3 + 9H_2\ . \qquad (16)$$

At room temperature aluminium and beryllium tetrahydroborates react explosively with water. However, in the hydrolysis only 70–80% of the theoretically necessary hydrogen is released and solid yellow–brown polymeric substances are formed[47].

The presence of traces of water (which is a catalyst of the oxidation) is necessary for the spontaneous ignition of mixtures of covalent tetrahydroborates and oxygen[24,29,50]. For example, uranium tetrahydroborate $U(BH_4)_4$ is only slowly oxidised in dry air, whereas all the covalent tetrahydroborates are spontaneously combustible in air[31,49–51].

The tetrahydroborates $M(BH_4)_n$ react with hydrogen chloride at –80°C with the formation of the chlorides of the corresponding metals, diborane, and hydrogen[24,28]. The main side-reaction here is the formation of halogen-substituted boron hydrides, for example:

$$B_2H_6 + HCl \rightarrow B_2H_5Cl + H_2\ . \qquad (17)$$

IV. STRUCTURE

The most effective method of studying the structure of the molecules of the volatile covalent tetrahydroborates $M(BH_4)_n$ was gas electron diffraction.

Bauer and Beach[52] made the first studies in this field. They found the $Al(BH_4)_3$ molecule to have the configuration of a trigonal prism with an equilateral triangle of B atoms in the equatorial plane. The Al atom is situated at the centre of the triangle and the H atoms of the AlH_2B bridging bonds at the vertices of the trigonal prism.

In principle, the electron diffraction results also do not contradict the other possible model (octahedral)[53,54], which differs from that considered above in the angle of slope of the plane of the AlH_2B bonds to the plane of the AlB_3 triangle: in the prismatic model this angle is 90°, in the octahedral 45°. The symmetry element σ_h is absent from the octahedral model. The choice between the two possible configurations was made on the basis of a detailed investigation of the infrared and Raman spectra of gaseous[55,56] and liquid[57] $Al(BH_4)_3$ and its isotope-substituted analogues $Al(^{11}BD_4)_3$, $Al(^{10}BH_4)_3$, and $Al(^{10}BD_4)_3$. As Table 2 shows, for the D_{3h} prismatic model of the $Al(BH_4)_3$ molecule there should be 13 absorption bands in the infrared spectrum and 5 polarised and 14 non-polarised bands in the Raman spectrum. For the D_3 octahedral model there should be 21 absorption bands in the infrared spectrum and 7 polarised and 14 non-polarised bands in the Raman spectrum. The experimental results agree better with the prismatic model (see Table 2).

Almeningen and coworkers[58] further refined the interatomic distances and valence angles in the prismatic model of $Al(BH_4)_3$. The model of the $Al(BH_4)_3$ molecule according to Almeningen is given in Fig. 1.

The NMR spectra of aluminium tetrahydroborate were investigated in 1955 [43] and in 1967.[59].

In the 1967 analysis of the NMR spectra of various specimens of $Al(BH_4)_3$ [59] the possibility of the molecular polymorphism of $Al(BH_4)_3$ was suggested, linked with the reversible conversion of the prismatic molecule into the octahedral, which hypothetically exists in the liquid phase or in benzene solution. This hypothesis is based on the fact that the structure of the NMR spectra characteristic for a BH_4 group with four equivalent protons appears for specimens of $Al(BH_4)_3$ which have undergone different preliminary treatments and are in different states of aggregation at different temperatures. However, our results[60] do not agree with hypothesis of the molecular polymorphism of aluminium tetrahydroborate.

We showed that the infrared spectra of crystalline $Al(BH_4)_3$ are almost constant in the temperature range from –75° to –90°C and identical with the infrared spectrum of the gas phase at room temperature. The frequencies of the vibrations of the terminal BH_2 group in the spectrum of $Al(BH_4)_3$ are close to those of the corresponding vibratio in the infrared spectrum of diborane[61]. There is an

intense absorption band at 602 cm^{-1} belonging to the stretching vibrations of the Al—B bond. The intense absorption band corresponding to the B—B vibration is at 794 cm^{-1} in the diborane spectrum[61]. To understand the nature of the chemical bond in the $Al(BH_4)_3$ molecule, just as in other covalent tetrahydroborates, the ideas developed earlier by Lipscomb and coworkers[62] for boron hydrides can be applied. The molecular structure of aluminium tetrahydroborate can be interpreted as follows. Two types of bond ($BH_{termina}$ and Al—B) are "normal" two-centre bonds, for the formation of which the boron and aluminium atoms use three sp^2 hybrid atomic orbitals.

Table 2. Activity of the normal vibrations in the infrared and Raman spectra for prismatic and octahedral models.

Activity	No. of normal vibrations	Symmetry type	No. of normal vibrations	Activity
Raman	5	$A_1' > A_1$	7	Raman
—	2	A_1''		
—	3	$A_2' > A_2$	7	IR
IR	4	A_2''		
Raman, IR	9	$E' > E$	14	Raman, IR
Raman	5	E''		

The fourth atomic orbital of the boron, supposedly p_z, perpendicular to the plane in which lie the B—H and B—Al σ bonds, interacts with two s atomic orbitals of hydrogen atoms and one of the three pd^2 hybrid atomic orbitals of the aluminium atom to form four-centre molecular orbitals occupied by two electrons.

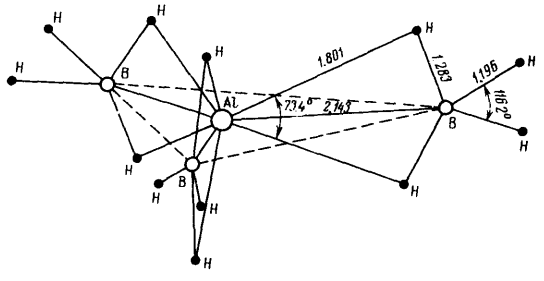

Figure 1. Model of the aluminium tetrahydroborate molecule.

Actually, the Al—B distance in the molecule is close to the sum of the so-called covalent radii and the BH_{bridge} and $Al—H_{bridge}$ distances are close to the corresponding distances in the B and Al hydrodes, in which these bonds are multicentre.

The crystal structure of aluminium tetrahydroborate was studied[60] in 1970. It forms two crystalline modifications (see Table 3) with enantiotropic transformation temperature of −76°C.

In the $Al(BH_4)_3$ crystal lattice all the intermolecular contacts are H---H contacts. The absence of any significant interaction between the molecules in the condensed phase explains the low melting point (−64.5°C) and boiling point (+44.5°C) of aluminium tetrahydroborate.

Table 3. Crystal-chemical results for the covalent tetrahydroborates.

Compound	Symmetry and unit-cell parameters				
	a, Å	b, Å	c, Å	space group	Z
α-Al $(BH_4)_3$	7.52	—	9.05	—	—
β-Al $(BH_4)_3$	7.50	12.15	5.94	$p2_12_12_1$	—
Be $(BH_4)_2$	13.59	—	9.92	$Aacd$	16
Zr $(BH_4)_4$	5.86	—	—	$p\bar{4}3m$	1

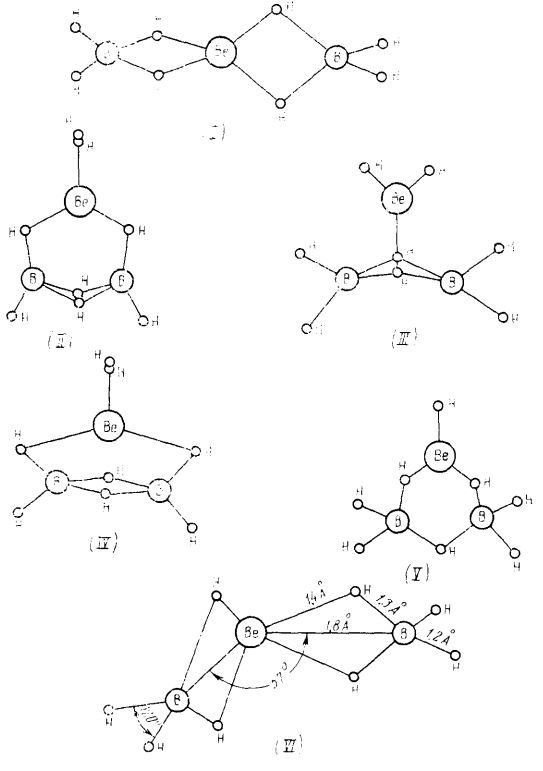

Figure 2. Molecular models of beryllium tetrahydroborate.

Silbiger and Bauer[54,63] were the first to investigate the molecular structure of beryllium tetrahydroborate $Be(BH_4)_3$ in the gas phase and they advanced two different interpretations of their experimental results. Both were based on the hypothesis of a linear configuration for the B—Be—B grouping. Fig. 2 (I) shows a model of the $Be(BH_4)_2$ molecule after Bauer[54]. Evidently, this model agrees well with classical views about the coordination four-covalency of beryllium.

In 1968 Almenningen and coworkers[1,64], in repeating the electron diffraction investigation of gaseous $Be(BH_4)_2$ by an improved experimental technique, came to an unexpected conclusion concerning the non-correspondence of Bauer's linear model with the experimental results. According to Almenningen, the three atoms (Be and B) are situated at the vertices of an almost regular triangle. The "triangular" configuration of the molecule agrees well with dipole moment (2.1 ± 0.5 D), measured[65] in 1969. Three polar molecular structures (Fig. 2, II, III, and IV) which exhibit the same symmetry C_{2v} can, in principle, be constructed on the base of the triangle of boron and beryllium atoms. Structures (II), (III), and (IV) are those of Almenningen, structure (V) was proposed by Cook[2] on the basis of a new interpretation (different from that of Almenningen and coworkers[1]) of the electron diffraction results.

Cook and Morgan[2] think that model (V) agrees better with the results of the investigation of the spectrum of beryllium tetrahydroborate, since it contains the $\diagdown BH_2$ grouping, which corresponds to the characteristic vibrations at 2630, 2531, and 974 cm^{-1} in the infrared spectrum†.

The presence of a band at 974 cm^{-1} is of special significance, since it has never before been observed in the infrared spectra of compounds with one terminal B—H bond[66].

In a further study of the infrared spectra of unsaturated vapour of $Be(BH_4)_2$ and its isotope-substituted analogues with ^{10}B and D, Cook and Morgan[67] were able to resolve P, Q, and R—the branches of the rotational structure in the spectrum. They showed the existence of terminal BH_2 groups and the absence of terminal BH groups in the $Be(BH_4)_2$ molecule.

An analysis of the vibrational-rotational contour of the absorption band with ν = 2521 cm^{-1} allowed the investigators to suggest the model of the $Be(BH_4)_2$ molecule shown in Fig. 2 (VI).

This model has C_{2v} symmetry. In the $\sigma_v(x, z)$ planes there are the boron atoms, the beryllium atom, and four terminal hydrogen atoms. The beryllium atom is linked with the boron atoms by twin hydrogen bridges. The planes of the bridging bonds are perpendicular to the $\sigma_v(x, z)$ plane.

The form of the infrared spectrum of saturated $Be(BH_4)_2$ vapour allowed the presence of polymeric beryllium tetrahydroborate molecules in this state to be proposed[67]. In 1952 Stosik[68] was the first to investigate the crystal structure of $Be(BH_4)_2$ (see Table 3), in 1952.

Marynick and Lipscomb[69] subsequently determined the dimensions and symmetry of the tetragonal unit cell more accurately (a = 13.62 ± 0.01 Å, c = 9.10 ± 0.01 Å, space group $I4\,Cd$) and interpreted the structure of beryllium tetrahydroborate in the crystalline phase.

In this structure the existence of polymeric spiral chains, not bonded to one another was observed. Polymerisation occurs owing to some of the BH_4 groups bonding beryllium atoms between them. The other BH_4 groups do not participate in the polymerisation and contain terminal BH_2 hydrogen bonds.

The structure of the zirconium tetrahydroborate $Zr(BH_4)_4$ molecule was investigated in both the crystalline and the gas phases by X-ray structural analysis and electron diffraction[70-72].

† The corresponding vibrations in the infrared spectrum of B_2H_6 are at 2612, 2525, 1035, and 979 cm^{-1}.

In every instance essentially the same result was obtained. The model of the $Zr(BH_4)_4$ molecule according to Plato and Heldberg's results[72] is shown in Fig. 3. Interestingly, in the $Zr(BH_4)_4$ molecule, unlike the $Al(BH_4)_3$ and $Be(BH_4)_2$ molecules, the $[BH_4]$ groups have C_{3v} symmetry and are connected with the zirconium atom by three hydrogen bridges. This symmetry of the BH_4 group and consequently of the molecular model with the metal atoms twelve-coordinated by hydrogen does not contradict the form of the infrared spectra of the zirconium and hafnium tetrahydroborates in the gas phase[73] and in solutions in non-polar solvents[73,74]. The intense absorption bands at 510 cm^{-1} and 602 cm^{-1} are assigned to the vibrations of the M—B bonds in zirconium and aluminium tetrahydroborates respectively. However, it is noteworthy that the spectrochemical investigations of these compounds are qualitative.

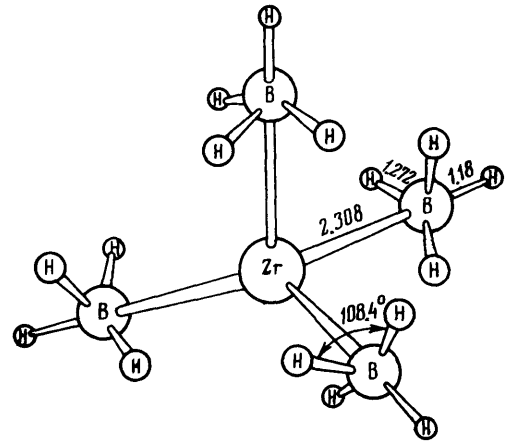

Figure 3. Model of the zirconium tetrahydroborate molecule.

The NMR spectrum of $Zr(BH_4)_4$ vapour[75] shows the equivalancy of all four protons in the BH_4 group. An analysis of the infrared spectrum of biscyclopentadienylzirconium bistetrahydroborate[76], that is, zirconium tetrahydroborate in which two BH_4 groups have been replaced by C_5H_5 groups, and an analysis of the infrared spectrum of $(C_5H_5)_2TiBH_4$ [77] showed the absence of absorption bands characteristic of BH_4^- ions in these compounds. The investigators suggested twin hydrogen bridging bonds between the boron atoms and the titanium and zirconium atoms. Consequently, unlike $Zr(BH_4)_4$, the local symmetry of the BH_4 group is C_{2v}. A comparison of the infrared spectra of these three compounds confirms the similarity of the infrared spectra of $(C_5H_5)_2Zr(BH_4)_2$ [76] and $TiBH_4(C_5H_5)_2$ and simultaneously the absence of the latter from the $Zr(BH_4)_4$ infrared spectra[73,74] in the range of the vibrations of the bridge and terminal B—H bonds, which shows that there are structural changes in the MBH_4 fragment in $(C_5H_5)_2Zr(BH_4)_2$ and $TiBH_4(C_5H_5)_2$ in comparison with $Zr(BH_4)_4$. The infrared spectra of the compounds $(Ph_3P_2)CuBH_4$,[78] $NiABH_4ClO_4$, and $NiA(BH_4)_2$ [79] (where A is 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetra-azacyclotetradecane) were interpreted on the basis of models with M—H—B and terminal BH_2 bonds.

In view of the fact that the structure of the $Be(BH_4)_2$ molecule in the vapour is still the subject of discussion some spectroscopic investigations have been made[80,81], which seemed desirable for an attempt at interpreting the infrared spectra of the unsaturated vapour of $Be(BH_4)_2$ itself.

A spectroscopic study of $MeBeBH_4$ vapour showed[81] that its gas phase is a mixture of monomeric and dimeric molecules. An analysis of the lines of the infrared spectrum allowed Cook and Morgan[81] to conclude that for both the monomeric and the dimeric molecules the skeleton was linear. The absorption bands in the $MeBeBH_4$ spectrum were assigned on the basis of the infrared spectrum of the Me_2Be vapour[80] and of the results obtained in the replacement of the boron and hydrogen atoms in the $MeBeBH_4$ molecule by the isotopes ^{11}B and D.

These results seemed useful in the assignment of the absorption bands in the spectrum of the $Be(BH_4)_2$ molecule in the vapour[67]. According to this assignment the absorption band with wavenumber 1014 cm^{-1} corresponds to the vibration of the Be—B bond and the absorption bands with wavenumbers 2172, 2069, and 1545 cm^{-1} to the vibrations of the BeH_2B fragment of the $Be(BH_4)_2$ molecule.

Since the experimental results on which the structural chemistry of the covalent tetrahydroborates is based are few and not systematic, it is at present impossible to draw a reliable picture of the nature of the chemical bond in the $M(BH_4)_n$ molecules.

However, undoubtedly the classical ideas of the valence and stereochemical possibilities of the atoms of the light metals Be and Al seem inapplicable for describing the structure and chemical properties of these compounds.

V. CHEMICAL REACTIONS

1. REACTION OF THE TETRAHYDROBORATES $M(BH_4)_n$ WITH ALKENES

Reactions of this type have been studied only for aluminium tetrahydroborate. Gaseous aluminium tetrahydroborate reacts readily at room temperature with ethylene, propene, and but-1-ene[82]. As a result of the reaction boron alkyls are formed, presumably with alkyl-substituted aluminium tetrahydroborates. Since the reaction rate is independent of the alkene concentration, the following possible mechanism is proposed for it:

$$Al(BH_4)_3 \rightleftarrows Al(BH_4)_2H + BH_3\,, \quad (18)$$

$$Al(BH_4)_2H + CH_2=CHR \rightarrow Al(BH_4)_2CH_2CH_2R\,, \quad (19)$$

$$BH_3 + 3\,CH_2=CHR \rightarrow B(CH_2CH_2R)_3\,. \quad (20)$$

The conversion rate is increased in the presence of traces of oxygen. The final products (boron alkyls) are inhibitors[82,83]. The reaction of aluminium tetrahydroborate with butadiene is more complex and evidently is not described by such a simple scheme[83].

2. REACTION WITH COMPOUNDS CONTAINING AN M—R BOND

Uranium tetrahydroborate reacts with trimethylboron at 50—60°C with the formation of methyldiborane and a green viscous liquid. Its fractionation allows us to obtain compounds of composition $U(BH_4)_3(CH_3BH_3)$ and $U(BH_3CH_3)_4$, which react with water, hydrogen chloride, and diborane, with the formation of methylboric acid or methyldichloroborane, uranium tetrahydroborate, and alkyl-substituted boranes[22]:

$$U(BH_3CH_3)_4 + 12\,HCl \rightarrow UCl_4 + 12H_2 + 4CH_3BCl_2\,, \quad (21)$$

$$U(BH_3CH_3)(BH_4)_3 + 12\,H_2O \rightarrow U(OH)_4 + 15\,H_2 + CH_3B(OH)_2 + 3HBO_2\,, \quad (22)$$

$$U(BH_3CH_3)(BH_4)_3 + B_2H_6 \rightarrow U(BH_4)_4 + CH_3BH_2BH_3\,, \quad (23)$$

$$U(BH_3CH_3)_4 + B_2H_6 \rightarrow U(BH_4)_4 + (CH_3)_4B_2H_2\,. \quad (24)$$

Reactions analogous to those described above, namely those leading to complication of the BH_4 group without change in the AlH_nB-bridging bonds are also known for aluminium tetrahydroborate, since its reaction with tetraborane and decaborane in ether lead to the formation of a series of compounds $Al(BH_4)_{3-x}(B_3H_8)_x$, where $x = 1$, 2, or 3, and $Al(BH_4)_{3-x}(B_{10}H_{13})_x$, where $x = 1$ and 2, respectively[84].

Aluminium tetrahydroborate[85] reacts vigorously with tetramethyltin and tetramethyl-lead with the formation of intermediate unidentified solid products, which decompose into Sn or Pb, H_2, methylated boranes, and $CH_3Al(BH_4)_2$. It is assumed that the intermediate unstable products have the composition $(CH_3)_2Sn(BH_4)_2$ and $(CH_3)_3Pb(BH_4)$. Aluminium tetrahydroborate reacts with trimethylchlorosilane according to the equation:

$$2\,Al(BH_4)_3 + 6\,(CH_3)_3SiCl \rightarrow 2AlCl_3 + 3B_2H_6 + 6\,(CH_3)_3SiH\,. \quad (25)$$

However, in silicon tetrachloride hydrogenation of the Si—Cl bonds by aluminium tetrahydroborate does not take place[86].

3. REACTION WITH OTHER ORGANIC COMPOUNDS

With organic and organosilicon compounds which are capable of being reduced the covalent tetrahydroborates react as very strong reductants. An example is the reaction of uranium tetrahydroborate with methyl borate[22]:

$$6\,U(BH_4)_4 + 2\,B(OCH_3)_3 \rightarrow 6\,U(BH_4)_3(BH_3OCH_3) + B_2H_6\,, \quad (26)$$

or that of aluminium tetrahydroborate with ethyl orthosilicate[85]:

$$2\,Al(BH_4)_3 + Si(OC_2H_5)_4 \rightarrow 2\,B_2H_6 + SiH_4 + 2Al(BH_4)\cdot(OC_2H_5)_2\,. \quad (27)$$

4. REACTION WITH NUCLEOPHILIC AGENTS—WITH NEUTRAL MOLECULES (L) OR IONS (X^-)

Reactions of this type are of the greatest interest. They are specific for the covalent tetrahydroborates and allow compounds of a new type to be obtained, containing Al and Be atoms in unusual valence states.

a. Formation of Compounds Containing the Anionic Complexes $[M(BH_4)_nX]^-$

The first mention of the formation of the complexes $M'X.M''H_n.mBH_3$, where M' is an alkali metal and M'' = Al or Be, was made in Wiberg's patents[87,88] in which the possibility of obtaining such compounds by the action of the corresponding covalent tetrahydroborate or of its ethereal solutions on the salts of alkali metals, or by the reaction of lithium tetrahydroaluminate with diborane in ethereal solutions was mentioned. In the latter instances, complexes containing the ether were formed.

Nöth[9], in referring to unpublished results[89], suggested the formation of such compounds in the reaction mixture in the production of aluminium tetrahydroborate by reaction (2).

Ashby and Foster[90] subsequently queried the existence of complexes in ethereal solutions. Later investigations of Nöth and coworkers[91] showed the possibility of the existence of equilibria in the $MX-Al(BH_4)_3-Et_2O$ systems:

$$Al(BH_4)_3 + LiX \xrightarrow{Et_2O} Li[Al(BH_4)_3X] \rightleftarrows LiBH_4 + Al(BH_4)_2X . \quad (28)$$

Complexes stable at room temperature were also obtained containing large organic or inorganic cations $[N(C_2H_5)_4][Al(BH_4)]_4$,[92] $[(C_8H_{17})_3NC_3H_7][Al(BH_4)_4]$, $[(C_8H_{17})_3NC_3H_7][Be(BH_4)_3]$, $[(C_8H_{17})_3NC_3H_7]_2[Be(BH_4)_5]$,[93] $[(C_4H_9)_4N][Al(BH_4)_4]$,[94] $K[Al(BH_4)_3Cl]$, and $K[Al(BH_4)_4]$.[95]

The stability of complexes with complex anions is known to depend on the charge: radius ratio of the outer-sphere cation z/r. For example, in the series $LiAlH_4-KAlH_4$ or $LiBH_4-KBH_4$ the thermal stability of the compounds increases rapidly. There is a similar regularity in the present instance. Actually, when the vapour pressure of aluminium tetrahydroborate above the complex $Li[Al(BH_4)_4]$ [88] is 2 mmHg the complexes with large organic cations, for example, $[N(C_2H_5)_4][Al(BH_4)_4]$ do not dissociate into the initial products even at 140°C.[92,94] The compounds $K[Al(BH_4)_3Cl]$ and $K[Al(BH_4)_4]$ probably have a somewhat lower stability and disproportionate at 130°C with an appreciable endothermic effect. It is noteworthy that the decomposition of the complexes at this temperature differ; whereas the complex $K[Al(BH_4)_4]$ dissociates mainly into the initial KBH_4 and $Al(BH_4)_3$, the compound $K[Al(BH_4)_3Cl]$ decomposes according to the following probable mechanism:

$$K[Al(BH_4)_3Cl] \rightarrow Al(BH_4)_2Cl + KBH_4 , \quad (29)$$

$$Al(BH_4)_2Cl \rightarrow Al(BH_4)_3 + AlCl_3$$

$$Al(BH_4)_2Cl \rightarrow AlB_xH_yCl + B_2H_6 + H_2 . \quad (30)$$

The NMR spectrum of solutions of the complexes $[(C_8H_{17})_3NC_3H_7][M(BH_4)_n]$ suggests the equivalence of all the BH_4 groups in the $[M(BH_4)_n]^{m-}$ anion[93].

b. Reaction with the Formation of Molecular Compounds of the $M(BH_4)_n.mL$ Type

Oxonium and sulphonium complexes. Beryllium and aluminium tetrahydroborates dissolve in ethers with considerable evolution of heat and with the formation of complexes, the composition and properties of which are given in Table 4.

The reactivity of the oxonium complexes and of their solutions is less than that of the initial tetrahydroborates—in air, they are oxidised and hydrolysed slowly, without spontaneous combustion; it reacts violently with water, but without explosion. At room temperature in a dry atmosphere the oxonium complexes are relatively stable and decompose at an appreciable rate only at 40—50°C.

Desolvation of the oxonium complexes is accompanied by decomposition of the molecules of the tetrahydroborate and ligand[34].

It is known that the equilibrium in the system:

$$Al(BH_4)_3Me_2S + Me_2O \rightleftarrows Al(BH_4)_3Me_2O + Me_2S \quad (31)$$

is shifted almost entirely to the side of the formation of $Al(BH_4)_3Me_2O$, which shows that the strength of the oxonium Al←O bond is greater than that of the sulphonium Al←S bond.

In several instances the interaction of tetrahydroborates with liquid and solid ligands is identical. For example, beryllium tetrahydroborate reacts with THF vapour at room temperature to form the saltlike complex $Be(C_4H_8O)_4(BH_4)_2$,[27] in the infrared spectrum of which absorption bands characteristic for the isolated BH_4^- group are present. In the reaction of the same compounds in the liquid phase a vitreous substance of indefinite composition is formed[27]. This is probably brought about by irreversible interaction of the complex formed initially with the excess of ligand. The corresponding complex of aluminium tetrahydroborate reacts with the excess of THF with loss of a BH_3 group[34], evidently in the form $BH_3.C_4H_8O$.

Table 4. Some physicochemical properties of oxonium complexes of beryllium, aluminium, and zirconium tetrahydroborates.

Compound	M.p., °C	p_{sat}, mmHg
$Be(BH_4)_2 \cdot Et_2O$	liquid at 20°C	—
$Be(BH_4)_2 \cdot 4C_4H_8O$	solid at 20°C	—
$Al(BH_4)_3 \cdot Me_2O$	0—1	0.5 at 20°C
$Al(BH_4)_3 \cdot Et_2O$	0.5—1.5	7.8 at 85°C
$Al(BH_4)_3 \cdot C_4H_8O$	24—26	—
$2[Be(BH_4)_2] \cdot 3[C_2H_4(OMe)_2]$	solid at 20°C	—
$Zr(BH_4)_4 \cdot C_4H_8O$	2	—

Oxonium complexes can also be obtained by other methods, for example, by reaction (12), which allows compounds of different composition described by the formula $H_nAl(BH_4)_{3-n}.xEt_2O$, where $x = 1$ or 2, to be obtained from the same initial substances taken in equal ratios. The second molecule of the ether in such complexes is weakly bound with the $H_nAl(BH_4)_{3-n}$ molecule and is readily removed in a vacuum. At elevated temperatures the decomposition of the complex proceeds further[34]. The diethyl ether in the compounds $H_nAl(BH_4)_{3-n}.xEt_2O$ is readily replaced by an equimolecular amount of THF:

$$H_nAl(BH_4)_{3-n} \cdot xEt_2O + xC_4H_8O \rightarrow H_nAl(BH_4)_{3-n} \cdot xC_4H_8O + xEt_2O \quad (32)$$

The thermal decomposition of the compound $HAl(BH_4)_2.2C_4H_8O$ was studied and takes place with the formation of butoxyaluminium bistetrahydroborate:

$$2HAl(BH_4)_2 \cdot 2C_4H_8O \rightarrow 2C_4H_8O + (BH_4)_2Al\langle O(C_4H_9)\rangle Al(BH_4)_2 . \quad (33)$$

In addition to complexes with ethers, aluminium tetrahydroborate forms stable compounds of the $Al(BH_4)_3 \cdot Al(OR)_3$ type on reacting with the corresponding alkoxides. The complexes obtained are liquids or solids, which vaporise without decomposition in a high vacuum[96].

Systems which contain ethers and heavy metal tetrahydroborates have been studied insufficiently. It is only known that when Zr tetrahydroborate reacts with THF the compound $Zr(BH_4)_4.C_4H_8O$ is formed[96].

The existence of this compound was found on the basis of a study of the equilibrium diagram in the $Zr(BH_4)_4-C_4H_8O$ system. Interestingly, on the equilibrium diagrams

of the $Zr(BH_4)_4$—dioxan[98], $Zr(BH_4)_4$—n-C_6H_{14}, $Zr(BH_4)_4$—cyclo-C_6H_{12}, $Zr(BH_4)_4$—C_6H_6, and $Zr(BH_4)_4$—$C_6H_6Zr(BH_4)_4$—$C_6H_5CH_3$ [99] systems there are only simple eutectics. It is noteworthy that neither structural nor physicochemical investigations of the oxonium complexes of the tetrahydroborates of aluminium, beryllium, and the Group metals have yet been made.

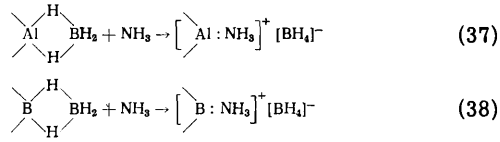
Compounds with Ammonia. The reaction of covalent tetrahydroborates with ammonia has been studied only for aluminium tetrahydroborate. In various investigations[3,5,28,100,101] the existence of several compounds has been found: $Al(BH_4)_3.nNH_3$, where n = 1, 2, 4, and 6. The aluminium tetrahydroborate ammines are solid substances stable at room temperature. The first to be obtained was aluminium tetrahydroborate monoammine, by the reaction of $Al(BH_4)_3$ with ammonia, taken in equimolecular proportions, initially at −80°C and then at room temperature. An attempt by Bird and Wallbridge[5] to prepare the monoammine in toluene solution at 1 : 1 molar ratio of the reagents and −78°C led to the production of aluminium tetrahydroborate diammine. A solution of the hexa-ammine complex is formed in the reaction of aluminium tetrahydroborate with an excess of liquid ammonia.

Another method for making an ammoniacal solution of the hexammine complex is the electrolysis of alkaline tetrahydroborates in liquid ammonia:

$$3\,NaBH_4 + Al + 6NH_3 \rightarrow Al(BH_4)_3 \cdot 6\,NH_3 + 3\,Na\,. \qquad (34)$$

A dissolving anode served as a source of aluminium[102]. When ammonia was removed from the solution, aluminium tetrahydroborate hexammine, stable at room temperature, was precipitated; it evidently contained clathrate ammonia[3]. X-Ray diffraction analysis showed the crystal structure of only a clathrate of composition $Al(BH_4)_3.6.7NH_3$.[3,5,99,101]. The infrared and NMR spectra show the presence of BH_4^- ions in the hexammine[5]. The ammoniacal solutions of aluminium tetrahydroborate hexammine evidently contain these ions, which react with aluminium chloride to form aluminium chloride hexammine and hydrogen:

$$Al(BH_4)_3(NH_3)_6 + 6\,NH_4Cl \rightarrow AlCl_3(NH_3)_6 + 3\left[\begin{matrix}NH_3\\NH_3\end{matrix}\!\!>\!BH_2\right]Cl + 6H_2\,. \qquad (35)$$



The reaction of aluminium tetrahydroborate hexammine with lithium in ammonia at −40°C proceeds according to the equation:

$$Al(NH_3)_6(BH_4)_3 + 2Li \rightarrow Li[Al(NH_2)_2(BH_4)_2] + H_2 + LiBH_4 + 4NH_3\,. \qquad (36)$$

The composition of the compound $Li[Al(NH_2)_2(BH_4)_2]$ was found by chemical analysis. Bird and Wallbridge[5] postulated the possibility of the $Al(H_2N)_2^+$ grouping in the anion of this complex being isoelectronic with allene $CH_2{=}C{=}CH_2$ and examined the possibility of its stabilisation according to the scheme $[H_2N{=}Al{=}NH_2]^+$.

Unlike aluminium tetrahydroborate its hexammine is slowly hydrolysed by cold water and is stable when heated to 50°C. When it is kept for a long period (11 days) at 50°C in a vacuum (10^{-5} mmHg) it yields a solid residue stable up to 400°C and the release of ammonia and volatile boron-containing compounds. Heating for 8 h at 105°C leads to the formation of analogous products[100].

Evidently, saltlike aluminium tetrahydroborate hexammine is the final product of the reaction between $Al(BH_4)_3$ and ammonia. Heterolytic breaking of the AlH_2B bridging bonds, which occurs in the $Al(BH_4)_3$ molecule under the action of NH_3, is analogous to the formation of the so-called "diborane ammine":

$$Al(H)_2BH_2 + NH_3 \rightarrow [Al:NH_3]^+[BH_4]^- \qquad (37)$$

$$B(H)_2BH_2 + NH_3 \rightarrow [B:NH_3]^+[BH_4]^- \qquad (38)$$

It seems that the initial stage of this process is the formation of unstable non-saltlike addition products of the $Al(BH_4)_3.nNH_3$ type; these may include the monoammine and diammine described earlier[4,28].

Compounds with primary and secondary amines, phosphines, and hydrazine. Nothing has been published on the reaction of aluminium tetrahydroborate with primary and secondary amines, phosphines, and hydrazine. Beryllium tetrahydroborate forms the following complexes with these ligands: $Be(BH_4)_2.NH(CH_3)_2$; $Be(BH_4)_2.3NH(CH_3)_3$; $Be(BH_4)_2.PH(CH_3)_2$; $Be(BH_4)_2.4NH_2.(C_4H_9)$;[102-103] $Be(BH_4)_2.3N_2H_4$.[104]

The monodimethylamine and phosphine derivatives are liquids; the others are crystalline[103-105]. It is suggested that like $Be(BH_4)_2.4C_4H_8O$ the complex of monobutylamine with beryllium tetrahydroborate has a saltlike structure with a BH_4^- anion[103].

The melting point has been measured only for tris(dimethylamine)beryllium tetrahydroborate (94°C), which decomposes at that temperature with release of hydrogen and the amine.

Compounds with tertiary amines, phosphines, and trimethylarsine. 1:1 complexes of beryllium and aluminium tetrahydroborates with tertiary amines or phosphines are obtained at low temperatures in the absence of an excess of the ligand. It is convenient to carry out the reaction in the presence of an inert solvent[104,106].

Table 5. Physicochemical properties of complexes of composition $M(NH_4)_nL$.

Compound	M.p., °C	T_{decomp}, °C	Other properties
$Be(BH_4)_2 \cdot N(CH_3)_3$	35	~140	$\lg P_{mmHg} = 8.353 - 2909/T$
$Al(BH_4)_3 \cdot N(CH_3)_3$	79 in rapid heating	50	monomer in vapour monomer in C_6H_6
$Al(BH_4)_3 \cdot N(C_2H_5)_3$	solid at 25°C	50	monomer in C_6H_6
$Be(BH_4)_2 \cdot P(CH_3)_3$	liquid at 20°C	--	volatile in a vacuum
$Be(BH_4)_2 \cdot P(C_2H_5)_3$	liquid at 20°C	—	P_{mmHg} = 0.01 at 68°C
$Be(BH_4)_2 \cdot PPh_3$	163 (decomp.)	122	monomer in C_6H_6
$Al(BH_4)_3 \cdot P(CH_3)_3$	78	—	monomer in C_6H_6
$Al(BH_4)_3 \cdot PPh_3$	186 (decomp.)	>70	monomer in C_6H_6
$Al(BH_4)_3 \cdot As(CH_3)_3$	57	—	—

Compounds of composition $M(BH_4)_n.L$ have been studied in relative detail. The physicochemical properties of such complexes are in Table 5.

As Table 5 shows, the 1 : 1 compounds are stable under ordinary conditions. The decomposition temperatures of most of the compounds have been determined but their pyrolysis has been insufficiently studied. An analysis of

published papers suggests that during the pyrolysis trialkylaminoboranes or trialkylphosphineboranes are formed, which are evidently thermodynamically the most stable compounds in the "ternary systems" MH_n—B_2H_6—NR_3 or MH_n—B_2H_6—PR_3.[4,28]

The amine and phosphine complexes of aluminium tetrahydroborate react with an excess of the ligand according to the following probable equation:

$$Al(BH_4)_3L \overset{+L}{\rightleftarrows} Al(BH_4)_3 \cdot 2L \rightleftarrows 'Al(BH_4)_2HL + BH_3L \overset{+L}{\rightleftarrows} \ldots\ldots \overset{+L}{\rightleftarrows} AlH_3 \cdot L \ddagger \quad (39)$$

Unlike the complexes of aluminium tetrahydroborate with tertiary amines and phosphines, the arsonium complex of composition $Al(BH_4)_3.As(CH_3)_3$ does not react with an excess of the ligand. The complex readily participates in an exchange reaction with trimethyl phosphine with the formation of $Al(BH_4)_3.P(CH_3)_3$, which is probably due to the greater strength of the Al←P bond compared with that of Al←As.

As already noted, beryllium tetrahydroborate does not form 1 : 2 complexes with trimethylamine and trimethylphosphine. When the trimethylamine complex of beryllium tetrahydroborate is heated it reacts with an excess of trimethylamine thus[29]:

$$Be(BH_4)_2 \cdot N(CH_3)_3 + N(CH_3)_3 \xrightarrow{100^\circ} \{HBe(BH_4)N(CH_3)_3\}_n + BH_3N(CH_3)_3 \quad (42)$$

The reaction of the phosphine complex of beryllium tetrahydroborate with an excess of the ligand evidently leads to the formation of beryllium hydride, which contains a certain amount of trialkylphosphine[102,103]:

$$Be(BH_4)_2 \cdot PR_3 + PR_3 \xrightarrow{70-180^\circ} \{BeH_2\}_n + 2PR_3BH_3 \quad (43)$$

The infrared spectra of compounds of aluminium tetrahydroborate and tetradeuterioborate with $N(CH_3)_3$, $P(CH_3)_3$, $As(CH_3)_3$, Et_2O, Me_2O, and Me_2S have been recorded[5,110] in the range 400—4000 cm^{-1}. Quantitative analysis and comparison of these spectra allows the following conclusions to be drawn:

1. Usually the frequencies of the vibrations in the coordinated $Al(BH_4)_3$ molecule are hardly displaced at all in comparison with the frequencies of the vibrations in free compounds.
2. Judging by the positions of the absorption bands characteristic for terminal BH_2 bonds, the structure of the tetrahydroborate group in the $Al(BH_4)_3.L$ molecules remains approximately the same as in the initial aluminium tetrahydroborate.
3. The equivalency of the three BH_4 groups in the $Al(BH_4)_3.L$ molecules can be postulated, since the significant splitting of the absorption bands belonging to the Al—H and B—H bridging vibrations was not observed.
4. The absorption bands due to the Al—B vibrations are shifted in the infrared spectra of the complexes into the longwave range, which can be interpreted as an increase in the Al—B interatomic distance, due to an expansion of the coordination sphere of the Al atom and an increase in its coordination number.

‡ The compounds $AlH_x(BH_4)_{3-x}L$, which are intermediates in reaction (39), were obtained independently by the reaction:

$$AlCl_{3-x}H_xN(CH_3)_3 + LiBH_4 \xrightarrow{C_6H_6} AlH_x(BH_4)_{3-x} \cdot N(CH_3)_3 + LiCl \quad (40)$$

Trialkylsiloxane derivatives of aluminium tetrahydroborate can be obtained in a similar manner:

$$R_3SiOAlCl_2 + 2LiBH_4 \xrightarrow{Et_2O} R_3SiOAl(BH_4)_2 + LiCl \quad (41)$$
$$(R = CH_3 \text{ or } C_2H_5)^{109}$$

However, these conclusions do not agree completely with the results of a direct X-ray diffraction investigation of the molecular structure of the complex $Al(BH_4)_3.N(CH_3)_3$.[111,112] Bird and Wallbridge observed two different molecular configurations of the complex $Al(BH_4)_3.N(CH_3)_3$. —"high-temperature" and "low temperature".

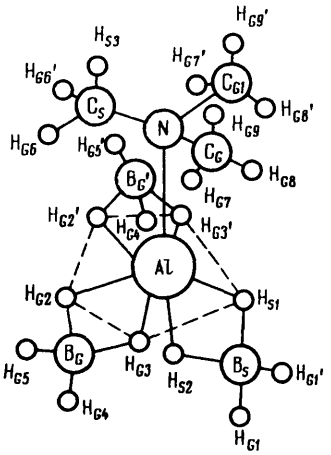


Figure 4. Model of a molecule of the compound $Al(BH_4)_3.N(CH_3)_3$.

In the "high-temperature" modification the B and N atoms are situated at the vertices of an almost regular tetrahedron, at the centre of which is the Al atom. The coordinates of the H atoms were not determined in this study, therefore the form and symmetry of the $[AlX_n]$ polyhedron, where X = N, B, or H cannot be determined.

Evidently, the investigations[5,11] of the infrared spectra relate to this configuration of the $Al(BH_4)_3.N(CH_3)_3$ molecule. An investigation of the low-temperature configuration at −160°C was more complete. The model of the $Al(BH_4)_3.N(CH_3)_3$ molecule is given in Fig. 4; Table 6 gives the valence angles and interatomic distances.

The boron atoms in the $Al(BH_4)_3.N(CH_3)_3$ molecule are clearly non-equivalent, the Al—H_{bridge} distances differing markedly from one another: from 1.75—1.83 Å for the Al—B_G group to 1.95—2.00 Å for the AlB_S group.

The coordination polyhedron around the aluminium atom is a distorted pentagonal bipyramid. Interestingly, whereas the Al—N interatomic distance is almost equal to the sum of the covalent radii of Al and N and does not differ from the Al—N interatomic distances in the molecules of the trialkylaminealanes $AlH_3.nNR_3$,[114] the Al—B interatomic distance is considerably greater than that in the $Al(BH_4)_3$ molecule, 2.257 Å compared with 2.14 Å.

An analysis of the structure suggests that it is produced by the displacement of one of the BH_4 groups, namely the group situated in the "trans position" to the $N(CH_3)_3$ molecule.

Actually, under the action of an excess of the ligand such a displacement takes place very readily, as already noted above . Evidently, in the $Al(BH_4)_3.N(CH_3)_3$ molecule and in the molecules (monotypical with it) of the complexes with trimethylphosphine, trimethylarsine,

triethylamine, etc., the atom for the formation of four two-centre bonds (three Al—B and one Al—L) uses a set of four sp^3 hybrid atomic orbitals.

Table 6. Valence angles and interatomic distances for the low-temperature configuration of $Al(BH_4)_3.N(CH_3)_3$.

$r_{Al-N} = 1.989 \pm 0.008$ Å	$B_S H_4$: $r_{B_S-H_{S1}} = 1.48 \pm 0.10$Å
$r_{Al-B_S} = 2.257 \pm 0.012$ Å	$r_{B_S-H_{S2}} = 1.16 \pm 0.011$Å
$r_{Al-B_G} = 2.227 \pm 0.011$Å	$r_{B_S-H_{G1}} = 1.15 \pm 0.08$Å
$r_{Al-H_{S1}} = 2.00 \pm 0.10$Å	$r_{H_{S1}-H_{S2}} = 2.29 \pm 0.15$Å
$r_{Al-H_{S2}} = 1.95 \pm 0.11$Å	$B_G H_4$: $r_{B_G-H_{G2}} = 1.18 \pm 0.07$Å
$r_{Al-H_{G2}} = 1.83 \pm 0.07$Å	$r_{B_G-H_{G3}} = 1.40 \pm 0.07$Å
$r_{Al-H_{G3}} = 1.75 \pm 0.08$Å	$r_{B_G-H_{G4}} = 1.22 \pm 0.11$Å
$\angle (N-AlH_{S2}) = 152.8 \pm 3.3°$	$r_{H_{G2}-H_{G3}} = 2.06 \pm 0.10$Å

The three four-centre AlH_2B bonds are formed from the *d* atomic orbital of the aluminium without participation of the *p* atomic orbital as in the $Al(BH_4)_3$ molecule. Because of this the strength of the bridging bonds in the $Al(BH_4)_3.L$ molecule should evidently be less than in the aluminium tetrahydroborate molecule. It is noteworthy that the existence of complexes of composition $Al(BH_4)_3.2L$ (see p. 10) does not contradict the above views.

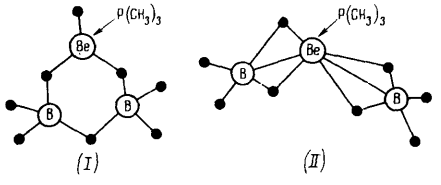

Figure 5. Probable structures of the $Be(BH_4)_2.P(CH_3)_3$ molecule.

The molecular structures of such compounds is of considerable interest. It can be postulated that the coordination polyhedron of the aluminium atom formed by the B and L atoms will be like that in the molecule of bistrimethylamine alane $AlH_3.2N(CH_3)_3$ with location of the boron atoms in the equatorial plane of the trigonal bipyramid.

X-Ray diffraction investigations of the complex derivatives of beryllium, zirconium, hafnium, thorium, and uranium tetrahydroborates have not yet been made.

A qualitative analysis of the infrared and NMR spectra of the compound $Be(BH_4)_2.P(CH_3)_3$ [103,104] allowed it to be ascribed the probable structure shown in Fig. 5 (I).

However, taking into account the most recent results on the structure of beryllium tetrahydroborate in the gas phase[68] another model of the structure of the $Be(BH_4)_2.PMe_3$, Fig. 5 (II), seems more probable.

It must be noted that the addition of a second molecule of the ligand to a beryllium tetrahydroborate molecule is always accompanied by the breaking of the Be—H—B bridging bonds. For example, the complexes $Be(BH_4)_2.4C_4H_8O$ and $Be(BH_4)_2.4C_4H_9NH_2$ are constructed from $[Be.4L]^{2+}$ cations and $[BH_4]^-$ anions[102].

This experimentally established fact can be explained as the consequence of the beryllium atom in the $Be(BH_4)_2L$ molecule using the entire set of four atomic orbitals and becoming "coordination saturated" as a result. It is to be hoped that further investigation of the structure and reactivity of the complexes of the tetrahydroborates of the light metals will yield results convenient for developing new ideas about the stereochemistry and nature of the chemical bond in the inorganic compounds of the light elements.

Electrochemical Behaviour of Uranium at a Mercury Electrode in Aqueous Solutions

R.Sh.Enikeev, S.I.Khan, and M.T.Kozlovskii (deceased)

In aqueous solutions hexavalent uranium is reduced at a mercury electrode to the quadrivalent or tervalent state and in some cases even to the metal itself. The number of stages observed in the cathodic process and also the final valence form of uranium depend on the composition of the solution, in particular on the presence of complex-forming agents and the pH of the medium. As an analytical method, the polarography of uranium is at present finding only limited applications. The bibliography includes 131 references.

The first studies dealing with the electrolysis of aqueous solutions of uranium salts at a mercury cathode were published in 1880.[1-2] In these and in subsequent investigations[3-9] carried out in 1901—1919, it was shown that a uranium amalgam is not formed when aqueous solutions of uranium(VI) chlorides, sulphates, nitrates, acetates, and carbonates are electrolysed, since, depending on the initial pH, precipitates of tetravalent or hexavalent uranium are deposited at the mercury cathode owing to the increase of the alkalinity of the solution during electrolysis (in the absence of effective complex-forming agents from the solution, hexavalent uranium is precipitated at pH > 4.5 and tetravalent uranium at pH > 3.5).[10-13] Indeed, the reduction of hexavalent uranium at the cathode involved hydrogen ions in accordance with the mechanism[10,14]

$$UO_2^{2+} + 4H^+ + 2e \rightarrow U^{4+} + 2H_2O,$$

while in the anodic process fewer hydrogen ions are produced for the same consumption of electricity:

$$H_2O - 2e \rightarrow 2H^+ + \frac{1}{2}O_2.$$

On the other hand, in the presence of ions which are oxidised at the anode, for example chloride or acetate ions, the increase in the alkalinity of the solution is more pronounced. For this reason, it is now generally believed that in the electrolysis of its aqueous solutions uranium is not reduced to the metal at a mercury cathode[10-12,15-18]. (The potential of the U^{3+}/U_{met} system is -1.8 V relative to that of the hydrogen electrode[19].) Moreover, in analytical practice electrolysis at a mercury cathode is a known method for the elimination of metallic impurities from uranium[10,14,20-24].

In 1901 a report was published claiming the preparation of a uranium amalgam by the electrolysis of a hydrochloric acid solution of uranium(IV) at a mercury cathode[25]. The author quotes in support of his claim the finding that the residue after vacuum distillation of mercury is pyrophoric. However, according to the literature, pyrophoric properties are characteristic not only of metallic uranium but also of some of its oxides[7,26,27]. Later special investigations[28,29] failed to confirm this report[25].

According to another report[29], the electrolytic preparation of uranium amalgam from aqueous solutions is possible only when certain conditions are fulfilled, namely a high acidity of the electrolyte ($>2\,N\ H_2SO_4$), a high cathodic current density (more than 6 A cm^{-2}), and intense cooling of the solution. Under these conditions, about 1 ml of amalgam paste containing 0.5 g of metallic uranium (3.3 wt.%), the solid phase of which can be separated from the liquid on a glass sinter, is formed after 4 h.

According to communications by the same investigators[29,30], uranium(VI) can be reduced to the metal not only by electrolysis at a mercury cathode, but also by incorporation with zinc and tin amalgams; this contradicts a number of literature data, which indicate that zinc and its amalgam can reduce uranium(VI) only to the tervalent state and tin amalgam can reduce it only to the quadrivalent state[10,14,23,31-33].

In the electrolysis of solutions of hexavalent and tetravalent uranium at moderate current densities (less than 0.5 A cm^{-2}) at a mercury cathode, uranium may be reduced at most to the tervalent state[28].

It has been claimed[34] that uranium amalgam containing about 0.016 wt.% of the metal may be obtained by the incorporation of hexavalent uranium with sodium amalgam (0.13 wt.%) in acetate solutions at pH 4.

In the electrolysis of aqueous solutions of uranium(VI) at solid cathodes (Pt, Al, Ta, Nb, Cu, Pb, etc.), crystalline cathodic deposits are formed[2,9,35-45]: UO_2 or UF_4 (in the electrolysis of fluoride solutions), which is used for the preparation of samples of uranium in the determination of its isotopic composition by the α-spectrometric method. Partial or complete replacement of water by organic solvents improves somewhat the physical properties of these deposits (density, uniformity of distribution on the surface of the cathode) without, however altering their composition[2,9,10,46-49]. The report[48] that uranium may be reduced to the metal at a solid cathode in anhydrous alcoholic solution was not confirmed[27].

Thus in the electrolysis of aqueous and non-aqueous solutions, uranium is not reduced to the metal at solid cathodes. On the other hand, the possibility of reducing uranium to the metal at a mercury cathode is due to the fact that uranium forms intermetallic compounds with mercury[11] which shifts the potential of the U^{3+}/U_{met} system towards less negative values. The formation of uranium amalgam is also promoted by a high overvoltage for the discharge of hydrogen ion at the mercury electrode.

As shown above, the principal aim of the studies on the electrolysis of solutions of various uranium compounds was to find the limiting degree of its reduction and in particular to elucidate the possibility of an electrolytic preparation of uranium amalgam. On the other hand, the kinetics of the stepwise transition of uranium from the highest to the lowest valence states were not as a rule studied. In this connection, polarographic data are of definite interest for the investigation of the electrochemical behaviour of uranium at a mercury electrode.

The first studies on the polarography of hexavalent uranium were published in 1925 and 1928.[50-52] It was stated that in hydrochloric acid solutions at pH 1—2 multistage reduction of hexavalent uranium to the tervalent states takes place at a dropping mercury electrode (d.m.e.

Starting in 1945, the publication of a series of studies devoted to the systematic investigation of the polarographic behaviour of uranium began. One should note that most of these studies were carried out to extend the analytical applications of polarography[10,23] and relatively few[53-62] were concerned primarily with the electrochemical behaviour of uranium at a mercury electrode. In particular, it was shown that the reduction of hexavalent uranium at a dropping mercury electrode is a multistage process which depends significantly on the composition of the solution. In acid solutions of uranium(VI) free from complex-forming agents, for example in chloride or perchlorate solutions, two principal waves are observed[53-69] (Fig. 1). The first wave in the range of potentials between 0.12 and −0.28 V (s.c.e.)† is generally believed to correspond to the reversible reduction of sexivalent uranium to the pentavalent state. With increase of the acidity of the solution above 0.1 *N*, the half-wave potential for the first stage in the reduction of hexavalent uranium shifts towards negative values[53] and the height of the wave increases if the uranium(VI) concentration remains constant. This phenomenon is explained in the following way[53]. Pentavalent uranium, formed as a result of the electrode reaction disproportionates according to the following mechanisms depending on the acidity of the solution[53-69]:

$$2\,UO_2^+ + H^+ \rightarrow UO_2^{2+} + UOOH^+ \quad (\text{at pH} < 1),$$

$$2\,UO_2^+ + 2\,H^+ \rightarrow UO_2^{2+} + UO^{2+} + H_2O \quad (\text{at pH} > 1).$$

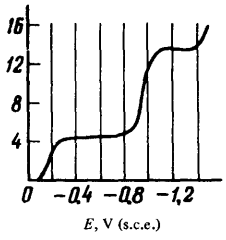

Figure 1. Polarogram for the reduction of uranium(VI) in 10^{-3} M UO_2Cl_2 + 0.03 M HCl + 0.1 M KCl solution containing 2×10^{-4}% of thymol[55].

With increased acidity of the solution, the rate of disproportionation of uranium(V) increases too, which in turn raises the rate of regeneration of uranium(VI) and hence the height of the first wave. This is confirmed by the decrease of the height of the first reduction wave for hexavalent uranium in the presence of tetravalent uranium, which reduces the rate of disproportionation of pentavalent uranium[53]. On the other hand, when precipitants and complex-forming agents for tetravalent uranium are added, the height of the wave increases as a result of the disproportionation of pentavalent uranium[60]. When the acidity of the solution is above 5 *N*, the wave becomes irreversible[60] owing to the elimination of oxygen atoms from the uranyl ion in the bulk of the solution[70]. One should note that the proportionality of the height of the first wave to the concentration of hexavalent uranium holds only in the acidity range 0.01−0.1 *N* and at higher acidities the height increases faster than the concentration of uranium(VI).[53-55] Thus the final product of the electrode reaction corresponding to the first main wave may be either tetravalent uranium or a mixture of tetravalent and pentavalent uranium (the literature data on this question are ambiguous).

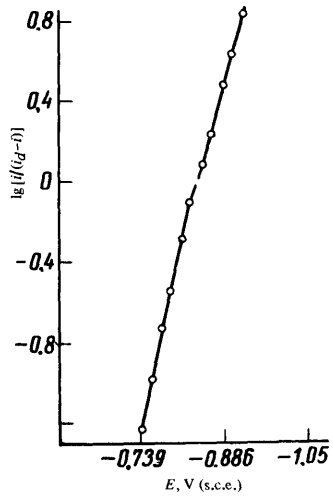

Figure 2. Analysis of the second wave for the reduction of uranium(VI) in 10^{-3} M $UO_2(ClO_4)_2$ + 0.1 M $HClO_4$ solution[59].

In aqueous chloride and perchlorate solutions of uranium(VI), the second main wave, observed in the potential range between −0.7 and −1.2 V (s.c.e.), is believed[53-67] to be due to the postulated limiting degree of reduction of uranium to the tervalent state. It is noteworthy that there is no generally accepted explanation of the nature of the second uranium(VI) wave, since it corresponds to the reduction of uranium to a valence state which has not been determined unambiguously. Thus, many investigators[53,61] believe that the wave corresponds to the reduction of pentavalent uranium to the tervalent state, while others[56,57] explain it by the reduction of a mixture of pentavalent and tetravalent uranium ions to the tervalent state. Some workers[59] think that in a hydrochloric acid solution (>0.1 *N*) the second main wave is associated with the reduction of only tetravalent uranium to the tervalent state owing to the high rate of disproportionation of pentavalent uranium. The plot of E against $\lg[i/(i_d - i)]$ corresponding to this wave has a break[53] or even a discontinuity[59], which indicates the complexity of the electrode process corresponding to the wave (Fig. 2). The height of the second wave is equal to that of the first when the acidity of the solution is about 0.1 *N*; on the other hand, with increase of the acidity above this value, the height of the second wave increases and in 6 *N* HCl is twice as high as that of the first wave, which, as stated above, also increases somewhat[60]. The increased heights of both uranium(VI) waves with increasing acidity of the solution can be accounted for by the fact that they correspond not only to the reduction of uranium but also to the catalytic

† Relative to the saturated calomel electrode.

discharge of hydrogen ions. One should note that kinetic data on the disproportionation of pentavalent uranium are necessary for an unambiguous explanation of the nature of both the second and first wave. However, the literature on this question does not meet this requirement (the most reliable method for the investigation of this reaction is at present the polarography of hexavalent uranium itself[71,72]).

At pH 2—3.5, in solutions free from complex-forming agents, the second uranium(VI) wave splits into two steps with half-wave potentials of −0.85 and −1.15 V (s.c.e.).[55,57,59,61]. There is no generally accepted explanation in the literature of the reasons for this phenomenon. For example, some workers[55,57] explain it in the following way. At a high pH, part of the hexavalent uranium or its reduction products form electrochemically indifferent deposits on the mercury cathode which rules out the possibility of quantitative reduction of uranium to the final (for aqueous solutions) tervalent state. On the other hand, starting from pH 2—3.5, the deposits dissolve. The low rate of this process is responsible for the marked kinetic arrest of the reduction of uranium in the deposits, which is in turn responsible for the appearance of the additional step on the second wave. However, the dissolution of uranium deposits in solutions at pH 2—3.5 rules out the possibility of their formation, so that the above explanation of the causes of the splitting of the second uranium wave fails. We believe that the reason for the separation of the second uranium(VI) wave into two steps is as follows. The pH range in which this phenomenon is observed coincides with the range where pentavalent uranium is most stable according to a number of reports[64-67]. According to some data[73], in this pH range the rate of disproportionation falls so much that the concentration of pentavalent uranium in solution can reach 10^{-3} M. Therefore, in the pH range 2—3.5, there is not sufficient time for the disproportionation reaction to convert pentavalent uranium fully into the hexavalent and tetravalent forms. The residual pentavalent uranium is reduced at potentials which are intermediate between those for the reduction of hexavalent and tetravalent uranium[74] and its reduction appears as a separate stage.

Additional data concerning the nature of the second uranium(VI) wave are provided by the results of certain studies on the polarography of tetravalent uranium. In particular the upper step on the second uranium(VI) wave has the same half-wave potential as the cathodic wave of tetravalent uranium[54,57,59]. This confirms the above hypothesis that in the pH range 2—3.5 hexavalent uranium is not reduced quantitatively to the tetravalent state because in the potential range of the second wave, corresponding to the reduction of uranium to the tervalent state, an additional wave, corresponding to the reduction of pentavalent uranium to the tetravalent state, appears.

As stated above, the limiting degree of reduction of hexavalent uranium in aqueous solutions at a mercury electrode is generally believed[50-56,59-69] to correspond to the tervalent state. However according to one report[57], in 0.1 N HCl a third wave with a half-wave potential of approximately −1.60 V (s.c.e.), corresponding in the author's view to the reduction of tervalent uranium to the metal, was observed together with the two principal uranium(VI) waves described above. This wave is largely masked by the hydrogen wave[57] and subsequently could not be reproduced even in special investigations[62].

Thus, in acid aqueous solutions free from complex-forming agents, uranium(VI) is reduced at a mercury electrode to the pentavalent state at potentials between −0.12 and −0.28 V (s.c.e.) and is then converted into the tetravalent form owing to the high rate of disproportionation. At potentials between −0.65 and −1.2 V (s.c.e.), tetravalent uranium is reduced to the tervalent state. Owing to a lower rate of disproportionation in solutions at pH 2—3.5, the reduction of pentavalent uranium takes place partly as a separate stage at potentials close to the reduction potential of uranium(IV).

Partial replacement of water by organic solvents does not have a significant influence on the electrochemical behaviour of uranium at a mercury electrode. In particular, as in aqueous solutions, uranium(VI) is reduced to the final tervalent state in two main stages[75-86].

The electrochemical behaviour of uranium at a mercury electrode in aqueous solutions containing complex-forming agents differs from that in chloride and perchlorate solutions. Thus, depending on the stability of the complexes, the primary effect is a widening of the pH range in which polarography of uranium is possible. In addition, there is a change in the very nature of its polarograms.

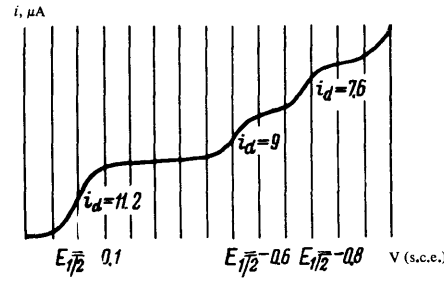

Figure 3. Polarogram for the reduction of uranium(VI) in 1.9×10^{-3} M UO_2SO_4 + 0.025 N H_2SO_4 + 0.1 N Na_2SO_4 solution[61].

In those cases where weak complex-forming agents are present in solution, for example sulphate ions {hexavalent uranium forms the sulphate complex[23] $[UO_2(SO_4)_2]^{2-}$ with $K_{inst} = 1.4 \times 10^{-3}$}, the maximum pH at which polarography of uranium is possible reaches 6—7; on the other hand, the principal characteristics of the behaviour of uranium at a mercury electrode remain the same[57,61,87-91]. In particular, in sulphate solutions, as in chloride and perchlorate solutions, two main waves are observed, the second of which corresponds to the reduction of uranium to the tervalent state[57,61,87-91] (Fig. 3). Compared with chloride and perchlorate solutions, the splitting of the second uranium(VI) waves into two steps in sulphate solutions is observed over a wider pH range (0—7) [89] (in chloride and perchlorate solutions the corresponding pH range is 2—3.5). With increase of acidity from 0.01 to 1.0 N (at a constant hexavalent uranium concentration), the height of the first wave increases and that of the lower step of the second wave falls, but their sum remains constant[88]. A number of investigators[61,88,89] believe that the reason for the splitting of the second wave into two steps in sulphate solutions is a lower rate of disproportionation of pentavalent uranium owing to its complex formation, i.e. the lower step of the second wave corresponds to the reduction of pentavalent uranium and the upper step to the reduction of tetravalent uranium to the final tervalent state.

In solutions of other weak complex forming agents, for example acetates, the following uranium(VI) complexes are known: $[UO_2Ac]^+$, $[UO_2Ac_2]$, and $[UO_2Ac_3]^-$ with $K_{inst} = 2.3 \times 10^{-3}$, 2.2×10^{-5}, and 5.7×10^{-7} respectively[23]; the electrochemical behaviour of uranium(VI) in such solutions does not differ significantly from its behaviour in sulphate solutions. Thus in uranium(VI) acetate solutions two main waves are observed as in solutions of its simple salts. Many investigators believe[54,55,92-96] that the first wave in their experimental pH range (2.5—6) corresponds to reversible one-electron reduction of uranium(VI) to the pentavalent state. On the other hand, the second wave corresponds to the irreversible reduction of pentavalent uranium to the tervalent state[92-96]. It should be noted that the somewhat higher stability of uranium acetate complexes compared with the sulphate complexes suppresses the disproportionation of pentavalent uranium to such an extent that the polarographic pattern is not complicated by the partial conversion of uranium into the tetravalent form in the first stage of the reduction of hexavalent uranium. As with solutions of simple uranium(VI) salts, the second wave splits into two steps at pH 3 [55,93] or at pH 5.[94,95] With increase in the concentration of acetate ions from 0.004 to 0.2 M (at a uranium concentration of 10^{-3} M), the half-wave potential for the second stage of the reduction of uranium(VI) shifts from −0.18 to −0.40 V (s.c.e.) without an appreciable change in the height of the wave[94]. Under the same conditions, the overall height of the second wave, observed at potentials of about 1 V (s.c.e.) falls to a value which is no longer susceptible to measurement[94]. Many investigators explain the splitting of the second uranium(VI) wave into two steps by the retardation of the disproportionation of pentavalent uranium in acetate solutions owing to its binding into acetate complexes[93,94]. It is difficult to agree with this explanation. Indeed, the independence of the height of the first wave of acetate ion concentration shows that the disproportionation of uranium(V) is slow in such solutions and therefore the second wave corresponds to the reduction of pentavalent uranium. We believe that the reason for the splitting of the second uranium(VI) wave into two steps is the considerable difference between the compositions and stabilities of uranium(V) and uranium(IV) acetate complexes {the complexes $[UO_2Ac]$ with $K_{inst} = 2.6 \times 10^{-2}$ and $[UOAc_2]$ with $K_{inst} = 2.4 \times 10^{-6}$ have been suggested for uranium(V) and uranium(IV) [93] respectively}. This means that at high acetate ion concentrations the reduction of uranium(V) to the tetravalent state takes place as a separate stage of the overall electrode process corresponding to the reduction of uranium(V) to the tervalent state. On the other hand, the decrease of the overall height of the second uranium(VI) wave with increase of the concentration of acetate ions can be accounted for by the formation of negatively charged uranium(V) acetate complexes, which are reduced at the negatively charged surface of the mercury electrode with a marked kinetic arrest.

Thus, in the presence of weak complex-forming agents the electrochemical behaviour of uranium(VI) at a mercury electrode does not differ significantly from its behaviour in solutions of its simple salts. On the other hand, in the presence of powerful complex-forming agents, the electrochemical behaviour of uranium differs sharply from that in its simple salt solutions or solutions containing weak complex-forming agents. It is then greatly influenced by the differences between the stabilities of complexes of uranium in different valence states. For example, in uranium(VI) carbonate solutions (pH > 10), owing to the low stability of the uranium(IV) carbonate complex (the composition of which has not established exactly[23,97]) and probably also the uranium(V) complex, only one wave is observed in the range of potentials between −0.9 and 1.20 V (s.c.e.); according to a number of investigators[55,97-106], this corresponds to the reduction of uranium(VI) to uranium(V), which is converted into the final (under these conditions) tetravalent state as a result of disproportionation.

In the pH range 8—10, yet another weak wave is observed in carbonate solutions[97,103-105]; the authors state that it arises because part of the tetravalent uranium is not involved in disproportionation owing to the formation of its hydroxide and is reduced to the tetravalent state (the lowest possible under these conditions) at more negative potentials, ranging from −1.2 to −1.4 V (s.c.e.). The absence of this wave in carbonate solutions at pH > 10 is explained by some workers[104,105] by the high rate of formation of a uranium dioxide deposit, which in turn accelerates the disproportionation of pentavalent uranium. In connection with the foregoing, studies on the electrolysis of uranium(VI) carbonate solutions at a mercury macrocathode are of definite interest. In particular, after the electrolysis of these solutions at pH 8—10, tetravalent uranium was detected, in addition to uranium(VI), both in solution and in the form of a uranium dioxide precipitate[104,105]. It has been reported[104] that under these conditions the solutions contain appreciable amounts of uranium(V), which is doubtful owing to the high rate of its disproportionation.

Uranium in different valence states forms complexes with ethylenediaminetetra-acetic acid (EDTA), the stabilities of which differ markedly. However, in contrast to carbonate solutions, in EDTA solutions uranium(IV) and not uranium(VI) complexes are the more stable[107-109]. Data on the polarography of uranium(VI) in EDTA solutions are not unambiguous. Thus, according to some results[95,110-113], obtained by the method of classical polarography, only one wave is observed for solutions containing EDTA. The half-wave potential for this process is independent of uranium(VI) and EDTA concentrations, but, when the pH is changed from 3 to 7, it shifts from −0.35 to −0.45 V (s.c.e.).[112,113] The height of this wave at pH 3—5 is proportional to the concentration of uranium(VI). However, with increase of pH at a constant uranium(VI) concentration, it diminishes and at pH > 7 merges with the wave of the supporting electrolyte[112]. The reason for this effect is a decrease of the concentration of uranium(VI) owing to its precipitation (in EDTA solutions at pH > 7.5, hexavalent uranium is precipitated quantitatively as the diuranate[107-109,112,113]).

According to other data[113] obtained by oscillographic polarography, two cathodic peaks corresponding to one-electron processes are observed in the same solutions at high rates of application of potential. The same investigators showed that, at relatively low rates of application of potential, the height of the first peak decreases with increasing pH, which they believe to be due to the limited rate of disproportionation of uranium(V). They state that in uranium(IV) solutions in the presence of EDTA cathodic peaks are not observed.

We believe that, despite a certain ambiguity of the polarographic data for uranium in EDTA solutions, they lead to the conclusion that, owing to the high stability of the uranium(IV) complex in such solutions, the rate of disproportionation of uranium(V) is also high and for this reason the final product of even the first stage in the

reduction of uranium(VI) is not only pentavalent but also tetravalent uranium.

The elucidation of the causes responsible for the absence of the wave corresponding to the reduction of uranium(IV) in solutions of hexavalent or tetravalent uranium containing EDTA is of definite interest. One of the possible causes may be a pronounced kinetic arrest of the reduction of uranium(IV) due to the formation of a negatively charged complex with EDTA. It has been found[112,113] that in this complex the ratio U^{IV} : EDTA = 1 : 1. This implies that uranium(IV) must enter into this complex in the ionic form UO^{2+}. Moreover, other investigators suggested[107-109] that, depending on the pH and the excess EDTA present, uranium(IV) enters into complexes in different ionic forms and that the molar ratio of EDTA and uranium in such complexes may exceed unity. The reasons for the absence of the uranium(IV) reduction wave may be also a high negative potential of the U^{IV}/U^{III} system due to the fact that the uranium(IV) complex of EDTA is much more stable than the corresponding uranium(III) complex. The lack of unambiguous data on the composition of uranium(IV) complexes of EDTA and also data on the stabilities of the possible uranium(III) complexes of EDTA precludes at the moment an unambiguous conclusion concerning this problem.

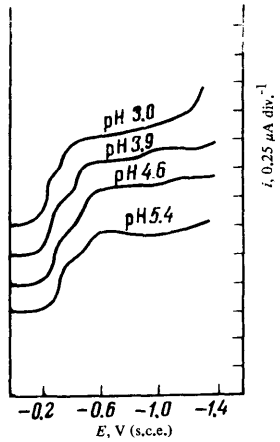

Figure 4. Polarogram for the reduction of uranium(VI) in 2×10^{-4} M $UO_2(NO_3)_2$ + 0.1 M H_3Cit + 0.1 M KCl solution containing 2.6×10^{-4}% of gelatine[117].

In solutions containing complex-forming agents which bind uranium in stable complexes in all its valence states, its electrochemical behaviour differs sharply from that in all the cases discussed above. For example, uranium(VI) forms the citrate complex[114] $[UO_2cit]^-$ with $K_{inst} = 2 \times 10^{-9}$, while according to other data[115,116] uranium(IV) forms compounds in which the citrate ion : uranium ratio varies from unity to two. The polarograms for the reduction of uranium(VI) in citrate solutions show two principal waves[63,117] (Fig. 4) as for the solutions of its simple salts. Thus at a pH of about 2, the corresponding half-wave potentials are −0.21 and −0.90 V (s.c.e.).[117] In the pH range 3—5, the first waves splits into two steps[117]. (Owing to the inhibition of the disproportionation of pentavalent uranium, in chloride and perchlorate solutions the second wave consists of two steps.) It is believed[117] that splitting of the first wave is due to inhibition of the disproportionation of uranium(V) caused by the formation of its complexes with citrate ions, as a result of which the reduction of pentavalent uranium to the tetravalent state takes place as an independent stage. With increase of the pH of the citrate solution from 3 to 5, the half-wave potentials for the two steps of the first wave shift towards negative values by approximately 30 and 20 mV respectively (until they completely merge); on the other hand, the sum of their heights remains constant[117]. Thus the first uranium(VI) wave in citrate solutions corresponds to its reduction to the tetravalent state.

With increase of the pH of the citrate solution from 3 to 5, the height of the second wave decreases until it merges completely with the wave of the supporting electrolyte[117]. The above investigators acknowledge that the nature of the second wave is ill-defined, since, according to their data for citrate solutions of uranium(IV), no waves are observed under these conditions[117]. We believe that this inconsistency is due to the appreciable difference between the composition of the uranium(IV) citrate complex prepared by mixing solutions of its simple salt and of the complex-forming agent and the composition of the uranium(IV) citrate complex obtained from the uranium(VI) complex as a result of a rapid electrode reaction, i.e. in the polarography of the uranium(VI) citrate complex the electrode process corresponding to the first wave results in the formation of an intermediate form of the uranium(IV) citrate complex which does not have sufficient time during the recording of the polarogram for conversion into the final electrochemically passive state.

Thus in citrate solutions uranium(VI) is reduced to the tervalent state in two stages. At pH 3—5, the first stage in the reduction of uranium(VI) to the tetravalent state also involves two stages.

Additional data on the electrochemical behaviour of uranium at a mercury electrode have been provided by oscillographic and cyclic polarographic studies and also by an investigation of the electrochemical oxidation of uranium in lower valence states at mercury and platinum electrodes. In particular, the results of these studies demonstrate that, depending on the composition of the solutions and their pH, two- and three-stage reduction of uranium(VI) to the tervalent state takes place at a dropping mercury electrode; the potentials of the cathodic peaks occur under these conditions in the ranges where the corresponding waves are observed on the classical polarograms for the reduction of uranium(VI).[113,118-125] However, whereas in the case of classical polarography the reduction of pentavalent uranium occurs as a separate stage only in solutions of specific composition, in oscillographic polarographic studies this stage in the reduction of uranium is observed when the rate of application of potential to the dropping mercury electrode is increased[118-125].

Together with the reduction of the higher valence forms of uranium, its lower valence forms are oxidised irreversibly at the dropping mercury electrode (the oscillographic polarograms show anodic peaks which are appreciably lower than the corresponding cathodic peaks and are displaced towards positive potentials relative to the latter)[121,125]. It is noteworthy that the relatively low heights of the anodic peaks compared with those of the cathodic peaks may be caused not only by the irreversibility of the anodic processes but also by diffusion of part of

the reduced uranium, obtained in the cathodic polarisation of the electrode, from the layer near the electrode into the bulk of the solution. Moreover, as shown above, the reduction of uranium at a mercury electrode should be accompanied by the catalytic discharge of hydrogen ions, which increases the heights of the cathodic peaks.

Polarographic data on the anodic oxidation of uranium(IV) are ambiguous. Thus it has been stated[59,125,126] that the oxidation of uranium(IV) takes place not only at a platinum electrode but also at a mercury electrode, while, according to another report[57], the oxidation of uranium(IV) is not observed even at platinum electrode potentials reaching +0.45 V (s.c.e.).

It is noteworthy that quantitative characteristics of the uranium reduction and oxidation processes at a mercury electrode have not yet been obtained from oscillographic polarographic data. The reason for this is the inadequacy of the theoretical interpretation of the experimental data. For example, in studies on the reduction of uranium(VI) [120] and the oxidation of lower valence forms of uranium[119,121], the processes were interpreted quantitatively (i.e. the diffusion coefficients, activation energies, and transfer coefficients were calculated) on the basis of the experimental data in terms of a theory developed for another case[127-129]. Indeed this theory is concerned with electrode processes involving substances diffusing from the solution to the surface of the electrode (and not conversely as in the oxidation of the lower valence forms of uranium obtained on the electrode during its brief cathodic polarisation in a hexavalent uranium solution[119,121]). Moreover, the theory does not provide for the possible disproportionation of the reduction products of the test substances.

A wave associated with the oxidation of uranium amalgam to uranium(IV) has been reported[130,131]. However, the results of this study and also their explanation are not sufficiently convincing, since the wave is observed in 1 *N* H_2SO_4 at potentials of −1.42 [130] or −1.52 [131] V (s.c.e.) (beyond the hydrogen wave), i.e. more negative than the potentials at which uranium(IV) is reduced reversibly to the tervalent state[53-55,59,61]. Moreover, according to another report[34], when uranium amalgam comes into contact with aqueous solutions it is oxidised to uranium(III), which is clearly detected.

As already stated, the height of the first wave for the reduction of uranium(VI) in chloride and perchlorate solutions, observed in the potential range from −0.1 to −0.25 V (s.c.e.), is proportional to its concentration in the range 10^{-5}—10^{-3} M when the acidity is between 0.01 and 0.1 *N*. In certain cases this can have analytical applications. However, the narrow range of acidities in which polarographic determination of uranium in solutions of its simple salts is possible involves a number of disadvantages. In the presence of even weak complex-forming agents, for example sulphate ions, the range of permissible acidities of the solution analysed extends to 0.01—2.5 *N*.[10,23] The use of more powerful complex-forming agents permits the determination of uranium in neutral and even alkaline solutions[23]. The complex dependence of the height of the second wave for the reduction of uranium(VI) on solution composition rules out its employment for analytical purposes. The available methods for the polarographic determination of uranium require the preliminary separation of a number of impurities which are reduced at potentials corresponding to the first wave of uranium(VI). Therefore these methods for the determination of uranium in most cases cannot compete with other available procedures, for example spectrophotometric techniques[23]. At the present time the polarographic method is mainly used for the remote monitoring of the concentration of uranium solutions in certain technological processes[10,23].

The Hydrogen Bond in Sulphur-containing Compounds

I.V.Zuika and Yu.A.Bankovskii

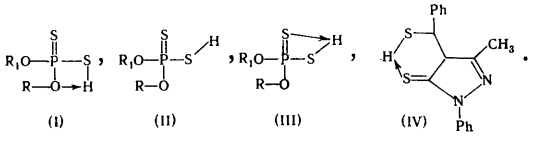
The contemporary state of the problem of the proton-donating ability of the mercapto-group and the proton-accepting ability of a sulphur atom in sulphur-containing compounds in the formation of a hydrogen bond is described. The effect of the hydrogen bond on various physicochemical properties of sulphur-containing compounds is examined. A comparison is also made of the ability of sulphur-containing compounds and their oxygen-containing analogues to form a hydrogen bond. 306 references.

CONTENTS

I. Introduction 22
II. Proton-donating ability of the mercapto-group in organic compounds in the formation of hydrogen bonds (S-H←S, S-H←O, S-H←N, S-H←Hal) 22
III. Proton-withdrawing ability of a sulphur atom in organic and inorganic compounds in the formation of hydrogen bonds (O-H←S, N-H←S, C-H←S). 25
IV. Comparison of the abilities of sulphur- and oxygen-containing compounds to form hydrogen bonds 29

I. INTRODUCTION

Several reviews have already appeared[1-9] which deal with the general problems of the hydrogen bond (HB) X–H←Y, its properties in various classes of compounds, and methods of investigation. The bulk of the information relates to HB of the types O–H←O, O–H←N, and N–H←O. The ability of the mercapto-group and a sulphur atom to form HB, that is, HB of the types S–H←Y, or X–H←S (where Y = O, N, S, F, Cl, or Br; X = O or N) has not been reviewed and all the information on this problem that has accumulated is scattered in individual papers.



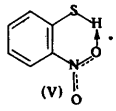
The present article reviews the available (including 1970) information on the HB S–H←Y and X–H←S (X and Y = O, N, or S) in various classes of organic compounds.

II. PROTON-DONATING ABILITY OF THE MERCAPTO-GROUP IN ORGANIC COMPOUNDS IN THE FORMATION OF HYDROGEN BONDS (S–H←S, S–H←O, S–H←N, S–H←Hal)

1. The S–H←S Hydrogen Bond

The ability of aliphatic and aromatic mercaptans to form S–H←S HB was questionable for a long time. Despite extensive investigations of various physicochemical properties of thiols[10-33] the opinion persisted until the 'fifties' that autoassociation in such systems did not exist.

In 1956, on the basis of the splitting of the ν_{SH} band in the infrared spectra of solutions of *o,o'*-diethyl and *o,o'*-dimethyldithiophosphoric acids [presumably *OO*-diethyl and *OO*-dimethyl *S*-hydrogen phosphorothiolothionates (Ed. of Translation)] in CCl_4, Menefee and coworkers[34] postulated the autoassociation of the molecules of these compounds by means of an S–H←S HB. The same type of association is assumed in dithiophosphoric[35,36], diphenyldithiophosphinic[37] [diphenylphosphinodithioic? (Ed. of Translation)], and dithiobenzoic[35] acids. However, recent cryoscopic studies showed that the dithiophosphoric acids [*S*-hydrogen phosphorothiolothionates (Ed. of Translation)] exist as monomers in benzene solution[38]. The observed splitting of the ν_{SH} bands in the vibrational spectra of the dialkyl *S*-hydrogen phosphorothiolothionates (~ 2550 and 2590 cm^{-1})[38-43] is explained by the existence of rotational isomers with an S–H←O intramolecular hydrogen bond (IHB) (I) between the SH group and an ester oxygen[38,42,43]. The band in the higher frequency region (~ 2590 cm^{-1}) evidently corresponds to the rotational isomer with a free SH group (II) and not the isomer with the S–H←S IHB (III)[42]:



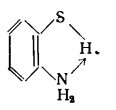
In the dithiobenzoic acid molecule (dilute solutions in cyclohexane) Issleib and Grundler[44] postulate chelation by a direct S–H←S IHB, which is responsible for the appearance of two energetically non-equivalent $n \rightarrow \pi^*$ transitions in the CSS group. The presence of an S–H←S IHB is also responsible for the absence of a concentration dependence of the ν_{SH} frequency of the ν_{SH} vibrations (2400 cm^{-1}) in the infrared spectra of solutions of 4-mercapto-3-methyl-1-phenylbenzylidene-5-thiopyrazole (IV) in CCl_4.[45] The association of ethylene trithiocarbonate [1,3-dithiolan-2-thione (Ed. of Translation)] and of thiofenchone with thiophenol, *p*-thiocresol, *p*-chlorothiophenol, *p*-bromothiophenol, and butane-1-thiol by means of an S–H←S HB is accompanied by a blue shift of the $n-\pi^*$ absorption band of the thiocarbonyl group.[46,47]

On the basis of the splitting of the ν_{SH} band in the infrared spectra (2580 and 2560 cm^{-1}), Spurr and Byers[48] established the ability of aliphatic thiols and thiophenol to undergo autoassociation by means of an S–H←S HB. Splitting of the ν_{SH} absorption band due to an S–H←S HB was also observed in the infrared spectra of solutions of *p*-chlorothiophenol (2583 and 2569 cm^{-1}) and *p*-methylthiophenol (2584 and 2571 cm^{-1}) in CCl_4.[49] Other results obtained as a result of investigations of the infrared and NMR spectra of thiophenol[49-54], the infrared spectra of the halogen derivatives of thiophenol[52], the NMR spectra of *o*- and *m*-methylthiophenols[55], the infrared and NMR spectra of aliphatic thiols[53,54,56-62], the infrared spectra of dithiocarbamic acid[63], and the NMR spectra of sulphanes

H_2S_x ($x = 1-9$),[64] also confirm the ability of thiols to undergo autoassociation by means of an S–H←S HB. The NMR spectra suggest that an S–H←S IHB exists in the H_2S_3 molecule[64]. Crystallographic results show the existence of an S–H←S HB in hydrogen sulphide[65]. The formation of dimers and trimers of hydrogen sulphide (matrix-isolated in solid nitrogen) was also proved recently by infrared spectroscopy[60].

2. S–H←O and S–H←N Hydrogen Bonds

According to results obtained in studying physicochemical properties in solutions of thiols in proton-withdrawing solvents associates are formed by means of S–H←O and S–H←N intermolecular HB[15,67-72], and this is also confirmed, despite various objections[29,33,73,74], by the results of spectroscopic investigations. Cleveland and coworkers[75] observed splitting of the ν_{SH} band (2536 and 2569 cm^{-1}) in the Raman spectra of solutions of thiophenol in dioxan, and this is attributable to an S–H←O HB. This is confirmed by the results of investigations of the association of thiophenol with dioxan and acetone by infrared spectroscopy[51]. Gragerov and Pogorelyi[76] determined the energies of the S–H←O HB of the associates of thiophenol, its derivatives, and thio-2-naphthol with acetone. A similar splitting of the ν_{SH} band is observed in the infrared spectra of solutions of thiophenol in diethyl, ethyl phenyl, and diphenyl sulphoxide[77] and of *p*-nitrophenol and *o*-nitrophenol in CCl_4.[78] Chelation by an S–H←O_2N IHB is presumed for *o*-nitrophenol (V). The S–H←O_2N HB leads to splitting of both $\nu_S(NO_2)$ and $\nu_{AS}(NO_2)$ absorption bands[78]. As was noted in Section II.1, an S–H←O IHB also exists in alkyl dithiophosphoric acids:



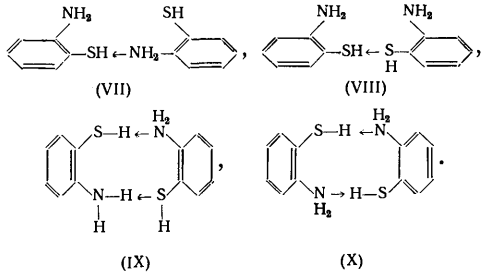
(V)

The association of thiophenol, *p*-nitrothiophenol, and *o*-nitrothiophenol with dioxan by an S–H←O HB is also accompanied by some increase in the dipole moment of these thiols in comparison with the dipole moment measured in benzene (Table 1).

It has been shown that the rate of proton exchange is increased in proportion to the strength of the S–H←O HB of the associates of thiophenol or its derivatives with acetone[79].

The ability of thiophenol to associate with proton-withdrawing solvents by an HB was shown in several NMR studies[46,80-82], and by infrared[83,84], and ultraviolet[46] spectroscopy. A similar type of interaction with proton-withdrawing solvents is also effected for methanethiol, propane-1-thiol, and hydrogen sulphide[56,85-87]. Table 2 gives the equilibrium constant (K_{26}) at 26°C and the energy ($-\Delta H$) of the S–H←Y HB (Y = O or N) for some 1 : 1 associates of thiophenol with proton-withdrawing solvents.

A thorough investigation of the ability of *o*-amino- and *o*-hydroxy-thiophenol to form an HB was made by David and Hallam[49]. Evidently, in *o*-aminothiophenol in CCl_4 there is an S–H←N IHB (VI)[49,88], although the dipole moment in benzene does not agree with the *cis*-configuration[89]:



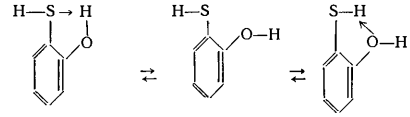
(VI)

However, it must be borne in mind that the S–H←N IHB may be destroyed with the formation of associates of benzene-*o*-aminothiophenol.

Table 1. Dipole moments of thiophenol and of its derivatives in benzene (B) and dioxan (D).[78]

Compound	μ_B, D	μ_D, D	$\Delta\mu_i=\mu_D-\mu_B$
C_6H_5SH	1.19—1.23	1.28	0.10—0.06
o-$NO_2C_6H_4SH$	4.69	4.81	0.12
p-$NO_2C_6H_4SH$	3.77	4.07	0.30

In concentrated solutions in CCl_4 *o*-aminothiophenol exists as dimers of open (VII or VIII) or cyclic (IX or X) structure[49]:

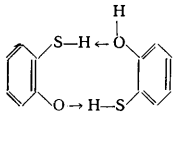


(VII) (VIII)

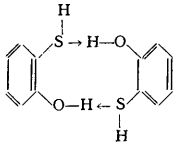
(IX) (X)

Table 2. Equilibrium constants and energies of the HB of thiophenol–proton-withdrawing solvent associates.

Solvent	K_{26}, litre $mole^{-1}$	$-\Delta H$, kcal $mole^{-1}$	Reference
Acetone	0.29	3.2	76
Pyridine	0.22	2.4	81
N-Methylpyrazole	0.14	2.1	81
Tributyl phosphate	0.43	2.0	81
Dimethylformamide	0.24	1.8	81
Benzene	0.04	0.5	81
N-Methylacetamide	—	0.9	80



The complex relation between concentration and the frequencies and intensities of the ν_{OH} and ν_{SH} bands in the infrared spectra of solutions of *o*-hydroxythiophenol in CCl_4 is due to the formation of a different type of HB between the OH and SH groups. As the concentration is raised the IHB of (XIa) and (XIb) are broken and dimers of *o*-hydroxythiophenol are formed (XIc) and (XId).

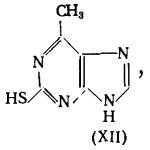


(XIa) (XI) (XIb)

$\nu_{(S-H)}$ 2595 cm^{-1} 2595 cm^{-1} 2547 cm^{-1}

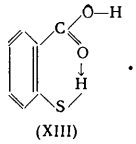
$\nu_{(O-H)}$ 3463 cm^{-1} 3606 cm^{-1} 3606 cm^{-1}

(XIc)
ν(S—H) 2535 cm^{-1}
ν(O—H) 3606 cm^{-1}



(XId)
2595 cm^{-1}
3463 cm^{-1}

The ability of 5-mercaptoquinoline to form associates by means of an S–H···Y HB is seen from the decrease in the frequency of the ν_{SH} band in benzene compared with that in carbon tetrachloride ($\Delta\nu$ = 21 cm^{-1}) and the increase in the dipole moment on going from benzene to dioxan as solvent ($\Delta\mu_1$ = 0.28D).[90-92]

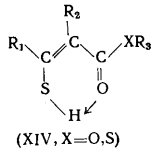


The previously expressed hypothesis of the absence of association in aliphatic aminothiols[33] was disproved by an investigation of the infrared spectra of solutions of aminothiols of the general formula $R_{3-n}N(CH_2CH_2SH)_n$ in CCl_4.[93] The splitting of the ν_{SH} band (2620 and 2560 cm^{-1}) in these systems is due to an S–H···N hydrogen HB. The autoassociation energy for various aminothiols $R_{3-n}N(CH_2CH_2SH)_n$ varies from 1.9 to 2.5 kcal mole^{-1} (calculated from $\Delta\nu$).

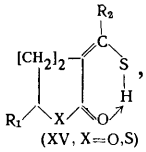
On the basis of spectroscopic results, the absence of association in thiocarboxylic acids RCOSH by means of a HB has been noted repeatedly[32,35,94,95]. However, thioacetic acid can evidently undergo this type of interaction in the liquid phase[96]. Recently published results confirm this opinion: as a result of autoassociation by an S–H···O HB both the $\nu_{C=O}$ and ν_{SH} absorption bands of thioacetic and thiobenzoic acids are split[97].

X-ray diffraction and neutron diffraction results show the possibility of the existence of an S–H···O HB in crystalline 2-mercapto-6-methylpurine (XII)[98]:

(XII)

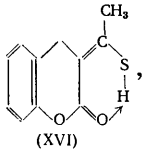


(XIII)

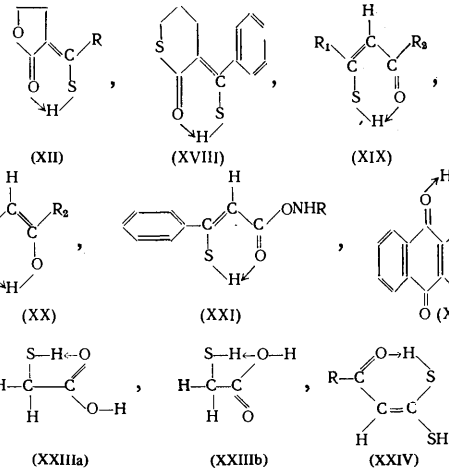


Chelation in the thiosalicylic acid molecule is effected by an S–H···O IHB (XIII), as a result of which the $\nu_{C=O}$ absorption band in the infrared spectra is split (1718 and 1730 cm^{-1}).[99]

The energy of the IHB in thiosalicylic acid is 0.9 kcal mole^{-1}. The presence of S–H···O IHB has been established in β-thioketoesters (XIV; X = O)[100-103], β-thioketothiol esters (XIV; X = S)[104-107], α-thioacyl-lactones (XV, XVI, XVII; X = O) and α-thioacylthiol-lactones (XV, XVIII; X = S)[108], monothio-β-diketones (XIX)[100,109-113], and the β-mercaptoamide of cinnamic acid (XXI)[106,114] by NMR methods and by infrared and ultraviolet spectroscopy.



Chelation of the S···H–O type (XX) in monothio-β-diketones has been suggested[115,116-119], but has not yet been proved satisfactorily[100]. Chelation by an S–H···O IHB was also found in 1-mercaptoanthraquinone (XXII)[120], thioglycollic acid (XXIIIa) and (XXIIIb)[121], and dimercaptopropenones (XXIV)[122]:

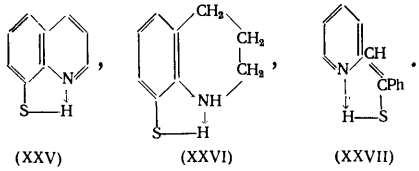


(XIV, X=O,S)

(XV, X=O,S)

(XVI)

(XII) (XVIII) (XIX)



(XX) (XXI) (XXII)

(XXIIIa) (XXIIIb) (XXIV)

The anomalously low frequency of the $\nu_{C=O}$ vibrations (1560 cm^{-1}) in dimercaptopropenones is due to the formation of a six-membered quasiaromatic ring (XXIV), which according to Shigorin[123] leads to the strongest IHB in oxygen-containing compounds.

Use of infrared spectroscopy and dipole moments enables us[91,92,124-126] to establish the existence of 8-mercaptoquinoline, its methyl and halogeno-derivatives in solutions and in the liquid phase in the *cis*-configuration with an S–H···N IHB (XXV), which confirmed the earlier assumption of chelation in the molecules of 8-mercaptoquinoline[127,128] and its 2-methyl derivative[129]. $-\Delta H$ of the S–H···N IHB is 2.4–3.2 kcal mole^{-1} for various 8-mercaptoquinoline derivatives. In polar organic solvents the S–H···N IHB in these compounds is not destroyed with the formation of associates having a direct intermolecular HB S–H···Y.

The 1,2,3,4-tetrahydro-8-mercaptoquinoline molecule also contains a ring with an S–H···N IHB (XXVI), the energy of which is 1.5 kcal mole^{-1}.[130] However, unlike 8-mercaptoquinoline, in this instance autoassociates are formed by means of S–H···S or S–H···N HB and also associates with proton-withdrawing solvents by means of S–H···Y HB. The strength of the S–H···N IHB being higher in 8-mercaptoquinoline than in 1,2,3,4-tetrahydro-8-mercaptoquinoline is due to the different hybridisations of the nitrogen atoms in these compounds[125]. According to the infrared spectra, there is an S–H···N IHB in phenyl 2-picolyl thioketone (XXVII)[131]:

(XXV) (XXVI) (XXVII)

3. The S–H···Hal Hydrogen Bond

Little information about the S–H···Hal HB is available. The assumption, based on measurements of the dipole moment, of the existence of *o*-chlorothiophenol and *o*-bromothiophenol in the *cis*-configuration with an S–H···Hal IHB[78] agrees well with the wavenumbers of the ν_{SH} vibrations (2552 and 2545 cm^{-1}, respectively), being appreciably lower than that for thiophenol (2587 cm^{-1})[52].

The infrared spectra and dipole moments suggest that chelation by an S–H⋯Hal IHB is also achieved in 6-fluoro-, 6-chloro-, and 6-bromo-5-mercaptoquinoline, and in 7-fluoro-, 7-chloro-, and 7-bromo-8-mercaptoquinoline[90,92,125]. The strength of the S–H⋯Hal IHB in these compounds increases from the bromo- to the fluoro-derivative.

III. PROTON-WITHDRAWING ABILITY OF A SULPHUR ATOM IN ORGANIC AND INORGANIC COMPOUNDS IN THE FORMATION OF HYDROGEN BONDS (O–H⋯S, N–H⋯S, C–H⋯S)

1. O–H⋯S and N–H⋯S Hydrogen Bonds

Owing to the presence of unshared electron pairs, sulphur atoms in organic compounds can participate in the formation of HB also as an acceptor of a proton (that is, a donor of electrons), and in particular this is confirmed by the existence of S–H⋯S HB in aliphatic and aromatic thiols (see Section II).

Table 3. Blue shift of the n-π^* band of the C=S group, association constant, and energy of the S→H–O HB of ETTC–proton-donating solvent associates.

$CHCl_3$	—	—	—	1.9	—

A reliable criterion of the formation of associates by compounds which contain a thiocarbonyl group, by means of a C=S→H–X HB is thought to be the blue shift of the absorption band of this group. The assumption of the formation of a C=S→H–O HB on the basis of this effect between ethylene trithiocarbonate [1,3-dithiolan-2-thione (Ed. of Translation)] (ETTC, XXVIII) and alcohols[46,132,133] agrees completely with the infrared spectra for the ETTC-(proton-donating solvent) systems[134]. The blue shift of the $n\rightarrow\pi^*$ band of the thiocarbonyl group, the association constant at 26°C,[132] and $-\Delta H$ of the C=S→H–O HB of the ETTC–(proton-donating solvent) associates[133] are given in Table 3. This shows a distinct correlation between K_{26} and the acidic properties (pK_{OH}), that is, with the proton-donating properties of the alcohols, which is characterised by the inductive constant of the hydrocarbon radical of the alcohol (σ^*).

A tendency is also noted for an increase in the blue shift of the n-π^* band of the C=S group with increase in the proton-donating ability of the molecule in various alcohols (Tables 3 and 4) and phenols (Table 5). However, a similar correlation between the proton-donating ability (pK_a or σ^*) of the compounds of various classes (alcohols, phenols) and the blue shift of the band of the C=S group (ETTC) is not observed.

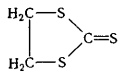
Table 4. Blue shift of the n-π^* band of the C=S group in alcohols[46].

Compound	$\Delta\nu(n\rightarrow\pi^*)$, cm^{-1}			
	CH_3OH	C_2H_5OH	iso-C_3H_7OH	t-C_4H_9OH
Thiazolidinethione	2100	1770	1600	1600
ETTC	825	705	585	585
Thiofenchone	430	440	300	270

Recently, the absence of a correlation between $-\Delta H$ of the C=S→H–O HB of ETTC–(phenols or acid derivatives of phenols) associates was also reported[138]. However, the reliability of the results and the conclusions of this work[138] are doubtful—for example, $\Delta\nu(n$-$\pi^*)$ is the same for solutions of ETTC in phenol, p-chlorophenol, and m-cresol. There are many published examples which show that for compounds of a single type RX–H (where X = O or S) there is a distinct correlation between their acidic properties and spectral ones and also the thermodynamic characteristics of the RX–H–Y HB with the same proton acceptor Y (Tables 3–6 and Section IV).

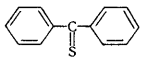
Table 5. Blue shift of the n-π^* band of the C=S group of ETTC in the phenols (R = C_6H_4OH).[46]

R	σ	pK_{OH}	$\Delta\nu(n\rightarrow\pi^*)$, cm^{-1}
p-Cl	0.23	9.38	1020
H	0.00	9.95	390
p-CH_3	−0.17	10.19	380
p-OCH_3	−0.27	10.20	235



We have observed a clear correlation between the proton-donating ability of normal aliphatic alcohols and $-\Delta H$ of the S^-→H–O HB of the associates of zwitter-ion form (8-mercaptoquinoline, 5-mercaptoquinoline, and their derivatives)—alcohol (Table 6)[139-142].

The decrease in $-\Delta H$ for the S^-→H–O HB for 8-mercaptoquinoline as compared with that of 5-mercaptoquinoline is due to the presence of an S^-→H–N IHB in the molecule of the former[141,142].



The blue shift of the n-π^* band of the C=S group for solutions of thiobenzophenone (XXIX) in ethanol[143,144], methyl (XXX; R = CH_3) and isopropyl thiocarbamates (XXX; R = Pr^i), thiocamphor (XXXI), ETTC (XXVIII) in phenol[145], alkylthioureas (XXXII) in phenol and ethanol[146], and 2-mercaptobenzothiazole (LIX) in acetic acid[147] are also due to C=S→H–O HB.

The association of alkylthioureas and thiocamphor with phenol by S→H–O HB[146,148,149] is also confirmed by the shift of the ν_{OH} band of phenol to lower frequencies. A similar type of interaction is also observed for the association of phenol with N≡CSN$(CH_3)_2$.[150] $-\Delta H$ of the

S→H–O HB for some of these systems are given in Table 7.

n-C_3H_7OH	0.115	0.76	0.70	1.45	0.82	0.75	1.54
n-C_4H_9OH	0.130	0.73	0.65	1.26	0.71	0.65	1.50

The energies of the S→H–O HB of the associates of thiocamphor with propanol and tetrafluoropropanol are 1.8 kcal mole^{-1} ($\Delta\nu_{OH}$ = 120 cm^{-1}) and 3.6 kcal mole^{-1} ($\Delta\nu_{OH}$ = 170 cm^{-1}) respectively[46].

X-ray diffraction studies show a strong S→H–O HB exists in the crystalline 6-thiopurine riboside hydrate[151] and sodium *NN*-diethyldithiocarbamate trihydrate[152]. There is also a similar interaction in crystalline monohydrates of bis(isoquinoline-1-carboxaldehyde thiosemicarbasonato)nickel[153], 6-mercaptopurine[154,155], potassium[156] and caesium[157] trithiocarbonates, and barium thiosulphate[158].

Table 7. Energy of the HB (−ΔH) between compounds containing a thiocarbonyl group and phenol.

Compound	−ΔH, kcal mole⁻¹	Reference	Compound	−ΔH, kcal mole⁻¹	Reference
Alkylthiourea	4—4.8	146	Thiocamphor	5.0	145
Thiocarbamates	4.0	145	Ethylenetrithiocarbonate (ETTC)	3.2	145

Spectroscopic investigation of the interaction of sulphides with proton-withdrawing solvents shows that in these systems association is also effected by means of S→H–O HB. The splitting of the ν_{OH} band in the infrared spectra of the *p*-chlorophenol–sulphide[159,160], phenol–sulphide[160,166], and phenol–aryl sulphide[167] systems is due to excitation of the OH group of the S→H–O HB with sulphide sulphur (Table 8).

The values[162,164] of −ΔH of the S–H→O HB of dibutyl sulphide–phenol and diethyl sulphide–phenol associates (Table 8) are evidently somewhat too high. According to Table 8, −ΔH of the S→H–O HB is greater in these instances than for associates of the corresponding sulphides with *p*-chlorophenol. However, bearing in mind the higher acidic properties of *p*-chlorophenol (pK_{OH} = 9.38[168]) compared with those for phenol (pK_{OH} = 9.98[169]) a strengthening of the S→H–O HB on going from phenol to *p*-chlorophenol can be postulated. The higher stability of the *p*-chlorophenol–sulphide associates compared with that of the sulphide–phenol associates is also shown by the greater shift of the ν_{OH} band to lower frequencies in the first instance. Δν and −ΔH vary symbathically for monotypical compounds[1], which is observed, for example, for the tetrahydrothiopyran–phenol and tetrahydrothiopyran–*p*-chlorophenol systems (Table 8). Consequently, the value of −ΔH = 3.40 kcal mole^{-1} [163] for associates diethyl sulphide–phenol is more probable than −ΔH = 4.60 kcal mole^{-1}.[164]

Table 8. Displacement of the ν_{OH} band and energy of the S→H–O HB of phenol and *p*-chlorophenol with the sulphides.

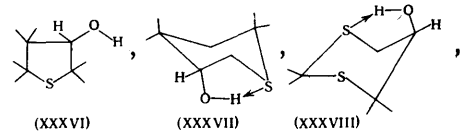
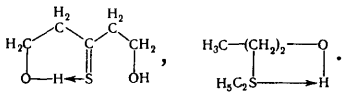
On the basis of the spatial position of the functional groups in 2-hydroxythiobenzophenone the formation of an S→H–O HB can be postulated (XXXIII), which evidently explains the absence of a blue shift for the n–π^* absorption band in proton-donating solvents (ethanol)[170]:

(XXXIII)

Finding the presence of an S→H–X IHB is often used in conformational analysis. Mertes[171,172] attributes the absorption at 3446 cm^{-1} (according to Szmant and Rigau[173], at 3500 cm^{-1}) and 3478 cm^{-1} in the infrared spectra of phenylmercaptoindanol (XXXIV) and 5-hydroxy-2-phenyl-1,3-dithione (XXXV) to the ν_{OH} vibrations of the *cis*-configuration, with an excited S→H–O IHB:



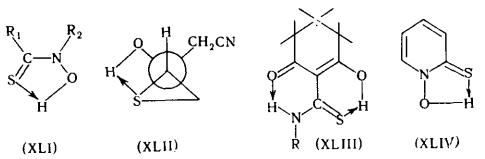
(XXXIV) (XXXV)



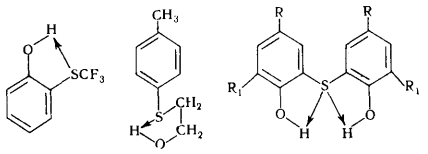
According to Szmant and Rigau, −ΔH of the S→H–O IHB in (XXXIV) is 2.5 kcal mole^{-1}.[173]

The shift of the ν_{OH} band to lower frequencies owing to the formation of an S→H–O type of IHB was also observed in the infrared spectra of thiocyclopentan-3-ol (XXXVI),[174] some of its derivatives[175], thiocyclohexanol (XXXVII),[174]

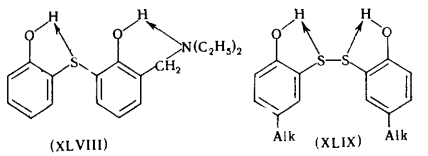
1,3-dithiocyclohexan-5-ol (XXXVIII),[174] its 2-phenyl derivative[176], 3-thiopentane-1,5-diol (XXXIX),[177] ω-ethylmercaptoalkanols (XL)[165,178], 2,2'-thiodiphenol[179], its derivatives[180], 2,2'-thiobis-(3,4,6-trichlorophenol), and 2,2'-thiobis-(4,6-dichlorophenol)[179]:



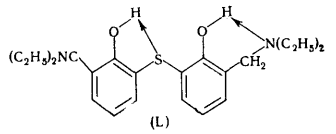
(XXXVI) (XXXVII) (XXXVIII)



(XXXIX) (XL)



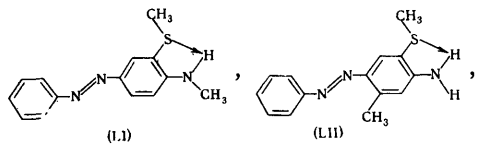
Chelation by S→H–O HB was also found in *o*-methylthiophenol, 2-methyl-6-methylthiophenol, *o*-isopropylthiophenol[181,182,183], thioacetylhydroxamic acid (XLI)[184], 1-cyano-3,4-epithio-2-hydroxybutane (XLII)[185] by NMR and infrared spectroscopy, in 4,4-dimethyl-2,6-dioxothiocyclohexanecarboxanilide (XLIII)[186], in monothio-β-diketones (XX)[115] by the NMR method, in 1-hydroxy-2-thiopyridone (XLIV)[188], and *o*-trifluoromethylphenol (XLV)[183] by infrared spectroscopy and in compounds of the (XLVI)–(L) type by dipole moments and infrared spectroscopy[180,188,189] and NMR[190,191].



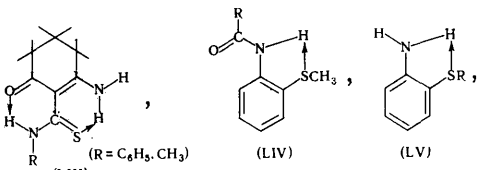
(XLI) (XLII) (XLIII) (XLIV)

(XLV) (XLVI) (XLVII)

(XLVIII) (XLIX)

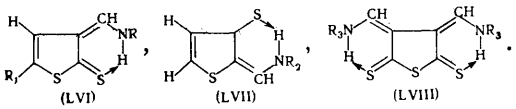


(L)



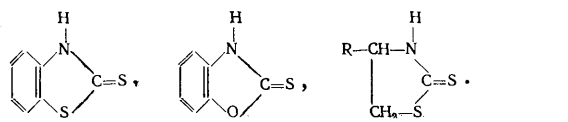
However, the problem of the presence of an S→H–O IHB in (XLVII) (when R_1 = H, CH_3), and also in XLVIII and XLIX) evidently cannot be regarded as settled. According to the results of recent investigations it seems that an S→H–O IHB can be formed only in the compounds (XLVII) with a sufficiently bulky substituent R_1 (t-butyl etc.).[190]

It is also noteworthy that the assumption of the presence of an S→H–O IHB in compounds (XX) based on the appearance in the NMR spectra of the signal of an OH group does not agree with the results of various other investigations[100,109-113] (section II.2).

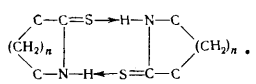


Chelation by means of an S→H–N type IHB has been established on the basis of the ν_{NH} band in the infrared spectra in dimetoate [sic. the compounds referred to in Ref. 192 are *o*-methylthio-derivatives of *N*-methylaniline and *N*-methyl-4-aminoazobenzene (Ed. of Translation)][192] and in compounds (LI) and (LII)[193], and by NMR spectroscopy in compounds (LIII)[186] and (LIV)[194]. NMR and infrared spectroscopy show that an S→H–N IHB exists in *o*-aminothiophenols (LV)[195] and mercaptoaldimines of the thiophene series (LVI)–(LVIII)[196,197]:

(LI) (LII)



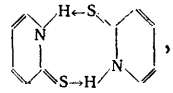
(LIII) (R = C_6H_5, CH_3) (LIV) (LV)



(LVI) (LVII) (LVIII)

Association by an HB of S→H–N type was first proved by Hopkins and Hunter[71] on the basis of cryoscopic measurements of the molecular weights of thioamides. This was later confirmed spectroscopically[198-204]. The broad band in the infrared spectra of 2-mercaptobenzothiazole (LIX), 2-mercaptobenzoxazole (LX), 2-mercaptothiazoline (LXI; R = H), and 2-mercapto-4-methylthiazole (R = CH_3) at 3050 cm^{-1} is due to the ν_{NH} vibrations of the associated molecules by the S→H–N HB[198]:

(LIX) (LX) (LXI) (R = H, CH_3)



The proton-withdrawing ability of the thiocarbonyl group of these compounds in the formation of HB is confirmed by the blue shift of the n–π^* band of the C=S group for solutions of 2-mercaptobenzothiazole in proton-donating solvents[147]. According to Kulevsky and Froehlich[205], the splitting of the ν_{NH} band in the infrared spectra of solutions of thiolactams in benzene is due to the formation of dimers of structure (LXII):

(LXII)

The value of $-\Delta H$ of the S→H–N HB of thiobutyrolactam is 5.8 kcal $mole^{-1}$, that of thiovalerolactam 3.1 kcal $mole^{-1}$, and that of thiocaprolactam 3.3 kcal $mole^{-1}$. A similar conclusion was reached[206] concerning the autoassociation of thiocaprolactam in benzene from the infrared spectra and dipole moments. The dimerisation of (LXII) leads to a considerable decrease in μ (2.78 D) in comparison with μ of the monomer (4.59 D). It is necessary to note the considerable discrepancy in the values of the dimerisation constants for thiocaprolactam

(K_D = 370 litre mole^{-1} [205] and K_D = 93 litre mole^{-1} [206]) is noteworthy. K_D = 370 litre mole^{-1} is evidently too high if it is taken into account that for caprolactam K_D = 270 litre mole^{-1} and $-\Delta H$ for the O→H–N HB of the caprolactam dimers is 5.5 kcal mole^{-1}. [206] Cryoscopic [207,208] and dielectric [209] measurements and also investigation of the infrared spectra [187] showed that 2-thiopyridone in benzene and chloroform is dimerised like thiocaprolactams by the S→H–N HB (LXIII):

(LXIII)

The dimerisation of 2-thiopyridone in benzene leads, as for thiocaprolactam, to a considerable decrease in μ (2.78 D) in comparison with μ of the monomer (5.26 D for the *N*-methyl derivative). The dimers of thiocaprolactam and 2-thiopyridone are destroyed in dioxan [207, 208].

The infrared spectra show the association of *N*-methylaniline with thiocamphor by an S→H–N HB, the energy of which is 5.7 kcal mole^{-1}. [46]

Intermolecular association by means of an S→H–N HB is also effected in the sulphide–thiocyanic acid system (Table 9). [209]

Table 9. Displacement of the ν_{NH} band and $-\Delta H$ for the S→H–N HB of thiocyanic acid with sulphides [209].

Solvent	$\Delta\nu$, cm^{-1}	$-\Delta H$, kcal mole^{-1}	Solvent	$\Delta\nu$, cm^{-1}	$-\Delta H$, kcal mole^{-1}
Dimethyl sulphide	380	3.48	Di-t-butyl sulphide	440	4.48
Ethyl methyl sulphide	390	3.47	Tetrahydrothiapyran	400	3.69
Diethyl sulphide	400	3.49	Tetrahydrothiophen	420	3.62
Di-n-butyl sulphide	400	3.59	Trimethylene sulphide	383	3.28

It is suggested that the anti-swelling action of 6-thioguanine [210] is due to the formation of an S→H–N HB between the sulphur atom in this analogue of guanine and the amino-group of cytosine, which is situated opposite the sulphur atom in DNA [211]. An analogous interaction is also assumed between the thiocarbonyl group of thionicotinamide and the amino-group of adenine in the sulphur-containing analogue of dihydrophosphopyridine nucleotide [212].

The formation of an S→H–N HB in crystals has been discussed [213–215]. In crystalline 2-mercaptobenzothiazole there is a considerable decrease in the N...S distance (2.48 Å) in comparison with the N...S distance due to the van der Waals interaction associated with the S→H–N HB [216]. Penfold [217] assumes the presence of an S→H–N HB in crystalline 2-thiopyridone, the strength of which is considerably less than in crystalline 2-mercaptobenzothiazole (the N...S distance in 2-thiopyridone is 3.26 Å). On the basis of crystallographic results (Table 10) an analogous type of intermolecular interaction can be assumed in crystalline ammonium diamidothiophosphate [218], diammonium amidothiophosphate [219], thiosemicarbazide [220–222], pyridazo-3-thione [213,223], 3-hydroxy-5-thio-1,2,4-thiazole [224], thioacetamide [225], 1-thiocarbamylimidazoline-2-thione [226], 2,5-diamino-4-mercapto-6-methylpyrimidine [227], xanthene hydride [228], triethylenediaminecadmium(II) thiosulphate [229], 3-ethoxy-2-ketobutyraldehyde bis(thiosemicarbazone) [230], 2,4-dithiouranyl [231], the thiourea–parabanic acid (oxalylurea) complex [232], 2-propyl-4-thiocarbamoylpyridine [233], 4-thiocarbamoylpyridine [234], 4-formylpyridine thiosemicarbazone [235], 2-formylthiophen thiosemicarbazone [236], thiocytosine [237], copper ammonium thiomolybdate [238], 2,2′-diaminodiphenyl disulphide [239], thiocarbohydrazide [240], dithio-oxamide [241], 2-mercapto-6-methylpurine [98], 1,2,4-trithiolane-3,5-dione [242], 6-thioguanine [243], thiourea [244,245], trimethylenethiourea [246], allylthiourea [247], and also (despite certain objections [248]) in ethylenethiourea [1].

Table 10. N...S intermolecular distance.

3.31	trimethylenethiourea	246
3.36	allylthiourea	247
3.44	ethylenethiourea	1

The existence of an S→H–N HB in crystalline thiourea and its tertiary derivatives was also shown by infrared spectroscopy [249,250].

2. The S→H–C Hydrogen Bond

The possibility of the formation of an HB of S→H–C type has also been noted. Engberts [251] recently suggested, on the basis of NMR results, such interaction between α-diazosulphones (RSO_2CHN_2) and thiophen. According to Bellamy and Rogasch [134], the association of chloroform with ETTC is assumed to be by an S→H–C HB. The ability of chloroform to form S→H–C HB with 8-mercaptoquinoline, its derivatives, their zwitter-ion forms, and aliphatic thiols has been postulated [56,125,141,252]. An analogous interaction, judging by interatomic distances, can evidently be presumed in crystalline 2,4-dithiouracyl [231], thiocarbamoyl-4-pyridine [234] and ethionamide [ethyl-2-thiocarbamoyl-4-pyridine] [253].

However, owing to the lack of experimental results the problem of an S→H–C type of HB still remains open.

IV. COMPARISON OF THE ABILITIES OF SULPHUR- AND OXYGEN-CONTAINING COMPOUNDS TO FORM HYDROGEN BONDS

The proton-donating ability of the X–H group in the formation of X–H···Y HB is usually linked with the acidic properties of the compounds RX–H (where X, Y = O or S)[251-262]. As the acidic properties of X–H increase there is an increase in the strength of the X–H···Y HB with the same acceptor of a proton. This correlation is also observed in the series of thiophenol derivatives[263] (Table 11). From this point of view a tendency (greater than for the hydroxyl group) for the mercapto-group to undergo association with the same proton-withdrawing molecule is to be expected. However, in reality on comparing proton-donating molecules with which the atom X (X–H) is situated in different Periods of the Mendeleev system, there is not a proportionality between the ability of the X–H group to act as a proton donor in the formation of an HB and its strength as an acid. For example, for the hydrohalogen acids the acidic properties of which decrease in the order HI > HBr > HCl > HF, the energy of the HB with the same proton-withdrawing molecule changes in the reverse order[264,265].

Table 11. Frequency characteristics of the ν_{SH} band of thiophenol and of its *p*-substituted derivatives in proton-withdrawing solvents.

Substituent	pK_a	CCl_4		Benzene		Acetonitrile		Acetone	
		ν_{SH}	$\Delta\nu$	ν_{SH}	$\Delta\nu$	ν_{SH}	$\Delta\nu$	ν_{SH}	$\Delta\nu$
NH_2	9.7	2559	0	2551	3.1	2547	4.7	2541	7.0
OCH_3	8.8	2572	0	2565	2.7	2561	4.3	2548	9.3
H	8.3	2590	0	2574	6.2	2565	9.7	2558	12.4
Cl	7.3	2588	0	2567	8.1	2557	12.0	2544	17.0
NO_2	5.8	2589	0	2562	10.4	2547	16.2	2519	27.0

An analogous effect is also observed for compounds which contain SH and OH groups. Compounds which contain an SH group always exhibit more acidic properties than their hydroxyl-containing analogues. However, under strictly equal conditions compounds of the RSH type form a less stable HB than compounds of the ROH type. For example, thiophenol (pK_{SH} = 6.5 [266]) forms less stable HB than phenol (pK_{OH} = 9.98 [169]) with proton-withdrawing solvents (Table 12).

An analogous effect is also observed for autoassociation of phenol and thiophenol, for which $10^2\Delta\nu/\nu$ (the relative displacement of the maximum of the ν_{XH} band in the formation of an HB) is 3.4 [273] and 0.73 [49] respectively. The effect of the S–H···O_2N IHB in *o*-nitrothiophenol on the displacement of the $\nu_s(NO_2)$ and $\nu_{as}(NO_2)$ bands ($10^2\Delta\nu/\nu$ = 1.54) is also considerably less than for the O–H···O_2N IHB of *o*-nitrophenol ($10^2\Delta\nu/\nu$ = 9.6 [78]). Several studies have shown that the rate of exchange of the protons in SH groups is several orders of magnitude less than in OH groups, which is the result of the strength of the S–H···S HB being less than that of the O–H···O HB.[76,274,275] The lesser ability of the mercapto-group to form HB is also confirmed by the lower association constants of aliphatic thiols compared with those of aliphatic alcohols (Table 13).

This agrees well with the investigation of chelation in thiosalicylic acid[99] and 8-mercaptoquinoline[125]. The energy of the S–H···O IHB in thiosalicylic acid ($-\Delta H$ = 0.9 kcal mole^{-1}) is considerably less than the O–H···O IHB in salicylic acid ($-\Delta H$ = 5 kcal mole^{-1} [278,279]) despite the lower acidity of the latter.

Table 12. Spectroscopic and thermodynamic characteristics of hydrogen bonds formed by thiophenol and phenol with proton-withdrawing solvents.

The strength of the S–H···N IHB in 8-mercaptoquinoline ($-\Delta H$ = ~ 3 kcal mole^{-1}) is much less than that of the O–H···N IHB in 8-hydroxyquinoline ($-\Delta H$ = ~ 6 kcal mole^{-1}).[125] The acidic properties of 8-mercaptoquinoline (pK_{SH} = 8.48 [280]) greatly exceed those of 8-hydroxyquinoline (pK_{OH} = 9.89 [281]).

Table 13. Association constants (K) of aliphatic alcohols and thiols.

Substance	K, litre mole^{-1}	Reference	Substance	K, litre mole^{-1}	Reference
Ethanol	0.64	276	Ethanethiol	0.021	48
n-Propanol	0.89	277	Propane-1-thiol	0.052	48
n-Butanol	0.78	277	Butane-1-thiol	0.016	48

The experimentally observed inverse relationship between the ability of the mercapto- and hydroxyl groups to form HB and their acidic properties is due to the difference in the nature of the S–H and O–H chemical bonds.

From the point of view of the covalent nature of the X–H···Y HB[282,283], the existence of a definite relation between the proton-donating ability of the X–H group and the tendency of the H atom of this group to receive electrons of atom Y is postulated[284]. Evidently two mechanisms of the transfer of electrons to the H atom are possible: to the vacant (antibonding[250,260-285]) orbital X–H or to the 1*s* orbital of the bonded H atom[283,286] with use therein of its residual overlap capability. The latter should increase with decrease in the *S*-integral for the overlap of the X–H bond[287]. The value of the *S*-integral

depends on the nature of the remaining part of the molecule (R) and the electronegativity (EN) of the atom X. With increase in the inductive nature of R and in the EN of atom X there is a decrease in the probability of the residence of the electrons in the overlap region which reduces S and increases the proton-donating ability of X–H. Consequently, the strength of the X–H···Y HB for a given donor of electrons Y depends on the degree of "protonisation" of the hydrogen atom[288]. For the same atom X the degree of "protonisation" and the acidic properties of the molecule due to the influence of the radical R on the X–H bond are symbatic to one another.

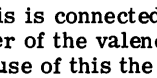
Table 14. Dipole moments of 2-thiopyridone, 2-pyridone, and their *N*-methyl derivatives in dioxan (μ_D).[208]

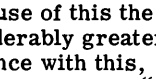
Compound	μ_D, D
2-Pyridone	2.94
N-Methylpyrid-2-one	4.07
2-Thiopyridone;	5.29
N-Methyl-2-thiopyridone	5.49

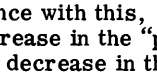
In comparing proton-donating molecules which contain different atoms X it is also necessary to take into account differences in the value of the *S* overlap integral[289]. For many compounds the proton-donating ability of the X–H group correlates well with the EN of atom X[289] and also with the size of the electron cloud (with the principal quantum number of the valence electrons of atom X[99,288,290]). These correlations are evidently a reflection of relation between the proton-donating ability and *S* already mentioned[289], since *S* is a function of both the difference in EN and the dimensions of the atoms being bonded[291,292]. Correlation of the proton-donating ability of the X–H groups with the EN of the atoms X is observed when there is a considerable difference in EN or when the sizes of atoms X are similar. When the atoms X have similar EN the sizes of the electron clouds must be considered (for example, N–H and Cl–H or C–H and I–H)[289].

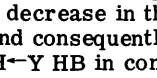
In compounds with an S–H group, as compared with their oxygen analogues, the valence orbitals of the sulphur atom are much more delocalised in space than those of the oxygen atom. This is connected with the greater principal quantum number of the valence electrons of the sulphur atom. Because of this the *S* overlap integral of the S–H bond is considerably greater than that of the O–H bond. In accordance with this, an increase in the *S* integral leads to a decrease in the "protonisation" of the H atom, that is, to a decrease in the proton-donating ability of the S–H group and consequently to a decrease in the strength of the S–H···Y HB in comparison with the strength of the O–H···Y HB. However, the S–H bond is considerably weaker than the O–H bond, owing to the greater delocalisation in space of the valence orbitals of the sulphur atom, compared with those of the oxygen atom. The lower energy of the bonding of the hydrogen atom in the S–H group is a reason for the higher acidity of the compounds with an S–H group compared with those of their oxygen analogues. Consequently, replacement of an oxygen atom by a sulphur atom in the X–H group (X = O or S) brings about, on the one hand, a decrease in the degree of "protonisation" of the hydrogen atom, leading to a weakening of the HB with the proton-withdrawing molecule, and, on the other, to the loosening of the X–H bond, increasing its ability for ionisation.

A comparison of the proton-withdrawing capability of sulphur and oxygen atoms in the formation of HB is also of interest.









2-Thiopyridone (Section III) is dimerised[208] in solutions in benzene, as also is 2-pyridone[208]. According to measurements of the dipole moments of 2-thiopyridone, 2-pyridone, and their *N*-methyl derivatives, the dimers of 2-thiopyridone (unlike 2-pyridone) are broken down in solutions (Table 14).

Table 15. $\Delta\nu_{OH}$ and $-\Delta H$ of the O–H···Y HB of $(C_4H_9)_2Y$–C_6H_5OH associates[162].

Y	$\Delta\nu_{OH}$, cm^{-1}	$-\Delta H$, kcal mole^{-1}
O	278	5.98
S	254	4.26
Se	210	3.72

According to results obtained in an investigation of $(C_4H_9)_2Y$–C_6H_5OH associates (Y = O, S, Se) the energy of the O–H···Y HB and the displacement of the ν_{OH} band to lower frequencies decreases in the order O > S > Se (Table 15).

Table 16. Displacement of the ν_{OH} band, association constant (K_{20}), and energy of formation of the associates ($-\Delta H$) of ethers and thioethers with phenol and its derivatives.

	O	220	5.95	3.75	—	—	—
	S	222	1.08	2.42	—	—	—

Investigations of the interaction of the esters and thioesters triethyl phosphate and triethyl phosphorothioate with proton-donating solvents (phenol and its derivatives) also showed that the strength of the O–H···Y HB formed by sulphur-containing compounds (Y = S) is much less than that for their oxygen-containing analogues (Y = O) (Tables 16 and 17).

For IHB an analogous relation between the strengths of the O–H⋯S and O–H⋯O HB was shown by examples of ω-ethylmercaptoalkanol and ω-methoxyalkanol[178]. The high strength of the O–H⋯S IHB compared with that of the O–H⋯O IHB in five-membered rings[181,183,184] is an exception. It seems that in five-membered rings the N–H⋯S IHB is also much stronger than the N–H⋯O.[195] This is explained by the sulphur atom being larger than the oxygen atom, which leads to a greater overlap of the orbitals having a lone pair with the 1*s* orbital of the hydrogen atom being greater for sulphur.

Table 17. Displacement of the ν_{OH} band, association constant (K_{20}), and energy of formation of the associates ($-\Delta H$) of triethyl phosphate and triethylthiophosphorothionate with phenol and pentachlorophenol[163].

Compound	Y	Phenol			Pentachlorophenol		
		Δν, cm^{-1}	K_{20}, litre $mole^{-1}$	$-\Delta H$, kcal $mole^{-1}$	Δν, cm^{-1}	K_{20}, litre $mole^{-1}$	$-\Delta H$, kcal $mole^{-1}$
$(C_2H_5O)_3P=Y$	O	345	350,5	6.7	481.1	153.1	5.2
	S	172	4.5	3.2	202	2.9	3.3

In the literature the proton-withdrawing ability of a molecule in the formation of an X–H⋯Y HB is usually correlated with the first ionisation potential of this compound[159,285,293–295]. Here however, it must be borne in mind that such a correlation is well achieved in a series of monotypical compounds, for example, in a series of ketones or esters[296–299].

From this point of view, taking into account that the bonding of the valence electrons of the sulphur atom is weaker than that for the oxygen atom, a higher electron-donating ability is to be expected for the sulphur-containing compounds. For typical donor–acceptor complexes with charge transfer the ability for complex formation is usually, with certain exceptions[300], higher for sulphur-containing compounds[145,163,301–304]. However, such a relation is not observed between the electron-donating ability of SR_2 and OR_2 and the strength of the HB formed by them with the same RX–H.

The experimentally observable higher ability of oxygen-containing compounds to form HB compared with that of their sulphur-containing analogues must be regarded from the viewpoint of the difference in the electronic structure of the sulphur and oxygen atoms.

Schneider[290] explains the difference in the proton-withdrawing abilities of sulphur and oxygen in the formation of HB by the degree of *s*-character of the orbitals of their non-generalised electrons. The unshared pairs of electrons of the sulphur and oxygen occupy hybrid *sp*-orbitals. According to published data the strength of the HB depends on the magnitude of the *s*-character of the hybrid *sp*-orbitals of the lone pair. For example, ethers (sp^3 hybridisation, 25% *s*-character) form stronger HB than ketones (sp^2 hybridisation, 33% *s*-character).[159,305] However, the strength of the HB formed by the lone pair increases with decrease in the *s*-character of its orbitals only up to a certain limit. For example, ethylene oxide, the lone pairs of which occupy pure *s*- and *p*-orbitals (hybridisation is absent) form less stable HB than ethers[159].

Hence the strength of the HB depends on the magnitude of the atomic dipole and the degree of spatial localisation of the lone pair: an increase in the *s*-character in the *sp*-hybrid orbital leads to a decrease in the asymmetry of the cloud of the unshared pair relative to the nucleus and to its spreading in space, which reduces the energy of interaction with the hydrogen atom. In ethers (esters) (Table 10) the C–O–C valence angle is close to 109°, but in the corresponding thioethers the C–S–C angle is always 7–12° less[306], that is, the orbitals of the lone pairs in the thioethers exhibit a considerably greater *s*-character than in ethers, in consequence of which the thioethers form less stable HB[159,160]. In triethyl phosphate the oxygen has sp^2 hybridisation and in triethyl phosphorothioate the unshared pairs of the sulphur occupy almost pure *s*- and *p*-orbitals (this also occurs in the C=O group as compared with the C=S group), which also leads to the P=S⋯H–O (C=S⋯H–O) HB being weaker than the P=O⋯H–O (C=O⋯H–O) HB.

Ginzburg[159] considers that the low energy of formation of HB involving a sulphur atom as the proton acceptor may also be partly due to the greater *s*-character of the lone pair orbitals. He thinks the main reason is that on going from an oxygen atom to a sulphur atom there is an increase in the principal quantum number of the electrons of the outer clouds which is accompanied by an increase in the symmetry of the lone pair orbitals and a decrease in their spatial localisation. For example, sulphur is known to form less stable covalent bonds than oxygen with the same atom. Consequently, the degree of overlap of the electron clouds in a C–S bond is less than in the C–O bond, that is, there is weakening of the bond owing to the orbitals of the sulphur atom being less localised in space. The greater "spreadability" of the orbitals of the sulphur atom with lone pairs than the corresponding orbitals of the oxygen atom is also mainly responsible for the lower ability of the sulphur atom to form HB in sulphur-containing compounds in comparison with the oxygen atom in their oxygen-containing analogues.

The Acid Properties of the Amino-group

A.F.Pozharskii and E.A.Zvezdina

The acid properties of primary *C*-amino-groups in amines, amides, and amidines have been examined. The methods of preparation and the physical and chemical properties of the metal salts of amines are discussed.
The bibliography includes 219 references.

CONTENTS

I. Introduction 37
II. Methods of preparation of *N*-anions 37
III. The nature of the nitrogen-metal bond and the structure and physical properties of metal salts of amines 45
IV. Reactions of metal salts of amines 46

I. INTRODUCTION

Amino-compounds are usually regarded as bases capable of combining with a proton to form an ammonium ion (I). A less well known property of the NH_2 group is its capacity for acid dissociation. Indeed primary amines can be regarded as dibasic acids, which, following the ionisation of N–H bonds, can give rise to two series of conjugate bases—the monoanion (II) and the dianion (III):

$$\underset{(I)}{\overset{+}{R}NH_3} \overset{H^+}{\rightleftarrows} \underset{(II)}{RNH_2} \rightleftarrows \underset{(III)}{RNH^-} + H^+ \rightleftarrows RN^{2-} + 2H^+ .$$

Many investigations of methods for the preparation of *N*-anions of type (II) and (III) and their chemistry have been made, but there are almost no reviews on the acid properties of the amino-group. In the literature there exists only a brief compilation of data of metal salts of amines in a handbook[1], a review of magnesylamines[2], and a monograph[3] in which the ionisation of N–H bonds in liquid ammonia is considered. Strange as it may seem, the question of the acid properties of the amino-group is not discussed either in the extensive monograph[4] published in 1968 and specially devoted to the chemistry of the amino-group.

The main aim of the present paper is to review the accumulated literature data concerning the acid properties of the primary amino-group linked to a carbon atom. The review is thus devoted to aliphatic, aromatic, and heterocyclic amines and also to acid amides and amidines. Compounds in which the amino-group is linked to non-carbon atoms (hydrazines, halogenoamines, etc.) are not considered. Selected data on the acid properties of secondary amines are discussed.

The first section of the review is concerned with the acidity of the N–H bonds in various amino-compounds and with methods for the preparation of *N*-anions. The second section deals with the chemical properties of *N*-anions and their employment in organic synthesis. By analogy with carbanions[5], *N*-anions can be defined as conjugate bases of the corresponding N–H acids. The term "*N*-anions" thus refers to all salts of primary amines with alkali metals. It is then immaterial whether the M^+ ion is linked to the *N* anion with formation of a closely linked ion pair or whether the N–M bond is fully ionised. Only in those cases where the N–M bond is clearly covalent (>N–HgR, magnesylamines) is the employment of the term "*N*-anion" unjustified.

II. METHODS OF PREPARATION OF *N*-ANIONS

1. IONISATION OF N–H BONDS

a. General Information about the Acidity of the Amino-group. Solvents and Bases Inducing the Ionisation of N–H Bonds

The acidity of N–H bonds is usually much lower than that of O–H bonds. For example, ammonia, the simplest N–H acid, is weaker by 20 powers of 10 than water [pK_a = 34 (Smith[3])† and 14 respectively]. Therefore N–H bonds in amines are as a rule ionised in non-aqueous solvents by treatment with strong bases. The solvents employed are aromatic hydrocarbons and ethers: tetrahydrofuran (THF), dimethoxyethane, dioxan, etc., dimethyl sulphoxide (DMSO), and hexamethylphosphoramide (hexametapol or HMPA). Liquid ammonia is particularly valuable as a solvent, because it exhibits a high solvent and ionising power.

The bases most often used to ionise N–H bonds are alkali metal amides and organometallic compounds. Sodium hydride and alkali metals are frequently employed for this purpose. Alkali metal and ammonium hydroxides can also be used to ionise relatively strong N–H acids. However, when the pK_a of the amine is appreciably above 14–16, it is necessary to use a solvent or system of solvents in which hydroxide ions have an enhanced reactivity. The DMSO–water system has been used to ionise amines with pK_a values not exceeding 25–26.[8] Thus in an aqueous mixture containing 99.6 mole % DMSO, it was possible to ionise 3-chloroaniline (pK_a = 25.6) by treatment with tetramethylammonium hydroxide[9]. Overall, the bases enumerated can be arranged in the following series in terms of their ionising activity: carbanions (alkyl- and aryl-metals), sodium hydrides, alkali metal amides, alkali metals, and alkali metal hydroxides.

In order to follow the acid–base reaction and to determine the number of ionising N–H bonds when amines in aprotic solvents are treated with lithium alkyls, metal amides, and metal hydrides (or the metals themselves), the gases evolved (hydrocarbon, ammonia, and hydrogen respectively) are measured quantitatively. When alkali

† Other values for the ammonia pK_a are also quoted in the literature: 35 (Bell[6]) and 36 (Audrieth and Kleinberg[7]). They all refer to 33°C.

metal amides are employed in liquid ammonia, it is difficult to determine which type of species (the monoanion or the dianion) is formed as a result of the reaction. In this case one relies on chemical evidence, physical methods, or the elemental analysis of the salt isolated. It is very convenient to follow the ionisation of N–H acids in liquid ammonia when the acids are treated with alkali metals [10]. The process is carried out by the gradual addition of sodium (or potassium) to a solution (or suspension) of the amine in liquid ammonia. Apart from the evolution of hydrogen, the occurrence of the reaction is demonstrated by rapid (1–2 min) disappearance of the initial blue colour characteristic of solutions of alkali metals in liquid ammonia. The number of ionised N–H bonds is inferred from the amount of metal required to form a stable blue colour.

It is noteworthy that certain amines (for example 1-alkyl-5-aminobenzimidazoles and aniline) do not react with sodium in liquid ammonia. Nevertheless their anions, obtained by another procedure, are capable of existing in this solvent without appreciable ammonolysis‡. There is a fairly small number of quantitative data on the acidity of primary amines. On McEwen's thermodynamic scale [11] (in ether), the same $pK_a = 27$ is quoted for three aromatic amines: aniline, *p*-toluidine, and *p*-anisidine. Although the acidity of aniline specified by the pK_a is probably close to the true value, it is unlikely that the *p*-methyl and *p*-methoxy-groups have no appreciable influence on the acidity of the NH_2 group (by analogy with the influence of these groups on the acidity of the amino-nitrogen).

Systematic determinations of the acid dissociation constants of series of anilines and diphenylamines containing electron-accepting substituents have been made by Stewart and coworkers [8,9,12,13]. They employed a technique in which H_- functions§ were derived for various indicators and solvent systems. Using the pyridine–water, sulpholane–water, and DMSO–water solvent systems and tetramethyl- and trimethylbenzylammonium hydroxides as bases, they determined spectrophotometrically the acid dissociation constants of amines up to $pK_a = 25.6$.

For the determination of the acidity of relatively strong N–H acids ($pK_a < 19$), other solvent systems were also proposed: ethylenediamine–water [14], ethanolamine–water [15,16], hydrazine–water [18,19], t-pentyl alcohol–water [20], and ethanol–water [21]. It is remarkable that the pK_a of the same N–H acids, determined in different solvents of the above series, differ little from one another with rare exceptions.

The use of liquid ammonia as a solvent made it possible to extend the measurements to the region of even lower acidities of amines. Three groups of investigators have worked on the development of an acidity scale for arylamines in liquid ammonia [22–24]. With the aid of ^{1}H NMR, Birchall and Jolly investigated the position of acid–base equilibrium in a mixture of two acids HA and HB in liquid ammonia in the presence of sodamide [22]. On the basis of the results, the difference between the strengths of the two acids was determined from the following formula:

$$\Delta pK_a = \lg\left[\frac{(HB)}{(B^-)}\right] - \lg\left[\frac{(HA)}{(A^-)}\right] .$$

The authors then found the difference $\Delta pK'_a$ between the acidities of the next acid pair (HB and HC). Having accumulated a large number of such measurements, they constructed a relative acidity scale for aromatic amines in liquid ammonia, in which 2,5-dichloroaniline, the most acidic of the amines investigated, was adopted as a standard ($pK_a = 0$). This scale covers a range of 6.58 pK_a units towards lower acidities. A disadvantage of liquid ammonia proved to be the impossibility of measuring the acidities of stronger N–H acids, in particular nitroanilines, since the latter formed Meisenheimer type complexes with ammonia or the amide ion.

Takemoto and Lagowski, who employed ^{1}H NMR combined with spectrophotometric analysis¶ of the position of equilibrium, related the acidities of many weak N–H and C–H acids and thereby established an absolute acidity scale in liquid ammonia [23]. *NN*-Dimethyl-*p*-phenylenediamine (the weakest of the N–H acids, whose pK_a has been determined) and di-(*p*-tolyl)methane were selected as the linking pair of N–H and C–H acids. The acidity scale of Takemoto and Lagowski [23] covers the range of 13 pK_a units, the limit of the series corresponding to 2,5-dichloroaniline.

Herlem and Thiebault calculated the acid dissociation constants of substituted anilines from the results of their potentiometric titration in liquid ammonia with a potassamide solution using a hydrogen electrode [24]. It is noteworthy that the pK_a (Table 2) determined by the ^{1}H NMR and potentiometric methods differ from one another by 7–12 powers of 10 in absolute magnitude. It is at present difficult to say whether this is a consequence solely of differences in the temperatures at which the measurements were made (+25 °C for the ^{1}H NMR method and −60 °C for the potentiometric method) or whether some other factors also play a role. At any rate the acidities of liquid ammonia at +25° and −60 °C [$pK_a = 27.7$ (Coutler et al. [25]) and 32.5 (Herlem [26]) respectively] do not differ from one another very markedly.

b. Alkylamines and Cycloalkylamines

Alkylamines are even less acid compared with ammonia (there are no quantitative data). Therefore they cannot be converted into salts in liquid ammonia either with the aid of alkali metal amides [27] or the metals themselves [7]. However, in aprotic inert solvents (toluene, octane, etc.) or altogether in the absence of a solvent, alkylamines and

---

‡ The term "ammonolysis" implies an acid–base reaction between ammonia and the conjugate states of an acid BH weaker than ammonia:

$$B^- + NH_3 \rightleftarrows BH + NH_2^- .$$

The weaker the BH acid the greater the shift of the above equilibrium to the right.

§ The function H_- defines the capacity of the solvent to abstract a proton from a neutral acid HA and is calculated from the formula [12]

$$H_- = -\lg\frac{a_{H^+}f_{A^-}}{f_{HA}} = pK_a + \lg\frac{[A^-]}{[HA]} .$$

In dilute aqueous solutions H_- is identical with pH.

¶ One of the disadvantages of the spectrophotometric method for solutions of liquid ammonia is the impossibility of measuring the acidity of amines weaker than aniline. This is due to the insignificant degree of ionisation of such acids and the consequent masking effect of the amide present in large excess, which absorbs at 350 nm. [22]

cycloalkylamines can be converted into metal salts by prolonged heating with alkali metal amides in nitrogen [28-30]. A necessary condition for the success of this reaction is the removal of the ammonia formed from the reaction zone. If ammonia is not removed, an equilibrium is established between the initial and final products [31]:

$$CH_3NH_2 + LiNH_2 \rightleftarrows CH_3NHLi + NH_3 .$$

Therefore it is technically simplest to obtain with the aid of this method metal salts of high-boiling amines (butylamines, cyclohexylamine, etc.).

Alkali metals dissolve in the lowest alkylamines to form blue solutions, the properties and structures of which are close to those of solutions of alkali metals in liquid ammonia [32]. However, on heating, a slow reaction takes place between alkylamines and cycloalkylamines on the one hand and the alkali metals on the other, and is accompanied by the evolution of hydrogen and the formation of the corresponding salt. This reaction is frequently employed for preparative purposes and is usually carried out without a solvent:

$$RNH_2 + M \rightarrow RNH^-M^+ + {}^1/_2H_2 .$$

In the preparation of metal salts of methylamine by this method, one should guard against a side reaction involving the formation of cyanides [33,34]. The conversion of methylamine into potassium methylamide can be achieved smoothly with the aid of potassium hydride [34].

The best method for the preparation of lithium salts of alkylamines and cycloalkylamines is apparently the reaction of amines with organolithium compounds. Usually lithium alkyls in benzene, hexane, or ethers are employed for this purpose. Table 1 gives a compilation of certain data for the preparation of metal salts of alkylamines and cycloalkylamines.

Table 1. Metal salts of certain alkyl- and cycloalkylamines.

Salt	Ionising agent	Conditions	Ссылки на литературу

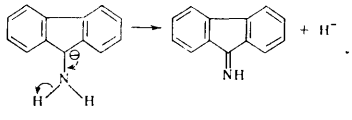
c. Arylalkylamines

On going from methylamine to benzylamine, diphenylmethylamine, and finally to triphenylmethylamine, the acidity of N–H bonds should increase somewhat owing to the electron-accepting influence of the aryl group. Simultaneously there should be an even greater increase in the acidity of the C–H bonds adjoining the amino-group. As a result, when strong bases act on benzylamine and particularly on diphenylmethylamine, the N–H and C–H bond ionisation processes compete. Hauser et al. established that, when diphenylmethylamine is treated with potassamide in liquid ammonia, a mixture of the carbanion (IV) and the *N*-anion (V) is formed[39]:

$$(C_6H_5)_2CH{-}NH^- \underset{NH_3}{\overset{KNH_2}{\rightleftarrows}} (C_6H_5)_2CH{-}NH_2 \overset{KNH_2}{\underset{NH_3}{\rightarrow}} (C_6H_5)_2\bar{C}{-}NH_2$$
(V) (IV)

$\downarrow$ 1. CO_2 2. H^+ $\downarrow$ 1. CO_2 2. H^+



$(C_6H_5)_2CHNHCOOH$ $(C_6H_5)_2C(NH_2)COOH$

(VII) (VI)

The formation of the carbanion (IV) is proved by the appearance of the red colour characteristic of arylalkyl carbanions and also its conversion into the aminoacid (VI) when the reaction mixture is carboxylated after the evaporation of ammonia. The presence in the mixture of the *N*-anion (V) has been less definitely established. The presence of the carbamic acid (VII) in the carboxylation products cannot serve in this case as unambiguous proof that the *N*-anion is present, since the initial diphenylmethylamine also gives rise to the acid (VII) on interaction with CO_2.

The formation of the carbanion is promoted by its resonance stabilisation, while the *N*-anion is stabilised in arylalkylamines only by the *-I* effect of the arylalkyl group.

Benzylamine itself is probably still a very weak acid. Thus Picon failed to obtain sodium benzylamide by the reaction of benzylamine with sodium or with $NaNH_2$ in liquid ammonia even after a long time in an autoclave [38]. However, the appearance of a red colour when benzylamine is treated with various bases [39-41] indicates the formation of a certain amount of carbanions. This is also suggested by certain indirect data. For example, 9-aminofluorene, diphenylmethylamine, and benzylamine are converted into the corresponding imines on standing in liquid ammonia in the presence of potassamide [42]. It appears likely that the reason for this phenomenon consists in the β-elimination of a hydride ion from the corresponding carbanion:

The fact that the amino-group in arylalkylamines is more acid in ammonia than in alkylamines can be inferred from the existence in liquid ammonia, without appreciable ammonolysis, of the dipotassium salts of diaminodiphenylmethane (VIII), obtained by the addition of two KNH_2 molecules to benzophenoneimine [43]:

$$(C_6H_5)_2C{=}NH + 2KNH_2 \rightarrow (C_6H_5)_2C(NHK)(NHK)$$

(VIII)

In this connection, it is difficult to understand why triphenylmethylamine fails to give an *N*-anion when acted upon both by potassamide in liquid ammonia [44] and by alkali metals in liquid ammonia or in ether [45]. Sodium and potassium in liquid ammonia cleave the C–N bond in triphenylmethylamine with formation of a carbanion and an amide ion [44]:

$$(C_6H_5)_3C{-}NH_2 \xrightarrow{M} \begin{cases} (C_6H_5)_3NH^-M^+ \\ (C_6H_5)_3C^-M^+ + MNH_2 \end{cases}$$

Steric factors can hardly be responsible for the difficulty of the ionisation of the N–H bonds in triphenylmethylamine, since triphenylmethane, where the steric effect

should be even more pronounced, readily ionises in liquid ammonia in the presence of metal amides and alkali metals. Such behaviour of triphenylmethylamine suggests that the ionisation of diphenylmethylamine and benzylamine (weaker N–H acids than triphenylmethylamine) involves preferentially the C–H bonds, i.e. the formation of a carbanion. Metallation of CH–NH systems is fairly common in organic chemistry. For example, acetamido-[46-48] and benzamido-malonic esters[49] give rise to carbanions and not *N*-anions when acted upon by bases, a fact which is used in the synthesis of aminoacids.

d. Arylamines

Although aromatic amines are very weak N–H acids, their acidity is nevertheless much greater than that of aliphatic amines and ammonia. This can be accounted for by the possibility of the resonance stabilisation of the arylamine *N*-anions:

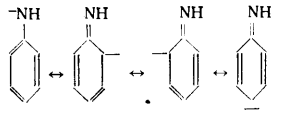


Table 2. Acid dissociation constants (pK_a) of a series of anilines.[a]

Substituent in benzene ring of aniline	Solvent, temp., °C			Substituent in benzene ring of aniline	Solvent, temp., °C		
	+25[9,12,13][b]	NH_3, +25[23]	NH_3, −60[24]		+25[9,12,13][b]	NH_3, +25[23]	NH_3, −60[24]
H	27.3[c]	21.2	28.8	4-Cl	—	19.9	27.4
2-NO_2	17.88	—	—	4-CN	22.68	15.9	28.5
3-Cl	25.63	—	—	4-NO_2	18.37	—	—
3-CF_3	25.40	18.7	—	2,4-$(NO_2)_2$	15.00	—	—
4-CH_3	—	22.1	—	2,4,6-$(NO_2)_3$	12.20	—	—
4-$N(CH_3)_2$	—	25.6	—				

[a] The acidity constants of many other anilines are quoted in the literature[9,12,13,23,24].
[b] The average pK_a values for various solvent systems: DMSO–water (99.9 mole % DMSO), sulpholane–water (95.5 mole % sulpholane), and others.
[c] pK_a = 27.3 was obtained for aniline by extrapolation.

Table 2 shows that aniline is a stronger acid by 6–7 powers of ten than ammonia. Introduction of electron-accepting substituents into the benzene ring of aniline cause an even greater increase of the acidity of the NH_2 group and the 2,4,6-trinitroaniline anion can exist even in water. The inductive effect of the nitro-group in the series of anilines is greater than in the series of phenols. It is believed that in the *N*-anions of *o*- and *p*-nitroarylamines most of the negative charge is localised at the NO_2 group, i.e. structure (IXb) makes a large contribution to the resonance state[50]:

In certain cases (3-nitroaniline), on treatment with hydroxyl-containing bases the ionisation of the N–H bond is accompanied by a competing process involving the nucleophilic addition of the $O\bar{H}$ ion to the aromatic ring. The two reactions can be distinguished spectrophotometrically: in contrast to the addition process, ionisation takes place instantaneously[9].

It has been found[22] that there is a satisfactory correlation between the σ constants of substituents (σ^- constants must be employed for the *p*-NO_2, *p*-CN, and *p*-F substituents) and the pK_a values of substituted anilines with a constant $\rho = -5.3$. Such a high value of ρ shows that the acidity of aniline depends significantly on the effect of substituents and, as shown by experiment, to a greater extent than the acidity of anilinium ions. The ρ constant for the acid dissociation of substituted diphenylamines is also very high (−4.07).[9]

Stewart and Dolman[50] (see also Birchall and Jolly[22]) established that there is a fairly satisfactory linear relation between the basicities pK_{BH^+} (acidities of anilinium ions) and the acidities of pK_{HA} of substituted anilines and diphenylamines (with the exception, for reasons stated above, of compounds with nitro-groups):

$$pK_{HA} = 21.4 + 1.30\ pK_{BH^+} . \quad (1)$$

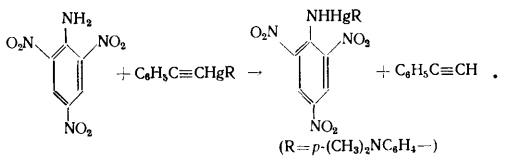
This equation can be used for an approximate estimation of the acidities of amines whose pK_{HA} have not been determined for one reason or another, but the basicity pK_{BH^+}, which can be determined more readily and accurately, is known. For example the basicities of aniline, *p*-toluidine, and *p*-anisidine are 4.60, 5.10, and 5.34,[51] from which we have the acidities 27.52, 28.03, and 28.34 respectively. The value 27.5 for aniline agrees satisfactorily with other data[11,24].

For preparative purposes, when it is necessary to employ aprotic solvents, the *N*-anions of aromatic amines are obtained by treating the amines with sodium hydride[52], lithium alkyls[53], lithium aryls[54], or organomagnesium compounds[2,55-57]. In the cold, the metal usually substitutes one hydrogen atom in the NH_2 group, while on brief heating the second hydrogen atom is also readily replaced at a temperature as low as 35–40°C:

$$ArNH_2 + RMgX \xrightarrow[-RH]{20-25^\circ} ArNHMgX \xrightarrow[\Delta]{RMgX} ArN\begin{matrix}MgX\\MgX\end{matrix} + RH .$$

This reaction serves as a basis for the quantitative determination of active hydrogen in arylamines[58].

At room temperature, neither sodium nor sodamide reacts with aniline at an appreciable rate, but, when aniline is refluxed with these bases in xylene[59] or in the absence of a solvent[35,60], the sodium salt of aniline is formed fairly readily. The use of HMPA, the high ionising power of which makes it possible to carry out the process under mild conditions[61,62], is extremely convenient in the preparation of sodium arylamides. It is believed[61] that, when two equivalents of sodamide are employed in HMPA, the disodium salts of aromatic amines are also formed. However, this conclusion is based on alkylation data which, as will be shown below, do not constitute convincing proof.



The preparation of the anions of more acid amines (for example *p*-nitroaniline) can be achieved in DMSO by treatment with alkali metal hydroxides[9].

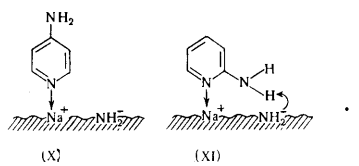
The generation of the *N*-anions of aromatic amines in liquid ammonia requires special consideration. The ionisation of the N–H bonds in aniline and its derivatives with electron-donating substituents on treatment with alkali metals or $NaNH_2$ takes place in this solvent only at room

temperature and under pressure [38]. Under the usual conditions for experiments in liquid ammonia (temperature between −33° and −60°C), the N−H bonds in aniline cannot be ionised by treatment with alkali metals or $NaNH_2$. This is very surprising bearing in mind that the sodium and potassium salts of diphenyl- and triphenylmethane, which are weaker C−H acids than aniline, are readily formed in liquid ammonia under analogous conditions. Probably the solvating power of liquid ammonia in relation to carbanions is greater than in relation to *N*-anions.

According to the data of Bunnett and Moyer [63], when aniline is treated with potassamide in liquid ammonia at a temperature as low as at −33°C, potassium anilide is readily formed. The ease of this reaction can probably be explained by the higher solubility of potassamide in liquid ammonia (450 g litre^{-1} at −33°C) compared with sodamide (1.5 g litre^{-1} 25°C). [64] However, one should note that rigorous proof of the complete conversion of aniline into its *N*-anion was not obtained, since the salt was not isolated in a pure form.

In a series of investigations, Nesmeyanov and Kravtsov showed that aromatic amines containing also acidifying substituents such as NO, NO_2, and −N=N− readily form arylmercury derivatives on reaction with arylmercury hydroxides [65-68]. For fairly acid amines (picramide), arylmercury derivatives of acetic acid, phenylacetylene, or *p*-nitroaniline can also be employed as bases [65]:

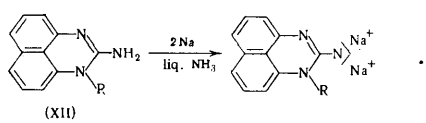
Aniline itself and its *p*-chloro- and *p*-bromo-derivatives do not form arylmercury derivatives under these conditions [65].



e. Heterocyclic Amines

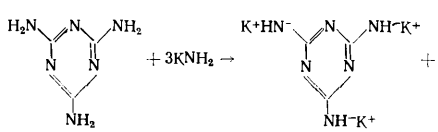
In the amino-derivatives of aromatic aza-systems, the amino-group is much more acidic than aniline owing to activating effect of aza-nitrogen. It appears that there are no quantitative literature data for the acidities of *N*-heteroaromatic amines. However, one can suppose that the pK_a for 2- and 4-aminopyridines should be intermediate between the acidities of 2-nitroaniline (pK_a = 17.9) and 2,4-dinitroaniline (pK_a = 15.0). This estimate is based on a comparison of the values of σ_p for the pyridine nitrogen atom and the NO_2 group, which are +0.93 and +0.778 respectively [69] (the literature values of σ_o for the pyridine N atom are +0.81, +1.02, etc.). [69]

It is therefore not surprising that α-amino-derivatives of pyridine [59,70-79], quinoline [88], isoquinoline [71], thiazole [80], benzimidazole [71], and pyrimidine [70,78,81] readily form salts when acted upon by alkali metal amides and hydrides, alkali metals themselves, and even their hydroxides under certain conditions [79]. Aromatic hydrocarbons, liquid ammonia, HMPA, and sometimes ether or dioxan are usually employed as solvents. It is noteworthy that in only a few cases these salts were isolated in a crystalline state and investigated [59,70,74]. Usually, after preparation in solution (liquid ammonia, HMPA) or in a suspension (ether, dioxan, hydrocarbons), the salts were immediately introduced into further reactions without preliminary isolation.



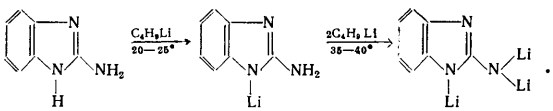
In β- and γ-aminoheterocycles containing a pyridine *N*-heteroatom, the amino-group is also appreciably activated and readily ionises when treated with alkali metals or their amides in liquid ammonia or in HMPA. [71,82,83] However, the formation of metal salts of such amines in weakly polar aprotic solvents proceeds with greater difficulty. For example, 4-aminopyridine hardly reacts (in contrast to 2-aminopyridine) with sodamide in ether [84], while in benzene and xylene the reaction proceeds very slowly even at 140−150°C and can hardly be used for preparative purposes [59,84].

This observation is in sharp contrast to the known sequence of acidities of the CH_3 group in isomeric picolines: 4-CH_3 > 2-CH_3 > 3-CH_3. [85] One of the possible reasons for the difficulty of the ionisation of the NH_2 group in non-polar aprotic solvents is that the reaction takes place in a heterogeneous medium. Therefore the amino-derivative may be sorbed on the surface of sodamide crystals via the coordination of the pyridine N-atom (the most basic centre in the molecules of α- and γ-aminoheterocycles) to the Na^+ ion as in (X). It is quite clear that, for geometrical reasons, such sorption should greatly increase the ionisation of the NH_2 group in 4-amino-derivatives. On the other hand, in the case of α-amino-compounds it should serve as an additional factor promoting the ionisation of the N−H bond, as in (XI):



In solvents where alkali metal amides are soluble (liquid ammonia, HMP), the ionisation of N−H bonds takes place equally readily for both α- and γ-amino-derivatives owing to the homogeneity of the system.

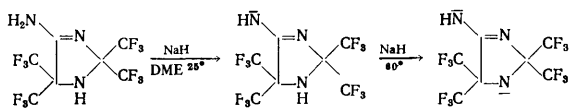
In *N*-heteroaromatic amines, one may expect a greater ease of formation of dianions compared with aromatic amines. Nevertheless, the vast majority of amines, including all three pyridylamines, form monoanions in liquid ammonia when acted upon by alkali metals and apparently metal amides [71]. Among all the amines investigated in this respect, only the 2-amino-derivatives of perimidine (XII) and aceperimidine form dianions under these conditions [71]:



Triamino-1,3,5-triazine (melamine) exhibits very acidic properties. In liquid ammonia it can give rise to mono-, di-, and even tri-anions when acted upon by potassamide [86]:

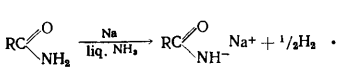
The amino-group in a benzene ring condensed with a heterocyclic nucleus can be both actived and passivated, depending on the nature of the latter. For example, aminoquinolines in liquid ammonia readily form anions on treatment with potassamide [87]. On the other hand, 1-R-5-aminobenzimidazoles cannot be converted into

N-anions in liquid ammonia by treatment with alkali metals or their amides [71]. Reductive cleavage of azides, discussed in section II, 2, gives very satisfactory results in the synthesis of such *N*-anions.



In *N*-heteroaromatic amines containing an endocyclic N–H pyrrole bond in addition to the NH_2 group, the former is as a rule more acidic and ionises first. This applies also to compounds containing an amino-group in the side chain (histidine [88], tryptophan [89]) and to true heteroaromatic amines. Thus, when 2-aminobenzimidazole (XIII) is treated with butyl-lithium or with butylmagnesium bromide, initially the H atom of the endocyclic N–H bond is substituted and only then, on heating to 40°C, is the trilithium salt or trimagnesylamine formed [90]:

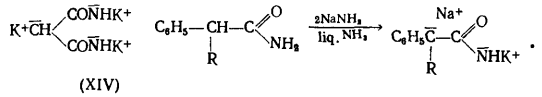
(XIII)



When the amine (XIII) is treated with an excess of an alkali metal amide in liquid ammonia, an equilibrium mixture of di- and tri-anions is formed, with the former predominating [91]. When sodium or potassium is employed as the base, the reaction stops at the monoanion stage [91].

In amino-derivatives of certain partly hydrogenated *N*-heterocycles, the amino-group may be ionised first provided that it is conjugated with an endocyclic C=N bond [92]:

f. Carboxylic Acid Amides



The amides of carboxylic and particularly thiocarboxylic acids exhibit a much greater acidity than other amino-compounds (Table 3). Thus the pK_a's for acetamide and benzamide are in the range 14–15. [93,94] The acidity of thioacetamide in liquid ammonia at −60°C is estimated as 4.6 pK_a units [24]. When treated with alkali metals or their amides, acid amides in liquid ammonia readily form monoanions [95–98]:

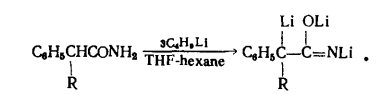
The report that dianions are formed under these conditions [96] was subsequently disproved by the same author [64]. Nevertheless, bearing in mind the very high acidity (among N–H acids) of acid amides, the possibility of the existence in liquid ammonia of their dianions, generated by another procedure, appears to be extremely probable.

Franklin obtained in liquid ammonia and isolated in a crystalline form a large series of carboxylic acid amide salts with alkali and alkaline earth metals [64]. When acid amides are treated with phenylmercury hydroxide, one H-atom of the NH_2 group also ionises and a phenylmercury derivative is formed [65].

The amides of dibasic acids can form in liquid ammonia also polyanions, in which, however, each amino-group carries only one negative charge. For example, malonamide forms a trianion (XIV) when treated with potassamide in liquid ammonia [64]. Phenyl- and diphenyl-acetamides give rise to *CN*-dianions under analogous conditions, the N–H bond being the first to ionise [99,100]:

(XIV)

The use of organometallic reagents gives rise to a wide scope for the ionisation of N–H bonds in acid amides. Hauser and coworkers showed that, when aliphatic and aromatic acid amides are treated with an excess of butyl-lithium in THF or ether, dilithium salts are formed, to which the structure of *ON*-dianions was ascribed [101,102]:



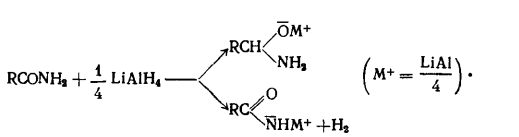


Table 3. Acid dissociation constants (pK'_a) of certain N–H acids.

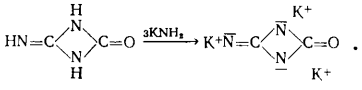
Compound	pK'_a	Conditions	Refs.	Compound	pK'_a	Conditions	Refs.
Acetamide	14	NH_3	3	Thiourea	8.5	NH_3,—60°	24
"	15	25°	93, 94	*N*-Phenylthiourea	3.8	NH_3,—60°	24
Benzamide	14—15	—	93, 94	Semicarbazide	25—33	NH_3,—33°	112
Thioacetamide	4.6	NH_3,—60°	24	Carbohydrazide	21—25	NH_3,—33°	112
Urea	12.9	NH_3,—60°	24	*NN'*-Diphenylguanidine	10.7	NH_3,—60°	24
"	25—33	NH_3,—33°	112	Cyanamide	7	NH_3	3
NN'-Diphenyl urea	7.0	NH_3,—60°	24	Hydrazine	13.5	NH_3,—60°	24

The reaction with organomagnesium compounds takes place similarly, and is used in the quantitative determination of active hydrogen in acid amides by the Tserevitinov method [103]. The amides of aliphatic-aromatic acids, containing a C–H bond in the α-position relative to the $CONH_2$ group, form trianions when acted upon by an excess of butyl-lithium [100,101]:

When acid amides are treated with lithium aluminium hydride, two competing reactions take place: the addition of $LiAlH_4$ to the C=O group and the ionisation of the N–H bond [104]:



Usually the addition reaction takes place preferentially, but when R is a fairly bulky group, mono- or di-metallated derivatives are mainly produced.

g. Urea, Thiourea, and Guanidine

It was established that, when acted upon by alkali metal alkoxides in an alcoholic medium, urea behaves as a monobasic acid [105]. However, when sodium [106,107] or potassamide [96,108] are employed as bases in liquid ammonia, it

is possible to obtain both mono- and di-anions. In contrast to the monopotassium salt of urea, its dipotassium salt is sparingly soluble in liquid ammonia and is usually precipitated when a second equivalent of the base is added[109]. The monosodium salt is also sparingly soluble in liquid ammonia[106]. Therefore it is clear that, when urea is treated with two equivalents of sodium or sodamide, a mixture of mono- and di-sodium salts is formed, i.e. the second ionisation takes place with somewhat greater difficulty. The monosodium salt of urea has been isolated in a crystalline form and investigated in detail[106].

Among urea derivatives, cyanourea, the cyclic form of which gives rise to a trianion when treated with potassamide in liquid ammonia, is of interest[110]:

In water cyanourea behaves as a monobasic acid.

Thiourea and guanidine can also behave as mono- or di-basic acids depending on the conditions. The monosilver and dipotassium salts of guanidine[86] and the monopotassium[111] and dipotassium[109] salts of thiourea have been obtained. The formation of dipotassium salts of urea, thiourea, and guanidine in liquid ammonia has been demonstrated unambiguously[109] by the potentiometric titration of liquid ammonia solutions of these acids with a potassamide solution. On this basis, the following sequence of relative acidities has been established:

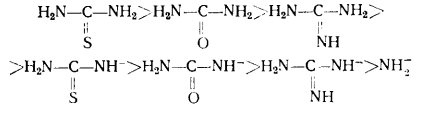


Table 3 presents quantitative data for the acidities of urea, thiourea, and certain related compounds. According to French workers, the first acid dissociation constants (pK'_a) of urea and thiourea in liquid ammonia are respectively 12.9 and 8.5.[24] The second dissociation constants (pK''_a) have not so far been determined, but, judging from the ease of formation of dianions by urea and thiourea in liquid ammonia, they should be in the range 25–30.

An attempt has been made to estimate the acidity of urea by titrating its ammonia solution with a solution of triphenylmethylsodium in the presence of indicators such as indene and fluorene[112]. It was found that the addition of even one drop of the triphenylmethylsodium solution to a mixture of urea and fluorene in liquid ammonia results in the appearance of the yellow colour characteristic of the fluorene anion. Assuming that pK_a for fluorene is 25, Corwin and Reinheimer[112] concluded that the acid dissociation constant of urea (judging from the experimental conditions, the constant is pK'_a) is in the range 25–33. However, this value contradicts all previously known facts concerning the acidity of urea and can probably be accounted for by the unsuitability of fluorene as an indicator in this case (possibly because of the greater kinetic acidity of fluorene, which is not always the same as the thermodynamic acidity).

h. Amidines

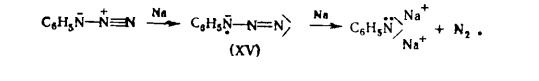
In water amidines behave as very powerful bases but in liquid ammonia they exhibit the properties of monobasic acids, readily forming monoanions when treated with alkali metals or metal amides[64,113]. A more usual method for the preparation of sodium and potassium salts of amidines involves the addition of an alkali metal amide to the corresponding nitrile[114,115]:

A large number of sodium, potassium, and calcium salts of aliphatic and aromatic amidines have been obtained in this way. The silver and copper salts of amidines, which are insoluble in liquid ammonia, can be obtained by the double decomposition between the potassium or sodium salt of the corresponding amidine and the metal nitrate[113].

i. Other Compounds

One of the simplest compounds containing the *C*-amino-group is cyanamide. It exhibits a very high acidity ($pK_a = 7$) and readily forms salts with alkali and alkaline earth metals in liquid ammonia. Numerous examples of such salts are quoted in a handbook[116] and in other publications[86,96].

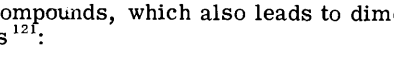
Carbamic acid can exist in liquid ammonia in the form of the mono- and di-potassium salts, which are obtained by treating ammonium carbamate with potassamide[108]. When acted upon by potassamide in liquid ammonia, ethyl carbamate forms an unstable potassium salt which decomposes according to the following equation:[108]



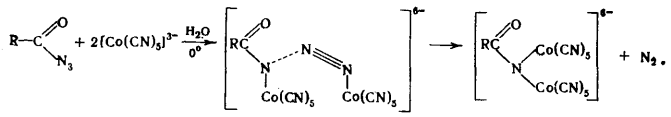
The formation of the *N*-anions of biuret, triuret, allophanic acid, biguanidine and certain other compounds with a *C*-amino-group in liquid ammonia has been discussed in a monograph[3].

2. REDUCTIVE CLEAVAGE OF N–X BONDS

a. Azides



Phenyl azide is reduced by metallic sodium in boiling ether with formation of the disodium salt of aniline and evolution of nitrogen[117]. The reduction proceeds via the stage in which a radical-anion (XV) is formed; it was detected by its characteristic red colour and the ESR spectrum:

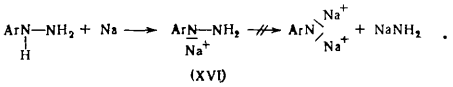


Later it was found for aromatic and heterocyclic azides that liquid ammonia is a very convenient solvent for this reaction[118,119]. The synthesis of *N*-anions via azides is the only one possible in those cases where the ionisation of the N–H bonds in the amino-group proceeds with difficulty or not at all[71].

Initially it was postulated that the dianions of aromatic amines obtained from azides are stable in liquid ammonia[118,119], although recently certain data have been obtained indicating their ammonolysis to the monoanions[71,120].

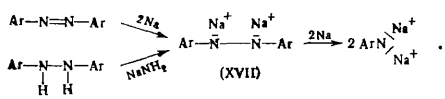
It was possible to reduce aromatic azides by organometallic compounds, which also leads to dimetal salts of the amines[121]:

Only one example of reactions of this type is known for acyl azides [122]:



b. Hydrazines

In an unpublished study, referred to by Smith [3] and Watt [10], Fernelius and coworkers investigated the action of sodium in liquid ammonia on a large number of various substituted hydrazines. They established that, when the nitrogen atom linked to the benzene ring in aromatic hydrazines is not joined to a free hydrogen atom, the N–N bond undergoes reductive cleavage on treatment with sodium, which results in the formation of the sodium salt of a secondary amine:



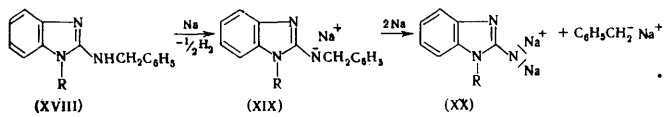
In hydrazines with a free N–H group in the α-position relative to the aromatic ring, the N–H α-bond is the first to ionise on treatment with sodium with formation of the resonance-stabilised N-anion (XVI), which is resistant to further reduction:

(XVI)

There are contradictory views in the literature concerning the possibility of the cleavage of the N–N bonds in the dianion of hydrazobenzene (XVII), formed when hydrazobenzene or azobenzene are treated with metal amides and alkali metals respectively:

(XVII)

Data [123] supporting such cleavage, which leads to disodium anilide, were not subsequently confirmed [124]. According to the observations of the authors of the review, the N–N bond in the dianions of heterocyclic hydrazocompounds is not cleaved either, for example in 1,1′-dialkyl-2,2′-hydrazobenzimidazoles.

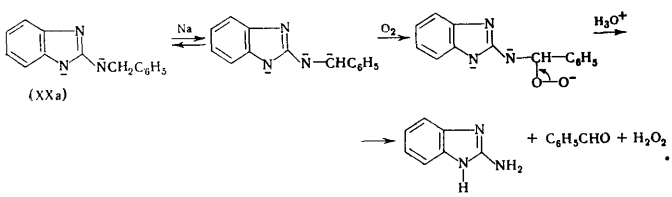


c. Cleavage of the N–C Bond in Benzylamines

The removal of the N-benzyl protecting group by solutions of alkali metals in liquid ammonia is a well known synthetic procedure. It is usually employed in the N-heteroaromatic series for compounds with a pyrrole nitrogen atom. The process takes place as a two-electron reduction of the C–N bond and leads to the formation of the N-anion of the secondary amine and the benzyl anion†, which subsequently undergoes ammonolysis and gives rise to toluene:

† The theory of reductive debenzylation with the aid of liquid ammonia solutions of alkali metals is described by Birch [125].

N-Benzyl derivatives of primary aromatic (for example benzylaniline [10]) and heteroaromatic amines enter into an analogous reaction. It has been shown for 2-benzylaminobenzimidazoles (XVIII) [90,120] that the action of sodium in liquid ammonia on such compounds begins with rapid ionisation of the N–H bond, which is followed by slow debenzylation of the N-anion (XIX). Ultimately, the amine dianion (XX) and the benzyl anion are formed and gradually undergo ammonolysis:



(XVIII) (XIX) (XX)

Reductive debenzylation proceeds more readily the greater the effective positive charge on the nitrogen atom to which the benzyl group is linked. Therefore the benzyl group joined to the pyrrole nitrogen atom is eliminated on treatment with sodium in liquid ammonia more readily than the benzyl substituent linked to an exocyclic amino-group [126,127].

If the benzyl group is joined to a negatively charged nitrogen atom, two outcomes are possible from the standpoint of the mechanism of the debenzylation process.

1. The negative charge on the nitrogen atom is effectively delocalised owing to conjugation with the aromatic π-electron system. In this case [a typical example is provided by the monoanion (XIX)] debenzylation still proceeds as a two-electron reductive process, albeit extremely slowly, and the reaction is accompanied by the formation of toluene.

2. The negative charge is located preferentially on the nitrogen atom. This case obtains when sodium acts upon 2-benzylaminobenzimidazole (XVIII, R = H) and on 1-benzyl-2-benzylaminobenzimidazole (XVIII, R = $C_6H_5CH_2$). [126] The dianion (XXa) is then formed initially. The addition of two-electrons to the C–N bond in this dianion should be extremely unfavourable on energy grounds. Indeed debenzylation should take place with difficulty and involve the formation of a considerable amount of benzaldehyde. Although the mechanism of this reaction is not in fact completely clear, it evidently includes an autoxidation stage and can be tentatively described by the following scheme:

(XXa)

Thus in principle one should distinguish two mechanisms of the debenzylation of benzylamines with the aid of solutions of metals in liquid ammonia—reductive and oxidative. The oxidative debenzylation mechanism requires further study.

Apart from the benzyl group, N-methoxymethyl [128] and other arylalkyl groups (ring-substituted benzyl groups, the diphenylmethyl group, the α-phenylethyl group [90], etc.) can undergo reductive elimination with formation of N-anions. When attempt was made to cleave the N–allyl bond by sodium in liquid ammonia, a difficulty was encountered owing to the reduction of the double bond of the allyl substituent, after which the N–C bond was no longer cleaved [129].

III. THE NATURE OF THE NITROGEN–METAL BOND AND THE STRUCTURE AND PHYSICAL PROPERTIES OF METAL SALTS OF AMINES

There have been few studies specially undertaken to investigate the nature of the nitrogen–metal bond in metal salts of amines. Two parameters of this bond, its polarity and the type of hybridisation of the N atom, can exert a major influence on the physical properties and reactivity of such salts. The use of Pauling's formula [130] $i = 100\,(1 - e^{-0.25(\chi_a - \chi_b)^2})$ to calculate the percentage ionic character of certain N–M bonds yields the results presented in Table 4 (here $\chi_N - \chi_M$ represents the difference between the relative electronegativites of nitrogen and metal atoms between which the bond is formed).

It follows from Table 4 that the bonds between nitrogen and alkali metals must be regarded as largely ionic, the amount of ionic character increasing in the sequence Li < Na < K. This agrees with the experimental measurements of the conductance of lithium [131] and caesium [132] cyclohexylamides in cyclohexylamine.

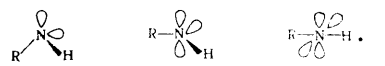
Table 4. Percentage of ionic character of certain nitrogen–metal bonds.

Bond	$\chi_N - \chi_M$	Amount of ionic character, %	Bond	$\chi_N - \chi_M$	Amount of ionic character, %
N—K	2.2	70	N—Mg	1.8	55
N—Na	2.1	67	N—Ag	1.2	30
N—Li	2.0	63	N—Hg^{II}	1.1	26

In magnesylamines, the N–Mg bond is equally covalent and ionic. The bond between nitrogen and metals such as copper, silver, and mercury is mainly covalent. Naturally, the degree of polarity of the N–M bond is also influenced by the type of hybridisation of the nitrogen atom and the nature of the hydrocarbon groups to which the nitrogen and metal atoms are linked (provided that the valence of the metal is greater than unity). These additional factors are not taken into account in the calculation of the percentage ionic character of the N–M bond.

Qualitative data on the amount of ionic character of the N–M bond agree fully with the properties of metal salts of amines. Thus silver and mercury salts of amines are as a rule resistant to the action of water and alcohol. They dissolve in certain organic solvents and can be actually recrystallised from them [68]. Although magnesylamines are usually readily decomposed by water, they are frequently soluble in ethereal solvents. In this respect they resemble the lithium salts of amines.

The sodium and potassium salts of alkylamines are highly hygroscopic and pyrophoric[34], like alkali metal amides. They are liable to explode in air and react vigorously with water and alcohols. Therefore they must be handled and stored in a completely inert atmosphere. Similar precautions must be observed in work with sodium, potassium, and lithium salts of arylamines and heterocyclic amines. However some of the latter (for example, the sodium salt of 2-aminopyrimidine [70,81]) are completely stable in air and are non-hygroscopic.



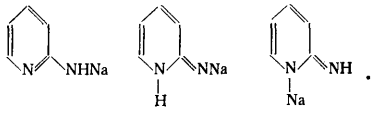
Many salts of amino-compounds with alkali metals are readily soluble in liquid ammonia, where they are apparently appreciably dissociated. This hypothesis is based on ultraviolet spectroscopic data for liquid ammonia solutions of potassamide [33], from which it follows that, depending on the concentration of the solution, the degree of dissociation of potassamide is 30–75%. DMSO [9,12,13] and HMPA [62] also exhibit a high solvent power in relation to metal salts of amines.

In solvents with a low dielectric constant, amides are dissociated into free ions only to an insignificant extent ($K_d \simeq 10^{-10}$–10^{-12} M) and are present largely in the form of ion pairs. The relevant data have been obtained by Streitwieser et al. for solutions of lithium and caesium cyclohexylamides in cyclohexylamine [131]. There is an important difference between the two salts. While caesium cyclohexylamide exists in cyclohexylamines in the form of monomeric ion pairs regardless of concentration [132], lithium cyclohexylamide also forms dimers, trimers, and other aggregates in equilibrium with the monomeric form [134,135].

The majority of metal salts of amino-compounds are extremely high-melting crystalline substances. It is somewhat surprising that the sodium salts of aniline and a number of other aromatic amines, obtained in liquid ammonia and then isolated in a pure form (judging from the results of elemental analysis), proved to be liquids [38].

There are apparently no literature data concerning the crystal structures of metal salts of amines. However, there are data on the structures of the crystal lattices of lithium [136] and sodium [137] amides. It is interesting that there are no hydrogen bonds in sodamide crystals. This is consistent also with the infrared spectrum of a crystalline specimen of sodamide, which contains sharp peaks at 3264 and 3218 cm^{-1}, associated respectively with antisymmetric and symmetric stretching vibrations of the N–H bonds, while bands which might be assigned to associated N–H groups are absent [59]. The infrared spectra of the potassium salt of methylamine [34] and the sodium salts of 5-aminoacridine and 2-amino-1-methylperimidine [59] are distinguished by similar characteristics, which indicates the absence of hydrogen bonds from their crystal lattices too. On the other hand, the spectra of the sodium salts of 2-aminopyridine and 1-alkyl-2-aminobenzimidazoles contain a number of diffuse bands in the region of N–H stretching vibrations, which is evidence of an appreciable association of the salts in the crystalline state.

Theoretically the nitrogen atom in the *N*-anions may be in the sp^3-, sp^2-, or *sp*-hybridised state:



sp^3-hybridisation sp^2-hybridisation *sp*-hybridisation

Infrared spectroscopic data indicate a change in the state of hybridisation of the nitrogen atom in the *N*-anions compared with the parent amines. Thus the N–H stretching vibration band in the spectrum of potassium methylamide occurs at higher frequencies than in the spectrum of dimethylamine [34,138]. A similar phenomenon was observed for sodium salts of 5-aminoacridine and 1-alkyl-2-aminobenzimidazoles [59]. This probably indicates an increase of the *s*-character of the nitrogen hybrid orbitals and consequently of the force constant of the N–H bond on conversion of the amine into the corresponding metal salt. However, there are also exceptions to this rule [59].

In the infrared spectra of crystalline specimens of metal salts of methylamine and heterocyclic amines, almost all the bands characteristic of the initial amine are

retained with only a slight displacement. This must correspond to tight binding of the counterions in the crystal lattices of the salts, so that the negative charge remains largely localised on the nitrogen atom.

The similarity of the infrared spectra of the sodium salts of heterocyclic amines to those of the amines themselves led to the conclusion that in the crystalline state they exist in the amino-form (XXI) and not in the imino-forms (XXIa) or (XXIb):

(XXI) (XXIa) (XXIb)

Infrared spectra have been used successfully to elucidate the structures of arylmercury derivatives of nitro-, nitroso-, and azoaryl-amines [66,68].

Certain information concerning the characteristics of the structure of *N*-anions can be obtained also from ultraviolet spectroscopic data. Measurements have been made [9,12,13] of the ultraviolet spectra of a large series of sodium salts of anilines containing electron-accepting substituents and it was concluded, in particular, that the sodium salt of *p*-nitroaniline exists mainly in form (Xb). The ultraviolet spectrum of lithium cyclohexylamide has also been measured [36]. This salt (in cyclohexylamine) absorbs appreciably at 375 nm, which is at the boundary with the visible region.

The aromatic proton signals in the ^{1}H NMR spectra of the *N*-anions of aromatic amines, measured in liquid ammonia, are appreciably displaced towards higher fields compared with the unionised molecules, on average by 1 p.p.m. [22,23] The shift for different protons decreases in the sequence *para* > *ortho* > *meta*, which suggests an appreciable mesomeric interaction between the negatively charged nitrogen atom and the aromatic π-electron sextet.

There are also data for the electronegativities of the *N*-anions of aromatic amines in liquid ammonia solution [124,139].

II REACTIONS OF METAL SALTS OF AMINES

1. N-ANIONS AS STRONG BASES

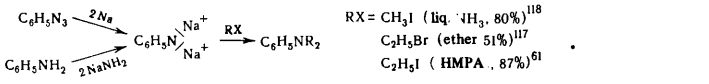
Shatenshtein was the first to employ the KNH_2-NH_3 system to determine the kinetic acidity of C–H acids, including weak acids such as alkanes [140,141]. These studies stimulated the search for other *N*-anionic systems which might be used as suitable bases for the ionisation of weakly acid X–H bonds. The lithium (or caesium) cyclohexylamide–cyclohexylamine system, proposed and investigated in detail by Streitwieser [36,142] (see Ref. 143 for a review of Streitwieser's studies), has been recognised as one of the most successful. It was found that the ionising capacity of the cyclohexylamide anion depends on the type of metal cation [142]. For example, caesium cyclohexylamide in cyclohexylamine completely converts diphenylmethane and triphenylmethane into the carbanions, while the reaction with lithium cyclohexylamide does not go to completion and the following equilibrium is established:

$$\rangle C-H + C_6H_{11}NH^-Li^+ \rightleftarrows \rangle C^-Li^+ + C_6H_{11}NH_2 .$$

The higher reactivity (by a factor of 3300) of caesium cyclohexylamide in the ionisation of weak C–H acids can be accounted for in the first place by the monomeric nature of this salt in solution and in the second phase by the higher ionic radius of Cs^+ compared with Li^+. As a result, the Cs^+ ion is more remote from the $C_6H_{11}NH^-$ counterion, which enhances the reactivity of the latter.

Lithium di-isopropylamide (a Hünig salt) has found a wide-scale application as a deprotonating agent. Its advantages are due to the steric blocking of the *N*-anionic centre, which reduces to a minimum the probability of nucleophilic side reactions [144].

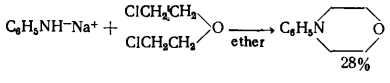
The 1,2,4-trihalogenobenzene → 1,2,5-trihalogenobenzene isomerisation in liquid ammonia, which involves a stage in which a C–H bond of the aromatic ring is deprotonated, proceeds most effectively in the presence of potassium anilide [63].



2. DEUTERIATION OF THE AMINO-GROUP VIA N-ANIONS

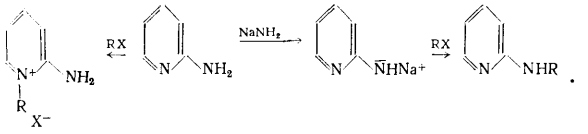
The amino-group is usually deuteriated by repeated refluxing of the amine in heavy water or in deuterio-alcohol [145]. For weakly acidic amines, deuterium exchange under these conditions is very slow. According to the results of the authors of this review, obtained for a series of *N*-heteroaromatic amines, and other data [101] for acid amides, a convenient method for the deuteriation of the NH_2 group consists in the decomposition of the metal salts of amines with heavy water (for a modification of this method, see Bassindale et al. [146]):

$$RN\bar{H}M^+ + D_2O \rightarrow RNHD + MOD,$$
$$RN^{2-}M_2^+ + 2D_2O \rightarrow RND_2 + 2\,MOD.$$



3. ALKYLATION

Many cases of alkylation of aromatic amines via *N*-anions have been described. For example, the aniline *N*-anions obtained from phenyl azide or aniline (by treatment with two moles of $NaNH_2$) give high yields of the corresponding *NN*-dialkylanilines with an admixture of the monoalkyl derivatives on alkylation with alkyl halides:



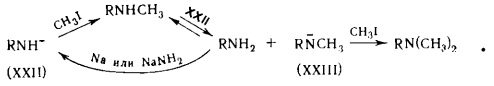
The preferential formation of the tertiary amine has been regarded as evidence for the involvement in the reaction of the disodium and not the monosodium salt of aniline.

Monosodium anilide is ethylated in ether at −40°C to monoethylaniline [38]. An unusual example of the employment of monosodium anilide is the following synthesis of *N*-phenylmorpholine [147]:

However, the alkylation of amines with a fairly active lone electron pair (these include aniline itself, aromatic amines with electron-donating substituents, and alkyl- and cycloalkyl-amines) can be carried out also without the preliminary ionisation of the N–H bond [148]. The alkylation of the amino-group via metal salts is important for amines with a reduced basicity, such as *p*-nitroaniline or 1-amino-1-phenylazonaphthalene.

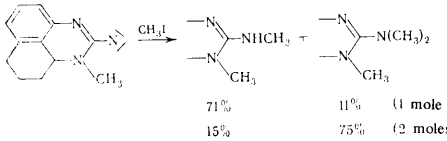
Similarly the alkylation of the *N*-anions of tautomeric heterocyclic amines of the 2-aminopyridine type, is hardly the only practical method for the direct introduction of substituents into the NH_2 group. On the other hand, it is known that, when alkyl halides act directly on *N*-heteroaromatic amines, the reaction involves the endocyclic *N* atom:

When the NH_2 group is alkylated, it is important to be able to control the degree of reaction with formation of mono- or di-alkyl derivatives. The type of solvent employed is significant in this respect. In the alkylation of monosodium salts of aromatic or heteroaromatic amines in aprotic solvents of low polarity (aromatic hydrocarbons, ethers, dioxan), the reaction as a rule proceeds smoothly up to the formation of the corresponding monoalkyl derivative. In particular, derivatives of 2-aminopyridines with the following substituents in the NH_2 groups were obtained in this way: methyl [76], ethyl [140], propyl [150], isopropyl [149,151], butyl [150], isopentyl [149,152], cetyl [151], benzyl [153], diphenylmethyl [154], allyl [77,151], and dialkylaminoalkyl [78,155]. The interaction of the sodium salt of 2-aminopyridine with $\alpha\omega$-dihalogenoalkanes leads to $\alpha\omega$-dipyridylaminoalkanes [156]. Examples of such monoalkylation of the amino-group have been described for the 2-amino-derivatives of pyrimidine [78,81,147], quinoxaline [157], thiazole [80,158], lepidine [78,159], 1-alkylbenzimidazoles [71], and adenosine [160].



In order to rule out completely the possible formation of the dialkyl derivatives, in some cases the NH_2 group is first protected by formylation [161] or benzylation [59].

An attempt to obtain the dialkylamino-derivative by treating the monosodium salt of the amine with an excess of alkyl halide in a non-polar solvent usually leads to a complex mixture of substances containing not less than 50% of the tertiary amine [75]. Excellent results in the synthesis of dialkylamino-derivatives are obtained when liquid ammonia [71,82,83] or HMPA [82] are used as solvents.



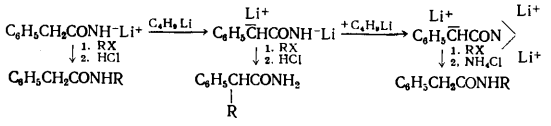
A remarkable characteristic of the reactions of the monoanions of aromatic and heteroaromatic amines with C_1-C_3 alkyl halides in liquid ammonia is that, regardless of the amine : alkyl halide ratio, the process does not stop at the monoalkylation stage [71,82]. Even in the presence of a deficiency of the alkyl halide, the corresponding dialkylamino-derivative is formed almost exclusively. The reaction is very fast with a high yield of the tertiary amine and undoubtedly constitutes the most convenient method of dialkylation of the amino-group. Similar results were obtained for the reaction of the *N*-anions of 4-aminoquinolines with halides of the allyl and benzyl type in HMPA [82].

The reaction of branched and more bulky (C_4 and above) alkyl halides with *N*-anions proceeds slowly snd gives mainly a low yield of the monoalkylation product [162]. It has been shown for aminoquinolines that γ-diethylaminopropyl chloride reacts with monoanions to form the monoalkyl-substituted derivative in nearly quantitative yield [87].

The preferential formation of the dialkylamino-substituted derivative on alkylation of monoanions with reactive alkyl halides in liquid ammonia and HMPA can probably be accounted for, as for the phenylacetonitrile carbanion [163], by the stepwise nature of the reaction. Of the two types of monoanions, (XXII) and (XXIII), present in solution, (XXIII) is probably alkylated at a rate which greatly exceeds that of (XXII). Therefore, despite the low equilibrium concentration of (XXIII), the dialkylamino-derivative and not the monoalkyl-amino-derivative accumulates continuously in the reaction mixture:

In contrast to the monoanions, the alkylation of the dianions in liquid ammonia is susceptible to definite control and, depending on the amount of the initial alkyl halide, the reaction can be directed towards the preferential formation of the mono- or di-alkyl derivative [71]:

This behaviour of the dianions is quite reasonable, since their reactivity should be higher than that of the monoanion of a secondary amine. As a result, the secondary amine, the alkylation of which becomes significant only after the disappearance of the dianion or a sharp decrease of their concentration, accumulates in the reaction mixture. The existence in solution of a particular anionic species has been frequently inferred in the literature from the results of alkylation experiments.

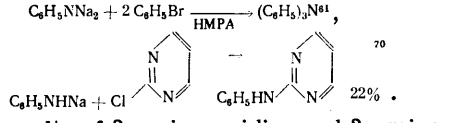


It follows from the foregoing data that the formation of the dialkyl derivative when an excess of alkyl halide acts on the *N*-anions of aniline and other amines in liquid ammonia [118] (and also in HMPA) cannot be regarded as unambiguous proof of the presence of dianions in solution. The same results might be obtained by the alkylation of the corresponding monoanions in the same solvents. It is more correct to employ as a basis the results of the alkylation of the *N*-anions by one equivalent of methyl iodide [71]. In this case the preferential formation of the dimethylamino-derivative should be regarded as evidence of the formation of the monoanion in solution and the formation of a secondary amine should indicate the presence of the dianion. The use of this test for the *N*-anions of 2- and 5-aminobenzimidazoles obtained from the corresponding azides [71] showed that the dianions, formed initially in liquid ammonia, are appreciably ammonolysed to the monoanions. Bearing in mind the low acidity of aniline, it is unlikely that its dianion, obtained from phenyl azide, is stable in liquid ammonia and does not undergo ammonolysis.

Incidentally, this test is not universal. It has been found that the monoanions of acidic amines capable of forming dianions simply on treatment with sodium, are not susceptible to stepwise alkylation in liquid ammonia and, on treatment with one mole of methyl iodide, form preferentially the monoalkylation product [71]. However, the identification of the *N*-anions of such amines presents no difficulties even without alkylation, since the very fact of their conversion into dianions on treatment with sodium is evidence of the stability of both their monoanions and dianions in liquid ammonia.

An interesting feature of the alkylation of the *N*-anions of heteroaromatic and aromatic amines consists in the fact that, despite their formal ambident nature [see, for example, structures (XXI) and (XXIb)], the reaction involves exclusively the amino-nitrogen, i.e. takes place

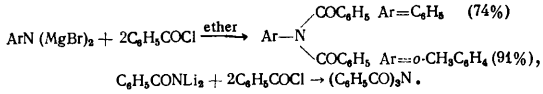
without transfer of the reaction centre. This indicates an appreciable localisation of the negative charge on the exocyclic N-atom not only in the isolated but also in the reacting molecule.



If the molecule contains several anionic centres, the centre formed last, i.e. the one to which corresponds the less acidic X—H bond, is the first to be alkylated [99,101]:

Less nucleophilic and hence less reactive N-anions correspond to acid amides as well as N—H acids stronger than amines. The alkylation and benzylation of the sodium salts of carboxylic acid amides in liquid ammonia [164], HMPA, [61] or non-polar aprotic solvents [165,166] takes place slowly and leads to the formation of N-monosubstituted derivatives in low yields. The sodium salt of urea does not react in liquid ammonia with butyl and dodecyl bromides, but monobenzylurea is formed by the reaction with benzyl chloride [106].

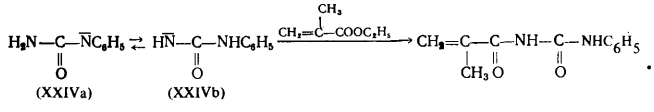
4. ARYLATION



The arylation of the amino-group and the introduction of heterocyclic substituents into it via the N-anions usually take place slowly and require heating of the reactants for many hours in a high-boiling solvent or even without a solvent. The yields of reaction products are as a rule low. Characteristic examples are provided by the following reactions:

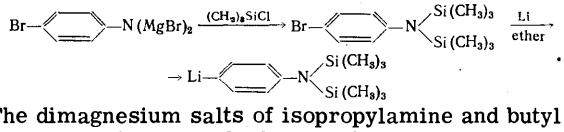
The sodium salts of 2-aminopyridine and 2-aminopyrimidine interact with 2-chlorothiazole to form 2-(α-thiazolylamino)-derivatives in yields of 40 and 9.5% respectively [70]. The reaction of the sodium salt of 2-aminopyrimidine takes place only in the absence of solvent, which can be accounted for by its lower nucleophilicity compared with the N-anion of 2-aminopyrimidine.

5. ACYLATION



The acylation of the amino-group via metal salts is usually achieved with the aid of carboxylic acid chlorides or esters. The use of the latter leads to monoacyl derivatives regardless of whether the mono- or di-anion is introduced into the reaction. When acid chlorides act upon monometal salts, monoacylation products are also formed, but with dimetal salts high yields of NN-diacyl derivatives can also be obtained. Examples of reactions of this kind are known for both a series of amines [55,167–169] and a series of acid amides [101]:

It is noteworthy that mainly the diacylation of the NH_2 groups via N-anions is of preparative importance, since almost all amines can be readily monoacylated as such with the aid of acid anhydrides or chlorides. On the other hand, the acylation of a second N—H bond in the monoacyl derivative formed is much more difficult without its conversion into the N-anion.

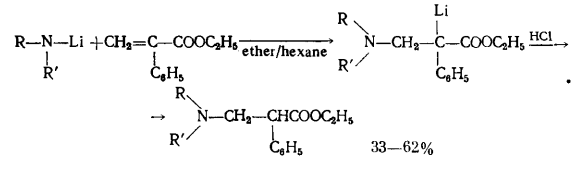


In only a few cases, when the acid chloride or anhydride is difficult to obtain or cannot be employed for one reason or another, the use of esters for the monoacylation of the amino-group also assumes synthetic importance. A characteristic example is provided by the acylation of aromatic amines via magnesylamines with the aid of ethyl β-hydroxy-$\beta\beta$-diphenylpropionate [168]. As might have been expected, dimagnesylamines are more reactive in this process [55].

The monosodium salts of urea and N-phenylurea are acylated in liquid ammonia or acetone with the aid of acid chlorides or esters [106], including ethyl methacrylate [169], to give the corresponding monoacyl derivatives. It is interesting that the reaction with N-phenylurea involves the primary amino-group, although the N-anion (XXIVa) and not (XXIVb) should be more stable in this case. Probably the anion (XXIVb), although present at a low concentration, reacts with the acylating agent much faster than does (XXIVa):

6. REACTION OF N-ANIONS WITH CHLOROTRIMETHYLSILANE

Magnesium [56,57] and lithium salts [146] of aromatic amines react under mild conditions with chlorotrimethylsilane, giving a high yield of the corresponding trimethylsilyl derivatives. The reaction has been used to protect the amino-group in organometallic syntheses [57,170]:



The dimagnesium salts of isopropylamine and butylamines do not form N-alkylhexamethyldisilazanes on treatment with chlorotrimethylsilane. However, the lithium salts of alkylamines, for example of t-butylamine [36] and N-phenylethylenediamine [171], react readily under these conditions.

7. NUCLEOPHILIC ADDITION OF N-ANIONS TO MULTIPLE BONDS

Compared with amines, N-anions are much more nucleophilic and add more readily to polarised multiple bonds. This factor is very widely used in organic synthesis.

a. Addition to Carbon—Carbon Multiple Bonds

Reactions of this type have been little investigated. It has been found that lithium salts of secondary amines add to the C=C bond of ethyl α-phenylacrylate according to the following mechanism [172]:

The mode of this reaction is the opposite of that of primary amine *N*-anions with ethyl methacrylate in which there is addition to the C=O bond followed by acylation of the amino-group.

Sodium anilide adds to the triple bond of dehydrobenzene, yielding *N*- and *C*-arylation products: diphenylamine, 2-aminobiphenyl, and 4-aminobiphenyl[173]. The formation of biphenyl derivatives in this reaction clearly demonstrates the ambident nature of the aniline *N*-anion.

b. Addition to the C=O bond

One of the examples of such reactions may be the carboxylation of the diphenylmethylamine *N*-anion by carbon dioxide leading to the formation of diphenylmethylcarbamic acid, as already mentioned above. The acylation of the amino-group via the *N*-anion by carboxylic acid esters also includes a stage involving addition to the C=O bond and constitutes another example of this kind.

It has been shown recently that the *N*-anions of primary amines add to the triple bond of carbon monoxide[174]. The lithium salt of t-butylamine gives rise to orange t-butylcarbamoyl-lithium (XXV):

$$(CH_3)_3CNH^-Li^+ + \bar{C}\equiv\overset{+}{O} \rightarrow (CH_3)_3CNH-\underset{\underset{O}{\|}}{C}-Li$$

(XXV)

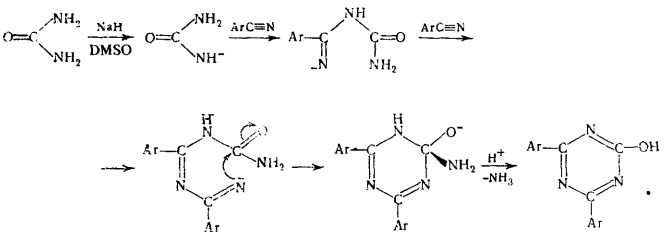
Many condensation reactions involve as an intermediate stage the formation of an *N*-anion, which behaves as an active species and adds directly to the carbonyl group. Such reactions include, in particular, the hydroxymethylation of carboxylic acid amides by formaldehyde in an alkaline medium[175].

Although the Schiff reaction is known to be usually catalysed by acids, cases of base catalysis have also been noted for amines with an inactive electron pair at the nitrogen atom. For example, 2-aminobenzimidazoles react with aldehydes of the furan series in the presence of alkali much more readily than in its absence[176]. Bearing in mind the enhanced acidity of the N–H bonds in such amines, there can be hardly any doubt that the species involved in such reactions is not the amine itself but the *N*-anion in equilibrium with it:

$$RNH_2 + OH^- \rightleftharpoons RNH^- + H_2O \xrightarrow{R'CHO} R-N(H)-CH(O^-)-R' \longrightarrow R-N=CH-R' + OH^-$$

It has been suggested that *N*-anions participate also in the complex Marschalk reaction in which the sodium salts of the leuco-derivatives of aminoanthraquinones are acted upon by aldehydes[177] with formation of *C*-alkylated aminoanthraquinones.

c. Addition to the C≡N Group



The addition of metal salts of amines to the C≡N bonds of nitriles constitutes the basis of one of the simplest methods for the synthesis of substituted amidines:

$$RNH^-M^+ + R'C\equiv N \rightarrow R'-C(=NM)-NHR \xrightarrow{HCl} R'-C(=NH)-NHR$$

Although this reaction has been known for a long time[2,178,179], it was not investigated in detail and for a large number of examples until 1970.[180] It was shown that the most suitable solvent for the process is liquid ammonia. The reaction then proceeds much faster and with a higher yield of amidine than in non-polar aprotic solvents. Good results are apparently obtained also in DMSO.[181]

However, only aromatic and heteroaromatic amines and nitriles enter into this reaction. The reaction with alkylamines (n-$C_4H_9NH_2$) takes place with a low yield or not at all (iso-$C_3H_7NH_2$). Somewhat better results were obtained for benzylamine and diphenylmethylamine. When these are acted upon by potassamide in liquid ammonia with subsequent introduction of benzonitrile, the yields of the substituted amidine are 29 and 73% respectively[180]. All these results apparently reflect the relative acidity of the N–H bonds in amines and the ease of formation by them of *N*-anions in liquid ammonia.

The interaction of the *N*-anion of urea and aromatic nitriles in DMSO is unusual. The product of the two-stage process is a 2-hydroxy-4,6-diphenyl-*s*-triazine[181]:

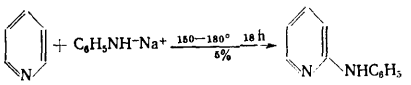
d. Addition to the N=O Bond

Aromatic amines, in particular aniline, are readily condensed with nitrobenzene and its derivatives in the presence of strong bases (for example t-BuOK in DMSO), yielding the corresponding azo-compounds[182–184]. The role of the base consists in the conversion of the amine into the *N*-anion, which is more reactive in relation to the nitroso-group:

$$ArNH_2 + B^- \rightleftharpoons ArNH^- + BH \xrightarrow{Ar'N=O} Ar-N(H)-N(O^-)-Ar' \longrightarrow Ar-N=N-Ar' + OH^-$$

This reaction is very important in the series of *N*-heteroaromatic amines which are otherwise difficult to convert into azo-compounds, since the amino-group is diazotised with difficulty and the corresponding diazonium salts are extremely unstable. Such amines include, for example, α- and γ-amino-derivatives of pyridine[72,73,79,185], quinoline[72], and benzimidazole[186].

A similar type of reaction constitutes the basis of the method proposed by Bamberger and Rust for the diazotisation of aromatic amines[187]. In this procedure, the aromatic amine is treated with pentyl nitrite in the presence of an alkali metal alkoxide, which results in the formation of the corresponding diazotate:

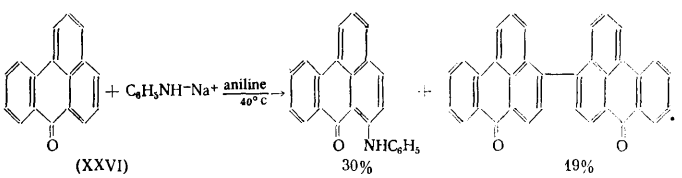


$$ArNH_2 + C_2H_5O^- \rightleftharpoons C_2H_5OH + ArNH^- \xrightarrow{C_5H_{11}ONO} Ar-N(H)-N(O^-)-OC_5H_{11} \longrightarrow$$

$$\longrightarrow Ar-N=N-O^-Na^+ + C_5H_{11}OH$$

Chichibabin showed for 2-aminopyridine that the sodium salt of the amine beforehand can also be introduced into the Bamberger reaction[188].

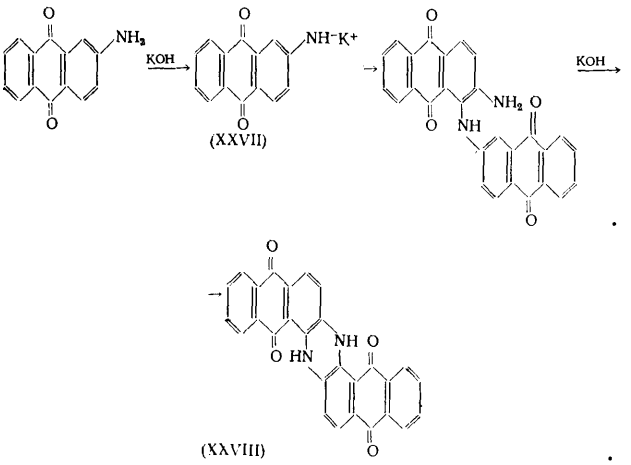
8. ALKYL- AND ARYL-AMINATION OF ORGANIC COMPOUNDS WITH THE AID OF N-ANIONS (REACTIONS WITH ELIMINATION OF THE HYDRIDE ION)



By analogy with the amination of nitrogenous heterocycles with sodamide (Chichibabin reaction)[189], it is very tempting to employ for the same purpose organic derivatives of sodamide. Chichibabin[190] already found that sodium anilide reacts with pyridine under severe conditions to form an insignificant amount of 2-phenylaminopyridine:

The formation of 2,2′-dipyridylamine as a side product in the reaction of pyridine with sodamide was also accounted for by the reaction of pyridine with the sodium salt of 2-aminopyridine formed as a result of amination[190,191].

However, on the whole the salts of aromatic amines are not sufficiently nucleophilic in relation to *N*-heterocyclic compounds and the yields of amination products are extremely low. Even more frequently, the reaction does not proceed at all, for example with quinoline[192] and isoquinoline[193] or when pyridine is acted upon by sodium *N*-methylanilide[194].

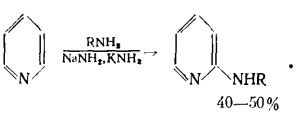


Phenylamination with the aid of sodium anilide takes place somewhat more readily in the series of certain polynuclear systems: mesobenzanthrone (XXVI),[195,196] 1,8,9-naphthanthr-10-one,[197] 1,9-pyrazolanthrone[60], and 1,8-naphthalimide[198]. Bradley, who made a detailed study of these reactions[196-199], showed that in all cases two competing processes take place—direct phenylamination and dimerisation of the initial compound:

(XXVI) 30% 19%

Bradley assumed that the dimerisation reaction is due to the ionisation of the C–H bond in the molecule of the initial compound under the influence of $C_6H_5NH^-Na^+$ with subsequent addition of the carbanion formed to another molecule of the initial compound[196]. However, bearing in mind that dimers are formed also when the above polynuclear compounds are acted upon by metal alkoxides in alcohol or by alkalis, which can hardly cause the ionisation of aromatic C–H bonds under the reaction conditions, a reductive dimerisation mechanism is more likely: electron transfer from the base to the aromatic substrate, cross-linking of the two radical-anions formed, and subsequent oxidation of the dihydro-derivative of the dimer to the aromatised dimer. The amination and dimerisation processes compete with one another also in the Chichibabin reaction (the reaction of sodamide with *N*-heteroaromatic compounds). It was shown recently that dimerisation in the Chichibabin reaction proceeds most probably via a stage involving the formation of a carbanion[90].

When β-aminoanthraquinone is heated with potassium hydroxide in pyridine or in the absence of solvent, the resulting *N*-anion (XXVII) can enter into a nucleophilic interaction with a molecule of the initial compound[199]. Ultimately this reaction leads to the formation of the dye indanthrone (XXVIII):[200]



(XXVII) (XXVIII)

The *N*-anion (XXVII) also adds to nitrobenzene[199]. The more readily formed but less nucleophilic *N*-anions of 2-amino-1-chloro- and 2-amino-1-nitro-anthraquinones do not react with nitrobenzene[199].

One may suppose that the reactivity of metal salts of alkylamines as nucleophilic agents should be greater. However, there are very few data concerning this problem. Thus, when quinoline is acted upon by sodium methylamide in ether, it forms 2-methylaminoquinoline (yield not stated)[201,202]. Alkali metal dialkylamides do not react at all (even when the conditions are altered) with nitrogenous bases or cause charring[193,201,203].

Bergstrom et al. succeeded in alkylaminating pyridine and quinoline in the 2-position by treating them with a eutectic mixture of sodamide and potassamide in the presence of primary aliphatic or alicyclic amines and potassium nitrate[204]:

40–50%

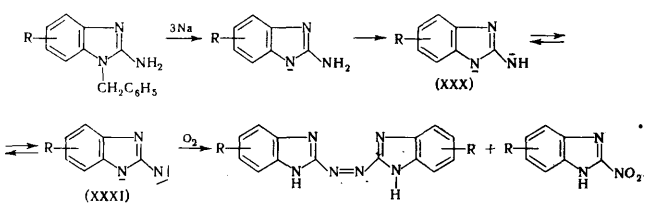
Kovacs and Vajda modified this method, having replaced the eutectic mixture of the two amides by metallic sodium[205-208]. Both groups of investigators failed to obtain evidence for the involvement in this reaction of the alkylamine *N*-anion as a nucleophilic agent (on the basis of the absence of visible signs of interaction between the amine and the base) and therefore the problem of its mechanism remains open. However, it is difficult to imagine a mechanism for this reaction other than one involving the alkylamide anion. It is likely that the formation of even a small equilibrium amount of the metal salt of the amine (it is quite possible under the reaction conditions) followed by its interaction with heterocyclic compounds gradually displaces the amine ⇌ *N*-anion equilibrium to the right.

The majority of alkyl- and aryl-amination reactions involving *N*-anions are not accompanied by the evolution of hydrogen, in contrast to the Chichibabin reaction. To eliminate the hydride ion from the intermediate σ-complex, oxidising agents must be employed: potassium nitrate, air, or pure oxygen.

9. OXIDATION REACTIONS OF N-ANIONS

In general *N*-anions are oxidised much more readily than the neutral amines. Most data have been obtained for the autoxidation reaction. The reactivity of metal salts of amines in relation to molecular oxygen may be extremely varied: ranging from nitroarylamine and 2-amino-pyrimidine salts, which are completely stable in air, to metal salts of alkylamines which react vigorously with oxygen. Thus less reactive amines give rise to more readily oxidised *N*-anions and conversely.

Sodium anilide and metal salts of arylamines with electron-donating substituents rapidly blacken in air and are converted into a mixture of high-molecular-weight autoxidation products. A controlled and mild autoxidation of the *N*-anions of aromatic amines to azo-compounds has been achieved in the NaH–THF,[52] t-C_4H_9OK–toluene[209], and t-C_4H_9OK–DMSO[183,184,210] systems. Two views have been expressed concerning the mechanism of this reaction. According to the first, on being acted upon by oxygen, the *N*-anion is converted into a radical (**XXIX**), which dimerises to the corresponding hydrazobenzene. The latter is then transformed (also via the *N*-anion) into azobenzene[209]:

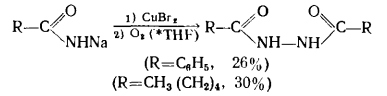


$$ArNH_2 + t\text{-}C_4H_9OK \rightleftarrows ArNH^-K^+ + t\text{-}C_4H_9OH,$$
$$2\,ArNH^-K^+ + O_2 \rightarrow 2\,ArNH + O_2^-,$$
(XXIX)
$$2\,\mathbf{XXIX} \rightarrow ArNH{-}NHAr \rightarrow Ar\overset{K^+}{N}{-}\overset{K^+}{N}Ar \xrightarrow{O_2} Ar{-}N{=}N{-}Ar + K_2O_2.$$

This mechanism probably obtains in many cases (see, for example, Filipskikh et al.[120]), but, as shown recently[182,210], the reaction involving aniline itself and its substituted derivatives proceeds via a different pathway involving the condensation of an intermediate nitroso-compound with the amine *N*-anion.

The *N*-anions of α- and β-aminoanilines form dibenzo[*a*,*h*]phenazine on oxidation with oxygen[209].

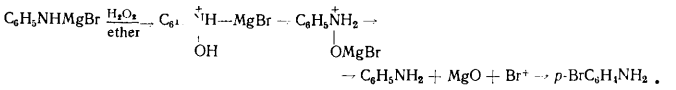
The monoanions of 2-amino-derivatives of pyridine, benzimidazole, thiazole, and other nitrogenous heterocycles react very slowly with oxygen. Usually the corresponding azo-compound is formed in low yields under these conditions[91]. An exception is the monoanion of the less acid 2-amino-4,5-diphenylimidazole, which readily oxidises in air to 2,2′-azoimidazole[91].



The polyanions of 2-aminobenzimidazole and certain other 2-aminoimidazoles exhibit an unusually high reactivity in the autoxidation reaction for reasons which are not obvious[91]. It was found that the polyanions (**XXX**) and (**XXXI**), formed on debenzylation of 2-amino-1-benzylbenzimidazoles with sodium or potassium in liquid ammonia, react rapidly with atmospheric oxygen at temperatures as low as −70°C, being converted quantitatively into a mixture of 2,2′-azo- and (unexpectedly) 2-nitrobenzimidazoles[91,211,212]:

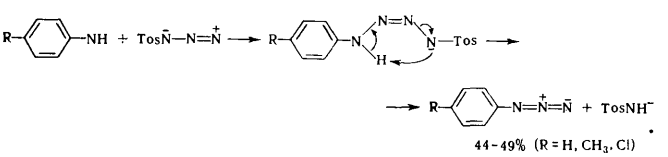
This reaction is the only known example of such ready autoxidation of the amino-group to the nitro-group.

The polyanions (**XXX**) and (**XXXI**) can also be obtained from 2-azido-,[119] 2-benzylamino-,[126] 2-amino-1-arylalkyl-,[90] and 2-amino-benzimidazoles.[91] The attempts to drive the autoxidation process towards the preferential formation of the more valuable 2-nitrobenzimidazole (analogue of the antibiotic azomycin) have so far remained unsuccessful: the maximum yield of the nitro-derivative achieved does not exceed 45%. The mechanism of the formation of 2-nitrobenzimidazole is still obscure; however, it has been established that the reaction is influenced by a series of factors: the type of the imidazole system, the nature of the solvent, the metal, the substituent at $N_{(1)}$, the method of generation of the *N*-anion, and others. For example, the trilithium salt of 2-aminobenzimidazole is oxidised by oxygen in ether only as far as 2,2′-azobenzimidazole (yield 90%).



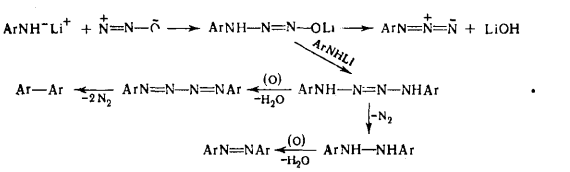
It has also proved possible to achieve the oxidative dimerisation of metal salts of acid amides and amidines. It was found that copper salts of N–H acids are oxidised by oxygen much more readily than the sodium or lithium salts[213]:

It is remarkable that copper(I) chloride catalyses (also, it is believed, via the formation of a copper salt) the autoxidation of aniline to azobenzene in pyridine solution[214,215].



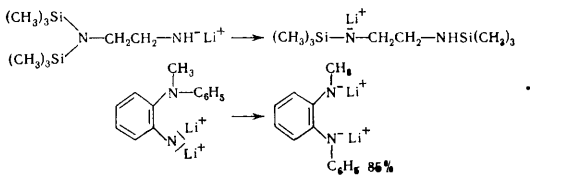
The oxidation of *N*-anions by other oxidising agents has been little studied. The anions of certain *N*-heteroaromatic amines (triazoles[216,217], benzothiazoles[218], and benzimidazoles[120,219]) are oxidised by $KMnO_4$, $K_2S_2O_8$, and NaOCl to the corresponding azo-compounds, the reaction being of preparative value in some cases.

When hydrogen peroxide in ether is allowed to react with the bromomagnesium salt of aniline, *p*-bromoaniline[220] (and not phenylhydroxylamine as reported earlier[221]) is formed. The mechanism proposed for this reaction involves the intermediate formation of positively charged bromine[220]:



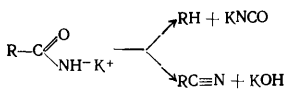
10. OTHER REACTIONS OF N-ANIONS

An unusual conversion of amine *N*-anions into azides with the aid of *p*-toluenesulphonyl azide (TSA), which plays the role of a diazo-transferring agent, was discovered by American workers[222]. The reaction is believed to proceed via a triazene intermediate and reduces in the initial stage to the addition of the *N*-anion to the azido-group of TSA in one of its resonance forms with the positive charge at the terminal nitrogen atom:

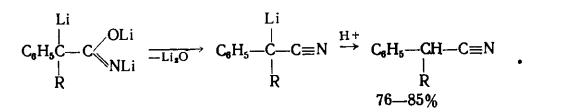


The *N*-anion of benzylamine has been converted into benzyl azide in a yield of 26%. The less nucleophilic *N*-anions of acid amides and *p*-nitroanilines could not be converted into azides in this way.

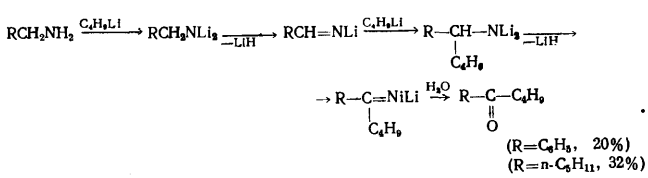
The interaction of the *N*-anions of amines with nitrous oxide[53,54] is closely related to the above reaction. However, in this case the yield of the azide does not exceed 10–35%. The corresponding biphenyl and azobenzene, which is the main reaction product, are also formed[54]. In general, the processes can be represented as follows:



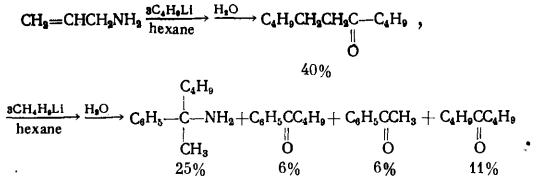
In a study of *N*-anionic rearrangements in the series of asymmetric hydrazines, West observed that to some extent they are characteristic also of the *N*-anions of aromatic and aliphatic diamines. The following two examples illustrate the 1,4-anionic rearrangements of this type[170,223]:



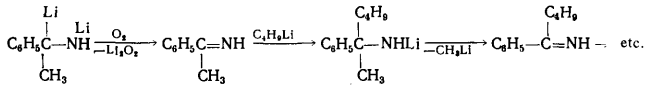
It is remarkable that in the case of *o*-aminobiphenylyl-*N*-methylamine, only the dianion undergoes a rearrangement[223].



Elimination reactions with conversion into nitrile and certain other compounds are characteristic of the *N*-anions of many acid amides. For example, the potassium salts of formamide and urea decompose extremely readily with formation of potassium cyanate and the evolution of hydrogen and ammonia respectively[224]. The *N*-anions of other amides of aliphatic[224] and aliphatic-aromatic[100] acids decompose on heating via two pathways—with formation of a hydrocarbon and a nitrile:



Hauser and coworkers used this property of the *N*-anions of acid amides for preparative purposes. They established that the trianions of aryl- and diaryl-acetamides are converted under mild conditions into the corresponding nitriles in high yields[98,99]:



Interesting reactions of the dilithium salts of primary alkyl- and arylalkylamines were discovered recently[225]. On refluxing in hexane in the presence of an excess of butyl-lithium and subsequent hydrolysis, the dilithium salts of alkylamines yield ketones with a butyl group. The authors suggested that the reaction proceeds according to the following elimination–addition mechanism

The reaction involving allylamine and α-phenylethylamine proceeds in a more complex manner:

Unfortunately the question of the possible ionisation of the C–H bond in the methine group of α-phenylethylamine was not investigated in the study quoted above. In the light of what has been said earlier concerning the metallation of CH–NH systems (p.39), this is a very likely possibility and the formation of all the products enumerated could be predicted theoretically also on the basis of the conversion of the *CN*-dianion:

---o0o---

Interesting studies on the gas-phase acidity of alkyl- and dialkyl-amines[226] and on the synthesis of substituted acid amides from esters and sodium salts of aryl- and cycloalkyl-amines[227] were published recently.

Dual Reactivity of Arylmethylmetal Compounds

D.V.Ioffe and M.I.Mostova

The review deals with the dual reactivity of ambident anions of arylmethylmetal compounds. Data on the mechanism of reactions of these compounds are described and the effect of various factors on the mode of reaction is discussed. The bibliography includes 93 references.

I. Introduction 56
II. Reaction mechanism 56
III. Factors influencing the mode of reaction 59

I. INTRODUCTION

The reaction of benzylmagnesium chloride with trioxymethylene leading to the formation of β-phenylethyl alcohol was described in 1903.[1] In the same year it was reported[2] that the product of this reaction is *o*-tolylmethanol and that benzylmagnesium chloride therefore exhibits dual reactivity in its reaction with trioxymethylene:

The first stage in the study of the dual reactivity (or the so called "anomalous" reaction of arylmethylmetal compounds) was the determination of the generality of the reaction. It was found that, together with organomagnesium compounds, arylmethyl derivatives of other Group I (potassium[3], sodium[4], and lithium[5]), Group II (zinc[6-8], cadmium[6], and mercury[9,10]), and Group III (aluminium[6] and boron[11-14]) metals react similarly. The dual reactivity was observed not only in relation to carbocyclic but also heterocyclic compounds, namely derivatives of furan[15], thiophen[16-18], and their benzo-analogues[19]. The range of electrophilic reagents entering into the aromatic ring proved to be extremely wide, including aldehydes, ketones, various acid derivatives (esters, nitriles, anhydrides, and acid halides), carbonic acid derivatives (carbon dioxide, ethyl chlorocarbonate, phosgene, dicyanogen, and dithiocyanogen), alkyl halides, sulphuric acid esters, deuterium chloride, heavy water, etc. It was found that, together with the more usual *ortho*-substitution, in many cases *para*-substitution takes place and in a few reactions this is in fact the dominant process.

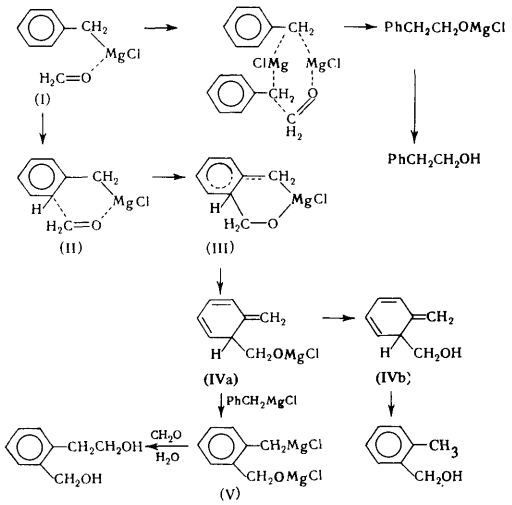
Some of the data obtained up to 1954 and dealing with reactions of organomagnesium compounds are summarised in Chapter XI of the monograph by Kharash and Reinmuth[20], who quote exhaustive factual data and put forward certain hypotheses concerning the reaction mechanism. Then, for a time, the reaction was hardly investigated. In the monograph by Ioffe and Nesmeyanov[21], only two isolated special studies[22,23] were added to those discussed in the previous review[20]. However, in recent years, interest in this reaction has been renewed, as can be seen from a considerable number of investigations dealing with the dual reactivity of arylmethyl compounds of both magnesium and other metals. The data which have now accumulated permit a general account of the dual reactivity of arylmethylmetal compounds and the determination of the general characteristics of the relevant reaction and of the effect of various factors on its course. The present review is an attempt at a general account of this kind.

II. REACTION MECHANISM

Tiffeneau and Delange, who were the first to describe the dual reactivity of benzylmagnesium chloride, already stated [referring to the corresponding reaction] that "this is a condensation of the same type as in the formation of primary aromatic alcohols by the reaction of formaldehyde with arylhydroxylamines or sodium phenoxide"[2]. In fact all investigators treat unamimously the "anomalous" reaction of arylmethylmetal compounds as a special case of electrophilic substitution in the aromatic ring activated as a result of the conjugation of the electrons of the carbon–metal σ-bond and the ring π-electrons†[24]. This conjugation accounts for the unusually high (compared with the effect of the methyl group) electron-donating effect of the CH_2M group, which is comparable to that of powerful electron-donating agents such as the amino- and hydroxy-groups (Table 1). The σ-π conjugation in the molecules of arylmethylmetal compounds explains their capacity to form *ortho*- and *para*-substitution products, but does not account for the finding that *ortho*-isomers predominate in the reaction products. Moreover the main product of the reactions of arylmethylmetal compounds is the *ortho*-isomer and the formation of the *para*-isomer may be regarded as exceptional. Selective *ortho*-substitution has been the starting point of the study of the reaction mechanism. Different related mechanisms, proposed to account for the dual reactivity of organomagnesium compounds[25-30], can be represented in a general form by Scheme 1 (c.f. Kharash and Reinmuth[20]) using as an example the interaction of benzylmagnesium chloride with formaldehyde.

Table 1. σ⁺ constants of the substituents[14,27].

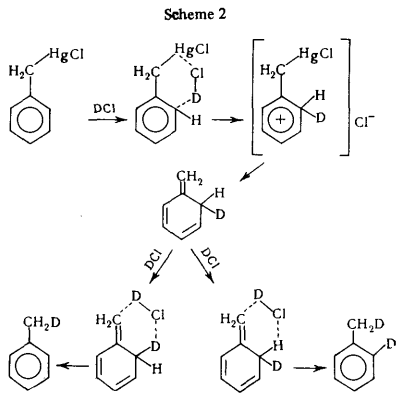
Substituent	σ+	Substituent	σ+
Me	—0.311	CH_2HgCH_2Ph	—1.14
OH	—0.92	NH_2	—1.3
$CH_2\bar{B}X_2OH$*	—1.11		



* X = acid residue

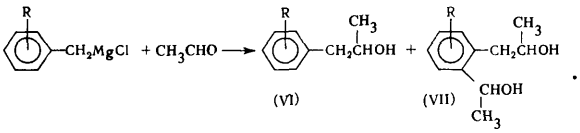
†The discussion which arose between Schmidlin[25], who attempted to justify the existence of two isomeric forms of benzylmagnesium compounds, and Chichibabin[26], who supported the idea of a dual reactivity of this compound, is of historical interest.

The first stage of the reaction is the formation of a Werner complex (I), which can react with a further molecule of benzylmagnesium chloride to form a quasi-six-membered ring, the decomposition of which leads to phenylethyl alcohol.



To account for the "anomalous" course of the reaction, one postulates the formation of an oriented π-complex (II), which is subsequently transformed into a σ-complex (III) and then into an *o*-metallated derivative of methylenecyclohexadiene (IVa). Hydrolysis of the latter results in the formation of methylenecyclohexadiene (IVb) the aromatisation of which leads to the final *ortho*-substitution product. Methylcyclohexadiene (IVa) can be metallated by an excess of the organomagnesium compound to form a new organomagnesium compound (V), which again reacts with formaldehyde.

Scheme 1

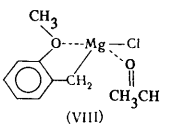


A similar scheme was proposed[31] to account for the dual reactivity of benzylmercury chloride (see Scheme 2).

Scheme 2

One must suppose that similar mechanisms can be put forward to account for the dual reactivity of the arylmethyl derivatives of other metals too. Scheme 2 is close to the mechanisms of electrophilic aromatic substitution reactions, for example the Kolbe reaction or the reaction involving the *ortho*-hydroxymethylation of phenols.

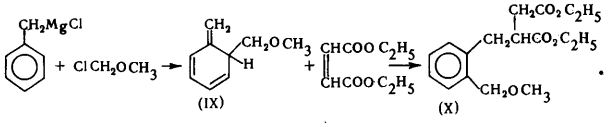
The individual stages of the proposed mechanism have been examined in various investigations and their occurrence with formation of intermediates has been demonstrated. Thus the formation of the oriented π-complex (II) as an essential stage in the formation of *ortho*-substituted products has been elegantly confirmed by Bernardon and Bourdais[32], who investigated the reaction of acetaldehyde with substituted benzylmagnesium chlorides:



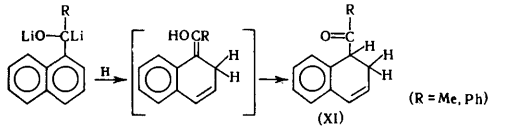
The reaction resulted in the formation of both the normal addition product, the secondary alcohol (VI), and of the "anomalous" diol (VII). The ratio of the yields of these products depends on the nature and position of the substituent in the phenol ring (Table 2).

Table 2. Effect of the substituent on the yield of products of the reaction of benzylmagnesium chloride and acetaldehyde.

Compound	R	Yield, %	Compound	R	Yield %
VI	H	10	VII	H	50
	o-OMe	70		*o*-OMe	0
	p-OMe	12		*p*-OMe	45
	o-Me	0		*o*-Me	85

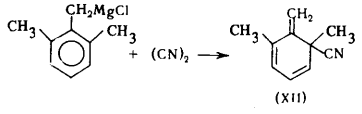


In the reaction involving *o*-methoxybenzylmagnesium chloride, the ring *ortho*-substitution product is not formed. Comparison with the reactions of *p*-methoxy- and *o*-methylbenzylmagnesium chlorides does not explain this phenomenon on the basis of the electronic or steric effects of the *o*-methoxy-group. The authors believe that the complex (I) formed in the reaction with *o*-methoxybenzylmagnesium chloride has structure (VIII), which rules out the formation of a π-complex and an *ortho*-substitution product.

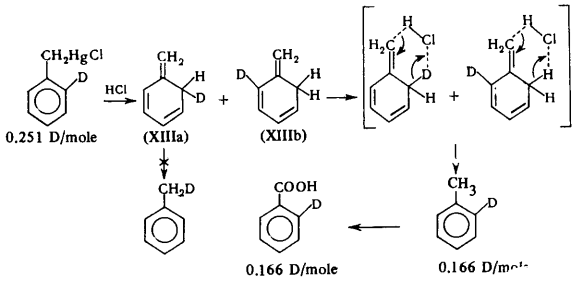


On the other hand, the steric effect of the *ortho*-methyl group favours the formation of a π-complex, the absence of the alcohol (VI) from the products being related to this factor. It is interesting to note that at an even earlier stage the absence of dual reactivity in ferrocenylmethyllithium was attributed to the impossibility of the formation of a cyclic transition state[33].

The formation of methylenecyclohexadiene in the course of reactions of arylmethylmetal compounds has been frequently postulated. The formation of considerable and sometimes predominant amounts of diaddition products is always explained by its presence. Bearing in mind the stability of methylenecyclohexadiene itself[34], its formation in the course of the reaction appeared extremely probable. Convincing proof of this was obtained[35-37]. In order to detect the methylenecyclohexadiene derivatives formed in the course of the reaction of benzylmagnesium chloride,

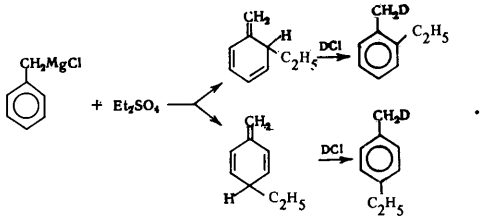


active substances, capable of reacting with these intermediates, were added to the reaction mixture. Thus the reaction mixture, obtained by allowing benzylmagnesium chloride to react with α-chloromethyl ether, was treated with diethyl maleate or maleic anhydride. The detection of diethyl α-(*o*-methoxymethylbenzyl) succinate (X) proved the existence of compound (IX):

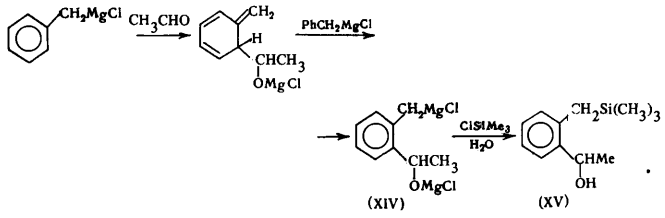


In a few cases, when the compounds with the methylenecyclohexadiene structure are stablised by additional factors, their formation may be demonstrated by spectroscopic methods. Thus, when α-hydroxyarylmethylmetal compounds of the naphthalene series were protonated, the formation of the diene system (XI) was demonstrated[38]:

Finally, compound (XII), formed in the reaction between 2, 6-dimethylbenzylmagnesium chloride and dicyanogen, was isolated[39]:



The data presented confirmed the hypothesis of the formation of methylenecyclohexadiene compounds in the course of the reaction. The problem of the aromatisation of the intermediates is somewhat more complex. At first sight it may appear that the simplest aromatisation pathway involves intramolecular proton migration. However, Kharash already pointed out that the aromatisation takes place intermolecularly, this being confirmed by a study of the reaction of *ortho*-tritiated benzylmagnesium chloride with formaldehyde[20]. The intermolecular mechanism of the aromatisation was proved[31]. in the reaction involving the protonation of and elimination of mercury from *ortho*-deuteriated benzylmercury chloride:



The lower deuterium content in toluene compared with the initial benzylmercury chloride is evidence of intermolecular aromatisation of compounds (XIIIa) and (XIIIb). The identical deuterium contents in toluene and in the benzoic acid obtained as a result of its oxidation suggest that the entire deuterium is located in the benzene ring, which could not occur in the intramolecular migration of the proton in compounds (XIIIa) and (XIIIb).

The intermolecular mechanism of the aromatisation of the methylenecyclohexadiene intermediates is also confirmed by the formation of deuteriated ethyltoluenes when the reaction mass obtained in the alkylation of benzylmagnesium chloride with diethyl sulphate is decomposed by deuterium chloride[37]:

It is also possible to postulate another pathway to the aromatisation of methylenecyclohexadiene compounds in this reaction: their interaction with an excess of the organometallic compound, the formation of a secondary organometallic derivative, and its reaction with deuterium chloride. However, not even traces of alkylation products of the secondary organomagnesium compounds could be detected in this case. The formation of the secondary organometallic product was demonstrated in another instance — in the interaction of benzylmagnesium chloride with acetaldehyde, which results in the formation of appreciable amounts of a diaddition product. The addition of the alkylating agent $ClSi(CH_3)_3$ to the reaction mixture yielded the alcohol (XV) — the alkylation product of the secondary organomagnesium compound (XIV):

Since the aromatisation of methylenecyclohexadiene compounds takes place via an intermolecular mechanism, it follows that the process (and hence the yield of the corresponding reaction products substituted in the aromatic ring) should depend on the nature of the neutralising agent. Experiments confirmed this conclusion[36]. Neutralisation of the reaction mass in the reaction of benzylmagnesium chloride with α-chloro-methyl ether by a strong acid (HCl) leads to higher yields of the "anomalous" products than neutralisation by a weaker acid (ammonium chloride). In the latter case there is apparently insufficient time for the dihydro-products to be aromatised and to undergo any changes (e.g. dimerisation[39]) in the course of subsequent isolation. On the other hand, the yield of the normal reaction product remains almost constant regardless of the agent employed.

The above mechanism covers also cases of *ortho*-substitution. There are no literature data on the basis of which a mechanism for *para*-substitution might be devised. One can suppose that, whereas *ortho*-substitution takes place via the interaction of one molecule of the nucleophilic agent with one molecule of an electrophilic agent, the *para*-substitution reaction requires the involvement of a larger number of molecules. One may point to the closely analogous instances where products of the 1, 2-, 1, 4-, and 1, 6-addition of a Grignard reagent to conjugated systems are formed[40, 41]. Whereas 1,2- and 1, 4-addition can be accounted for by a mechanism involv

the coordination of the metal to the carbonyl and the formation of a quasi-six-membered ring, the involvement of several molecules of the Grignard reagent is postulated to account for the 1,6-addition.

III. FACTORS INFLUENCING THE MODE OF REACTION

1. Electronic Structure of Arylmethylmetal Compounds

Examination of the mechanism of the reactions of arylmethylmetal compounds permits an approach to the consideration of the problem of factors affecting the mode of reaction. Although in the majority of studies on the chemistry of arylmethylmetal compounds, the influence of conditions on their reactivity has been demonstrated, there is no unanimous view in the literature on the causes responsible for changes in the mode of reaction. The number of studies specially undertaken on this question is small and the great sensitivity of the reaction to slight (at first sight) changes in conditions frequently makes it difficult to compare the results of different investigators. Comparable data have been taken as a rule from one investigation or from several investigations carried out under identical conditions.

We believe that it is valid to consider the reactions of arylmethylmetal compounds as process involving ambident anions. An ambident anion is one with two reaction centres combined into a single conjugated system. The factors responsible for the dual reactivity of ambident anions have been investigated and described in a series of reviews[42-44]. However, most studies dealt with the behaviour of ambident anions the reaction centres of which are of different chemical types. Usually one of these is a carbon atom and the other a heteroatom, or both centres are different heteroatoms. The negative charge is distributed between the two centres in such a way that most of it concentrated at the more electronegative atom; the second atom is as a rule more polarisable.

The benzyl anion and in general arylmethyl anions constitute a special case of ambident‡ anions of the allylic type. Its characteristic feature relative to other ambident anions (particularly relative to the phenoxide ion which has an isoelectronic structure) is that both nucleophilic centres are carbon atoms, although in different states of hybridisation. As in heteroambident anions, the negative charge is distributed between both centres. According to modern hypotheses, by virtue of the low amount of *s*-character of the hybridised orbital, the unsaturated sp^2-hybridised carbon atom is more electronegative than the saturated atom[45]. Therefore, to a close approximation, one may assume that the negative charge is largely concentrated on the carbon atoms of the aromatic ring. However, the formal sp^3-state of the methylene carbon atom in the benzyl anion does not of course correspond to its true state. The delocalisation of electrons in the carbon-metal bond should lead to partial rehybridisation of the α-carbon atom. In the limiting case, this atom should also be sp^2-hybridised and all the bonds should be equalised. The actual state of the α-carbon atom is intermediate and depends on the structure of the compound, the nature of the metal and the solvent, and other factors.

The question of the state of the methylene carbon atom in certain organolithium compounds of the arylmethyl series was investigated recently with the aid of ^{13}C NMR spectroscopy[46-48]. The ^{13}C chemical shift is an effective measure of the hybridisation and charge density. The average chemical shift of the sp^2-hybridised ^{13}C atom is 60 – 70 p.p.m. and that of the sp^3-hybridised ^{13}C atom is 160 – 170 p.p.m. For a given constant hybridisation of the carbon atom, the ^{13}C shift δ is proportional to the electronic density at the carbon atom, as can be seen from a comparison of the chemical shifts in methane and methyllithium or cyclopentadiene and cyclopentadienyl-lithium (Table 3)[46,49]. An increase of electron density in such cases leads to a shift of the signal towards a lower field. In contrast, on passing from arylmethyl hydrocarbons to their lithium derivatives, δ decreases, which can only be due to a change in the hybridisation of the α-carbon atom from sp^3 to sp^2. The data in Table 3 show that the hybridisation of the methylene carbon atom in the monophenylmethyl compound is closer to sp^3 than for the di- and tri-phenylmethyl compounds.

Table 3. Effect of the charge on the ^{13}C chemical shift.

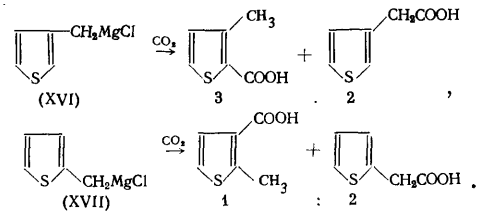
The charges at different positions in the benzene ring arising as a result of the delocalisation of electrons of the C - M bond were found from the ^1H NMR spectra of the organometallic compound (Table 4). For certain compounds, the charges were also calculated by the LCAO-MO and SCF methods[50], the result of the calculation by the SCF method agreeing satisfactorily with the experimental data. The charges on the central carbon atom were not determined experimentally. Their calculation, based on the assumption that the charge of the anion is -1, is

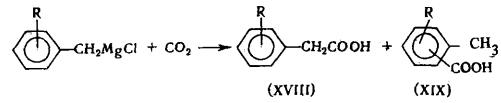
‡ In fact the benzyl anion is not an ambident but a polydent species; however, for the sake of simplicity we shall regard it as an ambident anion with two nucleophilic centres — the methylene carbon atom and an aromatic carbon atom without distinguishing the *ortho-* and *para*-positions.

inaccurate because the total negative charge is not located on the organic part of the molecules owing to the interaction between the cation and the anion.



Although all the data quoted for the distribution of electron density in arylmethylmetal compounds refer to alkali metal derivatives, one may suppose that the situation is similar for other metal derivatives. Thus the spectrum of dibenzylmercury indicates the presence of fractional charges in the *ortho*- and *para*-positions in the benzene ring[55].

Thus the charge distribution in the molecules of arylmethylmetal compounds accounts for the attack of electrophilic agents both on the methylene carbon atom and on the aromatic part of the molecule. The mechanism of substitution in the aromatic ring discussed above in fact constitutes a special case of electrophilic substitution. It is evident that any factors promoting electrophilic substitution will increase the yield of ring-substituted products and will correspondingly diminished the yield of α-substituted products.



Experimental data show that an increase of electron density at any carbon atom of the aromatic ring facilitates the reaction at this centre of the ambident anion. Sherman and Anstutz[15] were already able to compare successfully various aryl residues in the reaction of arylmethylmagnesium chlorides with carbon dioxide. The yield of ring-substituted products increases in the series benzylmagnesium chloride < 2-thienylmethylmagnesium chloride < 2-furfurylmagnesium chloride. When electronegative groups are introduced into the aromatic ring, the conjugation between the C–M bond electrons and ring π electrons should increase with a corresponding increase of electron density at the carbon atoms of the aromatic ring, which facilitates the introduction of the electrophilic agent.

On passing from monocyclic compounds to their benzoderivatives, the yield of ring-substituted products increases. This was observed for the first time for heterocyclic compounds[19] and was then demonstrated in a comparison of benzyl and naphtylmethyl derivatives[23, 56]. Reactions of organometallic derivatives of 2-methylnaphthalene lead to 3-substituted and not 1-substituted derivatives, which may be related to a lower energy of charge localisation when the electrophilic agent attacks the 1-position[56, 57].

It is interesting to compare the two organometallic compounds (XVI) and (XVII). Owing to the $+I$-effect of the sulphur atom, substitution in the ring of the β-isomer (XVI) takes place to a greater extent than in the ring of the α-isomer (XVII)[58]:

It is evident that substituents in the benzene ring should have similar effect also on the dual reactivity of arylmethylmetal compounds. Since electron density in the *ortho*- and *para*-positions relative to the methylene group is important for the ring-substitution reaction, electron-donating groups in the *meta*-position should have the greatest effect. This has been confirmed by a study[59] of the carboxylation of various substituted benzylmagnesium chlorides:

A study of the effect of ring substituents on the kinetics of simultaneous deuteriation and demercuration of benzylmercury chloride provided convincing evidence for the effect of electron-donating *meta*-substituents[61, 62]. The products of this reaction contain considerable amounts of deuterium in the ring, which suggests a dual reactivity.

Table 5. Effect of the substituent in the benzene ring on the dual reactivity of benzylmagnesium chloride.

Compound	R	Yield, %	Compound	R	Yield, %
XVIII	H	100	XIX	H	0
	o-Me	100		*o*-Me	1
	p-Me	90		*p*-Me	10
	m-Me	30		*m*-Me	64*

* 2,4-dimethylbenzoic acid[60]

The proposed reaction mechanism involves attack by DCl on the ring *ortho*-position in the rate-limiting stage of the process (see Scheme 2). Data on the kinetics of the reaction of benzylmercury chloride and its methyl derivatives with deuterium chloride showed that the introduction of methyl groups in the *ortho*- and *para*-positions accelerates the reaction only slightly while a *meta*-methyl group has a significant influence on the rate. The effect of two *metal*-methyl groups is shown particularly clearly (Table 6).

Table 6. Relative rate constants for the simultaneous deuteriation and demercuration of substituted benzylmercury chlorides.

Ring substituent	K_{rel}	Ring substituent	K_{rel}	Ring substituent	K_{rel}
H	1	*p*-Me	2.11	2.6-Me_2	0.36
o-Me	2.44	*m*-Me	24.40	3.5-Me_2	$2.5 \cdot 10^3$

It is noteworthy that the results of such studies fail to reflect sufficiently clearly the effect of ring substituents on the dual reactivity of arylmethylmetal compounds, which is most probably due to incomplete isolation of all the reaction products[63–65].

2. The Nature of the Metal and Solvent

As already stated above, the mode of the reactions of arylmethylmetal compounds is influenced decisively by the hybridisation of the α-carbon atom. Delocalisation of the C – M bond electrons and hence rehybridisation of the

α-methylene carbon atom should depend on the nature of the metal. In the series of organometallic derivatives of magnesium, mercury, lithium, potassium, and caesium, an increase of the polarity of the C–M bond leads to a more intense conjugation of its σ electrons and the π-electron system of the ring. This change has been clearly demonstrated in a study[66] where the absorption spectra of various arylmethylmetal compounds were obtained (Table 7).

Table 7. Dependence of the absorption maximum of the benzyl compounds $C_6H_5CH_2X$ on the nature of the metal.

Substituent	λ_{max}	Substituent	λ_{max}	Substituent	λ_{max}
H	207	MgCl	266	Na	355
HgCl	245	Li	330	Cs	356

The shift of the absorption maximum of the principal band of the benzene chromophore when the substituent is altered arises from the change in the hybridisation of the α-carbon atom. When X = H, the methylene atom is in the state of sp^3-hybridisation — there is then minimal overlapping of the hybrid orbital with the π-electron system of the ring. The observed bathochromic shift of the absorption maximum in the spectra of organometallic compounds is associated with an increase of the overlapping of the valence electron orbital with the π-electron system of the aromatic ring. The increase is related to the change in the hybridisation of the α-carbon atom, the orbital of the valence electrons assuming an increasing p-character with increase of the amount of ionic character of the C – M bond. The maximum bathochromic shift in the case of ionic structures of sodium and caesium derivatives corresponds to the sp^2-hybridisation of the α-carbon atom. An analogous bathochromic shift with increasing electropositive properties of the metal has been observed in the absorption spectra of diphenylmethyl, triphenylmethyl, and fluorenyl anions[67, 68].

The change in the hybridisation of the methylene carbon atom as a function of the nature of the metal entails a change in its nucleophilicity and affects the reactivity of the organometallic compound as a whole. The closer the state of the α-carbon atom to sp^3-hybridisation the smaller the amount of ionic character of the C – M bond and the greater the degree of shielding of the α-carbon atom by the metal atom. This hinders the attack on the central carbon atom by the electrophilic agent and consequently leads to an increase of the relative reactivity of the aromatic carbon atoms. Conversely, when the α-carbon atom is sp^2-hybridised (maximum ionic character of the C – M bond), the central carbon atom is most accessible to interaction with the electrophilic agent. Despite the more marked conjugation of the C – M bond electrons with the aromatic ring π-electron system, in this case the aromatic carbon atoms are not as a rule attacked. Consequently dual reactivity should be shown to the greatest extent by derivatives of the most electronegative metals, for example Group III metals, and to the smallest extent by alkali metals.

Unfortunately a systematic comparison of the reactivities of arylmethyl derivatives of various metals has not been made under identical conditions, particularly due to the differences in the methods used to prepare the arylmethyl derivatives of different metals and their different solubilities. However, it is known that in the reactions of α-chloromethyl ether[36], dipropyl sulphate[37], and dicyanogen[57] carried out under comparable conditions with benzylmagnesium chloride and benzyl-lithium, dual reactivity is observed only for the magnesium derivative. The hypothesis of an appreciable dual reactivity of Group III metals has been confirmed by studies on tribenzylaluminium[69, 70] and tribenzylboron[11–13] published in recent years.

Together with these qualitative observations, individual quantitative data, listed in Table 8, have been published recently.

Table 8. Effect of the metal on the dual reactivity.

Nucleophilic agent	Electrophilic agent	Metal (electronegativity)	Ratio of yields of ring-substituted products and α-carbon addition products	References

	iso-PrBr	K Na Li	0.1 1.0 3.0	71, 72
$\left[\begin{matrix}PhC{-}O\\ \vert\\ C_6H_{11}\end{matrix}\right]^{2-}2M^+$	CO_2	Na Li	1.7 2.4	74
$PhCH_2M$	$MeCH_2CHO$	Li $Mg_{1/2}$(1.23) $Al_{1/3}$(1.4)	0 0.4 5.0	75

The effect of the solvent on the reactivity of organometallic compounds is related primarily to the solvation of the cation and the state of the ion pairs in solution. The use of a polar (and particularly dipolar) solvent, which solvates effectively the metal cation, leads to an increase of the ionisation of the C – M bond, i.e. to an increase of the carbanionic properties of the compound. In other words, the solvent can influence the state of hybridisation of the α-carbon atom in the arylmethylmetal compound. This is confirmed by data for the dependence of the ^{13}C chemical shift in the NMR spectrum of $C_6H_5{}^{13}CH_2Li$ on the solvent (Table 9). (As already stated, the chemical shift reflects directly the state of hybridisation of the carbon atom.)

The data in Table[9] show that, with decrease of solvent polarity, the sp^3 character of the methylene carbon atom in benzyl-lithium increases.

The change in the state of hybridisation of the α-carbon atom naturally has an effect on the conjugation of the valence electrons of the C – M bond with the π-electron system of the ring. This is reflected in the absorption spectra of the organometallic compounds. Thus the main maximum in the absorption spectrum of 1, 1-diphenylhexyllithium undergoes a hypsochromic shift as the polarity of the solvent diminishes[76] (Table 10).

It is evident that the change in the state of hybridisation of the α-methylene carbon atom due to the change in the solvent or in the metal will have the same influence on

the reactivity of the compound as a whole. In a non-solvating (or in a weakly solvating) solvent, the state of the α-carbon atom approaches sp^3-hybridisation to the maximum extent, which hinders the reaction at this centre of the ambident anion. On the other hand, the use of a solvating solvent should promote the reaction at the α-carbon atom. The data in Table 11 show that a change in solvent polarity has a consistent influence on the proportions of the reaction products. It is important to emphasise that this relation has been found to hold for various reactions — alkylation, addition to the carbonyl group, and deuteriation. It is also significant that results in satisfactory agreement have been obtained for the same reaction by different workers. Admittedly, an unambiguous effect of the solvent is not observed in all cases.

Table 9. Effect of the solvent* on the ^{13}C chemical shift in benzyl-lithium[47, 48].

Solvent	$\delta^{13}C$	Solvent	$\delta^{13}C$
THF	163	Toluene	172
Ether	168.5	Benzene	174.5

* The following abbreviations are used in this and subsequent tables: THF = tetrahydrofuran; DME = 1,2-dimethoxyethane; TMED = tetramethylethylenediamine; HMP = hexamethylphosphoramide; DMF = dimethylformamide.

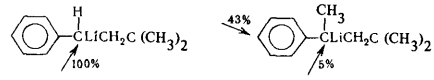

Table 10. Effect of the solvent on the absorption maximum of 1,1-diphenylhexyl-lithium.

Solvent	Dielectric constant	λ_{max}	Solvent	Dielectric constant	λ_{max}
THF	7.58	496	Propyl ether	3.88	422
DME	5.50	495	Benzene	2.28	426
Ethyl ether	4.33	438	Hexane	1.89	415

For example, the results obtained in the deuteriation of α-cumenylpotassium have not been explained, although replacement of ethyl ether by other solvents leads to the disappearance of dual reactivity regardless of solvent polarity. One must also point out the somewhat arbitrary nature of the table column labelled "solvent" — in many cases an excess of the given solvent was added to a solution of the organometallic compound in ethyl ether, so that the reaction actually took place in a mixture of the latter and the added solvent. This should not have an effect when a polar solvent, which effectively solvates the cation, is added, but becomes very significant following the addition of a solvent of low polarity. However, even with this stipulation, the principal feature, namely that a solvent solvating the cation facilitates the reaction with the α-carbon atom while a non-solvating solvent has the opposite effect, is evident.

3. Steric Factors

Only isolated data have been published on the effect of steric factors on the dual reactivity of arylmethylmetal compounds. Thus the difference between the reactions of chlorodimethylsilane with the organolithium compounds (XX) and (XXI) has been explained by steric factors[79].

(XX) (XXI)

Dual reactivity is shown by the organometallic compound (XXI), in which the carbon atom linked to the metal is tertiary. Similarly a change in reactivity is observed on passing from diphenylmethyl to triphenylmethyl derivatives of alkali metals. The reaction with ethyl benzoate[80], benzaldehyde, and benzophenone[81] results primarily in the formation of products of addition to the α-carbon atom, the secondary process yielding considerable amounts of products of *para*-substitution in the aromatic ring[82–84].

As already stated, derivatives of heavy alkali metals do not as a rule exhibit dual reactivity owing to their carbanionic properties. However, when cumenylpotassium is deuteriated[3], products resulting from attack on the ring are formed, which can probably be accounted for by steric

hindrance at the α-carbon atom. Steric factors have a particularly marked effect in those cases where both reactants (the nucleophilic and electrophilic agents) are sterically hindered. The interactions of alkali metal triphenylmethides with benzophenone[83] or chlorotriphenylsilane[4] can serve as examples:

The problem of the relation between the electronic and steric factors in reactions of dianions having the formula $Ar_2\bar{C}-\bar{X}$, where X = O or NC_6H_5, is somewhat more complicated. The presence of the second nucleophilic centre sharply increases the reactivity of the carbanion. Thus, in contrast to alkali metal diphenylmethides (XXII), which do not react with t-butyl chloride and acid nitriles in liquid ammonia[85,86], the dimetal derivatives of benzophenone (XXIII) interact with the above compounds under the same conditions[86,87]. The alkylation reaction proceeds not only with the α-carbon atom but also with ring carbon atoms. In the alkylation of these two compounds and also of compound (XXIV) with isopropyl bromide, the reaction proceeds in all cases, but compound (XXII) is alkylated only at the α-carbon atom, while (XXIII) and (XXIV) exhibit dual reactivity. The latter is probably due to the joint effect of both the electronic and steric factors:

$Ph_2CH^-M^+$ (XXII) $[Ph_2C-O]^{2-}\,2M^+$ (XXIII) $[Ph_2C-NPh]^{2-}\,2M^+$ (XXIV)

The study of the dual reactivity of the dianions $Ar_2\bar{C}-\bar{X}$ is complicated by two factors. Firstly, reactions involving the second anionic centre, for example *O*- or *N*-alkylation, are possible in addition to the dual mode of reaction of the ambident arylmethyl system. A reaction of the former type is observed in methylation but does not occur when more complex alkyls are employed[72,88]. Secondly, ring-substituted products can be formed not only as a result of electrophilic attack on the carbanion but also as a result of reactions by the intermediate radical-anion $Ar_2\dot{C}-X$. The formation of such radical-anions as a result of one-electron transfer in reactions of dianions has been postulated by a number of workers[72,89,90]. Radical-anions of the arylmethyl type are known to have a marked capacity for reactions involving ring carbon atoms (see, for example, Schenck and Matthias[91] and Holme and Crossland[92]).

4. Electronic Structure of the Electrophilic Agent

According to a familar rule, an increase of the positive charge on the electrophilic centre and also an increase of the polarity of the electrophilic agent should increase the tendency towards the reaction involving the atom of the ambident system which has the highest electron density. The numerous pieces of evidence supporting this hypothesis in relation to a series of ambident anions have been obtained as a rule in the alkylation reaction. In relation to arylmethyl anions, the reaction has been little studied, although there are isolated examples of a qualitative confirmation of the above rule in the case of alkylation[37]. The addition of the arylmethyl anion to the C = O bond (reactions with aldehydes, ketones, and acid derivatives) is more typical and better investigated. The electrophilic properties of carbon in these compounds increase in the series $CONR_2 < COOH < COOR < COR < COH < COCl$. The capacity of the reactants to form benzene ring-substituted products increases in the same sequence.

On the other hand, similar reactions have not been described for acids and amides, a few isolated observations have been made for esters, and aldehydes and acid chlorides are typical "anomalous" reactants. In a series of compounds of the same class, a change in the charge of the carbon atom due to the change in the properties of the aliphatic chain has a marked influence on the mode of reaction. Thus, whereas the reaction of benzylmagnesium chloride with acetonitrile results in the formation of the α-addition product only, the reaction with trifluoroacetonitrile yields up to 40% of the *ortho*-substituted products[7,8]. It has been shown[30,75] that in reactions of benzylmagnesium chloride with aldehydes, 100% substitution of the aromatic ring is observed only for formaldehyde, the yield of the ring-substituted product decreasing with increase in the length of the aliphatic chain. Branching at the α-atom, which reduces the charge of the carbonyl carbon atom§ has a particularly marked effect. On the other hand, when reactions of benzylmagnesium chloride with trifluoroacetaldehyde and acetaldehyde are compared, it is found that the ratio of the reaction product yields involving the ring and the α-carbon atom is greater by a factor of ten in the first reaction than in the second[35].

Table 12. Effect of reactant ratio on the yield of reaction products.

Nucleophilic agent	Electrophilic agent	Order of addition* and reactant ratio	Yield, %			References
			α-	*ortho*-	*para*-

* The forward order of addition is understood as the addition of the electrophilic agent to the nucleophilic agent.
** The overall yield of the *ortho*-substituted product and the product of the simultaneous substitution in the *ortho*-position and at the α-carbon atom

An unusual example is provided by the deuteriation of cumenylpotassium[3]. Deuteriation of the ring, which takes place mainly in the *para*-position, depends on the polarity of the deuteriating agent. Whereas interaction with heavy water leads to selective α-deuteriation ($K_\alpha/K_{ring} > 500$), the ratio is 65 and 4.5 respectively in the reactions of CH_3COOD and with DCl.

There are also quite definite literature data concerning the effect of the ratio of the electrophilic and nucleophilic agents on the dual reactivity. Scheme 1 shows that the presence of an excess of the organometallic compound should favour the formation of products of the reaction

§ In this case, one cannot rule out also the effect of steric factors, as pointed out by Sadaaki and Yuya [spelling of names uncertain (Ed. of Translation)][75].

involving the α-carbon atom, while an excess of the electrophilic agent should promote ring substitution. This has been confirmed by experimental data (Table 12). It is interesting to note that the yield of *para*-substituted products is almost independent of the ratio of the reactants.

A brief examination of the mechanism of the "anomalous" reactions of arylmethyl compounds and the factors influencing these reactions leads to the conclusion that we now know the main general characteristics of this process. Moreover, in certain cases it is possible to alter the mode of reaction in order to obtain the desired result. However, our knowledge of the reactions of arylmethylmetal compounds requires further expansion. The question of the *para*-substituted products is least clear — even simple accumulation of experimental data on this problem is of definite interest and can lead to a hypothesis concerning the mechanism of *para*-substitution. On the other hand, the determination of the mechanism will ultimately make it possible to treat the arylmethyl anion not as an ambident species, which was done in the present review as a necessary simplification, but as a polydent anion, and to find conditions for reactions by such systems which are selective with respect to α-carbon atoms and the *ortho*- and *para*-carbon atoms in the ring.

Radiation-chemical Processes in Radioactive Compounds

V.V.Gromov

Publications on the effect of the natural radiation of radioactive inorganic salts on their radiation-chemical stability are analysed. The main rules governing radiation-chemical processes in radioactive salts are examined. The effects of recoil atoms produced in radioactive disintegration, chemical impurities, and the intrinsic charge on the mechanism of the radiolysis of radioactive compounds are discussed. A detailed account is given of the effect of variation in the intensity of self-irradiation on the yield of decomposition products from certain radioactive salts (sulphates of Group II metals). A list of 55 references is included.

CONTENTS

I. Introduction 66
II. Primary radiation processes in radioactive materials 66
III. Self-radiolysis of radioactive materials 69

I. INTRODUCTION

Within a few years of the discovery of radioactivity by Becquerel and the early papers of Mme Curie [1] radioactive isotopes were employed as indicators for the qualitative and quantitative determination of several elements, in studying the structure of chemical compounds, and also for observing the progress of processes involving substances containing a radioactive tracer. All such experiments were based on the assumption that the physicochemical properties of isotopes of the same element are identical, and that the effect of radiation from the radioactive isotope on the test materials could be neglected [2]. The first condition is satisfied if the difference in mass between the isotopes is relatively small: in practice it can be regarded as satisfied for elements of atomic number above ten [3]. The second condition by no means applies in all cases: very often radiation-chemical processes in the test systems have a significant influence on the physicochemical properties of radioactive compounds [4,5]. This applies especially to solid radioactive materials, in which disturbances due to the radiation may accumulate and remain for a long time.

With the development of atomic industry and the wider use of radioactive isotopes in science and various branches of the economy, it becomes increasingly necessary to study the properties of highly radioactive materials, which are subject to continuous self-irradiation. In atomic technology and in the preparation of labelled compounds, for example, materials must be handled whose specific radioactivity reaches several curies and tens of curies per gram. For practical purposes, therefore, it is extremely important to assess the effect of self-irradiation on various properties of highly radioactive materials, to determine their radiation stability.

Frequently these problems cannot be solved merely by investigating the effect of corresponding external irradiation on the systems. Even with bombarding particles of the same nature and energy there are definite differences between self-irradiation and external irradiation: (*a*) self-irradiation is continuous in time (as long as the radioactive isotope is present); (*b*) the dosage rate is usually low in self-irradiation; (*c*) the action of self-irradiation is usually uniform throughout a solid of any dimensions even with particles of low energy (provided, of course, that the radioactive isotope is uniformly distributed throughout the sample); (*d*) chemical impurities, which may be in various valency forms, are produced in the system by radioactive disintegration; and (*e*) recoil nuclei play a significant role in radioactive materials.

The above features of radioactive compounds demonstrate the need for a careful investigation of radiation-chemical processes occurring in radioactive salts. Unfortunately, not so many publications have yet appeared on this topic, and there have been no reviews of work that has been published. The present survey makes an attempt to fill this gap.

The chemistry of hot atoms (and also the self-radiolysis of organic compounds), which often exhibit problems similar to those of the radiation chemistry of solid radioactive compounds, will not be considered here. This field of research is of intrinsic value, and involves mainly the study of phenomena in neutron-irradiated materials, the measurement of the distribution of isotopes between individual chemical forms, and the separation of isotopes by means of the Szilard–Chalmers effect. Full information on these aspects can be found in several publications [3,6-9].

II. PRIMARY RADIATION PROCESSES IN RADIOACTIVE MATERIALS

The nature and the accumulation of the primary radiolysis products of crystalline radioactive compounds has been studied most fully on the radioactive sulphates of barium, strontium, calcium, magnesium, and potassium [10-16]. Isolated experiments have also been made on several carbonates [17-21], cobalt formate [22], and other compounds.

Self-irradiation even by low-energy β-particles may lead to considerable radiation-chemical changes. In the β-disintegration of tritium ($\overline{E} \simeq 6$ keV), for example, the bonds in the chemical compound containing $^3H_1$ may be ruptured [23]. If conditions are produced in a radioactive material such that radiation disturbances are not annealed, defects may gradually accumulate to considerable concentrations [24,25]. Thus 5 min after the start of an experiment, Lambe detected by electron spin resonance the accumulation of paramagnetic centres in mixtures of tritium and krypton frozen at 4.2° and 77°K. [26,27]

The introduction of α-emitters into crystals of complex salts produces more fundamental radiation-chemical changes than does the addition of β-radioactive isotopes.

Radiation disturbances (recorded by electron spin resonance) have been observed in $La_2Mg_3(NO_3)_{12}.24H_2O$ at room temperature immediately after the addition of americium-241 (3 mc g^{-1}).[28] Yet the β-radiation of promethium, present in this compound in similar amounts to americium (~ 3 mc g^{-1}), has such a weak effect that an e.s.r. signal appeared only three weeks after preparation of the salt. The radiation defects observed in this salt were attributed to NO_3, NO_2^-, and NO_3^{2-} radicals, which appear also after exposure of the salt to γ-quanta. Boyd and Ward showed[29] that the intensity of radiolysis of lithium bromate resulting from the fission of lithium-6 after capture of a neutron exceeds fivefold the intensity from the action of cobalt-60 γ-rays under similar conditions, the dose absorbed being $(1-40) \times 10^{22}$ eV $mole^{-1}$. The same products are formed in the two cases: i.e. the mechanism of radiolysis does not vary significantly with the method of irradiation. However, the experimental results are greatly affected by increase in the linear energy transfer on exposure to neutrons and subsequent fission of lithium-6. These processes are accompanied by a considerable rise in temperature in the tracks, which accelerates the radiation-thermal decomposition of lithium bromate.

Careful investigations on radioactive (sulphur-35) sulphates of barium, calcium, strontium[10-12], magnesium, and potassium[14-16,31,32] show that radiation defects of the same nature arise in radioactive and in inactive salts. In this respect the actions of external irradiation and of self-irradiation are equivalent. The radical-ions SO_4^- and SO_3^- are the chief primary products ("defects") in the above salts. Prolonged storage of the radioactive materials involves gradual formation of the ions SO_3^{2-} and SO_2^- and probably of SO_2.[16,32] At low temperatures an appreciable quantity of other, less stable radiation defects, whose nature has not been established, is also formed. The main features of the mechanism of radiolysis which applies to non-radioactive sulphates are preserved:

$$c \rightsquigarrow SO_4^{2-} \rightarrow SO_4^- + 2e\,(SO_3^-,\ O^-,\ e) \quad (1)$$

$$SO_4^- + e \rightarrow \overset{\bullet}{SO}{}_4^{2-} \begin{cases} \nearrow SO_4^{2-} + h\nu \\ \searrow SO_3^- + O^-\,(O + e) \end{cases} \quad (2)$$

$$SO_3^- + e \rightarrow \overset{\bullet}{SO}{}_3^{2-} \begin{cases} \nearrow SO_3^{2-} + h\nu \\ \searrow SO_2^- + O^-\,(O + e) \end{cases} \quad (3)$$

$$SO_3^- + SO_3^- \rightarrow SO_3^{2-} + SO_2 \quad (4)$$

The main difference between externally irradiated and radioactive salts lies in the variation in the concentration ratio of paramagnetic centres. Thus $SrSO_4^*$ of initial specific radioactivity ~ 100 mc g^{-1} gave the ratio $[SO_4^-]/[SO_3^-] = 16.5$ after 4 years (absorbed dose 2×10^{22} eV g^{-1}). In externally irradiated strontium sulphate (dose 5×10^{22} eV g^{-1}) this ratio is 0.5. Hence the main product in radioactive materials is the radical-ion SO_4^-, with very little formation of SO_3^- radicals. Yet the concentration of the latter radicals is increased appreciably by irradiation with fast electrons and γ-rays (comparable temperature conditions and doses). The probable explanation is that the mean energy of sulphur-35 β-particles (~ 55 keV) is approximately one-tenth of that of the Compton electrons from cobalt-60 γ-radiation (410 keV) and far smaller than the energy of the fast electrons. In the former case (or with an external source of low emitted energy), therefore, ionisation effects predominate with the formation of SO_4^- radical-ions in the crystals of the radioactive sulphates, but the probability of cleaving sulphur–oxygen bonds to form SO_3^- radical-ions increases, on γ-irradiation (cobalt-60) and exposure to fast electrons. This interpretation of the results requires further experimental verification.

The temperature of irradiation also affects the relative proportions of SO_4^- and SO_3^- radical-ions: in the main the former predominate at low temperatures, and the latter at room temperature. Hence rise in temperature accelerates the dissociation of excited sulphate ions by reactions (2).[31,32] This is consistent also with experimental results on the thermal stability of radical-ions in sulphates[31-33]: the most stable is SO_3^-, which, for example, is annealed in strontium sulphate only at $\sim 500^\circ$C; the radical-ion SO_4^- begins to disappear even at room temperature. Probably the interconversion and recombination of paramagnetic centres during the prolonged storage of radioactive salts even at room temperature also determine in considerable measure differences in the proportions of the radicals compared with externally irradiated specimens.

Variation in the ratio of primary and secondary products of radiolysis may depend not only on the duration of self-irradiation but also on the appearance of impurities and the influence of ionisation processes accompanying radioactive disintegration on the course of subsequent radiation-chemical changes. Thus in the β-disintegration of radioactive lanthanum-143 some 60% of the cerium atoms formed are in the quadrivalent state, and the remainder in the tervalent[34]. External irradiation by accelerated electrons does not produce such effects.

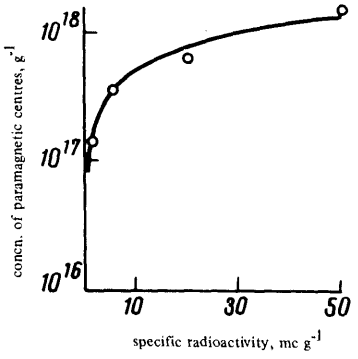

Figure 1. Dependence of concentration of paramagnetic particles on specific radioactivity of SrS^*O_4 at room temperature on keeping for 55 days.[11]

The radicals formed on exposure gradually accumulate to reach a limiting concentration[35-37]. This is a consequence either of kinetic effects directly in the irradiated zone or of afterprocesses in the thermodynamically non-equilibrium system. If the radicals are stable at room temperature (i.e. if they disappear slowly after exposure has ceased), it is easy to obtain curves representing the accumulation of paramagnetic centres. Fig. 1 shows the dependence of the total number of such centres on the specific radioactivity of strontium sulphate over the range 0.1–50 mc g^{-1}. In all cases the specimens were kept for 55 days, since the concentration of paramagnetic centres reaches its maximum value in this time. A similar variation is observed in all the radioactive sulphates investigated.

A characteristic feature of radioactive crystalline sulphates containing a "soft" β-emitter (sulphur-35) is that

the value of G_{pmc} in them is higher than in irradiated non-radioactive salts (Table), and the maximum concentration C^* of paramagnetic centres usually exceeds the corresponding values for externally irradiated materials (Fig. 2).

Parameters of the radiation stability of sulphates.

Sulphate	Crystal system	Radius of cation, Å	Ionicity of SO_4^{2-}	Lattice energy, kcal mole^{-1}	Free vol. of unit cell, Å^3	Self-irradiation at 25°C: initial specific radioactivity (^{35}S), mc g^{-1}	Self-irradiation at 25°C: G_{pmc}	External γ-irradiation at 30°C: G^*_{pmc}	External γ-irradiation at 30°C: $(SO_3^- + SO_2^-)$
$BaSO_4$	rhombic	1.43	0.46	589	88	20	0.7	0.5±0.18	(4±2.0)·10^{-2}
$SrSO_4$	rhombic	1.23	0.56	612	67	50	2.5	0.3±0.15	(2±0.7)·10^{-2}
$CaSO_4$	rhombic	1.09	0.71	647	76	50	—	(4±1.6)·10^{-2}	(7±3)·10^{-3}
$CaSO_4 \cdot 2H_2O$	mono-clinic	1.09	0.46	635	165	50	0.2	—	—
K_2SO_4	rhombic	1.32	0.5	432	136	—	—	5±1·10^{-3}**	1·10^{-4}

*G_{pmc} applies to the total paramagnetic centres formed on irradiation, but since $SO_4^- > SO_3^- + SO_2^-$ groups, it corresponds mainly to the primary products of radiolysis, which are SO_4^- radical-ions.
**Determinations made at −196°C.

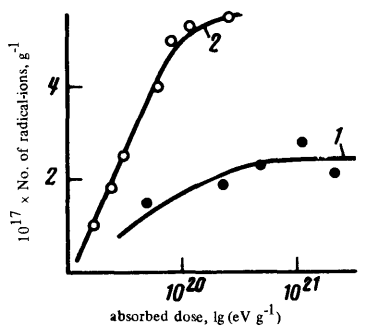

Figure 2. Accumulation of paramagnetic centres in barium sulphate at room temperature: 1) γ-irradiated salt; 2) radioactive BaS^*O_4 (20 mc g^{-1}).

Such relations between C_{irrad} and $C_{radioact}$ are characteristic of all the specimens studied, especially with small doses absorbed. This is probably because the radiation-chemical yield in radioactive salts corresponds to the number of paramagnetic centres in the zone of continuous irradiation. Hence, at any instant while self-irradiation is occurring, $C^*_{radioact}$ should exceed C_{irrad} by an amount corresponding to the number of paramagnetic centres that recombine rapidly after exposure has ceased (doses and dosage rates are assumed to be the same in comparable specimens). Experiment shows in fact that in radioactive sulphates $C^*_{radioact} \simeq (2-10)C_{irrad}$. Therefore the yields of paramagnetic centres are higher in radioactive salts than in externally irradiated specimens.

The appearance of a maximum in the time dependence of the concentration C of paramagnetic centres and the permanence of the relation $C^* > C_{irrad}$ can be explained [13] by an exponential decay in the intensity of self-irradiation with time, on the assumptions that radiation disturbances are reversible and are annealed both by direct recombination and under the influence of the emission itself (radiation anneal). The generation and destruction of radicals by a mechanism of "removal and addition" of electrons on exposure, which is characteristic e.g. of radioactive sulphates when the SO_4^- radical-ion is formed, satisfies these conditions. With the above limitations, and bearing in mind that [37,38] the annealing and production of defects have first-order kinetics, we obtain the formula [13]

$$\overset{*}{C}_t = a\exp\left[\frac{b}{\lambda}\exp(-\lambda t) - at\right]\int_0^t \exp\left[(\alpha-\lambda)t - \frac{b}{\lambda}\exp(-\lambda t)\right]dt \qquad (5)$$

where a, b, and α are coefficients depending on the probabilities of formation and disappearance of defects and on the initial intensity of irradiation, with $a > b$. Introduction of the dimensionless variable $\tau = \lambda t$ (in which λ is the disintegration constant and t the time), expansion of the integrand as a series, and integration yield

$$\overset{*}{C}_\tau = \exp(a e^{-\tau} - \sigma\tau)\sum_{n=0}^{\infty}\frac{(-\alpha)^n}{n!(n+\gamma)}\{1 - \exp[-(\alpha-\lambda)t]\} \qquad (6)$$

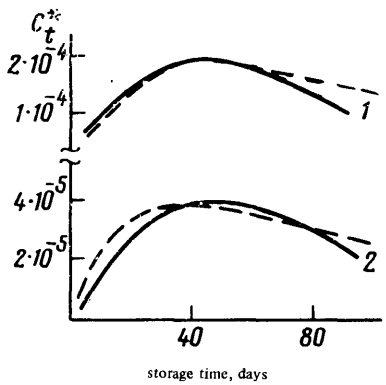

Figure 3. Variation in relative quantity of radicals in strontium and barium sulphates containing radioactive sulphur (20 mc g^{-1}):[13] 1) SrS^*O_4; 2) BaS^*O_4. Here C^*_t is the total number of paramagnetic centres divided by the number of irradiated molecules in 1 g.

Depending on the relation between the parameters α and σ the plots of the number of radiation defects C^*_T against the reduced time τ pass through a maximum, whose height and position are determined by the values of these constants.

Fig. 3 illustrates experimental and calculated ratios (to ±10%) of the number of radicals to the number of molecules irradiated in 1 g of BaS^*O_4 and SrS^*O_4. During storage of the radioactive material (the radioactive isotope disintegrates in conformity with the law $I = I_0\exp(-\lambda t)$,

where I is the emission intensity) a maximum occurs in C_t^*, and Eqn. (6) describes quite accurately the curves for the accumulation of radicals in radioactive materials. From the derivation of formulae (5) and (6) it follows that the maximum in the C_t^*–t curves is due to the fact that the spontaneous annealing of defects becomes of decisive importance with decrease in the emission intensity.

When the intensity of the emitter remains practically unchanged—i.e. $\lambda \simeq 0$ and $I = I_0 = \text{const}$—no maximum is observed. In this case the variation in Ct with time is represented by the formula

$$C_t = \bar{C}\{1 - \exp[-(b + \alpha)t]\}, \quad (7)$$

where the equilibrium concentration of defects is

$$\bar{C} = nAIP_1/(AP_1I + AP_2I + BP_3);$$

n is the number of irradiated molecules, P_1, P_2, and P_3 are the probabilities of the formation and disappearance of defects under the influence of irradiation and of their recombination, I is the dosage rate of the emission, and A and B are constants depending on the properties of the specimen and the conditions of irradiation.

Equations (6) and (7) show that an equilibrium number of defects may accumulate in the irradiated materials, their concentration at a given temperature depending solely on the properties of the medium and the intensity of self-irradiation[35,36,38].

It follows from Eqn. (7) that, with a constant intensity of irradiation, the number of radiation defects reaches $\bar{C}$ more rapidly the larger are P_1–P_3. Furthermore, Ct tends to $nP_1(P_1 + P_2)$ with increase in the dosage rate I (since $IAP_1 + IAP_2$ becomes $> BP_3$: i.e. spontaneous recombination of defects is small). Thus the equilibrium concentration of defects should be greater at higher values of I with the same dose absorbed. With decrease in the intensity of the emitter, Ct tends to $nIAP_1/BP_3$ (in this case $AP_1I + AP_2I > BP_3$). When $I = 0$, the formulae are devoid of physical meaning.

A possible reason why the number of radicals in materials containing radioactive isotopes is larger than in the externally irradiated non-radioactive compounds, under otherwise similar conditions[11–13], is that spontaneous annealing continues (rapidly at first, and then more slowly) after the termination of exposure, and by the time defects are recorded some of them have inevitably disappeared. Radioactive materials are under continuous irradiation, and therefore a higher concentration of defects is maintained in them. If the annealing of defects is negligible (e.g. at low temperatures), the same number of radiation disturbances accumulate in the two cases (external irradiation and self-irradiation). The formulae obtained for the accumulation of radiation defects in radioactive salts reflect only one aspect—the variation in the intensity of self-irradiation with time—of this complicated process. This effect is unable, of course, to explain all the features of radiation-chemical phenomena in radioactive crystals. As already mentioned, the accumulation of impurity atoms and specific aspects of the ionisation of electron shells in radioactive disintegration are of great significance here. Unfortunately, the influence of these factors has still not been adequately studied.

The above rules for the accumulation of paramagnetic centres apply only with identical or almost identical linear energy transfers in comparable specimens. Furthermore, if the transfer is large, a smaller quantity of disturbances may even accumulate in radioactive materials than in irradiated samples. In frozen water containing tritium (1 c ml^{-1}), for example, the yield of atomic hydrogen is about one-half of the yield in γ-irradiated ice with the same doses absorbed[24,25]. This is explained by intense recombination of radicals in the tracks. However, experiments with radioactive crystals of barium, strontium, and calcium sulphates revealed no variation in G(pmc) with the content of the radioactive isotope up to specific radioactivities of ~ 150 mc g^{-1}.

III. SELF-RADIOLYSIS OF RADIOACTIVE MATERIALS

Radioactive compounds may undergo considerable changes as a result of radiation-chemical processes. The radiolysis products gradually accumulate in them, and change the physicochemical properties of the radioactive specimens. Even the low-energy β-radiation emitted by carbon-14 affects the kinetics of the thermal decomposition of certain radioactive carbonates[17–21,39–41]. Thus the temperature of the vacuum decomposition (10^{-4}–10^{-5} mmHg) of CdC^*O_3 and $NaHC^*O_3$ of specific radioactivity up to 120 mc g^{-1} is about 60% [sic] lower than that of the non-radioactive salt. The form of the decomposition curves also changes: radioactive cadmium carbonate and radioactive sodium bicarbonate in a vacuum or in an atmosphere of nitrogen exhibit a maximum (sometimes even two maxima) on the rate curves (especially well defined with cadmium carbonate), whereas the non-radioactive salts show a minimum[40,41]. The composition of the gaseous products did not depend on the action of radiation.

These effects are explained[39] by increase in the reactivity of the radioactive carbonates due to the accumulation of radiation disturbances under the influence of the β-disintegration of carbon-14 (recoil atoms, the appearance of impurity centres—nitrogen atoms—rupture and distortion of chemical bonds, and the establishment of a local charge).

Cadmium carbonate was more sensitive to radiation than sodium bicarbonate. Thus CdC^*O_3 even of specific radioactivity 0.5 mc g^{-1} possesses enhanced reactivity, whereas $NaHC^*O_3$ of 95–120 mc g^{-1} (with respect to carbon-14) differs little in rate of thermal decomposition from the non-radioactive salt. Radioactive disintegration is assumed to facilitate the generation of a reaction centre but to have no appreciable effect on its migration inside the crystal. The second stage, almost unaffected by self-irradiation, is evidently the most important in the case of sodium bicarbonate. It is probable that not only different structure-sensitive properties of a solid but also various kinetic characteristics of a chemical reaction involving it will have different sensitivities to radioactive disintegration. This view is supported also by a kinetic investigation of the thermal decomposition of radioactive mercuric oxide (specific radioactivity (^{203}Hg) ~ 50 mc g^{-1}), whose kinetic parameters were identical with those of the non-radioactive analogue[42].

Detailed investigations have been made[43–47] of the spontaneous decomposition of plutonium and americium oxalates. At room temperature the simple and double oxalates of tervalent, quadrivalent, and sexivalent plutonium undergo vigorous decomposition with the evolution of gas under the influence of their own α-radiation[43–45]. After storage for 18 months the double ammonium, sodium, and potassium plutonium(IV) oxalates yielded a mixture of $PuOCO_3$ and $(Na, K)_2CO_3$. Pure plutonium(IV) oxalate gave a product corresponding in composition to plutonium oxide carbonate[44,45].

The decomposition of americium oxalate occurs so rapidly that the almost pure carbonate remains after

twenty days (Fig. 4). The efficiency of decomposition is 1.3 mol. per 100 eV of absorbed energy. The oxalate is converted into the carbonate, and carbon dioxide and monoxide are evolved. It is significant that the composition of the evolved gases and the final compound in the thermal decomposition of americium oxalate closely resemble the products of its radiolytic decomposition [46,48].

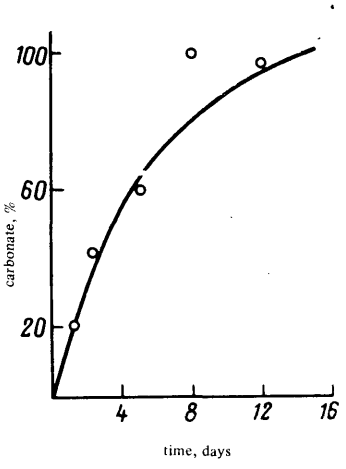

Figure 4. Variation with time in the carbonate content of americium oxalate crystals [47].

The addition of cobalt-60 to cobalt formate in amounts of 1.42 mc g^{-1} shortens the half-period of the topochemical decomposition of the radioactive salt to less than one-quarter. A gas comprising hydrogen and carbon dioxide is evolved. The effect of self-irradiation on the kinetics of the radiolysis of cobalt formate depends on the length of storage of the radioactive material, which involves the accumulation of radiation defects in the crystal lattice.

The contamination of silver azide with cadmium atoms by the disintegration of silver-110 (initial radioactivity ~ 3.5 mc g^{-1}) increases the detonation velocity of the azide by 50%. The accumulation of cadmium for 270 days changes the crystals from almost colourless to brown [49]. It is supposed that cadmium atoms and radiation defects (F-centres, displaced atoms) accelerated the decomposition of silver azide.

Insufficient data have been published on the self-radiolysis of radioactive materials for definite generalisations to be made. Barium, strontium, calcium, and potassium sulphates are exceptional in this respect.

An important parameter of the radiation properties of any system is the primary yield of products determined when the recombination of the disturbances can be neglected. Values of G_{pmc} for crystalline specimens are usually found from the initial linear portion of the curves representing the accumulation of paramagnetic centres at low temperatures. Values obtained with the irradiated salt at a high temperature, although different from the primary yields, can also characterise the radiation-chemical stability of solids (Table).

The Table shows that the yield of primary products of radiolysis of the sulphates, as well as of SO_3 groups + SO_2, which are formed mainly in secondary processes, decreases with increase in the lattice energy of the irradiated salts. Many workers have observed such a relation in series of compounds of the same type [50-52]. Hence the radiation stability of the crystalline anhydrous sulphates of the alkaline-earth metals conforms to the general rules of radiolysis established for other compounds. The ionicity† of the anion in the series of sulphates—barium, strontium, and calcium—has no appreciable effect on radiolysis (Table), the lattice energy being of decisive importance.

The radiolysis of radioactive sulphates under the influence of their own radiation supports the principle [51,53-55] that the radiation stability in the irradiated zone is greater in solids of smaller lattice energy: i.e. values of G_{decomp} are lower in crystals having smaller lattice energies (see "self-irradiation" column in Table). This is a characteristic feature of the self-radiolysis of radioactive salts, in addition to those noted previously—high values of G, rise in temperature, appearance of impurities and recoil atoms, and in some cases a maximum in the time dependence of the concentration of paramagnetic centres resulting from the exponential loss in intensity of self-irradiation.

The above experimental results are also a convincing demonstration that processes occurring in radioactive materials cannot always be simulated by external irradiation. The possible effects of self-irradiation must be thoroughly analysed in each specific case, and their role in the system carefully assessed.

Present State of the Theory of the Chromatographic Microreactor

M.I.Yanovskii and A.D.Berman

Published information on the use of a pulse chromatographic microreactor in catalytic investigations is reviewed systematically. Theoretical analysis of the processes occurring in such a reactor showed the possibility of using transient pulse methods to determine the adsorption and desorption rate constants for starting materials and products during a catalytic process, to study the effect of longitudinal and internal diffusion, to reveal the principal and subsidiary paths of complicated catalytic processes, etc. From an analysis of published data it is concluded that chromatographic methods should be introduced more widely to solve complex kinetic problems in heterogeneous catalysis. A list of 90 references is included.

I. INTRODUCTION

The invention in 1955 of the microcatalytic reactor, by Kokes et al. [1] just three years after Martin had formulated the principles of gas–liquid chromatography [2], advanced significantly the range of application of chromatography in catalysis. In essence the method is extremely simple: the reactor filled with the test catalyst is inserted into the gas circuit in front of the chromatographic column of an ordinary gas chromatograph. The microreactor is placed in a furnace to ensure a specified temperature in the catalyst bed, and a stream of an inert carrier gas is passed through continuously. A specified quantity of the reactant is periodically introduced as pulses into the microreactor. The reaction products and the unchanged material are carried into the chromatographic column by the stream of carrier gas.

Several modifications of the pulse method have now been described, but they all have the common features of rapidity, the possibility of using very small quantities of reactants and catalysts, and also great sensitivity [3].

Use of the microcatalytic reactor yielded within a short time voluminous and important information on both processes and catalysts for several important systems [4-6]. With highly sensitive detectors and efficient separating columns any side reaction, which might remain unnoticed in the usual method, could be recorded as well as the main reaction. In several cases we can begin to discern the chief features of the step-by-step mechanism of certain complicated reactions. It is already difficult to imagine a modern catalysis laboratory in which wide use would not be made of the microcatalytic reactor, together with the usual catalytic equipment, especially for the selection of new catalysts [7-10].

The present paper surveys the kinetics of catalytic reactions taking place in a microcatalytic reactor with the pulsed introduction of reactants. The kinetics of a process in a microcatalytic reactor may in general differ significantly from the kinetics in the flow-type and circulatory apparatus traditionally used for catalysis. We must distinguish several groups of factors responsible for these differences.

The first group depends on the difference in the state of the catalytic surface. In the microreactor the catalyst is continuously blown out at the reaction temperature by the stream of pure inert carrier gas.

Since a pulse usually introduces a very minute quantity of reactant into the microcatalytic reactor, results obtained for the first few pulses can often be regarded as representing the catalytic properties of a surface not yet subjected to the action of the reacting system. By introducing pulse after pulse or reactant into the microreactor, it is possible to trace a gradual change in catalytic activity during the catalytic process; this opens up the possibility of studying kinetics on catalysts operating under transient conditions. Belousov has paid close attention to this problem in a series of studies [11-13] of the mild oxidation of propene on a large number of oxide catalysts. When tested under steady-state conditions, the catalyst remains for a long time in contact with the reaction mixture, so that its surface is able to undergo significant changes. Many investigations have shown that the catalytic activity of a catalyst measured from the first few pulses in the microreactor sometimes exceeds by several powers of ten the activity determined under steady-state conditions.

The second group of factors responsible for the distinctive features of processes occurring in the microreactor depend on the movement of bands of starting materials and products along the catalyst layer, and also on the changes in the concentration profile and surface coverage resulting from diffusion, adsorption and desorption, etc. We shall examine below the effect of these processes on the kinetics of catalytic reactions in the microreactor.

II. IRREVERSIBLE REACTIONS

1. Reactions of Type A → B with a Linear Adsorption Isotherm for A, Rapid Establishment of Adsorption Equilibrium, and Absence of Diffusion Processes

An account of the theory of processes occurring in the microcatalytic reactor can easily begin with the simplest case, in which adsorption of the reactant A on the catalyst is rapid and is described by the linear Henry equation

$$a_A = \Gamma_A c_A \tag{1}$$

and the effect of diffusion on the blurring of the band can be neglected. Here c_A and a_A are the concentrations of A in gaseous and adsorption media respectively, while Γ_A is the Henry coefficient.

If we write the equation of continuity for flow of substance A across an elementary layer in the microcatalytic reactor, and take into account Eqn. (1) and the appropriate boundary conditions, we obtain a linear partial differential equation [14]. By solving this equation we can determine the concentration $c_A(x, t)$ of the reactant A in any cross-section x of the column at a specified time t:

$$c_A(x, t) = \psi(t - t_R)\exp(-t_R^{corr} k) \tag{2}$$

where $\psi(t)$ is a function describing the shape of the pulse fed to the microreactor, t is the time measured from the introduction of the pulse, t_R and t_R^{corr} are the usual parameters of a chromatographic experiment—the retention time and the "corrected" retention time [15] respectively—and k is the first-order rate constant of the heterogeneous catalytic reaction.

Equation (2) shows that the pulse of reactant A moves along the catalyst layer at a constant speed with a gradually diminishing height but without change in its original width. In this simple case the reaction rate constant can easily be determined by means of an equation analogous to the formula for a flow reactor:

$$k\Gamma = \frac{1}{\tau}\ln\frac{1}{1-\alpha} \tag{3}$$

where $\tau = v_{cat}/u_{vol}$, in which v_{cat} is the volume of catalyst in the microreactor and u_{vol} the space velocity of the carrier gas through the reactor; α is the degree of conversion, usually determined from the ratio of the peak area for A at the outlet from the microreactor to the corresponding area at the inlet.

For a first-order reaction α is independent of the distribution of the initial substance A along the reactor layer, i.e. on the form of the pulse. This enabled Habgood and Basset [16] to deduce Eqn. (3) without setting up differential equations relating the form of the pulse with time and position. This equation has been widely used to analyse experimental results obtained with the microcatalytic reactor [17,18]. Incidentally, experimental verification that α is independent of the form of the initial pulse for a first-order reaction has been reported in several papers [19,20].

Roginskii and Rozental' [21] examined the simultaneous occurrence of heterogeneous and homogeneous reactions in the microcatalytic reactor. Their solution was analogous to (2) with the constant k replaced by an effective constant

$$k_{eff} = \frac{(1-\varkappa)k\Gamma_A + \varkappa k^{hom}}{\varkappa + (1-\varkappa)\Gamma_A} \tag{4}$$

in which k and k^{hom} are the rate constants of heterogeneous and homogeneous reactions respectively, and $\varkappa$ is the free volume of the batch. The observed activation energy of the reaction E_{obs} can be determined from the temperature variation of k_{eff}. If only a heterogeneous reaction takes place in the reactor, we have

$$E_{obs} = E_{true} - Q_{ads} \tag{5}$$

When only a homogeneous reaction occurs, then

$$E_{obs} = E_{true} \tag{6}$$

Ample information on the kinetics of a reaction of type A → B in the microreactor can be obtained [22-25] from the form of the peak for product B recorded immediately beyond the microreactor. The form of this peak was described by solving the set of differential equations for the material balance of A and B with linear adsorption isotherms.

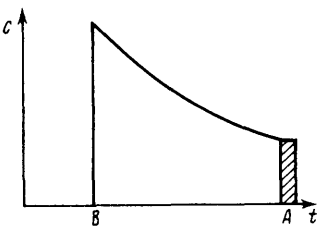

Figure 1. Diagram of chromatogram obtained directly after reactor, for the reaction A → B.

It was supposed [24,25] that a narrow band of the starting material A of width δ had been introduced into the originally empty microcatalytic reactor. The following picture of the movement of the bands of A and B along the catalyst bed emerges from these results. On the right of Fig. 1 is shown hatched the band of reactant A, which, without changing its initial width δ, moves at a speed inversely proportional to Γ_A, while gradually diminishing in height (e.g. Eqn. 2). The right-hand boundary of band B is adjacent to band A and moves at the same speed. The left-hand boundary of band B moves at a speed determined by the coefficient Γ_B. Thus the width of band B is governed by the difference $\Gamma_A - \Gamma_B$ and the form by the rate constant k. The retention time of band B can usefully be determined from the elution time of the centre of gravity of the band t_{cg}^B, for which the relation

$$t_{cg}^B = t_A^R + \frac{\Gamma_A - \Gamma_B}{\Gamma_A k} + \frac{t_A^R}{\alpha}\left[\frac{\Gamma_B}{\Gamma_A} - 1\right] \tag{7}$$

has been obtained [25]. For rapid reactions ($k \to \infty$, $\alpha \to 1$) it follows from (7) that

$$t_{cg}^B = t_A^R \frac{\Gamma_A}{\Gamma_B} \tag{8}$$

With small degrees of conversion

$$\alpha \approx 1 - \exp(-k t_R) \approx k t_R$$

we find that

$$t_{cg}^B \approx {}^1/_2 t_A^R \cdot \left(1 + \frac{\Gamma_B}{\Gamma_A}\right) \tag{9}$$

It has been shown also that the blurring of the band of products B is proportional to the square of the relative difference between the Henry coefficients for A and B, and depends also on k and α:

$$\sigma_B^2 = \left(\frac{\Gamma_A - \Gamma_B}{\Gamma_A}\right)^2 \left[\frac{1}{k^2} - \frac{t_A^R}{\alpha}\left(\frac{1}{\alpha} - 1\right)\right] \quad (10)$$

Formulae (7) and (10) can be used for the experimental determination of k and Γ_B.

Calculations have been made [22,23] of the form of the hydrogen band produced by dehydrogenation when a broad rectangular pulse of cyclohexane is admitted to a microreactor filled with a platinum–alumina catalyst. The microreactor was followed by a column containing activated carbon, which completely absorbed unchanged cyclohexane and the benzene formed, while hydrogen passed through. From the shape of the hydrogen band it was possible to calculate the reaction rate constant k and the activation energy for the dehydrogenation of cyclohexane to benzene.

2. Reaction of Type nA → B with a Linear Adsorption Isotherm for A and Rapid Establishment of Adsorption Equilibrium

The progress of an irreversible reaction of order n with a linear adsorption isotherm for the starting material A and rapid establishment of adsorption equilibrium has been considered in the paper cited above [14]. The equation of material balance together with the linear isotherm yields the solution

$$c_A(l, t) = \frac{\psi(t - t_{cg}^R)}{\sqrt[n-1]{1 + (n-1)\, k t_A^{coff} \Gamma_A^{n-1} \psi^{n-1}(t - t_R^A)}} \quad (11)$$

where $\psi(t)$ is the form of the entering pulse and l the length of the catalyst bed. The self-evident relation

$$1 - \alpha = \frac{\int_{t_A^R}^{T + t_A^R} c_A(l, t)\, dt}{\int_0^T \psi(t)\, dt} \quad (12)$$

exists between α and the size and shape of the pulse of A at the inlet to the microreactor. From Eqns. (11) and (12) expressions have been obtained [14] for calculating the constants k from definite experimental values of α with $n = 0$, 1, 2 for rectangular and triangular pulses.

It is possible to determine n and k by conducting the reaction at small values of α in the microreactor [28]. The rate w of a catalytic reaction in the microreactor can be written

$$w = \frac{\Delta m}{\Delta t \cdot v_{cat}} \quad (13)$$

where Δm is the quantity of material converted and Δt the residence time of the reactant band on the catalyst bed of volume v_{cat}. Although α depends on the form of the pulse when $n \neq 1$ the differences do not exceed 10–15% if pulses having the same mean concentration c_{av} are compared. The reaction velocity in the microreactor can therefore be related to the mean concentration in the pulse, and a correction then made for the shape of the latter:

$$w = \frac{\Delta m}{\Delta t \cdot v_{cat}} = k_{eff} \Gamma^n c_{av}^n \quad (14)$$

in which $k$eff is an effective rate constant based on c_{av}.

It follows from (14) that the order of the reaction is determined from the slope of the linear plot of $\lg w$ against $\lg c_{av}$, and $k$eff from the intercept made by this straight line on the vertical axis. To determine the true rate constant k we must introduce a correction for the form of the pulse:

$$k = k_{eff} \frac{\left[\frac{1}{T}\int_0^T \psi(t)\, dt\right]^n}{\frac{1}{T}\left[\int_0^T \psi^n(t)\, dt\right]} \quad (15)$$

This equation was obtained by expanding formula (11) for the elution curve as a Taylor series, and substituting the approximate value of $c_A(l, t)$ in (12). Germain [28] obtained an analogous expression by a somewhat different method.

When $n = 0$ or 1 the correction calculated from the ratio of integrals on the right-hand side of Eqn. (15) is unity: i.e. $k$eff $= k$ for reactions of zero and first order, independently of the form of the pulse. In the case of rectangular pulses this correction can be shown also to be unity for any value of n.

The above method has been used [29] to study the oxidative dehydrogenation of isopentenes to isoprene on a catalyst comprising a mixture of the oxides of iron, chromium, and zinc.

If the order of the reaction is determined from (14) and substituted in (11), the approximate formula

$$(1 - \alpha)^{1-n} = (n - 1)\, c_{av}^{n-1} k \Gamma^n \tau \quad (16)$$

can be obtained instead of the input function of the mean concentration c_{av} in the pulse. This gives another simple procedure for determining the apparent rate constant [27]. The slope of the dependence of $(1 - \alpha)^{1-n}$ on τ is $(n - 1)k\Gamma_A^n c_{av}^{n-1}$. Determining c_{av} from the form of the pulse at the inlet to the microreactor, we can calculate the approximate value of $k\Gamma_A^n$ by dividing the slope by $(n - 1)c_{av}^{n-1}$.

3. Effect of Diffusion on an nth-Order Reaction of Type nA → B

An examination has been made [30] of the kinetics of nth-order reactions with longitudinal diffusion and rapid establishment of adsorption equilibrium. Since the diffusion equations are non-linear in this case, a mathematical solution cannot be obtained. We therefore assumed that the reaction had no significant effect on the blurring of the band of the initial substance. This can be expressed mathematically by writing

$$c_A(x, t) = c_A^0(x, t)\, N(t)$$

where $c^0(x, t)$ is the solution of the corresponding problem for gas-adsorption chromatography in the absence of reaction, and $N(t)$ is a function of time. If the relation

$$\frac{dc_A}{dt} = k\Gamma^n c_A^n(x, t),$$

is satisfied at every point in the bed, integration with respect to x and substitution of the preceding expression for $c_A(x, t)$ yields for $N(t)$ an ordinary differential equation, whose solution presents no difficulty. This is fully analogous to the approach used by Frank-Kamenetskii [31].

To summarise the principal qualitative results[30], diffusion has hardly any effect on the degree of conversion in first-order reactions ($n = 1$). Longitudinal diffusion slows down the reaction more strongly the higher the order of the reaction above unity. With second-order reactions the rate decreases in proportion to the square root of the time, owing to the diminution in the concentration in the reaction zone caused by blurring of the band. This effect becomes greater with increase in the length of the reactor bed and decrease in the rate of flow.

4. Reaction of Type A → B with Slow Establishment of Adsorption Equilibrium

In order to discuss the progress of a first-order reaction in a microcatalytic reactor taking into account the kinetics of adsorption[21] the usual material balance equation was solved together with the differential equation of sorption kinetics

$$\frac{\partial a_A}{\partial t} = k_A^a c_A - (k + k_A^d) a_A \qquad (17)$$

in which k_A^a and k_A^d are the rate constants of the adsorption and the desorption of substance A. An expression was obtained[21] for the form of the elution curve of A which included Bessel functions.

In the Reviewers' opinion it is more convenient, in the experimental determination of the rate constants k, k_A^a, and k_A^d, to use the expressions for the main parameters of the peaks of starting materials and products that can be obtained by the statistical method of moments[32]:

$$1 - \alpha = \exp\left\{-\frac{x}{u}\left[\frac{(1-\varkappa)k_A^a k}{(k+k_A^d)}\right]\right\} \qquad (18)$$

$$t_A^R = \frac{x}{u}\left[\varkappa + \frac{(1-\varkappa)k_A^a k_A^d}{(k+k_A^d)^2}\right] \qquad (19)$$

$$\sigma_A^2 = \frac{2x}{u}\frac{(1-\varkappa)k_A^a k_A^d}{(k+k_A^d)^3} \qquad (20)$$

where u is the linear rate of flow and σ_A^2 is the dispersion of the concentration distribution at the exit from the reactor.

With regard to the physical significance of the results, if the reaction occurs in the kinetic range ($k \ll k_A^d$), Eqn. (18) passes into Basset's well known equation (3). Thus Eqn. (3) applies (as is usually supposed) not only when adsorption equilibrium is established instantaneously but also in the more general kinetic case with $k \ll k_A^d$. With this last condition it follows from Eqns. (19) and (20) that even the occurrence of a heterogeneous reaction has no effect on the retention time or the blurring of the reactant A band. If k and k_A^d are comparable, the occurrence of a reaction accelerates movement of the A band and diminishes blurring. When desorption is the limiting stage ($k \gg k_A^d$), the corrected retention time $t_A^{R\,corr}$ is inversely proportional to k^2, while σ_A^2 is inversely proportional to k^3.

If it is assumed that the initial substance A and the product B are sorbed independently, and that the adsorption of both substances conforms to a linear kinetic equation, it appears possible to study the kinetics of the catalytic reaction from the form of the B band. In this case[25] the set of equations for A must be supplemented by the material balance equation and the linear kinetic equation describing the movement of the B band. This set of equations has recently been solved by an operational method[25], to yield expressions for the retention time t_B and the dispersion of the band σ_B^2 of product B analogous to those obtained for A (Eqns. 18–20). Thus the retention time is

$$t_B = t_A + \frac{x(1-\varkappa)}{\alpha u}[\Gamma_B - \Gamma_A^{eff}] - \frac{k_B^a(k+k_A^d) - k_A^a(k+k_B^d)}{k \cdot k_B^d \cdot k_A^a} \qquad (21)$$

where $\Gamma_A = k_A^a k_A^d/(k + k_A^d)^2$ is the effective Henry coefficient for the starting material. It follows from (21) that the elution time of the reaction product should differ from its retention time in gas-adsorption chromatography, as has been confirmed experimentally[25]. In a study of the cracking of cumene on an aluminosilicate catalyst, a mixture of benzene and cumene was introduced into the reactor. The chromatogram obtained immediately following the reactor shows (Fig. 2) separate peaks for benzene added to the reactor and for benzene produced in the reaction.

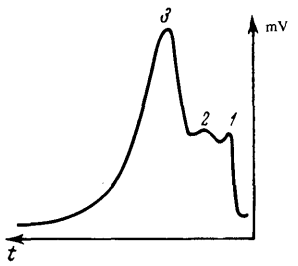

Figure 2. Chromatogram obtained after the microcatalytic reactor for the cracking of cumene on an aluminosilicate catalyst. A mixture of benzene and cumene was introduced into the reactor: 1) benzene added to the reactor; 2) benzene produced by the cracking of cumene; 3) cumene.

When $\Gamma_B = \Gamma_A^{eff}$, i.e. when the adsorption coefficients of starting material and product coincide, it follows from (21) that

$$t_B = t_A + \frac{1}{k_B^d} + \frac{1}{k + k_A^d} \qquad (22)$$

Thus even when $\Gamma_B = \Gamma_A^{eff}$ the peak of the product lags behind the peak of the initial substance a constant distance depending on the rate constant of the heterogeneous reaction and the desorption rate constants of starting material and reaction product.

An experimental method was also proposed[25] for studying the kinetics of adsorption during a catalytic reaction, involving the use of Eqns. (18)–(21) and corresponding expressions for complicated cases. The main difficulty to be overcome was that in this case the characteristics of the peaks due to individual substances at the outlet from the reactor were required for the calculation. Under normal conditions the separation of the components on the catalyst bed is seldom sufficient for direct measurements to be made. It was therefore suggested that the additivity

relations applicable to the reactor–column system[3] should be used:

$$t_c^R = t_p^R + t_\kappa^R$$
$$\sigma_s^2 = \sigma_r^2 + \sigma_{col}^2 \qquad (23)$$

where t_S^R and σ_S^2 are the retention time and the dispersion of the peak of a substance which has passed successively through the reactor and the column, t_r^R, σ_r^2 are the retention time and the dispersion of the peak of the substance after passing through the reactor, and t_{col}^R and σ_{col}^2 are the corresponding parameters for the peak after the substance has passed through the column.

The parameters t_S^R and σ_S^2 were determined from chromatograms at the outlet from the separation system, and t_{col}^R and σ_{col}^2 in a separate series of experiments in which a certain quantity of starting materials or products was introduced directly into the separating column. After this t_r^R and σ_r^2 were determined by means of Eqns. (23). This method was used to calculate the adsorption and desorption rate constants for cumene during cracking on an aluminosilicate catalyst.

5. Reactions of Type A → B in the Internal-diffusion Range

The method of moments was used by Rozental'[33] to analyse a complex case of movement of the band of substance A along the bed of the microcatalytic reactor, accompanied by a first-order reaction occurring in the inner-diffusion range. The analysis took into account also the kinetics of the adsorption of A on the internal surface of the catalyst. Effects of longitudinal diffusion were neglected. A set of three equations—(1) the kinetics of adsorption and the first-order reaction, (2) diffusion into the pores, and (3) material balance in the space between catalysts particles—was solved for this model. Application of the Laplace transformation to these equations yielded expressions for α, t_A^R, and σ_A^2 in terms of certain functions $f_0(z)$, $f_1(z)$, and $f_2(z)$ of the dimensionless variable $z = k\Gamma R^2/D_i$, in which R is the particle size of the catalyst and D_i the coefficient of internal diffusion.

The dimensionless parameter z defines the combined effects of adsorption, internal diffusion, and reaction on the form of the elution curve, while $f_0(z)$, $f_1(z)$, and $f_2(z)$ represent the effects of variation in α, t_A^R, and σ_A^2 as a result of diffusion in the pores during the reaction. Each of these functions decreases simultaneously with z and becomes unity when $z = 0$. This case corresponds to the absence of reaction or to rapid internal diffusion.

The function $f_0(z)$ is termed the fractional accessible surface[33]. It increases with decrease in Γ, k, and R; and decreases with decrease in D_i. Increase in $f_0(z)$ is accompanied by increase in α.

The quantity $\Gamma f_1(z)$ constitutes an effective adsorption coefficient. Diffusion combined with reaction diminishes the elution time of the peak of A. The contribution to dispersion due to the slowness of adsorption was also examined[33]. The occurrence of reaction was found to diminish the blurring due to diffusion into the pores.

6. Reactions of Type A → B allowing for Longitudinal Diffusion and Sorption Kinetics

The combined effect of adsorption kinetics and longitudinal diffusion on an irreversible first-order reaction has been examined by Kočirik[34]. The equations for the material balance and the adsorption kinetics of A are written

$$\varkappa \frac{\partial c_A}{\partial t} + (1-\varkappa)\frac{\partial a_A}{\partial t} + u\frac{\partial c_A}{\partial x} + k(1-\varkappa)a_A = D\frac{\partial^2 c}{\partial x^2}$$
$$\frac{\partial a_A}{\partial t} = k_A^a c_A - (k_A^d + k)a_A$$

where D is the coefficient of longitudinal diffusion.

The expressions for α and t_A^R obtained by the method of moments are

$$\alpha = 1 - \exp\left[\frac{u}{2D} - \frac{u}{2D}\sqrt{1 + \frac{4D(1-\varkappa)k\cdot k_A^d}{u^2(k+k_A^d)}}\right] \quad (a)$$
$$t_A^R = \frac{x}{u}\left[\varkappa + \frac{(1-\varkappa)k_A^a \cdot k_A^d}{(k+k_A^d)^2}\right]\frac{1}{r} \quad (b) \qquad (24)$$

where r denotes the square-root term in (24a). If the longitudinal diffusion coefficient D is small, Eqn. (24a) passes into (18). In general, however, diffusion combined with reaction accelerates the movement of A. Since r contains u^2 in the denominator, the effect of diffusion will be appreciable at low rates of flow.

An expression was also obtained[34] for the blurring of the band of A. In order to determine r and D experiments must be made at low rates of flow u; then k_A^a and k_A^d can be calculated from experimental results at high rates of flow.

7. Plate Theory of Heterogeneous Catalytic Processes in a Microreactor

The above discussion shows that considerable mathematical difficulties are involved in allowing for the simultaneous effects of adsorption kinetics and internal and external diffusion on retention times and dispersions. Several investigators have therefore tried to approach a solution to this problem on the basis of the "plate theory" employed in chromatography, which makes it possible to establish the effects of experimental parameters on the blurring of bands, although it will not reveal the mechanism of all the processes occurring in a column.

Kallen and Heilbronner[35] were the first to use the plate theory to analyse a process occurring in a microcatalytic reactor. On the assumption that the reaction A → B took place on every plate, differential equations were written for the material balance with respect to A and B. After solution by means of Laplace transformations, these yielded the following expression for the retention volume of A

$$v_{A\ reactn}^{R\ corr} = \frac{v_A^{R\ corr}}{1 + \frac{k v_A^{equiv}}{u_{vol.}}} \qquad (25)$$

Here $v^{R\,corr}$ is the corrected retention volume of A in the absence of reaction, and v_A^{equiv} the volume of developer necessary for the complete transfer of A from the nth to the $(n+1)$th plate.

Formula (25) is a qualitative indication of the same relations as obtained in preceding subsections, which allowed for adsorption kinetics and diffusion in analysing the process occurring in the microcatalytic reactor. In fact it follows from (25) that the reactant A moves more rapidly than in the absence of reaction, which is consistent with conclusions reached earlier for non-equilibrium

adsorption. The change in retention volume due to the reaction increases with increase in k. The retention volume decreases also with increase in v_A^{equiv}, i.e. with increase in the time required for the establishment of adsorption equilibrium.

The effect of reaction on the width b_A of the reactant A can also be assessed. On the basis of chromatographic theory[35] the width is determined by means of the relation

$$b_A = \frac{4\, v_A^R}{\sqrt{N}} \tag{26}$$

where N is the number of plates. According to (25) we have $v_A^{R\,reactn} < v_A^R$; therefore the width of the peak of reactant A is less than the width in the absence of reaction.

The equation

$$k = \frac{N\,(1-\sqrt[N]{1-\alpha})}{v_A^{R\,reactn}}\, u_{vol} \tag{27}$$

has been obtained to calculate k from data at different rates of flow of the carrier gas. Thus by determining α, $v_A^{R\,reactn}$, and N for different rates of flow it is possible to calculate the reaction rate constant.

Nakagaki and Nishino[36] calculated k for the catalytic isomerisation of cyclopropane into propene on a 13X molecular sieve, some of whose cations had been replaced by Ni^{2+}, using the catalytic chromatogram given by Basset and Habgood[16]. The equations for the profile of bands A and B obtained by means of the plate theory enabled several relations for the main characteristics of the peaks to be calculated[36] from the extent of reaction; these were qualitatively consistent with results obtained previously including kinetics and diffusion when analysing processes occurring in the microcatalytic reactor.

III. REVERSIBLE REACTIONS OF TYPE A ⇌ B

Two different approaches have been made to a theoretical analysis of reversible first-order reactions occurring in a microcatalytic reactor: in some papers the equations of material balance and kinetics have been solved; others have given a statistical treatment of the phenomenon, based on a probability study of the behaviour of molecules.

The reaction

$$A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B$$

has been examined[37] with instantaneous establishment of adsorption equilibrium and absence of diffusion complications. The statistical theory developed enables the concentration profile of A and B inside the microcatalytic reactor to be calculated for various series of parameters. The analyses show that, if a mixture of A and B is introduced into the microreactor, a broad band is formed initially, with peaks at the edges corresponding to A and B individually. After some time the band deforms into a single narrower peak containing both A and B in the equilibrium concentrations.

Klinkenberg[38] considered the occurrence of reversible reactions in a microreactor from a rather different point of view. In the case of linear adsorption, with instantaneous establishment of adsorption equilibrium and absence of diffusion complications, the material balance equation is written

$$u\frac{\partial c_A}{\partial x} + \varkappa\frac{\partial c_A}{\partial t} + (1-\varkappa)\frac{\partial a_A}{\partial t} = k_2 a_B - k_1 a_A = \left[u\frac{\partial c_B}{\partial x} + \varkappa\frac{\partial c_B}{\partial t} + (1-\varkappa)\frac{\partial a_B}{\partial t}\right] \tag{28}$$

Comparison of the result obtained by Klinkenberg on solving (28) with the result from Giddings' statistical method shows the same qualitative pattern. When a mixture of molecules of A and B is introduced into the microreactor, the peaks due to these components should disappear as equilibrium is approached, while an intermediate band containing molecules of A and B in equilibrium concentrations will steadily contract, approaching the width of the equilibrium band. The retention time of the equilibrium mixture is written

$$t_{AB}^{R\,eq} = \frac{x}{u}\,\frac{\frac{k_1}{\Gamma_B}[\varkappa + (1-\varkappa)\Gamma_B] + \frac{k_2}{\Gamma_A}[\varkappa + (1-\varkappa)\Gamma_A]}{\frac{k_1}{\Gamma_B} + \frac{k_2}{\Gamma_A}} \tag{29}$$

If a mixture of equilibrium composition is introduced into the microreactor, it will move at a mean speed, and emerge as a single peak after time $t_{AB}^{R\,eq}$. Thus, when for any reason it is important to avoid the occurrence of a reversible reaction in an analytical chromatographic column, a kind of "chromatographic azeotropy" will be observed, such that A and B will not be separated under the given conditions despite significant differences in Γ_A and Γ_B.

IV. THEORY OF REACTIONS UNDER CHROMATOGRAPHIC CONDITIONS

The separation of products and starting materials on the bed of the microreactor has a considerable effect on the course of the catalytic process. We shall show below, for example, that with reversible reactions the spatial separation of products or reactants has a significant effect on the degree of conversion by completely or partly suppressing the reverse reactions. In the case of consecutive reactions the separation of substances on the catalyst bed sometimes changes fundamentally the selectivity of the process.

The action of poisons will also be different under conditions of separation. Because of the difference in adsorption coefficients between poison and reactant, the poison band may not enter the reaction zone at all, and therefore not poison the catalytic process. Similar phenomena will sometimes be observed in the self-poisoning of the reaction by the products.

Finally we note that, with non-first-order reactions, the kinetics of the catalytic process is influenced also by the form of the concentration profile in the reaction zone, governed, as noted above, by the kinetics of adsorption and desorption, external and internal diffusion, etc.

The above features led us to combine in the same section cases in which the yield or the selectivity of the reaction is influenced by various chromatographic effects. Such reaction conditions in the microcatalytic reaction have been termed[39] "chromatographic". Theory shows[37] that the character of a chromatographic process is determined by the method used to move the chromatographic band along the layer of stationary phase. A chromatographic régime can therefore be established in various specific forms. We shall consider below mainly the elution

type of chromatographic process, which has recently been subjected to the most thorough theoretical analysis. However, this by no means exhausts the possibilities of the method.

1. Reaction of Type A ⇌ B + C

The equations describing processes occurring in the microcatalytic reactor with such reactions are non-linear. For the sake of simplicity, therefore, we shall consider only the case of a linear adsorption isotherm and instantaneous establishment of adsorption equilibrium. Let us examine first some general considerations[39].

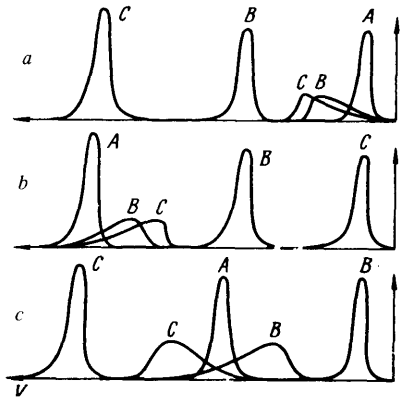

Figure 3. Diagram illustrating the establishment of a chromatographic régime.

Fig. 3 illustrates three possible relative arrangements of the A, B, and C bands on the catalyst bed, corresponding to the three relations among the adsorption coefficients —(*a*) $\Gamma_C > \Gamma_B > \Gamma_A$, (*b*) $\Gamma_A > \Gamma_B > \Gamma_C$, and (*c*) $\Gamma_C > \Gamma_A > \Gamma_B$. In case (*c*) (Fig. 3) the introduction of a narrow band of A should lead almost to cessation of reaction from right to left. In cases (*a*) and (*b*) the reverse reaction will be more strongly inhibited the larger the absolute difference $\Gamma_B - \Gamma_C$. This possibility of carrying out reversible reactions in one direction under chromatographic conditions was pointed out in Ref. 39, and has since been confirmed experimentally[40,41].

Magee[42] considered a reaction of type A ⇌ B + C under conditions such that its progress was limited solely by the equilibrium constant $K = c_B c_C / c_A$. He wrote down the equation of material balance, and solved it for the appropriate equilibrium condition by means of an analogue computer. He showed that with $K = 10^{-7}$ the reaction may be complete in a column 1 m long after only 17 s. It must be stressed that such large chromatographic effects, even with such small equilibrium constants, are due to the ideal character of the model, which disregards kinetic and diffusion effects. The displacement of equilibrium actually observed will always be smaller than the calculated shift.

To allow for the kinetics of a heterogeneous process with the present type of reaction under chromatographic conditions in a pulse microcatalytic reactor[27] the calculations are simplified by supposing that $\Gamma_A = \Gamma_C \neq \Gamma_B$.

Fig. 4 shows the dependence of α on the length of the layer calculated on an electronic computer. It is evident that α is significantly greater under chromatographic conditions than under dynamic conditions, but rather lower than for an irreversible reaction.

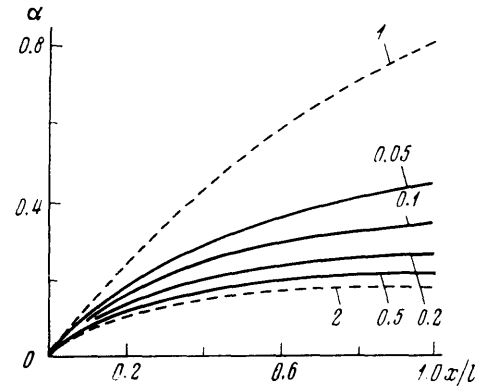

Figure 4. Dependence of degree of conversion α on dimensionless length x/l of catalyst bed for reaction of type A ⇌ B + C occurring under chromatographic conditions for different pulse widths τ_0 (numerals on full curves): 1) irreversible reaction; 2) flow-type reactor.

Hitherto we have been considering a single introduction of A into the microcatalytic reactor. However, if an attempt is made in the future to exploit in some measure the above chromatographic effects to develop a new technical process, the question should, of course, be raised of the possibility of introducing many such pulses into the reactor and of the interaction on the catalyst bed between bands from different pulses. Roginskii and Rozental'[43] tried to assess these effects by using an electronic computer to obtain calculated curves showing the dependence of α on length of bed for different durations of pulse and different intervals between their introduction. In all cases in such a cyclic process α reaches a maximum value in a reactor having an optimum bed length l_{opt}. The yield of reaction products could be increased by the chromatographic effects with a specified supply of starting material to the dynamic reactor and to the microcatalytic reactor.

When calculated values are compared with experimental results it must be borne in mind, however, that the kinetics of adsorption and diffusion were neglected in the above theoretical analysis of reactions of type A ⇌ B + C. In several cases these effects may be significant.

The reality of the chromatographic effects has been confirmed in several investigations. In a typical chromatogram (Fig. 5) obtained directly after the microreactor for the dehydrogenation of cyclohexane $C_6H_{12} \rightleftharpoons C_6H_6 + 3H_2$ on a platinum–alumina catalyst[40,44] the peaks due to cyclohexane and to benzene are clearly separated. Since an argon ionisation detector[3], was used, which was very insensitive to molecular hydrogen, the latter was not detected on the chromatogram. Comparison of the curves for the dehydrogenation of cyclohexane under

chromatographic conditions with the equilibrium curve and with the curve obtained in a dynamic reactor showed that chromatographic conditions raised the yield of benzene significantly above the equilibrium value. Matsen et al.[41] have since shown that chromatography can be applied to this system. The presence of chromatographic effects has apparently been recorded also in several other experimental investigations[45,46], in which study of the kinetics of the processes was not a matter of special concern.

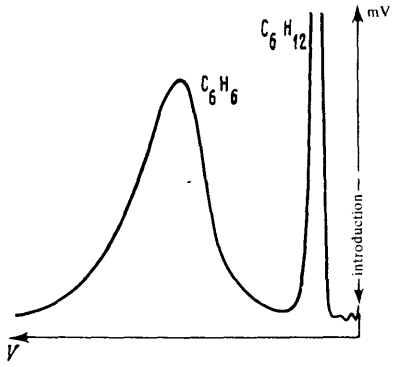

Figure 5. Chromatogram for the dehydrogenation of cyclohexane to benzene on a platinum–alumina catalyst.

2. Reaction of Type A ⇌ 2B

It has recently been shown[47] that reactions of the present type may also be influenced by chromatographic effects, although this cannot now be attributed to the spatial separation of molecules of the products on the bed of the microcatalytic reactor. Numerical calculations have again confirmed an increase in yield in the microreactor in comparison with the dynamic reactor, the difference gradually diminishing with increase in pulse width.

The increase in yield in this class of heterogeneous reactions is due to blurring of the product band resulting from the difference in adsorption coefficients between starting material A and reaction product B. This is entirely analogous to the above blurring of the product band for a first-order reaction. Nevertheless, the nature of the change in the yield occurring under non-stationary conditions in the present case is concealed in the differences between the adsorption coefficients Γ_A and Γ_B. When $\Gamma_A = \Gamma_B$, the effect should disappear.

Under the influence of diffusion the yield of the product may be higher than under stationary conditions even when $\Gamma_A = \Gamma_B$.[30] Since diffusion does not affect the rate of a first-order reaction, but diminishes the rate of reactions of higher order, the rate of the forward reaction will remain unchanged in the present case, whereas that of the reverse reaction ($n = 2$) will decrease. The yield of products B will therefore be higher than at equilibrium.

3. Consecutive Reactions

The main conclusion of the first kinetic analysis of a series of models of consecutive reactions[47] was that chromatographic effects could change significantly the selectivity of the catalytic process in comparison with a dynamic régime. For example, in both the reaction types

$$A \rightarrow B \rightarrow R \qquad R \rightarrow B \rightarrow S \quad (a)$$
$$A \rightarrow R \qquad 2R \rightarrow S \quad (b)$$

the yield y_R of the intermediate product R with a microcatalytic reactor might exceed tenfold the yield in a dynamic reactor. The yield y_R increases with decrease in the width of the entering pulse, since decrease in pulse width intensifies chromatographic effects.

These conclusions[47] were qualitatively confirmed by experimental investigations[48] on the cracking of cumene on an aluminosilicate catalyst in the microreactor. With a sufficiently narrow input peak of cumene yields of benzene exceeded the equilibrium values. The yield increased also when the microcatalytic bed was lengthened. By extrapolating the dependence of α on pulse width to zero, the reverse reaction (alkylation) can be neglected, and the rate constant can be calculated for the forward cracking reaction.

Cracking was accompanied by the disproportionation of cumene with the formation of di-isopropylbenzene[48]. The latter could occur in two possible ways:

$$\text{Cumene} + \text{Propene} = \text{Di-isopropylbenzene} \quad (c)$$
$$2\,\text{Cumene} = \text{Di-isopropylbenzene} + \text{Benzene} \quad (d)$$

In the case of reaction (c) a narrower pulse should give a lower yield of di-isopropylbenzene, since cumene and propene would then be more effectively separated. Since increasing the width of the sample has no effect on the yield of di-isopropylbenzene, it was concluded that catalytic disproportionation takes place in conformity with equation (d).

4. Reactions of Type A ⇌ B + C under a Chromatographic Régime

We have been considering the possible chromatographic effects under isothermal conditions of pulse developmental gas-adsorption chromatography. However, chromatographic separation can be accomplished in several ways[3], e.g. thermal displacement with a constant temperature field[49], chromathermographic[15], with a programmed rise in temperature[3], etc.

Let us consider, for example, the progress of the reaction A ⇌ B + C under the conditions of stationary chromathermography[50] suggested as long ago as 1950 to 1951 by Zhukhovitskii and Turkel'taub[51]. The essence of the method is that a band of material is moved along the bed of the stationary phase not only by a stream of carrier gas (as in the developmental form) but also by the simultaneous action of a moving temperature profile. This is usually accomplished by moving along the layer, in the same direction as the carrier gas, a furnace with a negative temperature gradient (i.e. a furnace in which the temperature is gradually raised will be advanced towards the bed at a speed w_n). The substance A introduced

orig inally into the microcatalytic reactor will be displaced along the charge, at a rate w_A inversely proportional to Γ_A, at the initial (low) temperature of the microreactor. No reaction will yet occur. During this initial period $w_n > w_A$, so that the band of A will gradually move into a region of higher and higher temperatures, which will accelerate its motion owing to the fall in Γ_A with rise in temperature.

At a certain "characteristic" temperature T_{char} the band of A will move along the layer at the same speed as the furnace. Zhukhovitskii and Turkel'taub showed that, under the conditions of stationary chromathermography, this temperature depends on the heat of adsorption Q_A and the linear rate of flow u of the carrier gas:

$$T_{char} = \frac{Q_A}{R \ln \frac{w_n}{u}} \quad (30)$$

At a given ratio w_n/u the characteristic temperature may be relatively low, and the reaction A ⇌ B + C will not take place. At a certain ratio w_n/u the characteristic temperature may be higher than the temperature T_{str} at which reaction begins. Migration of the band of A will then be accompanied by the formation of B and C, which will converge into zones corresponding to thei. characteristic temperatures $T_{char,B}$ and $T_{char,C}$. These features make chromathermography extremely promising for the attainment of considerable chromatographic effects. It must be emphasised that the reverse reaction C + B → A can be completely suppressed not only by the spatial separation of B and C on the bed in the microcatalytic reactor, as in the case of the isothermal pulse method, but also by the localisation of at least one of the products B or C (or their mixture) in a low-temperature zone. Thus even a reaction of type A ⇌ B can be conducted in one direction in a chromathermographic microcatalytic reactor.

Use of a chromathermographic microcatalytic reactor is sometimes advisable also because it always involves compression of the bands. Because a negative temperature gradient is present the front of the band, being situated in a cold region, moves more slowly than the rear portion, located in a hotter part of the bed. Since compression of the band entails an increase in concentration in the reaction zone, reactions above the first order must be expected to occur at higher rates than under isothermal conditions. In particular, reactions in which the products have smaller adsorption coefficients than the starting material, e.g. most cracking reactions, can be advantageously accomplished under such a régime.

A "thermal displacement" method can also be used in the absence of a stream of inert carrier gas[49]. Theoretical analysis shows[50] that movement of the furnace along the reactor causes the individual bands of starting materials and products to be situated along the catalyst bed in order of decreasing adsorption coefficients: i.e. the most sorbable substance will be "pressed" closest to the edge of the furnace, this will be followed by a less sorbable substance, and so on. In the case of the reaction A ⇌ B + C with $\Gamma_A > \Gamma_B > \Gamma_C$, for example, substance A will be converted, in the reaction zone adjacent to the furnace, into B and C, which will be removed continuously into the cold zone as adjacent bands of the pure substances. In this way a reversible reaction can be conducted in one direction.

The above considerations show that we are only at the very beginning of the study and the use of chromatographic effects in catalysis. There are grounds for supposing that further work on these lines will open up new prospects.

V. REACTIONS IN MICROREACTOR WITH A LANGMUIR ADSORPTION ISOTHERM

Above we have been considering reactions in the linear Henry range. The Japanese workers Hattori and Murakami[52] have discussed the kinetics of certain model reactions occurring in a microcatalytic reactor with Langmuir adsorption isotherms.

The equation of material balance for the ith component is written

$$\frac{\partial c_i}{\partial t} + q_{max.} \frac{\partial \theta_i}{\partial t} + u \frac{\partial c_i}{\partial t} + w_i = 0 \quad (31)$$

where q_{max} is the quantity of substance adsorbed when the surface is completely covered, θ_i the fraction of the surface occupied by the ith component, and w_i the rate of formation of this component. When equilibrium is established rapidly, the expression for θ_i has the usual form

$$\theta_i = \frac{\Gamma_i c_i}{1 + \sum_{i=1}^{n} \Gamma_i c_i} \quad (32)$$

where Γ_i is the adsorption coefficient of the ith substance. If adsorption equilibrium is reached slowly, equations of type (31) must be solved together with the kinetic equation

$$q_{max} \frac{\partial \theta_i}{\partial t} = w_{ai} + w_i \quad (33)$$

in which

$$w_{ai} = k_i^a \left\{ \left(1 - \sum_{i=1}^{n} \theta_i \right) c_i - \frac{\theta_i}{\Gamma_i} \right\} \quad (34)$$

and initial and boundary conditions are identical with those considered above for a linear isotherm.

The set of equations obtained after the introduction of dimensionless variables was solved by numerical methods for certain specific schemes.

1. Reaction A → R with Rapid Establishment of Adsorption Equilibrium

The dependence of the degree of conversion α on the length of bed was calculated in this case for different values of the parameter $\tau_0 = T/t_R$. Since T is the time of introduction of the pulse, and t_R the retention time of the initial substance, τ_0 is the dimensionless sample width.

It was found that α decreases with increase in τ_0, and reaches a minimum value as $\tau_0 \to \infty$, which corresponds to a flow-type reaction vessel. This result is easily explained by inhibition effects, which, of course, decrease with fall in concentration in the reaction zone. Blurring caused by the non-linearity of the adsorption isotherm is more marked and the degree of conversion is greater the smaller is τ_0. The difference between pulse and flow methods is due mainly to the decrease in concentration in the reaction zone.

2. Reaction A ⇌ R with Rapid Establishment of Adsorption Equilibrium

In this case, too, the degree of conversion is greater for the microcatalytic than for the dynamic reactor, owing to the diminished concentration resulting from blurring of the band. However, α cannot exceed the equilibrium degree of conversion, since blurring accelerates forward and reverse reactions to the same extent.

3. Reaction A ⇌ R + S with Rapid Establishment of Adsorption Equilibrium

For simplicity the case was considered [52] in which $\Gamma_A = \Gamma_S$ and $\Gamma_R = 0$. The degree of conversion in the microcatalytic reactor was shown to be lower than for the irreversible reaction A → R + S but considerably higher than for the reversible reaction A ⇌ R + S in a flow-type reaction vessel. The increase in α is due not only to a decrease in concentration in the pulse but also to chromatographic separation. Therefore the degree of conversion in the microcatalytic reactor increases with decrease in the width of the input pulse.

4. Reaction A → R with Slow Establishment of Adsorption Equilibrium

Differences between processes occurring in the microcatalytic reactor and the process in a dynamic reactor are still more clearly developed in this case, owing to the diminution in concentrations resulting from blurring of the peak and also from the difference in the initial surface coverage. In the microreactor the catalyst surface is unoccupied before the reactant is introduced, so that the rate of adsorption at the front of the band is high, as the denominator in the Langmuir equation is close to unity.

Since coverage in the first cross-section of the catalyst bed increases exponentially with pulse length, conditions can be selected [52] under which the difference in surface coverage between the pulse method and stationary conditions becomes insignificant. For "thin" pulses, however, the differences are very substantial.

Sadovnikov and Kislyuk note [53] that different conditions obtain in the pulse method and in the steady state when the catalytic reaction takes place at low surface coverage $\theta \ll 1$. Under stationary conditions this requires that $k^a < k^d$, but under pulse conditions small values of θ arise from the usual introduction of such a small quantity of starting material into the reactor that only a small part of the catalyst surface can be covered even on complete adsorption. Therefore the first order may be observed in the pulse method, but a fractional or even zero order under flow conditions.

Coverage of the portion of the catalyst bed on which the pulse is located depends also on k^a and k^d. It can be imagined that, when these constants are large (but equilibrium may still not be reached), the whole pulse is grouped on a very tiny part of the layer, where coverage is large. However, the situation described in Ref. 53 is also entirely possible. Unfortunately, to allow for all these factors quantitatively is quite a complicated task, since no analytical solution (even approximate) of the problem has been obtained, and the numerical calculations have been insufficiently detailed. A characteristic feature of this case would probably be variation in the order of the reaction with the volume of the sample at a constant initial concentration.

VI. KINETICS OF REACTIONS IN MICROREACTOR ON NON-UNIFORM SURFACES

Roginskii and Rozental' [54] analysed processes occurring on non-uniform surfaces (with respect to adsorption and catalytic properties) inside a microreactor. The equation

$$\frac{\partial\theta_A}{\partial t} = k_A^a c_A(1-\theta_A) - (k + k_A^d)\theta_A \qquad (35)$$

where θ is the relative coverage of active centres, applies to a group of sites having the same adsorption and catalytic properties. Applying the theory of catalytic processes on non-uniform surfaces [55], these workers obtained formulae for the quantity of substance adsorbed and the rate of the heterogeneous reaction. These enabled in principle equations for the form of elution curve of reactant A to be deduced from a known distribution function of sites with respect to adsorption and desorption rate constants $\rho(k_A^a, k_A^d)$. Analogous relations can be found also for the product B. Since a general solution of these equations presents considerable mathematical difficulty, certain particular cases were considered, for which quite simple expressions were obtained.

At low partial pressures (when $\theta_A \ll 1$), for example, the effect of non-uniformity for any distribution function $\rho(k_A^a, k_A^d)$ is merely to introduce an effective reaction rate constant calculated by means of the equation

$$k_{eff} = N_0 \int\int \frac{kk_A^d}{k_A^d - k}\rho(k_A^a, k_A^d)\,dk_A^a dk_A^d \qquad (36)$$

where N_0 is a constant depending on the number of active centres per unit surface, the specific surface, the density, and the porosity of the catalyst. An equation was obtained [54] enabling k_{eff} to be calculated from the measured quantity of unchanged substance $G(l)$, provided that the diffusion coefficient D was determined by an independent method. With low values of D the usual expression is obtained for a first-order reaction with a rate constant k_{eff} allowing for surface non-uniformity:

$$G(l) \quad G_0\exp-\left(\frac{k_{eff}l}{u}\right) \qquad (37)$$

Several other limiting cases were examined [54]. When adsorption equilibrium is established on every adsorption site, for example, the equations obtained have the same form as those for uniform surfaces. All the differences are covered by replacing the Henry coefficient and the rate constant of the heterogeneous reaction by integrated mean values for the non-uniform surface. Thus, with a known distribution function and a specified functional variation $k = k(\Gamma)$, the relations obtained for a uniform surface are easily generalised to apply to a non-uniform surface. The above cases by no means completely describe the processes occurring on non-uniform surfaces in a microcatalytic reactor. Future theoretical developments will probably enable the character of the surface non-uniformity with respect to adsorption and catalytic properties to be determined from the shape of the peaks of starting material or product measured under various experimental conditions.

VII. USE OF MICROREACTOR FOR DETERMINATION OF RATE CONSTANTS OF INDIVIDUAL PATHS IN COMPLICATED REACTIONS

It is clear from the above discussion of the kinetic features of the pulse method for studying catalytic reactions that quantitative analysis is at present possible only for relatively simple reactions. Detailed examination of the kinetics of complicated systems is as yet an unsolved problem. Nevertheless, even in this case, the use of a microcatalytic reactor may yield valuable information on the individual paths of a complex process. We shall confine the present Section to an analysis of the simplest cases of first-order reactions with rapid establishment of adsorption equilibrium and a linear adsorption isotherm.

The kinetics can be described approximately by the set of equations for steady-state operation of the reactor.

Before describing examples of the use of a microcatalytic reactor in investigating complicated catalytic reactions, let us consider briefly certain general aspects of the elucidation of formal kinetics from experimental data. Hitherto it has not been entirely clear [56-62] under what conditions all the paths of a complicated reaction can be determined with sufficient accuracy and the constants of individual transitions calculated from data obtained when all the processes in the system are occurring simultaneously. The main difficulty in the choice of the most probable mechanism for a complicated reaction is [58] that experimental errors do not permit differentiation between models yielding not greatly different calculated results. The position is considerably eased if statistical planning of the experiment [63] is used, but even then an unambiguous assessment of the adequacy of a model cannot always be expected.

The microcatalytic reactor has been used [64] to study the oxidative dehydrogenation of isopentenes to isoprene

$$2C_5H_{10} + O_2 \rightarrow 2C_5H_8 + 2H_2O \qquad (38)$$

on an iron–zinc–chromium oxide catalyst. The following assumptions were made on the basis of preliminary experiments and published information: (1) reaction (38) is irreversible, of first order with respect to the alkenes, and of zero order with respect to oxygen when it is in excess; (2) further oxidation to carbon monoxide and dioxide does not take place under the experimental conditions; and (3) isomerisation of the alkenes is described by a first-order equation. The above hypotheses are satisfied by the scheme in Fig. 6, which can be described by a linear set of equations.

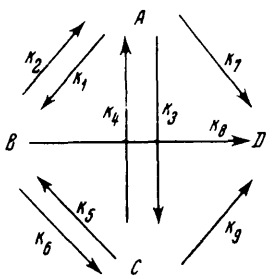

Figure 6. Scheme of interconversion in the oxidative dehydrogenation of isopentenes: A) 3-methylbut-1-ene; B) 2-methylbut-1-ene; C) 2-methylbut-2-ene; D) isoprene.

The initial rates wA, wB, wC, and wD were determined graphically [64] by differentiating the initial portions of the rate curves obtained for each set of compositions. Initial mixtures were prepared with compositions corresponding to the planning matrix of the complete factorial experiment [63]. Using as a first approximation the constants obtained by planning the experiment, more accurate values were found from the condition that differences between calculated and experimental partial pressures should be minimal. The values were refined from the experimental kinetic curves by the method of steepest descents [65]. This yielded for the rate constants (in s^{-1}) the values

$$k_5 = 12.8 \pm 0.4; \quad k_6 = 5.5 \pm 0.2;$$
$$k_7 = 0.7 \pm 0.2; \quad k_8 = 3.7 \pm 0.2;$$
$$k_9 = 1.1 \pm 0.1.$$

The values of k_1–k_4 in Ref. 64 were small. Since equating each of the constants to zero produced only an insignificant change in the calculated concentrations, it was impossible to determine their exact values. It was established, however, that $k_3 > k_1 > k_2 > k_4$. Additional kinetic experiments with the pure isomers were necessary in order to establish this sequence.

A microcatalytic reactor has been used also [66] to study the oxidative dehydrogenation of pentenes under conditions such that further oxidation of the pentenes and of isoprene also occurred. A set of differential equations was written on the above hypotheses that all reactions were of the first order, and these were solved by two methods—approximate integration by means of Simpson's formula [67] and numerical integration on an M20 computer—the rate constants being so chosen that concentrations calculated on the electronic computer approached as closely as possible to the experimental values. Good agreement was obtained between results obtained by the two methods.

VIII. USE OF MICROREACTOR AND RADIOCHROMATOGRAPHY FOR STUDY OF COMPLICATED CATALYTIC CONVERSIONS

Mathematical models evidently do not always give a clear and reliable criterion for distinguishing between particular schemes for a complicated process. The additional information usually employed for sifting certain hypothetical schemes is extremely useful. In order to select the most probable reaction scheme we must investigate the agreement between the chosen model and experiment with a wide variation in the experimental parameters. In this respect broad possibilities are opened up by combining the microcatalytic reactor with radiochromatography. The first attempt to do this was made in the fundamental work by Emmett and his coworkers [1]. However, these workers were unable to make any quantitative estimates of rates. Significant progress can be made by combining the microcatalytic reactor with the kinetic isotope method, which was suggested by Neiman more than fifteen years ago [68-70].

This latter combination of methods was first applied by Roginskii et al. [71-75] in studying the oxidative dehydrogenation of butenes to butadiene. The possible reactions can be represented by Fig. 7, in which [A]–[D] are the concentrations and α–δ the specific radioactivities of but-1-ene, *trans*-but-2-ene, *cis*-but-2-ene, and butadiene respectively. Three series of experiments were made by introducing into the microcatalytic reactor mixtures of two components of specified chemical and radiochemical composition—(I) butadiene + *cis*-[^{14}C]but-2-ene, (II) but-1-ene + *cis*-[^{14}C]but-2-ene, and (III) but-1-ene + *trans*-[^{14}C]but-2-ene—by the method of impinging pulses [75]. The concentrations of A–D and the specific radioactivities α–δ were determined by radiochromatographic analysis [76-78].

If all stages of the scheme had been reversible, the specific radioactivity of *trans*-but-2-ene would have been given by [70]

$$\frac{d\beta}{d\tau} = \frac{\delta-\beta}{[B]} w_{D-B} + \frac{(\gamma-\beta)}{[B]} w_{C-B} \frac{(\alpha-\beta)}{[B]} w_{A-B} \qquad (39)$$

where w_{D-B}, w_{C-D}, and w_{A-B} are the rates of conversion of butadiene, *cis*-but-2-ene, and but-1-ene respectively into *trans*-but-2-ene. Experiment showed that $d\beta/d\tau \simeq 0$. Further, it can be assumed with a certain approximation that $\gamma - \beta \simeq 0$ and $\alpha - \beta \simeq 0$. Since $\delta - \beta \neq 0$, Eqn. (39) is valid only when

$$w_{D-B} = 0;\ w_{D-A} = 0;\ w_{D-C} = 0$$

i.e. hardly any butene was formed from butadiene in the above experiments.

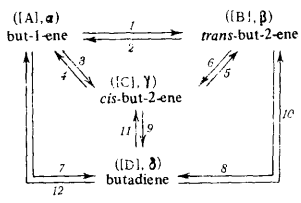

Figure 7.

Experiment showed that $w_{C-D} > w_{C-A}$. The variation in specific radioactivities found experimentally indicates that *trans*-but-2-ene and butadiene obtained from *cis*-[^{14}C]but-2-ene are diluted with but-2-ene and butadiene formed from but-1-ene:

$$\frac{d\beta}{d\tau} < 0 \qquad (40) \qquad\qquad \frac{d\delta}{d\tau} < 0 \qquad (41)$$

It was shown that butadiene was diluted considerably more strongly. Hence it follows that

$$w_{A-D} > w_{A-B}$$

Inspection of the curves obtained for series (III) indicated that the *cis* → *trans* isomerisation was more rapid than the reverse process:

$$w_{C-B} > w_{B-C} \qquad (42)$$

and also that

$$w_{C-D} > w_{B-D} \qquad (43)$$

Experiments were made with ternary systems (but-1-ene + *cis*-[^{14}C]but-2-ene + butadiene) in order to determine the immediate precursors of butadiene. The specific radioactivity of butadiene has a maximum value, which is lower than the specific activity of *cis*-[^{14}C]but-2-ene at time τ_{max}:

$$\delta_{\tau_{max}} < \gamma_{\tau_{max}} \qquad (44)$$

This implies that *cis*-but-2-ene is not the sole precursor of butadiene in the system. The ratio $\gamma\tau_{max}/\delta\tau_{max}$ indicated that the rate of formation of butadiene from but-1-ene was about double the rate from *cis*-but-2-ene:

$$w_{A-D} \approx 2w_{C-D} \qquad (45)$$

Radiochromatography has been combined with a microcatalytic reactor in order to estimate the six rate constants for the interconversion of but-1-ene, *cis*-but-2-ene, and *trans*-but-2-ene on an aluminosilicate catalyst [79].

A microcatalytic reactor has been combined with radiochromatography to study the oxidative dehydrogenation of butenes on a bismuth–molybdenum catalyst, the results being processed on an electronic computer [80]. Finding the kinetic constants encountered considerable difficulty owing to the simultaneous occurrence under the experimental conditions of nine separate reactions of isomerisation and mild oxidation, as in the study of the oxidative dehydrogenation of isopentenes (Fig. 6). The kinetics of oxidative dehydrogenation could be represented by a set of differential equations. Statistical planning of experiments [63] and non-linear programming [81] were also used. The preliminary values of the constants calculated by this method were then refined [80] using Neiman's kinetic isotope method and a microcatalytic reactor.

Rate constants for the conversion of stable compounds are determined in the kinetic isotope method by the simultaneous solution of the material balance equations of the reactants in terms of concentration and radioactivity. If the complete reaction scheme has been chosen correctly, the rate constants obtained should describe accurately the variation in the specific activities of the products with time.

If the specific radioactivities of but-1-ene, *trans*-but-2-ene, *cis*-but-2-ene, and butadiene are denoted by α, β, γ, and δ (Fig. 7), it can be shown by Neiman's method that the variation in the specific radioactivities of these hydrocarbons is represented by the equations

$$\frac{d\alpha}{dt} = \frac{1}{[A]}\{k_4[C](\gamma - \alpha) + k_2[B](\beta - \alpha)\} \qquad (46)$$

$$\frac{d\beta}{dt} = \frac{1}{[B]}\{k_1[A](\alpha - \beta) + k_5[C](\gamma - \beta)\} \qquad (47)$$

$$\frac{d\gamma}{dt} = \frac{1}{[C]}\{k_3[A](\alpha - \gamma) + k_6[B](\beta - \gamma)\} \qquad (48)$$

$$\frac{d\delta}{dt} = \frac{1}{[D]}\{k_7[A](\alpha - \delta) + k_8[B](\beta - \delta) + k_9[C](\gamma - \delta)\} \qquad (49)$$

Comparison of experimental and calculated specific radioactivities of products of oxidative dehydrogenation at 396°C (for the series but-1-ene + *cis*-[^{14}C]but-2-ene).

Time of contact, s	But-1-ene		*trans*-But-2-ene		*cis*-But-2-ene		Butadiene	
	expt.	calc.	expt.	calc.	expt.	calc.	expt.	calc.
0.0065	9.4	9.4	92.0	92.0	155	155	20.0	20.0
0.0090	11.0	12.7	93.0	93.0	151	152	30.0	32.8
0.0118	15.0	16.3	94.0	95.2	149	149	39.0	42.8
0.0144	17.5	19.5	94.5	97.0	145	146	48.0	50
0.0190	23.0	25.0	96.0	98.0	140	141	58.5	59.6

These were solved together with the equations of material balance, and the rate constants were calculated with an electronic computer from the condition that the calculated curves for the variation in concentrations and specific activities with time should be close to the experimental curves. The Table shows agreement between experimental and calculated values of the specific activities of the components for various contact times.

Rate constants determined by means of a microcatalytic reactor combined with Neiman's kinetic isotope method were given [80] for the individual reaction paths in the oxidative dehydrogenation of butenes to butadiene. The dehydrogenation of but-1-ene was the most rapid (especially at low temperatures). At high temperatures the oxidative dehydrogenation of *cis*- and *trans*-but-2-enes also becomes appreciable.

A promising approach was shown [80] for combining computer processing of kinetic curves obtained by means of a microcatalytic reactor with continuous checking of the results by radiochromatography. This makes calculation of the constants less formal, and also reduces considerably the volume of laborious and complicated isotopic experiments.

IX. PULSE METHOD FOR STUDY OF POISONING OF CATALYSTS

The poisoning of catalysts by various poisons is usually studied with the aim of obtaining information on the number and nature of the active centres. Pulse methods have recently begun to be used to study poisoning [82,83]. This usually involves introducing, into a stream of an inert carrier gas entering the reactor at the reaction temperature, a fixed dose of the poison, which is adsorbed on the catalyst surface. After this the activity of the poisoned catalyst is studied, also by a pulse method. This method of study was probably first applied to the dehydrogenation of butane to butenes and butadiene [7]. Turkevich et al. [82] introduced several successive doses of the poison into the reactor in order to study the dependence of the activity of the catalyst on the dose. However, it then emerged [83] that under pulse conditions catalyst poisoning is a transient process, and therefore irreproducible results may be obtained. The method was subsequently developed by Romanovskii, Topchieva, and their coworkers [83-85].

Until recently no theoretical examination had been made of poisoning in a pulse reactor. Romanovskii [86] pointed out that, for non-linear laws of poisoning, not only the quantity of poison absorbed by the catalyst surface but also its distribution along the bed are significant.

A quantitative theory of the pulse poisoning of catalysts has recently been developed [87,88] taking into account the adsorption characteristics of the poison. Two types of centres are supposed to be present on the catalyst surface. A first-order heterogeneous catalytic reaction takes place on the first group of centres; the starting material may be adsorbed reversibly on the second group, but this does not involve any reaction. It is assumed also that the poison is adsorbed considerably more firmly than the initial substance, and that adsorption of the poison is described by the Langmuir equation.

On the basis of the above model, equations were obtained for the time variation of catalytic activity after introduction of the poison. With reversible adsorption of the poison, the activity of the catalyst first falls, reaches a minimum value, and then gradually increases to the original level. The initial fall in catalytic activity is due to the fact that the poison is located entirely on the catalyst bed. The chromatographic band of the poison is blurred, and its molecules are redistributed between catalytic and adsorption centres. When the poison band reaches the outlet from the reactor, the activity of the catalyst increases, to reach its original value when the last poison molecules leave the reactor.

With an exponential law of poisoning the descending portions of the curves can be represented by the equation

$$\frac{A_g}{A_0} = y + 1 - (\sqrt{\mu} + \sqrt{y})^2 + \int_{y}^{(\sqrt{\mu}+\sqrt{y})^2} \exp - \nu_k \frac{\beta\left(\sqrt{\frac{z}{y}} - 1\right)}{1 + \beta\left(\sqrt{\frac{z}{y}} - 1\right)} dz \qquad (50)$$

and the ascending portions by the formula

$$\frac{A_g}{A_0} = y + \int_{y}^{1} \exp - \nu_k \frac{\beta\left(\sqrt{\frac{z}{y}} - 1\right)}{1 + \beta\left(\sqrt{\frac{z}{y}} - 1\right)} dz \qquad (51)$$

where $A_0 = \lg(1 - \alpha_0)^{-1}$ is the initial activity of the catalyst, α_0 the degree of conversion of the reactant before introduction of the poison, A_g the activity of the poisoned catalyst, $y = t/t_{max}$ the dimensionless time, t the time, t_{max} the time of complete regeneration of the catalyst, $\mu = m_0/q_{max}$ the reduced dose of poison, m_0 the quantity of poison introduced into the reactor, q_{max} the quantity of poison required for a monolayer, b_K the adsorption coefficient of the poison on the active centres, b the mean adsorption coefficient of the poison on catalytic and adsorption centres, and ν_K the number of poison molecules which can be adsorbed on one active centre in the catalyst surface.

The position of the minimum y_{min} in the experimental dependence of the relative activity of the catalyst on the dimensionless time can be used to determine q_{max}:

$$q_{max} = \frac{m_0}{(1 - \sqrt{y_{min}})^2} \qquad (52)$$

The mean adsorption coefficient of the poison b is determined from the time of complete regeneration of the catalyst:

$$b = \frac{v \cdot t_{max}}{q_{max}} \qquad (53)$$

where v is the space velocity of the carrier gas. Furthermore, the most probable law of poisoning can be selected from a comparison of calculated and experimental results, and the ratio of the adsorption coefficients β determined. The adsorption coefficient of the poison on the active centres is then found from the simple relation

$$b_k = b\beta \qquad (54)$$

The above theory of pulse poisoning has been verified in a study [88] of the poisoning by pyridine of an aluminosilicate catalyst for the cracking of cumene. Values of b and q_{max} calculated from the time variation of activity during poisoning were compared with direct measurement of the adsorption of the poison on the catalyst under the same conditions. Satisfactory agreement was obtained.

---oOo---

The information reviewed above shows that the pulse chromatographic method can be successfully applied to the solution of many problems in the field of catalysis. The range of application of the method has been continuously extended as the theory of the method has been improved. It must be borne in mind, however, that, since the method is transient, difficulties inevitably arise in processing the measurements, especially in the case of non-linear adsorption isotherms.

An attempt to avoid these difficulties led to a second form of the pulse method, in which a broad rectangular pulse, whose front and rear edges are as sharp as possible, is introduced into a relatively small reactor [89]. The idea is that, by introducing a "wide" pulse, it can be assumed that adsorption–chemical equilibrium is established, and the process can be regarded as stationary–microdynamic.

The results can now be processed by methods adopted in work with a flow-type reactor. When the properties of the catalyst vary slowly with time, it is possible to examine the effect of the reaction medium on the properties of the active surface. A weak point in the method is some arbitrariness in the choice of pulse width, which must correspond to the rate of establishment of adsorption–chemical equilibrium. However, it is not always a simple matter to estimate the rate of adsorption and desorption during catalysis. In particular, such a method may lead to errors in the case of slow irreversible chemisorption on the layer of catalyst. It must be remembered that the use of wide pulses is suitable mainly in work with low concentrations of the starting material, since, when a wide pulse with a high partial pressure of the starting material is introduced into the microreactor, it can no longer be always assumed that the properties of the catalytic surface remain unchanged during passage of the pulse along the catalyst bed.

A significant advance is the recently proposed[90] gradient free pulse method, in which the pulse of reactant is introduced into a microreactor containing a pseudo-fluidised bed of the catalyst. This has the advantage over the preceding method that, because of the absence of gradients, the reaction velocity can be measured directly under specified experimental conditions. However, this method is not free from the defects inherent in the above "microdynamic method"—those involving the choice of sample size and the need to work with low concentrations of the starting material.

In the present paper we have wanted to show that the theory of transient processes occurring under pulse conditions has recently been undergoing vigorous development. Such development has been stimulated by the great opportunities for pulse methods in the study of the kinetics and the mechanism of transient processes.

The chromatographic technique will yield information which it is sometimes impossible to obtain by traditional methods. In our opinion it is not necessary to strive to replace stationary by pulse methods. These methods should be used to solve different problems, supplementing each other.

Advances in the Coordination Chemistry of Azoles

A.D.Garnovskii, O.A.Osipov, L.I.Kuznetsova, and N.N.Bogdashev

A systematic account and review of the literature on complexes of azoles is given. Particular attention has been devoted to the problem of the location of the coordinate bond in the azole molecule, competitive coordination in ambident azole-containing systems, elementotropism in a series of *N*-element derivatives of azoles, and the polyhedral forms of chelate complexes in the azole series.
The bibliography includes 508 references.

CONTENTS

I. Introduction	89
II. Molecular complexes of azoles	89
III. *N*-metal and *N*-element derivatives of azoles	97
IV. Chelate complexes in the azole series	99

I. INTRODUCTION

In 1958 Dorothy Hodgkin's group summarised[1] the results of almost ten years work on the elucidation of the structure of vitamin B_{12} for which the Nobel Prize was subsequently awarded. The authors established that, in contrast to nucleic acid nucleotides, in the B_{12} nucleotide the base (skeleton) is not a purine or pyrimidine but the cobalt complex of 5,6-dimethylbenzimidazole[2,3]. More than anything else, this discovery[4] and also earlier data concerning the involvement of azole systems in the biochemical binding of metals (haemoglobin, cytochromes, etc.)[5] served as a powerful stimulus for the development of synthetic, physicochemical, and structural studies on metal complexes of azoles and their derivatives. This idea is confirmed by the finding that, whereas up to the end of the 1950's occasional synthetic or analytical studies were made on azole complexes[6-8], in the 1960's and the 1970's azole-containing systems began to occupy leading positions among nitrogen-containing ligands[9].

In the present review, a systematic account is given of data for different types of complexes formed by azole-containing ligands: (1) molecular complexes; (2) *N*-metal and *N*-element derivatives of azoles; (3) chelate complexes.

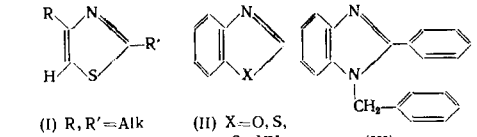
The review does not claim to give an exhaustive coverage of all data on azole complexes but it does include the main advances in the synthetic and structural chemistry of complexes of azole-containing systems during the last decade (1961–1971 and partly 1972).

II. MOLECULAR COMPLEXES OF AZOLES

The presence of several heteratoms in the quasiaromatic π system suggests that azoles can behave as polydentate ligands. Therefore the most important problem in the chemistry of the complexes of azole-containing systems is the site of the coordinate bond (competitive coordination[10]). Hitherto, this problem has not been unambiguously solved.

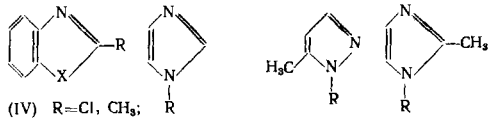
It is believed that, depending on the type of azole, metal, and reaction conditions, the coordinate bond may be located at the pyridine-type nitrogen atom [4,6,9-27], the oxygen or sulphur heteroatom [28-31], or the π system [32-36]. On the other hand, analysis of numerous literature data suggests that azoles are monodentate ligands† with a single centre where the coordinate bond is located—the nitrogen atom of the pyridine type. This conclusion has been justified not only theoretically [9] (by the finding of the maximum π-electronic charge at the pyridine nitrogen atom) but also by direct X-ray diffraction studies [36-40] and by NMR, [41] infrared [18,22,42-44], and ultraviolet [24] spectroscopy. The conclusion that transition metals may be coordinated to the oxygen atom of the oxazole ring [29,30], reached by Duff on the basis of infrared spectroscopic and magnetochemical studies of benzoxazole complexes, has little evidence to support it. Pyl's attempts [28] to account for the unusual properties of thiazolylformazan by the coordination of the metal to the sulphur atom of the thiazole ring is also unconvincing. Finally there is no rigorous evidence for the possibility of complex formation involving the π system of the azole rings: even typical π-complex forming agents, such as metal carbonyls, form with azoles predominantly σ complexes and not π complexes [9,34,35,45-48].

1. COMPLEXES OF AZOLES WITH GROUP I, II, VII, AND VIII BIVALENT METALS



The greatest number of studies have been made on the physicochemical properties and structures of the coordination compounds of monodentate azoles with metal (II) salts‡. In most cases complexes of this type are synthesised by heating the components in ethanol [49-66]. Sometimes methanol [25,26,67-69] and acetone [27,50,63,70] are used for this purpose or the azoles are fused together with metal halides [20]. However, these procedures yielded complexes containing a large number of ligand molecules. Therefore, to synthesise complexes with a low coordination number (C.N.) of the metal, the above complexes were decomposed *in vacuo* at 90–140°C. [31,55,64] The composition of the complexes varies from $MX_2.L$ to $MX_2.6L$ and depends mainly on the stoichiometry of the reactants.

The basicity (pK_a) of azoles has almost no influence on the coordination number of the metal: coordination compounds with compositions ranging from $MX_2.L$ to $MX_2.6L$ may be obtained both for imidazole ($pK_a = 7$) [9,71] and for tetrazole ($pK_a \simeq 0$). [72] Similarly in the series of *C*- and *N*-alkyl substituted pyrazoles, complexes with the composition $MX_2.nL$ ($n = 2-4$) have been obtained [23] regardless of the basicity (the pK_a varied from 4.12 to −1.96). However, in the series of benzazoles the effect of basicity on composition is fairly clear: complexes of the type $MX_2.4L$ are readily obtained for benzimidazole ($pK_a = 5.53$), [9] the less basic benzothiazole ($pK_a \simeq 2.0$) [9] forms coordination compounds having the above composition only with a limited number of metals and anions, and benzoxazole ($pK_a \simeq 1$) [9] forms complexes which do not contain more than two ligand molecules.



The metal has also little influence on the composition. Coordination compounds with the composition $CuX_2.6L$ cannot be isolated in most cases only for copper salts, although such complexes are known for imidazole [49] and its 4(5)-bromo-derivative [73].

The effect of anions and steric factors, which depend on the steric effectiveness of the ligand structure, on the composition of the coordination compounds is much more significant. Metals linked to ClO_4^- and BF_4^- show the greatest coordination capacity (complexes $MX_2.4L$ are formed), while NO_3 and NCY (Y = O, S, or Se) reduce the coordination number of the metal owing to their largely bidentate properties.

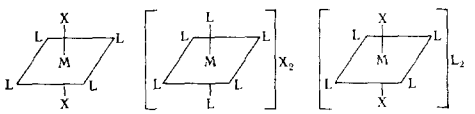
The introduction of bulky substituents into the ligand molecule reduces the number of coordinated azoles. Thus the complexes $MX_2.2L$ have been described [57,74] for alkyl-substituted thiazole (I). Benzo-analogues of azoles (II) form complexes which do not contain more than four ligand molecules even in the presence of the perchlorate anion [59,63]. On further increase of the complexity of the ligand, coordination compounds containing not more than two azole molecules are obtained, for example with 1-benzyl-2-phenylbenzimidazole (III). [75] In most cases other complexes, obtained with ligands containing in the 2-position of the azole ring substituents less bulky than the phenyl group [compounds (IV)], have the same composition [25,26,29,67,76,77].

(I) R, R′=Alk (II) X=O, S, Se, NH (III)

(IV) R=Cl, CH_3; X=O,S, NH (V) R=CH_3, n-C_4H_9 (VI) (VII) R=H, CH_3.

The above considerations concern only *C*-alkyl or *C*-aryl substituted derivatives in which the substituent gives rise to steric hindrance at the reaction centre (the pyridine-type nitrogen atom). On the other hand if the substituents are remote from the centre where the coordinate bond is located, the composition of the complexes is similar for substituted and unsubstituted azoles. This is probably the explanation of the finding that *N*-alkyl-substituted imidazoles (V) form $MX_2.6L$ complexes even in the presence of the bulky butyl substituent [44,78], while 5-methylpyrazole (VI) forms in addition [79] a complex with seven ligand molecules§. On the other hand, coordination compounds not containing more than four azole molecules have been described for 2-methylimidazole (VII, R = H) [73] and 1,2-dimethylimidazole (VII, R = CH_3). [70,80].

The type of polyhedra formed by azole complexes depends mainly on the coordination number of this metal and its electronic configuration, the nature of the anion and the ligand, and in many cases on the state of aggregation of the system. The complexes $MX_2.4L$ and $MX_2.6L$ have an octahedral structure with some distortion along the tetragonal axes due to the specific influence of the ligand and the anion.



† Azoles containing in the heterocyclic nucleus several sp^2-hybridised nitrogen atoms behave as bridge-type bidentate ligands (see below).

‡ Data for complexes of the most important azole-containing systems have been tabulated [9].

§ In the complex $MX_2.7L$ [L = (VI)], one of the ligand molecules is partly linked as a solvating species [79].

Usually, but not necessarily, coordination compounds of the type $MX_2.4L$ have a *trans*-octahedral structure (VIII). Distortion of the latter can lead to an elongated or shortened tetragonal bipyramid [81,82] and also to a tetrahedral configuration with weakly bound anions located along the tetragonal axes [68]. On the other hand, planar square polyhedra are also encountered among complexes of this type. These are characteristic of nickel [49,58,83] coordination compounds with I^-, ClO_4^-, BF_4^-, and NCS^- anions and of palladium [31] complexes with Cl^-, I^-, and NO_3^-.

The fundamental problem concerning the $MX_2.6L$ complexes is that of the octahedron formed: $[ML_6]_2X_2$ (IX) or $[MX_2L_4]L_2$ (X): [49]

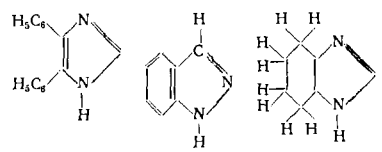
X-Ray diffraction [39,84] and spectroscopic [16,24,49,85] studies led to an unambiguous solution in favour of structure (IX) in which the metal is surrounded by six atoms of pyridine-type nitrogen. The polyhedral forms of the complexes $MX_2.2L$ are much more varied.

The electronic configuration of the metal in this type of coordination compound frequently plays a decisive role: mainly tetrahedral complexes are formed by Co^{II} (d^7) and Zn^{II} (d^{10}), planar and octahedral complexes are formed by Ni^{II} (d^8) and Cu^{II} (d^9), and only planar complexes are formed by Pd^{II} (d^8). However, this postulate cannot be regarded as valid without exception since among cobalt and zinc complexes coordination complexes are encountered with an octahedral structure [27,55] and there are tetrahedral copper and nickel complexes [19,58]. These deviations are associated primarily with the nature of the anions among which mention should be made of I, NCY (Y = O, S, or Se), and NO_3, which exhibit specific effects. When chlorine and bromine in the nickel complexes of imidazole [20], its 5-bromo-derivative [73], and benzoxazole [19] of the type $NiX_2.2L$ (X = Cl or Br) are replaced by iodine, there is a change from an octahedral to a tetrahedral coordination. On the other hand, in the 2-methylimidazole complexes the octahedron → tetrahedron transition is observed not only for nickel iodide but also for the bromide.

The replacement of chlorine and bromine by iodine frequently leads to a flattening of the tetrahedral configuration. The tetrahedron → planar square transition is characteristic of complexes of nickel halides with 1-benzyl-2-phenylbenzimidazole [75] and 2-aminobenzothiazole [86]. The structural characteristics of such complexes can be accounted for by the different degrees of polarisability of the halogens (I > Br > Cl) and their different sequence in terms of their effective contribution to the metal–ligand π-dative bond [87].

The specific effect of the NO_3^- and NCY^- groups is due to the fact that the nitrate ion frequently behaves as a bidentate ligand [88-91] and pseudohalide anions form bridge-type structures [9,10,92-95]. As a result, both anions increase the coordination number of the metal in the complexes $MX_2.2L$ to six and promote the formation of octahedral structures. The transition from tetrahedral and planar configurations to the octahedral configuration, which is frequently observed [19,50,64,81,96,97], was discussed in detail by Duff and coworkers for benzothiazole and benzoxazole complexes of transition metal nitrates [65]. The infrared and Raman spectra of these complexes show M–O bond vibration frequencies in the low-frequency region (at 270–350 cm^{-1}), which vary with the nature of the metal and the ligand. On the other hand, there have been a number of studies where it has been shown convincingly that the NO_3^- anion can also behave as a monodentate ligand. In this case, when complexes are formed with nitrate, the type of polyhedra formed by the $MX_2.2L$ coordination compounds remains the same [4,27]. Pseudohalide ions behave in the same way, since among the complexes $MX_2.2L$ containing the NCY^- anions not only bridge-type octahedral but also planar [75,76,98,99] and tetrahedral [27,63,77,100] structures are encountered. In the latter case the question of the mode of coordination of the pseudohalide ion is usually discussed and a decision in favour of the M–N bond is made for the azole complexes [27,44,63,76,77,98-100] on the basis of the generally accepted tests [9,10,92-94,101].

For the same composition, metal, and anion, it is possible to follow the influence of the fine structure of the ligand on the structure of the coordination compound. Thus, in contrast to the planar complexes of nickel thiocyanate with 2-methylbenzimidazole [76], the analogous benzimidazole complexes are octahedral [102]. Nickel chloride complexes of the type $MX_2.2L$ are tetrahedral with benzimidazole [60], while those with benzothiazole [63] and benzoxazole [19] are octahedral.

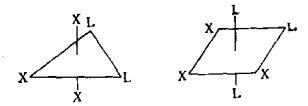


The amount of data available for the interpretation of the structures of the azole complexes of the type $MX_2.L$ and $MX_2.3L$ is much less. Depending on the electronic structure of the metal, planar (copper [31,55,63]), octahedral (nickel [20,31,61,63] and cobalt [20,55]), or tetrahedral (cobalt [20,31] and zinc [31]) configurations are attributed to complexes of the first type. Trigonal-bipyramidal [70] or polymeric-octahedral [29,57] configurations are postulated for $MX_2.3L$ coordination compounds. Rigorous proof has been obtained only for the 1,2-dimethylimidazole complex of copper(II) chloride: X-ray diffraction analysis definitely indicates a *cis*-trigonal bipyramidal structure [103]. Bearing in mind that in many cases the configuration of the complexes may alter in solution [9,104,105], the data quoted in this section must be treated with some caution. Whereas one can hardly expect a change in the form of the polyhedron on dissolution of coordination compounds of the type $MX_2.6L$ and $MX_2.4L$, the changes in the polyhedral forms of certain azole complexes of the type $MX_2.2L$ are very significant (as already shown above) [19,27,99].

The stability of the azole complexes of the type discussed above has not been the subject of systematic studies. Most data are available for the stabilities of the complexes of imidazole [106-114] and some of its derivatives [115,116]. Sklenskaya and Karapet'yants [114] determined the thermodynamic functions for the formation of complexes by bivalent copper, nickel, and cobalt ions with imidazole in aqueous solutions from measurements of the temperature variation of the instability constants in the range 10–50°C. They established that the instability constants of the imidazole complexes and the ΔH_1 vary in the sequence Cu > Ni > Co, which is the same as the Irving–Williams stability series generally adopted for nitrogen-containing ligands [117]. The ΔH_1 agree with the values found calorimetrically (7.6 kcal $mole^{-1}$ for copper and 5.8 kcal $mole^{-1}$ for nickel), the values for the imidazole complexes being significantly higher than for the ammines (5.6 kcal $mole^{-1}$ for copper and 4 kcal $mole^{-1}$ for nickel) [118].

2. COMPLEXES OF AZOLES WITH THE HALIDES AND TRIALKYL DERIVATIVE OF GROUP III ELEMENTS

With the exception of scandium coordination compounds, complexes of azoles with MX_3 (M = B, Al, Ga, In, Tl, or Sc and X = Cl, Br, I, or CH_3) are synthesised in aprotic absolute solvents [9,119-125]. The comparatively high stability of scandium halides and their complexes makes it possible to synthesise the latter in ethanol [121]. The trihalides of boron [119,126], aluminium [120,121], and gallium [9,119] and their trimethyl derivatives [119,122] form mainly 1 : 1 complexes with azoles, while the compositions $MX_3.2L$ and $MX_3.3L$ are more characteristic of the corresponding indium [9,119,123,124], thallium [125], and scandium [121] coordination compounds. This result is apparently due to the fact that a tetrahedral structure with an sp^3-hybridised metal atom is most characteristic of the boron, aluminium, and gallium complexes, while an octahedral or a trigonal-bipyramidal structure (with d^2sp^3 and sp^3d-hybridisation respectively) is typical for indium, thallium, and scandium coordination compounds [9,104,127-129].

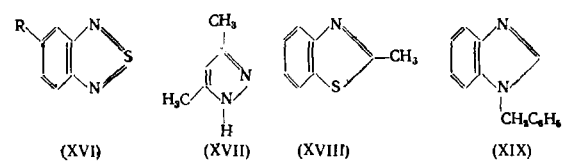


As for the azole coordination compounds with bivalent metals, the compositions of complexes of azole ligands with MX_3 depends more on the bulk than on the basicity of the ligand. Thus, whereas up to 4 (indium chloride [123]), 5 (aluminium bromide [120] and indium iodide [123]), and 6 (aluminium chloride [119,121] and scandium chloride [121]) molecules of imidazole(V), which has a relatively small bulk and a high basicity, combine with the metal halides, the number of coordinated molecules of the bulky 4,5-diphenylimidazole (XI), which has a similar pK_a, does not exceed unity for AlX_3 [9,119-121] or two for InX_3. [119,123] In the series of benzimidazole, pyrazole, and indazole (XII) derivatives, the basicity decreases while the composition remains unchanged ($InX_3.3L$). [123]

(XI) (XII) (XIII)

On the other hand, the increase of the basicity of certain imidazole derivatives with analogous structures is accompanied by an increase of the number of coordinated ligand molecules in the complex. Depending on the reactant ratio, aluminium bromide [120] and chloride [121] and scandium chloride [121] can combine with up to five molecules of tetrahydrobenzimidazole (XIII), while in the complexes with benzimidazole (IV, X = NH, R = H) the maximum number of coordinated molecules does not exceed three. Similarly indium trichloride and tri-iodide form complexes having the composition $InX_3.4L$ with (XIII) and $InX_3.3L$ with (IV, X = NH, R = H).

In order to obtain information about the structures of coordination compounds, studies have been made [9,119-123] on the infrared absorption spectra of the complexes and their dipole moments have been determined; infrared, Raman, and ESR spectra have been studied by Cotton and Gibson [124], mass spectrometric, NMR, and vibration spectra by Lee [125], and NMR spectra by Fratiello [126]. The stretching vibration frequencies of the azole rings were found to increase in the infrared spectra of complexes of the type $MX_3.nL$ ($n = 1-6$) which suggested [9,119-123] that the coordinate bond is located at the pyridine-type nitrogen atom of the heterocycle. In addition to this frequency increase, the infrared spectra of the coordination compounds $MX_3.nL$ (M = Al or B, $n > 1$; M = In or Sc, $n > 3$) showed bands due to non-coordinated ligands. On this basis, a solvate structure of the type $[MX_3.(n-m)L]mL$ was attributed to these coordination compounds [9,119-121,123]. One cannot rule out the possibility of the formation of solvates also in the case of gallium complexes of the type $GaCl_3.2L$, although the coordination capacity of this metal is consistent with the formation of trigonal-bipyramidal coordination compounds (sp^3d hybridisation). On the basis of the infrared spectra and the dipole moments, which vary in the range 4-7 D, a *cis*-trigonal-bipyramidal configuration (XIV) was attributed to the complexes $InX_3.2L$ and a *cis*-structure with C_{2v} symmetry (XV) was attributed to octahedral coordination compounds of the type $InX_3.3L$:



(XIV) (XV) [9,119,123]

A comparative estimate of the stabilities of the complexes was made from the frequency shifts of the stretching vibrations of the azole rings ($\Delta\gamma$). It was found that the $\Delta\gamma$ for the MX_3 complexes of the same composition and structure are satisfactorily correlated with the basicities of the azole ligands [9].

The conclusions based on the infrared spectroscopic studies have been confirmed in a few cases also by measurements of the dipole moments [9,119].

3. COMPLEXES OF THE AZOLES WITH THE TETRAHALIDES OF GROUP IV ELEMENTS

The azole complexes with MX_4 (M = Sn, Ge, Ti, Zr, Hf, or Th; X = Cl, Br, or I) known hitherto are confined mainly to complexes of imidazole-containing systems [9,130-132]. Only in the case of tin tetrachloride have complexes been obtained also with benzo-2,1,3-thiadiazole (XVI, R = H) and its 5-methyl derivative (XVI, R = CH_3), [133,134] and germanium tetrachloride was found to form complexes with 3,5-dimethylpyrazole (XVII) and 2-methylbenzothiazole (XVIII). [9]

(XVI) (XVII) (XVIII) (XIX)

The azole complexes with Group IV metal tetrachlorides were synthesised by mixing in the cold the benzene or chloroform solutions of the ligands with MX_4 solutions in benzene (M = Sn, Ti, or Ge) [9,130,132] or ether (M = Zr, Hf, or Th). [9,131,132]

As for the coordination compounds of other oxygen- and nitrogen-containing ligands [9,104,132-135], the compositions of complexes of this type are fairly rigorously correlated with the properties of the MX_4. [9,132] Regardless of the reactant ratio and the bulk and basicity of the ligand, tin [9,130,133], zirconium [131], and hafnium tetrahalides [131] form coordination compounds of the type $MX_4.2L$. The complexes $MX_4.3L$ are most characteristic of germanium tetrachloride although (XVII) forms the complex $GeCl_4.L$

and imidazole even $GeCl_4.5L$.[9] Depending on the reactant ratio, titanium tetrachloride was found to form the coordination compounds $TiCl_4.2L$ and $TiCl_4.L$.[9,130,132] Thorium tetrachloride complexes of definite composition could be obtained only with ligands containing bulky substituents in the azole rings [for example (XIX) and the 1-(α-phenylethyl), 1-(α-naphthylmethyl), and diphenylmethyl derivatives resembling it][131]. Thorium tetrachloride forms with imidazole, benzimidazole, and their *CN*-alkyl(aryl) derivatives coordination compounds having the composition $ThCl_4.2L.n(C_2H_5)_2O$ in which n varies from 6 to 14 depending on the bulk of the ligand[132].

The study of the structure of the coordination compounds of MX_4 with azoles led to the conclusion that the only complex-formation centre in the imidazole ring is the pyridine-type nitrogen atom[130]. The conclusion was based on the increase of the stretching vibration frequencies in the imidazole ring (1550–1570 cm^{-1}) on complex formation and the similarity of a number of chemical and physical properties (spectroscopic behaviour on coordination) of imidazole-containing systems and pyridine[9,130]. Subsequently this test was widely used to demonstrate that coordination involves the pyridine-type nitrogen atom of the azole ligand[9,99,119-121,130-132,136-138].

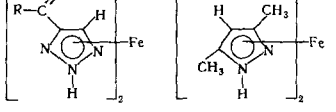
It was also established that the stretching vibration shifts $\Delta\gamma$ of the imidazole ring on coordination interaction with MX_4 are correlated with the basicity of the ligand[9,130-132].

The structure of the complexes $MX_4.2L$ with azoles was not studied in detail owing to their extremely low solubility and ready hydrolysability. However, low-frequency vibration spectra show that the $SnCl_4$ and $TiCl_4$ complexes with benzimidazole as well as a number of other nitrogen-containing ligands[139] have the *cis*-octahedral configuration in the crystalline phase[9].

4. COMPLEXES OF AZOLES WITH GROUP V METALS

Complexes of azoles with niobium pentachloride[140,141] and niobium oxide trichloride[142-144] have been isolated on a preparative scale and partly investigated. The complexes of both niobium derivatives were obtained by the interaction of the ether compound of the pentachloride[140,141] or the chloride trioxide[142-144] with azoles in benzene solutions.

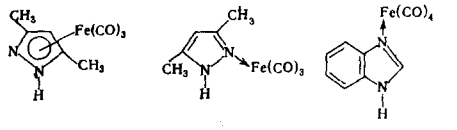
The composition of the coordination compound of $NbCl_5$ depends significantly on the basicity of the azoles and in many cases also on the reactant ratio and on the solvent. For azoles with a comparatively high basicity imidazole, benzimidazole, 2-methylbenzimidazole), the complexes $NbCl_5.nL$ with n = 1, 2, or 3 may be obtained for different reactant ratios[140,141]. As the basicity decreases (3,5-dimethylpyrazole and benzothiazole), the complexes $NbCl_5.L$ are formed[140,141]. When benzene is replaced by acetonitrile, the complex $NbCl_5.L.CH_3CN$ may be isolated[141].



In contrast to the $NbCl_5$ complexes, the composition $NbOCl_3.L$ is most characteristic of the $NbOCl_3$ coordination compounds[142-144]. However, it is difficult to reach final conclusions concerning the dependence of the composition of the $NbOCl_3$ complexes with azoles on structural factors and conditions of synthesis owing to the narrow range of azole-containing systems which have been introduced into the reaction with niobium oxide trichloride[142-144].

The properties of the $NbCl_5$ and $NbOCl_3$ coordination compounds have been investigated by magnetochemical and infrared spectroscopic methods. It has been shown[140,141] that, when $NbCl_5$ interacts with azoles, niobium is not reduced to the quadrivalent state¶: all the complexes synthesised, except $NbCl_5.2L.CH_3CN$, are diamagnetic. On the other hand, the weak paramagnetism ($\mu_{eff} \simeq 0.7$ Bohr magneton) of the complex containing an acetonitrile molecule has been explained[141] by the coordination of CH_3CN to $NbCl_5$ (the complex $NbCl_5.CH_3CN$ is also weakly paramagnetic—μ_{eff} = 0.6 Bohr magneton).[148]

In view of the increase of the vibration frequencies of the azole ring in the complexes $NbCl_5.nL$[140,141] and $NbOCl_3.L$,[142-144] it was concluded that the coordinate bond involves the pyridine-type nitrogen atom of the azole ring. It was also established that the interaction of $NbOCl_3$ with azoles entails a decrease of absorption due to the NbO bond by 30–65 cm^{-1} (in the range 700–800 cm^{-1}). On this basis, it has been suggested that the frequency shifts of the bond stretching vibrations can serve as a kind of measure of the stability of the donor–acceptor bond between the ligand and niobium oxide trichloride[143,144].

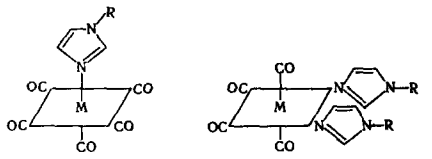


5. GROUP VI–VIII METAL CARBONYL COMPLEXES OF AZOLES

The synthesis and the study of the properties of the metal carbonyl complexes of azoles were undertaken mainly to investigate the possibility of the formation of π complexes in the azole series. On the basis of the available data concerning the successful synthesis of azoferrocene[149-152] and the similarity of a number of properties of azoles and pyrrole, Nesmeyanov et al.[33] allowed 4-butyryl(benzoyl)-1,2,3-triazoles and 3,5-dimethylpyrazole to react with iron nonacarbonyl. Elemental analysis, molecular weight measurements, and infrared spectra led the authors[33] to the hypothesis that the compounds (XX) and (XXI) obtained have the π-complex structure:

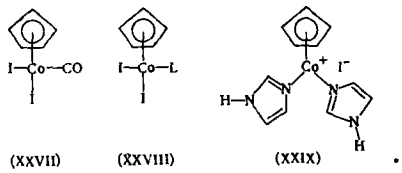
(XX), R = C_3H_7, C_6H_5 (XXI)

Later similar considerations were adduced concerning the structure (XXII) of azole complexes having the composition $LFe(CO)_3$[34-35] but σ-complex structures (XXIII) and (XXIV) were attributed to complexes of the type $LFe(CO)_4$ on the basis of mass spectrometric, infrared spectroscopic, and NMR studies[35,37]:



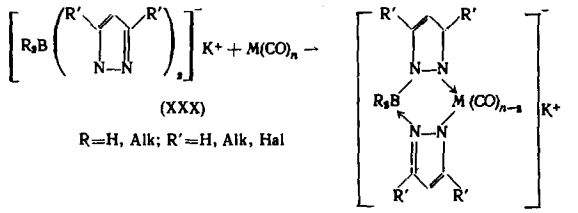
(XXII) (XXIII) (XXIV)

Complexes of a large group of azoles and their benzoanalogues with chromium, molybdenum, and tungsten hexacarbonyls were obtained by Beck et al.[41] and independently by Garnovskii and coworkers[46,48]. Elemental analysis [composition $LM(CO)_5$ or $L_2M(CO)_4$], infrared spectroscopy, dipole moment[46,48], and ^{14}N NMR measurements[41] suggested that all these compounds have the



¶ Earlier it was stated that, when $NbCl_5$ interacts with nitrogen-containing organic compounds, paramagnetic coordination compounds of the type $NbCl_4.nL$ are formed[145-147].

σ-complex structure with an M ← N bond involving the pyridine-type nitrogen atom of the heterocyclic ring, for example (XXV) and (XXVI):

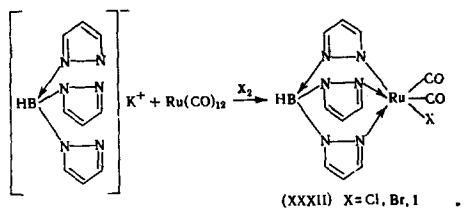


(XXV) (XXVI)

The reaction of cyclopentadienylcobalt di-iodide (XXVII) with imidazole, benzimidazole, indazole, and benzotriazole led to the synthesis of the complexes (XXVIII) and (XXIX) with a Co–N σ bond[153]:

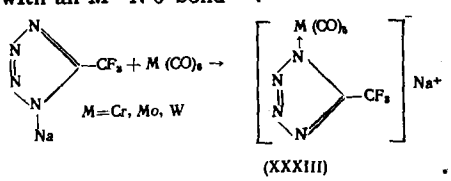
(XXVII) (XXVIII) (XXIX)

Alkali metal polypyrazolylborates (XXX) react with molybdenum hexacarbonyl[154,155] and bromomanganese pentacarbonyl or dimanganese decacarbonyl[156] to form anions with a σ-linked metal carbonyl residue (XXXI):



(XXX)

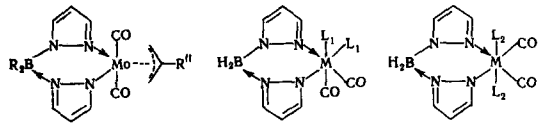
R=H, Alk; R′=H, Alk, Hal



(XXXI)

The reaction of potassium tripyrazolylborate with $Ru_3(CO)_{12}$ in the presence of a halogen (Cl_2, Br_2, I_2) yields the metal carbonyl derivatives (XXXII) in which an Ru–N σ bond is formed[157]:

(XXXII) X=Cl, Br, I



The anion (XXXIII), formed in the reaction of sodium 5-trifluoromethylpyrazolide with $M(CO)_6$, also has a structure with an M–N σ bond[166]:

M=Cr, Mo, W

(XXXIII)

The reactions of the above anions with unsaturated compounds[154] or phosphines (phosphites)[156] can yield the coordination compounds (XXXIV)–(XXXVI) respectively. In the case of phosphines, the ligands (L_1) occupy the *cis*-positions relative to one another [as in compound (XXXV)] and in the case of the phosphites (L_2) the complex has the *trans*-configuration (XXXVI):[156]

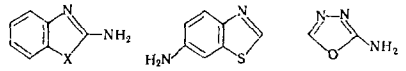
(XXXIV) (XXXV) (XXXVI)

Thus the data presented clearly demonstrate the preferential formation by azoles of σ and not π complexes even with powerful π acceptors such as metal carbonyls. We believe that the difficulty of obtaining π complexes in the series of azoles, in contrast to pyrrole[149–152,159,160] and other five-membered systems with one heteroatom[161,162], can be explained[9,48] by the combination in the azole molecule of a π-electron sextet with the unsaturated pyridine-type nitrogen atom, the electron-donating activity of which greatly exceeds that of the π-electron system†.

The study of the polar properties of complexes of the type $LM(CO)_5$ showed that the stability of the coordination compounds varies in parallel with the basicity of ligands of a similar type[9,48,48]: imidazole > benzimidazole > pyrazole > tetrazole. However, the stabilities of azole complexes containing oxygen or sulphur atoms in the heterocyclic ring (benzoxazole, benzothiazole) do not fit in the above sequence[9,46,48].

The considerable polarity (μ = 10 D) of azole complexes of the type $L_2M(CO)_4$ demonstrate their *cis*-octahedral configuration in solution[48,48]. According to infrared spectroscopic data, the complexes have the same structure in the crystalline phase too[41,48,48] (four bands in the range 1800–2000 cm^{-1}).

To conclude our discussion on coordination compounds with monodentate azoles, note that we have not discussed data for the coordination compounds of *N*-substituted tetrazoles, since a fairly complete review on this subject is available[72]. On the other hand, one must emphasise that, according to the latest X-ray diffraction data[165], the tetrazole ring can be coordinated not only via the $N_{(4)}$ atom[72] but also via the $N_{(3)}$ atom[166]. Together with the azole complexes discussed above, the coordination compounds of 2-methylbenzoselenazole[100], isothiazole[167,168], thia- and selena-diazoles[169–171], and also a number of azole solvates with the general formula $MX_2.2L.2H_2O$ (the latter have an octahedral configuration)[172] have also been investigated, albeit in less detail. Finally, in addition to the metals mentioned above, azole complexes of ruthenium[173,174], rhenium[175], and rhodium[171] have been synthesised.

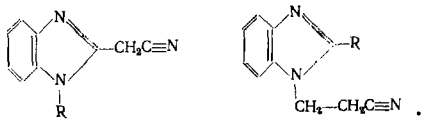


6. COMPLEXES OF AMBIDENT AZOLE-CONTAINING SYSTEMS

Azole ligands with several electron-donating atoms combined into a single conjugated system (ambident compounds[10,93]) are of considerable interest for the problem of competitive coordination in the chemistry of their complexes[9,10]; for this problem, it is useful to arrange the ligands of the azole series systematically in terms of the possible bonding atoms.

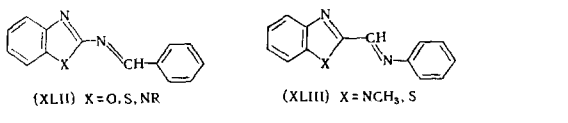
† The suggestion that π complexes are formed in the pyridine series[163] proved to be erroneous[164].

a. Azole-containing Ligands with Electron-donating Nitrogen Atoms



Amino-derivatives of azoles [(XXXVII)–(XXXIX)] containing two electron-donating nitrogen atoms hybridised in different ways are mainly monodentate ligands and form with transition metal salts [86,98,176-180] and the halides of Group I, [180] III, [9,119] IV, [9,132,181] and V [140-144] complexes in which the coordinate bond involves mainly the pyridine-type ring nitrogen atom:

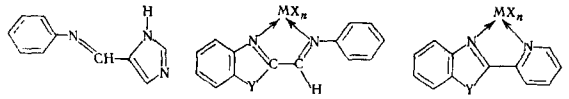
(XXXVII) (XXXVIII) (XXXIX)



X = O, S, NR; R = H, Alk, Ar

Only in a few cases has it been claimed that the complex may be formed with participation of both electron-donating centres [9,140,141] and, in the case of compounds (XXXVII) [180] and (XXXIX), [178] with participation of the amino-nitrogen. In amino-derivatives of azoles, coordinating attack is directed to the nitrogen heteroatom with the highest π-electronic charge (the X atom and the amino-nitrogen are positively charged) [9,181]. Although this result, which follows from infrared spectroscopic [9,132,140-144] and ultraviolet spectroscopic [86,176,177,180] studies, conflicts with Pauling's postulate that the electron-donating capacity of nucleophilic atoms increases with the amount of p-character of the hybrid orbitals [182], it is consistent with data showing that the coordinate bond involves the electron-donating centre with the maximum negative potential [183] and hence with the maximum negative π-electronic charge [10,184]. Similarly the coordinate bond in the cyano-derivatives of the azole series (XL) and (XLI) involves the nitrogen atom of the heterocyclic ring [9,185]:

(XL) (XLI)

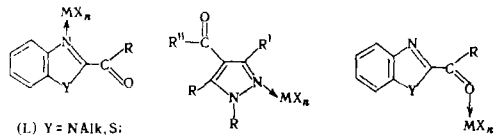


Similarly complexes are formed via the nitrogen atom with the maximum negative π-electronic charge in the series of azole-containing systems with equally hybridised nitrogen atoms: the anils (XLII) and (XLIII) via the azomethine nitrogen atom [9,10,181] and the azo-compounds (XLIV) [9,186] and formazans (XLV) [187,188] via the pyridine-type heterocyclic nitrogen atom:

(XLII) X = O, S, NR (XLIII) X = NCH$_3$, S

(XLIV) R = Alk, Ar, cyclo-C$_4$H$_8$ (XLV) X = O, S, NR$''$; R = CH$_3$; R$'$ = Alk, Het (XLVI) X = NH, S

At the same time, the ligands (XLIII), (XLIV), and (XLVI) [185,186,189-208] as well as (XLVII), [209] containing electron-donating nitrogen atoms in positions favouring the formation of cyclic structures, give rise to chelate complexes (XLVIII) and (XLIX):

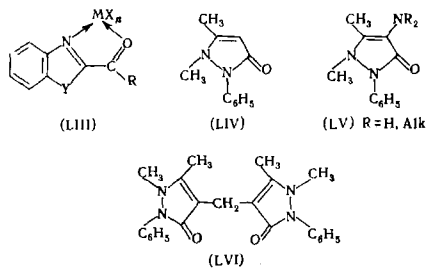


(XLVII) (XLVIII) (XLIX)

The composition and structure of complexes of ambident nitrogen-containing systems depend on the same factors as the complexes of monodentate azoles. 2-Aminobenzazoles (XXXVII) form mainly complexes of type $MX_2.2L$. [86,176,177] However, the coordination compounds of 2-aminobenzothiazole (XXXVII, X = S) with the composition $Co(ClO_4).3L$ may be isolated [176] and synthesis in a hydrochloric acid medium yields the complexes $MX_2.L$ (M = Cu, Co, or Hg). [179] Depending on the reactant ratio, 2-amino-1,3,4-oxadiazole (XXXIX) forms the coordination compounds $MX_2.nL$ (n = 2–6). [178] The type of polyhedra formed is determined by the electronic structure of the metal (the cobalt complexes are mainly tetrahedral [86,176,177]) but it depends also on the anion [86].

The bulky ligands (XLII)–(XLVI) tend to decrease the coordination number of the metal and to form mainly the complexes $MX_m.L$, [9] while the coordination compounds of bisazole systems (XLVI) give rise to planar or polymeric-octahedral structures [199,202,205].

b. Oxygen- and Sulphur-containing Derivatives of Azoles

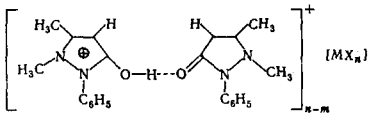


Infrared spectroscopic studies demonstrate fairly clearly that, in complexes of C-carbonyl derivatives of the azole series [(L) and (LI)], the coordinate bond involves mainly the nitrogen atom of the heterocyclic ring [9,119,210].

(L) Y = NAlk, S; R = H, Alk (LI) R = H, Alk (LII)

Only the "hardest" [10] Lewis acids $AlCl_3$ and $AlBr_3$ form complexes via the oxygen atom: (LII) and (LIII). [9,210]

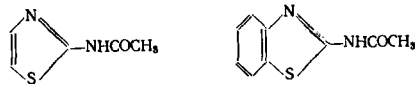
Antipyrine (LIV) and its derivatives (LV) and (LVI) form two types of complexes depending on the conditions of synthesis: $MX_m.nL$ in neutral or weakly acid media [9,132,211-226] and ionic association complexes of the antipyrinium cation in acid solutions [212,223,226-230].



(LIII) (LIV) (LV) R = H, Alk

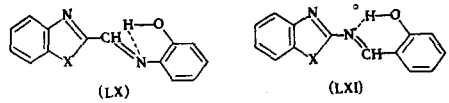
(LVI)

Regardless of the nature of MX_m, the formation of the complexes $MX_m.nL$ involves exclusively the exocyclic oxygen atom [9,132,211-230], which is consistent with the high



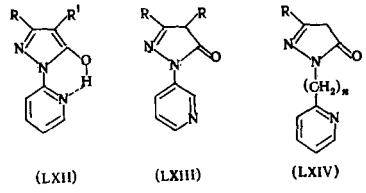
negative π-electronic charge of the oxygen atom [9,132,225,231,232]. In the ionic association complexes (LVII), the proton adds to the same electron-donating centre [226-230].

(LVII)



A cyclic structure with the metal coordinated to exocyclic oxygen and nitrogen atoms has been attributed [233-235] to 4-aminoantipyrine (LV, R = H) and its *N*-dimethylamino-derivative (LV, R = CH_3). Complexes of ligands of this type have an octahedral structure regardless of the metal and the anion [236].

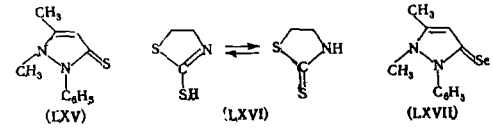
2-Acetamidothiazole (LVIII) and its benzo-analogue (LIX) are ambident systems whose complexes with different MX_2 may be formed in three ways: (1) via the nitrogen atom in the thiazole ring ($CuCl_2$), (2) via the amide oxygen atom and the heterocyclic nitrogen atom (NiX_2, X = Cl, Br, or I; $CuBr_2$), and (3) via the amide and ring nitrogen atoms [CuX_2, X = NO_3 or ClO_4; $Ni(NO_3)_2$]. [237]



(LVIII) (LIX)

o-Hydroxyanils of the azole series (LX) and (LXI) [9,132,189] and the 5-hydroxy derivatives of 1-pyridylpyrazole (LXII)–(LXIV) [185,204] are unusual ambident nitrogen- and oxygen-containing ligands.

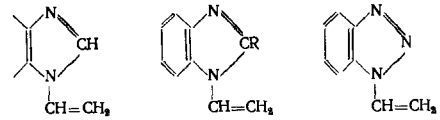
(LX) (LXI)



(LXII) (LXIII) (LXIV)

Compounds (LX)–(LXII) form complexes via the azomethine [compounds (LX) and (LXI)] [9,132,189] or pyridine-type nitrogen atoms [185,204]. However, for ligands with a preferential oxo-form [(LXIII) and (LXIV)], [9,185,204,238] the coordinate bond involves the oxygen atom of the carbonyl group [185,204].

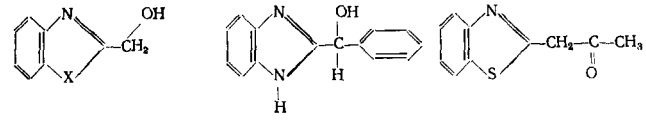
There are comparatively few data concerning the nature of the polyhedral forms of these complexes. Antipyrine complexes of the type $CuCl_2.2L$ and $CuBr_2.2L$ are known to be pseudotetrahedral and the complexes $Cu(NO_3)_2.2L$ are planar or have a distorted octahedral structure [214]. The complex $Cu(ClO_4)_2.5L$ has a pentacoordinate copper atom [215] and the copper complexes with acetate or arenecarboxylate anions have tetragonally distorted octahedral structures [224]. The octahedral configuration is characteristic of antipyrine complexes of the type $M(ClO_4)_2.6L$. [239]



Thiopyrine (LXV) [217] and thiazolidenethione (LXVI) [240] must be classified as sulphur- and nitrogen-containing ambident systems.

(LXV) (LXVI) (LXVII)

In the coordination compounds of both ligands, the coordinate bond involves the exocyclic sulphur atom. Similarly, the coordination interaction [9] of selenapyrine (LXVII) involves the exocyclic selenium atom. The complexes of thiazolidine-2-thione (LXVI) have been investigated in fair detail [240]. Magnetic and spectroscopic (ultraviolet and infrared) studies established that the complexes $MX_2.2L$ are tetrahedral (M = Co, X = Cl, Br, or I; M = Ni; X = I) or octahedral (M = Ni, X = Cl or Br). [240]

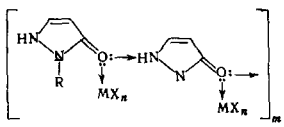


Apart from the ambident systems mentioned above, *N*-vinyl derivatives of azoles (LXVIII)–(LXX) have been used to form complexes with metal salts [137,138,241,242]:

(LXVIII) (LXIX) (LXX)

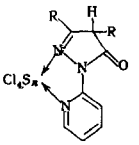
The study of the interaction of tin and nickel chlorides with the ligands (LXVIII)–(LXX) showed that in this case too the composition of the complexes depends on the reactant ratio and on the nature of the ligand and the solvent [241,242]. Infrared, ultraviolet, and NMR spectroscopic studies showed unambiguously that the coordinate bond involves the pyridine-type nitrogen atom of the azole ring. [137,138,241] A similar conclusion was reached concerning the structure of the cobalt complexes of *N*-vinylbenzimidazole and a number of its 2-alkyl(arylalkyl) derivatives (XIX). [242]

Together with the complexes of the amibdent systems, those of a number of azole ligands with isolated electron-donating centres have been obtained: 2-hydroxymethyl derivatives of benzimidazole (XXI) [68,81,243-247] and benzothiazole (LXXII), [26,96,248] 2-(α-hydroxybenzyl)benzimidazole (LXXIII), [249] and 2-acetonylbenzothiazole (LXXIV): [26]



(LXXI) X=NH
(LXXII) X=S (LXXIII) (LXXIV)

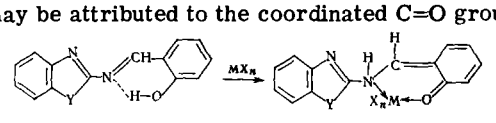
The ligands (LXXI)–(LXXIV) are bidentate; the complexes are formed via the pyridine-type nitrogen atom of the azole ring and the hydroxyl oxygen, as a result of which they have a chelate structure with an octahedral configuration. Apparently the ligand (LXXIV) also occupies two coordination sites in the coordination compound [26]. However, in order to reach a final conclusion concerning the mode of its coordination, it is necessary to make a detailed infrared spectroscopic study of the stretching vibration frequencies of the carbonyl group on complex formation.



7. STABILISATION OF TAUTOMERS AND CONFORMERS OF AZOLE-CONTAINING COMPOUNDS AS A RESULT OF COMPLEX FORMATION

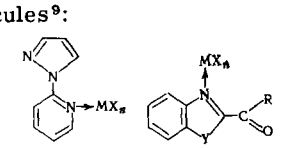
It is believed [250] that the formation of chelate complexes results in the stabilisation of specific tautomeric forms of the ligands (for example the enol and thiol forms in the metal chelates of acetylacetone [251] and its thio-analogues [252-254]). However, these examples of the stabilisation of one of the tautomeric forms as a result of complex formation are not altogether correct. In the coordinated ligand of a chelate complex, the bonds are known to be partly equivalent (acetylacetonates) and therefore it is difficult to speak of the stabilisation of a particular tautomeric form as a result of the formation of the chelate. On the other hand, it has been shown [9,255] that the hypothesis of the stabilisation of one of the tautomeric forms of the ligand as a result of complex formation is valid for molecular complexes in which the ligand [bonding] system is fully retained.

The infrared spectra of the complexes of pyrazolones as well as of the coordination compounds of antipyrine (LIV) show bands due to the NH group (2400–3300 cm^{-1}) and the protonated antipyrine ring (1550–1600 cm^{-1}). Moreover, frequencies characteristic of the complexes of MX_n with 3,4,4-trimethylpyrazolone-5-one do not occur in the region of 1700 cm^{-1}. These data suggest that in the pyrazolone complexes the antipyrine structure is stabilised and the complexes have the structure of coordination polymers (LXXV):



(LXXV)

(LXXVI) R = H, Alk

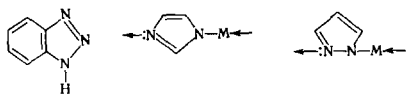


In the complexes of 1-(α-pyridyl)pyrazolones (LXII), the pyrazolone tautomeric form (LXXVI) is stabilised: the infrared spectra of the complex of (LXII) with $SnCl_4$ show absorption due to the free carbonyl group (1710 to 1715 cm^{-1}). [204]

A study of the infrared spectra of complexes of MX_n with o-hydroxyanils of the benzazole series led to the view [9] that the quinonoid form (LXXVII), which is "uncharacteristic" of o-hydroxyazomethines, is stabilised by complex formation: at 1650 cm^{-1} a band was observed, which may be attributed to the coordinated C=O group:

(LXXVII)

It has been established that not only tautomers but also conformers of compounds of the azole series may be stabilised by complex formation [9]. This may involve the retention or an alteration of the configuration of the ligand compared with the form of the non-coordinated azole molecule. In their complexes with MX_n, 1-(α-pyridyl)-pyrazoles [204] and 2-formylbenzazoles [210] retain the *S-trans*-configurations (LXXVIII) and (LXXIX) characteristic of free azole molecules [9]:



(LXXVIII) (LXXIX)

Only the complexes of carbonylazoles with AlX_3 (X = Cl or Br) form cyclic structures (LIII) in which the ligands assume the *S-cis*-form [9]. A similar conversion of the *S-trans-trans*-form into the *S-cis-trans*-configuration (XLVIII) is observed when anils of 2-formylbenzazoles (XLIII) react with MX_n. [9,189] It has been concluded [9] that the stabilisation of one of the conformers need not necessarily be due solely to the structure of the ligand system as is usually postulated for a whole series of bisheterocyclic systems (bipyridyl): the properties of the complex-forming agent (MX_n) play an extremely important role in this process.

III. *N*-METAL AND *N*-ELEMENT DERIVATIVES OF AZOLES

Azoles with an unsubstituted NH-group exhibit acid properties on interaction with metals. The acidity constants of tetrazole and its derivatives ($pK_b = 5$), which are the most acid of the azoles, are close to those of acetic acid ($pK_b = 4.76$), while imidazole, which is least acidic, has $pK_b = 14.52$. Despite the comparatively low pK_b values of azoles, *N*-metal-substituted derivatives of imidazole [13,16,49,50,122,172,256-263], pyrazole [113,264,265], triazoles [261,266-268], tetrazole [269-277], benzimidazole [4,57,278], and benzotriazole (LXXX) [261,279-285] are now known.

In contrast to the molecular complexes discussed in section II, *N*-metal-substituted azoles contain covalent M–N σ bonds and electron-donating (sp^2-hybridised nitrogen) and electron-accepting (metal atom) centres not involved in coordination interaction [compounds (LXXXI) and (LXXXII)]:

(LXXX) (LXXXI) (LXXXII)

Therefore molecules of types (LXXXI) and (LXXXII) tend to undergo self-association and to form polymeric structures [9,50,125,258-262,270]. Metal-containing polymers of the azole series have anomalous magnetic properties (the μ_{eff} are lower than the spin-only values), which is attributed to a metal–metal exchange interaction via the π-electron system of the azole rings [4,9,261,262,268] or to a metal–metal bond [50].

The study of the magnetic properties [4,50,57,258,259] and reflection spectra [4,50,57] leads to the conclusion that the type of polyhedra formed in the crystalline phase by *N*-metal-substituted azoles depends primarily on the nature of the metal [50]. Copper complexes of imidazole and benzimidazole [57] have distorted tetrahedral (almost planar) structures, cobalt and zinc coordination compounds have tetrahedral structures regardless of the type of ligand [4,49,50,113], and nickel complexes have predominantly planar structures [16,50,258,259].

The capacity of azoles with an unsubstituted NH group to form *N*-element-substituted compounds was observed in the 1960's by several independent groups of investigators [9]. Birkofer developed a method for the synthesis of *N*-silyl derivatives of azoles [286,287], which proved to be exceptionally reactive in the synthesis of numerous *N*-substituted azole derivatives [286-291]. Systematic studies on *N*-trialkylmetal derivatives of azole-containing systems have been made by Van der Kerk and coworkers [292-305].

The development of the chemistry of pyrazole derivatives of boron is associated mainly with studies by

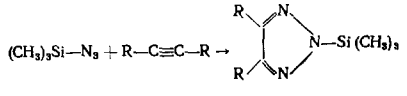
Trofimenko [154,155,265,302-306]. Other investigations in this field have also been made [125,307-311].

The choice of conditions for the synthesis of *N*-element-substituted derivatives depends on the acidity of the NH group of azoles, the reactivity of the metallating agents, and the resistance of the complexes obtained to hydrolysis. Tetrazole reacts with trimethylsilane under exceptionally mild conditions (benzene, 10°C), [287] while the synthesis of *N*-trimethylsilyl-substituted derivatives of other azoles requires heating of the azole system with hexamethyldisilazane for many hours [286]. The trimethyl derivatives of the majority of Group III elements react even with imidazole, the least acid compound of this series, in benzene or hexane in the cold [9,122], but BR_3 derivatives react only under comparatively severe conditions [9,119,302,305].

The majority of *N*-metal derivatives of the azole series are readily hydrolysed, but tin-, [297,299-301] germanium-, [296] and lead-substituted [298] compounds are comparatively stable. Therefore *N*-trimethylmetal derivatives can be obtained from the oxides [297] and hydroxides [293,298,308] of the corresponding elements:

$$(R_3M)_2O + 2HN\!\!\rangle \rightarrow 2R_3M{-}N\!\!\rangle + H_2O\ ,$$

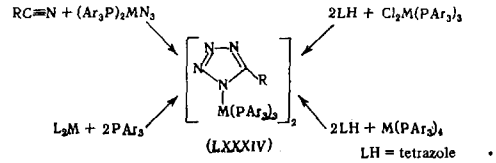
$$R_3MOH + HN\!\!\rangle \rightarrow R_3M{-}N\!\!\rangle + H_2O\ .$$



N-Element-substituted derivatives are obtained with the aid of the above reactions for a number of azoles and benzazoles and also purines [308]. *N*-Phenylmercury derivatives of imidazole, benzimidazole [312], and pyrazole [313] systems are obtained in the same way.

N-Metal carbonyl derivatives of the azole series are successfully synthesised by methods based on the interaction of alkali metal salts of azoles with metal carbonyl halides [154] or their π-cyclopentadienyl derivatives [34,35,45,314,315]:

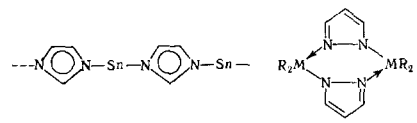
$$\rangle N{-}M + X\,(CO)_2FeC_5H_5{\cdot}\pi \rightarrow \rangle N{-}Fe\,(CO)_2C_5H_5{\cdot}\pi\ ,$$



where M = Na or K, X = Cl, Br, or I, and $\rangle N$ is a heterocyclic group. This reaction was first widely employed by Seel to prepared a series of σ-complexes of azoles with π-cyclopentadienyliron dicarbonyl [45,314]. Subsequently the analogous benzotriazole derivatives [34,35,315] and rhodium dicarbonyl complexes of pyrazoles [154] were synthesised in the same way. The reaction serves as a basis for the synthesis of rhodium and palladium complexes of pyrazole and its derivatives linked by π bonds to olefins [154,155].

N-Element-substituted derivatives of azoles can be obtained not only directly from the heterocycles but also by an indirect method. Thus Birkofer [287,289] employed the 1,3-cycloaddition of trimethylsilyl azides to synthesise *N*-trimethylsilyl derivatives of 1,2,3-triazoles (LXXXIII):

(LXXXIII)

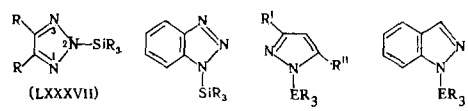


The synthesis of bis[tetrazolyltris(triphenylphosphine)-metal] complexes (LXXXIV) [8,90] in which the metal is copper, palladium, platinum, and ruthenium has been achieved on the same basis although other methods for the synthesis of complexes of this class from tetrazole or its *N*-metal derivatives have been developed [277,316]:

(LXXXIV) LH = tetrazole .

N-Element-substituted derivatives of azoles, like the *N*-metal-substituted derivatives discussed above, are mainly coordination-saturated oligomers or polymers [296-301,312,317]. Comparative viscometric studies showed that organotin polymers contain association complexes with much higher molecular weights than the organogermanium polymers [296].

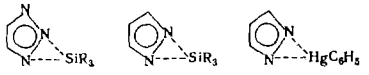
The structure of *N*-element-substituted derivatives of azoles has so far been very little investigated. It has been postulated, albeit without insufficient justification, that trialkyltin derivatives of imidazoles have a linear coordination-saturated structure (LXXXV) with a pentacoordinate tin atom and equivalent bonds [297,317]:



(LXXXV) (LXXXVI) M = B, Al .

According to NMR spectroscopic data, *N*-phenylmercury derivatives of 4,5-dichloro-2-methylimidazole have a similar configuration [312], *N*-dialkylmetal derivatives of azoles [9,119,122,265,303,306], *N*-trimethylsilylazoles [287,291], and *N*-phenylmercury derivatives of imidazole [312] and pyrazole [313] have been most thoroughly investigated among compounds of this class.

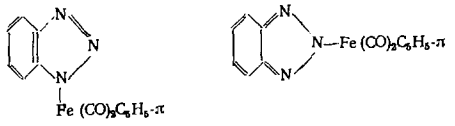
Cryoscopic (ebullioscopic) studies, NMR spectroscopy, and determinations of dipole moments showed [9,119,122] that the type of oligomers of the alkyl derivatives of Group III elements under consideration depends on the nature of the ligand (the distribution of nitrogen atoms in the heterocyclic ring) and on the properties of the ER_n substituent, where E is an element and R an organic group. *N*-Trialkyl-boron- [155,265,303] and -aluminium-substituted [9,122] pyrazoles are highly symmetrical dimers (LXXXVI), while the complexes of imidazole, benzimidazole, and tetrahydrobenzimidazole with the same substituents are probably linear polymers [9,119,122]. *N*-Dimethyl-gallium and -indium derivatives form cyclic tetramers or hexamers in solution regardless of the type of azole [9,122].



N-Trimethylsilyl(germyl)-substituted triazoles [289], pyrazoles [291,309], and indazoles [309] have been investigated mainly in connection with the determination of the position of the ER_n substituent in the azole ring [289,309] and of the elementotropic mobility of the ER_3 group [289,291]. Measurements of the dipole moments of a series of $NSiR_3$-substituted 1,2,3-triazoles showed that these complexes have the structure (LXXXVII) with the substituent in the 2-position of the triazole ring [289]. However, the analogous benzotriazole derivative (LXXXVII) contains the SiR_3 substituents in the 1-position [289]:

(LXXXVII) R = CH_3 (LXXXVIII) (LXXXIX) (XC) .

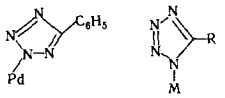
Elguero et al.[309] determined from NMR spectroscopic data the position of the ER_3 substituent (E = Si or Ge; R = CH_3 or C_2H_5) in pyrazoles (LXXXIX) and in indazole (XC).



In 1966 Birkofer[289] suggested that the SiR_3 group may migrate readily between the nitrogen atoms of the triazole ring (XCI):

(XCI) (XCII) (XCIII)

Subsequently this elementotropic mobility of the *N*-substituent was observed for methylsilyl derivatives of pyrazole (XCII)[304] and was demonstrated almost unambiguously in a series of *N*-phenylmercury derivatives of the same heterocycle (XCIII).[313]



The situation is different with the coordination-saturated *N*-substituted derivative of benzotriazole containing a substituent with a relatively low mobility—π-cyclopentadienyliron carbonyl[315]. In this case, it is possible to isolate two isomers in which the substituent is linked to different nitrogen atoms of the triazole ring [(XCIV) and (XCV)].[315]

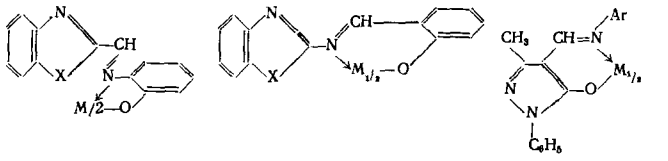
(XCIV) (XCV)

Thus even a limited number of examples demonstrate that not only is it possible to observe elementotropism in azole *N*-substituted derivatives of the elements but also one can isolate stable isomers involving different positions of the substituent relative to the nitrogen atoms of the heterocyclic ring. Nesmeyanov et al.[315] noted that the formation of similar isomers could probably be expected also for *N*-metal-substituted benzotriazole systems. We believe that, when the substituents and temperature conditions are suitably chosen, elementotropism may be observed or stable isomers isolated also for other *N*-element- and possibly *N*-metal-substituted triazole and tetrazole systems.

In this connection it is interesting to note that X-ray diffraction studies led to the discovery of a 2-palladium-substituted 5-phenyltetrazole derivative (XCVI),[277] while 1-metal-substituted structures (XCVII) have been postulated for other metals[269-277]:

(XCVI) (XCVII)

In conclusion we may note that the reaction of alkali metal borohydrides with pyrazole yielded polypyrazolylborates[154,302,303,305], which are exceptionally interesting ligands for the synthesis of metal chelates[165,265] and π complexes[154-157,306].



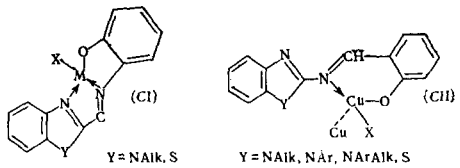
IV. CHELATE COMPLEXES IN THE AZOLE SERIES

Numerous chelate complexes synthesised from azole ligands‡ and containing chelate groups of the types MO_2N_2, MS_2N_2, MSe_2N_2, and MN_4, which are of greatest importance for coordination chemistry, are now known. In considering the methods of synthesis, the physicochemical properties, and the structures of complexes of this class, it is useful to arrange them systematically in terms of different types of coordination units.

‡ Azole-containing systems with chelating groups occupy an outstanding place among analytical reagents, metallochromic indicators, and extractants[6-9,318-338].

1. METAL CHELATES WITH AN MO_2N_2 COORDINATION UNIT

The hydroxyazomethines (LX)[9,339,340] and (LXI)[9,339] and 4-aminomethylene derivatives of pyrazolones[9] interact with bivalent metals salts to form chelates with five-membered [compounds (XCVIII)][9,340-344] and six-membered [compounds (XCIX) and (C)][9,189,344,345] metal-containing rings:



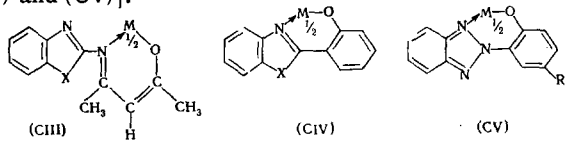
(XCVIII) (XCIX) (C)

The most typical composition of the chelates is ML_2, where LH are the ligands (XCVIII)–(C).[9,341-345] However, the anils (XCIX) form the complexes $ML.COOCH_3$ with copper(II), manganese(II), cadmium(II), lead(II), and $U^{II}O_2$.[341-344] Copper complexes of a similar type were obtained also for the azomethines (XCIX).[9,189] On the other hand, zinc and cadmium complexes with the composition ML_2 can be synthesised by refluxing the *o*-aminophenoxides of the above metals and the corresponding 2-formylbenzazoles in dioxan[344].

The chelate structure of the above complexes was established by comparing the infrared spectra of the coordination compound and the ligand: the hydrogen atoms of the hydroxy-group are found to be substituted [the bands corresponding to the OH stretching vibrations in the range 3400–3450 cm^{-1} for compound (LX)[339] and 3000–4000 cm^{-1} for compound (LXI)[9,189]] and the stretching vibration frequencies of the azomethine linkage increase[342,344]. Magnetic measurements showed that, as for the chelates of aromatic azomethines with a five-membered metal-containing ring[104,346-351], the complexes of the *o*-hydroxyanils (LX) have a tetrahedral or polymeric-octahedral configuration in the crystalline phase[343,344]. In contrast to the chelates of aromatic *o*-hydroxyazomethines with a six-membered metal chelate unit[104,352], coordination compounds of types (XCIX) and (C) have a polymeric-octahedral structure in the solid phase and a tetrahedral structure in solution regardless of the complex-forming metal[9,344,345]. These differences were explained[9,344] by the additional coordination of the metal to the pyridine-type nitrogen atom of the azole ring, which leads to an increase of the number of binding sites of the ligand actually employed (octahedron) or stabilises the tetrahedral configuration in solution.

Copper chelates with the acetate anion have unusual magnetic properties: while the chelates of the azomethine (XCVIII) have effective magnetic moments (μeff) corresponding to one unpaired electron (1.8–1.9 Bohr magnetons) the complexes of the *o*-hydroxyanils (XCIV) and (C) have the anomalous values μeff = 1.47–1.62 Bohr magnetons[9,344]. This result is attributed[9,344,351] to the formation in the first case of the coordination-saturated structure (CI) and metal–metal exchange interaction, while in the second

case the structure (CII) is believed to be formed via a Cu–Cu linkage or an acetate bridge [353,354]:

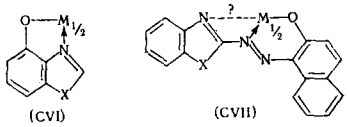


(CI) (CII)

Y = NAlk, S Y = NAlk, NAr, NArAlk, S

X = $OCOCH_3$

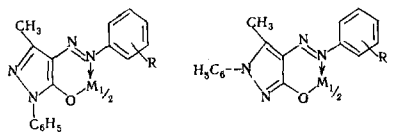
The six-membered metal chelate unit MN_2O_2 is also formed in the chelates of β-aminovinylketones [compounds (CIII)] [9] and 2-(*o*-hydroxyphenyl)benzazoles [compounds (CIV) and (CV)]. [9,14,191,355–361]



(CIII) (CIV) (CV)

X = S; NC_2H_5 X = O, S, NH R = H, CH_3; n-C_4H_9 .

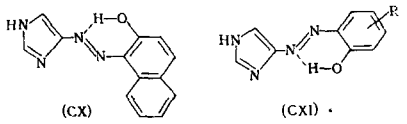
The synthesis of the chelates (CIII) was achieved by the reaction of the metal acetylacetonates with 2-aminobenzazoles [9] and compounds (CIV) and (CV) were obtained by direct interaction of metal salts (the acetates are best) [358,359] with 2-(*o*-hydroxyphenyl)benzazoles. In the crystalline phase, all these complexes apparently have a polymeric-octahedral structure [9,361]. The initial hypothesis of a tetrahedral configuration of the metal chelates (CIV) [359] was shown to be erroneous by X-ray diffraction studies [361] §: in the copper and palladium complexes the metal is located in the plane of the coordination unit, but, as a result of the intermolecular (axial) coordination of copper(II) or palladium(II) to the oxygen atom of an adjacent metal-containing ring, a polymeric-octahedral configuration is produced [361].



The 4-hydroxybenzazole complexes (CVI) were investigated [363–366] only in order to compare their stability with that of the chelates of the very important analytical reagent 8-hydroxyquinoline. It was found that, with the exception of the zinc complexes, the stability of the chelates fits the Irving–Williams series and is lower than that of the 8-hydroxyquinoline complexes [363–366]:

(CVI) (CVII)

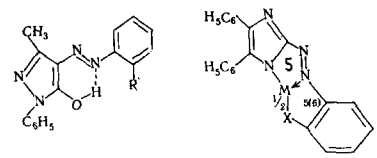
X = O, S, NH X = O, S, NR:
R = H, Alk .



Hydroxyazo-derivatives of benzazoles (CVII) [9,341,367] and pyrazolones [compounds (CVIII) and CIX)] [368–370] yielded chelates with a six-membered metal chelate unit MO_2N_2, which in the crystalline phase has mainly an octahedral structure [9,370,371,373] and in solution mainly a tetrahedral structure [9,373].

(CVIII) R = H: *o*, *m*, *p*-CH_3; OCH_3; SCH_3; Hal; NO_2 (CIX) .

The tetrahedral configuration of chelates of type (CVII) precludes the intramolecular coordination of the metal to the nitrogen atom of the heterocyclic ring [314,367] and was adopted *a priori* for complexes of pyridylazonaphthol and related heterocyclic compounds [374–377], including benzothiazolylazonaphthol [375,378].

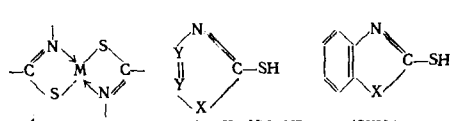


Snavely and coworkers have carried systematic determinations of the stability constants of chelates of types (CVIII) and (CIX). [369,370,372,378] The studies of Yamayichi et al. [379] of the properties of *o*-(4-hydroxyaryl)azoimidazole complexes (CX) and (CXI) had the same aim¶. However, thermodynamic data were not obtained in any of these investigations and therefore the conclusions arrived at must be treated with a certain amount of caution:

(CX) (CXI)

R = *p*-OCH_3, *m*-$N(CH_3)_2$.

Schetty's studies on the structures of the chromium chelate complexes of the tridentate azopyrazolone systems of type (CXII) need not be specially considered, since they have been reviewed by the author himself [380]:

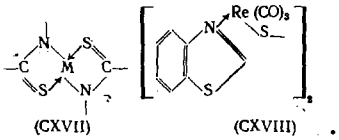


(CXII): R = OH, COOH (CXIII): X = O^-, COO^- .

We shall mention only that, after the publication of his review, a number of reports by the same author appeared, in which are described stereoisomeric chromium chelates of azopyrazolone derivatives (CXII, R = COOH) [381] and also complexes of 2-(*o*-hydroxyphenyl)-4,5-diphenylimidazoles with 5/5- or 5/6-metal-containing rings [382].

2. CHELATES OF TYPES MS_2N_2 AND MSe_2N_2

Complexes of 2-mercaptoazoles (CXV) [383–385] and 2-mercaptobenzazoles (CXVI) [386–393] with a five-membered metal-containing ring of type MN_2S_2 [structure (CXIV)] have been investigated. The majority of the studies were directed towards the analytical applications of compounds (CXV) and (CXVI) for a quantitative determination of platinum group metals [338,384–386,389,394,395].

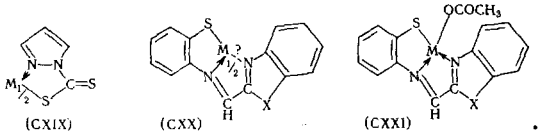


(CXIV) (CXV) X=NH, NR; Y=CR; Y=N (CXVI) X=NH, S .

However, in some of the investigations data have been obtained for the structures of the chelates synthesised from mercaptoazoles [387,392,393,396]. It is believed [392] that

§ In constructing a model of the metal chelate unit, Verkhovedova et al. [359] employed the usual [362] M–O bond lengths of 1.8–1.9 Å. However, in chelates of type (CIV) they actually exceed 2 Å.

¶ They described [379] the metal chelate (CXI–LH) with the composition LCuBr, in which according to infrared spectroscopy the hydrogen atom of the OH group and not the NH group is substituted by the metal.

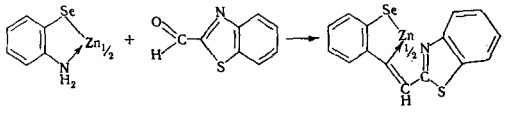


the bis(azathio)chelate unit (CXIV) is most probably formed rather than the thione configuration (CXVII):

(CXVII) (CXVIII)

The chelates of 2-mercapto-1-phenyltetrazoles (CXV, X = NH, Y = N) of type RuL_3 have an octahedral structure and those of types PtL_2 and $(RhL_2)_2$ have a planar structure [390]. The same derivatives of tetrazole with $Rh(PAr_3)_3Cl$ form mixed triphenylphosphine complexes of rhodium in which an Rh–S bond (300 cm^{-1}) and a metal chelate unit with a square planar configuration were found [396]. The dimeric octahedral complex (CXVIII) of 2-mercaptobenzothiazole with rhenium tricarbonyl is of undoubted interest [397].

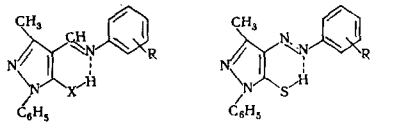
A five-membered metal chelate unit of the type under consideration is formed in 1-pyrazolyldithiocarboxylates (CXIX) [398] and in the chelates of *o*-mercaptoanils of 2-formylbenzazoles [compounds (CXX) and (CXXI)]. [9,343,344,399]



(CXIX) (CXX) (CXXI)

X = NCH_3, S

The complexes (CXX) and (CXXI) were shown to be metal chelates by infrared spectroscopy [9,343,399]. Magnetochemical studies make it possible to ascribe to the chelates (CXX) a polymeric-octahedral or tetrahedral configuration in the crystalline phase [9,343,399]. Intramolecular coordination of the metal to the nitrogen atom of the heterocyclic ring appears to be very probable in the complexes (CXXI), which have a normal magnetic moment [399].



Recently an azomethine complex (CXXII) of the azole series containing a five-membered metal chelate unit with nitrogen and selenium atoms was synthesised [9,400]:

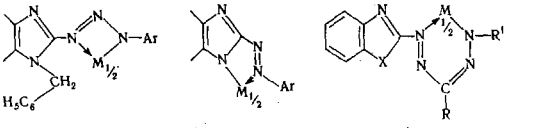
(CXXII)

As was to be expected [104], the zinc complex (CXXII) was found to have a tetrahedral structure in solution [400]. On the other hand, the pathways followed in the synthesis of this chelate with transition metals are still obscure†.

4-Phenylaminomethylene derivatives of thio- and selenopyrazol-5-one (CXXIII) [402] form chelates containing the six-membered coordination units MN_2S_2 [9,345,407] and MN_2Se_2, [9] which are rarely encountered with aromatic ligands [403–406]:

(CXXIII): R = H, *o*, *m*, *p*-CH_3, Hal, NO_2, OCH_3, $N(CH_3)_2$; X = S, Se

(CXXIV): R = H, *o*, *m*, *p*-CH_3, Hal, NO_2, OCH_3, SCH_3, $N(CH_3)_2$



† Selenium-containing azomethines are unstable. On the other hand, a reaction similar to that indicated above proceeds only with seleno- and thio-phenoxides of non-transition metals [400,401].

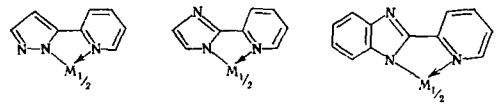
The nickel complexes of the ligands (CXXIII) have unusual magnetic properties in the crystalline phase: in contrast to the mainly diamagnetic (planar) metal chelates containing nitrogen and sulphur atoms in the coordination unit [362,408,409], these chelate complexes have intermediate effective magnetic moments varying in the range 1.3–1.8 Bohr magnetons [9,345,407]. This result is attributed to the formation in the solid phase of a mixture of square planar (diamagnetic) and polymeric-octahedral (paramagnetic) forms [345,407]. On the other hand, in solution the nickel, cobalt, and zinc chelates of (CXXIII) are tetrahedral [9,345,407] according to their dipole (Ni^{2+}, Co^{2+}, Zn^{2+}) and magnetic (Ni^{2+}, Co^{2+}) moments. The cobalt and zinc chelates apparently have the same configuration in the crystalline phase [9,345]. The nickel‡ metal chelates of thioazopyrazolones (CXXIV), synthesised for the first time by Snavely [368,369,410,411], have the same properties in the solid phase [373,410] as their azomethine analogues (CXXIII). However, in solution the chelates (CXXIV) assume the diamagnetic and polar ($\mu = 3$ D) tetragonal-pyramidal configuration with the metal atom raised above the plane of the metal-containing ring [373,412].

3. CHELATES WITH MN_4 UNITS

In his review, Hennig [207] described fairly completely the studies on chelates based on ligands with an acid NH group, including those of the azole series with an MN_4 coordination unit. Therefore we shall consider only some of the fundamental characteristics introduced by the azole moiety into the configuration of the complexes in which the metal is linked to the nitrogen atoms.

In contrast to the usually planar chelates of aromatic compounds with an MN_4 coordination unit [362,408,409], the analogous metal chelates of azole-containing systems have in the crystalline phase mainly a polymeric-octahedral structure and in solution a tetrahedral structure. This difference between the configurations of the metal chelate units was observed in a study of the magnetic and polar properties of the chelates of the azole series with four-membered [the triazene complexes [9,413] (CXXV)], five-membered [complexes of azo-compounds [9,186,414–416] (CXXVI)], and six-membered [complexes of formazans [9,28,132,416–429] (CXXVII)] metal-containing rings.

(CXXV): Ar = C_6H_4X; X = H, *p*-Alk, *p*-Cl



(CXXVI): Ar = C_6H_5, $C_6H_4CH_3$

(CXXVII): R = Alk, Ar; R' = Ar, Het

There is no doubt that the formation of polymeric-octahedral structures in the crystalline phase can be accounted for by the coordination of the metal to the nitrogen atom of the azole ring of an adjacent molecule (the monomeric units of such chelates are coordination-unsaturated) [9,418,422,424,425]. The only study in which intramolecular coordination of the metal to the sulphur atom of the thiazole ring in the nickel and cobalt complexes of *N*-thiazolylformazan [28] was postulated does not withstand criticism, since the above heteroatom virtually lacks electron-donating properties (see above). On the

‡ The chelates of thioazopyrazolones with other metals have been described and their stabilities have been determined [410,411].

other hand, planar polyhedra are encountered among chelates of the azole series with MN_4 metal chelate [207]. The latter include the nickel complexes (CXXVII) of pyridylpyrazoles, the planar structure of which has been demonstrated not only by magnetochemical [430] but also by X-ray diffraction [431] studies:

(CXXVIII) (CXXIX) (CXXX)

Possibly the above anomaly is associated with the comparatively low basicity of pyrazole. However, final conclusions will become possible only after detailed physicochemical and X-ray diffraction studies of the chelates of 2-pyridylimidazole (CXXIX) and its benzo-analogue (CXXX). [207,432]

ADDENDUM

During the preparation of the manuscript for the press, new data were published on the synthesis and structure of molecular complexes of azoles with transition metals [433-459] and complexes of polypyrazolyl borate ligands [460-462]§. Competitive coordination in the following ambident azole systems was considered: benzothiazole [445], benzoselenazole [457], *N*-vinylimidazole [439,440], 2-aminobenzazoles [463], pyridylmethylene-2-aminobenzothiazole [464], oligoheterocycles [465-470], and dinuclear copper complexes of 2-formylbenzimidazole aldoximes [471]. The structures and magnetic properties of complexes of the antipyrine series [472-483] and of acetamidothiazole [484] have been investigated.

Studies have been made on the physicochemical properties of *N*-metal-substituted 5-chloro- and 5-methoxyphenyltetrazoles [485], and 1-borylimidazole [486] and on the possible synthetic applications of silver and chloromercury salts of benzotriazole [487].

New metal chelates of *o*-hydroxyazo- [488] and *o*-hydroxyazomethine [489] derivatives of isoxazoles have been obtained. An electrochemical method has been developed [490] for the synthesis of chelates of types (XCVIII), (XCIX), (CIV), and (CV). Chelate complexes of copper(I) with 2-mercaptobenzothiazole [491] and of lanthanides with tetrazole-5-thione [492] have been synthesised.

Comparison of the properties of the chelates obtained [489,493] from pyrazole [(compounds (CXXIII)] [402] and pyrrole [494] mercaptoaldimines led to the conclusion that the heterocyclic moiety promotes a tetrahedral structure of the complexes with an MS_2N_2 coordination unit not only in solution [9,345,407] but also in the crystalline phase [489,493].

The ESR spectra of the copper complex (CXXVIII) of pyridylpyrazole have been investigated [495]. There has been a growth of interest in *C*-metal- and *C*-element-substituted derivatives of azoles [496-506]. *C*-Metal-substituted azoles have a polymeric-octahedral structure [496].

Electrochemical Oxidation of Carbon Monoxide in Aqueous Solutions

E.I.Konnik

The advances achieved recently in the electrochemical oxidation of carbon monoxide, which is a comparatively cheap fuel for electrochemical generators (fuel cells), are considered and the problems of the further improvement of the electrochemical oxidation of carbon monoxide are analysed. The electrochemical methods for the analysis of carbon monoxide, which are important for industry, medicine, and scientific research, are reviewed.
The bibliography includes 32 references.

1. INTRODUCTION

The electrochemical oxidation of carbon monoxide has been the subject of study for a long time. Together with the hydrogen and hydrazine electrodes, the carbon monoxide electrode as well as electrodes comprising hydrocarbons and other organic compounds as reducing agents are of great interest as negative electrodes in current sources and in other fields of applied electrochemistry.

However, whereas the improvement of the hydrogen electrode, by K.Kordesch, F.T.Bacon, E.Justi and coworkers, R.Kh.Burshtein and coworkers, and others, has led to a considerable increase of the current generated by porous catalytic hydrogen electrodes, the improvement of the carbon monoxide electrode has been less satisfactory.

The reversible thermodynamic potential of carbon monoxide is much more negative than that of the hydrogen electrode, particularly in 5 M KOH where it is -1580 mV at 25°C relative to the saturated calomel electrode, i.e. more negative by 450 mV than the reversible hydrogen electrode in the same solution (Justi et al.[1], p. 244). The e.m.f. of a system comprising this electrode and a reversible oxygen electrode should be 1680 mV under these conditions. However, the steady-state potential of the carbon monoxide electrode attainable at present is between only -1210 and -1230 mV.

The use of the carbon monoxide electrode in current sources appeared unpromising until recently. The rate of electrochemical oxidation of carbon monoxide on smooth metal electrodes was so low that the current generated at a moderate polarisation amounted to a few microamperes per cm^2 of the true surface. This caused workers in the 1940s and 1950s to attempt to use the carbon monoxide electrode in current sources at 700 to 900°C.[2,3] Moreover, the life of such a cell did not exceed several days and the current density at an acceptable polarisation was a few mA cm^{-2}; as shown below, the use of high temperatures is thermodynamically unfavourable.

2. THERMODYNAMIC PRINCIPLES AND HISTORY OF THE ELECTROCHEMICAL OXIDATION OF CARBON MONOXIDE

In studies on the thermodynamics of the electrochemical oxidation of carbon monoxide, one uses as the cathodic process the electrochemical reduction of oxygen, the characteristics of which at catalyst electrodes made of different materials are now being vigorously investigated in connection with the development of fuel cells employing different types of fuel. Thus the electrochemical system consists of the galvanic cell

$$^{-}\mathrm{CO} \mid \text{electrolyte} \mid \mathrm{O_2} + \qquad (1)$$

At constant pressure, the maximum amount of energy which may be obtained from an electrochemical current source is equal to the [decrease of the] free energy $-\Delta G$ of the reaction, described by the Gibbs–Helmholtz equation

$$-\Delta G = -\Delta H + T\Delta S = zFE\,, \qquad (2)$$

where ΔH is the change in the enthalpy of the system as a result of the reaction, T the absolute temperature, ΔS the change in the entropy of the system as a result of the reaction, z the number of electrons involved in the electrochemical reaction, E the e.m.f. of the current source, and F the Faraday.

Since the heat of reaction $Q = -\Delta H$, it follows that

$$zFE = Q + T\Delta S \qquad (3)$$

and further $E = Q/zF + T(\partial E/\partial T)_p$, where $(\partial E/\partial T)_p = \Delta S/zF$ is the temperature coefficient of the e.m.f.

According to Eqn.(3), the e.m.f. depends not only on the heat of the reaction in the current source, but also on the entropy term $T\Delta S = TzF(\partial E/\partial T)_p$. If $(\partial E/\partial T)_p > 0$ (the entropy increases so that $\Delta S > 0$), the e.m.f. increases with temperature.

The entropy change is equal to the difference between the entropies of the reaction products and the initial reactants:

$$\Delta S = \Sigma n_i S_{i_{prod}} - \Sigma n_i S_{i_{start}} \quad (4)$$

where n_i is the number of moles of the ith reactant.

The molar entropies of gaseous elements and many gaseous compounds differ little from one another and are considerably higher than the entropies of liquid and solid substances. In other words, since the degree of disorder in it is highest, the gas phase makes the greatest contribution to the entropies. Therefore $\Delta S > 0$ if the number of moles of the gaseous reaction products $n_{g.prod}$ is greater than the number of moles of the gaseous starting materials.

If $n_{g.prod} < n_{g.init}$, then $\Delta S < 0$, $(\partial E/\partial T)_p < 0$, and the e.m.f. decreases with temperature. If $n_{g.init} = n_{g.prod}$, then $\Delta S \simeq 0$, $(\partial E/\partial T)_p \simeq 0$, and the e.m.f. hardly depends on temperature, as, for example, the e.m.f. of the current source in which the following reactions take place:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O,$$
$$C + O_2 \rightarrow CO_2.$$

For the reaction $2CO + O_2 \rightarrow 2CO_2$, $n_{g.prod} < n_{g.init}$ and therefore the e.m.f. of the current source in which carbon monoxide is oxidised electrochemically by oxygen decreases with temperature, as can be seen from Fig. 1 which includes for comparison the temperature dependence of the e.m.f. of the hydrogen–oxygen cell.

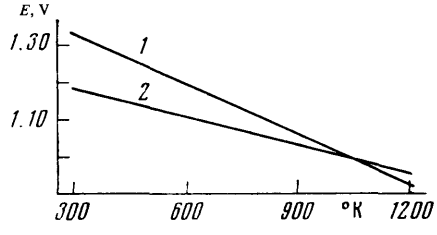

Figure 1. Temperature variation of the e.m.f.'s of gas cells: 1) carbon monoxide–oxygen cell; 2) hydrogen–oxygen cell.

The maximum (ideal) efficiency in the complete electrochemical oxidation of the fuel is

$$\eta = \frac{-\Delta G}{-\Delta H},$$

whence, using Eqns. (2) and (3), we obtain

$$\eta = 1 + T \cdot \frac{\Delta S}{Q}. \quad (5)$$

It is evident from Eqn. (5) that η may be greater than unity (i.e. greater than 100%) for a reaction with $\Delta S > 0$ ($n_{g.prod} > n_{g.init}$). In this case, the operation of the current source involves the removal of heat $\Delta Q = T\Delta S$ from the surrounding medium and its transformation into electrical energy. The cell itself does not become cold.

For example, a current source of this type would be one in which electrochemical oxidation of carbon occurs: $2C + O_2 \rightarrow 2CO$ (incomplete combustion of carbon).

In the electrochemical oxidation of carbon monoxide, $\Delta S < 0$, so that η of cell (1) decreases with temperature. This is evident from Table 1, which includes for comparison also data for the hydrogen–oxygen cell (Justi et al.[1], p. 32).

Thus the use of the carbon monoxide electrode in an electrochemical cell at a low temperature (not exceeding 100°C) under the conditions employed to develop active electrodes is more promising than at high temperatures, as was suggested at one time by Davtyan[2] and Daniel' Bek et al.[3] and comparatively recently by Chambers and Tantram[4].

Table 1.

Reaction	Z	T° K 300		600		900		1200		$\left(\frac{\partial E}{\partial T}\right)_p \cdot 10^3$
		E	η	E	η	E	η	E	η	
$2CO + O_2 \rightarrow 2CO_2$	4	1.33	0.91	1.2	0.81	1.06	0.72	0.92	0.63	0.445
$2H_2 + O_2 \rightarrow 2H_2O$	4	1.18	0.94	1.1	0.88	1.03	0.80	0.95	0.73	0.255

Justi and Grüneberg and coworkers, as well as other electrochemists including Soviet workers, have contributed to recent advances in the low-temperature electrochemical oxidation of carbon monoxide. One of the first attempts to employ the carbon monoxide electrode was in the Borchers cell (1894) (Davtyan[5], p. 39):

$$-CO\,(Cu)\,|\,HCl,\,CuCl\,|\,(Cu)\,O_2^+. \quad (6)$$

Borchers suggested that the electrodes were involved in the following reactions:

At the anode	At the cathode
$2Cl^- \rightarrow Cl_2 + 2e$,	$2Cu^{2+} + 2e \rightarrow 2Cu^+$,
$Cl_2 + CO_{soln.} + H_2O \rightarrow CO_2 + 2H^+ + 2Cl^-$	$^1/_2O_2 + 2Cu^+ + 2H^+ \rightarrow 2Cu^{2+} + H_2O$.
Overall process:	Overall process:
$CO_{soln.} + H_2O \rightarrow CO_2 + 2H^+ + 2e$.	$^1/_2O_2 + 2H^+ + 2e \rightarrow H_2O$.

However, the insignificant e.m.f. of this cell could not be due, according to some investigators, to the above reactions. Mond (Davtyan[5], p. 39) suggested that the e.m.f. of the Borchers cell is due to the electrodes employed. He justified this hypothesis by the fact that the replacement of the copper electrodes in the Borchers cell by carbon electrodes reduces the e.m.f. almost to zero. No data are available for the potential of the Borchers cell when the current is drawn to an external circuit.

More successful was the Hofmann cell[6,7]:

$$-\,CO\,(Cu)\,|\,KOH\,|\,(CuO,\,Cu)\,O_2\,+. \quad (7)$$

Here the potential close to that of the reversible hydrogen electrode is established at the copper|carbon monoxide electrode and Hofmann noted that this electrode gives a higher current for the same polarisation if the material of the electrode is partly in a carbon monoxide atmosphere (the idea which found a practical application in porous electrodes). The e.m.f. of this cell was 1.04 V, increasing to 1.17 V when platinum was employed as the material of the positive electrode. Apart from a fairly high e.m.f., another advantage of this cell when the electrode materials

described are employed is the use of an alkaline electrolyte in which copper is much more stable than in the electrolyte of the Borchers cell [cell (6)] and the rate of electrochemical reduction of oxygen is much higher. However, cell (7) suffers from the disadvantage that its electrolyte reacts with the product of the reaction.

3. KINETICS AND MECHANISM OF THE DIRECT ELECTROCHEMICAL OXIDATION OF CARBON MONOXIDE

Direct low-temperature electrochemical oxidation of carbon monoxide has been investigated at Group IB and VIII metals and also at tungsten, rhenium, and molybdenum. The electrodes were both smooth and porous (Raney type catalysts made of these metals were employed).

a. Acid Solutions

The experimental data available at present for the steady-state potentials of the carbon monoxide electrode made of different metals and their behaviour under the conditions of anodic polarisation are presented in Table 2 (the partial pressure of carbon monoxide is 1 atm throughout).

Almost all the few available data concerning sulphuric acid solutions demonstrate the difficulty of devising a carbon monoxide electrode in acid solutions. This is shown firstly by the finding that between 10° and 80°C the steady-state potential at platinum and palladium and platinised platinum electrodes not only does not approach the value for the reversible carbon monoxide electrode but does not even reach the potential of the reversible hydrogen electrode in this solution (Table 2). The only exception are data obtained recently by a group of German electrochemists for Pt-DSC † electrodes [11]. Secondly, this is indicated by the polarisation characteristics of the carbon monoxide electrodes made of these metals. At a smooth platinum electrode, an appreciable rate of electrochemical oxidation of carbon monoxide (about 0.1 mA cm^{-2}) is achieved only at a potential of 850–900 mV [8] and reaches a maximum (about 1 mA cm^{-2}) at a potential of 1000–1100 mV. The current depends both on the potential of the electrode (the state of its surface) and on the diffusion flux of carbon monoxide. On further increase of the potential, the current falls almost to zero owing to the passivation of the electrode by oxygen.

Recent data concerning the electrochemical oxidation of carbon monoxide in 3 *N* sulphuric acid are of considerable interest for the formation of a highly active carbon monoxide electrode at low temperatures [11]. The authors employed DSC electrodes about 1 mm thick comprising a Raney platinum catalyst. The steady-state potential of the carbon monoxide electrode measured at 100°C was 0.0 mV (Table 2), i.e. was more positive than the reversible carbon monoxide electrode only by 132 mV, while in experiments [1] in 5 *N* KOH (85°C) using Raney molybdenum as a catalyst, the steady-state potential was more positive than that of the reversible carbon monoxide electrode by 370 mV.

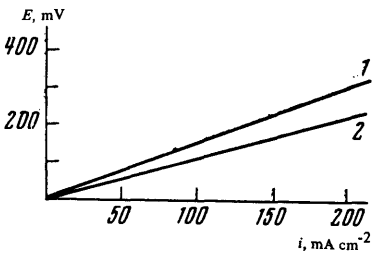

Figure 2. Steady-state polarisation characteristics of platinum DSC electrodes at 100°C (potentials given relative to the hydrogen electrode in the same solution): 1) carbon monoxide as depolariser; 2) hydrogen as depolariser.

Fig. 2 presents the steady-state polarisation characteristics for the electrochemical oxidation of carbon monoxide and hydrogen at a Pt–DSC electrode [11]. Evidently the rate of electrochemical oxidation of carbon monoxide at this electrode is fully comparable to the rate of electrochemical oxidation of hydrogen under these conditions for a not much higher polarisation. The polarisation characteristics of this Pt–DSC electrode in the electrochemical

† A double-skeleton catalyst electrode (Ed. of Translation).

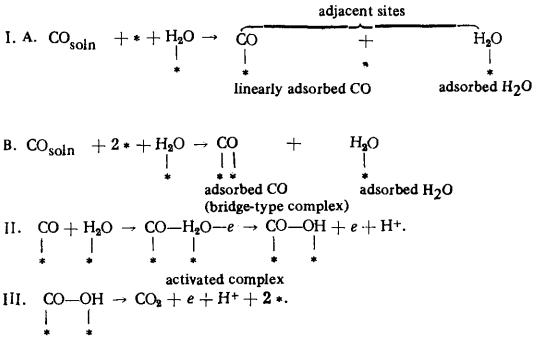
oxidation of carbon monoxide are much better than in the electrochemical oxidation of hydrocarbons such as methane, ethane, and ethylene. Thus the kinetic parameters available at present for the carbon monoxide electrode in acid solutions are satisfactory.

The process mechanism has been considered by many investigators, who established that the carbon monoxide adsorbed on platinum and palladium exists in two forms (Young [13], p. 30; Fasman et al. [14]): a bridge form (8a) and a less stable linear form (8b).

(8a)

(8b)

Carbon monoxide is adsorbed when the *d* shell of the metal contains unfilled levels [15] and the greater the number of *d* vacancies the more stable the adsorption bond. The fraction of *d* vacancies in palladium is 0.55 per atom [16] and the metal can form fairly stable chemical compounds with carbon monoxide. Their stability depends on the pH: [9] in alkaline solutions, they are less stable and are located on the surface of the electrode, while in acid solutions they penetrate also the crystal lattice of the metal and decompose only at an elevated temperatures.



Accordingly, when carbon monoxide is introduced on platinum in 1 *N* sulphuric acid [10] at a potential of 500 mV relative to the hydrogen electrode in the same solution (the so called double layer region) at 50–70°C, the potential shifts to 50–70 mV in 30–60 min. Then it begins to move slowly towards positive values, because at 10–15°C carbon monoxide undergoes physical adsorption and at 20–30°C CO is converted into CO_2 and H_2 by the reaction

$$CO + H_2O \rightarrow CO_2 + H_2 . \qquad (9)$$

At 50–70°C the conversion of carbon monoxide is accompanied by its stable chemisorption (the formation of bridge-type bonds) and the hydrogen formed initially is displaced from the surface of the electrode. Thus at 50–70°C the potential–time curve has a minimum which can be accounted for by the onset of the conversion of carbon monoxide. This is confirmed also by the analysis of the gas phase when the electrode is saturated with carbon monoxide. The maximum carbon dioxide and hydrogen contents were observed precisely at 20–30°C. [10] Similar relations are observed in the adsorption of carbon monoxide on palladium [9,17].

The form of the potential–time curves [10] leads to the conclusion that, in contrast to 1 *N* H_2SO_4, in 1 *N* $HClO_4$ on platinised platinum there is no conversion of CO, since, after the attainment of a steady-state potential, the latter no longer changes in the temperature range 10–50°C. In this case surface compounds with weak and stable bonds are formed.

The mechanism of the step involving the electrochemical oxidation of carbon monoxide in 1 *N* $HClO_4$ at a platinum electrode was investigated by Gilman [18] in a stirred CO-saturated solution through which a triangular potential pulse was applied at a rate of 0.04 V s^{-1} at potentials between 400 and 1800 mV (relative to the hydrogen electrode in the same solution). Up to a potential of 700 mV, the current was very low, reaching a maximum of approximately 4 mA cm^{-2} at a potential of 800 mV. Subsequently the current fell sharply and then increased again only at 1550 mV, owing to the evolution of oxygen. When the potential was varied in the opposite direction, the curve had a different form. Gilman suggests a three-stage mechanism for the electrochemical oxidation of carbon monoxide at a platinum electrode in an acid solution (* — active adsorption centre):

According to Gilman stages I (A and B) are very fast whatever the surface coverage not exceeding the equilibrium value, and their rate is determined by that of the diffusion of carbon monoxide. Stage II, which proceeds via the activated complex, determines the rate of electrochemical oxidation of carbon monoxide, which involves weakly adsorbed carbon monoxide. Stage III is fast.

The electrochemical oxidation of carbon monoxide,

$$CO + H_2O \rightarrow CO_2 + 2H^+ + 2e , \qquad (10)$$

in 2 *N* H_2SO_4 on polished platinum [12] is regarded as chemical oxidation of carbon monoxide by oxygen evolved on the electrode and chemisorbed in the atomic form. The oxygen atoms react rapidly with chemisorbed CO to form CO_2, which is desorbed from the electrode. As a result, platinum is freed for the adsorption of fresh CO molecules and the process mechanism can be represented as follows:

$$\begin{cases} Pt + H_2O \rightarrow Pt{-}O + 2H^+ + 2e , \\ Pt{-}O + Pt{-}CO \rightarrow Pt_2{-}CO_2 , \\ Pt_2{-}CO_2 \rightarrow 2\,Pt + CO_2 . \end{cases} \qquad (11)$$

In the same study [12], it was observed that the electrode potential varies comparatively little when the surface coverage by monoxide falls to zero, as can be seen from the following data:

	CO partial pressure, atm			
	1.0	0.1	0.0037	0.00
CO oxidation potential, mV (relative to the normal hydrogen electrode).	1.25±0.13	1.18±0.11	1.03	1.00±0.11

These data confirm that there is no direct electrochemical oxidation of carbon monoxide, since the potential should change more markedly with decrease of the surface coverage by carbon monoxide. In both investigations [12,18], it was concluded that the carbon monoxide molecule is not involved in electron exchange with the electrode. The difference between them is as follows: Gilman [18] postulates that carbon monoxide is oxidised via an activated complex with water, while Warner and Schuldiner [12] believe that it proceeds via the dissociation and adsorption of oxygen, the adsorption of carbon monoxide, and the chemical reaction between the adsorbed carbon monoxide and atomic oxygen according to Eqn. (11) with subsequent desorption of carbon monoxide.

It is at present difficult to make a well-founded choice between these two mechanisms. Probably the mechanism should depend on the nature of the metal and its capacity to adsorb carbon monoxide and water. The inhomogeneity of the surface of the metal, which involves the possibility that the process may occur via different mechanisms on its different parts, is also important.

The attainment of the hydrogen electrode potential at DSC electrodes [11] led the authors to the hypothesis that carbon monoxide reacts with water to form carbon dioxide and molecular hydrogen. However, under these conditions there is also a possibility of direct electron exchange between carbon monoxide and the electrode metal, since Raney catalysts reduce sharply the activation energy for the reaction. Therefore it may prove unnecessary for the reaction to proceed via an activated complex to reduce the activation energy and also there may be no need for the interaction with the surface oxides on the electrode metal or for the shift of the electrode potential towards positive values up to 1 V and above (relative to the hydrogen electrode in the same solution). The observation of DSC electrode potentials more negative than the reversible hydrogen electrode potential would confirm this possibility.

An important characteristic of platinum and gold electrodes is that in acid solutions (1 *N* $HClO_4$) at potentials in the region of 1.25 V (relative to the hydrogen electrode in the same solution), the electrode surface is poisoned during the oxidation of carbon monoxide at a constant potential [19]. The poisoning is due to the products of the competing electrode reaction involving the oxidation of CO to $(CO)^+$. The (CO^+) cation is removed slowly by electrochemical oxidation and subsequent slow desorption.

The capacity of the starting material to form a non-poisoning rather than a poisoning product is characterised by the selectivity constant S, which, like the rate constant kS for the electrochemical removal of the poison, i.e. $(CO)^+$, depends on the electrode material. According to these parameters, platinum is a better electrode metal than gold. For platinum, $S = 0.9742$ and $kS = 6.61 \times 10^{-2}$ s^{-1} and for gold, $S = 0.9148$ and $kS = 2.3 \times 10^{-4}$. [19]

b. Alkaline Solutions

The experimental data obtained hitherto for the steady-state potentials of carbon monoxide electrodes made of different metals and their behaviour under the conditions of anodic polarisation are presented in Table 3 (the partial carbon monoxide pressure is 1 atm throughout).

The data in Table 3 show that in alkaline solutions it is easier to form a carbon monoxide electrode with satisfactory polarisation characteristics. As in acid solutions, best results were achieved with DSC electrodes.

For a smooth copper electrode in 5 *N* KOH, there is a linear relation between the CO oxidation current and potential when the latter is varied from −100 mV (relative to the hydrogen electrode in the same solution) to 400 mV. [20] Next, anodic dissolution of copper begins and the current rises sharply. The negligible adsorption of hydrogen by the copper electrode leads to virtual absence from the polarisation curve for this electrode of the section corresponding to the oxidation of hydrogen. Moreover, copper has an exceptional hydrogen overvoltage [series (16)] and the probability of the evolution of hydrogen is low even at a potential of −100 mV. However, at a potential of 400 mV, the current density reaches not more than 10 $\mu A\ m^{-2}$, which is very low for such a high polarisation. There are no data for the dependence of the potential and the current on the diffusion flux at a copper electrode.

The rate of electrochemical oxidation of carbon monoxide at a smooth palladium electrode in 5 *N* KOH is very much higher [20]. Up to a potential of 100–120 mV (relative to the hydrogen electrode in the same solution), H_2 is oxidised and then up to a potential of 380–400 mV the oxidation of carbon monoxide takes place. Above this potential, the process reaches the region of the limiting current, which is approximately 150 $\mu A\ cm^{-2}$. At a palladium electrode, the current depends markedly on the diffusion flux.

Among DSC electrodes comprising different Raney catalysts, the most satisfactory electrode is one with a molybdenum catalyst, giving a current of 30 mA cm^{-2} for a polarisation of 130 mV at 83°C, which is comparable with the polarisation characteristic of the Ni–DSC hydrogen electrode (Justi et al. [1], pp. 246, 277).

*Double-skeleton catalyst electrode comprising a Raney catalyst made from the given metal (Justi et al. [1], p. 246).

At a new electrode comprising the nickel sulphide (Ni_3S_2) catalyst in 6 *N* KOH, steady-state potentials of −180 and −60 mV at 75° and 25° respectively have been attained [21], these being the most negative values found for alkaline solutions (Table 3). However, they are far from the thermodynamic electrode potentials of the CO/CO_3^{2-} system. At a potential of 200 mV and a partial CO pressure of 1 atm in the same system at 75°C, the current reaches 80 mA per cm^2 of the apparent surface. In 1 M K_2CO_3 + 1 M $KHCO_3$ at 75°C and a potential of 180 mV, the current reaches 0.1 mA cm^{-2}. [21] It is extremely interesting that at the nickel sulphide electrode the oxidation of carbon monoxide is selective and H_2, NH_3, methanol, and formate ions present in solution are not oxidised. Therefore, bearing in mind that at a constant potential the CO electrochemical oxidation current is proportional under these conditions to the carbon monoxide concentration, such an electrode can be used as an indicator in the electrochemical determination of carbon monoxide.

Two mechanisms have been proposed for the electrochemical oxidation of carbon monoxide in alkaline solutions. One of these was proposed by Hofmann, who investigated cell (7), and Grüneberg (Justi et al.[1], p. 243), who studied the process at Cu–DSC and Ni–DSC electrodes in alkaline solutions. According to these investigators, the electrode process proceeds via a preliminary purely chemical stage with subsequent electrochemical oxidation of the hydrogen formed:

$$CO + 2OH^- \rightarrow CO_3^{2-} + 2H_{ads} \quad \text{(chemical stage)}, \qquad (12a)$$

$$2H_{ads} \rightleftarrows 2H^+ + 2e \quad \text{(electrochemical stage)}. \qquad (12b)$$

Grüneberg found that the following reactions can also take place at Ni–DSC electrodes:

$$CO + OH^- \rightarrow HCOO^- \quad \text{(chemical stage)}, \qquad (13a)$$

$$HCOO^- + OH^- \rightarrow CO_3^{2-} + 2H_{ads}$$

$$2H_{ads} \rightleftarrows 2H^+ + 2e \quad \text{(electrochemical stage)}. \qquad (13b)$$

Hofmann and Grüneberg justified these conclusions on the basis of the experimental finding that, when carbon monoxide is passed over Raney nickel and Raney copper electrodes, the latter attain the reversible hydrogen electrode potential to within 20 mV. However, Hofmann and Grüneberg's hypotheses cannot be regarded as convincing, since potentials significantly more negative than the reversible hydrogen electrode value have now been attained at the copper electrode in the same solution (Table 3). Grüneberg's postulate concerning the course of reactions (13a) and (13b) also cannot be regarded as final, since, firstly, the hydrogen electrode potential of the Ni–DSC electrode is established with a low reproducibility and, secondly, the hydrogen overvoltage of this electrode is insignificant. Therefore the slight shift of the potential towards negative values from the reversible hydrogen electrode value causes liberation of hydrogen, which resists this shift. Consequently another mechanism for the electrochemical oxidation of carbon monoxide, proposed by Justi et al.[1] (p. 244) and by Miller et al.[8], which accounts for the fact that the potential of certain metals is more negative than that of the reversible hydrogen electrode (this cannot be explained on the basis of the Hofmann–Grüneberg mechanism), is more likely:

$$CC_{ads} + 2OH^-_{ads} \rightarrow \underset{\downarrow K_2CO_3}{CO_2} + H_2O + 2e \quad . \qquad (14)$$

When the reversible hydrogen electrode potential is attained, the reduction of H^+ ions, the rate of which is determined by the electrode potential and the hydrogen overvoltage of the electrode material, becomes possible together with the oxidation of carbon monoxide. The hydrogen liberated consumes a certain number of electrons, which increases the rate of electrochemical oxidation of carbon monoxide without electrons being given up to the external circuit. This reduces the coefficient of utilisation of carbon monoxide when a carbon monoxide electrode is used in electrochemical cells. Thus, at potentials more negative than the hydrogen electrode potential in the same solution, two reactions [reactions (14) and (15)] take place simultaneously on the electrode:

$$2H^+ + 2e \rightarrow H_2 \rightleftarrows 2H_{ads} \quad . \qquad (15)$$

Reaction (15) is secondary. The hydrogen liberated as a result of this process is adsorbed on the electrode, reducing its capacity to adsorb carbon monoxide and possibly occupying active centres on the electrode surface.

The reversible carbon monoxide electrode potential can be approached only for electrodes with a significant hydrogen overvoltage. It is then necessary to bear in mind the following series of metals in terms of their hydrogen overvoltages (Frumkin et al.[22], p. 154):

$$\underset{\text{increase of hydrogen over voltage}}{\overset{\text{increase of catalytic activity in recombination of H atoms}}{\longleftarrow \text{Pt, Pd, W, Ni, Fe, Ag, Cu, Zu, Sn, Pb} \longrightarrow}} \quad . \qquad (16)$$

Therefore the carbon monoxide electrode potential obtained for palladium, which has a much higher hydrogen overvoltage than platinum (Antropov[23], p. 352), was appreciably more negative than the potential of the reversible hydrogen electrode (Table 3). However this is not easy to achieve and not all the investigators obtained such a potential for palladium[9].

A platinum electrode potential more negative than that of the reversible hydrogen electrode has not been obtained[13]. On the other hand, the steady-state carbon monoxide electrode potentials of copper and gold[24], which have a significant hydrogen overvoltages according to series (16), are closer to the reversible value (Table 3).

Analysis of the literature data shows that, as in acid solutions, a high electrochemical activity in relation to carbon monoxide in alkaline solutions requires that the electrode metal should have unfilled *d* orbitals. The electrode potential of the carbon monoxide electrode (and the free energy to which it is proportional) are approximately proportional to the heat of chemisorption. Therefore a stronger bond between carbon monoxide and the chemisorbing metal (a higher heat of chemisorption) increases the irreversible losses of free energy and decreases the steady-state electrode potential.

Evidently a potential close to that of the hydrogen electrode in the same solution is established for palladium (Table 3, Young[13]), while in more alkaline solutions a still more negative potential, up to −150 mV, is reached (Table 3, Tyurikova[20]).

4. ELECTROCHEMICAL OXIDATION OF CARBON MONOXIDE IN THE PRESENCE OF ELECTRON TRANSFER REAGENTS (VARIABLE-VALENCE IONS) AND OF HOMOGENEOUS CATALYSTS

In the electrochemical oxidation of carbon monoxide, the reaction product is carbon dioxide which is absorbed by the electrolyte in alkaline solutions, decreases the activity of the alkali, and impairs the operation of the carbon monoxide electrode. Therefore the use of acid solutions, where this difficulty is absent, would appear to be more promising. However, the materials for DSC electrodes employed in such solutions are very expensive[11]. The difficulty might be resolved on the basis of recent studies of the electrochemical oxidation of carbon monoxide in acid solutions with the aid of variable-valence ions, which are sometimes referred to as electron transfer reagents. Apart from the sharp increase of the rate of reaction at smooth electrodes, an advantage of this procedure is the possibility avoiding the use of a complex system such as porous electrodes.

The guiding factor in the choice of electron transfer reagents is that the potential of their oxidation-reduction transition should be more positive than that of the reversible hydrogen electrode in the given solution and the redox system should be readily regenerated by carbon monoxide.

The effect of complex salts of palladium(II), rhodium-(III), and platinum(IV) [25] and also of ruthenium(IV), osmium(IV), and iridium(IV) [26] on the kinetics of the reduction of $Cr_2O_7^{2-}$, IO_3^-, Fe^{3+}, $[Fe(CN)_6]^{3-}$, Cu^{2+}, and Sn^{4+} ions by carbon monoxide in the liquid phase has been investigated. The rate of reduction in the presence of the above homogeneous catalysts varies in parallel with the standard oxidation-reduction potentials of the corresponding redox systems. The values of these potentials (E_0) at 25°C are presented in Table 4 (Vetter [27], p. 61).

Table 4.

Redox system	Electrode reaction	E_0, mV (rel. to normal hydrogen electrode)
$Cr^{3+}/Cr_2O_7^{2-}$	$2Cr^{3+} + 7H_2O \rightarrow Cr_2O_7^{2-} + 14H^+ + 6e$	+1330
I_2/IO_3^-	$^1/_2I_2 + 3H_2O \rightarrow IO_3^- + 6H^+ + 5e$	+1195
Fe^{2+}/Fe^{3+}	$Fe^{2+} \rightarrow Fe^{3+} + e$	+771
$[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$	$[Fe(CN)_6]^{4-} \rightarrow [Fe(CN)_6]^{3-} + e$	+360
Cu^+/Cu^{2+}	$Cu^+ \rightarrow Cu^{2+} + e$	+158
Sn^{2+}/Sn^{4+}	$Sn^{2+} \rightarrow Sn^{4+} + 2e$	+150

Thus the reducible ions investigated can be arranged in the following sequence:

$$\xrightarrow[\text{increase of standard redox potential and of rate of reduction by carbon monoxide}]{Sn^{4+},\ Cu^{2+},\ [Fe(CN)_6]^{3-},\ Fe^{3+},\ IO_3^-,\ Cr_2O_7^{2-}} \quad (17)$$

In terms of their activity, homogeneous catalysts can be arranged in the series $Pd^{2+} > Rh^{3+} > Pt^{4+}$ and the most active catalysts are the acido-complexes of the anion $[PdBr_4]^{2-}$. The rate of reduction by carbon monoxide is proportional to the amount of catalyst at its low concentrations and tends to a limit at high concentrations [25]. An excess of Cl^- ions inhibits the reduction reaction and an excess of Br^- ions accelerates it. In conformity with the laws of chemical kinetics, the experimental rate of reduction of the redox system is directly proportional to the partial pressure of carbon monoxide.

Carbon monoxide is readily adsorbed on copper and palladium. However, the dissolution of copper in acid solutions rules out its employment as the electrode metal. The first studies on the electrochemical oxidation of carbon monoxide at platinum and palladium using the Cu^+/Cu^{2+} redox system are now being made. The mechanism of the anodic process involving the Cu^+/Cu^{2+} system is described by the reaction

$$2CO + 2H_2O + 4Cu^{2+} \rightarrow 4Cu^+ + 2CO_2 + 4H^+ . \quad (18)$$

When this type of electrode is employed together with an oxygen electrode, the following overall reaction takes place at the cathode of the resulting cell:

$$O_2 + 2H_2O + 2e \rightarrow 2H_2O_2 + 2e \rightarrow 4OH^- . \quad (19)$$

The overall process in the carbon monoxide–oxygen electrochemical cell is

$$2CO + 4Cu^{2+} + O_2 \rightarrow 4Cu^+ + 2CO_2 . \quad (20)$$

The amounts of water consumed and formed in reaction (20) are identical. Thus water serves as an agent transferring oxygen from the cathode to the anode. The role of the redox system reduces to the transfer of electrons from the CO molecule to the anode. The redox system is regenerated by oxidation at the anode. The reaction product (carbon dioxide) is removed from the solution as it is formed.

However, the current densities obtained when the Cu^+/Cu^{2+} system is employed amount to several mA cm^{-2}. Such low current densities can be apparently accounted for by the fact that, although the redox system has a sufficiently negative E_0 (Table 4), according to series (17) the rate of reduction of the Cu^{2+} ion by carbon monoxide is low. Moreover, at this current density the electrode potential is markedly displaced towards positive values, which makes this redox system relatively unsuitable for use in electrochemical cells at the present stage of development. It is also necessary to investigate the effect of the Cu^+ and Cu^{2+} additives introduced into the electrolyte on the oxygen electrode.

5. THE PROBLEM OF THE ELECTROLYTE IN THE ELECTROCHEMICAL OXIDATION OF CARBON MONOXIDE

Until comparatively recently, the choice of an electrolyte for the electrochemical oxidation of carbon monoxide involved a vicious circle, which now can be regarded as having been broken. The point is that the rate of electrochemical oxidation of carbon monoxide in acid solutions at smooth electrodes is negligibly low (and porous electrodes have begun to be used only comparatively recently). In alkaline solutions, where not only the rate of electrochemical oxidation of carbon monoxide but also the rate of electrochemical reduction of oxygen is higher, the electrolyte absorbed the carbon dioxide formed, which entails a decrease in the activity of the alkali and impairment of the operation of the carbon monoxide electrode.

This difficulty was partly overcome for alkaline electrolytes by the suggestion of Matusevich and Bagotskii [28], who investigated the effect of carbon dioxide passed through a weakly alkaline electrolyte on the pH of the solution. In such a solution, carbonate and bicarbonate are in equilibrium:

$$CO_3^{2-} + CO_2 + H_2O \rightleftarrows 2HCO_3^- , \quad (21)$$

and the presence of OH^- ions is ensured by the hydrolysis of the bicarbonate. The alkalinity of the solution increases as the equilibrium in reaction (21) shifts to the left with increase of temperature. It was found that at 98°C this type of electrolyte, consisting of $K_2CO_3 + KHCO_3 + H_2O$, at an overall concentration between 3 and 5 N and with constant flow of carbon dioxide, undergoes hardly any change in pH. However, this investigation refers to weakly alkaline solutions (pH not exceeding 10), which are employed comparatively rarely.

It has been stated that Justi and Winsell [29] developed a more promising method involving electrodialysis, whereby the absorption of carbon dioxide by alkali may be prevented. In the operation of a carbon monoxide electrode in an electrochemical cell, not more than 10% of the electrical energy generated by the cell is consumed in the electrodialysis.

A Pd-DSC electrode, which can work in both alkaline and acid solutions [29], has also been developed. In addition there is a Pt-DSC electrode [11] the characteristics of which in acid solutions are not inferior to those of DSC electrodes in alkaline solutions (Table 2). However, in acid solutions both these electrodes have to be made of precious metals, while the DSC electrodes for alkaline solutions require comparatively cheap metals such as nickel, copper, tungsten, and molybdenum.

At present, when the problem of the prevention of the absorption of carbon dioxide by alkaline solutions is close to being solved, the use of alkaline solutions with appropriate DSC electrodes is more justified. However, the future development of DSC electrodes will probably lead to the creation of cheap effective porous electrodes for acid solutions too.

Thus the development of porous electrodes, which has yielded important improvements by accelerating the electrode process and the ways of solving the problem of the electrolyte which have become apparent bring us closer to the achievement of the electrochemical oxidation of carbon monoxide at current densities acceptable in practice.

6. THE APPLICATIONS OF THE CARBON MONOXIDE ELECTRODE

From the very beginning, the carbon monoxide electrode was studied with the aim of its employment in electrochemical cells. The cells proposed by Borchers [5], Hofmann [6,7], Davtyan [2], Daniel' Bek et al. [3], and Chambers and Tantram [4] were of this kind. This is because carbon monoxide is a cheap fuel, which forms part of the gaseous waste from many industrial processes. It can also be obtained by the subterranean gasification of coal.

There has been a particular growth of interest in carbon monoxide electrodes in connection with the problem of fuel cells. The satisfactory results obtained recently in the electrochemical oxidation of carbon monoxide at DSC electrodes in alkaline solutions (Table 3) show that under certain conditions the carbon monoxide electrode is promising as a negative electrode in fuel cells with a weakly alkaline electrolyte.

The studies on the carbon monoxide electrode designed for use in electrochemical cell have created a basis for the development of electrochemical methods for the analytical determination of carbon monoxide. However, their practical application involves many difficulties. One must bear in mind that, when the hydrogen electrode potential in a given solution is attained, the evolution of hydrogen becomes possible. The rate of this process is determined by the electrode potential and the hydrogen overvoltage of the electrode material. The evolution of hydrogen involves the consumption of a certain number of electrons, which increases the rate of electrochemical oxidation of carbon monoxide without transfer of electrons to the external circuit. This may distort the variation of the current or potential with carbon monoxide concentration. If the electrode potential shifts towards values more positive than the hydrogen electrode potential in the given solution, the accumulated adsorbed hydrogen gives rise to an additional anodic current, which also distorts the proportionality between the current and the carbon monoxide concentration. Therefore, for the analytical determination of carbon monoxide, it is particularly necessary to create an electrode at which only the electrochemical oxidation of carbon monoxide would occur. This can be achieved in two ways: by maintaining the electrode potential in the range of values more positive than the hydrogen electrode potential in the given solution or by using an electrode metal with a higher hydrogen overvoltage.

Ovenden [30], who developed an amperometric method for the analytical determination of carbon monoxide at a palladium electrode, followed the first procedure. Moreover, according to series (16), palladium has a higher hydrogen overvoltage than platinum. The experiments were performed at a vibrating steel microelectrode coated with palladium, platinum, rhodium, and iridium at carbon monoxide concentrations in the phase analysed (air) between zero and 100%. The maximum sensitivity (current) and maximum linearity of the variation of the current with carbon monoxide concentration were obtained at palladium, which is the most effective catalyst, among all the metals investigated by Ovenden [30], of the reaction between carbon monoxide and oxygen, in agreement with a number of other data [13,20,29]. The limiting diffusion current at palladium is attained when the potential is between 1.4 and 1.5 V relative to the hydrogen electrode in the same solution. The electrolyte consisted of 0.1 M sodium phosphate (pH 7) and 0.1 M sodium borate (pH 10) buffers and the diffusion coefficients of carbon monoxide in these solutions were found to be respectively 2×10^{-5} and 5×10^{-5} $cm^2\ s^{-1}$. In water, the diffusion coefficient of carbon monoxide is $(2.5 \pm 0.1) \times 10^{-5}$ $cm^2\ s^{-1}$. In the borate buffer [30], the limiting diffusion current was approximately twice as high as in the phosphate buffer, which is due to the difference between the diffusion coefficients of carbon monoxide in these solutions. In the region of the limiting diffusion current in the $CO-O_2$ mixture, the dependence of the current on the carbon monoxide concentration is almost linear at carbon monoxide concentrations between 0 and 100% and independent of electrode polarisation. This shows that in this case the limiting current is fully diffusion-dependent, which is very important for analytical purposes.

Roberts and Sawyer [32], who developed a polarographic method for the determination of carbon monoxide at a gold electrode, which has a high hydrogen overvoltage (Antropov [23], p.352), followed the second procedure. They used spherical and plate electrodes in 0.01 N KOH + 0.1 N K_2SO_4 solution. In the recording of the polarogram at a potential of approximately −500 mV (relative to the saturated calomel electrode), a distinct current peak, controlled by the diffusion of carbon monoxide, was observed. This peak current follows the equation

$$i_p = 3.01 \cdot 10^5 n [n_\alpha (1-\alpha)]^{1/2} A D^{1/2} c v^{1/2} \qquad (22)$$

where n is the number of electrons involved in the electrode reaction, n_α the number of electrons involved in the rate-determining stage of the electrode reaction, A the area of the electrode surface (cm^2), v the rate of increase of potential ($V\ s^{-1}$), c the concentration of carbon monoxide ($mole\ cm^{-3}$), and α the transport coefficient of the electrode process.

The current peak was directly proportional to the carbon monoxide concentration in the range between 0 and 100% in a carbon monoxide–molecular nitrogen mixture, the relation being linear over the entire concentration range investigated. The error of the method is not more than ±2%.

Heterophase Radical Polymerisation

V.A.Popov and G.P.Gladyshev

The review deals with the characteristics of the heterophase polymerisation of various monomers, the effect of the transition from a homogeneous to a heterogeneous system, and certain physical factors on the rate of polymerisation, the molecular weight of polymers, and the composition of copolymers. A general account is given of published data for the morphological structure of the polymer phase formed. The views of various investigators on the mechanism of the heterophase polymerisation are discussed and the kinetic mechanisms and models of heterophase polymerisation are examined critically.

The bibliography includes 164 references.

I. INTRODUCTION

One of the thoroughly investigated chemical reactions is radical polymerisation, a quantitative theory of which was developed as early as the 1940s and the 1950s. However, there are many processes in this field which deviate from the laws of ideal radical polymerisation and their rigorous kinetic analysis constitutes a difficult problem.

Such processes include radical heterophase polymerisation, characterised by the segregation of the polymer formed in a new phase with simultaneous occurrence of elementary chain propagation and termination stages in the solid phases, which are separated in space but can communicate via liquid or gaseous phases. The polymerisation of vinyl compounds such as acrylonitrile, acrylic and methacrylic acids, ethylene, and its halogeno-derivatives (vinyl chloride, vinylidene chloride, vinyl bromide, tetrafluoroethylene, chlorotrifluoroethylene, etc.) have all the properties characteristic of heterophase polymerisation. The appearance of a new phase is a characteristic of ω-polymerisation, the copolymerisation of certain monomers (for example styrene and maleic anhydride, methyl methacrylate, and methacrylic acid), and also the polymerisation of the usual monomers (styrene, methyl methacrylate, vinyl acetate, etc.) in media which do not dissolve the polymers.

A number of technically important polymers and copolymers have been obtained by heterophase polymerisation. Recently a method for the synthesis of poly(vinyl chloride) in bulk, with improved mechanical properties, high purity, and resistance to the atmosphere, has been developed and applied in industry[1-5]. However, the difficulty of temperature control at later stages of the reaction owing to the low thermal conductivity of the solid polymer phase hinders the application of this method to other monomers.

The study of heterophase radical polymerisation is of considerable theoretical as well as purely practical interest. Consequently many studies have been made of heterophase polymerisation, some of which have been described in a series of monographs and reviews[6-10]. However, since these reviews are concerned solely with the polymerisation of individual monomers and only give a general account of the results of earlier studies, we thought it desirable to give a systematic account of the extensive data which have now accumulated. Moreover, in recent years, certain definite advances have been achieved in the interpretation of the kinetic data and in studies on the morphology of the polymer phase, which have made possible considerable progress towards understanding of the mechanism of the heterophase polymerisation and have yielded qualitative and semiquantitative theories which give a generally satisfactory description of its characteristics.

This review also describes the results of certain earlier studies which were not considered in the above reviews, but which are of considerable interest in the light of modern ideas. Problems involving ω-polymerisation have been excluded from consideration, since they have been described fairly completely in a number of monographs[6,11].

II. KINETIC AND CERTAIN OTHER CHARACTERISTICS OF POLYMERISATION WITH FORMATION OF A NEW PHASE

1. Effect of Transition from a Homogeneous to a Heterogeneous System on the Rate and Degree of Polymerisation

Early studies[6,12,13] on the kinetics of the polymerisation of acrylonitrile and vinyl chloride in bulk already revealed their significant difference from the kinetics of the homogeneous polymerisation of the usual vinyl monomers: in the first case, the reaction takes place with self acceleration from the beginning, has higher average velocities, and gives higher molecular weights of the polymers formed. It has been shown that these anomalous properties are due to the formation of an insoluble polymer during the reaction. In the studies of recent years, the autocatalytic nature of the kinetic curves was noted for many monomers undergoing heterophase polymerisation in bulk or in precipitating media -vinylidene chloride[14], ethylene[15,16], tetrafluoroethylene[17,18], acrylic[19] and methacrylic acids[20], styrene[21], acrylamide[22], and others[23,24]. For example, Ryska et al.[25] observed the acceleration of the reaction from the instant of transition from a homogeneous to a heterogeneous polymerisation system comprising vinyl chloride in diethyl oxalate. The acceleration period depends on the physical and chemical properties of the medium and can continue up to conversions of 2—3% (as for acrylic and methacrylic acids) or much higher values (40% and above, as in the case of vinyl chloride).

Heterophase polymerisation is also distinguished by the formation of polymers with higher molecular weights. Fig. 1 shows the variation of the degree of polymerisation of vinyl chloride in tetrahydrofuran (THF) with the initial concentration of the monomer in solution[26]. At a monomer concentration in excess of 9 M, the polymer formed is segregated from the solution and its molecular weight increases sharply on further increase of the amount of monomer in THF. If the rate constant for chain transfer to the monomer is low, the degree of polymerisation usually increases with conversion[15,16,27-29].

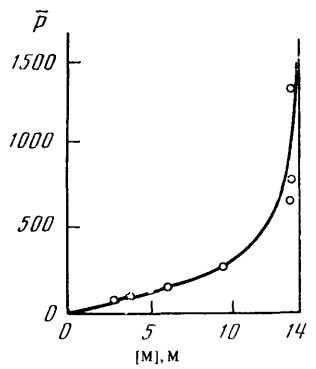

Figure 1. Variation of the degree of polymerisation of vinyl chloride with the initial monomer concentration [M] in THF.

The above anomalous phenomena in heterophase polymerisation (self acceleration, high average reaction rates and molecular weights of the polymers) are usually explained by a decrease of the rate of termination of the growing chains owing to the low mobility of the macroradicals in the solid phase. According to the theory of solutions of high-molecular-weight compounds[30], a macromolecule, in which there is an appreciable degree of freedom of rotation of the individual units relative to one another, coils up in solution. The structure of the coil depends on the solvent power of the medium. In "good" solvents, the coil has a very loose structure and is filled with solvent molecules to the extent of 95—99%.[9,31] In media which do not dissolve the polymer, the macromolecule and the macroradical becomes segregated from the solution in the form of a dense coil, access to the active radical of which is greatly hindered (the macroradical is occluded). Subsequent aggregation of the macromolecules into polymeric particles causes further blocking of the macroradicals and reduces the rate of chain termination—according to certain data[32], the rate constant for chain termination may decrease by 5—6 powers of ten. If one assumes that the rate of chain propagation does not change or changes insignificantly, because of the high mobility of the small monomer molecules, it becomes understandable why the rate of polymerisation increases following the appearance of the solid phase.

On decrease of the molecular weight of the polymer and after the introduction of active chain transfer agents, the self acceleration diminishes owing to the lower degree of occlusion of the macroradicals, the escape of small radicals (formed as a result of chain transfer) from the polymer particles to the liquid phase, and the increase of the rate of chain termination reaction[6,33,34].

One should recall that in certain studies[35] the above view on the nature of the self acceleration of heterophase polymerisation (occlusion of the active ends of macroradicals) is used also as a qualitative explanation of the "gel effect" in the polymerisation of certain vinyl monomers at advanced stages of the reaction.

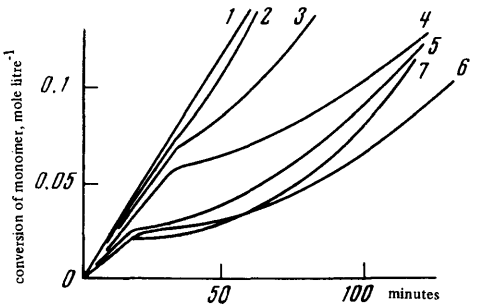

Figure 2. Polymerisation of vinyl chloride in diethyl oxalate at 25°C. The monomer concentration increases from 9.81 M (curve *1*) to 13.05 M (curve *6*). The breaks in the curves correspond to the formation of the polymer phase.

However, studies in recent years showed that, when the medium becomes heterogeneous, the morphological structure of the polymer phase, its swellability, the permeability of the polymer aggregates, the physical adsorption of monomer molecules on the solid phase, etc. have a marked influence on the rate of polymerisation. In many cases, at the instant when the medium becomes heterogeneous the polymerisation reaction is not accelerated but actually retarded, which indicates the influence of these physical factors not only on the chain termination reaction but also on the chain propagation reaction. Thus Ryska et al.[25], who studied the polymerisation of vinyl chloride in diethyl oxalate and 2,4-dichloropentane solutions, observed, on transition of the reaction from the homogeneous to the heterogeneous region, a stage with a sudden decrease of the rate followed by a rapid increase with conversion (Fig. 2). In the presence of an effective chain transfer agent (carbon tetrabromide), an increase of the ratio of the rates of chain transfer to carbon tetrabromide and of chain propagation was noted under heterogeneous conditions. On this basis, it was concluded[25] that transition to the heterogeneous region is accompanied by a decrease of the rate of chain propagation owing to the coiling up of insoluble macroradicals and their subsequent association, which hinders the access of the monomer molecules to the polymeric aggregates and reduces their local concentration in the vicinity of the active radical centres. According to approximate calculations of Bamford et al.[36], this local concentration of acrylonitrile is 1/180 of the macroconcentration of the monomer in the system. On the other hand, it is believed[25] that the rate of chain termination at the instant when the medium becomes heterogeneous changes less than might be

expected owing to the mutual approach of the active ends on association. However, as the amount of polymer increases, the rate of reaction rises with conversion, i.e. there is an acceleration effect owing to the further blocking of the macroradicals and a more marked effect of the solid phase on chain termination than on chain propagation.

Talamini and coworkers[37] observed a decrease of the initial rate of heterophase polymerisation of vinyl chloride in THF and in 1,2-dichloroethane with increase of monomer concentration. On the other hand, the average rate of reaction, measured at a specified degree of conversion, was always higher than in a homogeneous medium, owing to autocatalysis.

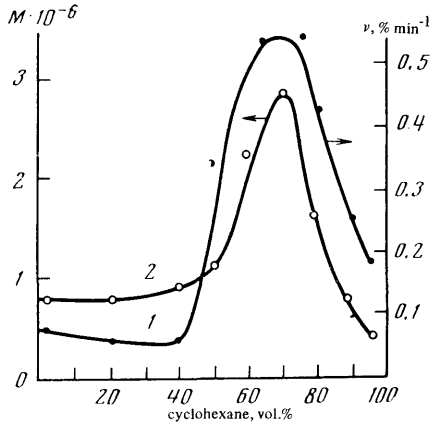

Figure 3. Variation of the maximum rate of polymerisation of methyl methacrylate (curve *1*) and the molecular weight of the polymer (curve *2*) with dilution of the monomer by cyclohexane at 55°C.

A decrease of the initial rate when the medium became heterogeneous was noted in the polymerisation of acrylonitrile in dimethylformamide (DMF) and ethylene carbonate[38] and of acrylic acid in methanol[39]. The variation of the maximum rate of polymerisation with the amount of precipitant in the methyl methacrylate system in cyclohexane was found to pass through a maximum[40,41] (Fig. 3). The authors explain these results by the influence of the swellability of the polymer phase, the permeability of the polymer aggregates, and the accessibility of the active centres on the elementary reactions. Since these factors depend on the type of polymer and solvent (or precipitant), the type of relation between the rate of polymerisation and monomer (or precipitant) concentration is different for specific monomers (vinyl chloride, acrylic acid, acrylonitrile, methyl methacrylate)[37-41]. When the precipitant content is high, the polymer phase is weakly swollen and the chain propagation reaction in it is retarded owing to the decrease of the local concentration of the monomer and its mobility in the relatively impermeable aggregate. The addition of solvent increases the swelling of the aggregate, which accelerates the diffusion of monomer molecules and increases the rate of polymerisation within the swollen particles. However, in the presence of a high content of the solvent, the increase of the mobility of the macroradicals and of the rate of termination of the growing chains plays a dominant role. Accordingly, the molecular weight of the polymers varies in parallel with the rate of polymerisation[37,38,40] (Fig. 3).

Somewhat different kinetic relation are observed in the polymerisation in a precipitant (cyclohexane) of acrylonitrile and acrylic and methacrylic acids, the polymers of which are incompatible with their monomers, in contrast to poly(methyl methacrylate)[41,42]. In this case, the rate of reaction decreases monotonically with dilution by cyclohexane, since access by monomer molecules to the occluded macroradicals is difficult owing to the incompatibility of the polymer and monomer and the low swellability of the polymer in the reaction medium. The unusual variation, involving a maximum in the dependence of the degree of polymerisation of acrylonitrile on temperature for the chemically initiated reaction, which was observed for the first time by Bamford and Jenkins[13] and Thomas and Pellon[12], is explained by the effect of swellability and mobility of the macrochains on the chain propagation and termination reactions:

Temperature, °C	30	40	50	60	70	80	90	100
Average molecular weight × 10^{-5}	4.3	6.25	8.64	10.73	6.36	3.76	2.17	1.38

Later similar results were obtained for the γ-initiated polymerisation of acrylonitrile[43] and ethylene[44].

An anomalous temperature effect was not noted[45] for vinyl chloride in the range 33–85°C owing to the high rate constant for chain transfer to the monomer. However, Talamini and Vidotto[46], who investigated its polymerisation at lower temperatures, found that the maximum molecular weight is reached at −30°C. According to another paper by the same investigators[47], the reason for this type of temperature variation is different degrees of crystallinity of the specimens obtained.

Bamford and Jenkins[48] examined certain cases of the secondary polymerisation of monomers initiated by macroradicals formed in the polymerisation of acrylonitrile (PAN) in bulk. The wide variety of kinetic curves obtained is due to the complex mutual relation between the swellability of PAN, the rate of diffusion of macroradicals and monomer molecules, and the kinetic characteristics of the process.

The rate of polymerisation of vinyl chloride in bulk at conversions less than 1% was found to be discontinuous by precise dilatometric measurements[49]. The study of the morphological structure of the solid phase formed made it possible to explain this decrease in the rate of polymerisation by the effect of the aggregation of macromolecules, which occurs on reaching the above conversions, on the elementary chain propagation and termination reactions.

Talamini and coworkers[37,38] examined the quantitative aspect of the decrease of the initial rate of polymerisation when the medium becomes heterogeneous. The reaction begins and continues in solution until the polymer concentration reaches a value such that the system separates into two phases. One of these is enriched and the other depleted in the polymer (we shall call these phases concentrated and liquid respectively). Using the steady-state hypothesis, the following expression was obtained for the ratio of the radical concentrations in the heterogeneous

and homogeneous systems before separation into different phases (Y):

$$Y = f_1^{1/2} \cdot v_1^{1/2} + \left(\frac{k_{tl}}{k_{tc}}\right)^{1/2} \cdot (1 - f_1)^{1/2} \cdot (1 - v_1)^{1/2} \quad (1)$$

where k_{tl} and k_{tc} are the rate constants for chain termination in the liquid and condensed phases respectively, v_1 is the volume fraction of the liquid phase, and f_1 the fraction of radicals formed per unit time in the liquid phase.

Eqn. (1) is valid also for the ratio of the rates of polymerisation in the heterogeneous and homogeneous systems on the assumption that the chain propagation rate constants remain unchanged. If $f_1 < v_1$ (the growing radicals and the polymeric molecules are more soluble in the concentrated phase) and $k_{tc} < k_{tl}$, the macroradicals pass to the concentrated phase at the instant of phase separation, y is less than unity, and the rate of polymerisation falls. The addition of a solvent accelerates polymerisation owing to the decreased probability of finding the growing chains in the precipitated phase. However, with increased conversion, Y becomes greater than unity faster the lower the value of k_{tc} compared with k_{tl}, i.e. phase separation gives rise to autocatalysis. For very high values of k_{tl}/k_{tc} (for example above 100), a decrease of the rate of polymerisation is observed only at low conversions (less than 1%). Autocatalysis becomes more pronounced with increasing conversion the more the growth of radicals in the concentrated phase predominates, i.e. the lower the solvent power of the medium.

An interesting effect of the presence of different phases on the conformation of polymethacrylic acid molecules was observed by Japanese workers[50]: in media precipitating polymers, the content of a syndiotactic polymer decreases owing to the active influence of the polymer phase on the addition of monomer molecules to the growing chain.

Thus the overall data presented above definitely demonstrate an active influence by the polymer formed not only on chain termination but also on chain propagation. It was shown that the apparent chain propagation rate constant decreases owing to the low swellability of the polymer (for example by 2—3 powers of ten in the polymerisation of acrylonitrile in bulk[32] compared with homogeneous conditions). Comparative analysis of the diffusion coefficients of low-molecular-weight substances in polymeric materials and of the rate constants for elementary reactions also demonstrates that, when the swellability of the polymer is low, the rate of chain propagation with $k_p > 10^2$—10^3 litre mole^{-1} s^{-1} is limited by diffusional parameters and not by kinetic parameters[51-55]. By altering the reaction medium and its interaction with the polymer, it is possible to influence actively the heterophase radical processes. For example, the rate of polymerisation of methyl methacrylate in methanol is much lower than in a methanol—water mixture owing to the greater swellability of the polymer and the higher mobility of macroradicals in the swollen solid phase in the first case[52].

The effect of pressure on the rate of heterophase polymerisation was studied by Gonikberg and coworkers[56-58], who observed an unusually marked acceleration of the polymerisation of butyraldehyde and isobutyraldehyde[56], α-methylacrolein[57], acrylonitrile[58], and methacrylic acid[20] at high pressures. This finding can be explained either by an increased rate of diffusion of the monomer in the polymer aggregates or by an increase of the degree of occlusion of the radicals (a decrease of the rate of chain termination).

When a chain transfer is introduced, the usual type of pressure variation of the rate and molecular weight is observed[58], which supports the second hypothesis. From this standpoint, one can understand the absence of anomalous phenomena in the polymerisation of vinyl chloride in bulk at high pressures[59,60].

2. The Role of the Polymer Phase in Heterophase Copolymerisation

The theory of homogeneous radical copolymerisation (in which the reactions are considered without considering the phase state of the system) makes it possible to calculate readily the composition of the copolymers when the relative activities of the monomers r_1 and r_2 are known. The study of the effect of heterogeneity on the composition of the copolymers led to the conclusion that the Mayo—Walling equation is inapplicable to heterophase copolymerisation. The majority of investigators[61-64] noted differences between the relative activities of the monomers of a particular binary system in different media. At present, the characteristics of heterophase copolymerisation can be accounted for solely on the basis of qualitative assumptions of different kinds.

Since the activity of comonomers is understood as the ratio of the chain propagation rate constants k_{11}/k_{12}, the deviations associated with the presence of the solid polymer can be explained by postulating that the rate of chain propagation reactions is determined by the rate of diffusion of the monomers to the active centres, or by a change in the elementary rate constants k_{11} and k_{12} owing to the specific features of the solid, or, finally, by the selective sorption of the monomers on the polymer phase, which leads to a change in the composition of the mixture of comonomers in the vicinity of the macroradical. Evidently the last factor has a major influence in the case of comonomers with markedly different polarities.

We shall consider certain experimental data using the sorption hypothesis. In this connection one must note the work of Brandrup[61,62] concerning the dependence of the composition of the copolymers of acrylonitrile and acrylic esters on the solvent. It has been shown that, on passing from a homogeneous to a heterogeneous system, the copolymer always becomes depleted in acrylonitrile as a result of a change in the water content in the solvent (DMF).

If the copolymerisation is carried out in water alone, then the copolymer is also always enriched in acrylic esters compared with homogeneous conditions. The lower the solubility of the acrylic ester in water the greater the probability of its incorporation in the copolymer. These findings can be readily explained if one assumes the preferential sorption of the less soluble acrylic esters by the polymer.

The above conclusion is confirmed also by the composition of the copolymers obtained in other precipitants (heptane, cyclohexane), where the opposite situation obtains, the copolymers being enriched in acrylonitrile relative to the initial mixture (Fig. 4). Since Brandrup's data show that acrylonitrile is less soluble in heptane and cyclohexane than acrylic esters, it is sorbed preferentially and its content in the copolymer increases.

Ryabov, Semchikov, and coworkers[40,42,65] found that, with increased concentration of the non-polar precipitant (cyclohexane) in the heterophase copolymerisation of methyl methacrylate with acrylonitrile, acrylic acid, or methacrylic acid, and also of vinylidene chloride with

acrylonitrile, the content of the more polar component in the copolymer increases. Since chain propagation occurs mainly within and on the surface of the polymer particles, i.e. in the zone of enhanced concentration of the sorbed polar monomer, this is responsible for its increased content in the copolymer. A definite piece of evidence supporting the selective sorption of one of the monomers is the decrease of the content of acrylic and methacrylic acids in the copolymers when the hydrogenated monomers (propionic and isobutyric acids) are added, which is due to the displacement of the unsaturated acids by the saturated acids from the sorption layers[66].

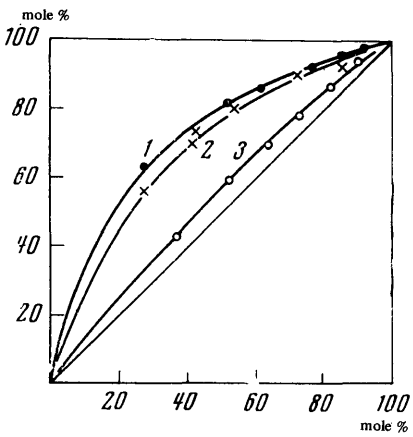

Figure 4. Composition curves for the acrylonitrile—ethyl acrylate copolymer in different media. The content of acrylonitrile in the copolymer is plotted against its content in the initial mixture: 1) heptane; 2) cyclohexane; 3) dimethylformamide (homogeneous media).

Graft copolymers of styrene with acrylonitrile or methyl methacrylate on polyethylene or Teflon are also enriched in the more polar monomer[67].

The local concentrations of the comonomers in the polymer phase $[M_i]_a$ may be related to their volume concentrations in the liquid phase $[M_i]$ by the Langmuir equation

$$[M_i]_a = \frac{k_{ad.\,i}[M_i]}{1 + k_{ad.\,i}[M_i]}; \quad i = 1.\,2 \qquad (2)$$

where $k_{ad.i}$ is the constant of the adsorption isotherm of the monomer in the polymer particles. Hence it follows that, when $k_{ad.1} \neq k_{ad.2}$, the composition of the copolymer formed in the solid phase $\{[M_1]_a/[M_2]_a\}$ will be different from the composition of the copolymer in the liquid phase $\{[M_1]/[M_2]\}$. The greater the difference between the constants k_{ad} the more pronounced is the inhomogeneity of the composition.

Moreover one should also expect a change in the rate constants for the elementary reactions. Thus copolymers with the same average composition (24% of potassium acrylate and 76% of acrylamide) obtained under homogeneous and heterogeneous conditions had different microstructures, i.e. different distributions of units in the chain, which indicates an effect of the solid phase on the elementary chain propagation reactions[64].

The curves describing the distribution of the compositions of the copolymers of acrylamide with maleic acid[68,69] and of methyl methacrylate with methacrylic acid[70] also form an anomalously broad peak compared with the theoretical curves, owing to the effect of phase heterogeneity on the chain propagation and macroradical recombination reactions.

Compared with sorption and the changes in rate constants, diffusion factors should have a smaller influence on the composition of the copolymers in view of the insignificant differences between the diffusion coefficients of the comonomers in such heterophase systems. For example, in the copolymerisation of acrylonitrile with methyl and propyl acrylates in bulk (heterophase conditions) and in the presence of an excess of acrylonitrile, the composition of the copolymers differs little from that obtained in the polymerisation in DMF solution. In this case, the rate of diffusion of monomers is so high that selective sorption is prevented[61].

If there is no preferential sorption of one of the monomers or if the added substance is a solvent for the copolymer causing its swelling and an increase of the rate of diffusion of the monomer molecules in the solid phase, phase heterogeneity has no effect whatever on the composition of the copolymer (provided that the chain-propagation rate constants remain unchanged); in this case the process has all the characteristics of homogeneous copolymerisation.

3. The Molecular Weight Distribution (MWD) of Polymers

Polymerisation involving the precipitation of the polymer formed is known to give rise to a broad or "irregular" molecular weight distribution with several maxima. Thus MWD of polyacrylonitrile obtained in dimethyl sulphoxide (homogeneous conditions) is much narrower than in the polymerisation of acrylonitrile in water (a heterogeneous system)[71]. A trimodal MWD was obtained by Pyrkov[72] in the polymerisation of acrylonitrile and by Eriksson[73] in the polymerisation of methyl methacrylate in water. Krozer and Czlonkowska[74] observed a distinct bimodal distribution for poly(vinyl chloride) polymerised in bulk at all conversions ranging from 18—78%. The MWD curves obtained by the fractional precipitation method for poly(vinyl chloride) polymerised in bulk also have two maxima[75]. Frenkel'[35] demonstrated for numerous instances of the polymerisation of acrylonitrile and vinyl acetate in water, vinyl acetate in heptane, ethylene under critical conditions, etc. that multimodal MWD is inevitably obtained in heterophase polymerisation. The multimodality arises as a result of the simultaneous occurrence of the elementary reactions in different phases (liquid and solid), each of which has its own characteristic monomer, radical, and initiator concentrations. In this case several distributions are superimposed. Part of the polymer is formed in solution and chain termination takes place in the liquid phase ($R^{\cdot} + R^{\cdot} \rightarrow P$); part of the growing macroradicals $P^{\cdot}$, trapped by the solid polymer particles, are deactivated either by the interaction of the dissolved macroradicals ($P^{\cdot} + R^{\cdot} \rightarrow P$) or by collision with another similar active polymer species ($P^{\cdot} + P^{\cdot} \rightarrow P$). This should result in a tri- or bimodal distribution function depending on whether chains are terminated by recombination or disproportionation. Fig. 5 presents trimodal

MWD for polyacrylonitrile obtained by polymerisation under heterogeneous conditions[35]. Evidently the distribution function is very broad and the ratio of the weight-average molecular weight of the polymer to the number-average molecular weight (P_w/P_n) is more than 10.

It has been shown[35] that detailed analysis of MWD and also of the variation of MWD with conversion may yield additional information about the mechanism of heterophase polymerisation, i.e. about the sites where chain propagation reactions occur, about the type of chain termination reaction, etc.

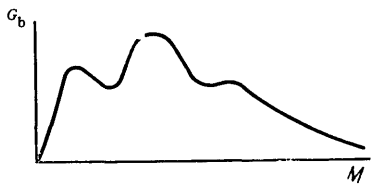

Figure 5. Molecular weight distribution of polyacrylonitrile obtained by the polymerisation of acrylonitrile in an aqueous medium; G_b—weight distribution function.

4. Post-polymerisation

The retardation of the rate of termination of macroradicals on formation of the solid phase leads to appreciable post-polymerisation. According to Magat's data[76], the rate of polymerisation of acrylonitrile in bulk decreased on switching off the radiation source to 1% of the initial value after 100 days and the conversion increased from 7 to 11%. The magnitude of the after effect depends on the duration of the initiated reaction[77].

Lyubetskii et al.[29] investigated the polymerisation of ethylene initiated by azobisisobutyronitrile at 70°C and a pressure of 100—600 atm. After cooling the system to 20°C ($v_{init} = 0$), the yield of polymer in 7 h increased from 125 to 156 g and the intrinsic viscosity increased from 1.10 to 1.70. Analogous results were obtained by Machi and coworkers[16,78,79].

Volkova and coworkers[17,18,80] observed an appreciable post-polymerisation of tetrafluoroethylene, vinyl fluoride, and vinylidene fluoride. Over a period of 60 min, the post-conversion of tetrafluoroethylene increased from 2 to 3.5% at 17.5°C. Fig. 6 illustrates the course of the post-polymerisation of acrylic acid in bulk at 20°C.[19]

Similar kinetic curves are characteristic of the post-polymerisation of acrylonitrile and vinyl chloride[32]. The after effect is appreciably suppressed with increase of temperature or when active chain transfer agents are introduced[32,43]. Analysis of the after effect can yield valuable information about the mechanism of the destruction of macroradicals, their lifetime, and kinetic constants.

If one assumes that in post-polymerisation macroradicals are destroyed as a result of bimolecular termination, it is easy to obtain the equations

$$\frac{1}{v_c} = \frac{k_t t}{k_p [M]} + \frac{1}{v_i}. \qquad (3)$$

and

$$\frac{\Delta [M]}{[M]} = \frac{k_p}{k_t} \ln ([R^\cdot] k_t t + 1), \qquad (3a)$$

where v_c and v_i are the rates of reaction at times t and $t = 0$ respectively. If chain termination proceeds via a mixed mechanism (bi- and mono-molecular)

$$-\frac{d[R]^\cdot}{dt} = k_t [R^\cdot]^2 + k_t' [R^\cdot], \qquad (4)$$

the following equation should hold:

$$\frac{\Delta [M]}{[M]} = \frac{k_p}{k_t} \ln \left(1 + \frac{k_p}{k_t'} [R^\cdot]\right) (1 - e^{-k_t' t}), \qquad (5)$$

where k_t' is the monomolecular chain termination rate constant.

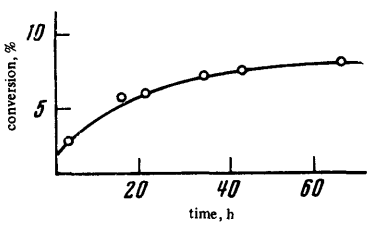

Figure 6. Post-polymerisation of acrylic acid at 20°C. The duration of polymerisation initiated by γ-irradiation was 20 min.

It has been found in a number of studies[32,43] that the post-polymerisation of acrylonitrile at 20—100°C and of vinyl chloride at −20°C is described by Eqns. (3) and (3a). However, in radiochemical polymerisation the linear relation $1/v_c = f(t)$ or $\Delta[M]/[M] = f(\ln t)$ has different proportionality coefficients at different conversions, which conflicts with the hypothesis that bimolecular chain termination with invariant k_t takes place. The authors attribute this to the occlusion of macroradicals. It has been shown that Eqn. (5) does not agree with the experimental data.

Markevich and coworkers[81] showed that Eqn. (3) holds for the dark polymerisation of tetrafluoroethylene in a precipitant (perfluorotriethylamine) and calculated k_t/k_p at 25°C. With increase of conversion, k_t/k_p decreases from 30 to 4 owing to the change in k_t. Under homogeneous conditions, the ratio k_t/k_p is constant at 70. k_p = 770 litre mole^{-1} s^{-1} has been determined by the method of inhibitors.

Using Eqn. (3a), Dainton and coworkers[82,83] found τ = 300 s for the polymerisation of acrylonitrile in water at 15°C, where $\tau = 1/k_t[R^\cdot]$. With increase of temperature to 30°C, τ falls to 150 s. The authors also concluded that the radicals in polymer particles are destroyed as a result of quadratic chain termination.

According to the data of Machi and coworkers[16,78,79], the rate of post-polymerisation of ethylene at a pressure of 250—400 atm increases with temperature in the range between 20° and 80°C, but remains constant for several hours at a specified temperature, which indicates the absence of chain termination reactions. However, at a

high temperature (140°C), the after effect is shown during a very brief period owing to the intense destruction of macroradicals.

Popov and Gladyshev[52] investigated the post-polymerisation of acrylonitrile in bulk at 17°C in the presence and absence of weak inhibitors of the type of diphenylamine (Fig. 7). It was shown that, when a solid phase is formed, the destruction of macroradicals takes place virtually at the instant of their interaction with the molecules of the weak inhibitor owing to the occlusion of active radical centres and the decrease of the rate of the R˙ + R˙ chain termination reaction; post-polymerisation is described by the equation

$$\ln \frac{v_{\text{нп}}}{v_c} = k_Z[Z](t - t_1) , \qquad (6)$$

where v_i and v_c are the rates of post-polymerisation at the initial instant t_1 and at any time t respectively, k_Z is the inhibition constant, and [Z] the concentration of the weak inhibitor.

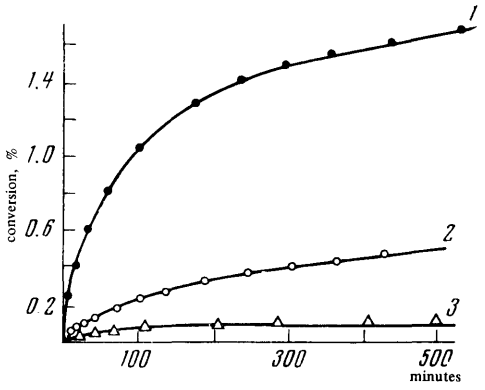

Figure 7. Post-polymerisation of acrylonitrile in bulk in the presence and absence of diphenylamine at 17°C; diphenylamine concentration (M): 1) 0; 2) 0.48×10^{-3}; 3) 1.21×10^{-2}. The polymerisation initiated by azobisisobutyronitrile (0.245×10^{-2} M) was continued up to a conversion of 3—3.5% at 60°C.

The constant k_Z was calculated from the linear relation between $\ln(v_i/v_c)$ and $t - t_1$ and was found to be 1.61×10^{-2} litre mole^{-1} s^{-1} for diphenylamine at 17°C. Thus the after effect method in heterophase polymerisation can yield valuable information about the reactivity of weak inhibitors of this kind, which previously could not be achieved in principle by the earlier Kise—Bagdasar'yan methods[11,84].

5. Quantitative Data

In heterophase polymerisation, the exponent n in the equation $v = k[M][I]^n$ is usually greater than 0.5. Thus, regardless of the method of initiation, $n = 0.8$ for acrylonitrile[7,85-87] and $n = 0.6$ for vinyl chloride[46,47]. An increased reaction order with respect to the initiator, which is characteristic also of other monomers undergoing heterophase polymerisation[6,16], is due to the occlusion of macroradicals and the catalytic effect of the polymer.

With increase of temperature, the degree of occlusion of active centres falls, the rate of termination rises, and n decreases to 0.5.[43,88]

The activation energy E_a for the polymerisation of acrylonitrile (thermochemical initiation) in bulk is fairly high, amounting to 35—37 kcal mole^{-1}.[12,89] With increase of temperature, E_a for radiation-induced polymerisation of acrylonitrile initially increases and then falls[43,90]:

Temperature, °C	0—20	20—60	60—70	70—90
E_a, kcal mole^{-1}	5	13.5—15	7.4	1.7

A similar relation between the apparent E_a and temperature was also found for methacrylic acid[88,91]: $E_a = 18.3$ kcal mole^{-1} at $T < 40°$, $E_a = 38.8$ kcal mole^{-1} at 40—75°C, and $E_a = 5.9$ kcal mole^{-1} at $T > 75$°C.

In the course of radiation-induced polymerisation of acrylonitrile, E_a increases up to a 20% conversion, then remains constant, and increases again at very advanced stages[92]:

Conversion, %	0	20—90	100
E_a (0-20°C), kcal mole^{-1}	4.65	6	10.4

The overall activation energy for the polymerisation reaction is defined as $E_a = E_p + nE_{init} - mE_t$, where $0.5 < n < 1.0$ and $m = 0.5$. Since E_t enters into this equation with a negative sign, the high value of E_a is evidently due to the diffusional component of the activation energy for chain propagation E_p and, in the case of thermochemical initiation, to the contribution of E_{init} owing to the increased value of n compared with homogeneous polymerisation. This equation also shows that E_t cannot be large. Indeed, according to certain experimental data, the chain termination activation energy for polyacrylonitrile[82,93,94] and poly(vinyl chloride)[95] under heterophase conditions is ~5—10 kcal mole^{-1} at $T < 100$°C.

The activation energy for the diffusion of macrochains in polymeric materials has been estimated as 25 ± 10 kcal mole^{-1}.[96,97] Since, as shown above, the active centres are deactivated by a bimolecular mechanism in heterophase polymerisation, the destruction of macroradicals is evidently not due solely to diffusion factors. Possibly, apart from quadratic chain termination, termination of the "relay" type as a result of chain transfer to the monomer and polymer, occurring by segmental and translational diffusion of macroradicals, plays an extremely significant role in this case.

This hypothesis is confirmed by a study of the heterophase polymerisation of certain monomers in the presence of weak inhibitors (inhibition constant $k_Z < 1$ litre mole^{-1} s^{-1}),[52] which are known not to affect the kinetics of homogeneous polymerisation. However, the sharp limitation of the rate of mutual termination of the growing chains when a solid phase is formed gives rise to a specific effect of relatively unreactive compounds of this kind owing to the increased importance of chain termination by the inhibitor. If the quadratic chain termination reaction may be neglected under certain conditions, it follows from the simplified mechanism that

$$v = \frac{k_p[M]}{k_Z[Z]} v_{in} , \qquad (7)$$

and

$$\bar{P} = \frac{k_p[M]}{k_Z[Z]} \qquad (8)$$

where [Z] is the concentration of the weak inhibitor. It has been shown that the rate of polymerisation of acrylonitrile in bulk decreases sharply from the very beginning

when small amounts of diphenylamine are added (Fig. 8). The reaction proceeds at a constant rate at least up to 50–60% conversion. In this case Eqns. (7) and (8) are valid and were used to calculate the ratio $k_Z/k_p = 0.151$ at 60°C.

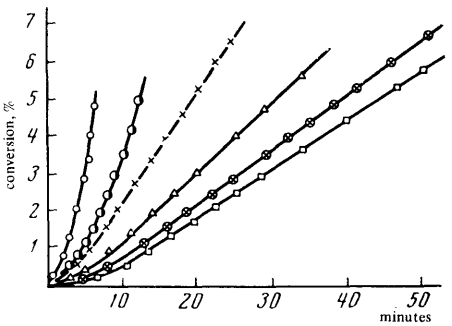

Figure 8. Polymerisation of acrylonitrile in bulk in the presence of diphenylamine at 60°C; concentration of azobisisobutyronitrile initiator 0.245×10^{-2} M; concentration of diphenylamine (M): 1) 0; 2) 0.12×10^{-2}; 3) 0.48×10^{-2}; 4) 1.21×10^{-2}; 5) 2.42×10^{-2}; 6) 3.64×10^{-2}.

In the polymerisation of methyl methacrylate in decane (a precipitant), diphenylamine has almost no effect on the reaction kinetics[52]. Evidently the degree of swelling of the polymer is in this case sufficiently high for chain termination by the recombination of macroradicals. However, the rate of polymerisation falls appreciably in methanol as a precipitant and even more so in a methanol–water mixture[52]. In the latter case, Eqns. (1) and (8) are also valid. The calculated k_Z are of the order of 10^{-1}–10^{-2} litre mole^{-1} s^{-1}. Thus the apparent reactivity of relatively inactive compounds increases sharply in heterophase polymerisation.

The constant for chain transfer to the monomer $C_M = k_{tr}/k_p$ is of the order of 10^{-5} for acrylonitrile[85,98]; $k_{tr} \simeq 10^{-2}$ litre mole^{-1} s^{-1} when $k_p \simeq 10^3$ litre mole^{-1} s^{-1}. Consequently, when one considers the mechanism of polymerisation with formation of a new phase, one must take into account reactions of this type. On the other hand, with increase of temperature the importance of physical factors (swellability of the polymer, diffusion of the monomer, occlusion of macroradicals) decreases, which leads to normal values of E_a.[88,90] If the polymer can undergo appreciable swelling, the overall activation energy is also close to the usual value, which has been noted, for example, for vinyl chloride (according to Gerren's data[99] the solubility of vinyl chloride in its polymer is 29% at 50°C and the constant for chain transfer to the monomer $C_m = 10^{-3}$).[26,100–102]

Some investigators[32,81,103] attempted to determine the rate constants for the elementary reactions. Thus Bawn et al.[32] found by the method of post-polymerisation that $k_p = 0.35$ and $k_t = 51$ litre mole^{-1} s^{-1} for acrylonitrile at 60°C and $k_p = 0.05$ and $k_t = 5$ litre mole^{-1} s^{-1} for vinyl chloride at −20°C. $k_p/k_t^{1/2}$ for acrylonitrile has a maximum at 50°C, which correlates satisfactorily with the temperature variation of the molecular weight[104]:

Temperature, °C	25	35	40	45	50	55
$k_p/k_t^{1/2}$	0.077	0.134	0.176	0.180	0.670	0.070

The values of k_p and k_t for ethylene calculated by different investigators show marked discrepancies[105–108].

Certain kinetic data may be obtained by studying heterophase polymerisation in the presence of inhibitors[52]. Then it is easy to calculate the ratio k_Z/k_p from Eqns. (7) and (8) and hence k_p if k_Z is known. On the other hand, k_p may be determined from the relation $v = k_p[M][R^\cdot]$ by measuring the concentration of macroradicals by the ESR method, since in the presence of an inhibitor the reaction proceeds under steady-state conditions. The values calculated for the polymerisation of acrylonitrile in bulk at 40°C are $k_p = 1.2$ and $k_t = 340$ litre mole^{-1} s^{-1}.

However, the observed rate constants for the elementary reactions are apparent values, since it was shown above that the rate of heterophase polymerisation depends on many factors and, moreover, there are not yet any quantitative data on the ratio of the monomer concentrations in the liquid and solid phases. However, first studies on these lines have been made[40,109,110].

III. MORPHOLOGY OF THE POLYMER PHASE

The first systematic studies on the morphology of the precipitated polymer were those of Thomas[10,12,111] on the polymerisation of acrylonitrile in bulk and in aqueous solution. At the beginning of the reaction (polymerisation in bulk), an opalescence appears with subsequent transition to a light turbidity. After 0.2–0.3% of the monomer has been converted into the polymer, the fine suspension of the polymer coagulates, forming a curd-like precipitate which fills the entire volume. When about 50% of the monomer has been converted, the reaction mixture consists of a white solid. Electron microscope studies showed that in the early stages the particles formed are dense globular, and identical in size. When the monomer conversion is about 1%, the particle diameter reaches 1000–2500 Å. The number of particles remains almost constant during the polymerisation process, and amounts to 10^{12}–10^{14} per cm^3 depending on the reaction conditions.

At high conversions (70–80%), a monolithic transparent solid is formed[112]. Kinetic studies on the polymerisation of acrylonitrile[89,112,113] and vinyl chloride[114] in bulk up to high conversions showed that the formation of a transparent polymer requires a correspondence between the rate of reaction and the rate of diffusion of the monomer molecules into the pores of the polymer particles. Under these conditions, the growth of the particles leads to close contact between them and to the disappearance of interfaces.

A series of studies dealing with the morphology of poly(vinyl chloride) polymerised in bulk and allowing a considerable understanding of the mechanism of the formation of the polymer phase were published in recent years[49,114–119]. In the initial stages of the process, the macromolecules are in a molecularly dispersed state in the monomer medium. When the degree of polymerisation of vinyl chloride exceeds 25–32, the macromolecules are no longer soluble in the monomer[49]. After the attainment of the critical concentration, the particles of a new polymer phase (possibly a polymer-monomer phase) are segregated. Their dimensions are determined by the

critical dimensions for nucleus formation. Bort[116] called these growing nuclei microglobules. Microglobules can grow both owing to the formation of the polymer within the particles and as a result of the adsorption of the polymer formed in the bulk of the monomer.

Microglobules are unstable with respect to aggregation and coalesce into macroglobules. According to the data of Cotman et al.[49], this occurs at a conversion of 0.2—0.9%. The morphology and number of macroglobules are influenced by the average rate of polymerisation, an increase of which entails an increase in the number of particles up to a constant value of about 10^{12} per cm^3.

In the course of polymerisation, new particles are not formed and their number remains constant. The number of microglobules in the macroglobule varies from 1 to several tens, depending on the rate of polymerisation. With increase of the degree of conversion, the size of the macroglobules increases from 0.1 to 1—2 μm. The narrow unimodal distribution of the particles with respect to size is evidence that the rate of growth remains almost constant for all the particles.

Since the globular structure persists up to 30% conversion and the number of particles remains unchanged during polymerisation, Bort et al.[116] reached the unambiguous conclusion that the increase in the mass of the globules is due to the macromolecules growing within the globules themselves rather than to those formed in the bulk of the monomer. Since the termination of the growing chains in the globule is greatly hindered, the rate of polymerisation in the particle will be higher than in the bulk of the monomer.

In the polymerisation of methacrylic acid in bulk, the polymer is also formed from the early stages as globules whose size is about 0.1 μm, which are then aggregated into larger globules[120]. In the general case, one assumes that the formation of the solid phase is closely related to the topochemistry of the polymerisation process, which in turn is determined by the nature of the interaction between the polymer and its monomer[118,121]. If the solvent power of the medium is sufficiently high for the formation of a monomer-polymer phase, i.e. a solution of the polymer in the monomer, the accumulation of the solid monomer may occur partly owing to the adsorption of the macromolecules from the solution on the surface of the polymer particles. Then the surface of the growing particle becomes "grown over". Consequently the structure of the particles may be varied from very dense to loose by a suitable choice of solvent[10,122]. In the presence of a large amount of solvent, the particles cease to be globular and the polymer consists of a monolithic mass, as shown for the polymerisation of methyl methacrylate in cyclohexane[40].

If the polymer particles produced are incapable of swelling, then the appearance of comparatively dense and smooth globular structures, owing to the settling on the surface of a fine "fraction" of the polymer from the liquid phase, is also to be expected.

The solid phase is formed somewhat differently in the polymerisation of monomers capable of crystallising. For example, in the polymerisation of vinylidene chloride, a mixture of lamellar crystals and globules is formed[14]. The presence of two types of structures in the reaction medium is due to the simultaneous occurrence of two processes: polymerisation and crystallisation.

Thus the characteristics of the morphological structure of the polymer phase formed depend on the polymerisation kinetics (the average rate of polymerisation), the swelling of the polymer particles, and the capacity of macromolecules to form part of crystalline structures.

IV. THEORIES AND KINETIC MECHANISMS OF HETEROPHASE POLYMERISATION

Analysis of the existing models of heterophase polymerisation reveals two opposed views concerning the site of the reaction in the formation of the polymer phase. According to the immobilised surface theory[45], the increase of the rate of polymerisation with conversion is explained by the increase of the area of the polymer phase formed. According to the occlusion theory[6], the mass of the polymer determines the characteristics of the heterophase polymerisation. There exist also other theories—in particular the heterophase polymerisation of certain monomers in water is regarded as analogous to polymerisation in emulsion[111].

The majority of the kinetic mechanisms are bases on the invariance of the rate constants for the elementary reactions, which constitutes an appreciable simplification.

1. The Surface Theory

The kinetic mechanism of Bengough and Norrish[45] is based on the fact that the polymer exhibits a cocatalytic activity on the polymerisation of vinyl chloride. The ease of chain transfer to the polymer leads to the formation of immobilised radicals and polymer particles. These radicals are almost incapable of bimolecular chain termination but do retain their capacity for growth. Growth continues until small mobile radicals are formed as a result of chain transfer via the monomer. In consequence of these transfer reactions, the chain returns to the liquid phase where bimolecular termination ultimately takes place.

The equation derived by the authors,

$$v = k[\mathrm{I}]^{1/2}[\mathrm{M}]\left\{1 + \frac{k'[\mathrm{P}]^{2/3}}{[\mathrm{M}]}\right\} \qquad (9)$$

where k and k' are constants and $[\mathrm{P}]$ is the amount of polymer per unit volume, shows that the rate of polymerisation is proportional to the amount of polymer raised to a power of 2/3, i.e. to the surface area of the polymer phase. According to this theory, the number of branches arising by chain transfer to the polymer is also proportional to conversion raised to a power of 2/3.[123]

Bearing in mind Bamford's critical comments[6] concerning the variability of the kinetic constants, Mazurek[124] derived the equation

$$v = v_i\,(1 + b[\mathrm{P}]^{2/3}), \qquad (9a)$$

where v_i is the initial rate of polymerisation and b the phase heterogeneity constant defined as the ratio of the rates of propagation in the polymer particles and in the liquid phase at a conversion of 1%. The following additional reactions were included in the usual kinetic mechanism:

$$\text{Transfer of radicals to the solid phase } R^{\cdot} \xrightarrow{k_a[\mathrm{P}]^{2/3}} R_a^{\cdot}$$

$$\text{Chain propagation in the solid phase } R_a^{\cdot} + M \xrightarrow{k_{pa}} R_a^{\cdot}$$

$$\text{Chain transfer to the monomer } R_a^{\cdot} + M \xrightarrow{k_{tra}} P + R^{\cdot}$$

where k_a is the rate constant for the transfer of radicals to the polymer phase and R_a are the radicals in the polymer phase.

It is assumed that the constant k_{pa} and k_{tra} vary with conversion but their ratio remains constant: $k_{pa}/k_{tra} \simeq$ const. On the basis of this mechanism, taking into

account the chain termination by radicals from different phases, and the concept of "live" polymer chains in the solid phase, Lyuberetskii and Mazurek[125] obtained an equation for the polymerisation of ethylene, which agrees satisfactorily with experimental data.

A mechanism has been proposed[86] for the polymerisation of acrylonitrile in water, which involves the adsorption and termination of macroradicals on the surface of polymer particles.

Certain indirect data also support the hypothesis that polymerisation takes place on the surface of the particles. Thus an interesting feature of heterophase polymerisation is the dependence of process kinetics on the physical state of the polymer formed, in particular on the particle size and hydrodynamic conditions[126-130]. For example, the rate of polymerisation of acrylonitrile, methyl acrylate, and methyl methacrylate falls on passing from a stable fine sol to a coarse polymeric precipitate, which may be attributed to the decreased surface area of the particles and the decreased number of radicals on the surface[127]. A similar effect was observed following the addition of electrolytes as coagulants[127,128]. On the other hand, the introduction of peptising agents or stabilisers into the system[82,127] (for example cetyltrimethylammonium bromide) increases the stability of the colloidal system and the rate of polymerisation. According to Chapiro[39], the kinetics of the polymerisation of acrylic acid in methanol are also determined by the form of the polymeric precipitate (gel or powder).

Roskin and coworkers[129,130] and Machi and coworkers[131] investigated the effect of stirring on the polymerisation of acrylonitrile in water and of ethylene in the gas phase. Electron photomicrographs led to the conclusion that the polymer-monomer particles approach one another on stirring, which increases the rate of collision of the globules and the rate of termination of the chains on their surface, decreasing the rate of polymerisation of acrylonitrile. Moor and Parts[132] found that the rate of polymerisation of acrylonitrile in the centrifuged polymeric precipitate is lower than in the suspension before separation. This may be due to the increased rate of chain termination when the particles are deposited, owing to their mutual approach and greater isolation of macroradicals from monomer molecules.

Dauphin et al.[44] believe that the role of the polymer phase reduces to an increase of the local concentration of the monomer owing to its adsorption on the polymer surface. However, it has been shown[133] that physical adsorption does not play the main role in the self-acceleration process. The above facts concerning the influence of the transition of the system to a heterogeneous state on the rate of polymerisation also constitute convincing evidence against this hypothesis.

2. The Occlusion Theory. The "Trapping" of Radicals

The immobilised surface theory of Bengough and Morrish[45], which is based on the ease of chain transfer reactions, is inapplicable to monomers such as acrylonitrile and tetrafluoroethylene and is not of general validity. Moreover, Eqn. (9) does not hold in the initial stages of the polymerisation of vinyl chloride (up to a conversion of about 8%).

Bamford and Jenkins gave a qualitative explanation of the characteristics of heterophase polymerisation on the basis of the occlusion theory†. Under conditions promoting the precipitation of the polymer, a macroradical, having reached a certain size, coils up to form a dense structure and is segregated from the liquid phase. The active end of the radical is then occluded in the coiled structure and the rate of the termination reaction falls significantly. During polymerisation, the macrochains coalesce into polymeric aggregates. The aggregation promotes further blocking of the radicals. It is postulated that aggregation entails an insignificant change in the rate of propagation compared with the rate of chain termination, which leads to an increase in the rate of polymerisation with time.

It follows from the occlusion theory that the self acceleration is not determined by the surface but by the mass of the polymer. According to this theory, polymerisation takes place within polymer particles, the degree of occlusion of the radicals and the magnitude of the polymer barrier preventing the penetration of the monomer to the radical end depending on the number and weight of the particles.

The occlusion theory is confirmed by many experimental facts. Thus one of its consequences is that the segregation of the monomer leads to anomalously long lifetimes and high concentrations of macroradicals. Indeed the overall concentration of macroradicals, determined by the ESR method, is 10^{-4}—10^{-5} M for various monomers[6,134-136]. For comparison, we may point out that in polymerisation in solution the concentration is less than 10^{-8} M (except at high conversions). The existence of long-lived radicals in the heterophase polymerisation of ethylene has been postulated by a number of workers[29,137].

If the initiating agent is removed in the initial stages of the polymerisation of acrylonitrile and the unreacted monomer is replaced by a fresh monomer, post-polymerisation is observed[6]. This shows that the radicals persist in the solid monomer and initiate the polymerisation of the fresh monomer. The concentration of these "trapped" radicals, determined by the ESR and inhibitor methods, is 10—13% of the total value, amounting to 7.8×10^{-5} M or 3.7×10^{16} spin ml^{-1} (at 20°C) [36] in a typical experiment.

With increase of temperature, the concentration of "trapped" radicals decreases appreciably[36]:

Temperature, °C	20	25	40	60
Number of "trapped" radicals per ml × 10^{-16}	3.7	2.3	0.8	0.1

Analogous results were obtained by Ingram et al.[134]

"Trapped" radicals have been detected by the ESR method in the polymerisation of methyl methacrylate and methacrylonitrile in hexane[135], in the polymerisation of methacrylic acid in bulk $\{[R^{\cdot}] \simeq 10^{-5}$ M$\}$,[138] in the polymerisation of other monomers[135,141], and in the copolymerisation of methyl methacrylate and methacrylic acid in benzene $\{[R^{\cdot}] = 10^{-4}$—10^{-5} M$\}$.[139] Kargin, Ryabov, and coworkers[120] found that the relation between the concentration of "trapped" radicals and conversion in the polymerisation of methacrylic acid in bulk passes through a maximum.

The "trapped" radicals can initiate the polymerisation of various monomers. Copolymers of acrylonitrile with vinyl acetate, vinylidene chloride, methyl methacrylate, and styrene have been obtained in bulk in this way[140]. At low temperatures, when chain transfer to the monomer is

† This theory is discussed in detail in the monograph of Bamford et al.[6]

insignificant, "trapped" radicals were detected in poly(vinyl chloride); following the addition of DMF, they are activated and initiate the polymerisation of styrene and methyl methacrylate[142]. Bamford and Jenkins[48] investigated the kinetics of the polymerisation of various monomers initiated by "trapped" polyacrylonitrile radicals.

The occlusion theory is qualitative, since it is difficult to express the quantitative relation between the rate constants and the degree of occlusion.

An interesting quantitative interpretation of the kinetics of heterophase polymerisation has been made by Mickley et al.[26], who attempted to eliminate the contradiction between the occlusion and surface theories. The authors suggested that in the initial stages the rate of polymerisation is proportional to the amount of polymer formed, since polymer particles are fairly small and do not prevent contact between the radicals "trapped" within the particles and the liquid phase. After subsequent growth and aggregation of the particles, only a thin surface layer of the aggregates remains in contact with the liquid phase and radicals are "trapped" either owing to chain transfer to the surface of the particles or owing to the penetration of the macroradicals diffusing from the liquid phase to the active surface region of the particles. In this stage, the rate of polymerisation is proportional to the volume of this active layer or approximately to the area of the polymer phase, i.e. $[P]^{2/3}$. The following kinetic equation for the stage in which the rate of polymerisation depends on the polymer volume V_P was derived on the basis of the above mechanism:

$$v = k[M][I]^{1/2} + k[I]^{1/2}\frac{k_{trP}D_L[R_a]V_P}{D_L k_{tr}a} \qquad (10)$$

For the stage where the rate of polymerisation depends on the surface area of the polymer phase S_P, we have

$$v = k[M][I]^{1/2} + k[I]^{1/2}\frac{k_{trP}D_L'[R_a^{\cdot}]\delta S_P}{D_L k_{tr}a}, \qquad (11)$$

where $k = k_p k_{in}^{1/2}/k_t^{1/2}$, [I] is the concentration of the initiator, k_{tr} and k_{trP} are the constants for chain transfer to the monomer and polymer respectively, D_L' and D_L are diffusion coefficients in the liquid phase of the macroradicals and monomeric radicals respectively, $[R_a^{\cdot}]$ is the average concentration of radicals in the active volume, V_P and S_P are the total volume and total surface area of the polymer particles per unit volume of the system, δ is the depth of penetration of the radicals into the particle, and a is the ratio of the concentrations of the monomeric radicals on the surface and in the active volume of the particles.

The proportionality of the rate of polymerisation of vinyl chloride to [P] in the first stage and to $[P]^{2/3}$ in the second stage has been confirmed experimentally[26]. However the usefulness of the above equations is doubtful in view of the difficulty of evaluating some of the parameters.

Cotman et al.[49] made a critical examination of the equation of Bengough and Norrish[45] and suggested that instead of the power exponent 2/3 one should use in Eqn. (9) a variable exponent α depending on the polymerisation conditions. The variation of α with the rate of polymerisation indicates a more complex relation between v and [P] than suggested by Bengough and Norrish. The studies by Bort[114-118] on the morphology of the polymer phase formed made a definite contribution to the elucidation of the question of the site where the chain propagation reaction occurs. Bort[148] obtained experimental evidence showing that the polymerisation of vinyl chloride takes place within the polymer particles, since a change in their surface area for a fixed mass of the polymer does not affect the form of the kinetic curves (except at high rates of polymerisation). Consequently the increase in surface area during heterophase polymerisation is not a factor responsible for self acceleration.

At high average rates of polymerisation, α approaches 2/3, which reflects the limiting relation between the rate v and the amount of polymer precipitated. In this case, the rate of polymerisation exceeds so much the rate of diffusion of macroradicals in the solid phase that there is not sufficient time during the chain propagation step for them to penetrate into the polymeric aggregate and therefore they remain on the surface. Moreover, the permeability of the aggregate decreases owing to the greater density of its structure at high rates of polymerisation and the increase of the polymer barrier to the diffusion of macrochains.

3. The Two-phase Model

Analysis of the morphological structure of the solid phase formed and of the kinetic data lead to the conclusion that in the general case the topochemistry of the polymerisation process is determined by the nature of the interaction of the polymer with the medium. It is possible to distinguish three regions where polymerisation takes place—the liquid phase, the surface, and the bulk of the polymer phase.

If the solvent power of the medium is sufficiently high for a solution of the polymer to exist, the polymer may accumulate largely owing to the formation of macromolecules in the solution. The usual kinetics of homogeneous polymerisation are characteristic of this process. When the swellability of the polymer is very low, the reaction takes place mainly on the surface and in the bulk of the particles formed. Kinetically, the radicals on the surface and in the bulk of the particles are non-equivalent, the activity of the latter being lower in the mutual termination and possibly propagation reactions.

On the basis of these concepts, Talamini[144] proposed a simple mechanism to describe the polymerisation of vinyl chloride in bulk. Since vinyl chloride is a poor solvent for its polymer (the Flory—Huggins constant for this system is 0.88 at 50°C [145]), the separation of the initially homogeneous system into two phases (a dilute liquid monomer-polymer phase and a concentrated solid polymer-monomer phase) takes place at very low conversions (about 0.1%). Subsequently the polymerisation process occurs simultaneously in both phases but at different rates, since the properties of the phases are different (viscosity, monomer concentration, etc.). With increase of conversion, the amount of the dilute phase diminishes and that of the concentrated phase rises. Assuming that the ratio of the rates of polymerisation in the two phases is constant, and that the kinetic constants do not vary with conversion, the following equation was obtained[144,146]:

$$\frac{\Delta[M]}{[M]} = \frac{1}{g}\exp(gk[I]^{1/2}t - 1) \qquad (12)$$

where $k = k_p k_{in}^{1/2}/k_t^{1/2}$ is a constant, $g = -\{1 + [M]_c/[P]_c - v_c[M]_c/v_d[P]_c\}$ is an acceleration factor characterising the autocatalytic effect (the subscripts c and d refer to the concentrated and dilute phases respectively, and v is the

rate of polymerisation. When the exponential function is expanded as a series, we obtain

$$\frac{\Delta[M]}{[M]} = \frac{1}{g}\left\{gk[I]^{1/2}t + \frac{g^2k^2}{2!}([I]^{1/2}t)^2 + \frac{g^3k^3}{3!}([I]^{1/2}t)^3 + \ldots\right\} \quad (13)$$

Eqn. (13) accounts for the higher (more than 0.5) order of the reaction with respect to the initiator. The agreement between the experimental data and the theoretical curve calculated by Eqn. (12) is fairly satisfactory for vinyl chloride up to 50—60% conversion (polymerisation temperature 50°C, initiators—benzoyl and lauroyl peroxides and azobisisobutyronitrile)[146]. Russo et al.[147] used this hypothesis as a basis for a kinetic mechanism of radiation-induced polymerisation of vinyl chloride.

Among the available models, that described above gives perhaps the most accurate description of the quantitative aspect of the kinetics of heterophase polymerisation of vinyl chloride. It postulates the proportionality of the rate of reaction to the weight of the polymer formed and is also confirmed by Bort's data[114] concerning the existence of a solution of poly(vinyl chloride) in the monomer. However, it is still not clear to what extent it is applicable to the polymerisation of acrylonitrile, where the solubility of the polymer in the monomer is much lower than in the poly(vinyl chloride)—vinyl chloride system.

Of the kinetic mechanisms giving a clear and correct description of the physical and chemical processes occurring in heterophase polymerisation, we shall also mention Dainton's mechanism[82,83] proposed for the polymerisation of acrylonitrile in water. It includes reactions in the liquid and solid phases and takes into account interfacial processes—the aggregation of macromolecules and primary polymer particles (microglobules), the "trapping" of the radicals from the liquid phase, chain termination reactions at the interfaces between the phases and within the phases, and adsorption of monomer molecules by polymer particles.

A. Reactions in the liquid phase. 1. Initiation $I \rightarrow 2R_1^{\cdot}$. 2. Chain propagation $R^{\cdot} + M_{aq} \rightarrow R^{\cdot}$. 3. Chain termination $R^{\cdot} + R^{\cdot} \rightarrow P$.

B. Processes in the polymer phase. 1. Conversion of the critical particles p into primary polymer particles P:

$$p + p \rightarrow P$$

and

$$p + P \rightarrow P\ .$$

2. Slow aggregation of the primary particles:

$$\begin{matrix} P + P \rightarrow P \\ P + P^{\cdot} \rightarrow P^{\cdot} \end{matrix}$$

3. Particle growth:

$$P^{\cdot} + M_a \rightarrow P^{\cdot}\ .$$

C. Interfacial processes. 1. Weak adsorption of the monomer by polymer particles $M_{aq} \rightarrow M_a$. 2. Activation of the particles—trapping of radicals by polymer particles:

$$R^{\cdot} + P \rightarrow P^{\cdot}\ .$$

3. Chain termination by radicals from different phases:

$$R^{\cdot} + P^{\cdot} \rightarrow P\ .$$

Kiuchi et al.[148] were able to relate the concentration of the adsorbed monomer (acrylonitrile) $[M]_a$ to its concentration in the aqueous phase $[M]_{aq}$:

$$[M]_a = \frac{\beta}{V_e^{0.5}}[M]_{aq}^2\ , \quad (14)$$

where β is a coefficient varying with the dimensions and the physical state of the polymer particles and V_e is the effective volume of the reactant.

4. The Emulsion Polymerisation Model

Some investigators[10,11] stress the similarity of the systems under consideration, particularly of polymerisation in an aqueous medium, to typical emulsion polymerisation systems. This analogy is based on the morphological and kinetic characteristics of both processes—self acceleration, high average rates and high molecular weights of the polymers, globular nature of the particles, etc. In both cases, the number of polymer particles remains constant in the course of polymerisation. In heterophase polymerisation, the number of particles per cm^3 of the medium is 10^{12}—10^{14}, which is the lower limit in emulsion polymerisation. The monomer consumed in the growing polymer particles is constantly replenished, as in emulsion polymerisation, by diffusion of the monomer molecules from the liquid phase.

Thomas and Webb[150], who employed emulsion polymerisation as a model, calculated k_p from the rate of polymerisation of acrylonitrile in water. The resulting value $k_p = 2 \times 10^4$ litre $mole^{-1}$ s^{-1} agrees satisfactorily with Dainton's data[82,83].

Kiuchi et al.[149] concluded that the principal centres of heterophase polymerisation of acrylonitrile are polymer particles, as in emulsion polymerisation. However, it was found that the relation between the rate of polymerisation and the number of particles is much less pronounced than in typical emulsion polymerisation. The authors explain this difference by the fact that in the first case the heterogeneity of the system due to the insolubility of polyacrylonitrile in the monomer allows each polymer particle to contain more than one radical and therefore it cannot be regarded as an independent centre of propagation of the reaction.

Recently a kinetic mechanism, based on the Smith—Ewart theory was proposed[151] (polymerisation of methyl methacrylate in water). It was suggested that chain propagation takes place on the surface of the particles, the number of which remains constant after the coalescence of the macromolecules. Then

$$v = k_p\frac{\bar{n}N}{N_A}[M]_a, \quad (15)$$

where N is the number of particles, $\bar{n}$ the average number of radicals per particle (proportional to the surface area of the particle or its volume raised to the power 2/3), N_A the Avogadro number, and $[M]_a$ the concentration of methyl methacrylate in the polymer particle assuming it to be proportional to its concentration in the aqueous phase, i.e. $[M]_a = k_1[M]_{aq}$.

After rearrangement, we obtain

$$v = k_p k_1 V_p^{2/3}\frac{N^{1/3}[M]_{aq}}{N_a}\ , \quad (16)$$

where V_p is the overall volume of the polymer phase. It follows from Eqn. (16) that the rate of polymerisation is proportional to the number of particles raised to the power 1/3 and to the concentration of the monomer raised to the power 5/3. Experimental data agree satisfactorily with these conclusions.

5. Theory of Monomolecular Chain Termination. Other Theories.

According to the theory of Thomas and Pellon[12], the occlusion of certain macroradicals can reach such an extent that they become incapable of chain propagation and bimolecular chain termination reactions. This effect resembles the monomolecular chain termination reactions. Thus one may assume that radicals are destroyed via bi- and mono-molecular reactions:

$$-\frac{d[R^{\cdot}]}{dt} = k_t[R^{\cdot}]^2 + k_t'[R^{\cdot}]$$

Having postulated a steady state, the authors obtained an equation for the polymerisation of acrylonitrile in bulk:

$$v = (A^2 + B[I])^{1/2} - A \qquad (17)$$

where

$$A = \frac{k_t'k_t[M]}{2k_t}; \quad B = \frac{k_{in}(k_p[M])^2}{k_t}.$$

Eqn. (17) agrees with experimental data up to 50% conversion of the monomer. Bamford and Jenkins[6] criticised the theory of monomolecular chain termination on the grounds that, for the theory to be valid, the concentration of blocked radicals must be much higher than that of the "trapped" radicals found experimentally.

Durup and Magat[152] suggested that, when the degree of blocking of the macroradicals is a maximum, chain termination is due solely to the primary radicals. However, this hypothesis fails because post-polymerisation takes place at a decreasing rate despite the removal of the source of primary radicals.

Schindler and Breitenbach's analysis[153] of kinetic data for the polymerisation of vinyl chloride is based on the relation which the authors found between the decrease of the chain termination constant owing to the occlusion of free radicals and conversion:

$$k_t = \frac{k_{ti}}{(1 + k^*C)^{1/2}}, \qquad (18)$$

where C is the conversion, k_{ti} the constant for the initial rate of termination, and $k^* = 50$ is a dimensionless constant.

It was established that, up to 20% conversion at 50°C, the following equation holds:

$$C = \frac{k^*v_i^2}{4}t^2 + v_i t \qquad (19)$$

where v_i is the initial rate of polymerisation. This expression is analogous to Eqn. (13) to within the second term.

However, Cotman et al.[49] showed that the constant k^* depends on the rate of polymerisation and tends to increase with the increase of the initial rates of polymerisation. A deficiency of the kinetic equations (17)—(19) is their empirical nature and hence limited applicability.

Magat[154] examined the quantitative aspect of the polymerisation of vinyl chloride. He believed that a steady state is not attained by the system for a long time owing to the low rate of chain termination. Thus self acceleration is caused by the increase in the concentration of macroradicals during the reaction. Despite the fact that the results for vinyl chloride agree satisfactorily with the experimental data, the equation obtained for a non-steady state is inapplicable to the polymerisation of acrylonitrile and vinylidene chloride[154].

If the polymer is capable of crystallising, the kinetic mechanism is complicated still further, since it is then necessary to take into account the differences between the rate constants for the elementary reactions involving the crystalline and amorphous phases[17,155]. The kinetics of heterophase polymerisation can be influenced also by the different reactions of the radicals, as shown for polyethylene[106,156].

---o0o---

One may suppose that further advances in the field of heterophase polymerisation will be achieved by studying both chemical and physical processes accompanying the formation of the polymer phase, in particular by studying different chemical reaction in such systems, the morphological structure and swelling of the polymer particles, the adsorption and diffusion of monomer molecules in the particles, the ratio of the concentrations of the monomer in the liquid and solid phases, etc.

ADDENDUM

Quite recently a number of studies were published on the kinetics and mechanism of heterophase polymerisation and copolymerisation[157-164]. Among these, an investigation[157] where the kinetics of the polymerisation of vinyl chloride in bulk were interpreted qualitatively and quantitatively on the basis of the two-phase theory, is of interest. It is noted that the polymer phase consists of particles swollen in the monomer, the composition of which remain constant up to about 70% conversion. However, in contrast to the theory developed by Talamini[144], the above theory does not include the hypothesis of a steady distribution of radicals between the two phases corresponding to thermodynamic equilibrium, since owing to sorption processes the concentration of radicals in the polymer particles increases continuously with conversion, which is the reason for the autocatalytic nature of the polymerisation. Quantitative calculations showed that at low conversions the chain propagation and termination reactions already take place preferentially within the particles and the number of radicals in the liquid phase is independent of the rate of their termination. The proposed mechanism accounts for the decreased rate of polymerisation (discussed above) on formation and aggregation of particles as due to the increased rate of termination of radicals within the particles in consequence of the increase of their concentration in the effective volume of the condensed phase; the increase in the initial rate of polymerisation of vinyl chloride in bulk and the decrease of self acceleration following the introduction of chain transfer agents[33,34] are explained by the increase of the rate of liberation (desorption) of radicals into the liquid phase.

The kinetic data[158] obtained for the polymerisation of vinyl chloride in bulk (weak post-polymerisation at 25°C, low radical concentration, and a reaction order close to 0.5 with respect to intensity of irradiation) can also be interpreted satisfactorily on the basis of the two-phase model.

Thus, despite their somewhat limited applicability to different monomers, some of the theories discussed (the occlusion and two-phase theories) permit a satisfactory explanation of many characteristics of heterophase polymerisation.

Electrode Behaviour of a Suspension of Insoluble Material

M.R.Dausheva and O.A.Songina

The electrochemical behaviour of suspensions of insoluble materials at different electrodes is discussed, with special emphasis on recent studies of the adhesion of particles of a suspension to the surface of the dropping mercury electrode and of the rotating amalgamated disk electrode. 89 references.

I. INTRODUCTION

Processes in which electron transfer involves insoluble materials (in addition to the electrode metal and the electrolyte) have recently attracted a great deal of attention among electrochemists. We can distinguish three separate cases[1]:

1. The electrode is made of an insoluble compound (single crystal, pressed powder, solidified melt); electron transfer takes place between the electrolyte and the insoluble substance.

2. A metallic electrode is covered with a film of an insoluble substance (for example, an oxide film); in this case electron transfer takes place between the electrolyte, the insoluble substance, and the electrode metal.

3. The insoluble substance is present in suspension in the electrolyte; electron transfer between the insoluble substance and the electrolyte can occur either directly or through dissociation of the substance into electrochemically active ions.

Cases 1 and 2 have been fully investigated in theoretical electrochemistry, and are widely used in practice (for example, in accumulators, cells, and rectifiers). On the other hand, relatively little work has been done on the electrochemical behaviour of suspensions (case 3), largely because of the difficulties arising in studies of heterogeneous systems. If these difficulties could be overcome, new prospects would be created in theoretical and in applied electrochemistry. This review attempts to systematise existing data on the electrochemical behaviour of suspensions.

II. MECHANISMS OF ELECTROCHEMICAL REACTIONS INVOLVING SUSPENSIONS

Most of the published papers on the electrochemical behaviour of suspensions† relate to their reduction. We shall therefore discuss the mechanisms by which suspensions can be electrochemically reduced. However, the same mechanisms can be invoked, in general, for the oxidation of suspensions.

The following mechanisms are possible for the electrode reactions of suspensions.

Mechanism I is an electronic mechanism, involving direct discharge of the solid particle

for salts

$$[M^{n+} + n\,A^-] + ne \rightarrow M + n\,A^- \qquad (1)$$

for oxides

$$\left[M^{n+} + \frac{n}{2}\,O^{2-}\right] + ne + \frac{n}{2}\,H^+ \rightarrow M + \frac{n}{2}\,OH^- \qquad (1')$$

In the case of reduction of oxides the process has been termed[2] electronic–protonic.

Eqns. (1) and (1′) give only a very general description of the process. The detailed discussions of reduction processes found in the literature on oxide electrodes are beyond the scope of the present review. However, we can state that the mechanisms considered for oxide electrodes[2,3] are also applicable, in general, to the discharge of particles of a suspension in contact with the electrode surface.

Mechanism II. An intermediate (X) formed at the electrode during the process takes part in the electron transfer:

for salts

$$[M^{n+} + n\,A^-] + n\,X \rightarrow M + n\,X^+ + n\,A^- \qquad (2)$$

for oxides

$$\left[M^{n+} + \frac{n}{2}\,O^{2-}\right] + n\,X + n\,H^+ \rightarrow M + n\,X^+ + \frac{n}{2}\,H_2O \qquad (2')$$

Mechanism III. The particle of insoluble substance decomposes into ions; the metal ions or the anions are discharged at the electrode:

for salts

$$[M^{n+} + n\,A^-] \rightarrow M^{n+} + n\,A^- \qquad (3)$$

for oxides

$$\left[M^{n+} + \frac{n}{2}\,O^{2-}\right] + n\,H^+ \rightarrow M^{n+} + \frac{n}{2}\,H_2O \qquad (3')$$

$$M^{n+} + ne \rightarrow M \qquad (3'')$$

† The term "suspension" is used to denote unstable, coarsely dispersed systems (particle size $\gg 1\ \mu m$), in contrast to colloids which are stable for very long periods.

Evidently, the decomposition of the particles into ions is determined (for an insoluble substance) by the solubility product of the compound and by the nature of the electrolyte.

Thus, direct electrochemical discharge of an insoluble substance at an electrode occurs only by mechanism I.

It is often difficult to identify the discharge mechanism for the particles of a suspension, and as a result different interpretations of a given process are sometimes found. Thus, the debate on the mechanism of reduction of manganese and tungsten oxide suspensions is well known[4-7]. Kobozev[4,5] states that tungstic oxide is reduced by free hydrogen atoms when hydrogen is evolved at a high-overvoltage cathode (such as lead); on a low-overvoltage (platinum) cathode the reduction involves excited hydrogen molecules (mechanism II). According to Kobozev, manganese dioxide is not reduced at either cathode in spite of its good electrical conductivity. Bagotskii and coworkers[6], and also Lukovtsev[7], prefer mechanism I, and state that tungsten trioxide and manganese dioxide are reduced at high-overvoltage cathodes (mercury, or amalgamated copper) without involving any form of active hydrogen whatsoever: by direct electron transfer, or (in the case of manganese dioxide) by interaction with the mercury of the electrode.

The difficulty of identifying the electrochemical reaction mechanism of a suspension stems from the large number of factors which can influence the electrochemical reduction or oxidation of a suspension: electrode material, electrolyte composition, current density, electrical conductivity of the solid phase, solubility product of the suspended phase, the contact between the solid phase and the electrode, etc.[3,8-11].

It is usually assumed that an electronic discharge mechanism must be involved in the reduction of compounds possessing an appreciable electrical conductivity (10^{-2}–10^{-5} ohm^{-1} cm^{-1}). Poor conductors, on the other hand, are reduced by mechanisms II and III. Evidently, depending on the electrolysis conditions, the process can occur by several mechanisms, but one mechanism usually predominates. For example, the decomposition of particles of an insoluble substance (mechanism III) is accompanied to a greater or lesser extent, depending on the solubility product and on the nature of the electrolyte, by processes which involve the first two mechanisms.

III. BEHAVIOUR OF SUSPENSIONS OF INSOLUBLE SUBSTANCES DURING ELECTROLYSIS

Most of the work on the electrolysis of suspensions has been concerned with their reduction on platinum electrodes. The first publication on this topic was due to Fischbeck[12], who studied the reduction of powdered metal oxides, sulphides, and halides at a platinum cathode in sulphuric acid solutions. Many workers have shown[13-21] that silver halides are easily reduced at a platinum electrode, the silver being deposited on the cathode as a metallic sponge with a very good current yield. The reduction of silver chloride occurs mainly in the solid phase[14-18], i.e. by mechanism I; however, mechanism III can occur at low current densities[8]. Suspensions of lead halides are also easily reduced[14-21]. In a potassium chloride solution they are reduced by direct electron transfer from the electrode (mechanism I), but Sancelme[22] suggests that atomic hydrogen is involved in the reduction of lead halides (mechanism II).

The medium plays a very important role in the reduction of suspensions. Cupric oxide, cuprous oxide, and copper hydroxide are fully reduced to metallic copper only in sufficiently acid solutions. In dilute acids, and also in alkalis, the reduction is slow and does not go beyond a mixture of metallic copper and cuprous oxide[8,10]. Evidently, reduction in acid solutions is assisted by partial dissolution of the oxides (mechanism III). Lead sulphate[19,21] is not easily reduced at a platinum electrode in dilute neutral solutions, and is entirely unaffected in solutions of sulphuric acid. This is thought to be due to the poor electrical conductivity of lead sulphate; furthermore, the dissociation of lead sulphate into ions is hindered in sulphuric acid solutions, and reduction by mechanism III is impossible. Thus, lead sulphate is easily reduced in solutions of hydrochloric acid, sodium carbonate, and sodium hydroxide in which it is partly soluble. Lead phosphate, chlorophosphate, and chromate also can be reduced only in electrolytes in which they are appreciably soluble[19]. Vanadium pentoxide is smoothly reduced to vanadium in dilute sulphuric acid solutions[22]. The hydroxides of tervalent iron and nickel[23] are reduced to the hydroxides of the bivalent metals in neutral solutions. A suspension of α-Fe_2O_3 is reduced to the metal in a concentrated sodium chloride solution, mainly by the action of atomic hydrogen but with a contribution by the electronic mechanism[24].

Platinum is not the only electrode metal on which the reduction of suspensions of insoluble compounds has been investigated. As stated above, some workers have used a mercury cathode[7] and cathodes of amalgamated lead[5] and copper[7]. The reduction of lead, copper, cadmium, zinc, and titanium oxides at a lead cathode has also been studied[25]. A lead cathode has been used to reduce the sulphides and other salts of various metals[26,27]; a silver cathode has been used to reduce a suspension of silver suboxide[28]. Vrebosch and Tiggelen[20] studied the reduction of silver halides and of copper sulphide suspended in dilute solutions of sodium chloride and sulphuric acid, using silver and copper electrodes respectively. It can be seen from the "potential–time" curves for a mixture of silver chloride, bromide, and iodide that the processes corresponding to the reduction of each halide can be resolved in time[20]. The reduction of copper sulphide at a copper electrode in dilute sulphuric acid goes as far as metallic copper, and is accompanied by the evolution of hydrogen and hydrogen sulphide[20]. The reduction of a suspension of cupric and cuprous oxide[8] at a copper cathode in 0.1 *N* sodium hydroxide proceeds mainly by direct electron transfer:

$$CuO + 2e \rightarrow Cu + O^{2-} \quad (4)$$

$$Cu_2O + 2e \rightarrow 2Cu + O^{2-} \quad (4')$$

$$O^{2-} + H_2O \rightarrow 2OH^- \quad (4'')$$

The reduction of cupric and cuprous oxide begins at potentials more negative than the theoretical values by 338 and 616 mV respectively, indicating the presence of a slow step (overvoltage). The authors[8] suggest that reduction by hydrogen adsorbed on the electrode also occurs, but to a smaller extent:

$$H_2O + M + e \rightarrow MH_{ads} + OH^- \quad (5)$$

$$CuO + 2MH_{ads} \rightarrow Cu + H_2O + 2M \quad (5')$$

The symbol M denotes the electrode metal.

The reduction of cupric hydroxide on a copper cathode is attended by a very large overvoltage, and occurs at a

potential 954 mV more negative than the theoretical value[8]. It is concluded that the reduction of cupric hydroxide has a greater dependence on the participation of adsorbed hydrogen than does the reduction of the copper oxides:

$$Cu(OH)_2 + 2MH_{ads} \rightarrow Cu + 2H_2O + 2M \quad (6)$$

With the hydroxide, however, dissociation is possible, and the reaction proceeds partially through the reduction of copper ions:

$$Cu(OH)_2 \rightarrow Cu^{2+} + 2OH^- \quad (6')$$

$$Cu^{2+} + 2e \rightarrow Cu \quad (6'')$$

In the above examples the intermediate (X) which is formed at the electrode and reacts chemically with the insoluble substance is hydrogen. However, this role can be played by other substances, for example metal ions which can exist in two valency states. Addition of such ions to the electrolyte is suggested[29] as a means of increasing the rate of the electrochemical reduction of suspensions of insoluble compounds. For example, suspensions of bismuth oxide and cuprous chloride are reduced electrolytically at a lead cathode in the presence of quadrivalent titanium:

$$Ti^{4+} + e \rightarrow Ti^{3+} \quad (7)$$

$$Bi_2O_3 + 6Ti^{3+} + 6H^+ \rightarrow 2Bi + 6Ti^{4+} + 3H_2O \quad (7')$$

$$CuCl + Ti^{3+} + H^+ \rightarrow Cu + Ti^{4+} + HCl \quad (7'')$$

Some electrochemical studies of the anodic oxidation of suspensions have also been reported. A suspension of arsenious oxide is oxidised to arsenic acid[30]; manganous hydroxide, formed by mixing solutions of manganous sulphate and ammonia, is oxidised to manganese dioxide at an iron anode[31]; manganous carbonate in a sodium chloride solution is also oxidised to manganese dioxide[32]. The oxidation of suspensions of bivalent nickel and cobalt hydroxides and of lead oxide on graphite in sodium chloride solutions[29] involves the chlorine formed at the anode, and the oxidation products are tervalent nickel and cobalt hydroxides and lead dioxide.

Only a few individual papers have dealt with the practical applications of the electrolysis of suspensions. The process has been used as a preparative method for manganese dioxide[31,32], and to convert sparingly soluble compounds into a soluble form[10,22]. The work[33-35] on the production of pure metals directly from their ores could have great practical importance. One of these papers[35] deals with the electrochemical "extraction" of lead compounds. The lead ore, suspended in a chlorate solution, is introduced into the anode compartment of the electrolytic cell and vigorously stirred throughout the reaction. The lead gradually goes into solution, is transferred to the cathode compartment, and is deposited as a sponge on the lead cathode in 86–90% yield. Electrolysis of a suspension of galena in a mixed melt of potassium and sodium chloride yields[33,34] the metal at the (molten lead) cathode and sulphur at the anode. A technical process for the continuous electrolysis of lead concentrates in fused salts could be based on this experiment. The yield of lead is 96–97%, and the purity of the deposited metal is 99.8–99.9%.

Several workers[36-38] have begun to use the suspended electrode method for studies of catalysts. A conventional electrode of the pressed catalyst acts as a current carrier and a carrier of catalytic activity at the same time: by using a suspension of the catalyst these two functions can be separated. The method has been used to study the anodic behaviour of a suspension of Raney-nickel in a sodium hydroxide solution on platinum and gold electrodes, and the cathodic behaviour of a suspension of aluminium oxide (carrier) with additions of silver (catalyst).[36] When the catalyst contacts the electrode, hydrogen is oxidised in the anodic process and oxygen is reduced in the cathodic process. The method has been recommended for studying the oxidation of organic compounds in fuel cells[36]. The electrolytic oxidation of hydrogen and methanol has been studied[37] by the suspended electrode method, using suspensions of platinised and nickel-coated carbon, and Raney-nickel. The effectiveness of catalysts for the porous diffusion electrode of a fuel cell[38] has been assessed by using suspended electrodes of platinum black and Adams' catalyst (finely divided PtO_2). With these suspended electrodes the material in suspension does not react electrochemically at the electrode, and therefore work in this area falls outside the scope of the present review.

Suspensions of sparingly soluble compounds can be reduced by cementation with liquid amalgams[39-41] as well as by electrolysis. When a suspension is stirred with an amalgam the metal from the compound in suspension goes into the mercury, from which it can be extracted by shaking the resulting amalgam with a solution of mercurous nitrate. The liquid amalgam can be brought into intimate contact with the particles, and the electrochemical reaction is therefore favoured. The cementation reaction, which takes place at high negative mixed potentials, is accompanied by hydrogen evolution. Hence, there is a possibility that the reduction of suspensions of sparingly soluble compounds by cementation with amalgams will occur by mechanism II (with participation of the evolved hydrogen) as well as by an electronic mechanism. It has been shown[40] that the behaviour of suspensions in this respect is fully consistent with the electrochemical theory of cementation processes[42]. The cementation method is used mainly to separate precipitates and to convert insoluble into soluble compounds. Thus, cementation with zinc amalgam[39] has been used analytically to separate lead sulphate quantitatively from barium sulphate, and cementation with sodium amalgam has been used to bring into solution heavy metal chlorides, sulphates[40], and carbonates[41].

IV. ELECTROCHEMICAL BEHAVIOUR OF SUSPENSIONS ON SOLID MICRO-ELECTRODES UNDER AMPEROMETRIC TITRATION CONDITIONS

The reduction or oxidation of insoluble substances at an electrode is often encountered in amperometric titrations by the precipitation method[43-51]. The precipitate formed during the titration is sometimes reduced or oxidised at the platinum microelectrode either directly (by contact between the particles and the electrode) or by partial dissolution of the precipitate (if its solubility product is not too small). As a result, the equivalence point on the titration curves becomes ill-defined, and precision is lost. Because of this problem, special electrochemical studies of suspended precipitates with platinum microelectrodes have been undertaken.

Songina and Zakharov[43] made a detailed study of the reduction and oxidation of mercuric iodide precipitates in 1 M sulphuric acid. The oxidation and reduction polarograms of mercury iodide show clearly defined limiting current plateaux: the reduction begins at +0.3 V and the

oxidation at +1.0 V (relative to the mercury/iodide electrode). Because of the very low solubility product of mercuric iodide (5×10^{-29}), it has been suggested that the reduction and oxidation of this compound proceed by the electronic mechanism

$$HgI_2 + 2e \rightarrow Hg + 2I^- \quad (8)$$

$$HgI_2 - 2e \rightarrow Hg^{2+} + I_2 \quad (8')$$

By comparing the polarograms for the reduction of mercuric ions and for the oxidation of iodide ions with those for the oxidation and reduction of a suspension of mercuric iodide it can be shown that the reduction potential of the suspension is 0.4 V more negative, and the oxidation potential 0.4 V more positive, than the corresponding potentials for the mercuric and iodide ions respectively. It is concluded that sharp titration curves can be obtained by carefully setting the potential at a value where neither oxidation nor reduction of the precipitate can occur.

Detailed studies have been reported also of the reduction of silver halide[45-47] and of silver and mercury molybdate and tungstate suspensions[48-51].

The reduction of a sparingly soluble precipitate of silver chloride was used as the basis of an original method for the amperometric titration of iodide in the presence of chloride by a solution of silver nitrate[52]. Particles of silver chloride are formed after the end-point of the titration of the iodide ions: their reduction (at a graphite electrode maintained at a potential of +0.38 V relative to another graphite electrode coated with silver) produces a sharp increase in current.

V. ELECTROCHEMICAL BEHAVIOUR OF SUSPENSIONS ON MERCURY MICRO-ELECTRODES

Micka and Kalvoda's papers on the reduction of suspensions of sparingly soluble compounds (termed "insoluble depolarisers") by classical[53-55] and by oscillographic polarographic methods[56,57] began to appear in the 1950's. Micka used a dropping mercury electrode and conventional polarographic base electrolytes (solutions of sulphuric acid, salts, etc.). The polarograms of his stirred suspensions usually showed a current step over a well defined potential region[53,55], accompanied by sharp current fluctuations associated with the irregular collisions of the solid particles against the electrode (Fig. 1). At more negative potentials the current falls back to the background value. The polarogram plotted without stirring is indistinguishable from the polarogram for the base electrolyte, because the precipitate settles and cannot contact the dropping mercury electrode. The peak height and the frequency of the current fluctuations increase with the rate of stirring and with the number of solid particles in suspension. Micka examined suspensions of several dozen sparingly soluble compounds (sulphides, oxides, chlorides, elemental sulphur, etc.[55]), and determined the potentials corresponding to the maxima in their reduction polarograms.

Kalvoda studied the reduction of suspensions by Heyrovsky and Foreit's oscillographic polarography method[56,57]. He plotted $dE/dt = f(E)$ curves for single-sweep and repeated-sweep polarisations of the dropping electrode. Lobes were found in the oscillograms (Fig. 2) at potentials close to those of the maxima obtained by Micka using classical polarography[55]. By comparing the oscillograms given by single-sweep and multiple-sweep polarisations, Kalvoda concluded that in many cases the direct reduction of solid particles is accompanied by reactions involving the products of interactions between the particles and the electrolyte. For example, suspensions of sulphides and elemental sulphur in acid solutions give an additional peak on the polarogram, corresponding to electronic processes involving the SH^- ions formed at the electrode, and the oscillograms of many substances show additional peaks due to the reduction of metal ions produced by the partial dissolution of the solid particles or to chemical reaction of the sulphide with mercury ions produced by dissolution of the mercury electrode under anodic polarisation:

$$MS + Hg^{2+} \rightarrow M^{2+} + HgS \quad (9)$$

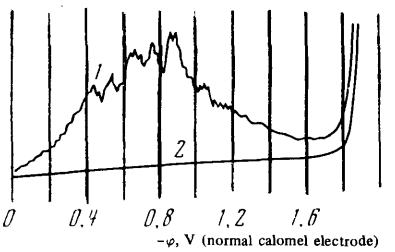

Figure 1. Polarograms obtained with a carbon suspension (20 mg) in a 1 M NH_4Cl base electrolyte (5 ml) using a dropping mercury electrode: 1) stirred, 2) unstirred (from Ref. 53).

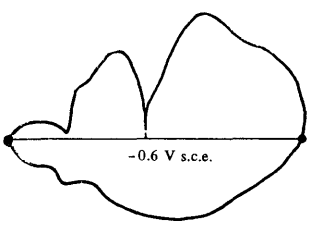

Figure 2. Oscillographic polarogram of a suspension of AgI in 0.5 M KCl, measured with a dropping mercury electrode[56].

Kalvoda points out that the electrochemical behaviour of suspensions of sparingly soluble compounds can be predicted from a knowledge of the position of the metallic component in the electrochemical series: the more noble the metal, the more easily are its sparingly soluble compounds reduced. For example, suspensions of copper, mercury, silver, etc. compounds are easily reduced. Conversely, suspensions of the insoluble compounds of metals such as calcium and magnesium are not reduced at all.

Micka made a detailed study[54,58] of the reduction at a dropping mercury electrode of suspensions of sulphides

of the iron-group metals (Fe_2S_3, FeS, CoS, NiS). The reduction polarograms obtained in the presence of ammonium salts have a sharp current maximum (peak) at potentials 1.5–1.7 V more negative than the normal calomel electrode. The following mechanism is proposed[54,58]:

$$MS + 2e \rightarrow M + S^{2-} \quad (10)$$

$$S^{2-} + 2\,NH_4^+ \rightarrow H_2S + 2NH_3 \quad (10')$$

$$M + H_2S \rightarrow MS + H_2 \quad (10'')$$

There are serious objections to this mechanism, since reactions (10′) and (10″) are impossible under these conditions. Firstly, the reaction between sulphide ions and ammonium ions in aqueous solution should lead to the formation of ammonium sulphide: this, being the salt of a weak acid and a weak base, should be almost completely hydrolysed with formation of SH^- ions and ammonium hydroxide. Secondly, it is hard to accept the oxidation of a metal on the surface of the electrode at a fairly negative potential by hydrogen ions from hydrogen sulphide. Alternative mechanisms, suggested by Micka, seem more convincing: 1) since metals of the iron group are insoluble in mercury, the metal atoms formed by reaction (10) do not penetrate into the mercury but remain on the electrode surface, and the reduction of hydrogen takes place on the metal rather than on mercury, i.e. at a lower overvoltage; 2) as a result of the relatively high electrical conductivity of the heavy metal sulphides the particles of the suspension acquire the potential of the electrode when they collide with its surface, and the hydrogen is reduced at a lower overvoltage.

The catalytic evolution of hydrogen at a dropping mercury electrode in the presence of suspensions of semiconductors‡ was studied by Japanese workers[59] in a 1 M NH_4Cl base electrolyte. The aim of this work was to correlate the properties of the semiconductor (Si, Ge, P, As, Sb, CdSb, CdTe, Sb_2S_3, ZnS, Bi, S, Se, Te, PbS, Bi_2Te_3, InAs) with the shape of the polarogram. As with the sulphides of the iron group[54], the polarograms of suspensions of semiconductor catalysts have a current maximum at a potential more negative than −1.0 V. The height of the maximum depends on the electrophysical properties of the semiconductor and on the concentration of the suspension. The potential of the maximum depends on the width of the forbidden gap of the semiconductor. Electrolysis on the macro scale has shown[59] that a semiconductor suspension lowers the overvoltage for hydrogen evolution. A possible mechanism is the following[59]:

$$\underset{\text{on electrode}}{(\text{Catalyst}) + NH_4^+} \rightarrow \underset{\text{on electrode}}{(\text{Catalyst})H^+} + NH_3 \quad (11)$$

$$\underset{\text{on electrode}}{2(\text{Catalyst})H^+} + 2e \rightarrow \underset{\text{on electrode}}{2(\text{Catalyst})} + H_2 \quad (11')$$

The particle itself is not reduced. An analogous mechanism has been proposed[60] for cobalt sulphide. It should be noted, however, that with sulphide suspensions one must consider, in addition to catalytic hydrogen evolution (for sulphides of the iron group[54,60] metals) and to direct reduction of the solid particles of the suspension (for sulphides of metals such as copper, mercury, etc.[55]), also the reduction of the mercury sulphide film formed at the surface of the mercury drop by the sulphide and hydrogen sulphide ions present in these suspensions. The formation and the reduction of such a film in solutions containing S^{2-} and SH^- ions and a suspension of elementary sulphur has been discussed by Kiselev and Zhdanov[61–64].

‡ The term "semiconductor" is used[59] in the wider sense to include electrical insulators.

VI. MECHANISM OF THE ATTACHMENT OF SUSPENDED PARTICLES TO THE ELECTRODE SURFACE

The reduction of insoluble substances at a dropping mercury electrode in a well defined potential region (Fig. 1) is ascribed by Micka to the existence of adsorption forces between the electrode and the solid particles at these potentials[53]. At very negative potentials repulsive forces arise, and the current falls off[65]: this conclusion is reached from the work of Voropaeva and coworkers[66], who measured the repulsive forces between two crossed wires (gold and platinum) in various electrolytes as a function of the potential of the wires, and found that the force is a minimum at a definite potential.

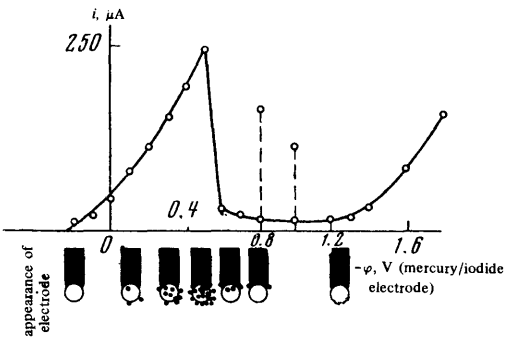

Figure 3. Reduction polarogram of a suspension of Hg_2I_2 (0.01 mole litre^{-1}) in 0.1 M KNO_3, measured[67] with a "hanging mercury drop" electrode and a mercury/iodide reference electrode.

Measurements of the polarographic reduction[67] of insoluble halide and mercury oxide suspensions with a "hanging mercury drop" electrode have shown that an increasing proportion of the particles becomes attached to the electrode surface as the cathodic polarisation is increased to −(0.4–0.5) V relative to the mercury–iodide electrode, but at −(0.5–0.6) V the particles are strongly repelled (Fig. 3). The maximum current in the polarogram corresponds to the maximum number of particles attached to the surface, and the decrease in current corresponds to expulsion of the particles: in other words, the polarographic currents of the suspension are related to the attachment of particles to the electrode surface and to their subsequent reduction. The potential region corresponding to the current maximum extends on either side of the zero-charge potential ($\varphi_{\epsilon=0}$). Electrocapillarity measurements by the mercury drop time method[68] in suspensions of mercury oxides and halides have confirmed that the potential of the current peak is close to the potential of the maximum on the electrocapillarity curve, i.e. to the zero-charge potential.

Jones and Kaye[69] also stressed the significance of $\varphi_{\epsilon=0}$ in their work on the reduction of suspensions of various carbons on mercury-pool and hanging-mercury-drop electrodes. They ascribe the current maximum on the reduction polarograms of their suspensions to the damping of the motion of the mercury surface near the zero-charge potential, which enables the particles to come into contact

with the mercury surface, rather than to attraction of the particles by the surface: as the potential deviates from $\varphi_{\epsilon=0}$ in either direction, the surface of the mercury and the adjacent layer of electrolyte experience violent motions (as in the case of polarographic maxima of the first kind) which destroy the contact between the particles and the surface. However, it is difficult to reconcile this explanation with the absence of a reduction current at high cathodic polarisations even when intensive stirring is applied to increase the frequency of collisions between the particles and the electrode[53,67]. The loss of the contact between the particles of the suspension and the surface of the electrode at potentials well removed from $\varphi_{\epsilon=0}$ has also been pointed out by other workers[70].

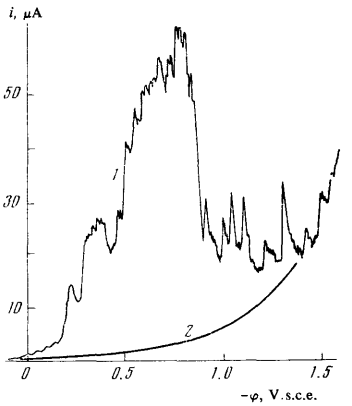

Figure 4. 1) polarogram obtained with a dropping mercury electrode in a suspension of positive oxidised carbon (10 mg) in a 1 M $HClO_4$ base electrolyte (25 ml), deaerated and stirred; 2) polarogram of the base electrolyte (from Ref. 71).

Stirred suspensions of activated oxidised carbons give rise to large polarographic currents, due to the reduction of oxygen-containing surface groups (Fig. 4)[71]. If these suspensions (which are relatively stable, and settle very slowly[72]) are left unstirred, their polarograms lose all the reduction peaks and become identical to the polarogram of the base electrolyte (curves *1* and *2* of Fig. 5). In the presence of molecular oxygen the polarogram develops a reproducible maximum in the region of the oxygen reduction wave at potentials which include the point of zero charge (curve *4* of Fig. 5). The current maximum is due to the reduction of molecular oxygen on the electrode surface, enhanced by the attachment of carbon particles[71,73]. The shape of polarograms for suspensions of active carbons, measured in the presence and in the absence of oxygen, indicates that the particles in unstirred suspensions are not reduced although they adhere to the surface of the electrode at potentials near $\varphi_{\epsilon=0}$. A similar phenomenon was reported by Micka[65], who found that particles at rest on the mercury surface are not reduced.

These phenomena, and the link between $\varphi_{\epsilon=0}$ and the degree of adhesion, are convincingly explained by some observations of Frumkin[74,75] on the relative stabilities of liquid films of different thickness, which are determined by the relationship between the surface tension and the thickness of the layer[74]. When the layer of liquid between a gas bubble and the solid surface is made progressively thinner, a critical thickness is reached beyond which instability sets in. The liquid layer is disrupted, and the bubble can attach itself to the surface, but a very thin film of liquid nevertheless remains between the bubble and the surface. In the case of a metallic surface the adhesion depends on the potential[75]: for example, the attachment of a hydrogen bubble to a mercury surface is instantaneous at the zero-charge potential, because the liquid layer of electrolyte becomes labile in the absence of charge and is easily disrupted by the approaching bubble. As the potential moves away from $\varphi_{\epsilon=0}$ the liquid layers are stabilised by the electrical double layer, and the attachment of the bubbles becomes slower[75]. The surface tension of the layer of electrolyte between the bubble and the electrode (and therefore also the force needed to separate the layer) is proportional to the square of the potential difference between the metal and the solution. Hence, the wettability of the metal by the liquid increases as the potential departs from the point of zero charge, and the angle of contact observed after the attachment of a bubble decreases[76]. The bubble is held in contact with the electrode surface by capillarity forces acting on the perimeter of the area of contact.

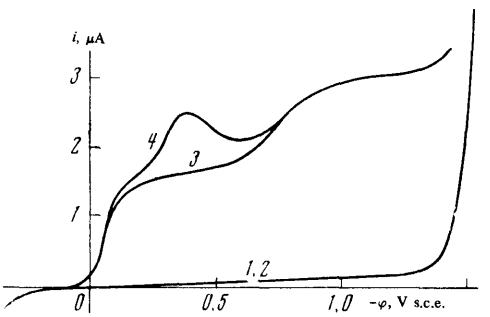

Figure 5. Polarograms measured in 1 M KNO_3 with a dropping mercury electrode: 1) without oxygen or carbon (base electrolyte only), 2) without atmospheric oxygen but in the presence of a suspension of positive oxidised carbon (10 mg in 25 ml); 3) in the presence of atmospheric oxygen but without carbon; 4) in the presence of atmospheric oxygen and a suspension of positive oxidised carbon (10 mg ml^{-1}) (from Ref. 71).

The adhesion phenomenon has been studied also for mercury droplets on glass[77]. The force of attraction between the mercury and the glass surface varies with the potential of the mercury in much the same way as the adhesive force of gas bubbles.

In the case of suspensions, the layer of liquid between particle surface and electrode surface behaves very probably as described above. Thus, the fact that the solid particles become attached to the electrode surface only in a well defined region of potentials can be ascribed to the disruption of labile layers of electrolyte near the zero-charge potential.

By comparing the peak potentials in the polarograms for positive and negative oxidised carbon suspensions[73]

we conclude that the electrostatic effect of the charges on the particles is negligibly small: with a negative carbon the adhesion of the particles reaches a maximum at a charge on the mercury surface slightly more positive (no more than 0.07 V) than with a positive carbon, but the region of adhesion is the same for the two carbons [−(0.3–0.6) V relative to the saturated calomel electrode]. This suggests that the adhesion results primarily from the ready disruption of electrolyte layers in the region of $\varphi_{\epsilon=0}$, rather than from interaction between the charges on the electrode surface and on the particles of the suspension.

In contrast to other types of attachment to an electrode (for example, the interaction of freshly precipitated particles with an electrode, due to the influence of their surface charges), the attachment of particles at potentials close to the point of zero charge may be termed electrocapillary attachment.

The exaltation of the reduction current of dissolved oxygen in the presence of a carbon suspension[71] can be used as a measure of the degree of attachment of the particles to the surface of a dropping mercury electrode as a function of the experimental conditions. The method has been used to demonstrate the dependence of electrocapillary attachment on the amount of carbon in suspension (the "concentration" of the suspension) and on the height of the mercury column (h).[71] By increasing the "concentration" of the suspension we can increase the number of particles attached to the electrode surface, and thus obtain enhanced reduction currents of dissolved oxygen in the potential region which favours attachment of the particles. However, since the drop has a limited surface area, there is a critical "concentration" beyond which further increase has no effect on the oxygen reduction current. The dependence of electrocapillary attachment on h has the characteristic form of slow adsorption processes, in which the maximum in the first oxygen wave is suppressed. This dependence also can be easily explained by invoking the analogy between the adhesion of bubbles and the adhesion of solid particles to the electrode surface. For a bubble of a given size we can define an "induction period": the time for the disruption of the layer of electrolyte between the bubble and the electrode surface immediately before the bubble becomes attached[75]. Evidently, this definition applies also to the particles of a suspension. For low values of h the life time of the drop (τ) is greater than the "induction period", and particles can adhere to the surface of the drop until the drop becomes detached. As h increases the drop time of the mercury decreases, and only those particles whose size corresponds to an "induction period" smaller than τ can become attached. Lastly, at large values of h attachment is impossible because τ is smaller than the "induction period" of even the smallest particles.

Decreasing the concentration of the base electrolyte increases the exaltation of the oxygen reduction current in the presence of a carbon suspension, i.e. it increases the electrocapillary attachment of the carbon particles to the electrode[73]. This effect arises from the increased diffuseness of the double layer, i.e. from the increased double layer thickness: theory predicts[75] that under these conditions the stability of the layers of electrolyte adjacent to the electrode should decrease, and hence the attachment of particles should be enhanced.

Assuming (by analogy with the case of a bubble) that a very thin layer of electrolyte remains between the electrode surface and the particle attached to it, it is easy to see why adsorbed oxygen in unstirred carbon suspensions is not reduced at the electrode (see curve *2* of Fig. 5), in spite of the attachment of particles to the electrode[71]. When the suspension is stirred, however, the layers of electrolyte between electrode and attached particles become even thinner, and may disappear completely, thus allowing the reduction of the oxygen bound to the carbon (see Fig. 4). Frumkin has pointed out[74] that stable layers can become unstable under the influence of quite small external disturbances. If we assume that even the thinnest layers of electrolyte can prevent the reduction of a solid particle at the electrode, we must conclude (from the fact that large currents are observed in stirred but not in unstirred suspensions) that neither the complete disruption of the electrolyte film nor the direct reduction of a particle can be excluded in the case of stirred suspensions.

At potentials too negative to permit electrocapillary attachment the reduction of solid particles of polarographically active suspensions such as mercury halides is suppressed even with vigorous stirring, in spite of the collisions between the particles and the electrode[67]. However, for small negative excursions from the region of attachment potentials [−(0.7–0.9) V s.c.e.] the particles colliding with the electrode squeeze the layer of electrolyte adjacent to the electrode to a very small thickness, or even disrupt it completely, and can be reduced without attachment. Hence, on stirring, the potential region where reduction can occur is shifted towards values more negative than the region of electrocapillary attachment [−(0.3–0.6) V]. For example, a carbon suspension in a neutral base electrolyte gives a current peak at −0.8 V when stirred. In the light of this discussion, the high negative peak potentials observed in the reduction polarograms of other insoluble substances[55] should cause no surprise. Some of the more energetic particles can "puncture" the layer of electrolyte at still more negative potentials, as shown by the sharp and random current surges observed in the polarogram[67].

Summing up, the behaviour of suspensions of insoluble substances at a dropping mercury electrode may be described by the following steps: 1) breakdown of the layer of electrolyte adjacent to the electrode as the particle approaches the surface; 2) attachment of the particle to the electrode surface under the influence of capillarity forces; 3) discharge of the solid particle at the electrode.

As shown above, the second step may be absent, and discharge without attachment can occur if the particle collides with the electrode surface with sufficient energy to disrupt the boundary layer of electrolyte. The third step also is not invariably observed, but only occurs at sufficiently negative potentials.

It is interesting to note that freshly precipitated iron, cobalt, and nickel sulphides (in the form of a very slight turbidity) are not polarographically active[54]. A reduction current appears only when the colloidal sulphide begins to coagulate, i.e. when the particles begin to grow. The lack of electrochemical activity of a freshly precipitated compound (silver bromide) was pointed out also by Bowers and Kolthoff[78]. Most probably, particles of typically colloidal dimensions ($0.1 < r < 1\ \mu m$) such as those of a freshly formed turbidity cannot become attached to the electrode and be reduced because their kinetic energy is insufficient to overcome the disjoining influence of the layer adjacent to the electrode surface. (Deryagin[79] discusses the relationship between the size of colloidal particles and the repulsive forces acting on the particles. It may be assumed that the size of the particle influences also its interaction with the electrode surface.) Reduction currents at a dropping mercury electrode are sometimes

observed in colloidal systems, but they are not usually associated with the direct reduction of the particles. For example, the current in finely divided carbon suspensions[80,81] arises from the reduction of quinoid groups transferred to the solution from the surface of the carbon particles. In transparent colloidal solutions of iron hydroxide (particle radius < 0.1 μm) a reduction wave is observed[82] rather than a maximum. Evidently, the reduction of these colloidal solutions is governed by the same diffusion laws as the reduction of ions in true solutions.

Pairs of maxima have been observed in the reduction polarograms of mixtures (HgS and PbS[53], HgS and FeS[54]). However, the appearance of two current maxima does not necessarily imply that the potential of maximum attachment is different for the two kinds of particle. The particles of the two compounds adhere to the electrode over a wide range of potential, which includes the zero-charge potential, but only the mercury sulphide particles can be reduced at low negative potentials. At the same time, the film of mercury sulphide[61,62] formed on the electrode because of the presence of sulphide ions in the suspension is also reduced. At more negative potentials the reduction of the PbS and FeS particles can take place—or catalytic hydrogen evolution in the presence of FeS—and the second maximum is formed, followed by a decrease in current due to the loss of adhesion at sufficiently negative potentials.

A pair of maxima is observed also in the reduction polarograms of suspensions of manganese dioxide, plotted with a dropping mercury electrode in solutions of sulphuric acid and ammonium sulphate: the first maximum occurs at +0.1–(–0.2) V s.c.e., the second at much more negative potentials [–(1.3–1.4) V][65]. Their origin is not discussed[65], but it is assumed that solid particles are reduced in both cases (to give manganese ions of different valencies). However, the first maximum is more likely to be due to the reduction of mercury ions, formed by the direct oxidation of the metallic mercury of the electrode by particles of adhering manganese dioxide. (A weak electrocapillary attachment can be expected even at the potentials of the first maximum, since they are not too far removed from $\varphi_{\epsilon=0}$.) We have shown[83] that mercury ions can be formed in the presence of an oxidising agent. The fall in current after the first peak can be ascribed to the inhibiting effect of the increasingly cathodic potential on the reaction between the manganese dioxide and the mercury. Reduction of MnO_2 occurs at high negative potentials (second peak). Although the electrocapillary attachment is not very strong at these potentials, the particles colliding with the electrode can overcome the disjoining effect of the interfacial layer of electrolyte and remain briefly in contact with the electrode. The reduction process is accompanied by catalytic hydrogen evolution[65], made possible by the decreased overvoltage on the MnO_2 particles.

A second maximum at very cathodic potentials(–1.2 V relative to the normal calomel electrode) has been observed also in the reduction polarograms of heat-treated silver carbonate[84]. This maximum is ascribed to the formation of a new form of silver carbonate with a high density of lattice defects; it is not very sharply defined, and consists of a collection of current surges probably associated with particularly energetic collisions outside the region of electrocapillary attachment.

Thus we may conclude that particles of a suspension of insoluble material are reduced at a dropping mercury electrode by virtue of the electrocapillary attachment of the particles to the electrode in the region of potentials around $\varphi_{\epsilon=0}$, or by collisions between the particles and the electrode at potentials not too far removed from this value. The following conditions are necessary: 1) the reduction potential of the insoluble substance must not be more negative than the region of potentials at which attachment occurs: 2) the particle size of the suspension must be greater than average colloidal dimensions ($r > 1$ μm), i.e. the suspensions must be coarsely disperse according to the conventional classification used in colloidal chemistry: 3) stirring (not necessarily vigorous) of the suspension is essential.

In all the work discussed above stirring was produced by a stream of inert gas or by a magnetic stirrer. However, the random collisions of the particles with the electrode produce irregular current surges, and therefore the polarograms are not easy to reproduce. A novel design of polarographic cell has been proposed[85] with the aim of providing a more regular stream of particles colliding with the electrode: a stream of gas, supplied at a constant flow rate, induces circulation of the solution towards the electrode, also at a constant rate. External means of ensuring regular drop detachment are provided. A cell of this design was used to measure the rate of dissolution of lead salts in various media, but the results were disappointing[85]. Evidently, an even flow of particles towards the electrode had not been achieved.

VII. BEHAVIOUR OF SUSPENSIONS ON AN AMALGAMATED ROTATING-DISK ELECTRODE

An even flow of the particles of a suspension towards the electrode can be achieved only by using a rotating disk electrode. Suspensions of activated oxidised carbon[86,87] and of insoluble mercury halides[88] have been studied on an amalgamated rotating-disk electrode. Strong attachment of the particles to the electrodes is again observed in the potential region corresponding to the point of zero charge of mercury. However, the region of electrocapillary attachment is much broader with the rotating disk electrode than with the dropping mercury electrode, and can extend over 1.0–1.1 V. This is because the layers of electrolyte between the solid particles and the electrode surface are more easily disrupted when the electrode is a rotating disk, which produces a very energetic flow of particles, and adhesion becomes possible at potentials quite far removed from $\varphi_{\epsilon=0}$. Carbon particles attached to the electrode[86] are retained even when the potential is moved still further from $\varphi_{\epsilon=0}$: down to potentials of –(1.7–1.9) V s.c.e. At still more cathodic potentials the particles are eventually detached. Thus, with carbon suspensions the amalgamated electrode is covered with particles over a range of potentials extending over almost 2 volts.

In the polarisation curves given by suspensions of oxidised carbons the reduction current is directly proportional to potential over a wide range of potentials. This current is due to the reduction of oxygen groups on the surface of carbon particles attached to the electrode (Fig. 6). The steeper increase in current which sets in at –(1.0–1.2) V in neutral and in alkaline solutions, and at –(0.7–0.8) V in acid solutions, is due to the evolution of hydrogen on the surface of the particles, since the hydrogen overvoltage on carbon is lower than on mercury. The polarograms for the neutral and the alkaline electrolyte show a steep fall in current at –(1.7–1.9) V, due to the detachment of the carbon particles. In acid solutions the detachment potential is not reached because hydrogen evolution begins at lower voltages. (Note that detachment is not observed

with the dropping mercury electrode, discussed in Section VI, because the surface of that electrode is constantly renewed.) The detachment is the result of the enhanced disjoining action of the interfacial layer of electrolyte at potentials sufficiently far removed from $\varphi_{\epsilon=0}$. The reduction currents of attached particles are independent of the rate of rotation of the electrode, but they show a slight increase with the "concentration" of the suspension. The detachment potential of the particles, on the other hand, depends on the rate of rotation of the electrode (ω): the greater ω, the more readily are the particles detached, evidently because of the centrifugal forces acting on them[86].

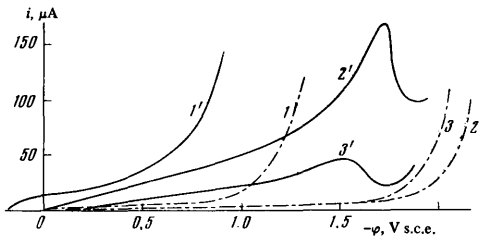

Figure 6. Polarisation curves measured with an amalgamated rotating-disk electrode in 0.1 M solutions of $HClO_4$ (*1*, *1'*), KCl (*2*, *2'*), and KOH (*3*, *3'*) in an argon atmosphere without (*1*, *2*, *3*) and with (*1'*, *2'*, *3'*) a suspension of positive oxidised carbon; ω = 3890 revolutions min^{-1} (from Ref. 86).

In the course of studies of carbon suspensions it was realised that information could be obtained on a number of electrochemical processes (such as the reduction of dissolved molecular oxygen and hydrogen peroxide[86,87]) which can occur on the surface of carbon particles attached to the electrode. By making a number of simplifying assumptions, the degree of screening (θ) of the surface of the amalgamated electrode by the carbon particles could be calculated[86]: it was found to be independent of the rate of rotation of the electrode, but slightly dependent on pH (θ = 0.4 in alkaline electrolyte and 0.5 in a neutral electrolyte). In acid solutions θ cannot be evaluated, but it is reasonable to assume an even higher screening because the reduction currents in acids are higher than in alkalies by a factor of 2–4.

The reduction currents on a rotating amalgamated electrode of suspensions of mercury halides are an order of magnitude greater than the reduction currents of carbon suspensions on the same electrode, since the whole of the attached particle is reduced, and not just the oxidised surface groups[88]:

$$Hg_2Br_2 + 2e \rightarrow 2Hg + 2Br^- \qquad (12)$$

Thus, under reducing conditions the particles of mercury halide attached to a rotating amalgamated electrode are continually disappearing, and the electrode surface is continually restored: this is shown in the polarograms by periodic negative current surges. Hence, the steep fall in the polarographic current (Fig. 7) is not due to the detachment of particles, but to the weakening of the electrocapillary attraction effect as the potential swings beyond $\varphi_{\epsilon=0}$. Increasing the speed of rotation of the electrode strengthens the onrush of the particles towards the surface, and helps them to overcome the disjoining effect of the interfacial layers of electrolyte at more negative potentials, thus causing a shift of the sharp drop in current towards more negative potentials.

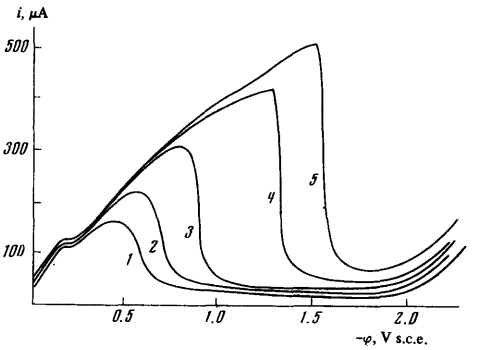

Figure 7. Polarisation curves for the reduction of a suspension of Hg_2Br_2 (0.05 mole $litre^{-1}$) in 0.1 M Na_2SO_4 on an amalgamated rotating-disk electrode: 1) ω = 1030, 2) 1970, 3) 3890, 4) 5700, 5) 7660 revolutions min^{-1} (from Ref. 88). Periodic current surges are not shown.

The fact that the suspensions do not give a reduction current at high negative potentials, in spite of the very vigorous stirring and of the powerful collisions of the particles with the surface of the disk electrode, is further proof of the reality of the attachment of particles to the surface of a mercury or amalgamated electrode at potentials close to $\varphi_{\epsilon=0}$, and strengthens our conclusion that direct reduction of the solid particles of a suspension under polarographic conditions can occur, in general, only if the particles are attached to the surface of the electrode.

---o0o---

Our recent study of mercury halide suspensions on a solid (rotating) disk electrode[89] has shown that the particles of coarse suspensions do not adhere to the surface of a solid electrode. Accordingly, no reduction currents are produced by the particles of these suspensions. Most probably, the electrocapillary attachment of solid particles to an electrode surface is possible only when the surface is liquid (as in the case of the dropping mercury electrode or the amalgamated electrode), i.e. mobile and capable of sufficient deformation to produce the angle of contact at the three-phase boundary (electrode–electrolyte–particle) needed to accommodate the capillarity forces which hold the particle to the electrode surface. Frumkin[77] has invoked deformation of the surface of a liquid electrode in his discussion of the attachment of gas bubbles and of glass surfaces to mercury. It should be noted that small, colloidal particles were always present in the coarse suspensions of mercury halides used in our work with a rotating electrode. These particles are reduced at a platinum electrode (see Section IV): they can reach the electrode surface by diffusion, and furthermore these very small particles are subject to forces of adhesion (but not electrocapillary attraction) to the electrode by virtue of their roughness and of their surface charge.

Quantitative Cusp Paper Chromatography

V.N.Aleskovskaya and V.B.Aleskovskii

A relative assessment of the main methods of quantitative chromatography is given. The theory and practice of cusp chromatography (a new variant of precipitation chromatography, developed by the writers) are discussed, and examples are given of the determination of cations and anions, singly and in mixtures, and over a very wide range of concentrations. 38 references.

III. The cusp paper chromatography method 149

I. INTRODUCTION

A short review of the development of precipitation chromatography, beginning with the work of its originators (Gapona and Gapon[1,2]), and also a discussion of the theory and many interesting practical applications of precipitation chromatographic analysis, can be found in the monograph by Obshanova and coworkers[3], and more recent developments in a review article by Lur'e[4]. The potential uses of partition chromatography are discussed in a recently published symposium[5].

The bands of precipitation chromatograms are formed by chemical reactions under well defined and reproducible conditions. The direct proportionality between the size of the bands in precipitation chromatograms and the amount of material being analysed has been stressed by many workers[7-14]. This feature of precipitation chromatography distinguishes it from partition and from sorption chromatography, and offers (in principle) a simple and reliable method of quantitative determination by measuring the size of the bands in precipitation chromatography. The most convenient form of the method from this point of view is precipitation chromatography on paper, and in particular one of its variants which allows the bands to be obtained in the shape of cusps[15]. However, much of the earlier work was aimed at the study of chromatograms of a different type[7,16-18]. No attempt was made to determine the optimum conditions for the formation of cusp chromatograms, and even the reason for the formation of bands in the shape of cusps was not discussed. In general, cusp chromatography was ignored. A recent symposium[5] deals with quantitative chromatography by physicochemical methods: in the present review we shall discuss the direct determination of the amount of material in the band by measurements of the size of the bands (and, in particular, the height of the cusps[6]).

II. QUANTITATIVE CHROMATOGRAPHY BY MEASUREMENT OF THE SIZE OF BANDS

There is general agreement[4] that sorption and partition chromatography on columns do not lend themselves to quantitative determinations from measurements of the size of the bands, mainly because these bands have indeterminate stoichiometries and geometries. The concentration of the substance being analysed in the bands, and the size and shape of the bands themselves, show a complicated dependence on the composition and concentration of the solution under study, on the composition and specific surface area of the sorbent or of the carrier—stationary phase mixture, and also on the dynamics of the process (which can be further complicated by diffusion in the bulk of the sorbent or through the porous carrier). On the other hand, paper chromatography and thin-layer chromatography offer the possibility of quantitative analysis directly from the chromatogram (e.g. by scanning the bands with a densitometer or with a radioactivity detector if suitable tracers are used). However, we cannot yet "rely on the reproducibility and precision of the results"[5]. This is not surprising, since the composition of the stoichiometrically indeterminate bands depends on the chromatographic conditions and on the relative order and duration of the various steps. These uncertainties disappear completely when we turn to precipitation chromatography on paper: bands consisting of precipitates have a definite stoichiometry and (in the case of paper chromatography) a very small and constant thickness. Simple calibration (by determining the width of a standard band) is sufficient for precise measurement of the amount of material present in the precipitate: this presupposes that the sample for chromatography is deposited on the paper as a band of constant width, or (preferably) that the band is produced in the form of a cusp with a constant, narrow base[15].

Kokk and Aleskovskii[19,20] were led by similar considerations to use thin threads as columns of the wick type, and were able to claim enhanced sensitivity for quantitative column chromatography.

The paper specially produced for chromatography has a constant density. If a uniform, stationary layer of precipitant is deposited on such a paper, quantitative chromatography of substances which form sparingly soluble compounds with the precipitant becomes possible.

An immobile layer of precipitant—one of the main requirements of quantitative chromatography—is obtained by impregnating the paper with a relatively insoluble precipitant. Soluble precipitants should be avoided, because they are partially eluted during the chromatographic separation and the reproducibility of the results is thereby impaired. For this reason, the more recent work[22-24] on cusp paper chromatography was done with paper impregnated with sparingly soluble precipitants, in contrast to the earlier work[15,20,21], in which the cusps had been obtained on paper impregnated with soluble reagents. This small improvement has resulted in satisfactory

reproducibility of the cusps and has established cusp chromatography as a strictly quantitative method.

A uniform distribution of precipitant in the bulk of the paper is obtained using appropriate impregnation conditions, established experimentally. The uniformity of the precipitate in a column of inert carrier has been demonstrated[25,26] by scanning the column (anhydrous alumina) with a counter after precipitation of silver iodide containing radioactive iodine. The uniformity and the attachment of the precipitate on paper are, obviously, no worse than in a column, as shown by the excellent reproducibility of quantitative measurements on paper impregnated with sparingly soluble precipitants. The layer of deposit is believed[25] to consist of charged colloidal particles which are held on the surface of the carrier by electrostatic attraction. Recrystallisation, leading to growth of the primary crystals, is also thought of occur.

The exact size of the band is ultimately determined by the particle size of the precipitate. Hence it is important to adopt chromatographic conditions favouring the formation of crystallites of a reproducible size.

In order to ensure that the whole of the sample deposited on the chromatographic paper comes into contact with the impregnant (precipitant), the primary chromatogram is eluted in various ways[3] with a solution free from the ions being analysed. For example, the paper containing the sample can be steeped in water or in an aqueous solution of glycerol to elute the primary chromatogram.

Another important condition for good results in quantitative paper chromatography is a large difference in solubility between the impregnant and the precipitates of the elements being analysed. Evidently, the impregnant should be more soluble than the precipitates. Under these conditions, Lur'e concludes[4] from a consideration of the dynamics of sorption that "we can expect a discrete distribution of the precipitates in eluted chromatograms in the form of individual bands, practically free from impurities of other components", as other workers had previously reported from experimental work.

The solubility of the precipitates in the various bands can be increased by varying the acidity of the chromatographic solution or by increasing the concentration of complexing agents in solution. It follows that the pH must be optimised and controlled, and in general the concentration of all the constituents of the solution which influence the solubility of the precipitates in the chromatographic bands must also be controlled.

Yet another important condition to be satisfied in quantitative chromatography is very rapid formation of the precipitates: this must be faster than the rate of penetration of the solution through the paper during elution[27].

The difference in the degree of utilisation of the precipitant observed during chromatographic separation of different ions, e.g. zinc sulphide during the separation of silver and copper ions, is ascribed to the different rates of the corresponding replacement reactions: "this difference is greatest when the difference in solubility product between the reactants and the final products is greatest[28]".

Kulaev points out[16,29] that the size of the bands of various precipitates varies in direct proportion with the following factors: 1) the solubility product of the sparingly soluble precipitate; 2) the concentration of the original solution; 3) the drop volume of the original solution. It is also "determined by the conditions under which the precipitate is formed, particularly since the last stages of formation of the precipitate take place in the narrower regions". Kulaev also stresses that "other conditions being the same, the width of the band ... depends only on the solubility product of the sparingly soluble compound", a fact which he ascribes to the dependence of the rate of migration of the precipitation front upon the solubility product. Lur'e[4] does not accept this argument, and suggests that the width of the band is determined by the difference in reaction rates of the components of the solution with the precipitants, which is directly related to the difference between the solubility products of the impregnant and of the precipitate in the final chromatographic band.

Obviously, this controversy can be resolved by a study in depth of the mechanism of precipitation chromatography.

True precipitation chromatograms on paper are often obtained in simple spot tests[30,31]. For example, 0.05—0.25 μg of copper can be detected on paper impregnated with rubeanic acid in the presence of a large excess of cobalt and nickel. These elements produce separate, differently coloured annular bands on the paper. According to Feigl[31], unsized paper is simply an assembly of compressed fibres. The mixture to be analysed is separated by diffusion and adsorption in the capillaries of the paper. The precipitate formed in the interstices between the paper fibres has a fine-grained structure: it can migrate with the solution, cover the surface of the fibres, and eventually plug up the capillaries. In this way a small amount of precipitate can cover a relatively large area of paper, thus making the spot test on paper more sensitive than on a smooth tile or in a test-tube. Because of their small particle size and large surface area, the precipitates formed in the capillaries of the paper are more soluble than the same precipitates formed in test-tubes.

The sensitivity of spot tests can be increased by treating the paper with gelatine. The main difference between paper chromatography and spot-test analysis resides in the method of applying the sample and in the subsequent treatment of the chromatogram. Kulaev[16-18,29] suggests the following procedure[16].

Filter-paper is impregnated with 1—4% solutions of sodium silicate, hydrogen phosphate, or arsenate, or with solutions of potassium ferrocyanide or chromate. The excess of solution is allowed to drain off, and the paper is air-dried whilst still hanging in a vertical position. Samples of the solutions to be analysed are deposited from a capillary dropping pipette or a microburette (drop volume 0.025 ml) on a 65 mm square piece of the paper. The drop should be allowed to fall on the paper from a height "no more than 5 mm from the surface". A circular spot is formed on the paper. This primary chromatogram is eluted by adding 5—6 drops of water, each drop being allowed to spread fully before the next drop is added. The colourless bands are developed by spraying a suitable developer, in repeated small doses, onto the dried chromatogram.

When a mixture of two or more elements is chromatographed, the band corresponding to the least soluble of the elements remains in the centre as a circular spot; the more soluble precipitates surround the central spot in concentric rings disposed in order of increasing solubility. In Kulaev's experiments the impregnated paper contained a small excess (a factor of 2—3) of precipitant over the amount required to react with the ions under study (mercury, iron, bismuth, chromium, aluminium, cadmium, lead, silver, copper, zinc, manganese, cobalt, nickel, barium, strontium, and several others). The width of the band was measured to the nearest 0.1 mm. The procedure used in cusp chromatography, though outwardly similar, is fundamentally different.

This method of quantitative chromatography was first proposed[15] for the determination of copper and nickel on paper impregnated with a 0.1% aqueous solution of sodium diethyldithiocarbamate or a 0.1% alcoholic solution of rubeanic acid (for copper) or with a 1% alcoholic solution of dimethylglyoxime or rubeanic acid (for nickel). A drop of a solution of copper or nickel salt of known concentration is deposited from a calibrated capillary pipette (1.5 μl volume) on a piece of paper impregnated with the appropriate reagent. The edge of the paper below the drop is immersed in a 14% aqueous solution of glycerol contained in a beaker covered with a glass plate. The solvent is drawn into the paper: it entrains any ions which have not yet reacted, and transports them upwards, forming a cusp-shaped band.

The height of the cusp was found to be linearly related to the concentration of the ion being determined and to the amount of precipitant on the paper. By analogy with the spot-test technique, an attempt was made to increase the sensitivity of the determination by treating the paper with a 0.013—0.05% solution of gelatin after the deposition of the precipitant. This amount of gelatin has a negligible effect on the speed of travel of the solvent, but it gives a sharper and more deeply coloured spot.

Kokk and Aleskovskii[21] subsequently developed a method of determining as little as 5×10^{-2}% of copper in micro-quantities of cadmium selenide (0.50—1.00 mg) on grade B chromatographic paper (density 85 g m^{-2}) impregnated with sodium diethyldithiocarbamate. The relative error of the determination was not greater than 17%; cadmium ions interfere, and they had to be removed from the cadmium selenide.

The same authors[19] determined submicrogram amounts of copper in micro-quantities of cadmium selenide (0.5—1.0 mg) on cotton, artificial silk, and natural silk fibres.

Analysis on fibres is probably the most attractive variant of the quantitative chromatography of elements. Whereas in paper chromatography only the thickness of the bands is constant, it is possible to standardise both the thickness and the width of the bands by using fibres of constant diameter, and furthermore the sensitivity of the method can be increased dramatically by choosing very narrow fibres and by measuring the length of the bands under a microscope. Thus, amounts of copper as small as 5×10^{-4} μg were determined in the above experiments[19]. However, paper chromatography is simpler and more convenient for visual estimation, and therefore cusp chromatography is more likely to find general application.

III. THE CUSP PAPER CHROMATOGRAPHY METHOD

The potential advantages of cusp chromatography as a method of chemical analysis and physicochemical research have been demonstrated in the writers' laboratory[22-24,27,32-34].

1. Chromatographic Procedure

In the preferred method[23,27,32], sheets of chromatographic paper (density 90 g m^{-2}) are cut into 6×15 cm strips. Each strip is drawn through a solution of impregnant of the required concentration. In order to produce a precipitate on the fibres of the paper, the sheet is also drawn through a solution containing a 1.5—2-fold excess of precipitant (as compared to the concentration of the ion to be analysed in the test solution).

The impregnated paper is dried; for work at maximum sensitivity the paper is impregnated with a solution of gelatin and dried again.

Paper containing a stoichiometric amount of precipitant ion is prepared by introducing the precipitant ion first, followed by the exchangeable ion (grade "O" paper). The paper can also be impregnated in the reverse order: the exchangeable ion first, followed by the precipitant ion, i.e. the ion of opposite sign to the ion under test. Due to sorption effects, this procedure gives a paper containing an excess of the precipitant ion (grade "R" paper).

Two pencil lines are drawn on the impregnated paper: an immersion line (0.5 cm from the edge of the paper) and a start line (2—2.5 cm from the edge of the paper). Four or five pencil marks are made on the start line 1.0—1.5 cm apart. Solutions of the test ions are deposited on these marks by touching the paper with calibrated glass pipettes of 0.001—0.002 ml capacity, drawn out to a conical point and ground to a smooth tip.

The paper strips with their spots of test solution are dried in the air: the resulting primary chromatograms are eluted in a 500 ml beaker containing 50 ml of a 12% aqueous solution of glycerol, or water, into which the paper is dipped up to the immersion line. The chromatogram is held in the beaker by means of a glass plate and Petri dish of special design, which ensures that the paper cannot touch the bottom or the walls of the beaker. As the solvent seeps into the paper, it entrains the ions under test which have not yet reacted and displaces them upwards. At the end of the experiment, the precipitate (which does not move with the solvent) forms a trace in the shape of a regular cusp. The elution time is 30—40 min: when elution is complete the chromatogram is air-dried for 10—15 min and the height of the cusp is measured with a pair of dividers and a ruler. The reproducibility of the measurements is good, and in practice only 1 or 2 measurements are needed once the procedure has been established.

In some chromatograms the band fails to develop fully, and only the initial part of the cusp is visible. The apex of the cusp must then be found by extrapolation, by producing the sides of the cusp until they intersect.

2. Conditions Under Which Cusp Chromatograms Are Formed

The chromatographic conditions have been fully discussed by one of us[27].

a. The primary chromatogram

We assume that the paper is uniformly impregnated with a sparingly soluble, microcrystalline precipitant for the ion under test. The volume of the sample of solution, and the thickness and density of the paper, are constant.

As soon as the solution from the capillary pipette begins to wet the paper, precipitate begins to form in a cylindrical region of increasing diameter d (see Fig. 1), and solution denuded of the ions being chromatographed (say, A_a^-) begins to filter outwards through the cylindrical surface of this region.

Some of these ions are transferred to the precipitate by an exchange reaction with the impregnant, and some are adsorbed onto the precipitate. Thus, the ions being chromatographed are held within a cylinder of diameter d, as though it were a chromatographic column, consisting of a very thin layer of freshly deposited $M_u A_a$ spread over

the surface of the paper fibres and therefore in a highly reactive state. As the concentration of the ion under test in the original solution increases, the diameter of this column also increases until it becomes comparable with the diameter of the water spot d_w. Initially, as long as the ions in excess of the stoichiometric requirements of the impregnant are held only by sorption forces, the quantity of both adsorbed and precipitated ions is proportional to the volume of the column, and therefore the total amount a of ions under test is a function of the volume of the column and hence of the square of its diameter. We can write

$$d = D\sqrt{a} \qquad (1)$$

where D is a constant coefficient. However, as d approaches the value d_w, the processes by which the test ion is accommodated in the spot become more complicated.

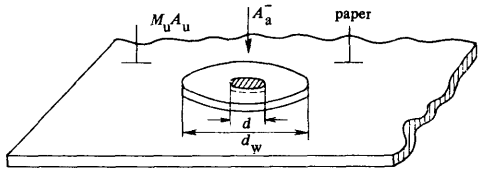

Figure 1. Spot formation in the primary chromatogram.

When the whole of the impregnant within the spot has reacted to give a precipitate (e.g. $M_uA_a.nM_aA_a$, where nM_aA_a denotes the amount of adsorbed ions in excess of stoichiometry), increasing amounts of the free compound (M_aA_a) of the test ion begin to accumulate within the volume of the spot. This effect complicates the relationship between the diameter of the spot and the amount of ions under test. Finally, in the limit the spot size becomes constant, for obvious reasons:

$$d = d_w = \text{const.} \qquad (2)$$

Evidently, within the range of a values to which Eqn. (1) can be applied we can use the spot diameter to characterise the sorption of ions by their precipitates, and thus investigate precipitation reactions quantitatively.

The quantitative study of the sorption of ions by their precipitates in the form of primary bands in paper precipitation chromatograms has been discussed[27] by reference to the following observations. With very small samples of ions, just above the limit of detection, the spot diameter of the primary chromatogram is always smaller than the diameter of a water spot deposited on the paper with the same capillary pipette.

Thus, in experiments with a 2 μl pipette the diameter of the water spot was 0.70 cm. The diameter of a spot of silver iodide (containing 0.5 μg of iodine) was only 0.50 cm, and copper diethyldithiocarbamate gave spot diameters of 0.55 and 0.10 cm for copper contents of 0.5 μg and 0.01 μg respectively. As the content of the chromatographic ion in the sample is gradually increased, the spot diameter in the primary chromatogram increases almost exactly as expected on the assumption that the ion is adsorbed on its precipitate. The departure from a straight-line relationship at small values of a can be ascribed to sorption of the test ion on the precipitate formed by a double decomposition reaction between the test solution and the impregnant, and not to sorption of the test ion on the paper[27].

b. The secondary chromatogram, and cusp formation

As stated above, the secondary chromatogram is obtained by eluting the primary chromatogram with a solvent (e.g. aqueous glycerol, or pure water). Elution is carried out simply by allowing the solvent to seep into the paper. The spot containing a precipitate, formed in the primary chromatogram, may or may not retain an excess of the precipitant. Hence we can define two special cases[32]:

$$\text{I. } a \leqslant uS; \quad \text{II. } a > uS$$

where u is the titre of the paper (mg-equiv cm^{-2}), and S is the area of the spot of precipitate (cm^2).

In the first case the whole of the sample of ions within the spot is bound in the precipitate as M_uA_a or M_aA_u, but in the second case only part of the test ions is bound (by precipitation or sorption on the precipitate), and the remainder is in its original form of the soluble compound M_aA_a and its ions. In this latter case the stoichiometric excess of ions will be washed out of the circular spot by the eluting solvent and carried along the interstices of the paper, where it will meet a fresh supply of the impregnant M_uA_u. Under these conditions, the precipitation of the ion under test will extend beyond the area defined by the primary spot.

The inequality $a \leqslant uS$ defines the system studied by Kulaev[16-18,29] and others, whereas the inequality $a > uS$ defines the conditions for cusp chromatography. In the first case the size of the bands on the chromatograms is determined mainly by the solubility of the precipitates and by diffusion of ions, and is related to the concentration of the ions only through the diffusion effect. In the second case ionic diffusion plays only a secondary role: the main contribution comes from convection, i.e. the transport of ions by the flow of solution.

Depending on the magnitude of the difference

$$a - uS = \Delta \text{ mg-equiv.}, \qquad (3)$$

a more or less extensive trace of the ion under test is formed on the paper in the direction of motion of the solvent, and under favourable conditions this trace has a regular cusp shape.

A simple geometrical construction is sufficient to show that cusp formation must follow from the circular shape of the original spot and from the uniform transport of ions under test along the plane of the paper by the flow of eluent (Fig. 2). The quantity of ions transported by the solvent from different section of the circular spot decreases from the centre towards the periphery, in inverse proportion to the length of the chord parallel to the direction of flow. It has been shown experimentally[27] that regular cusps can be obtained by allowing solvent to seep into the primary chromatogram only if the original spot is truly circular, and then only if the moving solvent front remains strictly parallel to the edge of the paper immersed in the liquid.

3. Fundamental Aspects of Cusp Chromatography

As stated above, the height of the cusp increases with the difference $\Delta = a - uS$. Obviously, it must decrease as the titre of the paper (u) increases. This relationship can be expressed by the formula

$$h = \frac{k_1\Delta}{u} = \frac{k_1(a - uS)}{u} \quad (4)$$

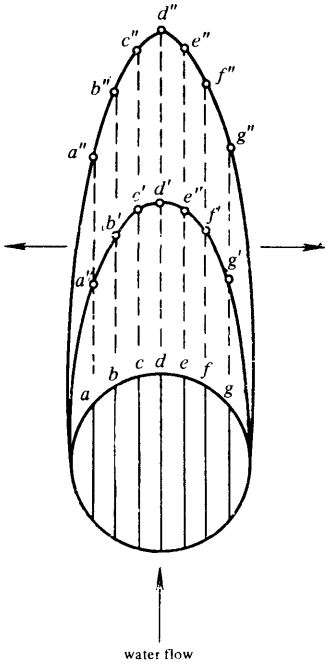

Figure 2. Cusp formation. The points a, b, c, d, e, f, g correspond to the condition $a \leqslant uS$; the points marked with the single prime and the double prime correspond to a small excess and a large excess, respectively, of the test ion in comparison with uS.

This equation was deduced[27] by assuming that the cusp can be approximated by a triangle of height h connected by its base to a semicircle of diameter a (equal to the diameter of the circular spot in the primary chromatogram).

The titre of the paper is approximately equal to the ratio of a to the height of this triangle:

$$u \simeq \frac{2a}{dh} \text{ mg-equiv. cm}^{-2} \quad (5)$$

If the sample volume and the titre of the paper remain constant, the product uS is constant to a first approximation, and the height of the cusp is linearly related to the quantity of ions in the sample:

$$h = \frac{k_1 a}{u} - k_1 S = k_2 a - B \quad (6)$$

Hence

$$a = \frac{h + B}{k_2} \quad (7)$$

As an example of the application of this linear relation, we may quote the results obtained for the chromatographic analysis of iodide ions on paper impregnated with silver chloride[22-24], and also of silver ions on "O" grade paper impregnated with lead diethyldithiocarbamate[27,32]. From the same data, plotted as $h = f(u)$ for constant a, we obtain a family of hyperbolae.

It is possible to calculate[27] the concentration P of the precipitant in solution which should be used to impregnate the paper for the chromatographic analysis of a mg-equiv of an ion. The calculation assumes that the strip of paper retains V ml of the solution of impregnant, and that the whole of the precipitant (G grams) contained in this volume remains in the paper after impregnation. For dilute solutions we can write

$$\frac{G \cdot 100}{V} = P, \%,$$

whence

$$G = \frac{P \cdot V}{100}$$

and the titre of the paper is $u = \dfrac{G.10^3}{\text{equiv wt.} S_p}$ mg-equiv cm^{-2}, where S_p is the area of the strip of paper in cm^2. Inserting the value of G into this formula we obtain

$$u = \frac{PV \cdot 10^3}{\text{equiv. wt.} \cdot S_p \cdot 100} = \frac{10PV}{\text{equiv. wt.} \cdot S_p} \quad (8)$$

Then, using formula (5), we obtain an expression relating the percentage concentration of the solution of impregnant to the amount of ions under test and to the cusp height:

$$u \approx \frac{2a}{dh} \simeq \frac{10PV}{\text{equiv. wt.} \cdot S_p}, \text{ whence}$$

$$P = \frac{2a \text{ equiv. wt.} \cdot S_p}{10 \cdot Vdh} = \frac{0.2 \text{ equiv. wt.} \cdot S_p}{Vdh} \quad (9)$$

All the quantities in formula (9) are either known or easily determined experimentally.

Formulae (5) and (8) have been tested[27,35] by direct analytical determinations of the titre of the paper.

Having established the titre of the paper, known amounts of iodide, bromide, and thiocyanate were chromatographed. The results were used to calculate the titre of the paper by formula (5), and an independent estimate of the titre was obtained by inserting the volume V of impregnant solution and the area S_p of the paper into formula (8).

The titre of the paper calculated by formula (8) agrees with the results of chemical analysis within experimental error, and the values obtained by the approximate formula (5) are also in fairly good agreement.

For thiocyanate these values are closer to the titres obtained by direct chemical analysis than for iodide and bromide. This is because, as shown by chemical analysis of the precipitates in the halide cusps, the atomic ratio of iodide and of bromide to silver increases and tends to 1.5 as the titre of the paper and the amount of halide are increased, suggesting the formation of a complex of the type $K_2Ag_2I_3$. For thiocyanate, on the contrary, the ratio decreases from 1.0 to 0.7. Thus, the effective equivalent of the halide was not the same as the assumed value. Hence we conclude that formula (5) should include a correction equal to the atomic ratio of the amount of precipitant ion (for example, M_u^+) to the amount of the chromatographic ion:

$$u \approx \frac{2a}{dh}\left(\frac{M_u^+}{A_a^-}\right) \approx \frac{2a}{dh} \cdot n \quad (5a)$$

The values given by formula (5a) for the titre of the paper agree somewhat better with the results of chemical analysis.

It is worth noting that, if the titre of the paper is known, the composition of the precipitate in the cusp can be determined from chromatographic data only (d, h, and a): this is a very rapid method of determining the composition of complexes in the solid state.

4. Sensitivity Considerations

The smallest amount of an element which can be estimated by chromatography is that which corresponds to the smallest reproducible cusp height h_0: we find[27] that $h_0 = d$, where d is the diameter of the primary circular spot. Hence, the sensitivity of determinations by the cusp method is approximately the same as that of the corresponding spot tests. In general, the reproducibility of analytical procedures becomes acceptable when the sample size is at least one order of magnitude greater than the limit of detection: we therefore recommend[27] a choice of conditions leading to a minimum cusp height of 10 spot diameters.

The sensitivity of the cusp method is influenced by a number of factors, the most important being those which determine the solubility of the precipitate in the cusp. They include: the pH of the solution, the concentration of complexing agents in solution, the ionic strength and temperature of the solution, the volume of the eluting solution held by the paper, and some others.

Obviously, we should consider first of all the volume of solution taken up by the paper, which directly determines the amount of impregnant which dissolves and hence the amount of precipitate formed by the ion under test.

When the solution used to elute a primary precipitation chromatogram rises to a height H in a strip of paper of width L, the compound of the test ion M_uA_a (e.g. AgI) can form a cusp only if it is present in sufficient amount to saturate a volume $V = H.L.\delta$ cm^3 (where δ is the thickness of the paper) without going completely into solution.

If 1 ml of a saturated solution of M_uA_a contains a_p mg-equiv of the test ion, the paper strip will contain $V.a_p$ mg-equiv of the ion in solution. Hence, if the sample contains a mg-equiv of the test ion, the amount which goes into the precipitate is

$$a - V \cdot a_p = a^* \text{ mg-equiv.} \qquad (10)$$

The height of the cusp is correspondingly decreased, i.e. the dissolution of the precipitate lowers the sensitivity of the determination. Let a^* equal u_0S (the smallest quantity of precipitate of the test ion which can be detected on paper). Inserting this quantity into Eqn. (10) we obtain $a - V.a_p = u_0S$. Hence we arrive at an expression for a_0, the sensitivity of the chromatographic analysis:

$$a_0 = Va_p + u_0S \qquad (11)$$

In the simplest cases, for example in the determination of halide and thiocyanate ions on paper impregnated with silver chloride, we can assume

$$a_p = [A_a^-] \text{ g-ion litre}^{-1}$$

From the equation for the reaction $M_uA_a \rightleftharpoons M_u^+ + A_a^-$ we can write

$$[A_a^-] = \frac{SP_{an}}{[M_u^+]},$$

but $[M_u^+]$ is the solubility of the impregnant, which in the present case can be written $[M_u^+] \simeq \sqrt{SP_{imp}}$. Thus, $[A_a^-] = \dfrac{SP_{an}}{\sqrt{SP_{imp}}}$. Inserting the resulting value of $a_p = [A_a^-]$ into Eqn. (11) gives $a_0 = \dfrac{V.SP_{an}}{\sqrt{SP_{imp}}} + u_0S$. Turning to Eqn. (10), we note that for $a = V.a_p$ the quantity a^* equals 0, i.e. analysis becomes impossible when

$$a = \frac{V \cdot SP_{an}}{\sqrt{SP_{imp}}}$$

or, in general,

$$a_{lim} = \frac{V \cdot SP_{an}}{S_{imp}} \qquad (12)$$

where a_{lim} is the smallest detectable amount of the test ion in the sample, which is a constant for one particular ion and impregnant under a given set of conditions, and S_{imp} is the solubility of the impregnant.

Thus, the sensitivity of the method is higher, other conditions being equal, the smaller the solubility product of the analytical precipitate and the higher the solubility of the impregnant.

One of us[27] has tabulated the values of a_{lim} calculated by Eqn. (12) for thiocyanate, bromide, and iodide on paper impregnated with silver chloride or silver oxide.

It is evident from Eqn. (11) that the sensitivity of detection of ions is determined by their limiting amount a_{lim}, with an additive correction given by the product u_0S. (The latter is greater than a_{lim} by many orders of magnitude for very insoluble compounds of the ion being analysed, but for relatively soluble compounds it does not differ from a_{lim} very significantly.) Hence it is clear that the sensitivity of detection of thiocyanate, bromide, and iodide must increase in the order of decreasing a_{lim}, with very similar values for thiocyanate and bromide. According to our results[27], the sensitivity should be higher on paper impregnated with Ag_2O than on paper impregnated with AgCl. Since the solubility of Ag_2O is greater than that of AgCl†, this conclusion is consistent with the theoretical prediction that the sensitivity must increase with the solubility of the impregnant if other conditions remain constant. Experimental confirmation has been obtained[22-24] that the sensitivity of detection of thiocyanate and halide ions is higher on paper impregnated with Ag_2O than on paper containing silver chloride.

5. Range of Detection of Ions

It can be seen from Eqn. (4) that the height of the cusp can be controlled within any prescribed limits by varying the titre u of the paper. Hence, we can assign to every range of a values a value of u such that the cusp height h will fall within the prescribed limits, e.g. such that the largest cusp shall fill a strip of chromatographic paper 15 cm long. It may be convenient to divide[27] the very wide range of analytical levels of detection found in practice into a number of more limited ranges, each corresponding to a factor-of-ten variation in the size of the sample (e.g. from 10^{-6}—10^{-5} mg-equiv for range 1 to 10^{-3}—10^{-2} mg-equiv for range 4). This allows us to estimate

† The solubilities of AgCl and Ag_2O are 1.2×10^{-5} and 1.9×10^{-4} mg-equiv ml^{-1} respectively.

the amount of ions in each sample under the most favourable conditions, ensuring that the paper is always impregnated with the optimum amount of precipitant.

Clearly, by increasing the titre of the paper we can lower the cusp height by the amount needed to ensure that the cusps for high as well as for low concentrations of the test ion are contained within a chromatogram of a given size. As regards analytical range and sensitivity, the best results are obtained at some particular values of the titre (e.g. 2.0×10^{-5} and 3.3×10^{-5} mg-equiv cm^{-2} for silver and copper respectively).

These general rules for micro-concentrations of test ions can easily be extended to the determination of high concentrations of ions by the cusp method. We have described[27] the chromatographic analysis of concentrated solutions of potassium iodide and bromide up to saturation conditions, with test samples containing up to 500—800 μg of halide.

6. Chromatographic Analysis of Mixtures of Ions

It has been shown experimentally[27] that when the test solution contains a mixture of ions capable of reacting with the impregnant to form a precipitate, a cusp consisting of the least soluble precipitate is formed first of all, followed by the other precipitates in order of increasing solubility.

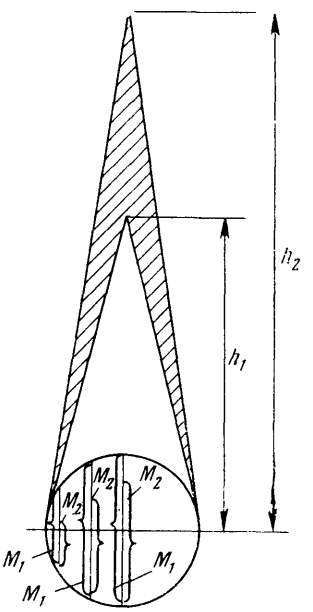

Figure 3. Double cusp formed by two different ions M_1 and M_2 with the same impregnant. (The precipitate formed by M_1 is less soluble than the precipitate formed by M_2.)

Hence, it was suggested that the equality $a_1 + a_2 = uS_1 + uS_2$ (or in general $\Sigma a = u\Sigma S$) can be applied to precipitates of a given type, where a_1 and a_2 are the amounts of two different ions in the sample, u is the titre of the paper, and S_1 and S_2 are the areas of the corresponding bands.

It is evident from Fig. 3 that

$$S_2 \simeq \frac{1}{2} h_2 \cdot d - \frac{1}{2} h_1 \cdot d = \frac{1}{2} d (h_2 - h_1),$$

whence

$$a_2 \simeq \frac{ud}{2} (h_2 - h_1),$$

and putting $\frac{ud}{2} = m$ we obtain

$$a_2 = m (h_2 - h_1) \qquad (13)$$

i.e. the amount of precipitate for the more soluble ion is proportional to the difference in height between the cusps for the more soluble and the less soluble ion.

By a similar argument it can be shown that the amount $a_{(n+1)}$ of an ion mixed with n other ions which form more insoluble precipitates with the same impregnant is proportional to the difference in cusp height

$$a_{n+1} = t \cdot \Delta h \qquad (14)$$

Experiment shows[27] that this relationship applies only when the titre of the paper has been optimised with respect to the ion which forms the most soluble precipitate.

Various mixtures of anions and cations have been analysed by applying these considerations. Thus, mixtures of traces and of relatively large amounts of halides have been chromatographically separated and estimated on paper impregnated with silver oxide.

Precipitation chromatography can be applied in qualitative as well as quantitative analysis. For example, chloride and bromide impurities in potassium iodide can be separated and determined by cutting out the different constituents of the cusp. The effectiveness of this new method of analysis has been confirmed by separating a complex mixture of cations (silver, copper, lead, and cadmium).

---o0o---

Recent studies[22-24,27,32] of the conditions under which cusp-shaped bands are formed in precipitation paper chromatography have led to the development of a new quantitative method for the determination of ions: cusp paper chromatography. This method differs from existing chromatographic procedures in that it relies on accurate measurements of length, and furthermore it depends on stoichiometric relationships like the classical methods of quantitative analysis. It differs from the latter, however, in being a true chromatographic method, and therefore it offers all the advantages of speed and simplicity which one associates with chromatographic analysis.

Cusp chromatography is a particularly fast method, and is suitable for use in works laboratories and under field conditions, for example in the wet assay of mineral deposits. It can be used to determine anions and cations, in solutions varying in concentration from very dilute to almost saturated. Mixtures of ions as well as single ions can be detected by cusp chromatography, and the method can tolerate the presence of many extraneous substances. 40—50 tests can be done in one hour, and since each test requires only 1—2 μl of solution, a complete analysis can be done on a drop of solution (0.01 ml). The sensitivity of the method is comparable to that of conventional spot tests: for example, 0.2 μg or 1.6×10^{-6} mg-equiv for iodide and 0.02 μg or 6.3×10^{-7} mg-equiv for copper. The relative error of determinations within the same concentration range is 2—10% (for example, 2—7% for iodide ions).

It is important to stress the fact that this is a genuine micro-method of analysis, since only 1—2 μl of solution are needed for each determination. The precision (usually 1.5—11%) can be improved by calibrating the capillary used to deliver the sample (or by using a micro-syringe or micro-pipette), and also by measuring the cusp height to 0.1 mm or better. Evidently, this method of determining micro-quantities of ions can be combined with some method of concentrating trace elements (for example, the "sinking particle" method[36,37]); in this way, the contents of a 1-litre sample of solution can be concentrated into a volume of 0.1 ml, and the range of detection can be extended by 3—4 orders of magnitude.

Another advantage of the method is the possibility of obtaining quantitative information from imperfectly formed cusps, by graphically extending the edges of the cusp and using their intersection to locate the missing apex.

Paper chromatography by the cusp method offers an almost instantaneous method of qualitative and quantitative analysis of large groups of ions (and their mixtures) having closely similar properties: for example, chloride, bromide, and iodide. The elements can be separated by cutting the complex cusp into bands, corresponding to the individual elements.

The theoretical relationships between the height of the cusp and the amount of test ion, and between the height of the cusp and the titre of the paper, and also the formulae for calculating the titre of the paper, have all been confirmed experimentally for both anions and cations. The deviation from linearity of the initial portion of the function $h = f(a)$ has been shown to be due to sorption of the ion by its precipitate (formed by a double decomposition reaction with the impregnant), which is more significant at low concentrations of the test ion. The simple relationship between the diameter of the circular spot formed in the primary chromatogram and the amount of test ion in the sample applied to the paper can be used to study the sorption of various ions by the precipitate formed by their reaction with the impregnant. The observation that a small spot formed within the thickness of the paper acts as a miniature chromatographic column will be applied in future studies of the sorption properties of many precipitates. In the analysis of thiocyanate and halide ions on paper impregnated with silver oxide or silver chloride the cusp height was found to be unmistakably related to the concentration of the silver nitrate solution used to impregnate the paper, and therefore also to the titre of the paper.

However, in the analysis of silver, copper, and some other cations on paper impregnated with metal diethyldithiocarbamates a simple relationship was found only with "O" grade paper, prepared as described above. This observation led to the following empirical rule for the preparation of paper for selective cusp chromatography: the paper should be impregnated first with the precipitant ion, followed by the ion of the same sign as the test ion.

The rule is confirmed by experiments on cadmium and lead, chromatographed singly or in admixture with silver and copper on "R" grade paper, i.e. paper impregnated with lead diethyldithiocarbamate "not according to the rule". Although neither lead nor cadmium should develop a stain on paper impregnated with lead diethyldithiocarbamate, cusps were obtained on this paper, but not on "O" paper (impregnated with lead diethyldithiocarbamate in stoichiometric proportions). This anomaly can be explained only by sorption and coprecipitation phenomena on the "R" grade paper. Evidently, quantitative observations of coprecipitation phenomena can be made on chromatographic paper of this type.

Starting from simple considerations, we have established a relationship between the sensitivity of the determination and the solubility of the precipitates in the simplest case of an exchange reaction between the singly charged test ion and the (more soluble) compound of the singly charged precipitant ion. The resulting formula states that the greater the solubility of the impregnant, and the smaller the solubility of the precipitate formed on the paper by the test ion, the lower is the loss of test ions by dissolution in the eluent and therefore the more quantitative is the formation of the cusp. This explains why the sensitivity increases in the order of decreasing solubility product when a series of ions is analysed on paper of a given titre containing a given impregnant.

Thus, previous assumptions that the size of the bands in precipitation chromatograms is determined by the relationship between the velocity of the precipitate front[16,38] or the rate of precipitation[14,28] on the one hand, and the solubility product on the other hand, cannot be upheld. The same conclusion can be reached, even more simply, by noting that the size of the bands cannot be determined by the rate of any particular process since equilibrium is established when the bands have grown to their full size.

Elementary Reactions of Oxidation Inhibitors

E.T.Denisov

The review gives a systematic account and a critical analysis of the experimental data on the elementary reactions of phenols and aromatic amines in hydrocarbons undergoing oxidation. The results of the measurements and semiempirical estimates of the strength of the In-H bond (InH = inhibitor) in phenols and aromatic amines are examined. From the experimental data presented in the review, evidence is adduced for reaction mechanisms in the inhibited oxidation of hydrocarbons and a combined approach to the concept of the efficiency of the oxidation inhibitor is formulated.
The bibliography includes 110 references.

I. INTRODUCTION

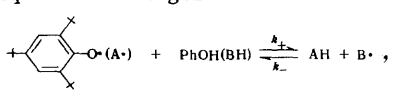
Inhibitors of oxidation reactions (antioxidants) have acquired considerable importance in modern chemistry. They are used widely to stabilise plastics, synthetic fibres, rubbers, lubricating oils, fats, and medicinal preparations. Experimental data on antioxidants have been compiled in monographs[1-6], symposia[7,8], and reviews[9-13]. Among the wide variety of organic compounds used as antioxidants, phenols and aromatic amines continue to attract most attention. In recent years, important new results were obtained in studies on the detailed mechanism of the action of these inhibitors. It was shown that the radicals formed from the inhibitor react with the hydrocarbons[14] and the hydroperoxide[15], thus participating in chain propagation. The exchange reactions between the radical of one inhibitor and the molecule of another play an important role[16]. The unique phenomenon of the regeneration of inhibitors in chain termination steps has been discovered[17]. The reactions of inhibitors with the hydroperoxide[18] and oxygen have been investigated[19,20]. The chemistry of stable free radicals

has developed rapidly[21-24] and extensive data on the reactions of peroxy-radicals with inhibitors have accumulated[25].

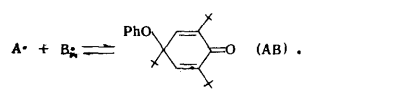
These new findings have made it necessary to revise the ideas about the mechanism of the inhibiting effect of phenols and amines, to analyse critically previous results and concepts, to compile data on elementary reactions involving oxidation inhibitors, and to formulate a mechanism of the action of inhibitors on the basis of modern results. Such an attempt is made in the present review.

II. STRENGTH OF THE In–H BOND IN PHENOLS AND AROMATIC AMINES

1. PHENOLS



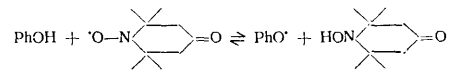
Peroxy-radicals react very rapidly with phenols[25]. At first sight, this can be explained by the low strength of the O–H bond. Therefore it is useful to examine the available data for the dissociation energy of the O–H bond in phenols ($D_{O\text{-}H}$). Several studies have been published recently in which quantities permitting the calculation of $D_{O\text{-}H}$ in phenols were determined by different methods.



1. Mahoney et al.[26] determined calorimetrically the heat of the reaction

$$2PhO^{\cdot} + C_6H_5NHNHC_6H_5 \rightleftharpoons 2PhOH + C_6H_5NNC_6H_5$$

in benzene and found the difference $\Delta H_{PhO\cdot} - \Delta H_{PhOH}$ for certain stable phenoxy-radicals. Since $\Delta H_{PhOH} = \Delta H_{PhO\cdot} + \Delta H_H - D_{O\text{-}H}$, it follows that $D_{O\text{-}H} = \Delta H_{PhO\cdot} - \Delta H_{PhOH^+} + \Delta H_H$ and $\Delta H_H = 52.1$ kcal mole^{-1}. For tri-t-butylphenol, $\Delta H_{PhO\cdot} - \Delta H_{PhOH} = 29.14 \pm 0.08$ and $D_{O\text{-}H} = 29.1 \pm 52.1 = 81.2 \pm 0.1$ kcal mole^{-1}.



2. To measure the heat of formation of active phenoxy-radicals, a study was made[27] of the kinetics of the reaction between the tri-t-butylphenoxy-radical and various phenols and its heat was measured. The reaction includes two equilibrium stages:

The enthalpy of reaction is $\Delta\Delta H = -\Delta H_A + \Delta H_{AH} + \Delta H_B - \Delta H_{BH} + E_+' - E_-'$, the difference $\Delta H_A - \Delta H_{AH}$, measured by method 1 in chlorobenzene, is 28.25 ± 0.1 kcal mole^{-1}, E_-' was measured experimentally, and $E_+' \simeq 2$ kcal mole^{-1} since the recombination of phenoxy-radicals is rapid, its rate being limited by diffusion[27]; $D_{O\text{-}H} = \Delta\Delta H + E_-' + 78.3$ kcal mole^{-1}.

3. Vasserman et al.[28] and Kalashnikova et al.[29] measured the heats of the reversible reaction

and calculated from $D_{O\text{-}H}$ in hydroxylamine, which is 71.9 ± 3 kcal mole^{-1},[30] the values of $D_{O\text{-}H}$ for a number of phenols giving rise to stable phenoxy-radicals.

4. $D_{O\text{-}H}$ in phenols can be estimated from the activation energy for the reaction $PhOH + O_2 \xrightarrow{k_+} PhO^{\cdot} + HO_2^{\cdot}$. The reverse reaction $PhO^{\cdot} + HO_2^{\cdot} \xrightarrow{k_-} PhOH + O_2$ takes place in solution at a rate which is most probably diffusion-limited. This is supported by the finding that the rate of the analogous reaction $HO_2^{\cdot} + HO_2^{\cdot} \rightarrow HOOH + O_2$ in a hydrocarbon solution is limited by diffusion ($k \simeq 10^9$ litre mole^{-1} s^{-1}).[25] One can assume that $E_- = 1$ kcal mole^{-1} for the diffusion of $HO_2^{\cdot}$ in benzene, where k_+ was measured. The O_2 – H bond strength is 44–50 kcal mole^{-1}.[31] If we put $Q_{H\text{-}O_2} = 49$ kcal mole^{-1}, we obtain

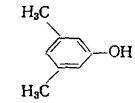
$$q = E_- - E_+ = Q_{H\text{-}O_2} - D_{O\text{-}H} = E_+ + 48 \text{ kcal mole}^{-1}.$$

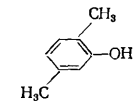
5. Hush[32] proposed a method for the estimation of $D_{O\text{-}H}$ from the critical oxidation-reduction potential[33], which can serve as a measure of the normal oxidation-reduction potential. The strength of the O–H bond in phenols is calculated from the formula[32] $D_{O\text{-}H} = FE_c + 57$ kcal mole^{-1}, where E_c is the critical potential in volts and $F = 23$ kcal equiv.$^{-1}$ V^{-1} is the Faraday. The results of the calculation of $D_{O\text{-}H}$ for phenols are presented in Table 1.

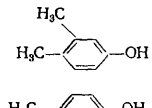
2. AROMATIC AMINES

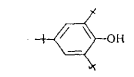
The N–H bond dissociation energies in aromatic amines are unknown. $D_{N\text{-}H}$ can be estimated, as for phenols, from the activation energies for the reaction $InH + O_2 \rightarrow In^{\cdot} + HO_2$ (Denisova et al.[19]) by the formula $D_{N\text{-}H} = E + 48$ kcal mole^{-1}. It is also possible to estimate $D_{N\text{-}H}$ from the critical potentials for amines using the same formula as for phenols[32]: $D_{N\text{-}H} = FE_c + 57$ kcal mole^{-1}. The values of $D_{N\text{-}H}$ are presented in Table 2.

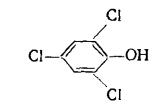
III. REACTION OF PEROXY-RADICALS WITH INHIBITORS

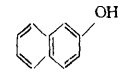


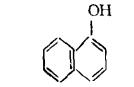


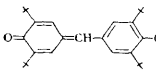


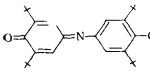












1. THE ISOTOPE EFFECT

If the peroxy-radical attacks the O–H bond of a phenol or the N–H bond of an amine, an isotope effect should be observed when hydrogen is replaced by deuterium. In a number of studies, where the inhibiting effect of phenols and aromatic amines on the oxidation of hydrocarbons was investigated[34-42], there was no isotope effect or it differed little from unity (1–1.3). A large isotope effect (10.6 for phenol at 65°C) was observed by Howard and Ingold[43] in the sensitised oxidation of styrene. The experimental difference between the activation energies[43] is $E_D - E_H = 1.1$ kcal mole^{-1}. Calculation yields a similar value[43]: $E_D - E_H = \frac{1}{2}h(\nu_{O\text{-}H} - \nu_{O\text{-}D}) = 1.36$ kcal mole^{-1}. The absence of an isotope effect in the reaction of $RO_2^{\cdot}$ and InH in the oxidation of other hydrocarbons can be accounted for by the formation of the hydroperoxide and rapid exchange via the reaction $InD + ROOH \rightleftharpoons InH + ROOD$. The oxidation of styrene yields a polymeric hydroperoxide which does not contain OOH groups and does not exchange hydrogen with the deuteriated inhibitor. An isotope effect was also observed for amines[44,45] and hydroxylamines[46] (Table 3).

2. THE REACTION MECHANISM

The isotope effect in experiments with deuteriated phenols and amines (Table 3) demonstrates convincingly that the rate-limiting stage in the reaction of $RO_2^{\cdot}$ with the inhibitor is the abstraction of a hydrogen atom: $RO_2^{\cdot} + InH \xrightarrow{k_7} ROOH + In$. The finding that phenolic ethers and tertiary aromatic amines do not exhibit an inhibiting effect is satisfactorily consistent with this mechanism. The molecular products of the reaction of inhibitors correspond

* Kalashnikova et al.[29] obtained erroneously another value of D_{O-H} for hydroxylamine, namely 71.9 kcal mole^{-1}. The error arose because they employed in the calculation D_{O-H} for the >NO–H bond in 4-dihydroxy-2,2,6,6-tetramethylpiperidine (D = 65 kcal mole^{-1}), while they investigated the equilibrium between phenol and 2,2,6,6-tetramethyl-1-hydroxy-4-oxopiperidine (D = 71.9 kcal mole^{-1})[30].

a. The Polar Activated Complex $RO_2^{\cdot}$...H...In

Phenoxy-radicals react with phenols and amines, the corresponding rate constants being 10^4–10^6 litre mole^{-1}s^{-1} at 40–80°C. The question arises whether such high values of k_7 can be explained by the low strength of the In–H bond. We shall compare the values of k for the abstraction of H by the peroxy-radicals from tri-t-butylphenol (D_{O-H} = 81 kcal mole^{-1}, Table 1) and cumene (D_{C-H} = 76 kcal mole^{-1}): $\lg k\,(RO_2^{\cdot} + RH) = 6.51 - 10.13/\theta$ (Denisov[25]) and $\lg k\,(RO_2^{\cdot} + InH) = 6.58 - 3.4/\theta$ (Denisov[25]), where $\theta = 4.57 \times 10^{-3}\,T$. At 60°C, the ratio $k(RO_2^{\cdot} + InH)/k(RO_2^{\cdot} + RH) = 3 \times 10^4$. Thus the peroxy-radical

reacts with phenol 10^4 times faster than with cumene despite the fact that in cumene the C–H bond is somewhat weaker than the O–H bond of the phenol; the difference between the rate constants is associated with the difference between the activation energies. This can be explained by the markedly dipolar structure of the activated complex for the reaction between $RO_2^{\cdot}$ and InH, where the hydrogen atom is between two oxygen atoms (Fig. 1). Owing to the high electron affinity of oxygen atoms, a considerable proportion of the electron density of the O–H bond in the activated complex is located at the oxygen atom. The Coulombic attraction between $\overset{\delta-}{RO_2^{\cdot}}$, $\overset{\delta+}{H}$, and $\overset{\delta-}{OPh}$ causes a decrease of the potential barrier relative to that in the reaction between $RO_2^{\cdot}$ and RH. A similar situation obtains with aromatic amines, where the activated complex RO – O˙...H...N< is formed.

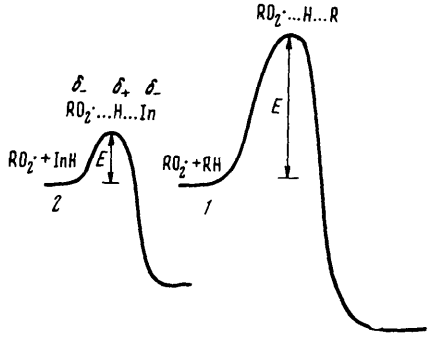

Figure 1. Schematic representation of the energy profiles for the reactions of the phenoxy-radicals with cumene (curve *1*) and ionol (curve *2*).

b. The $RO_2^{\cdot}$...HX Hydrogen Bond

Peroxy-radicals form a hydrogen bond of the type R'OO˙...HOR with the O–H group of water and alcohols[47–49]; this suggests that phenols and amines, which tend to form hydrogen bonds, react with peroxy-radicals via the preliminary formation of an association complex[50]:

$$RO_2^{\cdot} + InH \overset{k}{\rightleftharpoons} InH \ldots OOR \overset{k}{\rightarrow} In^{\cdot} + ROOH$$

Evidently the formation of the hydrogen bond between $RO_2^{\cdot}$ and InH increases the rate of reaction. It is not fortuitous that k_7 for the reaction of 2,6-dimethylphenol with the tetralylperoxy-radical[25] ($k_7 = 1.1 \times 10^4$ at 50°C) is higher than for the reaction involving 2,6-di-t-butylphenol[25] ($k_7 = 1.3 \times 10^3$): dimethylphenol forms a hydrogen bond with $RO_2^{\cdot}$, while di-t-butylphenol does not. In those cases where InH forms a hydrogen bond with the peroxy-radical, $k_7 = Kk$, $\Delta S_7^{\neq} = \Delta S_h + \Delta S^{\neq}$, $E_7 = E - Q_h$, and $\Delta H_7^{\neq} = \Delta H_h + \Delta H^{\neq}$, where the subscript h denotes a hydrogen bond. The quantity $K_{RO_2^{\cdot}\ldots HOPh}$ is unknown; for comparison, one can adduce K(phenol – dioxan) = 15.2 litre mole^{-1} in benzene at 25°C.[51]

3. DEPENDENCE OF k_7 ON THE STRUCTURE OF THE INHIBITOR.

The values of k_7 have been measured for a large number of phenols and amines[25] (the methods of measurement of k_7 have been described in a monograph[3]), but the vast majority of the measurements have been made at a single temperature. The activation energies for the reaction between $RO_2^{\cdot}$ and InH have been rarely measured. Table 4 shows that the values of E_7 are in the range 3.5–5.5 kcal mole^{-1}. However, one should bear in mind that the true activation energy for the reaction $RO_2^{\cdot}\ldots HIn \rightarrow ROOH + In^{\cdot}$ is higher and equal to $E_7 + \Delta H_h$ and ΔH_h = 3–4 kcal mole^{-1}. The rate constant k_7 is almost independent of the structure of the peroxy-radical of the hydrocarbon (Table 4).

However, acylperoxy-radicals react with hydroquinone faster than do alkylperoxy-radicals[25]. Substituents in the benzene ring have a marked influence on the activity of the inhibitor: electropositive substituents increase and electronegative substituents decrease k_7. There is a linear correlation between $\lg k_7$ and σ^+ (Table 5).

4. EFFECT OF THE SOLVENT

When oxygen-containing compounds (H_2O, ROH, RCOOH, etc.) are added to the hydrocarbon, the rate of reaction of peroxy-radicals with the inhibitor decreases significantly[61-63]. This is primarily due to the formation of an intermolecular hydrogen bond In–H...Y, which blocks the susceptible O–H or N–H bond of the inhibitor and thus inhibits the reaction between $RO_2^\cdot$ and InH. In those cases where the solution contains the molecules of a hydroxy-compound (other than the inhibitor), the peroxy-radicals form with them a radical type hydrogen bond $RO_2^\cdot$...HOX, which causes additional inhibition of the reaction between peroxy-radicals and the inhibitor[62,63]. In the presence of compounds forming a hydrogen bond, we are dealing with the following series of stages in the inhibited oxidation reaction:

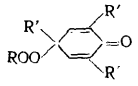
$$RO_2^\cdot + HIn \rightleftarrows RO_2^\cdot \ldots HIn \rightarrow ROOH + In^\cdot ,$$

$$InH + XOH \rightleftarrows InH \ldots O\begin{matrix}H\\X\end{matrix} ,$$

$$RO_2^\cdot + HOX \rightleftarrows RO_2^\cdot \ldots HOX ,$$

$$RO_2^\cdot \ldots HOX + InH \rightarrow ROOH + In^\cdot + HOX .$$

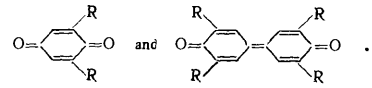
IV. REACTION OF In$^\cdot$ WITH $RO_2^\cdot$



1. REACTION PRODUCTS

In the inhibited oxidation of hydrocarbons and polymers, free radicals (detected by ESR) are formed from the inhibitor. In the oxidation of octadecene at 171°C, a free radical (probably a nitroxide radical) is formed from phenyol-α-naphthylamine[64], its maximum experimental concentration being $[In^\cdot]_{max} \simeq 10^{-3}$ M for $[InH]_0 = 0.1$ M. A diphenylnitroxide radical is formed in the reaction of cumenylperoxy-radicals with diphenylamine[65]. Phenoxy-radicals have been detected in the oxidation of polypropylene by α-naphthol[66] {200°C, O_2 pressure 400 mmHg, $[In^\cdot]$ 10^{-5} M} and β-naphthol[66] {200°C, O_2 pressure 400 mmHg, $[In^\cdot]_{max} \simeq 2 \times 10^{-6}$ M}. The formation of labile coloured compounds was observed when the RH–O_2–amine system (diphenylamine, *N*-methylaniline, *NN'*-diphenyl-*p*-phenylenediamine)[67] was irradiated with electrons.

Molecular products are formed in the reaction of In$^\cdot$ radicals with $RO_2^\cdot$ and with one another. Hydroquinone is converted into quinone via the mechanism[68]:



2,4,6-Trialkylphenols are converted into compounds of the type[69-71]

via the mechanism

$$InH \xrightarrow{RO_2^\cdot} In^\cdot \xrightarrow{RO_2^\cdot} ROOIn .$$

2,6-Dialkylphenol are converted into quinones[71-73]:

Diphenyl-*p*-phenylenediamine is converted quantitatively into quinonedi-imine[69], the reaction being analogous to that of hydroquinone.

2. THE STOICHIOMETRIC INHIBITION COEFFICIENT

The stoichiometric inhibition coefficient f is defined as the number of chains terminated by the inhibitor molecule and its reaction products under the given conditions. On the basis of the structures of the stable reaction products of hydroquinone, diphenyl-*p*-phenylenediamine, and 2,4,6-tri-t-butylphenol, one may conclude that $f = 2$ for these reference inhibitors. This permits the measurement of f for other inhibitors, by comparing the induction periods in initiated oxidation in the presence of the given and reference inhibitors. The values of f in cumene undergoing oxidation have been measured[69,74] and for the majority of phenols and aromatic amines proved to be close to two (the values of f are quoted in the author's handbook[25]).

3. REACTION OF THE DIPHENYLNITROGEN RADICAL WITH $RO_2^\cdot$

In the oxidation of cumene inhibited by diphenylamine, Thomas[65] detected a nitroxide radical by ESR. The same radical was also formed in cumene undergoing oxidation from a diphenylnitrogen radical (tetraphenylhydrazine served as a source of diphenylnitrogen radicals). Like diphenylamine, the diphenylnitroxide radical inhibits the oxidation of cumene, reacting with $RO_2^\cdot$ (the rate constant is 2.5×10^3 litre mole^{-1}s^{-1} at 68.5°C).[75] The ratio of the rate of formation of diphenylnitroxide radicals to the rate of initiation w_i is 0.11–0.19 for secondary peroxy-radicals and 0.20–0.33 for tertiary peroxy-radicals[76]. The following mechanism has been proposed for the reaction of diphenylamine (and other secondary amines) with peroxy-radicals[76,77]:

$$RO_2^\cdot + (C_6H_5)_2NH \rightleftarrows RO_2^\cdot \ldots HN(C_6H_5)_2 \rightarrow ROOH + (C_6H_5)_2N^\cdot ,$$

$$RO_2^\cdot + (C_6H_5)_2N \rightleftarrows ROON(C_6H_5)_2 \rightarrow [RO^\cdot + (C_6H_5)_2NO^\cdot] ,$$

$$[RO^\cdot + (C_6H_5)_2NO^\cdot] \rightarrow RO^\cdot + (C_6H_5)_2NO^\cdot ,$$

$$[RO^\cdot + (C_6H_5)_2NO^\cdot] \rightarrow \rangle C{=}O + (C_6H_5)_2NOH \text{ (for s-}RO_2^\cdot)$$

$$(C_6H_5)_2N^\cdot + RO_2^\cdot \rightarrow$$

This mechanism explains why the rate of formation of $(C_6H_5)_2NO^\cdot$ is always lower than w_i and why the ratio is smaller for secondary peroxy-radicals than for tertiary radicals. Diphenylnitroxide radicals terminate chains by reacting with $RO_2^\cdot$ and R$^\cdot$. The mechanism and the products of the reaction of $(C_6H_5)_2NO^\cdot$ and $RO_2^\cdot$ are so far unknown. Primary aromatic amines do not form oxides in reactions with peroxy-radicals[77]. It has been suggested that they give rise to nitroso-compounds[77]:

$$RO_2^\cdot + ArNH_2 \rightleftarrows ROO^\cdot \ldots HNHAr \rightarrow ROOH + ArN\dot{H} ,$$

$$ArN\dot{H} + ROO^\cdot \rightarrow [ArNHOOR] \rightarrow ArNO + ROH .$$

4. CHEMILUMINESCENCE IN THE REACTION OF $RO_2^{\cdot}$ WITH In$^{\cdot}$

In liquid-phase oxidation, chemiluminescence arises owing to the formation of excited molecules by the reaction between two peroxy-radicals[78]. This fact has served as a basis of the chemiluminescence methods for the investigation of oxidation reactions[78]. It was established recently that chemiluminescence can arise in liquid-phase oxidation in the presence of amines and polar molecules[79].

If an aromatic amine is added to cumene undergoing oxidation, the intensity of the luminescence decreases owing to the decrease in the rate of reaction between $RO_2^{\cdot}$ radicals. When an amine is added to cyclohexanol or chlorobenzene undergoing oxidation in the presence of t-butylalcohol and an initiator, the luminescence intensity increases despite the fall of $[RO_2^{\cdot}]$. Separate experiments showed that the decrease of luminescence is observed only in the presence of peroxy-radicals (initiator + O_2), aromatic amines, and polar (oxygen-containing) molecules (H_2O, ROH, R_2O). It was concluded that luminescence arises as a result of the reaction between peroxy-radicals and radicals generated from the aromatic amines. These are not nitroxide radicals, since luminescence is observed both with secondary amines (which give rise to nitroxide radicals) and with primary amines (which do not). Primary amines probably generate nitrogen radicals:

$$AmH + RO_2^{\cdot} \rightarrow Am^{\cdot} \xrightarrow{RO_2^{\cdot}} \Pi^{*} \rightarrow \Pi + h\nu$$

(only in the presence of polar molecules). The involvement of an amine radical in luminescence is confirmed by the finding that the addition of α-naphthol, which decreases $[Am^{\cdot}]$ owing to the reversible reaction

$$Am^{\cdot} + PhOH \rightleftharpoons AmH + PhO^{\cdot},$$

lowers the luminescence intensity. The occurrence of a new reaction generating chemiluminescence (in addition to the reaction between $RO_2^{\cdot}$ radicals) necessitates a very cautious approach to the employment of the chemiluminescence method for the investigation of the kinetics of the oxidation of organic compounds inhibited by amines and for the determination of its parameters.

V. REACTION OF INHIBITOR RADICALS WITH THE HYDROPEROXIDE

In a study of the effect of the hydroperoxide on the initiated oxidation of cumene in the presence of inhibitors, Thomas established[15] that the addition of the hydroperoxide accelerates the oxidation of cumene in the presence of phenol but has no influence if the oxidation of cumene is inhibited by 2,6-di-t-butylphenol and ionol. The experiments were performed at a low temperature (57.2°C) in the presence of azobisisobutyronitrile (8×10^{-3} M) when the additional initiation owing to the hydroperoxide was very insignificant. This can be accounted for by the reaction

$$PhO^{\cdot} + RO_2H \xrightarrow{k_{-7}} PhOH + RO_2^{\cdot},$$

as a result of which the concentration of peroxy-radicals increases in the presence of the hydroperoxide. The difference between the experiments with phenol and 2,6-di-t-butylphenol can be explained by the different reactivities of the phenoxy-radicals: a reactive phenoxy-radical is formed from phenol, while the 2,6-di-t-butylphenoxy-radical is relatively inactive and reacts slowly with the hydroperoxide. One can postulate the formation of a

* Calculated on the assumption that $k_8 = 10^9$ litre mole^{-1}s^{-1}.

hydrogen bond between phenol and the hydroperoxide, which should also retard the reaction between phenol and $RO_2^{\cdot}$:

$$PhOH + ROOH \rightleftharpoons PhOH \ldots \overset{H}{O}OR \quad \text{or} \quad PhOH \ldots \overset{OH}{O}R .$$

Calculation of the association constant from the relation between the rate of oxidation and [ROOH] yields an unreasonably large value of 300 litre mole^{-1} for the association constant of phenol with cumenyl hydroperoxide (at 57°C in cumene), while the same constant in carbon tetrachloride at 25°C is 12 litre mole^{-1} (determined from spectroscopic data). Evidently the hydrogen bond alone cannot account for this effect. A decrease of the relative overall rate constant for the reaction of the inhibitor with peroxy-radicals after the introduction of the hydroperoxide is observed also for aromatic amines[61]. As in the case of phenol, this is associated with the exchange reaction between the amine radical and the hydroperoxide (Denisov et al.[61] regarded this erroneously as a result of complex formation between the amine and the hydroperoxide).

The kinetics of inhibited oxidation in the presence of the hydroperoxide also demonstrate convincingly the occurrence of reaction between In$^{\cdot}$ and ROOH.

The inhibited oxidation of a hydrocarbon can be represented as follows taking into account the reaction between In$^{\cdot}$ and ROOH:

$$\text{initiator.} \rightarrow r^{\cdot} \xrightarrow{RH} R^{\cdot}, \quad (i)$$

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}, \quad (1)$$

$$RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot}, \quad (2)$$

$$ROOH + RH \rightarrow RO^{\cdot} + H_2O + R^{\cdot}, \quad (3)$$

$$R^{\cdot} + R^{\cdot} \rightarrow R\text{–}R, \quad (4)$$

$$R^{\cdot} + RO_2^{\cdot} \rightarrow ROOR, \quad (5)$$

$$RO_2^{\cdot} + RO_2^{\cdot} \rightarrow \text{mol. products}, \quad (6)$$

$$RO_2^{\cdot} + InH \rightarrow ROOH + In^{\cdot}, \quad (7)$$

$$ROOH + In^{\cdot} \rightarrow RO_2^{\cdot} + InH, \quad (-7)$$

$$RO_2^{\cdot} + In^{\cdot} \rightarrow ROOIn . \quad (8)$$

At a fairly high partial pressure of oxygen when $[RO_2^{\cdot}] \gg [R^{\cdot}]$ and in the presence of an initiator when $W_i \gg k_3[ROOH][RH]$, reactions (3)–(5) may be disregarded. If the inhibitor radical is incapable of chain propagation owing to the reaction with the hydroperoxide, reaction (7) is responsible for chain termination and therefore $W_i = fk_7[InH][RO_2^{\cdot}]$; the rate of oxidation (for sufficiently long chains) is $W = k_2[RH]w_i/fk_7InH$, where k_2 refers to the reaction between $RO_2^{\cdot}$ and RH. When reaction (-7) is rapid $\{k_{-7}[ROOH][In^{\cdot}] \gg k_8[In^{\cdot}][RO_2^{\cdot}]$, k_8 refers to the reaction between $RO_2^{\cdot}$ and $In^{\cdot}\}$, chain termination is due to reaction (8), $W_i = 2k_8[In^{\cdot}][RO_2^{\cdot}]$, $k_7[InH][RO_2^{\cdot}] = k_{-7}[In^{\cdot}][ROOH]$, and $W = k_2[RH][RO_2^{\cdot}] = k_2[RH]\{k_{-7}W_i[ROOH]/2k_8k_7[InH]\}^{1/2}$. The experimental results are consistent with these formulae: for ionol in cumene[15] and tetralin[80] undergoing oxidation, $W \propto W_i/[InH]$, and for phenol in cumene[15] and tetralin[80], $W \propto \sqrt{W_i}/[InH]$. For phenol, the ratio $k_{-7}/k_8 = 5.7 \times 10^{-5}$ in cumene[15] at 57.2°C and $k_{-7} = 2.3 \times 10^5$ litre mole^{-1}s^{-1}, i.e. is very high. The values of k_{-7} are listed in Tables 6 and 7.

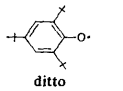
VI. CHAIN PROPAGATION VIA THE REACTION OF In$^{\cdot}$ WITH THE HYDROCARBON

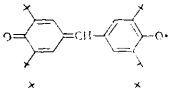
Phenoxy-radicals can abstract a hydrogen atom not only from the hydroperoxide but also from hydrocarbons. If the phenoxy-radical is reactive and the hydrocarbon has a fairly weak C–H bond, such a reaction will be comparatively fast and will affect the retarding action of the inhibitor. Bickel and Kooyman[14], who studied the kinetics of the inhibited oxidation of 9,10-dihydroanthracene, established that the relation $W/[InH]^{1/2} = C_1 + C_2[InH]$, which is consistent with the involvement of In$^{\cdot}$ in chain propagation via the reaction with the hydrocarbon, holds for 4-t-butyl-2,6-dimethylphenol. In a study of the sensitised oxidation of tetralin in the presence of phenols, Mahoney and Ferris[84] established the following relation between the rate of oxidation and the concentrations of phenol, the hydrocarbon, and the initiator: $w = \text{const.}\,[RH]^{3/2}[C_6H_5OH]^{-\frac{1}{2}}[\text{initiator}]^{\frac{1}{2}}$. This relation agrees satisfactorily with the oxidation mechanism involving reactions (i) and (1)–(6) and the following reactions involving the inhibitor:

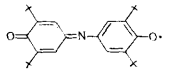
$$RO_2^{\cdot} + InH \rightarrow ROOH + In^{\cdot}, \quad (7)$$

$$RO_2^{\cdot} + In^{\cdot} \rightarrow ROOIn, \quad (8)$$

$$In^{\cdot} + In^{\cdot} \rightarrow In\text{—}In, \quad (9)$$







$$In^{\cdot} + RH \rightarrow InH + R^{\cdot} . \quad (10)$$

According to this mechanism, the rate of oxidation for $k_9[In^{\cdot}] \ll k_8[RO_2^{\cdot}]$ is

$$W = k_2\left(\frac{k_{10}w_i}{2k_7k_8}\right)^{1/2}[RH]^{3/2}[InH]^{-1/2} .$$

The constants k_{10} for stable phenoxy-radicals are listed in Table 8.

Table 8. Rate constants for the reaction In$^{\cdot}$ + RH → InH + R.

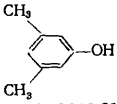
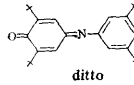
In 1955 Hammond et al.[35] established that the rate of oxidation of cumene in the presence of phenol and *N*-methylaniline is directly proportional to $\{[\text{initiator}]/[InH]\}^{\frac{1}{2}}$. On this basis, they proposed the following mechanism for chain termination involving the inhibitor:

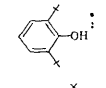
$$RO_2^{\cdot} + InH \rightleftharpoons RO_2^{\cdot} \ldots InH ,$$

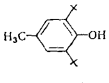
$$RO_2^{\cdot} + RO_2^{\cdot} \ldots InH \rightarrow ROOH + ROOIn .$$

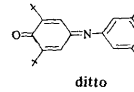
This mechanism accounts for the relation $W \propto \{W_i/[InH]\}^{\frac{1}{2}}$ but it is inconsistent with the isotope effect for deuterium-substituted phenols and amines and the absence of an inhibiting effect of phenolic ethers and tertiary amines. There is also a difference between the kinetic relations which follow from the Boozer–Hammond mechanism and the mechanism involving In$^{\cdot}$ in chain propagation. According to the Boozer–Hammond mechanism, $W \propto [RH]$, while according to the mechanism involving reactions (7), (8), and (10), $W \propto [RH]^{3/2}$. The latter relation is in fact observed experimentally[35]. Therefore the mechanism involving the reaction between In$^{\cdot}$ and RH must be regarded as valid for phenols and amines in hydrocarbons undergoing oxidation; the Boozer–Hammond mechanism does not obtain in hydrocarbons in the presence of phenols and amines.

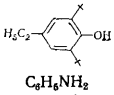








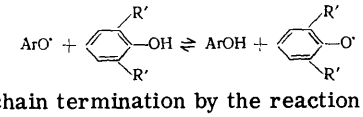




VII. THE EXCHANGE REACTION $In_1^{\cdot} + In_2H \rightleftharpoons In_1H + In_2^{\cdot}$

1. AMINE + PHENOL

In a study of the combined action of β-naphthylphenylamine and 2,6-di-t-butylphenol on the oxidation of ethylbenzene, Karpukhina et al.[16] established an interesting fact: if the phenol is present in a hydrocarbon undergoing oxidation, the amine is hardly consumed, a rapid decrease of its concentration in the oxidation process beginning only after the phenol has been used up. This finding cannot be accounted for by the fact that the amine reacts with peroxy-radicals more slowly than the phenol. On the contrary, for the amine $k_7 = 1.3 \times 10^5$ litre mole^{-1}s^{-1}, while for the phenol $k_7 = 0.95 \times 10^4$ litre mole^{-1}s^{-1} (ethylbenzene, 60°C). The unusual kinetics of the consumption of the amine in the presence of the phenol can be explained by the reaction $Am^{\cdot} + PhOH \rightleftharpoons AmH + PhO^{\cdot}$. The reaction has been demonstrated in experiments with tetraphenylhydrazine[16]. The dissociation of tetraphenylhydrazine results in the formation of diphenylnitrogen radicals, which are converted into diphenylamine in the presence of ionol. In the absence of the phenol, very little diphenylamine is formed. The exchange reaction between Am$^{\cdot}$ and PhOH leads to a synergic effect: a mixture of the amine and the phenol gives rise to more prolonged inhibition of the oxidation of ethylbenzene at 120°C than either inhibitor separately[87–91].



This can be explained by the fact that the amine gives rise to a radical capable of chain propagation by reaction with the hydrocarbon. Therefore the inhibition of the oxidation by the amine is incomplete despite the high rate constant k_7. The dialkylphenol forms relatively inactive phenoxy-radicals incapable of chain propagation, but it reacts with peroxy-radicals more slowly than does the amine. The rapid exchange reaction between Am$^{\cdot}$ and ArOH makes it possible to combine two valuable properties, namely the rapid chain termination by the reaction of $RO_2^{\cdot}$ with the amine and the inactivity of ArO$^{\cdot}$ in chain propagation reactions. β-Naphthylphenylamine is not consumed in oxidation in the presence of phenols giving rise to inactive phenoxy-radicals and the equilibrium $Am^{\cdot} + PhOH \rightleftharpoons AmH + PhO^{\cdot}$ is displaced to the right. Investigation showed that this is true of 2,6-dialkylphenols, while in the case of *p*-substituted and mono-*o*-substituted phenols the effect of the replacement of Am$^{\cdot}$ by PhO$^{\cdot}$ is absent[55,91]. *p*-Phenylenediamine and also hydroxy-derivatives of diphenylamine and β-naphthylphenylamine likewise fail to give rise to this type of effect[92] (apparently the Am$^{\cdot}$ radicals derived from these amines are relatively inactive).

2. PHENOL + PHENOL

An analogous exchange mechanism was investigated by Mahoney[94] in mixtures of two inhibitors, one of which was a 2,6-dialkylphenol and the other a phenol with a substituent in the *para*-position. A 2,6-dialkylphenol reacts with $RO_2^{\cdot}$ relatively slowly, but it gives rise to inactive radicals. A phenol with a substituent in the *para*-position reacts rapidly with $RO_2^{\cdot}$, but the phenoxy-radical formed from it is reactive and can cause chain propagation by reaction with the hydrocarbon (if the latter has a weak C–H bond) and with the hydroperoxide (see above). When two such phenols are introduced sumultaneously, the rapid exchange process (equilibrium displaced to the right)

causes fast chain termination by the reaction of $RO_2^{\cdot}$ and ArOH, while the ArO$^{\cdot}$ radicals take little part in chain propagation reactions, since they undergo rapid exchange for the inactive 2,6-dialkylphenoxy-radicals. The rate constants for the exchange reactions involving phenoxy-radicals are listed in Table 9.

VIII. REACTION OF THE INHIBITOR WITH THE HYDROPEROXIDE

Rapid chain termination by inhibitors (phenols and aromatic amines) is due to the fact that the peroxy-radical is a powerful oxidant and the inhibitors are reductants. Another oxidant (the hydroperoxide), which can react with the inhibitor, is formed and is present, apart from $RO_2^{\cdot}$, in organic compounds undergoing oxidation. If its reaction with the inhibitor results in the formation of molecular products only, it leads merely to an additional consumption of the inhibitor. If it involves the formation of free radicals, it can serve as an additional source of initiation. This must be borne in mind in the analysis of the mechanism of the inhibited oxidation of hydrocarbons and polymers.

The reaction of phenols with cumenyl hydroperoxide was investigated in chlorobenzene solution[18]. The rate of reaction is $w = k[\mathrm{PhOH}][\mathrm{ROOH}]$. It results in the formation of radicals, which initiate the oxidation. This has been demonstrated in experiments on the oxidation of cumene with the hydroperoxide and *p*-methoxyphenol.

Under these conditions, the oxidation mechanism in the absence of an initiator includes reactions (1)–(6) and the following reactions with the inhibitor:

$$\mathrm{InH} + \mathrm{RO_2^{\cdot}} \rightarrow \mathrm{In^{\cdot}} + \mathrm{ROOH}\,, \qquad (7)$$

$$\mathrm{ROOH} + \mathrm{In^{\cdot}} \rightarrow \mathrm{RO_2^{\cdot}} + \mathrm{InH}\,, \qquad (-7)$$

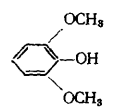
$$\mathrm{In^{\cdot}} + \mathrm{RO_2^{\cdot}} \rightarrow \mathrm{InOOR}\,, \qquad (8)$$

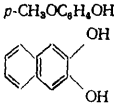
$$\mathrm{InH} + \mathrm{ROOH} \rightarrow \mathrm{In^{\cdot}} + \mathrm{H_2O} + \mathrm{RO^{\cdot}}\,. \qquad (11)$$

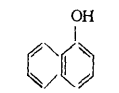
The radicals formed by reaction (11) are partly destroyed in the cage and are partly released into the bulk phase, so that the rate constant for initiation owing to this reaction is $k_{i11} = 2ek_{11}$, where e is the probability of the release of the radicals into the bulk phase. The rate of oxidation $W = k_2[\mathrm{RH}][\mathrm{RO_2^{\cdot}}]$,

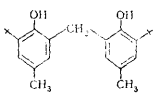
$$[\mathrm{RO_2^{\cdot}}] \simeq \sqrt{\frac{k_{-7}[\mathrm{ROOH}]^2 W_i}{2k_7 k_8 [\mathrm{InH}]}};\quad W_i = 2k_3[\mathrm{ROOH}][\mathrm{RH}] + 2ek_{11}[\mathrm{ROOH}][\mathrm{InH}]\,,$$

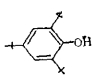
and











$$\frac{W^2[\mathrm{InH}]}{[\mathrm{ROOH}]^3} = \frac{k_2^2[\mathrm{RH}]^2 k_{-7}}{2k_7 k_8}\cdot(2k_3[\mathrm{RH}] + 2ek_{11}[\mathrm{InH}])\,.$$

This type of relation is in fact observed experimentally, which indicates the formation of radicals in the reaction between the phenol and the hydroperoxide. By comparing k_{11} (determined from the rate of decomposition of the hydroperoxide) with k_{i11} {determined from the relation between W and [InH]}, $e = 0.27$ at 120°C was found. The formation of phenoxy-radicals in the reaction between ROOH and the phenol was demonstrated by the ESR method for tri-t-butylphenol. For sterically hindered phenols, it is reasonable to postulate the formation of a hydrogen bond between the phenol and the hydroperoxide. The reaction mechanism is as follows:

$$\mathrm{ROOH} + \mathrm{PhOH} \overset{K}{\rightleftharpoons} \mathrm{ROO}\cdots\overset{\mathrm{H}}{\underset{\mathrm{HOPh}}{}} \xrightarrow{k} [\mathrm{RO^{\cdot}} + \mathrm{H_2O} + \mathrm{PhO^{\cdot}}] \rightarrow \mathrm{RO^{\cdot}} + \mathrm{H_2O} + \mathrm{PhO^{\cdot}} \quad \mathrm{mol.\ products}\,.$$

The experimental rate constant $k_{11} = Kk$, where K is the effective equilibrium constant (one must bear in mind that the phenol and the hydroperoxide forms several hydrogen-bonded association complexes, of which only one reacts). The rate constant k_{11} depends very markedly on the structure of the phenol (Table 10). The reaction between amines and peroxides has been discussed in a review[13].

Table 10. Rate constants for the reactions of phenols with cumenyl hydroperoxide[18] (solvent—chlorobenzene and n-decane in experiments with 2,4,6-tri-t-butylphenol).

Phenol	k_{11} at 140°C, litre mole^{-1} s^{-1}	E, kcal mole^{-1}	lg$A$ (litre mole^{-1} s^{-1})
	$6.5\cdot10^{-3}$	22.9±1.1	9.91±0.63
p-$CH_3OC_6H_4OH$	$4.3\cdot10^{-3}$	23.3±1.4	9.95±0.78
	$4.5\cdot10^{-3}$	25.8±0.8	11.33±0.45
	$6.7\cdot10^{-4}$	24.2±1.0	9.63±0.89
	$4.2\cdot10^{-4}$	26.0±0.7	10.36±0.42
p-$CH_3C_6H_4OH$	$2.0\cdot10^{-4}$	26.2±2.0	10.15±1.11
	$7.8\cdot10^{-5}$	25.9±1.0	9.60±0.54

The hypothesis has been put forward[96] that the inhibitor is involved in degenerate chain branching via its interaction with a pair of radicals in a solvent (or polymer) cage. On decomposition of the hydroperoxide by the reaction

$$\mathrm{ROOH} + \mathrm{RH} \rightarrow \mathrm{RO^{\cdot}} + \mathrm{H_2O} + \mathrm{R^{\cdot}}$$

or as a result of the consecutive reactions

$$\mathrm{ROOH} \rightarrow \mathrm{RO^{\cdot}} + \mathrm{HO^{\cdot}},\quad \mathrm{HO^{\cdot}} + \mathrm{RH} \rightarrow \mathrm{H_2O} + \mathrm{R^{\cdot}},$$

one cage contains both RO$^{\cdot}$ and R$^{\cdot}$ radicals. Some of these pairs recombine and some are released into the bulk phase. It is suggested that the inhibitor in the cage reacts with one of the radicals and thereby increases the probability of liberation of the radicals from the cage. A bifunctional inhibitor allegedly reduces the probability of the release of the radicals into the bulk phase by reacting with two radicals. However, in order to influence the liberation of the radicals from the cage (to increase or decrease the probability), the inhibitor must compete successfully with the diffusion of the radicals from the cage. In the usual solvents with low viscosity (benzene, heptane, etc.), the rate constants for the diffusion of molecules and radicals at about 20°C are very high (10^9–10^{10} litre mole^{-1}s^{-1}). The concentration of the inhibitor is usually low (10^{-4}–10^{-2} M). Therefore the specific rate of diffusion of the radical from the cage is always much higher than the rate of its reaction with the inhibitor even when the rate constant for this reaction is large {$k_7 \simeq 10^7$ litre mole^{-1}s^{-1}, $k_D \gtrsim 10^9$, $k_7[\mathrm{InH}] \lesssim 10^5$}.

Experiment confirmed this conclusion. Waits and Hammond[97] investigated the decomposition of the dinitrile of azocyclohexanecarboxylic acid in the presence of active acceptors of alkyl radicals such as I_2, Br_2, and diphenylpicrylhydrazyl, which react with alkyl radicals, the rate constant being close to k_D. It was established that free radical acceptors do not influence the yield of recombination products within the cage up to a concentration of 0.1 M. In a viscous medium (a polymer melt) at a high temperature (180°C and above), rapid release of radicals into the bulk phase from the cage is insured by intense segmental diffusion (if two macroradicals are formed).

The inhibitor has no influence on the initiation efficiency in the solid phase either, as shown by measurements of the rate of consumption of inhibitors (α-naphthol, α-naphthylamine) in polyethylene and polystyrene when the radicals are generated from azobisisobutyronitrile. Thus the hypothesis of the involvement of the inhibitor in initiation via the reaction of radicals in the cage is contrary to both experimental facts and theoretical estimates.

IX. REACTION OF THE INHIBITOR WITH OXYGEN

Phenols and aromatic amines react with molecular oxygen bimolecularly[19,20]:

$$InH + O_2 \rightarrow In^{\cdot} + HO_2^{\cdot}$$

The activation energy for this reaction is close to its endothermicity, which makes it possible to estimate the strength of the weakest bond in the inhibitor from the value of E (Tables 1 and 2). The pre-exponential factor varies over the range 10^9–10^{12} litre mole^{-1}s^{-1} (Table 11), i.e. is fairly close to the frequency factor for binary collisions in a liquid. According to the collision theory, in a liquid[93] $A = KP(6\nu/z)E/RT$, where P is the steric factor, ν the molecular vibration frequency in the liquid, z the number of neighbouring molecules surrounding the reacting molecules, E the activation energy, and K the equilibrium constant for the reaction $RH + O_2 = [RH + O_2]$. Hence we have $A = 2 \times 10^{14} P$ for $\nu = 10^{13}$ s^{-1}, $z = 12$, $E = 30$ kcal mole^{-1}, $K = 1$ litre mole^{-1}, and $T = 400$°K; when $A = 2 \times 10^{11}$, $P = 10^{-3}$.

Table 11. Rate constants for the reaction of InH with O_2 in benzene[19,20].

Inhibitor	k at 180°C, litre mole^{-1} s^{-1}	E, kcal mole^{-1}	lg$A$ (litre mole^{-1} s^{-1})
C_6H_5OH	$0.9 \cdot 10^{-4}$	35	12.845
p-$CH_3C_6H_4OH$	$1.2 \cdot 10^{-4}$	32	11.48
p-$CH_3OC_6H_4OH$	$7.4 \cdot 10^{-4}$	27	9.875
β-$C_{10}H_7OH$	$4.5 \cdot 10^{-4}$	29	10.65
α-$C_{10}H_7OH$	$2.0 \cdot 10^{-3}$	25	9.34
α-$C_{10}H_7NHC_6H_5$	$1.7 \cdot 10^{-5}$	32	10.545
β-$C_{10}H_7NHC_6H_5$	$5.6 \cdot 10^{-5}$	31	10.46
α-$C_{10}H_7NH_2$	$6.0 \cdot 10^{-5}$	30	10.175
β-$C_{10}H_7$—NH——NH—β-$C_{10}H_7$	$1.4 \cdot 10^{-2}$	23	9.145

It has been suggested[99,100] that the reaction of the inhibitor with oxygen is the main source of initiation in the induction period of the inhibited oxidation process. The finding[99] that in polypropylene undergoing oxidation α-naphthol was consumed in a first-order reaction and the specific rate of its consumption increased with oxygen pressure supported this hypothesis. In the initial period of the oxidation reaction, initiation is due to reactions involving oxygen: $RH + O_2 \rightarrow R^{\cdot} + HO_2^{\cdot}$ and $2RH + O_2 \rightarrow 2R^{\cdot} + H_2O_2$. The reaction between InH and O_2 plays a significant role if its rate is comparable to (or higher than) the rate of chain initiation w_0. Comparison of the experimental values of w_0 with the rate of reaction between InH and O_2 shows that, even for a comparatively active inhibitor such as α-naphthol, $W_0 \gg W(InH + O_2)$ in polymers undergoing oxidation.

Indeed in polyethylene at 118°C and an oxygen pressure of 1 atm, $W_0 = 1.5 \times 10^{-7}$ mole kg^{-1} s^{-1} and the rate of reaction of α-naphthol with oxygen for $[InH] = 10^{-3}$ mole kg^{-1} is approximately 2×10^{-11} mole kg s^{-1}; in polypropylene at 130°C and an oxygen pressure of 1 atm, $W_0 = 2.4 \times 10^{-6}$ mole kg^{-1} s^{-1} and $W(InH + O_2) \simeq 6 \times 10^{-11}$ mole kg^{-1} s^{-1} {[α-naphthol] = 10^{-3} mole kg^{-1}}.

X. REGENERATION OF THE INHIBITOR IN CHAIN TERMINATION STEPS

Chain termination in the reaction between the peroxy-radical and the inhibitor is accompanied by destruction of the latter. For the vast majority of phenols and amines, the stoichiometric inhibition coefficient[25] is close to two, which can be accounted for by the following chain termination mechanism:

$$RO_2^{\cdot} + InH \rightarrow ROOH + In^{\cdot},$$
$$RO_2^{\cdot} + In^{\cdot} \rightarrow \text{mol. products}.$$

In a study of the oxidation of cyclohexanol[101], it was established that α-naphthylamine inhibiting the initiated oxidation of cyclohexanol is consumed at a rate smaller by a power of several tens than the rate of initiation. An analogous phenomenon is observed in the oxidation of other secondary and primary alcohols[102] and is characteristic not only of α-naphthylamine but also of other aromatic amines. This phenomenon is due to the regeneration of the aromatic amine in the alcohol undergoing oxidation and the repeated involvement of a single amine molecule in chain termination. The mechanism of the regeneration of the amine was discovered by Kharitonov and Denisov[103], who established the formation of diphenylamine from the diphenylnitrogen radical in cyclohexanol undergoing oxidation. Chain propagation in an alcohol undergoing oxidation is due to the hydroxyperoxy-radical $\rangle C(OH)OO^{\cdot}$, which exhibits a dual reactivity: it can oxidise by abstracting a hydrogen atom from the molecule via its peroxy-group and it can reduce the radical by giving up to it the hydrogen atom from its hydroxy-group. The latter reaction leads to the regeneration of the inhibitor and irreversible destruction of the latter takes place as a result of the reaction of the radical In$^{\cdot}$ with the peroxy-group of the hydroxy-peroxy-radical:

$$\rangle C(OH)OO^{\cdot} + InH \xrightarrow{k_7} \rangle C(OH)OOH + In^{\cdot},$$
$$\rangle C(OH)OO^{\cdot} + In^{\cdot} \xrightarrow{k_8'} InH + O_2 + \rangle C{=}O,$$
$$\rangle C(OH)OO^{\cdot} + In^{\cdot} \xrightarrow{k_8} InOO(HO)C \rightarrow \text{products}.$$

The degree of regeneration of the amine depends on the ratio of the rate constants for reactions (8) and (8′): $f = w_i/w_{InH}$; the rate of initiation w_i is equal to the rate of

chain termination, i.e. $w_i = \{k_7[InH] + (k_8 + k_8')[In^\cdot]\}[RO_2^\cdot]$ and $w_{InH} = k_7[InH][RO_2^\cdot] - k_8'[In^\cdot][RO_2^\cdot]$, whence we find

$$f = \frac{k_7[InH] + (k_8 + k_8')[In^\cdot]}{k_7[InH] - k_8'[In^\cdot]}, \quad [In^\cdot] = \frac{k_7[InH]}{k_8 + k_8'}, \quad f = 2\left(1 + \frac{k_8'}{k_8}\right) .$$

The mechanism of the regeneration of α-naphthylamine in cyclohexanol undergoing oxidation was investigated recently in greater detail[104]. In an alcohol undergoing oxidation, chain termination takes place via the reactions:

$$\rangle\dot{C}OH + O_2 \xrightarrow{k_1} \rangle C(OH)OO^\cdot ,$$
$$\rangle C(OH)OO^\cdot + \rangle CHOH \xrightarrow{k_2} \rangle C(OH)OOH + \rangle\dot{C}OH .$$

The hydroxyhydroperoxide formed decomposes into a ketone and hydrogen peroxide, the latter generating hydroperoxy-radicals by reaction with hydroxyperoxy-radicals:

$$\rangle C(OH)OOH \rightleftharpoons \rangle C{=}O + H_2O_2 ,$$
$$H_2O_2 + \rangle C(OH)OO^\cdot \rightarrow HO_2^\cdot + \rangle C(OH)OOH$$

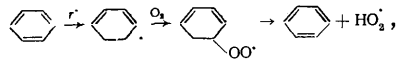
Therefore an alcohol undergoing oxidation contains simultaneously hydroxyalkyl, hydroxyperoxy-, and hydroperoxy-radicals, each of which can reduce In$^\cdot$ to InH. To confirm the role that each of these radicals plays in the regeneration of α-naphthylamine, a study was made of the relation between f in an alcohol undergoing oxidation on the one hand and the partial pressure of oxygen and the concentration of hydrogen peroxide on the other. Since hydroxyalkyl radicals are consumed by the reaction with oxygen and are formed by reaction (2), their steady-state concentration is inversely proportional to the concentration of dissolved oxygen:

$$[\rangle\dot{C}OH] = \frac{k_2}{k_1}\frac{[\rangle CHOH]}{[O_2]}[\rangle C(OH)OO^\cdot] .$$

By changing $[O_2]$, it is possible to follow the regeneration of the inhibitor by the reaction with hydroxyalkyl radicals. In the absence of oxygen, the regeneration can be achieved only by hydroxyalkyl radicals. In the experiments of Bardanyan et al.,[104] measurements were made of the rate of consumption of α-naphthylamine in cyclohexanol being oxidised at 120°C with $W_i = 1.86 \times 10^{-6}$ mole litre^{-1}s^{-1} and $[InH] = 8 \times 10^{-4}$ M at different partial pressures of oxygen. The experimental results[104] are presented below:

Partial oxygen pressure	= 0	61	160	300	760 mmHg.
f =	16.6	25	36	44	48

It is evident from these data that the degree of regeneration of the amine in the reaction with peroxy radicals is higher than in the reaction with hydroxyalkyl radicals and that the role of hydroxyalkyl radicals in regeneration at atmospheric oxygen pressure is insignificant. (Calculation shows that 95% of In$^\cdot$ is converted into InH as a result of the reaction with peroxy-radicals at an oxygen pressure of 1 atm.)



Experiments with different concentrations of hydrogen peroxide in cyclohexanol at 75°C and with $W_i = 3.7 \times 10^{-7}$ mole litre^{-1}s^{-1} showed that, as $[H_2O_2]$ increases, the coefficient f diminishes from $f = 90$ in pure cyclohexanol to $f = 20$ for $[H_2O_2] \geq 0.08$ M. Consequently hydroperoxy-radicals also reduce In$^\cdot$ to InH, but in this case k_8'/k_8 is significantly lower than for hydroxyperoxy-radicals. With increased concentration of hydrogen peroxide in the alcohol undergoing oxidation, the role of $HO_2^\cdot$ radicals in the regeneration of the inhibitor becomes more pronounced. The following values of k_8'/k_8, characterising the relative capacity of various radicals to regenerate the inhibitor, were obtained from experimental data for α-naphthylamine in cyclohexanol at 75°C: 47 ± 5 for the hydroxyperoxy-radical, 9 ± 2 for the hydroperoxy-radical, and 6 ± 2 for the hydroxyalkyl radical. The regeneration is characteristic of many aromatic amines.

Since the hydroxyperoxy-radical is a reductant, one may expect that chain termination in an alcohol being oxidised can be caused by oxidant molecules, for example quinones. It has been shown[105] that a quinone Q inhibits the oxidation of isopropyl alcohol owing to the reactions

$$\rangle C(OH)OO^\cdot + Q \rightarrow {}^\cdot QH + \rangle C{=}O + O_2 ,$$
$$\rangle\dot{C}OH + Q \rightarrow {}^\cdot QH + \rangle C{=}O .$$

At an oxygen partial pressure of 1 atm, 86% of chain termination is due to the first reaction, the quinone being regenerated in the oxidation process.

The regeneration of inhibitors in chain termination steps occurs also in the oxidation of certain unsaturated hydrocarbons, in particular 1,3-cyclohexadiene[106]. The oxidation of cyclohexadiene is propagated by hydroperoxy-radicals, which exhibit a reducing effect:

$$HO_2^\cdot + In^\cdot \rightarrow InH + O_2 .$$

The degree of regeneration of the inhibitor depends on its structure and varies over a wide range (Table 12). In the case of phenols, regeneration is observed rarely (hydroquinone); this can probably be accounted for by the very rapid recombination of PhO$^\cdot$ and $RO_2^\cdot$.

Table 12. Inhibition coefficients f for different substances undergoing oxidation.

In hydrocarbons undergoing oxidation, $f \simeq 2$ as a rule. An exception is provided by Chien's study[107], where a coefficient $f > 2$ (6–10) is quoted for 2,6-di-t-butylphenols in squalene and cyclohexene undergoing oxidation. The coefficient f was determined from the duration of the induction period in the initiated oxidation process. This measurement yields a correct value for f only if all the chains

are terminated by the inhibitor and $k_7[InH] \gg k_6[RO_2^{\cdot}]$. In the general case we have

$$W_i = k_6[RO_2^{\cdot}]^2 + fk_7[InH][RO_2^{\cdot}],\ W_{InH} = k_7[InH][RO_2^{\cdot}] \text{ and}$$

$$\frac{W_i}{W_{InH}} = f + \frac{k_6[RO_2^{\cdot}]}{k_7[InH]} = f + \frac{k_6 W_{InH}}{k_7^2[InH]^2}.$$

The coefficient f is found from the plot of w_i/w_{InH} against $w_{InH}/[InH]^2$. Such calculation based on Chien's data[107] yields $f = 2.3$ for ionol in squalene undergoing oxidation[108]. These experiments yielded an unduly high value of f because in the calculation no account was taken of chain termination by the reaction between $RO_2^{\cdot}$ radicals. Vardanyan's redetermination[108] of f for 2,6-di-t-butylphenols in cyclohexene at 80°C (in the presence of azobisisobutyronitrile as an initiator) yielded $f = 2$ for these phenols. Thus a check on Chien's results[107] failed to confirm the high values of f obtained in his study for 2,6-dialkylphenols.

XI. THE MECHANISM OF INHIBITED OXIDATION

In the absence of an inhibitor and an initiator, the mechanism of the oxidation of C–H bonds of organic compounds in the condensed phase can be represented by the following series of elementary reactions[3]:

$$RH + O_2 \rightarrow R^{\cdot} + HO_2^{\cdot}, \quad (0)$$

$$2RH + O_2 \rightarrow 2R^{\cdot} + H_2O_2, \quad (0)$$

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}, \quad (1)$$

$$RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot}, \quad (2)$$

$$ROOH \rightarrow RO^{\cdot} + HO^{\cdot}, \quad (3)$$

$$ROOH \rightarrow \text{mol. products}, \quad (M)$$

$$2RO_2^{\cdot} \rightarrow \text{mol. products} \quad (6)$$

After the introduction of an inhibitor, new elementary reactions involving InH and In$^{\cdot}$ take place:

$$RO_2^{\cdot} + InH \rightarrow ROOH + In^{\cdot}, \quad (7)$$

$$In^{\cdot} + RO_2H \rightarrow InH + RO_2^{\cdot}, \quad (-7)$$

$$In^{\cdot} + RO_2^{\cdot} \rightarrow \text{mol. products} \quad (8)$$

$$In^{\cdot} + In^{\cdot} \rightarrow \text{mol. products} \quad (9)$$

$$In^{\cdot} + RH \rightarrow InH + R^{\cdot}. \quad (10)$$

As a rule, the reactions of the inhibitor with the hydroperoxide and oxygen do not play a significant role. The kinetics of inhibited oxidation can be described by a set of differential equations. Each individual substance oxidised–inhibitor system is characterised by a definite set of rate constants for reactions (0)–(10). For a comprehensive kinetic analysis of such systems, it is insufficient to base the treatment solely on experimental results. Firstly, there are very few systems in which each elementary stage has been investigated. Secondly, in the experiment it is always possible that a number of factors (and elementary reactions) have not been taken into account. There is a possibility that the presence of substances (impurities) may complicate the mechanism, etc. Therefore, in a study of complex reactions such as the inhibited oxidation processes, the experimental research techniques can be usefully supplemented by the so called numerical experiment where the mechanism is specified in the form of a set of differential equations and rate constants and a computer calculation yields the rates of accumulation of reaction products. The numerical experiment yields the reaction kinetics for strictly specified mechanism and constants; the element of uncertainty associated with incomplete control over the reaction mechanism in a real experiment is excluded here; the reaction mechanism can be varied at will, which makes it possible to establish clearly the role of a particular elementary reaction in the overall process. Such a calculation has been carried out[110] for the simplest case where the inhibitor is involved only in reaction (7) and In$^{\cdot}$ is involved only in reaction (8). A more complicated mechanism, including reactions (7)–(10) was examined with the following rate constants: $W = \{k_0 + k_0'[RH]\}[RH][O_2] = 10^{-10}$ mole litre^{-1} s^{-1}, $k_2[RH] = 50$ s^{-1}, $k_3 = 2 \times 10^{-6}$ s^{-1}, $k_M = 5 \times 10^{-5}$ s^{-1}, $k_6 = 10^6$ litre mole^{-1}s^{-1}, $k_7 = 2 \times 10^5$ litre mole^{-1}s^{-1}, $k_{-7} = 10^5$ litre mole^{-1}s^{-1}, $k_8 = 10^9$ litre mole^{-1}s^{-1}, $k_9 = 10^8$ litre mole^{-1}s^{-1}, and $k_{10} = 10$ litre mole^{-1}s^{-1}. To elucidate the role of each of these reactions involving In$^{\cdot}$, a numerical experiment was carried out including the mechanism of individual (but not all) reactions of the In$^{\cdot}$ radical.

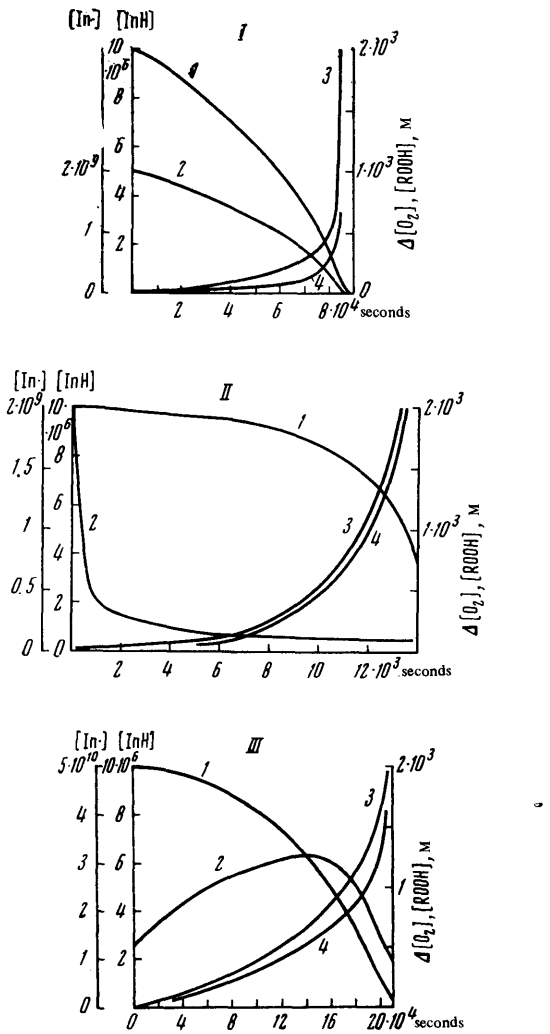

Figure 2. Kinetic curves for the consumption of InH (curve *1*) and In$^{\cdot}$ (curve *2*), the absorption of O_2 (curve *3*) and the accumulation of ROOH (curve *4*) in mechanisms I, II, and III respectively.

Mechanism I: the inhibitor and the radical In$^{\cdot}$ react with $RO_2^{\cdot}$, the rate constants for the remaining reactions of In$^{\cdot}$ being zero. In this case the oxidation develops very slowly and the transition from slow inhibited oxidation to rapid oxidation takes place abruptly (Fig. 2, I). The concentration of In$^{\cdot}$ varies in parallel with [InH]. At the end of the induction period, the concentration of ROOH is less than that of the absorbed oxygen.

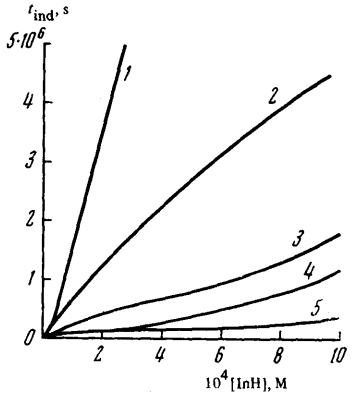

Figure 3. Dependence on the induction period on the concentration of inhibitor: 1) mechanism I; 2) mechanism III + Q with $k_Q = 1$; 3) mechanism III + Q with $k_Q = 0.2$; 4) mechanism III + Q with $k_Q = 0.02$; 5) mechanism II; Q = inhibitor decomposing the hydroperoxide; $[Q]_0 = 10^{-3}$ M.

Mechanism II: the radical In$^{\cdot}$ reacts only with $RO_2^{\cdot}$ and ROOH. Fig. 2, II shows that the oxidation develops more rapidly than in mechanism I, the proportion of the hydroperoxide decomposing during the induction period is small, and the concentration of In$^{\cdot}$ decreases rapidly during the reaction. The reaction emerges from the induction period smoothly long before the complete consumption of the inhibitor.

Mechanism III: the radical In$^{\cdot}$ reacts with $RO_2^{\cdot}$, In$^{\cdot}$, and RH. The oxidation develops faster than in mechanism I; the reaction emerges from the induction period smoothly, the concentration of In$^{\cdot}$ passing through a maximum (Fig. 2, III). Comparison of mechanisms (I)–(III) (Fig. 2) shows that a change in mechanism causes a significant change in the kinetics of the accumulation of In$^{\cdot}$. There is also a change in the nature of the relation between the induction period and [InH] (Fig. 3). For mechanism I, the relation is close to linear. When In$^{\cdot}$ causes chain propagation via the reaction with RH, the induction period ceases to depend on [InH] beyond a certain value $[InH]_{min}$. For mechanism II, the relation between t_{ind} and [InH] is represented by a line with positive curvature. In the presence of an additional inhibitor Q decomposing the hydroperoxide, the t_{ind}–[InH] relation is represented by an inverted S-shaped curve (Fig. 3). Evidently different mechanisms of inhibitor action lead to different relations between t_{ind} and [InH]. However, one should bear in mind that the mechanism of inhibitor action cannot be inferred unambiguously from the t_{ind}–[InH] relation.

XII. CRITERIA OF THE EFFICIENCY OF INHIBITORS

We have seen that the mechanism of the action of inhibitors is fairly complicated. The efficiency of the inhibiting effect depends on a series of reactions involving In$^{\cdot}$, $RO_2^{\cdot}$, InH, and ROOH, i.e. is determined by a series of reactions. Therefore the efficiency of the inhibitor cannot be expressed by any one parameter but must be represented in the general case by a set of formulae (inequalities), which take account of the contributions by all the reactions on which the rate of the oxidation process depends.

If the radicals In$^{\cdot}$ are only weakly involved in chain propagation,

$$k_6[RO_2^{\cdot}] \gg k_{10}[RH] + k_7[ROOH] \quad \text{or}$$
$$k_6 W_i / f k_7 [InH] \gg k_{10}[RH] + k_{-7}[ROOH],$$

the inhibiting effect is stronger for higher values of k_7 and [InH]:

$$f k_7 [InH][RO_2^{\cdot}] \gg k_6 [RO_2^{\cdot}]^2 \text{ and } f k_7 [InH] \gg \sqrt{W_i k_6} \quad \text{(IV)}$$

If In$^{\cdot}$ is involved in chain propagation via reaction (10), then strong inhibition requires that the following inequality should hold:

$$k_2[RH][RO_2^{\cdot}] + k_{10}[RH][In^{\cdot}] \ll k_2[RH]\sqrt{W_i/k_6} \quad \text{or}$$
$$1 + \frac{k_7[InH]}{k_2[RH]} \ll k_2 \left\{ \frac{2k_8}{k_6} \frac{k_7[InH]}{k_{10}[RH]} + \frac{2k_9}{k_6} \left(\frac{k_7[InH]}{k_{10}[RH]} \right)^2 \right\}^{1/2}.$$

The above inequality is valid when another inequality holds:

$$\frac{1}{k_{10}} \gg \frac{k_6[RH]}{8k_2^2 k_8} \left(1 + \frac{1}{k_7[InH]} \right) + \frac{\sqrt{k_6}}{4k_2\sqrt{2k_9}} \left(\frac{1}{k_2} + \frac{[RH]}{k_7[InH]} \right), \quad \text{(V)}$$

i.e. when k_{10} is fairly large, it is impossible to achieve effective inhibition by increasing [InH] if

$$\frac{1}{k_{10}} \lesssim \frac{k_6[RH]}{8k_2^2 k_8} + \frac{\sqrt{k_6}}{4k_2^2\sqrt{2k_9}}.$$

If In$^{\cdot}$ causes chain propagation via the reaction with the hydroperoxide, we obtain the following inequality for effective inhibition:

$$[RO_2^{\cdot}] \ll \sqrt{W_i/k_6}, \quad [RO_2^{\cdot}] = \left\{ \frac{W_i k_{-7}[ROOH]}{2k_7 k_8 [InH]} \right\}^{1/2}$$

and

$$k_{-7} \ll \frac{2k_7 k_8 [InH]}{k_6 [ROOH]} \quad \text{(VI)}$$

In certain cases one should also bear in mind the reaction of the inhibitor itself with the hydroperoxide:

$$ROOH + InH \rightarrow RO^{\cdot} + H_2O + In^{\cdot} \quad (11)$$

When account is taken of this reaction in the presence of InH, $W_i = W_0 + 2k_3[ROOH] + 2ek_{11}[ROOH][InH]$. If we consider the case where In$^{\cdot}$ is responsible for chain propagation only via the reaction with the hydroperoxide, then, when account is taken of reaction (11), we obtain the following inequality for effective inhibition:

$$\frac{k_{-7}[ROOH](1 + ek_{11}[InH]/k_3)}{2k_7 k_8} \ll \frac{1}{k_6} \quad \text{or}$$
$$\frac{k_{-7}}{[InH]} + \frac{ek_{-7}k_{11}}{k_3} \ll \frac{2k_7 k_8}{k_6 [ROOH]}. \quad \text{(VII)}$$

Inequalities (IV)–(VII) represent a combined kinetic criterion for an effective inhibitor in the given compound being oxidised. These inequalities take into account all the reactions involving the inhibitor currently known.

They reflect both the specific characteristics of the inhibitor, its kinetic features (the constants k_7, k_{-7}, k_8, k_9, k_{10}, and k_{11}), and the specific features of the substance being oxidised (W_0, k_2, and k_{10}), its peroxy-radicals (k_2, k_6, k_7, and k_8), and its hydroperoxide (k_3, k_{-7}, and k_{11}).

---o0o---

The review shows that the principal reactions involved in oxidation inhibited by phenols and aromatic amines have now been established. The rate constants for reactions with peroxy-radicals have been measured for many phenols and aromatic amines. Unfortunately in the vast majority of cases these measurements have been made at only one temperature, which makes it difficult to employ the results at other temperatures. The reactions of phenoxy- and phenylnitrogen radicals have been less well investigated, particularly in the case of the reactive radicals In$^{\cdot}$, such reactions playing a major role in inhibited oxidation. There are few data for the rates of the reactions between In$^{\cdot}$ and $RO_2^{\cdot}$ and between In$^{\cdot}$ radicals alone. Overall, a quantitative study of the mechanism of the action of inhibitors requires further research to establish from the available fragmentary data a well-founded mechanism of inhibitor action.

Kinetics of the Photochemical Oxidation of Polyolefins

O.N.Karpukhin and E.M.Slobodetskaya

The review gives a general and systematic account of data on the kinetics of the thermal and photochemical oxidation of polyolefins and the kinetic parameters obtained by different investigators are compared. The kinetic parameters found at different temperatures and extrapolated to natural conditions are quoted and kinetic curves for the photochemical oxidation of polyolefins are calculated. The curves agree satisfactorily with experimental data on the accumulation of polyolefin photochemical oxidation products.
The bibliography includes 104 references.

I. INTRODUCTION

Polyolefins are polymers which consist of weakly branched hydrocarbon molecules. The most common and industrially most important examples of this series of polymers are polyethylene (PE) and polypropylene (PP).

On ageing, the mechanical properties of articles made of these polymers are impaired, they become brittle, yellow-coloured, and covered in cracks, their tensile strength falls, etc. The main cause of these changes is oxidative degradation of the polymer[1].

According to modern ideas, the oxidation of polymers is a degenerate branched radical chain process, the principal stages of which are initiation of the oxidation chains, their propagation and termination, the formation of a degenerate-branching agent, and degenerate-branching of the chains by this species. The characteristic features of the mechanisms of each of these stages at high temperatures (120—150°C) have been fairly well investigated. The branching agent is a peroxide formed in the chain propagation step. In air, alkyl radicals are largely converted into peroxy-radicals, which are responsible for the propagation of the oxidation chain. Chain termination occurs in the peroxy-radical disproportionation step with formation of alcohols and carbonyl compounds. The polymeric molecule is ruptured in the chain propagation stage, during the decomposition of the peroxy-radicals, and possibly in the branching stage during the decomposition of the hydroperoxide[2]. In the case of a pure polyolefin, the overall process is satisfactorily interpreted as a degenerate-branched chain reaction with quadratic destruction of active centres[2].

When polymers are used close to room temperature, the rate of chain branching due to the thermal decomposition of the peroxide becomes low due to the high activation energy for this reaction (about 30 kcal mole^{-1}). Under these conditions, the photochemical reactions in the polymer begin to play an important role. The oxidation products of polyolefins absorb light much more effectively than the initial polymeric molecule. Therefore one may expect that the photochemical oxidation of polyolefins is also a degenerate branched chain process in which the initiation and chain branching steps involve light quanta.

At the beginning of the present review, each stage of the process is considered separately and then the results of the treatment are compared with the macroscopic relations observed experimentally.

II. SENSITISED PHOTOCHEMICAL OXIDATION OF POLYOLEFINS

A saturated hydrocarbon molecule of any length and with any degree of branching does not absorb light at wavelengths above 200 nm, i.e. does not absorb sunlight reaching the surface of the earth. Fig. 1 presents the absorption spectrum of saturated hydrocarbons and the spectral composition of sunlight on the earth's surface† and at the limit of the atmosphere. It shows that the spectra hardly overlap, i.e. pure olefins should not be decomposed by sunlight and the reason for their chemical degradation must be some light-absorbing impurities.

Probably all the impurities present in polymers can be divided into two groups. Firstly, these are extraneous impurities which enter the polymer in some way: the residues from the catalyst, impurities sorbed by the polymer in the course of its manufacture and use, special additives to polyolefins, fillers, thermostabilisers, etc. Secondly, these are polymer reaction products: peroxides, carbonyl compounds, olefinic compounds, etc. Impurities of the first type can initiate the photochemical oxidation of the polymer, while those of the second type are responsible for degenerate chain branching during photochemical oxidation.

Fig. 2 presents the absorption spectra of the main impurities usually detected in polyolefins. They all absorb light at longer wavelengths much more effectively than polyolefins. Many of these impurities are photochemically active. For example, thermostabilisers

† The spectrum of sunlight in space in the earth's orbit was taken from Ref. 4 and the emission spectrum of the sun in the upper layers of the atmosphere and for different positions of the sun above the horizon was calculated from the absorption spectrum of ozone, which absorbs the ultraviolet component of the sun's spectrum.

usually contain phenols or aromatic amines. Compounds of both classes are known to be effective photosensitisers[3]. Attention has been drawn[3] to the fact that the photochemical degradation of polyolefins is much faster in the presence of aromatic hydrocarbons sorbed from air. Fig. 2 shows that the extinction coefficients of these substances are very large and their photosensitising activity is also well known.

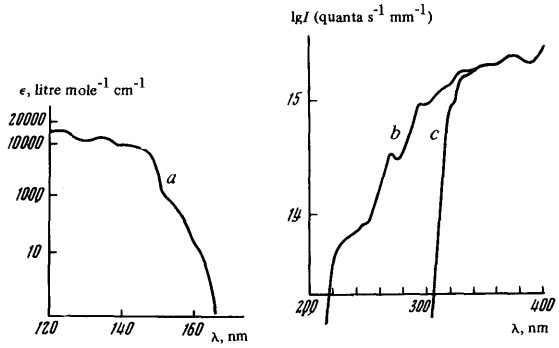

Figure 1. Absorption spectrum of n-butane (*a*) and the spectral composition of sunlight at the limit of the atmosphere (*b*) and on the surface of the earth (*c*).

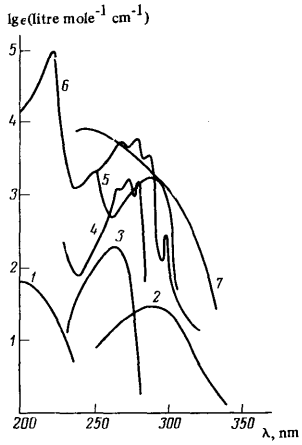

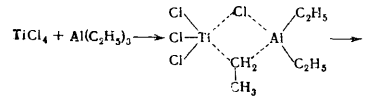

Figure 2. Absorption spectra of the main impurities in polyolefins: 1) acetic acid; 2) aliphatic ketones; 3) benzene; 4) phenol; 5) aniline; 6) naphthalene; 7) $Ti(OC_4H_9)_4$.

In a number of studies, it has been asserted that the main cause of the photochemical degradation of polymers is the presence of residues from the catalyst in the polymer. However, the photochemical activity of these compounds has not yet been investigated in detail. Moreover it is difficult to specify an individual substance responsible for their photochemical activity[4,5]. One can only point to studies where it has been shown that the presence of the catalyst at a low concentration accelerates the photochemical degradation of the polymer[5-8].

Ziegler—Natta catalysts, which are nowadays most widely employed, consist of a mixture of compounds of variable-valence metals (titanium, chromium, molybdenum, vanadium, etc.) and organometallic compounds, mainly aluminium derivatives. The principle of their action can be illustrated by the following scheme[9]:

$$\longrightarrow (C_2H_5)_2AlCl + Cl_3Ti{\cdots}C_2H_5 \longrightarrow TiCl_3 + C_2H_5^{\cdot}$$

Catalysts are removed from polymers by washing them with alcohols (isopropyl, butyl, etc. alcohols) but part of the catalyst nevertheless remains in the polymer. According to the data of Balabau and Preisler[10], less than 0.005% (0.001 M) of titanium and aluminium derivatives remains in polypropylene purified in this way. The residual catalyst has a fairly high extinction coefficient at about 300 nm (Fig. 2). The absorption of a light quantum may result in the formation of free radicals by the reaction[6]

$$M^{n+}X^{\cdot} + h\nu \rightarrow M^{+(n-1)} + X^{\cdot}$$

The occurrence of this reaction is postulated[6] by analogy with the corresponding reactions in a liquid, usually aqueous solution[11]. Neither the quantum yield of reactions of this kind nor details of the mechanism have been investigated.

The concentration of impurities in the polymer is of the order of 10^{-2}—10^{-3} M, i.e. it corresponds approximately to the concentration in the polymer of macromolecules with a molecular weight of 10^5—10^6. Thus if the impurities were decomposed in the photosensitisation step, the molecular weight of the polymer would decrease at most by a factor of several units and polymer degradation would then stop. The rate of the degradation process would then decrease with time. In fact, according to the literature, the accumulation of carbonyl groups, for example in the photochemical oxidation of polypropylene[12-14], is autocatalytic and the initial rate of these processes is very low. When the residual catalyst is introduced at a concentration up to 0.03 M (Ti), the photochemical reaction remains autocatalytic[10].

The data quoted show that impurities can have a significant influence only in the initial stage of the process, while at advanced stages of the latter impurities of the second kind, i.e. products formed in the course of the degradation of the polymer, play the main role.

III. DEGENERATE CHAIN BRANCHING IN THE PHOTOCHEMICAL OXIDATION REACTION (PHOTOLYSIS OF THE POLYOLEFIN OXIDATION PRODUCTS)

As mentioned above, degenerate chain branching in the photochemical oxidation of polyolefins can involve hydroperoxides and ketones. For a better understanding of this stage of the process, we shall consider the photolysis of these compounds.

1. Photochemistry of Aliphatic Ketones

The mechanism of the photolysis of low-molecular-weight aliphatic ketones has been investigated very intensively and is now believed to be largely understood.

Aliphatic ketones have an absorption maximum in the range 270—290 nm, their absorption bands extending up to 320—330 nm (for example the molar extinction coefficient of diethyl ketone is $\epsilon_{313} = 2.07$). This absorption is due to a forbidden singlet—singlet transition with electron transfer from the non-bonding n orbital located on the oxygen atom to the more delocalised π^* orbital of the carbonyl group. The same transition probably occurs in a polymer containing keto-groups. For example, the maximum in the absorption spectrum of the ethylene—carbon monoxide copolymer (1% CO), which has the same physical properties as low-pressure polyethylene, is very close to the absorption maximum of an aliphatic ketone[15] (Fig. 3).

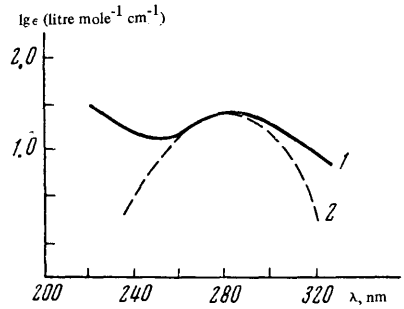

Figure 3. Absorption spectra of the ethylene—carbon monoxide (1%) copolymer (curve *1*) and of the ketone $CH_3(CH_2)_{10}CO(CH_2)_{10}CH_3$ (curve *2*) in heptane at 80°C.

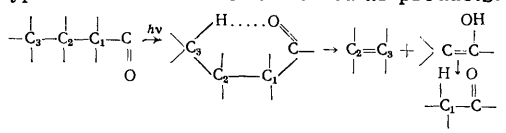

A very short time after the absorption of a light quantum, of the order of 10^{-11} s in the condensed phase, the excited electronic singlet state $^1(n, \pi^*)$ of carbonyl compounds is thermally equilibrated with the medium, whence the molecules can pass to the triplet state $^3(n, \pi^*)$ or can dissipate the excess energy in the form of heat.

Carbonyl compounds in the singlet and triplet excited states can also enter into chemical decomposition, addition, isomerisation, etc. reactions.

Numerous studies on the photolysis of ketones have shown that there are two main pathways to their decomposition, which are referred to in the literature as the Norrish type I and II reactions. The decomposition of ketones via the type I reaction results in the formation of free radicals:

$$R_1—\underset{\underset{O}{\|}}{C}—R_2 \xrightarrow{h\nu} R_1—\underset{\underset{O}{\|}}{C}\cdot + R_2^{\cdot} \quad \text{or} \quad R_1^{\cdot} + R_2^{\cdot} + CO$$

which can then react with the solvent. The decomposition via the type II reaction leads to molecular products:

Since decomposition via the type II reaction requires the formation of an intermediate six-membered complex, only ketones with at least one hydrogen atom in the γ-position relative to the carbonyl group can decompose via this pathway, i.e. in polyolefins with C=O groups in the main chain there is a possibility of an intramolecular hydrogen transfer in which an olefin and an enol are formed, the latter in its turn giving rise to a ketone with a shorter chain.

Hartley and Guillet[16] investigated the photolysis of model aliphatic ketones R—C(O)—R, with the chain length of the alkyl group ranging from C_7 to C_{43}, under the influence of light at a wavelength of 313 nm. It was shown that the decomposition quantum yields φ_I and φ_{II} depend on the chain length of the alkyl group in the ketone, viscosity, and temperature. Fig. 4 shows the variation of φ_I and φ_{II} with the chain length of the alkyl group. It is seen that an increase in the length of the carbon atom chain entails a decrease of φ_I and φ_{II}, φ_I reaching a limiting value at C_{40} and φ_{II} falling rapidly with increase of chain length and reaching 0.06 for the ketone containing 43 carbon atoms. After this, φ_{II} decreases much more slowly reaching a value of 0.025 in the polyethylene copolymer containing 1% CO.

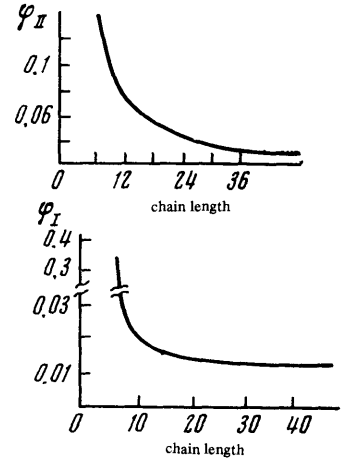

Figure 4. Variation of the quantum yields φ_I and φ_{II} of the decomposition of ketones with the length of the chain of the alkyl group (in liquid paraffin at 70°C).

The decrease of the quantum yield is probably caused by an increase in the probability of radiationless dissipation of energy with increase of the number of atoms in the ketone molecule. Table 1 presents the temperature variation of the quantum yields for the formation of the photochemical decomposition products of pentadecan-8-one, which decomposes according to the mechanism

$$CH_3(CH_2)_5CO(CH_2)_6CH_3 \xrightarrow[II]{h\nu} CH_2{=}CH(CH_2)_3CH_3 + CH_3CO(CH_2)_6CH_3,$$

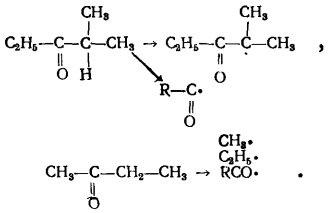
$$CH_3(CH_2)_5CO(CH_2)_6CH_3 \xrightarrow[I]{h\nu} CH_3(CH_2)_6\cdot + \cdot CO(CH_2)_6CH_3$$

$$CH_3(CH_2)_6\cdot + CO.$$

The data in Table 1 show that the quantum yield of the type II reaction does not depend appreciably on temperature ($E_{act} \simeq 1$ kcal mole^{-1}). On the other hand, the quantum yield in the formation of heptane via the type I reaction increases fairly rapidly with temperature ($E_{act} = 4.8$ kcal mole^{-1}). The results can be explained bearing in mind that the type I reaction involves the dissociation of a bond in the molecule with formation of radicals. Consequently it should depend on temperature, albeit not as

markedly as the analogous thermal bond dissociation. An essential requirement for the type II reaction is the formation of a six-membered complex, which depends only on the extent to which the internal rotation of the groups in the molecule is free and this in turn is independent of temperature above the glass point of the polymer. φ_I and φ_{II} were found to be virtually independent of viscosity, which was varied from 0.28 to 9.2 cP.

Table 1.

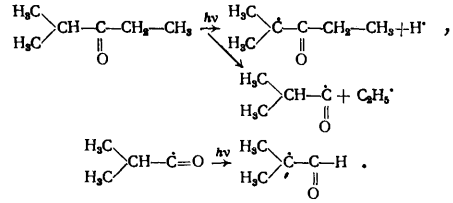


T, °C	$\varphi_I \times 10^4$	φ_{II}	φ_{II}
	heptane	hex-1-ene	nonan-2-one
30	0.22	0.066	0.067
60	0.42	0.068	0.067
90	0.87	0.091	0.086
120	1.4	0.087	0.091
145	1.9	0.092	0,102

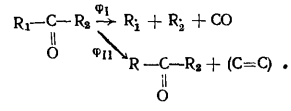
Table 2.

T, °C	Quantum yield of rupture reactions $\varphi_I + \varphi_{II}$	Quantum yield for accumulation of vinyl groups	
		φ_{II}	φ_I
120	0.05	0.025	0.025
90	0.04	0.025	0.015
25	0.028	0.025	0.003
—25	—	0.025	—
—50	—	0.020	—
—68	—	0.013	—
—95	—	0.005	—
—150	—	0.000	—

Both singlet and triplet states are involved in the photolysis of aliphatic ketones. Thus the photochemical decomposition of undecan-6-one is inhibited by cyclooctadiene (COD), a triplet acceptor, to an extent not greater than 55%;[17] similar results were obtained for certain other ketones and acceptors in studies[18-23] where it was shown that approximately 60—90% of the reactions in the photolysis of aliphatic ketones involve triplet levels. These results suggest that an appreciable proportion of the ketones decompose with participation of triplet states, but the mechanism of the decomposition, which is not inhibited by triplet acceptors, remains obscure.



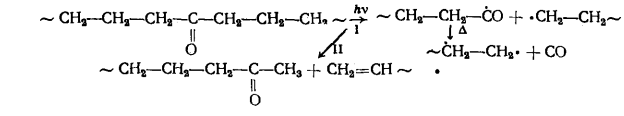
At low temperatures (77°K) the photochemical decomposition of aliphatic ketones (at wavelengths from 260 to 360 nm) leads to the formation of radicals at an appreciable concentration[24]. For example, the photolysis of ethyl isopropyl and ethyl methyl ketones results in the formation of radicals via the reactions



When specimens are irradiated with light at a wavelength higher than 400 nm and heated to −140°C, the singlet line of the R—Ċ=O radicals in the ESR spectrum disappears and only radicals in which the C=O group and the unpaired electron are separated remain:

On the basis of these data, the following mechanism has been proposed[24] for the photolysis of aliphatic ketones with dissociation of the C—C bonds adjoining the carbonyl group:

Thus analysis of data for the photolysis of low-molecular-weight aliphatic ketones made it possible to predict certain photochemical properties of polymeric ketones. The $R_1-\underset{\underset{O}{\|}}{C}-R_2$ polymeric ketone should probably decompose via type I and II Norrish reactions like aliphatic ketones:

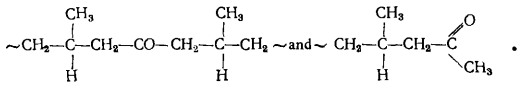


All polymeric ketones should decompose at room temperature via the type I reaction with a quantum yield of 0.05—0.1. Only ketones capable of forming the necessary six-membered complex, i.e. having a hydrogen atom joined to the carbon atom in the γ-position relative to the C=O group, decompose via the type II reaction.

On reducing the temperature, the quantum yield of the type I reaction changes slowly and the activation energy is 5 kcal mole^{-1}. The type II reaction depends significantly less on temperature but its contribution diminishes sharply with increase of the length of the R_1 and R_2 groups. Its importance can be appreciable only above the glass point of the polymer, since at lower temperatures the free rotation of the groups in the units of the macromolecule is inhibited, or in the decomposition of ketones with a C=O group close to the end of the polymer chain when at least one of the radicals formed is small.

The breaks in the polymer molecule lead to a significant change of the molecular weight of the polymer in both reactions only when the recombination of radicals formed in the type I reaction is ruled out. These conclusions have been confirmed quantitatively by the results of studies on the photolysis of pre-oxidised polypropylene and of the ethylene—carbon monoxide copolymer[15].

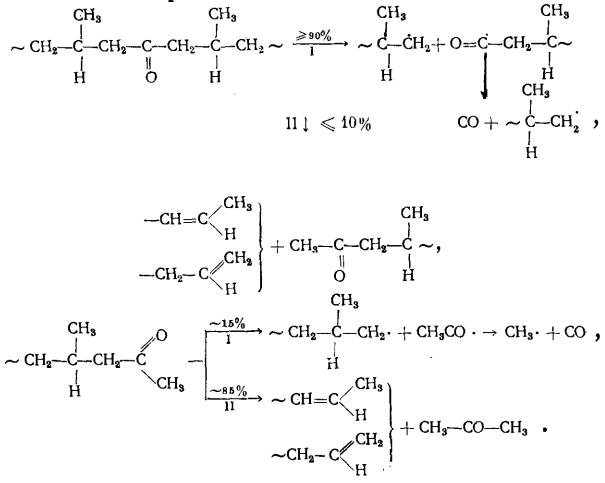
The physical properties of the ethylene—carbon monoxide copolymer containing 1—9% of carbon monoxide are the same as those of a low-pressure polyethylene. The polymer was irradiated with monochromatic light at a wavelength of 313 nm in decalin solution, and a decrease of its molecular weight, evolution of carbon monoxide, and the formation of vinyl groups were observed. These results were accounted for by the following reactions in the polymer:



Carbon monoxide and polymeric radicals are formed by the type I reaction and the type II reaction gives rise to terminal ketones and vinyl groups. Polymer chains are ruptured in both reactions. In solution the polymeric radicals abstract a hydrogen atom from the solvent molecule and do not recombine with one another, so that the quantum yield of the rupture reactions is equal to the sum of the quantum yields of both reactions. The quantum yield of the type II reaction was determined from the change in the concentration of vinyl groups. Table 2 presents the relation between the quantum yields of both reactions and temperature.

Table 2 shows that the quantum yields of the type I reaction becomes significant above 25°C, where the quantum yield of the type II reaction is independent of temperature. This can be explained as follows. It has been established[25,26] that at −30°C free rotation about the C—C bond in polyethylene is hindered and hindered joint rotation of at least three units arises. At −120°C, the joint rotation is also inhibited. Since the properties of the copolymer are similar to those of low-pressure polyethylene, retardation of free rotation about the C—C bond can also be expected near −30°C, the probability of the formation of a six-membered complex and hence φ_{II} diminishing. At −120°C, φ_{II} becomes zero. Above −30°C, where rotation is not hindered, φ_{II} should be independent of temperature, which is in fact observed experimentally.

In the solid polymer the quantum yield of the formation of vinyl groups at 25° and 90°C does not differ from φ_{II} in solution[15]. This can be explained by the fact that the destruction of radicals formed in the type I reaction does not involve the formation of double bonds (the radicals do not disproportionate but recombine). Therefore in this case the quantum yield of the rupture reactions is probably determined by φ_{II}. Unfortunately Hartley and Guillet[15] did not make such measurements. The type I and II reactions probably also occur in the photolysis of poly(methyl vinyl ketone) containing the C=O group in the side chain[27]. The quantum yield of the type I reaction, determined from the evolution of carbon monoxide and methane, increases with temperature, as for the copolymer (25—80°C), and the occurrence of the type II reaction was established on the basis of the increase of the optical density in the range 220—230 nm, which was attributed to the accumulation of double bonds.



It has been shown[17] that at 80°C the triplet quenching agent COD retards the photochemical degradation of the ethylene—carbon monoxide copolymer in solution and the accumulation of vinyl groups in the solid phase by a factor not greater than two. In contrast to the ethylene—carbon monoxide copolymer, where the carbonyl groups were distributed only in the centre of the polymer chain, preoxidised (225°C) polypropylene contains two main types of keto-groups[28]:

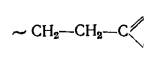
(A) (B)

In the photolysis of oxidised polypropylene containing type (A) and (B) keto-groups, a decrease in the weight of the polymer was observed and the composition of the volatile products and the change of the optical density at the absorption maxima of the fragments (A) and (B) (1718 and 1726 cm^{-1} respectively) were analysed. The quantum yields for the decomposition of both ketones were approximately identical, amounting to 0.07 and 0.08 respectively.

Analysis of the volatile products (CH_4, CO, CO_2, C_2H_6, etc.) led to the conclusion that the ketones A and B decompose via the Norrish type I and II reactions, the ketone (A) decomposing mainly into radicals and the ketone (B) into molecular products:

This set of reactions provides a satisfactory description also of the kinetics of weight loss by the polymer.

Despite the fact that the photolysis of ketones involves the rupture of the chain, an appreciable decrease of viscosity on irradiation was not observed[28]:



η before irradiation = 0.63; $M_v = 5.2 \times 10^4$,

η after irradiation = 0.60; $M_v = 4.8 \times 10^4$.

The present authors' calculation of the quantum yield of the rupture reactions on the basis of these data is 4×10^{-3}, which is consistent with the fact that the chain is ruptured only on decomposition of the central ketone (A) via the type II reaction. The macroradicals formed from the ketone (A) via the type I reaction and following the abstraction of a hydrogen atom from the macromolecule by the methyl radical [formed from the ketone (B) via the type I reaction] probably recombine, which does not lead to a decrease of the molecular weight of the polymer.

As was to be expected, the quantum yield for the decomposition of the terminal ketone via the type II reaction is higher by a power of ten, since the mass of one of the radicals adjoining the carbonyl group is small. The quantum yield of the type (I) reaction determined by Carlsson and Wiles[28] also exceeds the quantum yield of this reaction in the ethylene—carbon monoxide copolymer. We believe this to indicate that the rupture of the copolymer in the type II reaction takes place closer to the end of the molecule; owing to a change in the molecular weight distribution, the quantum yield of the rupture reactions found by Hartley and Guillet[15] from the change in viscosity is not equal to the sum of the quantum yields of the type I and II reactions and the values of $\varphi_I + \varphi_{II}$ and φ_I quoted in Table 2 are significantly too low.

We explain the change in molecular weight observed during the photolysis of the ethylene—carbon monoxide copolymer in decalin by the fact that the macroradicals formed abstract a hydrogen atom from the solvent, which results in the formation of a macromolecule with a lower molecular weight. We have been unable to find any studies on the photolysis of preoxidised polyethylene, but, if the latter contains terminal ketones,

their decomposition via the type I reaction should lead to the formation of low-molecular-weight CH_3 radicals. The recombination of these radicals with the polymer macroradicals gives rise to molecules with a lower molecular weight and the quantum yield of the rupture reactions should be relatively high, since the probability that the methyl radical abstracts a secondary hydrogen atom from polyethylene is lower than the probability that it abstracts a tertiary hydrogen atom from polypropylene.

2. Photolysis of Hydroperoxides and Peroxides

The decomposition of dialkyl peroxides (dimethyl peroxide[29], diethyl peroxide[30,31], ethyl t-pentyl peroxide[29], di-isopropyl peroxide[32,33], t-butyl isopropyl peroxide[29], and di-t-butyl peroxide[34-40]) in the gas phase has been investigated most thoroughly. It has been established that even in the gas phase the absorption spectra of these peroxides do not exhibit any structure (Fig. 5). This suggests that the O—O bond is dissociated immediately on absorption of a light quantum, without proceeding via an intermediate excited state, and two free radicals are formed.

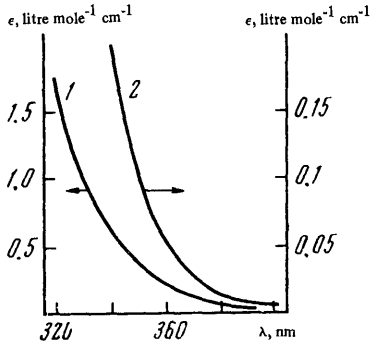


Figure 5. Absorption spectra of di-t-butyl peroxide (curve *1*) and t-butyl hydroperoxide (curve *2*).

The energy of the O—O bond in peroxides is less than 40 kcal mole^{-1}. Consequently, on irradiation with light at a wavelength of 254 nm, the excess energy of about 70 kcal mole^{-1} is distributed between two radicals. Therefore the absorption of each light quantum leads not only to the dissociation of the O—O bond but also to the formation of so called hot radicals carrying the excess energy.

The presence of a large energy excess in the radicals formed is confirmed by the analysis of the products of the photolytic decomposition of peroxides. Hot radicals readily decompose until they attain thermal equilibrium. For example, in the photolysis of di-t-butyl peroxide, acetone, methane, and ethane were detected in addition to other products; these can be accounted for by the following reactions:

$$(CH_3)_3CO^{\cdot *} \rightarrow CH_3^{\cdot} + CH_3COCH_3,$$

$$CH_3^{\cdot} + CH_3^{\cdot} \rightarrow C_2H_6 \text{ etc.}$$

McMillan[32], who investigated the photolysis of peroxides in the presence of nitric oxide (NO) as an inhibitor, reached the same conclusion. Apart from nitrites and nitrates, other products, mainly acetone, were detected in the peroxide decomposition products. On the hypothesis that only "non-hot" radicals react with the inhibitor and "hot" radicals decompose during this period, the fraction α of "hot" radicals formed in the photolysis of peroxides was determined. For example, $\alpha_{313} = 0.21$ and $\alpha_{254} = 0.6$ for di-isopropyl peroxide.

The characteristics of the photolysis of peroxides and hydroperoxides in solutions are largely the same as those of their decomposition in the gas phase. As in the gas phase, they decompose into radicals, probably without proceeding via an intermediate excited state. The absence of any long-lived excited state of the peroxide in the condensed phase is suggested to some extent by the finding that no investigation showed a retardation of their photochemical decomposition by any excited state quenching agents.

Nevertheless, the dependence of the composition of the photochemical decomposition products on the wavelength of the exciting light (Table 3) indicates the existence of hot species or complex pathways in the decomposition of peroxides by light of shorter wavelengths. The primary radical formed in the decomposition of dicumenyl peroxide (DCP) can decompose into acetone and a phenyl radical or into acetophenone and a methyl radical. This decomposition can occur in the primary photochemical step

$$[C_6H_5(CH_3)_2CO]_2 + h\nu \rightarrow \begin{cases} C_6H_5C(CH_3)_2O^{\cdot} + CH_3COCH_3 + C_6H_5^{\cdot} \\ 2C_6H_5(CH_3)_2CO^{\cdot} + 2CH_3^{\cdot} \text{ etc.} \end{cases}$$

Table 3. Yield of the main products of the decomposition of DCP at 20°C [42] as a percentage of the peroxide decomposed.

Decomposition product	Solvent			
	n-hexane		CCl_4	
	wavelength, nm			
	313	254	313	254
Dimethylbenzyl alcohol	95—100	90—95	—	—
Acetophenone	2	4	95—100	30
Acetone	—	—	5	70

The principal distinctive feature of the photochemical decomposition of peroxides in the condensed phase is a significant influence of the solvent on the composition of the decomposition products and the occurrence of induced decomposition of peroxides. For example, a study has been made[41,42] of the decomposition of t-butylhydroperoxide (TBHP) and DCP in n-hexane and carbon tetrachoride. Tables 3 and 4 present the compositions of the photolysis products of these peroxides.

The authors explain the observed composition of the products by the fact that, in solvents capable of hydrogenating the radicals (n-hexane), an alcohol may be formed by the reaction between the alkoxy-radical and the solvent. The occurrence of these reactions leads to an increase in the quantum yield of the photolysis of the peroxide owing to the induced radical decomposition. For example, the quantum yield of the decomposition of TBHP is 3.9 in n-heptane and 1.57 in DCP.

According to Martin and Norrish[41], in a solvent incapable of hydrogenating the radicals (carbon tetrachloride) the induced decomposition of the peroxide is due to the radicals formed from it.

Table 4. Main decomposition products of TBHP at 20°C [41] at 313 nm.

Decomposition products in CCl_4	Yield, % of decomposed peroxide	Decomposition products in n-hexane	Yield, % of decomposed peroxide
Oxygen	41.7	Oxygen	7.1
Carbon monoxide	0.72		
Carbon dioxide	—	Formic acid	1.2
t-Butyl alcohol	97	Alcohol	156
Acetone	3.1	Acetone	8.3
Water	5.4	Water	21

The validity of the above mechanisms for the decomposition of peroxy-compounds is confirmed by ESR data. Despite numerous attempts by various investigators, alkoxy-radicals were not detected in the photolysis of peroxides and hydroperoxides[43-46]. In solvents with a mobile hydrogen atom, an ESR signal was observed in the photolysis of hydroperoxides and their mixtures with peroxides and was attributed to peroxy-radicals from the solvent or the hydroperoxide. In solvents incapable of hydrogenation, a signal due to the peroxy-radicals formed from the hydroperoxide was observed. The absence of signals due to alkoxy-radicals can be explained by their high reactivity which results in their conversion into peroxy-radicals. This is illustrated by the data in Table 5, which lists, for clarity, the rate constants for the interaction of cumenyloxy- and cumenylperoxy-radicals with different substrates.

Table 5. Comparison of the rate constants for the interaction of hydroxy and peroxy-radicals.

Reaction	k, litre mole^{-1} s^{-1}	T°, C	References
RO· + cumene	$2.5 \cdot 10^8$	25	47
RO· + tetralinyl hydroperoxide	$2.0 \cdot 10^6$	25	48
RO· + cumene	0.64	57	49
RO· + tetralinyl hydroperoxide	12.0	67	49

In the photolysis of peroxides in aprotic solvents and sometimes at a low temperature in the absence of oxygen, radicals formed as a result of the decomposition of alkoxy-radicals are observed. For example, the signal due to methyl radicals formed by the reaction

$$(CH_3)_2C_6H_5CO\cdot \rightarrow CH_3\cdot + CH_3COC_6H_5$$

is observed in the photolysis of DCP at 77°K. Thus ESR data agree with the homolytic dissociation of the O—O bond as the primary step in the photolysis of the peroxide, with formation of alkoxy-radicals, which then enter into further reactions.

In certain cases, the ESR method makes possible a more detailed investigation of the step involving the decomposition of the peroxides into radicals[52]. Thus in the photolysis of acyl peroxides from peroxydisuccinic acid, peroxydiglutaric acid, and lauroyl, benzoyl, and acetylbenzoyl peroxides at 77°K (wavelength of irradiating light 300 nm), the ESR spectra consist of broad doublets which are attributed to radical pairs (RP). When a radical pair is exposed to a second light quantum, its constituent radicals emerge from the cage. A six-line spectrum due to the alkyl radicals R· is then observed. The formation of alkyl radicals from acyl peroxides under the influence of light proceeds via the following two-quantum mechanism:

$$R{-}\overset{\overset{O}{\|}}{C}{-}O{-}O{-}\overset{\overset{O}{\|}}{C}{-}R \xrightarrow{h\nu_1} RP \xrightarrow{h\nu_2} R\cdot + CO_2$$

$$[R{-}\overset{\overset{O}{\|}}{C}{-}O\cdot\cdot R]$$

Indeed, it has been established[50-52] that the yield of the radicals R· at 77°K in the photolysis of peroxides of aliphatic acids (butyric, lauric, caproic, and capric) is proportional to the square of the light intensity. Probably these results are related to the low mobility of the radicals in the solid matrix at liquid nitrogen temperature. At higher temperatures, the rate of photochemical decomposition of acyl peroxides is proportional to the light intensity and the fraction of acyl (70%) and alkyl (30%) radicals formed at 20—40°C is independent of temperature[53].

Table 6. Effect of sensitisers on the decomposition of peroxides.

3. Photosensitised Decomposition of Peroxides

Usually the dissociation of the O—O bond in the peroxide requires an energy of less than 40 kcal mole^{-1}. However, the absorption spectra of peroxides suggest that direct decomposition of peroxides requires a considerable amount of energy, of the order of 100—110 kcal mole^{-1} (300—250 nm). Therefore the decomposition of peroxides can occur in sensitised reactions when the sensitiser absorbs light at much longer wavelengths. Photosensitising reactions may be of two types. The absorption of light by the sensitiser can lead to the decomposition of the peroxide into radicals following energy transfer from the sensitiser to the peroxide[54-57] or the sensitiser can propagate the free radical-induced decomposition of the peroxide[58,59]. The sensitisers may be ketones[54,57], aromatic hydrocarbons[55], compounds with condensed nuclei[56], and variable-valence metals[60]. The commonest sensitisers of the

photochemical decomposition of peroxides are various ketones. Table 6 presents data for the effect of ketones on the decomposition of peroxides[56].

Probably sensitisation involves energy transfer from the triplet level of the sensitiser to the peroxide molecule, since the table shows that the sensitisers may be compounds with $n\pi^*$ and $\pi\pi^*$ excited states, where the energy of the triplet level is higher than 55 kcal mole^{-1}. Anthracene, which according to Tsvetkov et al.[68] sensitises the decomposition of peroxides via an excited singlet state with an energy of 76 kcal mole^{-1}, is an exception.

The mechanism of the sensitised decomposition of peroxides can probably be represented as follows[54]:

$$S \xrightarrow[\varphi']{h\nu} S^*$$

$$S^* \xrightarrow{k_d} S$$

$$P + S^* \xrightarrow{k_t} S + P^*$$

$$P^* \xrightarrow{k_d'} P$$

$$P^* \xrightarrow{k_r} \text{products},$$

where S is the sensitiser and P the peroxide. Hence

$$1/\varphi = \left(1 + \frac{k_d'}{k_r}\right)\left(1 + \frac{k_d}{k_t}[P]\right)$$

where φ is the quantum yield of the decomposition of the peroxide.

It has been found for the decomposition of benzoyl peroxide sensitised by benzophenone at room temperature that

$$\frac{k_d}{k_r} = 2.92 \text{ and } \frac{k_d}{k_t} = 0.03 \text{ mole litre}^{-1},$$

i.e. approximately 25% of the peroxide molecules decompose into radicals, while the remaining molecules return to the initial state as a result of the recombination of the radicals in the cage.

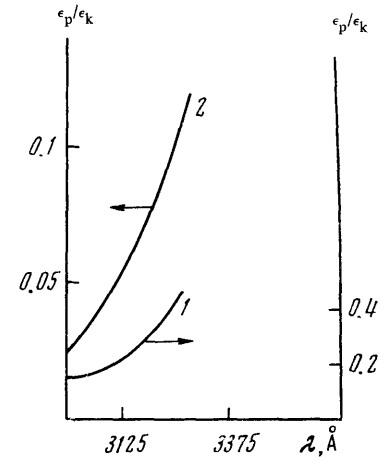
4. Photolysis of Polyolefin Hydroperoxides

The study of the photolysis of polymeric hydroperoxides is complicated by the fact that it is virtually impossible to obtain a polymer containing only hydroperoxy-groups[62]. In the low-temperature thermal and photochemical oxidation, hydroperoxy- and carbonyl groups accumulate simultaneously (Fig. 6). Therefore the photolysis of hydroperoxides is always accompanied by the photolysis of ketones.

The ratio of the molar extinction coefficients of hydroperoxides and ketones increases in the long-wavelength part of the spectrum (Fig. 7). Therefore the characteristics of the photolysis of hydroperoxides are clearly shown when they are irradiated with light at a wavelength longer than 365 nm. The decomposition of polypropylene hydroperoxide (PPHP) (at a concentration of 0.1—0.3 M) was observed[28] under these conditions, while the presence of ketones (0.01—0.1 M) in the polymer did not have a significant influence on this process.

As for low-molecular-weight hydroperoxides, the decomposition of polymeric hydroperoxides under the influence of light probably proceeds without an intermediate state. It involves the formation of two radicals, one of which (OH) can readily abstract a hydrogen atom from the polymer with formation of water. Indeed it has been shown[28], that, when PPHP is irradiated with light at a wavelength of 365 nm, each decomposed hydroperoxide molecule results in the formation of one water molecule.

Figure 6. Infrared absorption spectra of oxidised polypropylene films: *a*) oxidation in the melt at 225°C in air, thickness 37 μm: *b*) photochemical oxidation (λ = 370 nm) for 200 h, thickness 40 μm.



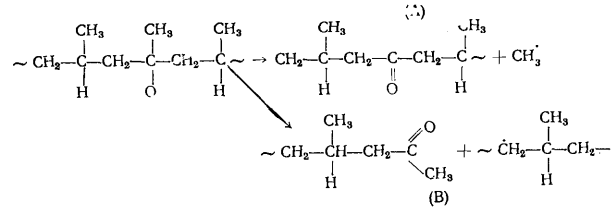


Figure 7. Dependence of the ratio of the molar extinction coefficients of the peroxides and 2,6-dimethylheptan-4-one on the wavelength of the light: 1) di-t-butyl peroxide; 2) t-butyl hydroperoxide.

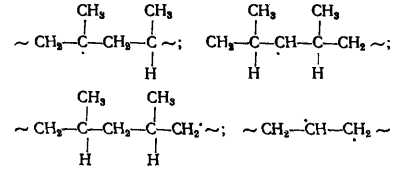
The radical RO can abstract a hydrogen atom from the polymer with formation of an alcohol and can decompose via the following reactions:

Analysis of the photolysis products of PPHP leads to the conclusion that the ketones (A) and (B) are formed in approximately identical yields. The decomposition of

low-molecular-weight hydroperoxides in solution would result in the preferential formation of the ketone (B).[63,64] This is probably due to the reduced mobility of the high-molecular-weight skeleton of the molecules, which results in a decrease in the quantum yield of the main chain rupture reactions.

The amount of alcohol formed was determined by measuring the absorption in the region of 3400 cm^{-1} (corresponding to the hydrogen-bonded hydroxyls) before and after treating the film with SO_2 in order to remove hydroperoxides[65]. Since the concentration of the hydroperoxide greatly exceeds that of the alcohol, the error in the determination of the latter can be fairly large. However, the data of Carlsson and Wiles[28] indicate its presence in the photolysis products.

Data for the quantitative yield of water in the photolysis of PPHP and the weight loss by the specimen on decomposition of one mole of the peroxide (22 g $mole^{-1}$) show that the photolysis of each hydroperoxy-group gives rise to the formation of one OH· radical and that there is no induced decomposition of the hydroperoxide. This is also indicated by the low yield of the alcohol.



However, at a low temperature, the photolysis of this hydroperoxide is accompanied by the formation of the peroxy-radical $RO_2^{\cdot}$ [66] which can be formed in the absence of oxygen only as a result of the induced decomposition of the peroxide. However, details concerning the removal of oxygen dissolved in the polymer film are not given in Ershov's paper[66]. Possibly the $RO_2^{\cdot}$ radical is formed from the RO· or R· radical by reaction with oxygen. Thus the question of the induced decomposition of PPHP remains open. In the study of Carlsson and Wiles[28], the quantum yield of the decomposition of PPHP was found to be 4.0 ± 0.5, which the authors attribute to the difference between the molar extinction coefficients of PPHP and t-butyl hydroperoxide, the spectrum of which was used to determine the amount of absorbed light.

Sensitised decomposition by the ketones present in the polymer is not observed in the decomposition of PPHP under the influence of light at a wavelength of 365 nm. The quantum yield of the decomposition of the peroxide does not change when the concentration of ketones is altered almost by a power of ten. Thus the photolysis of PPHP occurs with a decomposition quantum yield close to unity with formation of alkyl radicals (polymeric or $CH_3^{\cdot}$), a ketone, and hydroxyl-radicals. The latter give a quantitative yield of water and alkyl radicals. The alkyl radicals probably do not recombine with one another, as shown by the small change in the molecular weight of the polymer during irradiation.

Very small amounts of methane and ethane, formed in different reactions of methyl radicals, were detected in the volatile photolysis products.

5. Radical Formation in Polyolefins

Degenerate branching of the photochemical oxidation chains occurs in those reactions of hydroperoxides and ketones where they give rise to free radicals. The formation of free radicals in the photolysis of polyolefins at low temperatures can be detected by the ESR method. However, sufficient data are not yet available for a quantitative comparison of the compositions of the photolysis products of oxidised polyolefins with the quantum yields for radical formation in these processes. The majority of studies on the amounts and structures of the radicals formed have been made with γ-irradiated specimens[68-70] and the effect of ultraviolet irradiation on polyolefins has been investigated very much less thoroughly[71-73]. When polyethylene is irradiated with ultraviolet light (77°K, total light of a mercury lamp) *in vacuo*, a signal, consisting of a mixture of a sextet (with a splitting of 21 G) and a quintet (with a splitting of 120 G) is observed. By analogy with data obtained for γ-irradiated specimens, the sextet is attributed to the radical $CH_2-\dot{C}H-CH_2$ and the quintet to the terminal radical $-CH_2-\dot{C}H_2$. The latter is detected only when polyethylene is irradiated by ultraviolet light; in particular it can be the radical formed by the photolysis of carbonyl compounds. When polypropylene is irradiated with ultraviolet light, a signal, consisting of two superimposed quartets with a splitting of 23 G is observed[24,67,71,73,74]. The narrower of the quartets refers to the methyl radical CH_3 and the second, broader, and more diffuse quartet refers to a mixture of radicals:

As with the γ-irradiated polymers, the fraction of each radical was not determined. When the irradiated polymer is heated to 178°K for 10 min, approximately 40% of the initial concentration of radicals remain, while on heating to room temperature all the radicals vanish[71]. On repeated irradiation of the specimen by light at wavelengths less than 270 nm, the broad signal of the polymeric radicals is partly converted into the narrower signal of methyl radicals[24].

When partly oxidised polypropylene is irradiated *in vacuo*[24,67,75], a complex asymmetric signal is observed, in which the singlet line of an oxygen-containing radical (RO· according to the authors) predominates. At the same time alkyl radicals are formed in the system. The fraction of each of these radicals and the quantum yields for their formation were not determined.

Unfortunately in all the studies quoted above the nature of the absorbing centres in the polyolefins and their role in the accumulation of radicals in the polymer were not investigated. Admittedly, the accumulation of radicals in oxidised polypropylene has been attributed[75] to the photolysis of hydroperoxides but the role of the keto-groups inevitably present in the polymer was not taken into account quantitatively.

Some investigators[3,24] believe that the absorbing centres in polyolefins responsible for radical formation are admixtures of aromatic hydrocarbons—naphthalene, anthracene, phenanthrene, etc., known to be photosensitisers of the ageing of polymers[4]. According to their data, the ESR spectrum obtained on irradiation of polypropylene with ultraviolet light in the presence of added phenanthrene agreed fully with the ESR spectrum of irradiated commercial polypropylene[24].

The differences between the ESR spectra of oxidised polypropylene and polypropylene containing photosensitising impurities are probably associated with the difference between the reactivities of the primary excited molecules or radicals obtained on low-temperature irradiation (77°K). The composition of the photolysis products of oxidised polypropylene shows that at higher temperatures methyl and alkyl radicals are also formed in the polymer[28].

In the photosensitised degradation of polypropylene, the initial rate of radical formation is proportional to the square of the light intensity[3,24]; this can be accounted for

by the transition of the impurity to a photochemically active state in a two-quantum process proceeding via a triplet state. The formation of radicals in polyolefins sensitised by aromatic compounds can probably be regarded as a result of transfer of excitation energy from the highest triplet levels of the sensitiser to the matrix or as a result of a two-quantum degradation of the sensitiser with subsequent reaction between the products and the polymer[76,77].

Naturally, similar two-quantum processes play a significant role at a low temperature and a high light intensity. The extrapolation of these data to natural conditions must be performed with much caution.

The free radicals formed in polyolefins under the influence of light can undergo various interconversions. Thus polymeric alkyl radicals can be converted into allyl radicals under the influence of the light of a xenonormercury lamp. The mechanism of this process has not so far been established. It is only known that the reaction is reversible and the reverse process was investigated in fair detail[78,79].

Photolysis of polymeric alkyl radicals by light at wavelengths less than 270 nm and low temperature leads to the formation of methyl radicals[24,89]. Photolysis of polymeric peroxy-radicals by light at wavelengths greater than 280 nm and also at low temperature yields an excited peroxy-radical which abstracts a hydrogen atom from the polymer and gives rise to a hydroperoxide and an alkyl radical via the reactions[89]

$$RO_2^{\cdot} + h\nu_{<280} \rightarrow RO_2^{*},$$
$$RO_2^{*} + RH \rightarrow [RO_2H + R^{\cdot}],$$

Under the influence of short-wavelength light (<280 nm), a peroxy-radical is probably formed in another excited state $RO_2^{*'}$ or the product is an exciplex decomposing into radicals:

$$RO_2^{\cdot} + h\nu_{<280} \xrightarrow{RH} [RO_2^{*'} + RH] \rightarrow \dot{R} + \dot{R}O + \dot{O}H \xrightarrow{+RH} 2\dot{R} + \dot{R}O + H_2O$$

i.e. in this case the photolysis of the peroxy-radical leads to branching of the oxidation chain.

Close to room temperature, appreciable concentrations of free radicals are not detected when polyolefins are irradiated by light under any conditions, i.e. the lifetimes of the radicals are then short. All the photochemical reactions of radicals are secondary photochemical processes and therefore their role can be appreciable only when the lifetime of the radical is long. Consequently the role of these processes in the photochemical oxidation of polyolefins is insignificant.

Thus one can regard it as established that free radicals are formed in the initiation steps and in the degenerate branching of the photochemical chain oxidation of polyolefins. There have not yet been any rigorous quantitative studies permitting the determination of the nature of the radicals and the quantum yields of the radical formation processes and enabling the role of the two-quantum processes and the photolysis of the polymeric radicals formed to be taken into account. However, the principal features of the reactions occurring in the degenerate branching step of the polyolefin photochemical oxidation chain are clear.

Hydroperoxides with an absorption spectrum of the type shown in Fig. 5 are decomposed with a quantum yield close to unity. The occurrence of sensitised decomposition of hydroperoxides has not been established exactly. The terminal and central aliphatic ketones have approximately identical absorption spectra (Fig. 3) and accumulate during the oxidation process in approximately equal concentrations. The average quantum yield of their photochemical decomposition is close to 0.1. Each ketone molecule decomposed yields on average of one alkyl radical and one molecule of another ketone with a single break in the chain of the polymer molecule.

In the presence of an excess of oxygen, all the alkyl radicals are converted into peroxy-radicals and, apart from the peroxy-radical, each alkoxy-radical gives rise to one ketone molecule and each hydroxy-radical yields a water molecule.

As a result, the degenerate chain branching stage in the photochemical oxidation can probably be represented as follows:

$$POOH + h\nu - PO + OH \xrightarrow{2O_2+2PH} H_2O + K + 2PO_2,$$
$$K + h\nu \xrightarrow{+O_2} PO_2 + K + S(=),$$

where POOH is the polymer hydroperoxide, PO and PO_2 are the alkoxy- and peroxy-radicals of the polymer, K is the ketone, and S(=) represents compounds with a double bond.

IV. PROPAGATION AND TERMINATION OF OXIDATION CHAINS

The chain propagation and termination stages in the photochemical oxidation of polyolefins probably do not differ from the analogous reactions in thermal oxidation and proceed without the involvement of light. Both these stages in the thermal oxidation of polyolefins have now been discussed in the literature[90-92], but we are not aware of analogous studies on photochemical oxidation. The oxidation chain propagation and termination stages can be best investigated separately in the course of sensitised oxidation. The kinetic mechanism of this process in the presence of an excess of oxygen can be represented by the following set of reactions:

$$\begin{aligned} &Y \xrightarrow{w_i} \dot{r} \xrightarrow{(O_2)} R \ (1) \text{ chain initiation},\\ &RO_2 + RH \xrightarrow{k_p} RO_2H + \dot{R} \ (2),\\ &R + O_2 \xrightarrow{k_p'} RO_2 \ (3) \text{ chain propagation},\\ &RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_t} (4) \text{ quadratic chain termination}, \end{aligned} \qquad (I)$$

where Y is a sensitiser decomposing into radicals at a rate w_i and k_p and k_t are the rate constants for chain propagation and termination.

The rate of oxidation w is determined by the rate of chain propagation. Therefore the rates of accumulation of hydroperoxides in reaction (2) and of absorption of oxygen in reaction (3) determine the value of w:

$$w = \frac{d(\text{ROOH})}{dt} = \frac{d(O_2)}{dt} - nw_i = \frac{k_p}{\sqrt{k_t}}\sqrt{w_i}(\text{RH})$$

where nw_i is a term taking into account the absorption of oxygen in the chain initiation step and its evolution in the chain termination.

However, it is hard to study the pure sensitised oxidation of polyolefins because it is difficult to introduce sensitisers capable of decomposing into free radicals at a sufficiently low temperature where the principal branching agents (hydroperoxides) do not decompose. There have been only two investigations where studies of this kind were made, namely the oxidation of atactic polypropylene and an ethylene—propene copolymer (with benzoyl peroxide as a sensitiser) in the temperature range 85—110°C [93] and the oxidation of low-pressure polyethylene (with DCP as an initiator) at 110—130°C.[94] The parameters $k_p/\sqrt{k_t}$ found are listed in Table 7.

Table 7. Rate constants for chain propagation and termination in the oxidation of polypropylene.

*These values of $k_p/\sqrt{k_t}$ were obtained in the sensitised oxidation of polymers.
**Low-pressure polyethylene.

The chain propagation and termination rate constants for polyolefins were obtained mainly in studies on degenerate branched-chain thermal oxidation. Degenerate branched-chain oxidation and unimolecular chain branching and quadratic termination reactions have been discussed[95]. The accumulation of the peroxide and the absorption of oxygen in such a system in the initial stages is described by a parabola in accordance with equations (5) and (6):

$$ROOH = ROOH_\infty (1 - e^{-\frac{k_0}{2}t})^2 \simeq ROOH_\infty \left(\frac{k_0}{2}t\right)^2, \quad (5)‡$$

$$\Delta O_2 = ROOH_\infty (2k_0 t - (5 - e^{-\frac{k_0}{2}t})(1 - e^{-\frac{k_0}{2}t}) \simeq ROOH_\infty \left(\frac{k_0}{2}t\right)^2, \quad (6)$$

where $ROOH_\infty$ is the limiting concentration of the peroxide and k_0 is the hydroperoxide decomposition rate constant.

It has been shown[90,91] that the thermal oxidation of polypropylene in the initial stage does indeed obey Eqns.(5) and (6) and at more advanced stages of the reaction, where the consumption of the polymer oxidised cannot be taken into account, the rate of oxidation decreases according to the law

$$\frac{1}{RH_0 - \Delta O_2} = 2\frac{k_p^2}{k_t}t + \text{const.} \quad (7)$$

Eqns. (5)—(7) make it possible to determine the same parameter $k_p/\sqrt{k_t}$ from the initial section of the kinetic curve and from the section where the concentration of the peroxide reaches a limiting level. The values of the parameter $k_p/\sqrt{k_t}$ found by these two procedures agree, which demonstrates the validity of the mechanism employed.

The absolute values of the constants k_p and k_t have been determined[84]. In the same study, the rate of steady-state autoxidation of polypropylene after the induction period was investigated. Under these steady-state conditions, measurements were made of the rate of absorption of oxygen $(dO_2/dt)_s$ and of the concentration of the hydroperoxide $(ROOH)_s$ and it was found that the decomposition of the peroxide in the formation of two radicals:

$$k_p = (-dO_2/dt)_s/(RO_2)(RH),$$
$$k_t = (-dO_2/dt)_s/2(RO_2)^2,$$

Table 7 list the values of k_p, k_t, and of the parameter $k_p/\sqrt{k_t}$ obtained. For comparison, the parameter $k_p/\sqrt{k_t}$ for polyethylene is also included. This value agrees well with the corresponding parameter for 1,3,5-trimethylpentane[96]:

$$\frac{k_p}{\sqrt{k_t}} = 8 \cdot 10^{-4} \text{ litre mole}^{-1}\text{ s}^{-1/2} (130°).$$

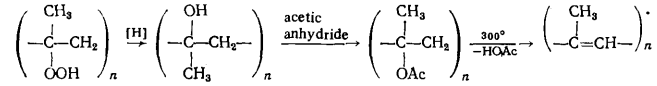
‡ Eqns. (1)—(4) are missing in the Russian original (Ed. of Translation).

The activation energy for the parameter $k_p/\sqrt{k_t}$, determined in the temperature range 110—140°C, is approximately 10 kcal mole^{-1}, which is also close to the corresponding value for low-molecular-weight compounds. Thus the chain propagation and termination stages in the oxidation of polyolefins above 100°C proceed in the same way as for low-molecular-weight compounds in the liquid phase.

At 200—250°K the kinetics of the destruction of radicals should not be determined by their chemical reactivity but by their mobility in the polymer matrix[88,89]. Therefore at a somewhat higher temperature, close to room temperature, the specific features of the solid phase can presumably also influence significantly the mechanisms of the chain propagation and termination reactions. However, we are unaware of any studies in which a detailed investigation was made of the influence of the specific features of the solid phase on the mechanism of the oxidation of polyolefins. One can only point to a study where a relation between the kinetics of the thermal oxidation of polypropylene and the supermolecular structure of the specimen was observed[97].

V. CHARACTERISTICS OF THE OXIDATION OF POLYMERS

The above discussion of the principal stages in the oxidation of polymers showed that, as in the oxidation of low-molecular-weight compounds, the principal products of the oxidation of polyolefins are peroxides, ketones, alcohols, and ethers. However, the great length of the polymer chain is responsible for certain specific features of the structure of these compounds. For example, polypropylene oxidised in a solution containing a sensitiser consists of "blocks" which incorporate between two and eight hydroperoxy-groups[98]. Data for the distribution of the hydroperoxy-groups in the blocks have been obtained by analysing the ultraviolet spectra of polyenes obtained from the hydroperoxide via the mechanism



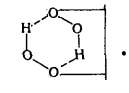


Fig. 8 presents data on the distribution of "adjacent" (located at neighbouring carbon atoms) hydroperoxy-groups in polypropylene hydroperoxide. The figure shows that the majority of the blocks contain two hydroperoxide groups. PPHP does not contain any isolated hydroperoxy-groups[98].

Analysis of the infrared absorption spectra of PPHP showed in addition that more than 90% of the hydroperoxy-groups are linked by hydrogen bonds. The PPHP structure can be represented as follows:

This structure shows that in each block with an odd number of groups one hydroperoxy-group is involved in hydrogen bonding.

By analogy with these data, it is believed[99] that isolated hydroperoxy-groups are also not encountered in polyethylene hydroperoxide (PEHP). The structure of PEHP can be represented by the formula

where P is a hydroxy- or carbonyl group. This structure of polyolefin hydroperoxides is consistent with ESR data. It has been noted[100] that the form of the ESR line associated with peroxy-radicals in polypropylene and polyethylene hardly changes with temperature in the range between −200° and 100°C. On the other hand, in Teflon, for example, the line form does depend significantly on temperature[101]. This result implies that the O—O group in polyolefins remains immobile in the temperature range investigated. The authors attribute this to the fact that fairly strong hydrogen bonds, capable of fixing the O—O group in a specified position, are formed in polypropylene and polyethylene.

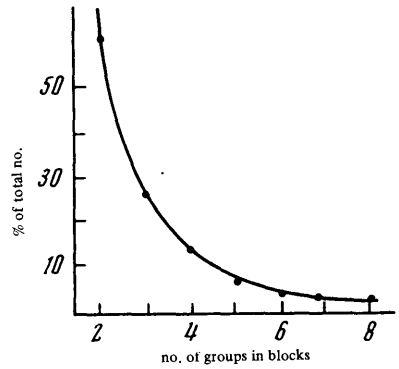

Figure 8. Distribution of hydroperoxy-groups in the blocks of oxidised polypropylene.

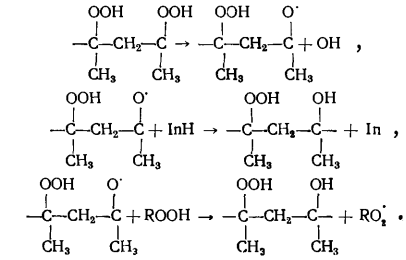
This structure of the polymer oxidation products is associated with the fact that the oxidation proceeds to a considerable degree via an intramolecular mechanism in the presence of a high local concentration of oxidation products. The presence of several functional groups in the immediate vicinity of one another within a single macromolecule alters their properties and reactivities. For example, thermal decomposition of PPHP and PEHP *in vacuo* proceeds according to a complex law and can be represented by two consecutive unimolecular reactions with rate constants differing by more than a power of ten[90,99,102,103]. Table 8 presents the rate constants for the slow and rapid stages of the decomposition of PPHP and PEHP.

The faster stage of the decomposition of the hydroperoxide is attributed to the decomposition of the hydroperoxy-groups linked by hydrogen bonds to similar OOH groups[99,102]. The slow stage is attributed to the decomposition of a β-hydroxyhydroperoxide. This interpretation is supported by the increase in the fraction of hydroperoxy-groups, undergoing a slower decomposition at more advanced stages of the hydroperoxide decomposition process and also in the presence of oxidation inhibitors, for example 2,6-di-t-butyl-*p*-cresol[102]§.



The rate constants for both stages of the decomposition of polyolefin hydroperoxides in solution and in crystalline and amorphous polymers are similar. This confirms that the decomposition of the hydroperoxide proceeds intramolecularly. The bulk of the polymer oxidation products are obtained as a result of further reactions of the hydroperoxides, the structures of the products being determined by the characteristics of the hydroperoxide structures. For example, the infrared spectra of oxidised polypropylene have a broad band in the region of absorption by the carbonyl group (1720 cm^{-1}), which, as already stated, is a result of a superposition of the absorption bands due to several ketones (Fig. 6).

By interpreting their spectra on a computer, Carlsson and Wiles[28] established that at least 9 ketones are formed in polypropylene at 220°C in air:

This result is probably not entirely unambiguous, since Adams[104] obtained a similar spectrum, which he interpreted as a result of the superposition of the absorption bands of ketones, aldehydes, acids, esters, and γ-lactones. At present it is apparently difficult to specify exactly the composition of the polyolefin oxidation products. Presumably they include two ketones corresponding to the location of the C=O groups at the end and in the middle of the chain and having absorption maxima at 1718 and 1726 cm^{-1} respectively.

§ In both these cases, the β-hydroxyhydroperoxide accumulates at a comparatively high concentration as a result of the reaction

Even the qualitative composition of the products accumulated in the polymer depends on its oxidation conditions. For example, under the conditions of the industrial processing of olefins (at about 200°C), polyolefin hydroperoxides decompose almost completely and from the entire range of oxidation products polymeric ketones are mainly obtained. At a lower temperature, considerable amounts of peroxides accumulate in the polymers[62,90,92]. However, it is almost impossible, as already stated, to obtain the pure polymeric peroxide by the oxidation reaction. It is always accompanied by decomposition products (ketones)[62].

VI. KINETICS OF THE PHOTOCHEMICAL OXIDATION OF POLYOLEFINS

The above discussion of the individual stages of the photochemical oxidation of polyolefins showed that the kinetic mechanism II of this process can be formulated as follows:

$$S_1 + h\nu \rightarrow PO_2 \quad (8)$$

$$POOH + h\nu \rightarrow PO^{\cdot} + OH^{\cdot} \xrightarrow{2O_2+2PH} 2PO_2 + H_2O + K \quad (9)$$

$$K + h\nu \xrightarrow{2O_2} (PO_2) \text{ for } (K + S(=)) \quad (10)$$

(II)

$$PO_2 + PH \xrightarrow[k_p]{O_2} POOH + PO_2 \quad (11)$$

$$PO_2 + PO_2 \xrightarrow{k_t} K + POH + O_2 \quad (12)$$

where S_1 is the sensitising impurity in the polymer PH.

The photochemical oxidation of polymers which hardly absorb light thus differs from the thermal oxidation only by a greater complexity of the degenerate chain branching and chain termination steps. The kinetics of this process can be described by the following set of differential equations:

$$\frac{d(POOH)}{dt} = -\frac{\alpha I_0 (POOH)}{2} + \frac{k_p}{\sqrt{k_t}} \Pi H \sqrt{(\alpha POOH + \alpha_1 K + \alpha_0 S) I_0}, \quad (13)$$

$$\frac{d(O_2)}{dt} = (\alpha POOH + \alpha_0 S + \alpha_1 K)\frac{I_0}{2} + \frac{k_p}{\sqrt{k_t}} pH \sqrt{(\alpha POOH + \alpha_1 K + \alpha_0 S) I_0}, \quad (14)$$

$$\frac{dK}{dt} = \alpha I_0 POOH \quad (15)$$

where the coefficients α_0, α, and α_1 are products of the molar extinction coefficient and the quantum yield for the formation of free radicals in the photolysis of the impurity, the peroxide, and the ketone respectively.

Eqns. (13)—(15) become identical with Eqns. (5) and (6) describing the thermal oxidation of polyolefins when $\alpha_1 = 0$. The solution becomes particularly simple when $\alpha_0 = 0$; then, in the absence of photolysis of impurities, the mathematical description of the process becomes analogous to the description of the thermo-oxidative degradation given by Pudov[90]:

$$\frac{POOH}{POOH_\infty} = (1 - e^{-\frac{\alpha I_0}{4} t})^2,$$

$$\frac{K}{POOH_\infty} = \alpha I_0 t - 2(3 - e^{-\frac{\alpha I_0}{4} t})(1 - e^{-\frac{\alpha I_0}{4} t}), \quad (16)$$

$$\frac{\Delta O_2}{POOH_\infty} = \alpha I_0 t - (5 - e^{-\frac{\alpha I_0}{4} t})(1 - e^{-\frac{\alpha I_0}{4} t}),$$

where

$$POOH_\infty = \frac{4k_p^2 PH^2}{\alpha k_t I_0}$$

is the limiting concentration of the peroxide which can accumulate in the system. The equations show that the concentration of the reactants initially increases autocatalytically according to a parabolic law:

$$\frac{\Delta O_2}{POOH_\infty} \simeq \frac{POOH}{POOH_\infty} \simeq \left(\frac{\alpha I_0}{4} t\right)^2, \quad \frac{K}{POOH_\infty} \simeq \frac{2}{3}\left(\frac{\alpha I_0}{4} t\right)^3; \quad (16')$$

After a time of the order of $0.2/\alpha I_0$, a significant concentration of the peroxide accumulates, whereupon after a time $t = 4 \ln 2/\alpha I_0$ the rate of accumulation of the hydroperoxide reaches its maximum value $\alpha I_0 (POOH)_\infty/8$ and after a time of the order of $10/\alpha I_0$ its concentration reaches a steady-state value.

The steady-state concentration of the peroxide is inversely proportional to the light intensity, but it is attained faster at higher light intensities. This is illustrated by the data in Fig. 9, which presents kinetic curves for the accumulation of the peroxide calculated from Eqn. (16) for light intensities differing by a factor of 100.

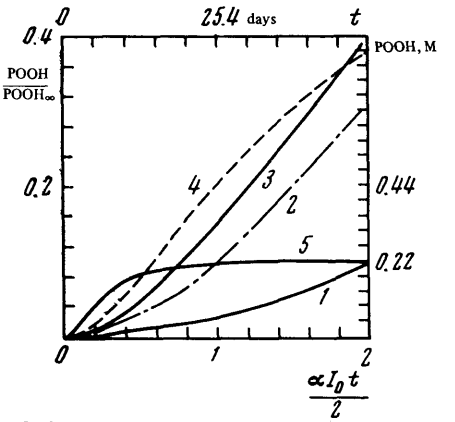


Figure 9. Calculated kinetic curves for the accumulation of peroxides at different incident light intensities: 1) $0.1\,I_0$; 2) $0.5\,I_0$; 3) I_0; 4) $2\,I_0$; 5) $10\,I_0$; $POOH_\infty$ corresponds to curve *3*. The right-hand and upper scales correspond to $I_0 = 10^{16}$ quanta s^{-1} cm^{-2} (365 nm monochromatic light of PRK-7 lamp 6 cm from the centre). The extinction coefficient of the peroxide at 365 nm is 0.012 litre $mole^{-1}$ cm^{-1}.

The kinetic curves for the accumulation of peroxides and carbonyl groups and for the absorption of oxygen in the course of the photochemical oxidation are presented in Fig. 10. At the beginning of the process, the entire absorbed oxygen is used to form the peroxide; along this section, the kinetic curves *1* and *2* coincide. At more advanced stages of the oxidation process, the kinetic curves for the absorption of oxygen remain parabolic, while the accumulation of peroxides slows down, since their decomposition becomes significant. At roughly this time, relatively high concentrations of ketones accumulate.

The kinetic curve for the accumulation of ketones in the initial stages is close to a cubic parabola. After this,

as the concentration of the peroxide reaches its steady-state value, the rates of absorption of oxygen and of accumulation of carbonyl compounds also reach their steady-state values, which are equal. The kinetic curves in Figs. 9 and 10 were calculated for the condition where the polymer is free from impurities and does not absorb light in the first instants. Thus one can calculate the kinetic curves for the photochemical oxidation of "ideally" purified polyolefins, which is, so to speak, the curve for the slowest photochemical oxidation of polyolefins.

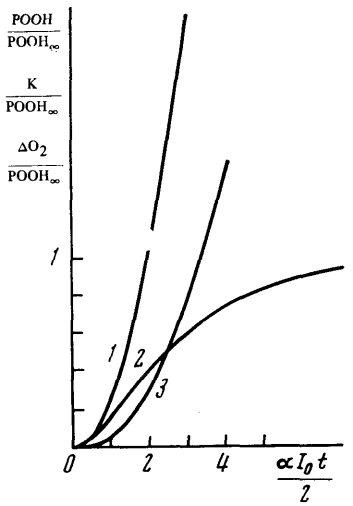

Figure 10. Calculated kinetic curves for the absorption of oxygen (curve *1*) and the accumulation of peroxides (curve *2*) and carbonyl groups (curve *3*) in photochemical oxidation.

We attempted to perform such a calculation for a real system. Fig. 9 presents the kinetic curve for the accumulation of peroxides in thoroughly purified isotactic polypropylene (curve *3*, the upper and right-hand side scales) on irradiation with light corresponding to the 365 nm line of the PRK-7 lamp at a distance of 7 cm from the source. The parameter $k_p/\sqrt{k_t}$ was calculated by extrapolating Chien and Ross's data[92] to a low temperature. Fig. 9 shows that under such conditions significant concentrations of the peroxide can accumulate in the purified polypropylene over a period of the order of one month.

The conditions $\alpha_1 = 0$ and $\alpha_0 = 0$ are fulfilled when polyolefins are irradiated with long-wavelength light whose spectral composition is close to that of sunlight [ketones do not absorb sunlight (Fig. 3) and, as shown above, impurities can have a significant influence only on the initial sensitisation].

If the sensitising impurity is not consumed in the course of the process, then its effect in the initial stage is characterised by the parameter

$$\varphi = \frac{\sqrt{\alpha_0 s I_0 k_t}}{k_p \mathrm{PH}} .$$

The initial stage of the accumulation of the peroxide is described in this case by the equation

$$\frac{\mathrm{POOH}}{\mathrm{POOH}_\infty} = \varphi \alpha I_0 t + \frac{1}{4}\left(\frac{1}{4} + \varphi\right)(\alpha I_0 t)^2 .$$

Fig. 11 presents rigorous solutions of Eqns. (13)–(15) for different values of the parameter $\varphi = \sqrt{\alpha_0 I_0 k_t s}/k_p \mathrm{PH}$. Evidently the quantity φ, characterising the role of extraneous impurities, has the greatest influence in the initial stages of the process and, when $\varphi \ll \alpha I_0 t/16$, it can be neglected. It is difficult to say anything about the value of φ owing to the wide variety of impurities in polyolefins, but, as stated above, the appreciable self-acceleration of the photochemical oxidation process suggests that it is small and decreases with time owing to the consumption of the impurity.

The absorption of light by ketones begins to be appreciable at advanced stages of the photochemical oxidation process and can be neglected when

$$I_0 \alpha t \ll \frac{(3 \div 4)\,\alpha}{\alpha_1} .$$

The ratio α_1/α is probably close to unity, since the extinction coefficient of ketones in the long-wavelength part of the spectrum is higher approximately by a power of ten than that of peroxides and the quantum yield of their decomposition into radicals is lower by a factor of 10–20 (data of Carlsson and Wiles[28,62] and Figs. 3 and 5). Thus the sections of the curves for the accumulation of peroxides up to the point of inflection should be described by Eqn. (7) for highly purified polymers.

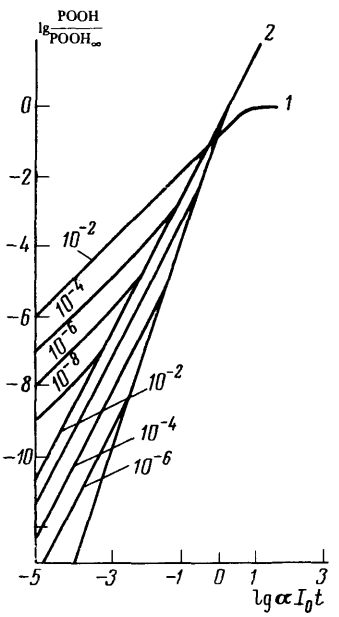

Figure 11. Logarithmic kinetic curves for the accumulation of peroxides (curve *1*) and ketones (curve *2*) in photochemical oxidation for different values of φ.

Unfortunately we were unable to find any studies in which a kinetic analysis of the photochemical oxidation of polyolefins has been carried out. Some investigators observed the accumulation of carbonyl groups in the course of photochemical oxidation and described it by an exponential relation[12] or by a curve with an induction period[13,14]. In all cases interpretation of the data quoted

permits their satisfactory description by a quadratic and cubic parabola within the framework of mechanism (II) quoted above, which corresponds to Eqns. (8)—(12). Fig. 12 presents experimental kinetic curves for the accumulation of carbonyl compounds in the photochemical oxidation of atactic polypropylene[13]. It also includes curves calculated from Eqns. (13)—(15).

For a quantitative description of the kinetics of the photochemical oxidation of polyolefins with the aid of Eqns. (13)—(15), it is necessary to know the spectral composition and absolute intensity of the light sources employed as well as the value of the parameter $k_p/\sqrt{k_t}$. It is then possible to make a quantitative calculation of the kinetic curves for the accumulation of peroxides and carbonyl compounds and for the absorption of oxygen. However, comparison of such calculation with experimental data involves certain difficulties. This is because the parameter $k_p/\sqrt{k_t}$ has not been measured at room temperature and its calculation by extrapolation of the data obtained at higher temperatures can lead to considerable errors. On the other hand, in many reports the necessary data concerning experimental conditions are lacking. Nevertheless we attempted to compare the kinetic curves for the accumulation of carbonyl compounds in the oxidation of polypropylene taken from Balaban et al.[12] with the calculated results; the parameter $k_p/\sqrt{k_t}$ was obtained by extrapolating Chien and Ross's data[92] to 30°C ($k_p/\sqrt{k_t} = 3.6 \times 10^{-5}$ litre mole^{-1} s^{-1}); the probability of the absorption of light quanta by a peroxide molecule ($\int \epsilon I d\lambda$) ^{105} was calculated from the absorption spectra of the light filters employed, the emission spectrum of the light source, and the absorption spectrum of the peroxide (Fig. 5), which are quoted by Melchore[13].

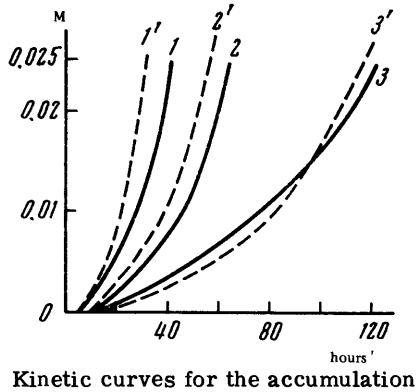

Figure 12. Kinetic curves for the accumulation of carbonyl compounds in the photochemical oxidation of atactic polypropylene[13]: 1)—3) from Melchore's data[13]; 1')—3') calculated data [1) without a filter; 2) and 3) with different light filters].

If the parameter $k_p/\sqrt{k_t}$ is calculated from the results of Pudov and coworkers[90,91], the accumulation of carbonyl compounds is found to be slower than in the experiments.

Thus Eqns. (13)—(15) apparently give a correct prediction of the scale of the phenomenon. However, in order to test rigorously the validity of mechanism (II), it is necessary to carry out special investigations.

It follows from Eqns. (13)—(15) that the dependence of the induction period, determined from the absorption of oxygen τ_{O_2}, the accumulation of the peroxides τ_{ROOH}, or the accumulation of ketones τ_K on light intensity and temperature is qualitatively different in each case. At the beginning of the process the induction period based on the accumulation of peroxides τ_{ROOH} is inversely proportional to the square root of the light intensity and corresponds to the same activation energy E_{ROOH} as the parameter $k_p/\sqrt{k_t}$. The induction period based on the accumulation of ketones is inversely proportional to $I^{2/3}$ and corresponds to the activation energy $(2/3)E_{ROOH}$. Indeed it has been shown[14] that the activation energy associated with τ_{ROOH} is 7 kcal mole^{-1}, which is close to the activation energy associated with the parameter $k_p/\sqrt{k_t}$, measured by Chien and Ross[92] (9 kcal mole^{-1}).

On the other hand, if the sensitivity of the method used to determine peroxides or ketones is relatively low, deviations from the above relations may be observed. It has been shown[12] that the induction period for the accumulation of ketones (τ_K) is inversely proportional to the square root of the light intensity. A small discrepancy may be due to the fact that degenerate chain branching owing to the photochemical decomposition of ketones, occurring because the irradiation was carried out with the unfiltered light of the mercury lamp, had an appreciable influence on this process.

Advances in the Synthesis of 3,7,9-Heteroanalogues of Bicyclo[3,3,1]nonane

N.S.Zefirov and S.V.Rogozina

The heteroanalogues of bicyclo[3,3,1]nonane are of great theoretical and practical interest, which has stimulated synthetic studies in this field. These compounds are used as physiologically active substances and as intermediate in organic synthesis (for example in the synthesis of heteroadamantanes); a heterobicyclononane fragment occurs in the structures of certain alkaloids. The compounds are convenient models for stereochemical and conformational studies.
Despite the very large number of novel studies on the synthesis of compounds of this type, relevant reviews are not available. The present review gives a systematic analysis of typical mechanisms of the synthesis and the synthetic scope of each method and the limits of its applicability are discussed.
The bibliography includes 140 references.

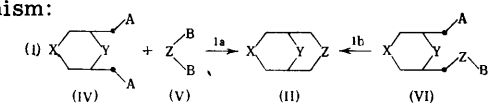
1. INTRODUCTION

Bicyclic and skeletal compounds are now attracting increased attention owing to their unique physical or chemical properties, which makes them interesting models for the study of theoretical problems in conformational analysis, the mechanisms and the stereochemistry or reactions, the transmission of electronic effects, etc. Heteroanalogues of bicyclic systems are of special interest. The introduction of heteroatoms usually involves the retention of the general geometry characteristic of the parent hydrocarbon but can greatly modify the physical properties or the chemical behaviour of the functional groups. In many cases this leads to an extension of the range of unusual properties, which increases the scope of the application of these compounds both in theoretical studies and for important practical purposes, for example as physiologically active substances. As an example, one can point to studies using heteroanalogues of norbornane [1-4] which is one of the most widely used model compounds in theoretical studies.

This review deals with methods of synthesis of heteroanalogues of one of the bicyclic systems—bicyclo[3,3,1]-nonane (I). Derivatives of this compound are finding many applications both in conformational studies [5-10] and for synthetic purposes [11-14].

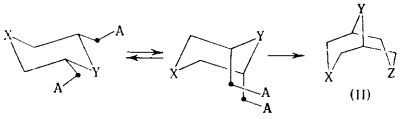


(I) (II) (III)

The methods of synthesis of bicyclo[3,3,1]nonanes are discussed exhaustively in a new review [15] and there is an extremely large literature on the synthesis of heteroanalogues of this series. Here we shall confine ourselves to a discussion of compounds with heteroatoms in the 3-, 7-, and 9-positions [compounds(II)]. Apart from the limited amount of space available, this restriction is based both on the great theoretical importance of heteroanalogues of this type and on their extensive synthetic applications, in particular in the synthesis of adamantane structures of type (III). [11-14,16-18] We may also emphasise that the 3(7)- or 9-azabicyclo[3,3,1]nonane fragment occurs in the structures of many natural alkaloids. For example, 3,7-diazabicyclononane occurs in the skeleton of alkaloids in the plant family *Papilionaceae*: lupanine, sparteine, and anagyrine; the 3-azabicyclononane fragment also occurs in the structure of certain diterpene alkaloids [20]; a series of alkaloids are also based on the 9-azabicyclononane fragment [19,21]. Special mention should also be made of the use of these compounds as physiologically active agents. Thus 3-oxa-9-azabicyclo[3,3,1]nonane and many of its derivatives have a marked effect on cholinergic systems in the organism [22]. Quaternary amino-derivatives of this series exhibit a curare-like activity [22]. Many derivatives of 3,9-diazabicyclononane exhibit similar properties [23]. A number of derivatives of 3-azabicyclononane have ganglion-blocking and hypotensive activities [24,25]. Derivatives of 1,5-diphenyl-3,7-diazabicyclonan-9-one behave as local anaesthetics [26]. Other pharmacological properties of 3,7-diazabicyclo[3,3,1]nonane ("bispidine") are described by Chiavarelly et al. [27]

The available literature data have been classified in this review on the basis of the type of the formal mechanism of synthesis and not on the basis of the type of heteroatoms. This treatment makes it possible to find typical methods of preparation, reveals the genetic relation between structures with different heteroatoms, and permits the most compact systematic account of the data. We may also note that Italian authors have published a review on 3,7-diaza-derivatives covering the literature up to 1968. [27] Therefore, in the discussion of bispidines we shall consider mainly the new literature, selecting from the older studies only those which are fundamentally essential for a systematic description.

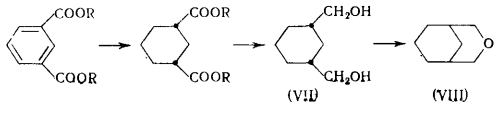
2. SYNTHESIS FROM *cis*-1,3-DISUBSTITUTED HETERO-ANALOGUES OF CYCLOHEXANE



One of the commonest methods of synthesis of hetero-bicyclononanes involves the cyclisation of 1,3-disubstituted cyclohexanes and their heteroanalogues via the following mechanism:

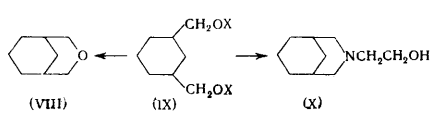
(IV) (V) (II) (VI)

The bicyclic structure can be synthesised either by the interaction of the bifunctional compound (IV) with a suitable reagent (V) [mechanism (1a)] or via intramolecular cyclisation according to mechanism (1b). Possibly the true mechanism of the conversion of compound (IV) into (II) includes the intermediate formation of the derivative (VI). When Z = nitrogen or sulphur, the commonest procedure involves the condensation of a dihalide (IV, A = halogen), di(toluene-p-sulphonate) (IV, A = OTs), or di(methane-sulphonate) (IV, A = OMs) with an amine or sodium sulphide respectively. Although mechanism (1a) has been used to synthesise oxygen-containing compounds (II, Z = O) by the reaction of a dihalide with silver oxide[28], the commonest procedure in this case involves the intramolecular cyclisation of diols (VI, A = ZB = OH) with elimination of the elements of water[29-31].



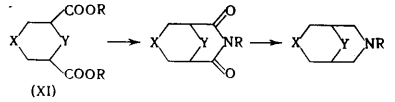
Evidently cyclisation with formation of compound (II) is possible only for *cis*-1,3-disubstituted cyclohexanes in the diaxial conformation:

(II)



When the size of the substituent is moderate, the *cis*-isomers of 1,3-disubstituted cyclohexane usually assume the diequatorial conformation, becoming more stable in consequence than the equatorial-axial *trans*-isomers. Thus the difference between the free energies of the *cis*- and *trans*-isomers of 1,3-dimethylcyclohexane is 1.96 kcal mole^{-1} at 25°C.[32] Hence the problem of the synthesis of heterobicyclononanes reduces to the synthesis of the *cis*-isomer of a 1,3-disubstituted heteroanalogue of cyclohexane. For this purpose, one must choose either a stereoselective reaction or the mechanism must include a thermodynamically controlled stage, as a result of which the more stable *cis*-isomer predominates.

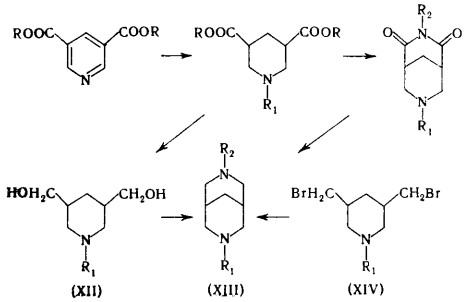
One of the commonly used reactions is catalytic hydrogenation of 1,3-bifunctional six-membered aromatic systems. Thus hydrogenation of isophthalic acid ester leads to the diol (VII), the dehydration of which yields oxabicyclononane (VIII):[29]



(VII) (VIII)

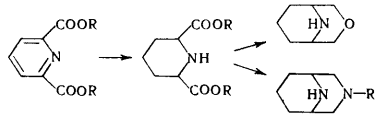
Catalytic hydrogenation of the ring and reduction of the methoxycarbonyl group can be carried out in stages[33]. The cyclisation has also been achieved by heating the di(methanesulphonate) (IX, X = Ms) with potassium hydroxide[33]:

(VIII) (IX) (X)



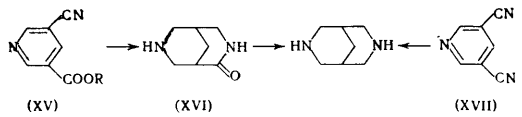
The interaction of the di(toluene-p-sulphonate) (IX, X = Ts) with ethanolamine leads to a derivative of azabicyclononane (X).[34,35] The latter is readily obtained also by the reduction of the imide of hexahydroisophthalic acid (IX, X = Y = CH_2) with lithium aluminium hydride[34]:

(XI)



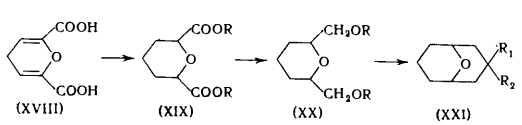
This scheme has been used to synthesise also other heteroanalogues[36-47].

The starting material for the synthesis of bispidines (XIII) may be a pyridine-3,5-dicarboxylic acid ester[12]:

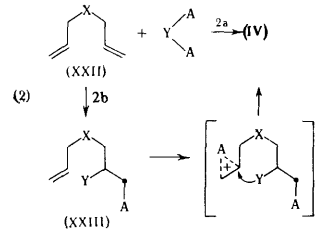


(XII) (XIII) (XIV)

Other versions of this synthesis involve the cyclisation of the dibromide (XIV)[48] or the diol (XII) in the presence of hydrogen bromide[11]. Similarly 3-oxa-9-aza[30] and 3,9-diaza-bicyclononane have been obtained from pyridine-2,6-dicarboxylic acid[46]. The same scheme has been used to synthesise 9-methyl-3,9-diaza-compounds[37]:

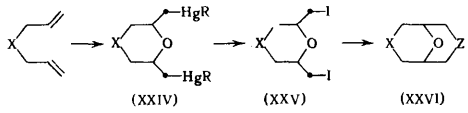


Catalytic hydrogenation of the mononitrile (XV) leads to bispidone (XVI), which is readily reduced to bispidine[49]:



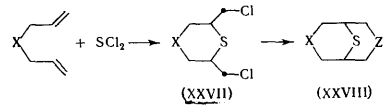
(XV) (XVI) (XVII)

Sometimes the catalytic hydrogenation and cyclisation occur in a single stage. Thus the hydrogenation of the nitrile (XVII) under severe conditions yields bispidine at once[50]. It is readily seen that the catalytic hydrogenation method is restricted mainly to benzene and pyridine derivatives, although instances of the use of other unsaturated systems are known. Thus the reduction of pyrandicarboxylic acid (XVIII) to the tetrahydro-compound (XIX, R = H) with subsequent reduction of the ester leads to the diol (XX, R = H) with the *cis*-configuration. Tosylation of the diol followed by treatment with sodiomalonic ester leads to the oxa-derivative (XXI).[51] However, we may note that 9-oxa-derivatives are more conveniently obtained from cyclo-octadiene (see below).



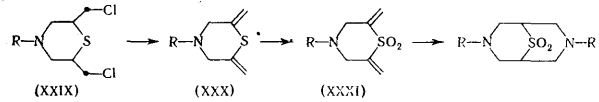
(XVIII) (XIX) (XX) (XXI)

Another general method of synthesis involves the formation of a *cis*-1,3-disubstituted cyclohexane fragment from acyclic 1,6-diene systems of type (XII) via mechanism (2):



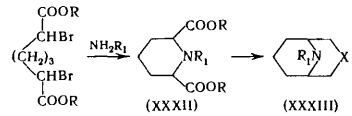
The reaction of electrophilic agents with dienes of this type can involve both double bonds [mechanism (2a)]. Another version of this process may be the addition of an electrophilic agent to one double bond with formation of the intermediate (XXIII), the functional group Y of which is capable of nucleophilic attack on the intermediate 'onium ion in the second stage of the electrophilic addition [mechanism (2b)]. Thus the second stage may be regarded as coupled addition to a multiple bond. The wide variety of electrophilic agents, the possibility of varying the heteroatom in the initial diene system, and the ease of varying the heteroatom in the last stage of the cyclisation of the 1,3-disubstituted heteroanalogue of cyclohexane make this method very convenient for the synthesis of different 3,7,9-heterobicyclononanes.

The easily available diallyl ether, diallyl sulphide, or diallylamine can be used as the diene components. The choice of the electrophilic agent is restricted by the following requirements. Firstly, it must be capable of cyclisation via two bonds and therefore the number of the usual addition products must be reduced to a minimum. Normally this condition is fulfilled by relatively weak electrophilic agents (mercury salts, sulphur dichloride). Secondly, an intermediate (XXIII) must be obtained, in which the Y group must be capable of further nucleophilic reaction or at any rate can be easily transformed into such a group. Both requirements are satisfied by the hydroxymercuration reaction. Thus hydroxymercuration of diallyl ether [52-54], diallyl sulphide [55], and diallylamine [14] leads to chloromercuri-derivatives of tetrahydropyrans of type (XXIV):

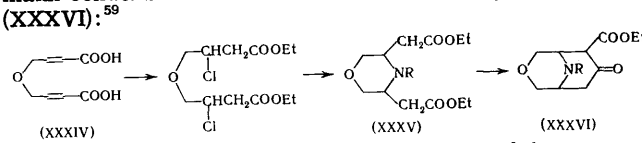


In most cases the reaction is stereoselective and leads to *cis*-isomers, although the presence of *trans*-isomers has also been established in a number of cases [53-55]. Treatment of mercuri-derivatives with iodine converts them smoothly into di-iodides (XXV). Cyclisation of the di-iodide (XXV, X = O) with silver oxide yields 3,7,9-trioxabicyclononane ("Stuehr's ether") [28]. Similarly treatment of compounds of type (XXV) with amines yielded 7-phenyl-3,9-dioxa-7-azabicyclononene (XXVI, X = O, Z = NPh) [53] and a substituted 9-oxabispidine (XXVI, X = NR_1, Z = NR_2). [14] Condensation of compounds of type (XXV) with sodium sulphide gave 9-oxa-3,7-dithia- [55] and 3,9-dioxa-7-thia-bicyclononanes [56] (XXVI, X = Z = S and X = O, Z = S respectively). It is interesting that bis-iodomethyloxathiane (XXV, X = S) reacts smoothly with sodium selenide to form 9-oxa-3-thia-7-selenabicyclononane (XXVI, X = S, Z = Se). [56]

Another widely used reaction involves the addition of sulphur dichloride. The addition of this reagent to diallyl ether [57], diallyl sulphide [57], and diallylamine [58] proceeds with formation of dichlorides of type (XXVII)

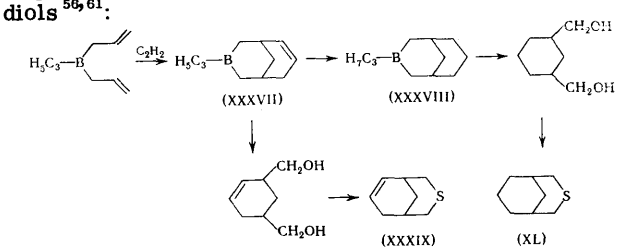


3-Oxa-7-9-dithia-, 3,7,9-trithia-, and 3-phenyl-7,9-dithia-3-azabicyclononanes were obtained by this procedure [56].

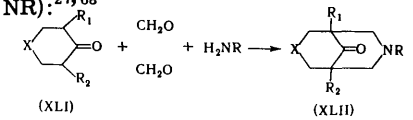


The sulphides formed can be oxidised to the sulphoxides or sulphones [57]. In many cases this permits an alternative type of cyclisation in the last stage, which can be used when the configuration of compound (XXVII) is unfavourable. For example, treatment of the bischloromethyl derivative (XXIX) with alkali yielded the diene (XXX), which was further oxidised to the sulphone (XXXI). The presence of the unsaturated sulphone fragment makes it possible to carry out nucleophilic addition to multiple bonds and thus obtain the sulphone of 3,7-disubstituted 9-thia-3,7-diazabicyclononane [58]:

Another typical reaction leading to bifunctional heteroanalogues of cyclohexane is the cyclisation of 1,5-dihalogeno-derivatives. Thus the reaction of the 2,6-dibromomopimelic ester with amines yields piperidines (XXXII), which have been used to synthesise 3,9-diaza- (XXXIII, X = NR_2) [43] and 3-oxa-9-aza-bicyclononanes (XXXIII, X = O): [31]

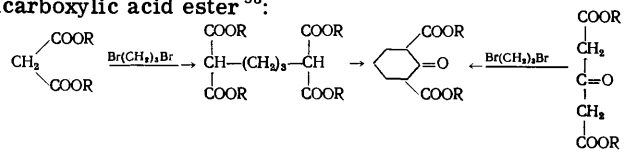


The addition of hydrogen chloride to the unsaturated acid (XXXIV) and subsequent cyclisation give rise to morpholine (XXXV). The latter was subjected to Dieckmann condensation with formation of the bicyclic ketoacid (XXXVI): [59]

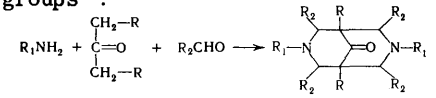


The synthesis of *cis*-1,3-disubstituted cyclohexanes from borabicyclic compounds is extremely interesting and promising. Triallylboron condenses with acetylene to give a high yield of borabicyclononene (XXXVII). [60] The latter can be converted into the saturated analogue (XXXVIII). In turn, these compounds can also be converted into *cis*-diols by the usual hydroboration method.

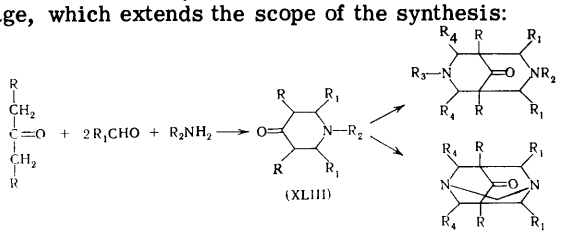
The 3-thiabicyclononene (XXXIX) and 3-thiabicyclononane (XL) have been obtained by the reaction of sodium sulphide with the di(toluene-*p*-sulphonates) of these diols [56,61]:



One of the typical reactions employed in the synthesis of bicyclononane structures is the Mannich condensation. With the cyclohexanones (XLI, X = CH_2), the reaction leads to 3-azabicyclononanes (XLII, X = CH_2).[38,62-67] The interaction of piperidinones (XLI, X = NR) with formaldehyde and amines results in the formation of bispidines (XLII, X = NR):[27,68]

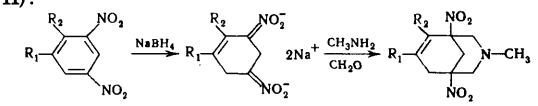


(XLI) (XLII)



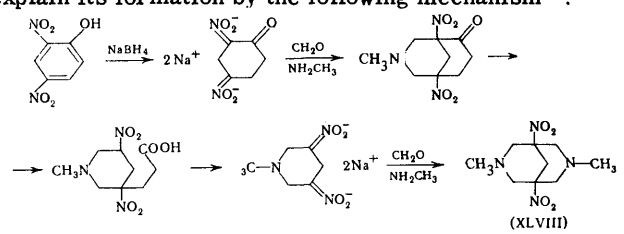
Usually R_1 and R_2 are ethoxycarbonyl groups[62,63,67,68], although the reaction takes place also when $R_1 = R_2 = H$.[65] The carboxy-groups in the aminoketone (XLII, $R_1 = R_2$ = COOH) can be readily removed by acid hydrolysis[38,63]. The corresponding diethoxycarbonylcyclohexanone can be obtained from β-dicarbonyl compounds[38] or from acetonedicarboxylic acid ester[38]:

Bispidines can also be synthesised from ketones with two methylene groups[27]:



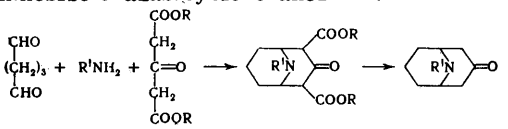
The method permits an extensive variation of the substituent, since the reaction can be carried out in stages with isolation of the intermediate monocyclic compound (XLIII). Then another aldehyde can be employed in the second stage, which extends the scope of the synthesis:

(XLIII) (XLIV)



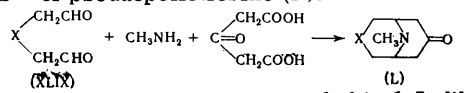
In many cases the reaction product is a compound of type (XLIV) with an adamantane structure, which can be reconverted into a bicyclic compound[69-72].

An interesting method for the synthesis of 3-azabicyclononanes is based on the use of *m*-dinitrobenzenes. The reduction of the latter leads to compounds (XLVI), the Mannich condensation of which yields the aza-derivatives (XLVII):[73-75]



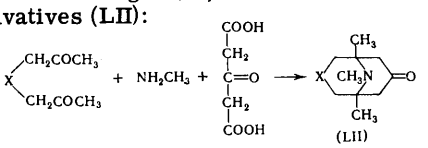
(XLV) (XLVI) (XLVII)

It is interesting that the dinitrophenol (XLV, R_1 = H, R_2 = OH) gives rise under these conditions to an anomalous product—the dinitrobispidine (XLVIII). The authors explain its formation by the following mechanism[75]:

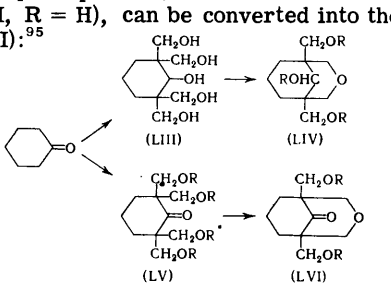


(XLVIII)

The Robinson–Schopf condensation can be used extensively to synthesise 9-azabicyclononanes[76,77]:

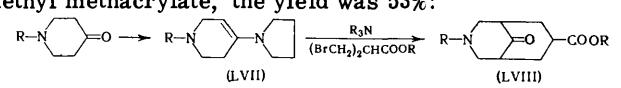


We may note that the synthesis of N-methyl-9-azabicyclo[3,3,1]nonan-3-one ("pseudopelletierine") plays an important role in the determination of the structure of cyclo-octatetraene[78,79]. This reaction makes it possible to vary the substituents, is convenient for preparative purposes, and usually takes place with a high yield[13,80-87]. It can be extended to glutaraldehydes with functional substituents, for example 3-phenyl[83] or 3-ethoxy-derivatives[13]. Heteroanalogues of glutaraldehyde (XLIX) have also been used in this reaction, which permitted the synthesis of thia-,[88,89] oxa-,[89] selena-,[88] and *N*-methylaza-analogues[88] of pseudopelletierine (L):



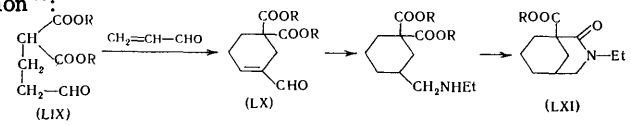
(XLIX) (L)

Recently this condensation was extended to 1,5-diketones[90]. Thus the condensation of heptane-2,6-dione (LI, X = CH_2) and its 4-thia-analogue (LI, X = S) leads smoothly to the aza-derivatives (LII):



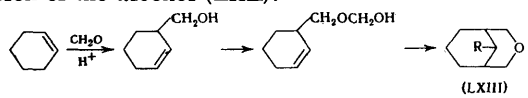
(LII)

As early as 1891, Tollens showed that the condensation of aliphatic aldehydes and ketones with formaldehyde in the presence of calcium oxide yields polyhydric alcohols[91]. Under these conditions, cyclohexanone forms the pentahydric alcohol (LIII),[92] which is dehydrated by hydrogen chloride to form the cyclic ether (LIV, R = H).[92,93] Treatment with acetic acid yields the acetate (LIV, R = Ac).[94] When the condensation is carried out under milder conditions, the carbonyl group is not involved and the tetra(toluene-*p*-sulphonate) obtained from the tetrahydric alcohol (LVI, R = H), can be converted into the cyclic product (LVI):[95]



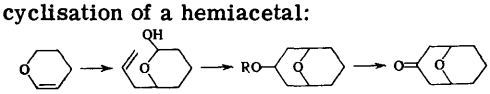
(LIII) (LIV) (LV) (LVI)

In synthetic studies on steroids, it was found that the concentration of unsaturated ketones and cyclic ketones and diketones can proceed via the intermediate formation of compounds with the bicyclo[3,3,1]nonane skeleton[96]. Similarly cyclisation of enamines of cyclic ketones with unsaturated carbonyl compounds or β-halogenocarbonyl compounds likewise constitutes a general method of synthesising bicyclononanes[15]. These reactions can be achieved also when the initial compounds contain heteroatoms. Thus the aza-compound (LVIII) was obtained in 80% yield from the enamine (LVII) by condensation with $\beta\beta$-dibromoisobutyrate[97]. In the reaction with β-bromomethyl methacrylate, the yield was 53%:[97]



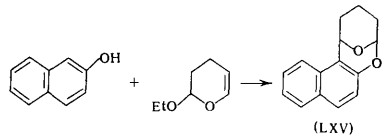
(LVII) (LVIII)

The reaction with acrolein proceeds similarly [98]. An example of the condensation of an unsaturated aldehyde with an aliphatic carbonyl compound leading to a cyclic product is the interaction of the diethoxycarbonylaldehyde (LIX) with acrolein. The resulting unsaturated aldehyde (LX) cyclises to the lactam (LXI) after reductive amination [99]:



(LIX) (LX) (LXI)

The reaction of formaldehyde with cyclic olefins (the Prins reaction) has found some application in the synthesis of oxygen-containing bicyclononanes. According to Blomquist and Wolinsky [100] and Dolby and Schwarz [101], the formation of substituted 3-oxabicyclononanes from cyclohexane is stereoselective and proceeds via the intermediate formation of the alcohol (LXII):

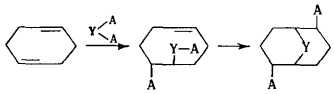


(LXII) (LXIII)

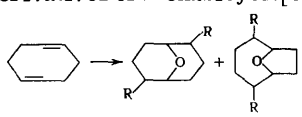
Various substituted oxabicyclononanes of type (LXIII) have been obtained by means of this reaction [100-103]. When the condensation is carried out in the presence of hydrochloric acid, the main product is the *anti*-9-chloro-derivative (LXIII, R = Cl). [104] This chloride is readily reduced to 3-oxabicyclo[3,3,1]nonane [104]. 9-Oxabicyclononane (LXIV) was obtained from dihydropyran by a procedure [105] involving the cyclisation of a hemiacetal:

(LXIV)

Here it is also appropriate to describe the formation of the tricyclic compound (LXV) with the 2,9-dioxabicyclo[3,3,1]-nonane moiety from ethoxydihydropyran and β-naphthol [106]:



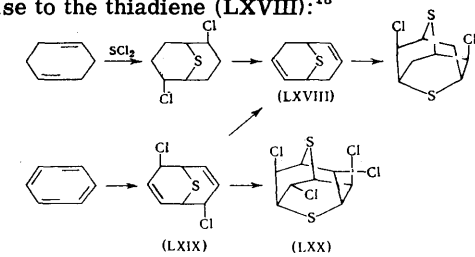
(LXV)



3. SYNTHESIS FROM CYCLO-OCTANE DERIVATIVES

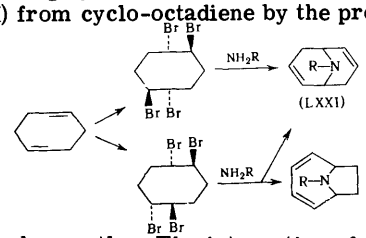
One of the versions of the synthesis of the above bicyclic compounds under consideration involves the cyclisation of compounds which already contain an eight-membered ring in their structure. Such cyclisation can be achieved by electrophilic addition to cyclo-octa-1,5-diene via the following procedure:

(3)



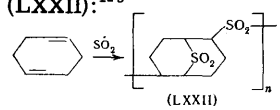
Evidently all the remarks made above concerning the addition to the 1,5-diene system are valid also for this type of addition. Indeed the hydroxymercuration reaction readily yields derivatives of 9-oxabicyclo[3,3,1]nonane [107-110]:

(LXVI) (LXVII)



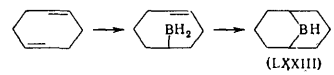
A detailed study of this reaction showed that, together with compounds having the structure of bicyclo[3,3,1]nonane, derivatives of bicyclo[4,2,1]nonane (LXVII) are also formed [108,109]. Their proportions depend sometimes on the reaction conditions, which makes it possible to drive the process towards the preferential formation of compounds of the bicyclo[3,3,1]nonane series (LXVI). [109]

The reaction with sulphur dichloride [111,112] and Se_2Cl_2 (Lautenschlaeger [16]) takes place similarly. It is interesting that cyclo-octatetrane can be introduced into the reaction with SCl_2. [18,113] The reaction can be stopped at the stage of the diene (LXIX), the subsequent interaction of which with a second mole of SCl_2 yields dithia-adamantane (LXX). The reduction of the dichloride (LXIX) gives rise to the thiadiene (LXVIII):[18]



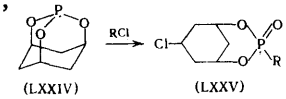
(LXVIII) (LXIX) (LXX)

An interesting synthesis of 9-azabicyclononane-2,6-diene (LXXI) from cyclo-octadiene by the procedure [114]



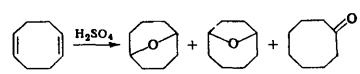
(LXXI)

was described recently. The interaction of cyclo-octa-1,5-diene with sulphur dioxide in the presence of radical initiators takes place in an interesting way. The reaction product is a polymer, the structural unit of which is a bicyclic sulphone (LXXII):[115]



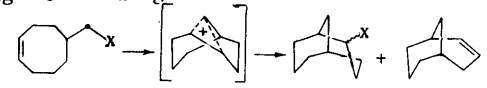
(LXXII)

Evidently the range of electrophilic agents which react according to this mechanism can be extended. For example, it is known that diborane reacts with cyclo-octadiene to form 9-borabicyclononane (LXXIII) [116]:

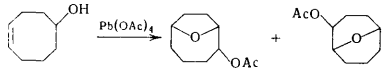


(LXXIII)

Probably one can select conditions for the synthesis of other organic derivatives of the elements using suitable selenium, phosphorus, etc. compounds as electrophilic agents. We may note that bicyclic phosphonates of type (LXXV), which are formed by the Arbuzov reaction between the heteroadamantane (LXXIV) and an alkyl chloride [117],

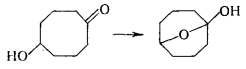


(LXXIV) (LXXV)

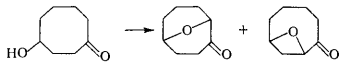


have been described. The interaction of cyclo-octadiene with sulphuric acid can also be included among reactions of this type [118]:

A second set of reactions includes transannular processes in eight-membered rings, for example those involving the following mechanism:

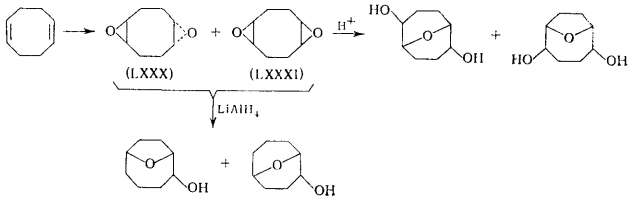


We shall not consider the mechanism of these reactions, which has been dealt with fairly thoroughly in the literature [119–122], and shall discuss the synthetic aspect of the problem. These reactions are usually employed to synthesise 9-oxa-derivatives. Thus cyclisation of the unsaturated alcohol (LXXVI) lead tetra-acetate yields smoothly the bicyclic compounds (LXXVII) and (LXXVIII):[123]

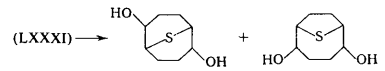


(LXXVI) (LXXVII) (LXXVIII)

According to Cope et al. [108], 5-hydroxycyclo-octanone exists in the hemiacetal form:

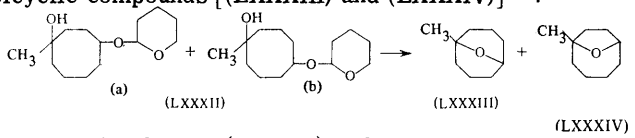


A transannular reaction was observed when the hydroxyketone (LXXIX) was brominated and the crude product was treated with potassium hydroxide [108]:



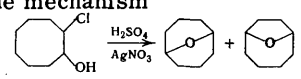
(LXXIX)

The formation of derivatives of isomeric bicyclononanes as a result of ring opening in the epoxides (LXXX) and (LXXXI) [124] belongs to reactions of the same type:

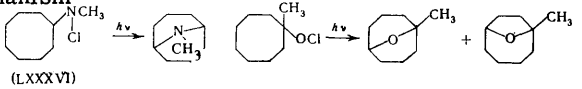


(LXXX) (LXXXI)

When the *cis*-diepoxide (LXXXI) is treated with sodium sulphide, a 9-thia-derivative is formed [124]:



On treatment with acid, a mixture of cyclic tetrahydropyranyl ethers (LXXXII, a and b) also give a mixture of bicyclic compounds [(LXXXIII) and (LXXXIV)] [125]:

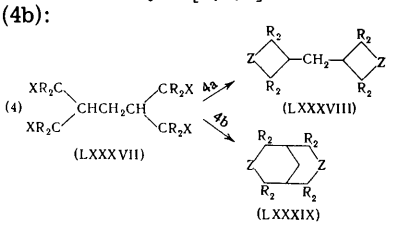


(a) (LXXXII) (b) (LXXXIII) (LXXXIV)

The chlorohydrin (LXXXV) undergoes transannular cyclisation via the mechanism [126]

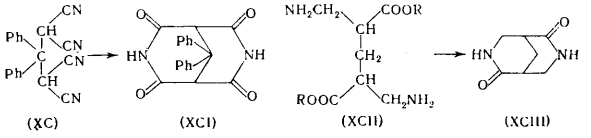
(LXXXV)

Chloroamines are known to be cyclised under the influence of sulphuric acid or on heating into cyclic amines [127]. Similarly irradiation of the chloroamine (LXXXVI) is accompanied by transannular cyclisation according to the mechanism [128]



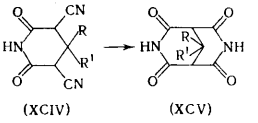
(LXXXVI)

A similar transannular rearrangement is observed for 1-methylcyclo-octyl hypochlorite [125]. There is no doubt that photochemical transannular cyclisation is extremely promising.



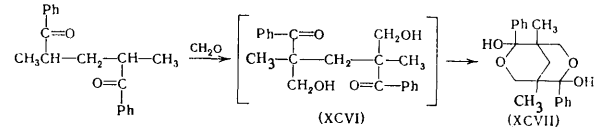
4. SYNTHESIS FROM 1,1,3,3-TETRASUBSTITUTED PROPANES

Symmetrical 1,1,3,3-tetrasubstituted propanes (LXXXVII) can be converted into bicyclo[3,3,1]nonanes (LXXXIX) via mechanism (4b):



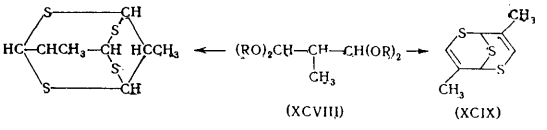
(LXXXVII) (LXXXVIII) (LXXXIX)

However, the cyclisation can also follow the alternative mechanism (4a) with formation of cyclobutane derivatives (LXXXVIII). The relative contributions by these two mechanisms depend on the type of reaction. Thus the cyclisation of the tetra(toluene-*p*-sulphonate) of 2,4-di-(hydroxymethyl)pentane-1,5-diol (LXXXVII, R = H, X = OTs) by reaction with disodiomalonic ester proceeds via mechanism (4a) with formation of the tetraester [(LXXXVIII), Z = C(COOR')$_2$]. [129] On the other hand, acid hydrolysis of the tetranitrile (XC) leads to the diimide (XCI), which has a bicyclononane skeleton [130]:



(XC) (XCI) (XCII) (XCIII)

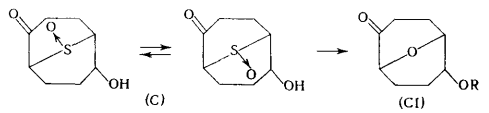
The formation of the dilactam (XCIII) from the bis-aminoester (XCII) proceeds similarly [131]. In these cases the cyclisation can probably be carried out in stages. At any rate, acid hydrolysis of the dinitrile (XCIV) also yields compound (XCV) with a bispidine structure [132–134]:



(XCIV) (XCV)

The cyclisation of the intermediate ketol (XCVI), leading to the formation of a derivative of 3,7-dioxabicyclononanediol (XCVII), takes place in a similar manner [135]:

(XCVI) (XCVII)



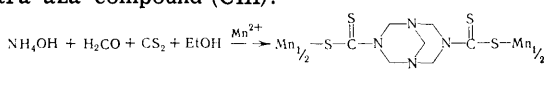
In the synthesis of tetrathia-adamantane from the diacetal (XCVIII) and hydrogen sulphide, the diene (XCIX) is formed as a side product [136]:

(XCVIII) (XCIX)

5. SPECIAL METHODS OF SYNTHESIS

In conclusion we shall describe several unique reactions involving changes in the heteroatoms in the bicyclic system under consideration. Thus the β-ketosulphoxide (C) is converted into the 9-oxa-derivative (CI) on irradiation [137]:

(C) (CI)



The reaction of pseudopelletierine methiodide (CII) with sodium sulphide, which leads to a smooth replacement of the heteroatom, is very interesting [138,139]:

(CII)

It is possible to put forward several versions of the mechanism of this reaction, in particular an elimination–addition mechanism; however, it would be interesting to make an experimental study of this problem.

Examples of polycondensations leading to structures with a bicyclononane skeleton are known. For example, the reaction of formaldehyde with ammonia and carbon bisulphide in the presence of manganese(II) sulphate yields the tetra-aza-compound (CIII):[140]

(CIII)

The mechanism of this condensation is not known in detail and it maybe that the reaction involves one of the mechanisms described above.

---o0o---

The foregoing data show that synthetic methods leading to heteroanalogues of bicyclo[3,3,1]nonane are fairly varied and include many procedures of preparative organic chemistry. It is quite evident that in future one may expect an increase in the number of studies in this field in view of the practical importance of compounds of this series and the enormous advances in the development of synthetic methods in general. The development of methods in the chemistry of organic derivatives of the elements gives rise to the self-evident possibility of extending the range of heteroatoms in this bicyclic system. The appearance of many new reactions involving coupled addition to a multiple bond greatly extends the scope of the heterocyclisation of diene systems. Finally, the new photochemical reactions which have been developed are also promising for the synthesis of heterobicyclononanes.

Carbonylation of Polyunsaturated Hydrocarbons and of Saturated and Unsaturated Alcohols and Halogeno-derivatives

Ya.T.Eidus, A.L.Lapidus, K.V.Puzitskii, and B.K.Nefedov

A survey is made of the catalytic carbonylation of various di- and poly-unsaturated hydrocarbons, alcohols and halogeno-derivatives by carbon monoxide in the presence of complexes of Group VIII metals and acid catalysts. A list of 200 references is included.

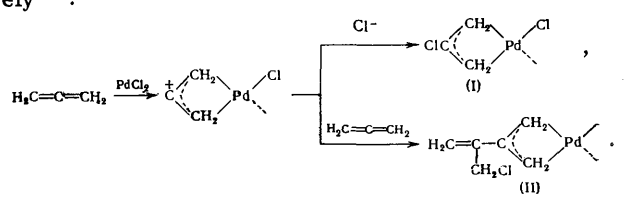
I. INTRODUCTION

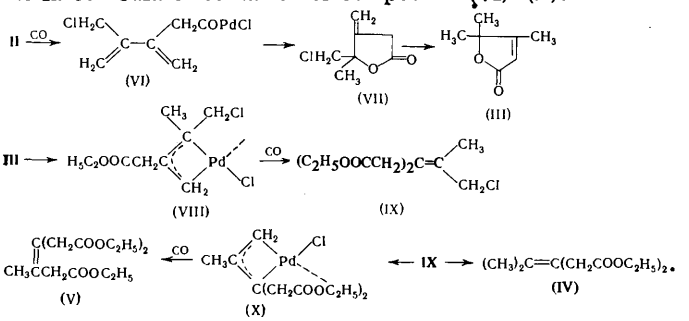
Active investigations of carbonylation with carbon monoxide have been made not only on unsaturated hydrocarbons containing one multiple bond [1] but also on polyunsaturated hydrocarbons together with various alcohols and halogeno-derivatives. These reactions take place under conditions of homogeneous catalysis in the presence of catalysts based on Group VIII metals (predominantly complexes). The carbonylation of saturated alcohols and of polyenes with well separated double bonds occurs under conditions of acid catalysis. The survey covers these reactions except for those involving hydroformylation, which has been widely discussed in the literature.

II. CARBONYLATION OF DI- AND POLY-UNSATURATED HYDROCARBONS



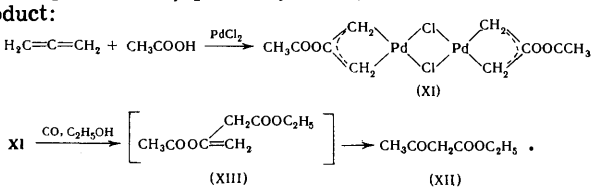
1. Reactions of the presence of Catalysts based on Group VIII Metals

(*a*) Enynes and Diynes

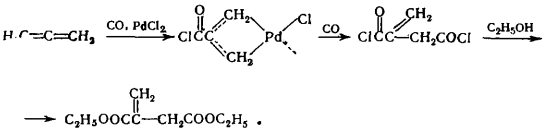


Butenyne is more difficult to carbonylate by means of tetracarbonylnickel than are hydrocarbons containing only a triple bond. The chief product is the cyclic dimer of 2-methylenebut-3-enoic acid [2]. The reaction is accelerated by the addition of pyridine [3,4]. It has not proved possible to carbonylate butadiyne [5].

(*b*) Dienes and polyenes

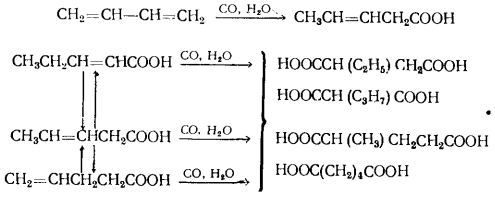


With palladium dichloride allene forms the complexes (I) and (II) in benzene and methanolic solution respectively [6-8]:



The formation of derivatives of $\beta\gamma$-unsaturated acids from π-allyl complexes of palladium has been investigated [9-12]. Complex (I) in an alcoholic medium at 100°C under carbon monoxide pressures of 100–110 atm yields the 3-chlorobut-3-enoic ester [13]; and complex (II) forms the γ-lactone of 4-hydroxy-3,4-dimethylpent-2-enoic acid (III), the β-isopropylideneglutaric diester (IV), and a triester (V), with the intermediate formation of compounds (VI)–(X):

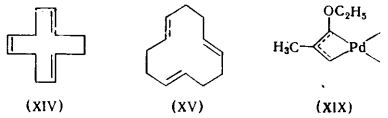
The carbonylation of allene in the presence of palladium dichloride and the carboxylate ion (in a solution of sodium chloropalladate and acetate in acetic acid) at room temperature gives the di-μ-chlorobis-(2-acetoxy-π-allylpalladium) complex (XI); and the latter in benzene at 100°C and a carbon monoxide pressure of 100 atm forms the compound (XII), probably with (XIII) as intermediate product:



Carbon monoxide acts on allene in ethanol to give a low yield of itaconic ester [13]:

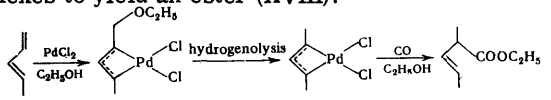
In the presence of small quantities of ruthenium nonacarbonyl or trichloride in methanol at 150°C and a carbon monoxide pressure of 900 atm allene is converted into methyl methacrylate (18%) and dimethyl $\alpha\alpha$-dimethyl-α'-methyleneglutarate (23%), but on the addition of pyridine the products are methyl methacrylate and methyl 1,3,4-trimethylcyclohex-3-enecarboxylate. In an aqueous medium methacrylic acid or the lactones of 3- and

4-hydroxy-1,3,4-trimethylcyclohexanecarboxylic acids are formed (at 700–1000 atm) [14].



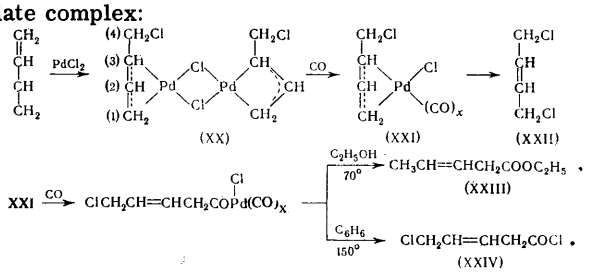
The carbonylation of butadiene gives a mixture of dicarboxylic acids, with the intermediate formation of vinylcyclohexene [15]. Rudkovskii and his coworkers [16–21] obtained from butadiene, carbon monoxide, and water in the presence of bistetracarbonylcobalt at 160–200°C and 250 atm pent-3-enoic acid and products of the carbonylation of this acid (and its isomers)—unsaturated C_6 dicarboxylic acids—contaminated with valeric acid:

This process is accomplished by the addition of pyridine, which reacts with unsaturated acyl carbonyls, thereby preventing side-reactions [22,23]. The yield of reaction products was raised by using 4,4′-bipyridyl instead of 2,2′-bipyridyl as solvent [24,25].



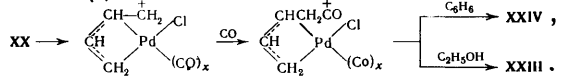
Cobalt carbonyl is the best catalyst for the reaction in pyridine solution. Rhodium and iridium carbonyls are less active and less selective. Iron carbonyl has little activity, and nickel carbonyl is completely inactive. The selectivity (with respect to pent-3-enoic acid) falls in the sequence cobalt > rhodium > iridium [20]. Addition of the elements of formic acid H–COOH can occur also at the 1,2-positions with the formation of pent-4-enoic and 2-methylbut-3-enoic acids. The latter isomerises to 2-methylbut-2-enoic and α-methylenebutyric acids [16]. The rates of formation of pent-3-enoic acid (yield up to 95%) and C_6 tricarboxylic acids (up to 65%) are directly proportional to the concentrations of catalyst and butadiene, decrease with increase in the concentration of water, and pass through a maximum with increase in the pyridine concentration and the carbon monoxide pressure [21]. The reactivity of dienes diminishes in the sequence—buta-1,3-diene, isoprene > hexa-1,5-diene > penta-1,3-diene, hexa-2,4-diene > 2,3-dimethylbuta-1,3-diene. The diene undergoes rapid *cis–trans* isomerisation under the reaction conditions, but its geometrical configuration has no significant effect on the reaction velocity. Penta-1,3-diene undergoes secondary hydrogenation to pentane [17]. In the presence of a palladium catalyst, e.g. $[Pd((C_6H_5)_3P)_2]\cdot Cl_2/HCl$, the carbonylation of butadiene takes place at ~120°C with the formation of pent-2-enoic acid [26–28]. In the absence of pyridine, rhodium catalysts promote the formation of unsaturated esters from conjugated dienes [29].

Carbon monoxide acts on the *cis–trans–trans* and *trans–trans–trans* forms of cyclododeca-1,5,9-triene (XIV and XV) in the presence of a finely dispersed metal, salt, or carbonyl (nickel or cobalt) to give cyclododecanecarboxylic acid or (in methanol) its ester in 60% yield, together with cyclododecadiene, cyclododecene, and cyclododecylmethanol [30].



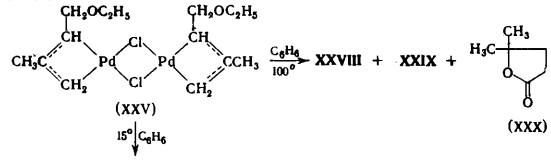
(XIV) (XV) (XIX)

The carbonylation of penta-1,3-diene in ethanolic solution in the presence of small quantities of palladium dichloride at 110°C and 120 atm depends on intermediate formation of ethoxy-π-allyl (XVI) and symmetrical (XVII) complexes to yield an ester (XVIII):[31]



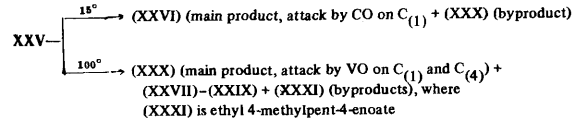
(XVI) (XVII) (XVIII)

Intermediate formation of the complex (XVI) is based on results [32] indicating that the carbonylation of butadiene and isoprene involves intermediate formation of the complex (XIX), which undergoes hydrogenolysis, as is indicated by the production of pent-3-enoic and 4-methylpent-3-enoic esters. In the presence of palladium dichloride various derivatives of unsaturated acids are formed depending on the reaction conditions, in conformity with two modes of attack by carbon monoxide on the intermediate complex:

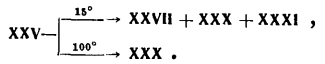


(XX) (XXI) (XXII) (XXIII) (XXIV)

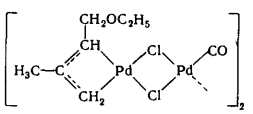
The relative yields of (XXII) and (XXIV) are 3 : 2 in benzene and 1 : 2 in ethanol. Compound (XXIII) is formed by the attack of carbon monoxide on the $C_{(1)}$ atom followed by hydrogenolysis and detachment of chlorine from $C_{(4)}$. Attack by carbon monoxide on $C_{(4)}$ with hydrogenolysis at $C_{(1)}$ is also possible. Product (XXIV) can be produced by the attack of carbon monoxide on $C_{(4)}$ with the appearance of an intermediate carbonium ion and by the attack of chlorine on $C_{(1)}$.[32]



In the reaction with isoprene, attack by carbon monoxide at $C_{(1)}$ and $C_{(4)}$ atoms leads to the formation of different products:

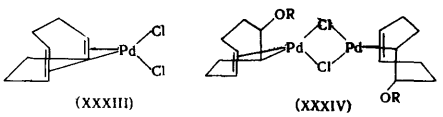


(XXV) (XXVI) (XXVII) (XXVIII) (XXIX) (XXX)

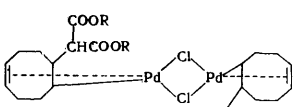


The 4-ethoxyl in the complex (XXV) is readily eliminated, as is chlorine from (XX), to form a carbonium ion. In benzene a mixture of acid chlorides and esters is formed, mainly as a result of attack by carbon monoxide on $C_{(1)}$ at room temperature and on this atom and $C_{(4)}$ at higher temperatures. At room temperature (XXVI) is the main product, while (XXVII) and (XXVIII) are side-products; at 100°C the main product is (XXVIII), with (XXIX) and (XXX) (γγ-dimethylbutyrolactone) as secondary products. In ethanol the reaction is

When hydrogen chloride is introduced into the reaction mixture at room temperature, attack by carbon monoxide on $C_{(4)}$ is accompanied by hydrogenolysis:



In benzene and alcohol at room temperature a new complex

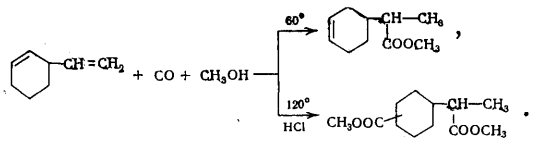


(XXXII)

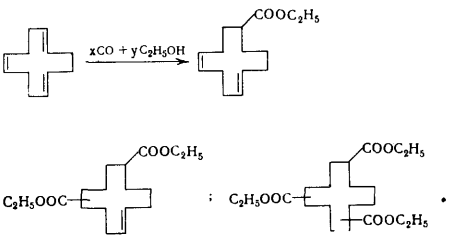
is formed[33].

Metallic palladium is active only in the presence of hydrogen chloride. The reaction of cyclo-octa-1,5-diene involves intermediate formation of the complex (XXXIII), which could be isolated. The products were a monoester and a mixture of diesters, with the possibility of selective formation of the monoester. Carbonylation of (XXXIII) yields cyclo-oct-4-enecarboxylic and cyclo-octane-1,4- and -1,5-dicarboxylic esters. The bridged dinuclear complex (XXXIV), obtained by the action of sodium carbonate on (XXXIII) in alcohol[34], is converted by carbon monoxide in benzene at 60°C into 8-methoxycyclo-oct-4-enecarboxylic ester[35]. Cyclo-octa-1,3-diene gives a low yield of cyclo-oct-2-enecarboxylic ester. When (XXXIII) is treated with excess of ethyl malonate in the presence of sodium carbonate, the complex (XXXV) is obtained[36]. Cyclododeca-1,5,9-triene forms mono- and di-esters without ring-opening. Triesters have not been detected[37].

(XXXIII) (XXXIV)



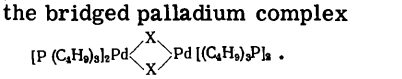
(XXXV)



Cyclic ketones are obtained in the presence of bistetracarbonylcobalt at 165°C and a carbon monoxide pressure of 70 atm: hexa-1,5-diene yields 2,5-dimethylcyclopentanone (35%) and 2,5-dimethylcyclopent-2-enone (6%), penta-1,4-diene gives 2-methylcyclopentanone, and hepta-1,6-diene forms 2-ethyl-5-methylcyclopentanone[38].

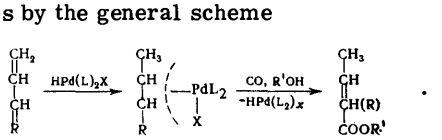
Halides and chelate compounds of Group VIII metals, in particular ruthenium(III) acetylacetonate, catalyse the reactions of dienes with carbon monoxide and water in pyridine to form saturated monohydric alcohols. Butadiene yields pentanol and isopentanol, and hexa-1,5-diene gives heptan-1-ol, heptan-1-al, and dihexenyl ketone[39,40].

Complex compounds of palladium, platinum, and nickel with such ligands as chlorine, bromine, iodine, tertiary amines, arsines, phosphines, organic sulphides, sulphones, or phosphates in excess of alcohol are active catalysts for the carbonylation of conjugated dienes in alcoholic or phenolic medium at 200°C and carbon monoxide pressures up to 2000 atm to form esters[41]. Unstable polyenes are carbonylated in the presence of complexes of general formula PdL_mX_n, where L is a ligand (e.g. phosphine, nitryl, amine, alkene), X is an acid radical, and $m + n = 3-4$. The greatest catalytic activity is observed when $X = Cl^-$ and Br^-. These complexes exhibit catalytic activity even at concentrations of 0.05% and below at 50–140°C and 300–700 atm[42]. The reaction of vinylcyclohexene catalysed by palladium complexes is represented by the scheme[42]



The carbonylation of several polyenes has been accomplished almost without side-reactions. Cyclododeca-1,5,9-triene forms mono-, di-, and tri-esters in up to 90% yield based on the triene that has reacted[37,42]:

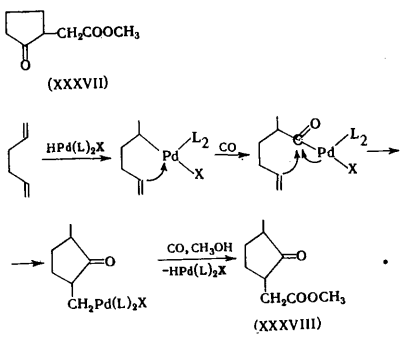
The reaction is used for the industrial synthesis of trideca-1,3-lactam[42,43]. The di-μ-chlorodi-π-but-2-enyldipalladium complex is converted by carbonylation into pent-3-enoic acid[44].



Carbon monoxide acts on butadiene in the presence of rhodium carbonyls and hydrogen chloride to give low yields of α-methylbutyrolactone and 1,3-dichlorobutane[45], but in the presence of rhodium carbonyls[46] or palladium dichloride[32,47] in an alcoholic medium pent-3-enoic esters are obtained. Alkenes react readily with palladium dichloride to form π-complexes or π-allyl complexes[48]. Buta-1,3-diene and palladium dichloride give 1-chloromethyl-π-allyl-palladium chloride[33]. The complex of palladium dichloride with butadiene is converted by carbon monoxide in benzene at 20°C and 50 atm into 5-chloropent-3-enoyl chloride and 1,4-dichlorobut-2-ene, but in an alcoholic medium at the same pressure and 70°C the products are ethyl pent-3-enoate and 1,4-dichlorobut-2-ene[47].

Complexes of palladium vary in their catalytic activity[49]. Sodium chloro- and bromo-palladates give only 1–2% yields of pent-3-enoic esters from butadiene at 70°C and 1000 atm, but with sodium iodopalladates yields of 35–40% are obtained. Modifying the catalyst by adding tributylphosphine enhances the catalytic activity and makes the catalyst thermally stable up to 150°C. In the case of palladium di-iodide the yield of esters is increased to 68%, but with the dichloride to 20%. The most active was the bridged palladium complex

(XXXVI)

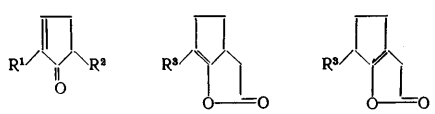


Esters of $\beta\gamma$-unsaturated acids are obtained from conjugated dienes by the general scheme

(L = ligand; X = Cl, Br, I)

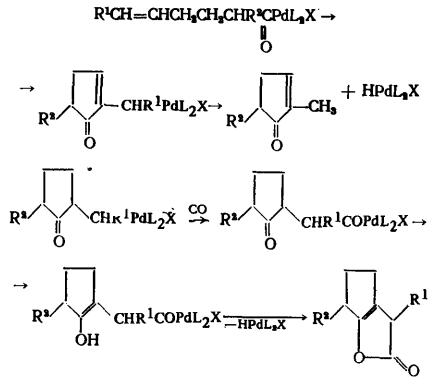
Penta-1,3-diene gives methyl 2-methylpent-3-enoate (yield 34%), cyclopentadiene the cyclopent-2-enecarboxylate (70%), 2,3-dimethylbuta-1,3-diene the 3,4-dimethylpent-3-enoate (50%), and isoprene the 3-methylpent-3-enoate (15%), 4-methylpent-3-enoate (38%), and 4-methylpent-4-enoate (10%). Unconjugated dienes react more rapidly than conjugated dienes with carbon monoxide and methanol in the presence of bistributylphosphinepalladium di-iodide at 150°C and 1000 atm, to form unsaturated monoesters and saturated diesters [50]. Cycloocta-1,5-diene is converted into methyl cyclo-oct-5-enecarboxylate (45%) and the dimethyl ester of a saturated dicarboxylic acid (30%); cyclo-octa-1,3-diene gives a monoester (14%) and a diester (3%).

$\alpha\omega$-Dienes form not only unsaturated monoesters and saturated diesters but also compounds containing a ketonic group—the cyclic γ-keto-ester (XXXVII) (10%) from penta-1,4-diene, and the compound (XXXVIII) (50%) from hexa-1,5-diene:



(XXXVII)

(XXXVIII)



Hepta-1,6-diene gives only traces of ketonic products.

The addition of toluene-*p*-sulphonic acid to the palladium complex enables the pressure to be lowered from 1000 to 250 atm, while the reaction velocity is raised, but addition of a base, e.g. calcium acetate, lowers the rate of the reaction [50]. In the presence of 1% of bistributylphosphinepalladium di-iodide cyclo-octa-1,5-diene is converted in oxolan solution (at 150°C and 1000 atm) into bicyclo[3,3,1]non-2-en-9-one [51], but in the presence of palladium dichloride at 100°C and 100 atm the products are cyclo-oct-4-enecarboxylic and cyclo-octanedicarboxylic esters [35, 52].

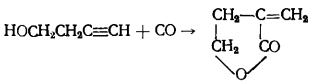
(XXXIX) (XL) (XLI)

In the presence of bistributylphosphinepalladium di-iodide in oxolan at 200°C and 1000 atm $\alpha\omega$-dienes are converted into unsaturated ketones and lactones: penta-1,4-diene into 2-methylcyclopent-2-enone (XXXIX: $R^1 = CH_3$; $R^2 = H$) and a mixture of unsaturated lactones (XL, XLI: $R^3 = H$); hexa-1,5-diene into 2,5-dimethylcyclopent-2-enone (XXXIX: $R^1 = R^2 = CH_3$) and enelactones (XL, XLI: $R^3 = CH_3$); and hepta-1,6-diene into 5-ethyl-2-methylcyclopent-2-enone (XXXIX: $R^1 = C_2H_5$; $R^2 = CH_3$). Hepta-1,6-diene probably isomerises into hepta-1,5-diene before carbonylation. The addition of one carbon monoxide molecule to 1,4- and 1,5-dienes yields unsaturated cyclic ketones, but two carbon monoxide molecules give unsaturated lactones [53]:

In the presence of hydrogen iodide and nickel acetate at 270°C and a carbon monoxide pressure of 300 atm cyclo-octa-1,5-diene gives a good yield of cyclo-octanecarboxylic acid [54].

2. Reactions in the presence of Acid Catalysts

The lower dienes polymerise rapidly under the influence of strong mineral acids, and therefore are not used for the preparation of dicarboxylic acids. The latter are formed only from branched dienes in which the double bonds are separated by at least 5–8 carbon atoms. 2,5-Dimethylhexa-1,5-diene in the presence of sulphuric acid with formic acid as carbonylating agent at room temperature and atmospheric pressures gives $\alpha\alpha\alpha'\alpha'$-tetramethyladipic acid in 2–3% yield together with monocarboxylic acids (20–40%) such as 2,2,5-trimethylhexanoic acid, a dimeric C_{17} acid, and 1,2,4-trimethylcyclopentanecarboxylic acid, as well as neutral products such as esters, lactones, hydrocarbons, and 2,2,5,5-tetramethyloxolan. 2,11-Dimethyldodeca-1,11-diene forms 2,11-dimethyldodecanedicarboxylic acid (30%). [55] Cyclic polyenes—cyclododeca-1,5-diene and cyclododeca-1,5,9-triene—yield the expected di- and tri-carboxylic acids. A transannular reaction takes place with hydride migration, resulting in tricyclic systems, which combine with carbon monoxide to form acids having a carboxyl attached to the bridge carbon atom. Cyclododeca-1,5-diene forms a mixture of *cis*- and *trans*-decahydronaphthoic acids; a mixture of isomeric perhydroacenaphthenecarboxylic acids is obtained from cyclododeca-1,5,9-triene. Dienes in which the double bonds are isolated are carboxylated in the presence of the same catalyst under similar conditions to form low yields of dicarboxylic acid, and only if the double bonds are separated by 7–9 carbon atoms [56].



III. CARBONYLATION OF ALCOHOLS

1. Reactions in the presence of Catalysts based on Group VIII Metals

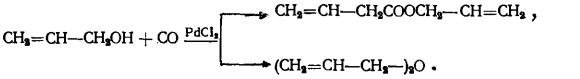
(*a*) Acetylenic alcohols

When acetylenic compounds undergo carbonylation, the carboxyl appears on a carbon atom attached to a substituent (A)—e.g. Alk, Ar, CH_2OH, CH_2CH_2OH, $CH_2CH_2CH_2OH$, $CH_3COOCHR$, $CH_2CH_2O\overline{CHO[CH_2]_3CH_2}$—that "attracts" carbon monoxide. Substituents of type B, which "repel"

carbon monoxide—e.g. H, CHROH, CR_2OH, COOH, $COOCH_3$, $COOC_2H_5$, $COCH_3$, $CH_2C(CH_3)_2OH$—promote its addition at the other carbon atom forming the triple bond. If in any compound XC : CY the substituents X and Y are both of type A, carbonylation will be rapid. When X is of type A, and Y of type B, the reaction is still quite rapid, the compound XC(COOH) : CHY being formed. If X and Y are both of type B, reaction is slow, and only after prolonged heating are unsaturated carboxylic acids formed in low yield. An exception is unsubstituted acetylene, which is carbonylated easily and smoothly [1]. Acetylenic compounds containing a primary or secondary hydroxyl give unsaturated hydroxy-acids, which under the reaction conditions often polymarise or form lactones. This route has been used to synthesise the natural antibiotic α-methylenebutyrolactone [4,5,57]:

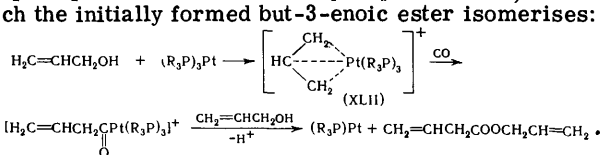
Prop-2-ynyl alcohol reacts with carbon monoxide in ethanol in the presence of stoichiometric quantities of tetracarbonylnickel at 55°C and atmospheric pressure to give $CH_2 : C(CH_2OH)COOC_2H_5$ (58%) and $HOCH_2CH : CHCOOC_2H_5$ (11%). The methyl, n-butyl, and isobutyl esters have been prepared similarly. With catalytic quantities of the carbonyl reaction takes place at 85 to 145°C and 1.4–14 atm. A maximum pressure corresponds to a fixed reaction temperature, and exceeding this pressure by 10% brings the reaction to a halt [58]. Secondary $\alpha\beta$-acetylenic carbinols react readily with tetracarbonylnickel to form unsaturated acids:

Under similar conditions tertiary $\alpha\beta$-acetylenic carbinols, e.g. 1,1-dimethylprop-2-ynol, hardly react with stoichiometric quantities of tetracarbonylnickel [57], but in anhydrous butanol containing hydrogen chloride this carbinol gives at room temperature and atmospheric pressure a product containing $(CH_3)_2C(OH)CH : CHCOOC_4H_9$. [59] 1-Ethynylbutyl acetate in a mixture of ethanol and acetic acid reacts readily with tetracarbonylnickel at 70°C to form $CH_3CH_2CH_2CH(OCOCH_3)C(COOH) : CH_2$ (40%). [59]



Acetylenic alcohols and glycols are carbonylated also in the presence of bistetracarbonylcobalt. In the intermediate complexes the triple bond is perpendicular to the cobalt–cobalt bond [60].

Prop-2-ynyl alcohol in methanolic hydrogen chloride, in the presence of small quantities of palladium on carbon at 100°C and a carbon monoxide pressure of 100 atm gives methyl itaconate (63%) and aconitate (10%) contaminated with methyl α-methoxymethylacrylate. Substituted prop-2-ynols react similarly [61].



(b) Olefinic alcohols

Aliphatic 2,3- and 3,4-unsaturated alcohols and their alkylated derivatives react with carbon monoxide in the presence of bistetracarbonylcobalt or rhodium trichloride in benzene at 200–250°C and 300 atm to form γ- or δ-lactones. 2,2-Disubstituted primary alcohols give the highest yield of lactones. Primary and secondary 2,3- and 3,4-unsaturated alcohols isomerise under the reaction conditions into carbonyl compounds, the aldehydes condensing by the Tishchenko reaction. The carbonylation of tertiary 2,3- and 3,4-unsaturated alcohols is a slow reaction accompanied by dehydration. The reaction is slower in the presence of hydrogen tetracarbonylcobaltate than with bistetracarbonylcobalt [62]. Allyl alcohol gives a 60% yield of γ-butyrolactone with the latter catalyst at carbon monoxide pressures of 100–300 atm in the presence of 6–10% of hydrogen at 100–170°C. The addition of pyridine accelerates the reaction, and the use of acetonitrile and its derivatives as solvents tends to increase the rate and enhance the selectivity [63–65].

A feature of the use of palladium catalysts in the carbonylation of allyl alcohols is that the double bond may be preserved with the formation of an ester of a β-unsaturated acid [42,66]. Ethyl esters of $\beta\gamma$-unsaturated carboxylic acids are obtained from allyl alcohols in ethanol in the presence of palladium dichloride at 80–120°C and 100 atm. In the absence of a solvent the reaction is

Under the same conditions substituted allyl alcohols, e.g. but-2-enol and but-3-enol, are converted into the same product, ethyl pent-3-enoate [67]. Allyl alcohol reacts with carbon monoxide in the presence of tristri-*p*-fluorophenylphosphineplatinum to form mainly allyl crotonate, into which the initially formed but-3-enoic ester isomerises:

The π-allyl complex (XLII) is formed at 1000 atm and 200°C from allyl alcohol and a catalyst [68].

The interaction of allylic alcohols with carbon monoxide in the presence of acetylene, alcohol, tetracarbonylnickel, and hydrogen chloride yields dienoic acids with intermediate formation of allyl halides [69,70].

(c) Saturated alcohols

The earlier investigations on the carbonylation of saturated alcohols using catalysts based on Group VIII metals have been reviewed previously [71]. The carbonylation of methanol to acetic acid $CH_3OH + CO \rightarrow CH_3COOH$ has now acquired great practical importance, the most effective catalyst being cobalt acetate modified with potassium iodide. The reaction is conducted with the addition of 0.1% of the catalyst at temperatures of 220–260°C and pressures above 300 atm with 30–70 mole % of water in the methanol [72,73]. The conversion of methanol into acid is 50–80% with a constant of 40–60% of acetic acid in the reaction products. Methyl acetate is formed as an intermediate [72], the rate constant is proportional to $[CO]^2$, and its (Arrhenius) temperature dependence is non-linear [74]. The reaction has also been conducted as a continuous process at 200°C and 400 atm with an initial mixture comprising (mole %) 47.5 CH_3OH + 50.0 H_2O + 2.5 CH_3COOH and a conversion of methanol of 60.5% [75] The activity of the catalyst is adversely affected by replacing potassium iodide by iodine [76]. It has been shown spectroscopically that, in the presence of excess of iodide ions, most of the cobalt(II) forms the tetrahedral complex ion $[CoI_n(OCOCH_3)_{4-n}]^{2-}$ ($n = 1-4$) instead of carbonyls. The content of this ion increases during the reaction. The course of the reaction is affected by the addition of potassium acetate. With the proportions $CH_3COOK : Co^{II} = 1-2$ the reaction velocity is a maximum, and the formation of acetone is inhibited; if, however, this ratio is 4, reaction

does not take place. The formation of cobalt carbonyl is accelerated by the addition of potassium acetate [77]. Similar effects are exerted by lithium, sodium, magnesium, and manganese acetates, potassium propionate, and sodium benzoate [78]. The productivity of the catalyst is 0.1–0.2 kg litre^{-1} h^{-1}. [77] When sufficient water is present, the methyl acetate and acetone formed as byproducts are hydrolysed to methanol [79]. Another selective catalyst is nickel acetate modified with iodine [80]. The following scheme has been suggested for the reaction

$$2CoI_2 \xrightarrow[-(HI+CO_2)]{CO+H_2O} Co_2(CO)_8 \xrightarrow[-CO_2]{CO+H_2O} 2HCo(CO)_4;$$

$$CH_3OH \xrightarrow[-H_2O]{HI} CH_3I;\ HCo(CO)_4 \underset{HI}{\overset{CH_3I}{\rightleftarrows}} CH_3Co(CO)_4 \rightarrow CH_3COCo(CO)_3 .$$

Acetic acid may then be formed in two ways:

$$\underset{CO\downarrow\uparrow -CO}{CH_3COCo(CO)_3} \xrightarrow{+H_2O} CH_3COOH + \underset{CO\downarrow\uparrow -CO}{HCo(CO)_3},$$

$$CH_3COCo(CO)_4 \xrightarrow{+H_2O} CH_3COOH + HCo(CO)_4 .$$

In 1964 an installation producing 1000 metric tons of acetic acid per month was started up in West Germany [79]. Several large works are operating this process in the U.S.A. and West Germany [81–83]. Acetic acid is obtained in 90% yield based on methanol and 70% based on carbon monoxide with the use of cobalt(II) iodide at 250–260°C and 650–700 atm. In the presence of cobalt diacetate and sodium, potassium, lithium, and calcium iodides with a catalyst concentration of 1–20 mole % at 180–220°C and 300–500 atm the reaction of methanol with a mixture of carbon monoxide and hydrogen (1.5 : 1) is used to obtain acetic esters (40–60%), acetaldehyde, and the hydrogenation product of the latter—ethanol [84].

Rhodium and iridium catalysts are employed for the carbonylation of methanol under homogeneous reaction conditions—e.g. $RhCl_3.3H_2O$, $Rh_2O_3.5H_2O$, $RhCl(CO).(P(C_6H_5)_3)_2$, $(RhCl(CO)_2)_2$, $IrCl_3.3H_2O$, $Ir_4(CO)_2$, $IrCl(CO)(P(C_6H_5)_3)_2$—modified with halides and halogens (iodine, hydrogen iodide, calcium iodide dissolved in benzene, water, methanol, nitrobenzene, acetic acid) [85]. These catalysts are active at 175–250°C and low pressures, even subatmospheric, when the selectivity reaches 99%.

In the presence of a rhodium sesquioxide–carbon catalyst modified with methyl iodide or hydrogen iodide, under conditions of heterogeneous catalysis at 1–15 atm, the conversion of methanol into acetic acid and methyl acetate is 93%. [86]

The carbonylation of alcohols in the presence of α-oxides and carbonyls of cobalt, rhodium, and iridium at ~300 atm and 120–250°C has been used to prepare [87] hydroxy-carboxylic esters in yields up to 97%.

2. Reactions in the presence of Acid and Basic Catalysts

The early results on the carbonylation of alcohols in the presence of catalysts of acidic and basic character have been discussed in a previous review [71].

The carbonylation of saturated alcohols at carbon monoxide pressures of 50–90 atm and 15–70°C occurs in two stages in the presence of 96–98% sulphuric acid [88]. The first stage involves interaction of the initial alcohol, carbon monoxide, and sulphuric acid, with the assumed formation of acylsulphuric acids in equilibrium with acylium and hydrogen sulphate ions. In the second stage water or alcohol is added to the reaction mixture, which results in the formation of carboxylic acids or their esters mixed with small quantities of the free acids:

$$ROH + H_2SO_4 \xrightarrow{-H_2O} R^+ + \bar{O}SO_2OH \xrightarrow{CO} R'\overset{+}{C}O + \bar{O}SO_2OH \rightleftarrows$$

$$\rightleftarrows R'\underset{\underset{O}{\|}}{C}OSO_2OH \xrightarrow[-H_2SO_4]{HX} R'\underset{\underset{O}{\|}}{C}-X$$

where R′ is a radical isomeric with R but more branched, and X = OH, OR″. With C_{3-5} aliphatic alcohols the yield of acids and esters increases with the molecular weight of the alcohol and on passing from a straight-chain alcohol to a branched-chain isomer. The main reaction products are carboxylic acids (or their esters) containing one more carbon atom than in the initial alcohol, with a quaternary or more rarely a tertiary carbon atom in the α-position. Propyl and isopropyl alcohols give isobutyric acid, n-butanol yields α-methylbutyric acid, isobutanol forms αα-dimethylpropionic acid, n-pentanol yields a mixture of αα-dimethyl- and α-ethyl-butyric acids (1.7 : 1), and isopentanol gives αα-dimethylbutyric acid. The total yield of acids and esters from C_{6-10} alcohols is 70–95%, and varies little with the molecular weight of the alcohol [89]. Cyclohexanol yields 1-methylcyclopentanecarboxylic and cyclohexanecarboxylic acids (2 : 1), cyclopentanol gives cyclopentanecarboxylic and *cis*-decahydronaphthalene-9-carboxylic acids (20 : 1), and *p*-menthol forms methane-*p*-carboxylic acid [90]. Raising the carbon monoxide pressure from 5 yo 75 atm increases the total yield of esters on methoxycarbonylation. In the case of isobutyl alcohol the content of the αα-dimethylpropionic ester is independent of the carbon monoxide pressure at ~80%; [91] but in the case of n-pentanol the content of the α-ethylbutyric ester increases at the expense of the αα-dimethylbutyric ester, the total yield of esters at 70 atm being 82–86%. [92] The composition of the products of the methoxycarbonylation of n-pentanol is almost independent of the molar ratio of sulphuric acid to alcohol in the range 4–10. The optimum temperature in the first stage of the reaction is ~60°C. [93]

Carboxylic acids are synthesised from alcohols with formic acid as carbonylating reagent in the presence of sulphuric acid at atmospheric pressure and room temperature. Alcohols of the neopentyl type, which cannot be directly dehydrated to alkenes, also undergo the above reaction [94]. This shows that alcohols may not be dehydrated to alkenes under the influence of an acid catalyst, but may form carbonium ions directly, which then react with carbon monoxide.

Neopentyl alcohol gives αα-dimethylbutyric acid, 2,2-dimethylbutanol yields a mixture of αα-dimethylvaleric and α-ethyl-α-methylbutyric acids (1 : 2), and 1′-methylcyclopentylmethanol forms 1-methylcyclohexanecarboxylic acid. In the case of 1′-methylcyclohexylmethanol and its homologues the hydroxymethyl carbon enters an alkyl side-chain. Bicyclo[3,3,0]oct-1′-ylmethanol gives bicyclo[3,3,1]nonane-1-carboxylic acid, hexahydroindan-8′-ylmethanol yields a mixture of *cis*- and *trans*-decahydro-9-naphthoic acids, decahydronaphth-9′-ylmethanol a mixture of decahydro-1- and -2-methylnaphthoic acids contaminated with bicyclo[5,4,0]undecane-1-carboxylic acid [95,96], and adamantan-1-ol is converted into adamantanecarboxylic acid [97].

Diprimary diols give on carbonylation mainly unsaturated monocarboxylic acids and lactones contaminated with dicarboxylic acids. Nonane-1,9-diol and decane-1,10-diol yield respectively αα′α′-tetramethylpimelic acid (33%) and αα′α′-tetramethylsuberic acid (7%). [55]

The course of carbonylation of ditertiary diols of general formula $HO.CR_2.[CH_2]n.CR_2.OH$ ($n = 4-8$; $R = CH_3$, C_2H_5, $n\text{-}C_4H_9$) is not affected by increase in the size of the alkyl groups provided that the distance between the hydroxyls is maintained. 2,7-Dimethyloctane-2,7-diol ($n = 4$) forms a mixture of four isomeric C_{11} cyclic monocarboxylic acids in ~70% yield. 3,8-Diethyldecane-3,8-diol and 5,10-di-n-butyltetradecane-5,10-diol ($n = 4$) give only cyclic monocarboxylic acids (~70%), and 2,8-dimethylnonane-2,8-diol ($n = 5$) yields a mixture of monocarboxylic (40%) and dicarboxylic (42%) acids. The products from 2,9-dimethyldecane-2,9-diol ($n = 6$) and 2,10-dimethylundecane-2,10-diol ($n = 7$) are dicarboxylic acids (61–63%); the total yield of mixtures of carboxylic acids is 87%, consisting mainly of $\alpha\alpha\alpha'\alpha'$-tetramethylsebacic and $\alpha\alpha\alpha'\alpha'$-tetramethylbrassylic acids respectively, together with 16 to 24% of cyclic monocarboxylic acids. 2,11-Dimethyldodecane-2,11-diol ($n = 8$) yields a mixture of carboxylic acids (69%) containing 34% of dicarboxylic acids, mainly 2,2,11,11-tetramethyldodecanedioic acid, and monocarboxylic acids (15%) together with polymeric acids (20%), a neutral oil (15%), and polymers (10%).[55]

Carboxylic esters are obtained in two stages from alcohols and formic acid in the presence of a large excess of sulphuric acid at atmospheric pressure; in the second stage water is replaced by alcohol. This method has been used to prepare methyl $\alpha\alpha$-dimethyl- and α-ethyl-alkanoates from C_4-C_7 saturated alcohols and cyclohexanol using methanol in the second stage. The free acids are formed together with the esters. The total yield of esters and acids increases with the molecular weight of the initial alcohol and the degree of branching of its molecule[98]. 1-Methyl-, 1-ethyl-, and 1-propyl-cyclohexanols are methoxycarbonylated to form the corresponding methyl 1-alkylcyclohexanecarboxylates in yields up to 40%, cyclohexylmethanol to form methyl 1-methylcyclohexanecarboxylate, cyclopentanol to give methyl cyclopentanecarboxylate (45%) and *cis*-decahydro-9-naphthoate (2%), and 1-methyl- and 1-ethyl-cyclopentanols to yield methyl 1-methylcyclopentanecarboxylate (1%) and 1-methylcyclohexanecarboxylate (4%) respectively[99].

Concentrated orthophosphoric acid is also used as catalyst for the carbonylation of saturated alcohols by carbon monoxide. The optimum temperature for the reaction lies between 125° and 175°C, i.e. 100 deg higher than in the presence of sulphuric acid. The optimum pressure of carbon monoxide is 70–80 atm. Variation in the molar ratio of orthophosphoric acid to alcohol in the range 10–2.5 : 1 has no significant effect on the course of the reaction. The acid can be used repeatedly[100]. The main products of the carbonylation of saturated C_4-C_7 alcohols are their $\alpha\alpha$-dimethyl-, α-ethyl-α-methyl-, and α-ethyl-alkanoates together with the alkanoic acids themselves—derivatives of monomeric, dimeric, and trimeric forms of the initial alcohol—as well as products of the disproportionation of carbonium ions formed from the initial alcohol. Cyclopentanol and cyclohexanol yield only the corresponding free acids, predominantly derivatives of the dimeric form: cyclopentanol gives a mixture of *cis*- and *trans*-decahydro-9-naphthoic acids; cyclohexanol produces not only derivatives of the dimeric form but also small quantities of 1-methylcyclopentanecarboxylic and cyclohexanecarboxylic acids[101-103].

Hydrates of boron trifluoride are active catalysts for the carbonylation of alcohols. In the presence of the dihydrate at 100°C and a carbon monoxide pressure of 100 atm 2-methylpropan-1-ol gives up to 76% yields of $\alpha\alpha$-dimethylpropionic acid or up to ~90% of its isobutyl ester[104]. In the presence of the monohydrate pentan-1-ol and 3-methylbutan-1-ol form a mixture of carboxylic acids containing mainly $\alpha\alpha$-dimethylbutyric acid; the former alcohol produces also α-methylvaleric and α-ethylbutyric acids. In the presence of other hydrates of boron trifluoride, containing 1.5–3.0 H_2O, pentyl $\alpha\alpha$-dimethylbutyrate is obtained from pentan-1-ol, and the isopentyl ester from 3-methylbutan-1-ol; the yield of these esters passes through a maximum at the dihydrate as the water content is decreased[105]. Hexan-1-ol gives hexyl $\alpha\alpha$-dimethylvalerate and α-ethyl-α-methylbutyrate with maximum yields of 76% and 30% respectively, the reaction occurring only in the presence of the sesquihydrate[106]. Heptan-1-ol forms heptyl α-ethyl-α-methylvalerate and 2,2-dimethylhexanoate with respective maximum yields of 46% and 42%; if the hydrate contains more than 1.5 H_2O, hardly any reaction occurs with heptan-1-ol[106]. With pentanol and 3-methylbutanol in the presence of boron trifluoride monohydrate the reaction mixture separates into two layers—carboxylic acids and catalysts—at the end of the reaction only after water has been added. With a catalyst having a higher water content the reaction is accompanied by a sharp separation of reaction products from the catalyst phase without the addition of water, probably because of the presence of a sufficient quantity of water in the catalyst itself[107]. The reaction is represented by the scheme

$$RCH_2CH_2OH + [BF_3 \cdot (n-1)H_2O \cdot OH]^-H^+ \rightarrow R\overset{+}{C}HCH_3 + BF_3 \cdot nH_2O,$$

$$R\overset{+}{C}HCH_3 \xrightarrow{CO} R'\overset{+}{C}O \xrightarrow[-H^+]{ROH} R'COOR.$$

Mixtures of oxiran, methyloxiran, or phenyloxiran with salts (sodium, potassium, or calcium formate, acetate, or benzoate), amines, arsines, or phosphines may serve as catalysts for the carbonylation of methanol with carbon monoxide at 200 atm and 170°C. Methyl formate is obtained in yields up to 64% when the ratio by weight of salt to alkene oxide is 1 : 10. The catalytic activity is ascribed to an alkoxide ion formed, e.g. when the catalyst system comprises oxiran and triphenylphosphine, by the scheme

$$RCOO^- + \underset{\diagdown O \diagup}{CH_2—CH_2} \rightarrow RCOOCH_2CH_2O^- \xrightarrow{CH_3OH} RCOOCH_2CHO_2H + CH_3O^-,$$

$$(C_6H_5)_3P + \underset{\diagdown O \diagup}{CH_2—CH_2} \rightarrow (C_6H_5)_3P\overset{+}{C}H_2CH_2O^- \xrightarrow{CH_3OH} (C_6H_5)_3P\overset{+}{C}H_2CH_2OH + CH_3O^-.$$

The true catalyst of the latter reaction is regarded[108] as the compound

$$(C_6H_5)_3\overset{+}{P}CH_2CH_2OCH_2\overline{O}CH_3$$
(XLIII)

formed from the alcohol, oxiran, and the base.

IV. CARBONYLATION OF HALOGENO-DERIVATIVES

1. Acetylenic Halogeno-derivatives

In the presence of tetracarbonylnickel α-iodoacetylenes are reduced to acetylenic hydrocarbons, which are not carbonylated[4,57,109]. α-Chloroacetylenes form allenic acids mixed with substituted malonic acids and ketones. The carbonylation of β- and γ-halogenated acetylenes occurs more easily the more remote is the halogen from the triple bond[110-112]. Prop-2-ynyl chloride, carbon monoxide, and water in the presence of tetracarbonylnickel give a 70% yield of a mixture of butadienoic and itaconic acids[112]:

$$CH_2{=}C(COOH)CH_2COOH \xleftarrow[-HCl]{2CO+2H_2O} CH{\equiv}CCH_2Cl \xrightarrow[-HCl]{CO+H_2O} H_2C{=}C{=}CHCOOH.$$

In the presence of small quantities of water itaconic acid is the main product [111]. Prop-2-ynyl bromide reacts with tetracarbonylnickel in alcoholic solution at atmospheric pressure and 70°C to form ethyl 3-bromobut-3-enoate in ~20% yield. Reaction is less vigorous under carbon monoxide pressure, probably because in the first stage the complex of the acetylenic compound with the carbonyl is formed with the evolution of carbon monoxide [113]. It is preferable to prepare allenic acids in an aqueous–alcoholic buffer by the reaction

$$R^1C{\equiv}CCR^2R^3Cl \xrightarrow[-HCl]{Ni(CO)_4,\ H_2O} HOOCCR^1{=}C{=}CR^2R^3$$

than by means of Grignard reagents and carbon dioxide. The possibility of initial rearrangement of the α-chloroacetylene into a chloroallene is eliminated, since chloroallene does not react under these conditions [114].

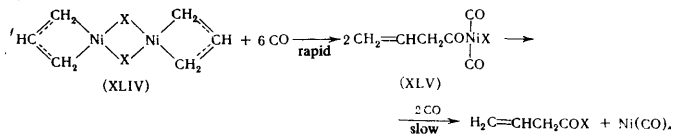
In the presence of palladium dichloride at ~20°C and 100 atm carbon monoxide pressure prop-2-ynyl chloride in methanolic solution reacts with carbon monoxide to form methyl itaconate in 66% yield together with small quantities of methyl 3-chlorobut-3-enoate [61].

2. Ethylenic Halogeno-derivatives

Unsaturated acids or their esters are obtained by the carbonylation of alkenyl halides in aqueous or alcoholic solution in the presence of tetracarbonylnickel under carbon monoxide pressure. With unbranched 1-halogenoalkenes the reaction is

$$RCH{=}CHCH_2Cl + CO + R^1OH \xrightarrow{Ni(CO)_4} RCH{=}CHCH_2COOR^1 + HCl$$

accompanied by the side-reaction



$$2\,RCH{=}CHCH_2Cl + Ni(CO)_4 \rightarrow (RCH{=}CHCH_2)_2 + 4CO + NiCl_2\ .$$

Allyl chloride yields crotonic acid by isomerisation of the initially formed but-3-enoic acid [112], but-2-enyl chloride gives pent-3-enoic acid, and 5-chloropent-3-enonitrile forms the mononitrile of dihydromuconic acid, which on hydrogenation is converted into caprolactam.

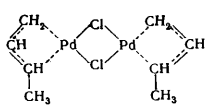
The catalytic activity of tetracarbonylnickel is explained by the intermediate formation of a complex carbonyl-π-allylnickel chloride $[Ni(CO)_3CH_2CH{:}CHR]^+Cl^-$, which breaks down under the influence of carbon monoxide and alcohol [112,114–118]. Five-coordinated nickel complexes of the type $[NiHalCO\pi\text{-allyl}.(C_6H_5)_3P]$ are assumed to be formed as intermediates in the carbonylation of allyl compounds. These complexes are obtained by the reaction of allyl halides with tricarbonyltriphenylphosphinenickel in a mixture of methanol and benzene [119]. The carbonylation of bis-π-allylnickel halide complexes (Hal = Br or I) in the presence of tetracarbonylnickel yields methyl methacrylate (50–70%) contaminated with methyl crotonate [120,121]. The main product of the carbonylation of allyl halides with carbon monoxide at 50 atm and 100°C is methyl but-3-enoate, which is also obtained by the carbonylation of bis-π-allylnickel bromide [122]. The reaction is represented by the scheme [123]

$$RCH{=}CHCH_2Br + 2\,Ni(CO)_4 \rightarrow [RCH{=}CHCH_2\cdot Ni(CO)_3]^+Br^- \rightarrow$$
$$\rightarrow RCH{=}CHCH_2COOR^1 + Ni(CO)_4 + HCl\ .$$

The carbonylation of allyl halides is conducted under milder conditions. In the reaction of π-allylnickel iodide with carbon monoxide in ether at 0°C, infrared spectroscopy has detected nickel carbonyl and butenoyl iodide. An unstable intermediate dimeric halogeno-π-allylnickel complex (XLIV) has been isolated, which can exist in ethereal solution at 0°C, and reacts rapidly with carbon monoxide to form a carbonylbutenoylnickel halide (XLV):[124]

(XLIV) (XLV)

$$\xrightarrow[slow]{2\,CO} H_2C{=}CHCH_2COX + Ni(CO)_4$$



Compounds of noble metals are active catalysts for the carbonylation of unsaturated halogeno-derivatives by carbon monoxide. In the presence of palladium dichloride dehalogenation occurs at the same time, and rise in temperature favours the formation of derivatives of unsaturated acids. Vinyl chloride in benzene solution yields $\beta\beta$-dichloropropionyl chloride, but in alcoholic solution saturated with hydrogen chloride at 130°C and 600 atm the ethyl ester is obtained, and at 80°C and 100 atm a mixture of ethyl β-chloropropionate and propionate. Allyl chloride in benzene solution at room temperature and 100 atm forms 3,4-dichlorobutyryl chloride, and at 130°C but-3-enoyl chloride; in alcoholic solution at 120–170°C the products are ethyl but-3-enoate together with the but-2-enoic and isobutyric esters, and at 80°C and 100 atm a mixture of ethyl butyrate, isobutyrate, and β-chloro-α-methylpropionate. These reactions are catalysed also by metallic palladium alone and on carbon, alumina, or a zeolite.

Heating the complex of palladium dichloride with allyl chloride yields but-3-enoyl chloride [9,42,67,125–127]. This complex catalyses the carbonylation by carbon monoxide of allyl chlorides to form chlorides or esters of alk-3-enoic acids [11]. In the presence of bistriphenylphosphinepalladium dichloride the carbonylation of allyl chlorides also takes place with maintenance of the double bond:

$$CH_2{=}CHCH_2X + CO + ROH \rightarrow CH_2{=}CHCH_2COOR + HX$$

where X = Hal and R = Alk or Ar. [66] Pyridine, benzonitrile, and other compounds may also serve as ligands in palladium dichloride.

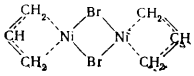
1-Chlorobut-2-ene and 3-chlorobut-1-ene react with carbon monoxide in the presence of di-π-allylchloropalladium at 100°C and 150–180 atm via the intermediate complex

(XLVI)

to form pent-3-enoyl chloride in 80% yield. 3-Methylbut-3- and -2-enoyl chlorides are obtained from 3-chloro-2-methylpropene [11]. The carbonylation of allyl chlorides in the presence of metallic palladium and rhodium, their complexes or salts, to give acid halides is accelerated by additions of acetylene, cycloheptadiene and cyclopentadiene hydrocarbons, indene, and fluorene [128].

3. Allyl Halides in the presence of Acetylene

Acetylene may enter into the reaction of allyl halides with carbon monoxide, water, or alcohol in the presence of metal carbonyls and their salts, generally tetracarbonylnickel, in hydroxylated solvents at 20–60°C to form unbranched dienoic acids or their esters. When 20% of the stoichiometric quantity of nickel carbonyl is used, $\alpha\beta : \delta\epsilon$-dienoic acids and their esters are obtained:

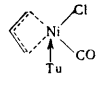


$$RCH{=}CHCH_2X + CO + R^1OH + CH{\equiv}CH \rightarrow RCH{=}CHCH_2CH{=}CHCOOR^1 + HX$$

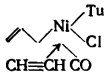
(X = Hal). The reaction goes best at room temperature and atmospheric pressure, with yields up to 80%.[116,129,130] Allyl chloride is converted into hexa-2,5-dienoic acid and its methyl, ethyl, and other esters, which possess a pleasant odour and are stable compounds. Hepta-2,5-dienoic and 5-methylhexa-2,5-dienoic acids are obtained from but-2-enyl and methylallyl chlorides respectively. Secondary react more slowly than primary chloro-derivatives to form the same unbranched dienoic acids. Carbonylation is slowed down or completely inhibited by an electronegative substituent at the double bond. The reactions are favoured by an allyl and also by a phenyl group conjugated with the double bond[131-136]. The following mechanism has been suggested for the reaction involving tetracarbonylnickel[123]:

$$RR^1C{=}CR^2CHR^3Cl + Ni(CO)_4 \rightarrow [(CO)_3NiCHR^3CR^2{=}CRR^1]^+Cl^- \xrightarrow{C_5H_5} \rightarrow \text{cis-}[(CO)_3NiClCOCH{=}CHCHR^3CR^2{=}CRR^1 \xrightarrow{CO} \rightarrow \text{cis-}[(CO)_3NiCOCH{=}CHCHR^3CR^2{=}CRR^1]^+Cl^- \xrightarrow{CO+R^4OH} \rightarrow \text{cis-}\ RR^1C{=}CR^2CHR^3CH{=}CHCOOR^4 + Ni(CO)_4 + HCl\ .$$

The *cis*-configuration of the alkenoyl complex, which favours cyclisation, is confirmed also by the formation of up to 97% yields of acetic esters of phenols when the resulting dienoic acids are treated with acetic anhydride in the presence of zinc, aluminium, or tin(IV) chloride or sulphuric acid as catalyst[123,137].



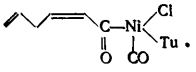
A mixture of carbon monoxide and acetylene reacts with the dimer of π-allylnickel bromide (XLVII) in ether at 0°C to form a dienoyl bromide[124]:



(XLVII)

$$+ 10\,CO + 2\,C_2H_2 \rightarrow 2\,CH_2{=}CHCH_2CH{=}CHCOBr + 2\,Ni(CO)_4\ .$$

The carbonylation of allyl compounds by carbon monoxide in the presence of acetylene can be accomplished in three ways—by the use of nickel carbonyl previously prepared at 20°C and atmospheric pressure, by generating an intermediate compound as catalyst *in situ* at the same temperature and pressure, and finally by using nickel compounds at 150–200°C and pressures of carbon monoxide and acetylene of 30–100 atm—the latter two of which did not require use of the extremely toxic tetracarbonylnickel. For example, a mixture of Raney nickel with thiourea or a mixture of nickel dichloride, thiourea, and iron powder is employed, when the nickel chloride is reduced by the iron powder[117,131,138]. The catalyst may be the five-coordinated nickel complex formed by reducing nickel dichloride hexahydrate with an iron alloy containing 80% of manganese and with thiourea as ligand[139]. The structure of the complex was based on data on five-coordinated halogeno(carbonyl)triphenylphosphine-π-allylnickel[140] and halogeno(thiourea)-π-allylnickel[141] complexes. In the presence of carbon monoxide and acetylene at room temperature and atmospheric pressure the complex catalyst converts methanolic allyl chloride into methyl hexa-2,5-dienoate in ~75% yield. The chief side-products are hexa-1,5-diene, methyl but-3-enoate, 2-oxocyclopent-3-enylacetate, and γ-oxo-δ-2-oxocyclopent-3-enylvalerate, phenyl hexa-2,5-dienoate, and *S*-allylisothiourethane chloride. The five-coordinated nickel complex

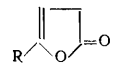


(Tu = thiourea) gives hexa-1,5-diene with allyl chloride, methyl but-3-enoate with carbon monoxide, and *S*-allylisothiourethane chloride with urea[139]. These molecules easily displace acetylene from the complex

(XLVIII)

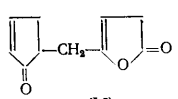
before reaction with the allyl group. In the presence of carbon monoxide this reaction yields

(XLIX)



This is followed either by cyclisation to a cyclopentene ring and then the formation of methyl 2-oxocyclopent-3-enyl acetate on the absorption of carbon monoxide, or by cyclisation to phenol and its reaction with carbon monoxide to form phenyl hexa-2,5-dienoate. Further reactions of the 2-oxocyclopent-3-enylacetic ester followed by hydrogenation of the double bond lead to formation of the γ-oxo-δ-2-oxocyclopent-3-enylvaleric ester[142,143].

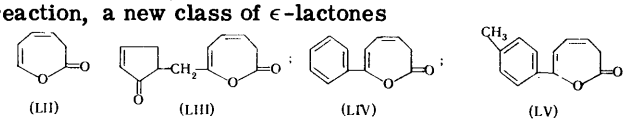
The course of the reaction is affected by the nature of the solvent. When allyl halides react with carbon monoxide and acetylene in the presence of tetracarbonylnickel in ethereal or ketonic solution, the main products are not unsaturated acids and their esters, as is observed in aqueous or alcoholic medium, but cyclopentenonic acids or lactones. In a ketone solution allyl halides with electron-accepting substituents give satisfactory yields of the corresponding dienoic acids[144]. Acetone, ethyl acetate, dioxan, and oxolan are used as solvents. Methylallyl chloride yields derivatives of cyclohexane and bicyclo-[3,1,0]hexane; but allyl bromide yields hexa-2,5-dienoic and 2-oxocyclopent-3-enylacetic acids, and also lactones of 4-hydroxy-2-isopropylidene-5-(2-oxocyclopent-3-enyl)-pent-3-enoic and 4-hydroxy-5-(2-oxocyclopent-3-enyl)-pent-3-enoic acids. The reaction of allyl chloride with propyne in the presence of tetracarbonylnickel in aqueous acetone leads to the formation of 4-methyl-5-oxocyclohex-3-enecarboxylic acid[145].



The reactions of allyl halides in ketone solutions are accompanied by the intermediate formation of carbonylhexadienoylnickel chloride[146]. The effect of the solvent on the reaction is due to stabilisation of the acyl group resulting from donor–acceptor interaction with the carbonyl group of the solvent, perhaps in a complex of the type

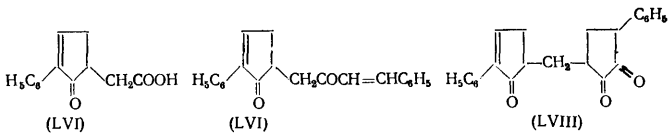
$$[R^1R^2C\dot{O}{-}CRO{-}\dot{N}i(X)CO].$$

Allyl chloride, carbon monoxide, and substituted acetylenes in the presence of tetracarbonylnickel yield ketone and lactone derivatives containing oxocyclopentenylacetic and oxocyclohexenecarboxylic acids. An intermediate complex of the acetylenic compound with the carbonyl reacts with allyl chloride to close the cyclopentene or cyclohexene ring with the addition of carbon monoxide. After this the ring opens to form the acid or, with further addition of carbon monoxide and acetylene, also ketones and lactones[147]. In ketone solutions allyl halides, acetylene, and carbon monoxide in the presence of tetracarbonylnickel form $\beta\gamma$-unsaturated γ-lactones of the types[146,148,149]



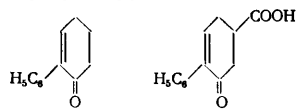
(L)

(LI)



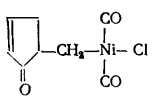
The reaction takes place with the stoichiometric quantity of the carbonyl at 40–50°C. If the concentration of carbon monoxide is low, and water is added at the end of the reaction, a new class of ϵ-lactones

(LII) (LIII) (LIV) (LV)



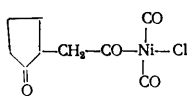
is obtained having two double bonds in the ring. They are formed by the addition of two molecules of acetylene and one molecule of carbon monoxide to an acyl group followed by lactonisation [150].

In the reaction of allyl halides with phenylacetylene and tetracarbonylnickel the allyl group usually adds by means of its primary carbon atom to the unsubstituted carbon in the acetylene, whereas the carbonyl group attacks the hydrocarbon on the opposite side, to form the compound $CH_2:CHCH_2CH:C(C_6H_5)CONiX$. Ring closure results in the formation of cyclopentenone derivatives

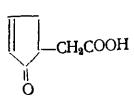


(LVI) (LVI) (LVIII)

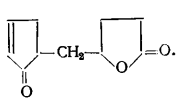
or cyclohexenone derivatives



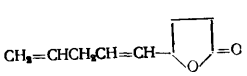
(LIX) (LX)



together with γ-lactones similar to the above [151]. The carbonylation of allyl halides with cyclisation is stereospecific. *cis*-Hexa-2,5-dienyl chloride reacts with tetracarbonylnickel in diethyl ether, benzene, or heptane forming



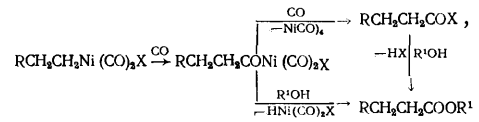
or



in both of which the carbonyl group can be replaced by other ligands, but in the absence of acetylene

is formed. In the presence of acetylene the course of the reaction is strongly dependent on the solvent; in a ketone medium a γ-lactone

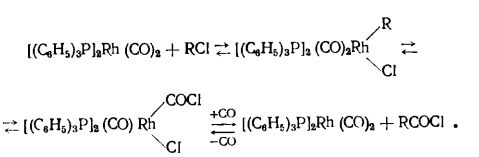
is formed. *trans*-Hexa-2,5-dienyl chloride is not cyclised under the same conditions, but reacts similarly to an acid chloride. In acetone it is mainly converted into a γ-lactone [152].



4. Saturated Halogeno-derivatives

(*a*) Catalysts based on Group VIII metals

The preparation of carboxylic acids from alkyl halides, carbon monoxide, and water is accomplished in the presence of tetracarbonylnickel at 350–450°C and 100 atm.[153,154] The alkyl halide may react directly with the carbonyl [124]:



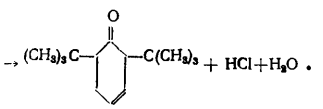
$$Ni(CO)_4 + RCH_2CH_2Cl \rightarrow RCH_2CH_2Ni(CO)_3X,$$

Reaction then takes place with carbon monoxide and an alcohol:

Cobalt carbonyls also catalyse this reaction. In the presence of sodium tetracarbonylcobaltate in alcoholic solution at atmospheric pressure carboxylic esters are obtained in yields up to 80% from alkyl halides. Methyl iodide gives an acetic ester, pentyl iodide forms a hexanoic ester, and 1-chloro- and 2-iodo-octanes give a nonanoic ester. Other catalysts are pent-4-enoyltricarbonylacrylonitrilecobalt, tricarbonyl-π-allylcobalt, acetyltricarbonyltriphenylphosphinecobalt, and sodium tetracarbonylferrate [155]. Ethyl butyrate and isobutyrate are obtained from butyl iodide and carbon monoxide in the presence of potassium tetracarbonylcobaltate in an alcoholic medium. Isomeric compounds are formed by the isomerisation of alkyl- and acyl-cobalt tricarbonyls [156]. In the presence of bistetracarbonylcobalt aldehydes are obtained from alkyl halides and mixtures of carbon monoxide and hydrogen in the proportions 1:4–4:1 at 130–140 atm and 160°C: e.g. octyl bromide yields nonanal (90%). [157] Fluoroalkenes form a complex with bistetracarbonylcobalt at 100°C: tetrafluoroethylene yields μ-tetrafluoroethylene-bistetracarbonylcobalt $(CO)_4Co.CF_2:CF_2.Co(CO)_4$. [158]

Rhodium(II) complexes are also effective catalysts for the carbonylation of alkyl halides to form halides of carboxylic acids [159]. The reaction with chloro-carbonyl-bistriphenylphosphinerhodium(II) can be written [160]

(*b*) Acid catalysts



High yields of acid chlorides are obtained by the reaction of alkyl chlorides with carbon monoxide (at 120 atm) in the presence of aluminium trichloride at 50°C. Polyhalogenated alkanes react at 200°C and 900 atm. Carbon tetrachloride gives a 37% yield of trichloroacetyl chloride, chloroform 21% of dichloroacetyl chloride, and dichloromethane 2% of chloroacetyl chloride. Compounds $C_6H_{6-n}Cl_{n-1}COCl$ and $C_2H_{6-n}Cl_n$ are formed in low yields. [161] In the presence of iron trichloride the reaction takes place under milder conditions (150°C and 50 atm), but with still smaller yields [162]. The following

series of reactions is assumed between t-butyl chloride and carbon monoxide (150 atm) in the presence of aluminium or iron(III) chloride at 5°C:[163]

$$(CH_3)_2C{=}CH_2 + HCl \rightleftarrows (CH_3)_3CCl \overset{+CO}{\underset{-CO}{\rightleftarrows}}$$

$$\rightleftarrows \underset{6-12\%}{(CH_3)_3CCOCl} \overset{+CH_2=C(CH_3)_2}{\rightleftarrows} \underset{12-21\%}{(CH_3)_3CCOCH{=}C(CH_3)_2} + HCl;$$

$$(CH_3)_2C{=}CH_2 + 2\,(CH_3)_3CCOCl \xrightarrow[-AlCl_4^- \text{ or } FeCl_4^-]{AlCl_3 \text{ or } FeCl_3}$$

$$\rightarrow (CH_3)_3C\text{–}C_6H_4\text{–}C(CH_3)_3 + HCl + H_2O\,.$$

Carboxylic acids are prepared from alkyl halides, carbon monoxide, and water in the presence of hydrogen fluoride at 150°C and 45 atm[164]. With carbon monoxide and hydrogen fluoride in the presence of boron trifluoride secondary alkyl chlorides and bromides give high yields of the fluorides of carboxylic acids[165]. t-Pentyl chloride reacts with carbon monoxide and water at high pressures of the former in the presence of silver perchlorate or fluoroborate in nitrobenzene solution to form $\alpha\alpha$-dimethylbutyric acid in quantitative yield[166]. Alkyl halides are converted into carboxylic acid by using, instead of carbon monoxide, formic acid with a large excess of concentrated sulphuric acid at atmospheric pressure and 20–40°C. This method has been employed to obtain α-methylbutyric acid (30%) from s-butyl chloride, and $\alpha\alpha$-dimethylpropionic acid (76%) from t-butyl chloride[167,168]. In the presence of boron trifluoride dihydrate at 25°C and 150 atm methylallyl chloride yields chloro-$\alpha\alpha$-dimethylpropionic acid, and in the presence of a mixture of orthophosphoric acid and boron trifluoride at 70°C and 50 atm carbon monoxide pressure 8-bromo-octene gives a mixture of two isomeric acids—7-bromo-2,2-dimethylheptanoic and 6-bromo-2-ethyl-2-methylhexanoic[169].

Ethyl fluoride in anhydrous hydrogen fluoride under carbon monoxide pressures of 40–400 atm at 120–180°C is converted into a high yield of propionic acid, the reaction being catalysed by the hydrogen fluoride[170]:

$$C_2H_5F \rightarrow C_2H_5^+ + F^-;\ C_2H_5^+ + CO \rightarrow C_2H_5CO^+ \xrightarrow{F^-} C_2H_5COF\,.$$

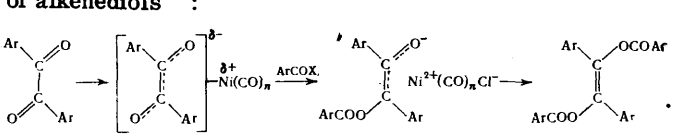
5. Aromatic Halogeno-derivatives

Aromatic acyl fluorides can be prepared from aryl halides in the presence of tetracarbonylnickel and sodium fluoride at 380°C and 600 atm of carbon monoxide[171]. The same compounds are formed when arenediazonium fluoroborates are heated with carbon monoxide in absolute alcohol saturated with hydrogen chloride in the presence of tetracarbonylnickel[172]. Aryl iodides and acetylene in the presence of this carbonyl at 120–140°C and 30 atm give high yields of γ-keto-acids[173]:

$$C_6H_5I + C_2H_2 + Ni(CO)_4 + ROH + HX \rightarrow C_6H_5COCH_2CH_2COOR + NiIX + 2CO$$
(X=OH, OR, Cl, Br, I; R=Alk.)

Chloro- and iodo-benzenes in the presence of nickel and its di-iodide (1 : 3) under 240–320 atm of carbon monoxide at 250–300°C give 95–100% yields of benzoic acid. This method is used to prepare terephthalic (~ 30%), *o*-toluic (60%), 2-naphthoic (52%) acids[174]. An unusual reaction takes place with aryl halides at 250 to 375°C and 300–600 atm of carbon monoxide in toluene or cyclohexane solution in the presence of tetracarbonylnickel and an alkali-metal carbonate or phosphate: bromobenzene gives a mixture of phthalic anhydride (up to 75%) and benzoic anhydride (intermediate product) with benzene, *p*-chlorotoluene forms 4-methylphthalic anhydride (20%), *o*-bromotoluene produces 3-methylphthalic anhydride (45%), *p*-bromobiphenyl yields phenylphthalic anhydride (35%), and 1-chloronaphthalene gives naphthoic anhydride (4%).[175,176] In the presence of alloy catalysts formed by nickel with copper and chromium singly and together methyl terephthalate is obtained in 55–80% yield from *p*-dichlorobenzene, carbon monoxide, and methanol at 250–450°C and 200–1500 atm. Under similar conditions trichlorobenzene is converted into a mixture of benzene-mono-, -di-, and -tri-carboxylic esters[177]. Raney nickel catalyses the formation of carboxylic acids from aryl halides and carbon monoxide at 210–320°C and 100 atm[178]. Nickel formate and dichloride are less active in this reaction.

In the presence of small quantities of tetracarbonylnickel and water at 190–260°C and 200 atm aryl bromides are converted into the corresponding carboxylic acids. Additions of potassium acetate and sodium benzoate increase the yield of acids to 90% and above by keeping down the concentration of the strongly inhibiting hydrogen bromide formed in the reaction. The rate of the reaction is directly proportional to the concentrations of bromobenzene, tetracarbonylnickel, and water and inversely proportional to the pressure of carbon monoxide. When the composition of the reaction mixture is close to stoichiometric, the yield of aromatic carboxylic acids in the presence of nickel diacetate tetrahydrate at 250–260°C increases sharply[179].



Methyl *p*-chlorobenzoate and dimethyl terephthalate are obtained in 30% and 10% yield respectively from *p*-dichlorobenzene in the presence of dicarbonylbistriphenylphosphinenickel in methyl acetate under 350 atm of carbon monoxide at 345–360°C.[180] In benzene solution under 250–350 atm of carbon monoxide at 200–300°C, with the complex $((C_6H_5)_3P)_2NiBr_2.C_4H_9Br$ or a mixture of nickel and iodine as catalyst, a mixture of terephthalic (17–25%) and *p*-chlorobenzoic (75–83%) acids is obtained[181]. The carbonyls of nickel[182–184], cobalt[185,186], and iron[185] are also used in this reaction. *p*-Chlorobenzoic acid, which is an intermediate in the synthesis of terephthalic acid, may be formed either from the acid chloride obtained from carbon monoxide and dichlorobenzene[181] or via a complex of the catalyst with dichlorobenzene[182]. However, the true reaction mechanism has not been finally elucidated.

Tetracarbonylnickel is able to undergo different stoichiometric reactions with aryl halides depending on the solvent employed. Boiling an aryl iodide with the carbonyl and a solvent is assumed to produce an intermediate complex (LXI), which in alcoholic solution then gives esters in quantitative yield, but in an aprotic solvent, e.g. oxolan or n-hexane, is converted into a diketone:

$$ArI + Ni(CO)_4 \rightarrow \underset{(LXI)}{ArCONi(CO)_nI} \rightarrow \begin{cases} \xrightarrow{ROH} ArCOOR + HI + Ni(CO)_n \\ \xrightarrow{oxolan} ArCOCOAr + NiX_2 + CO \end{cases}$$

$$\rightarrow ArC{=}CAr \quad (ArCOO,\ OOCAr)$$

Aryl chlorides, aryl bromides, and alkyl halides do not react with the carbonyl under these conditions[187–190]. Sterically hindered aryl iodides, such as *o*-tolyl and 1-naphthyl iodides, form not only diketones but also esters of alkenediols[188]:

Esters are obtained by the reaction of aryl halides with carbon monoxide and alcohols under high pressures at 350–400°C in the presence of nickel, cobalt, and strontium salts, especially the chlorides, nitrates, naphthenates, and oleates [191].

The reaction of benzyl chloride with potassium tetracarbonylcobaltate has led to the isolation not only of phenylacetyltricarbonylcobalt but also of *o*-toluoyltricarbonylcobalt, an isomerisation product whose formation is strongly promoted by adding hydrogen tetracarbonylcobaltate and also by conducting the reaction in an atmosphere of nitrogen. This isomerisation, which is not observed at 0°C, already occurs at 30–50°C. [192]

Aryl and cycloalkyl halides undergo carbonylation in the presence of palladium, its salts, and its complexes [127,128,193]. This involves the intermediate formation of a complex similar to that obtained in the decarbonylation of acid halides to aryl halides at 35–60°C. [194] The carbonylation of aryl halides takes place also in the presence of alkali metals at 300–380°C and 5–500 atm of carbon monoxide to form high yields of carboxylic acids. Excess of water stops the reaction. Intermediate formation of an alkali-metal formate is assumed [195–197].

Esters are obtained in up to 95% yield from aryl halides and certain alkyl halides in methanolic or butanolic medium in the presence of tetracarbonylnickel and potassium or sodium methoxide or butoxide. The relative proportions of halide, carbonyl, and alkoxide are 1:6:1–3. The reactivity of the halides increases in the sequence RCl < RBr < RI. The system containing the t-butoxide is considerably more active than that containing the methoxide [198].

Among non-aromatic cyclic halogeno-derivatives that undergo carbonylation are also those of adamantane. 1-Bromoadamantane and carbon monoxide in the presence of an acid catalyst yield adamantanecarboxylic acid [199].

---o0o---

The results cited in this Review show that catalysts based on nickel, cobalt, and rhodium carbonyls are the most active in the carbonylation of the compounds under consideration [200]. Catalysts based on platinum and palladium chlorides are also extremely active in the carbonylation of halogeno-derivatives. Carbonylation of almost all the compounds takes place also in the presence of acid catalysts such as sulphuric, orthophosphoric, and hydrofluoric acids, boron trifluoride, etc. Special interest attaches to the possibility of effecting the reaction in the presence of these catalysts at atmospheric pressure, with the use of formic acid as carbonylating agent. Carbonylation catalysts based on Group VIII metals, especially with the addition of phosphines, arsines, and amines, are usually more selective than acid catalysts.

So called "stoichiometric" methods, in which tetracarbonylnickel is most often the source of the carbonyl group, can be used as well as catalytic methods.

The conditions of carbonylation and the nature of catalysts and solvents have a marked effect on the course of the reactions. Thus unsaturated monocarboxylic and saturated dicarboxylic acids and their esters, lactones, and chlorides can be obtained from di- and poly-unsaturated hydrocarbons. Saturated and unsaturated acids, their esters, and lactones have been obtained from alcohols. Halogeno-derivatives yield saturated and unsaturated acids, their esters, $\alpha\beta:\gamma\epsilon$-dienoic acids and esters, the difficultly accessible $\beta\gamma$-unsaturated γ-lactones, chloroalkanoic and chloroalkenoic esters, and acid chlorides and fluorides of carboxylic acids.

The production of acetic acid from methanol and the carbonylation of cyclododeca-1,5,9-triene in order to obtain 13-tridecalactam have been accomplished on an industrial scale.

2-Arylindane-1,3-diones—A New Class of Radical-active Compounds

V.V.Moiseev and I.T.Poluktov

Being cyclic β-diketones, 2-arylindane-1,3-diones play an active part in radical reactions: they react vigorously with stable radicals, inhibit the autoxidation of hydrocarbons and polymers, accelerate radical polymerisation, are effective chain-transfer agents in polymerisation, and are oxidised by oxygen and inorganic oxidants. In several radical reactions they behave like phenols, and are more reactive than the latter. A list of 141 references is included.

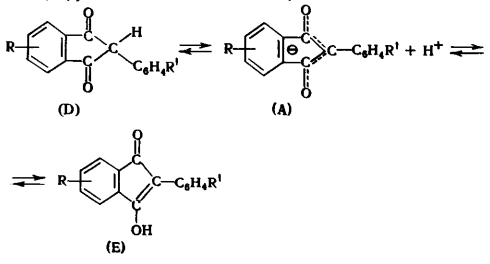
I. INTRODUCTION

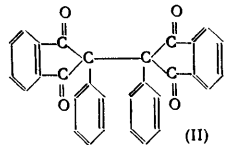


Phenols, amines, thiols, sulphides, and phosphorus-containing compounds are the main classes of organic compounds which actively influence radical reactions. They are widely used as inhibitors of the autoxidation of organic compounds in the liquid phase, stabilisers for polymers, regulators of polymerisation, and inhibitors of radical polymerisation[1-6].

During recent years a new class of radical-active compounds, 2-arylindane-1,3-diones, has been attracting the interest of research workers. The best known representative of this type is 2-phenylindane-1,3-dione

(I)

which was first synthesised in 1893 by Nathanson[7]. In the past a great deal of work was done on the preparation of its derivatives. The synthesis of 2-arylindane-1,3-diones is quite simple and can be accomplished by several methods[8-15]. All known 2-arylindane-1,3-diones are crystalline compounds, several of which are coloured[16]. They can exist in three forms[17]—in the diketo-form (D), as an anion (A), and as an enol (E):

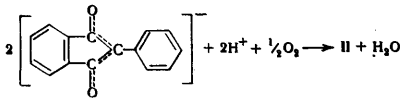


(D) (A) (E)

Equilibrium is established between these forms depending on the nature of substituents, the pH of the solution, and the medium, which makes 2-arylindane-1,3-diones extremely useful subjects for investigation from many points of view. Work on the preparation of substituted derivatives was stimulated by their practical application as blood anticoagulants. 2-Phenylindane-1,3-dione has been used in medical practice under the name "Fenilin".[10]

Although the first radical reactions were observed long ago by Nathanson, study of the oxidation of 2-phenylindane-1,3-dione by oxides of nitrogen and other oxidants was only the beginning of the investigation of these reactions as applied to 2-arylindane-1,3-diones. The need to study the behaviour of these compounds in radical reactions has arisen[18] as part of the problem of the interrelationship of structure, reactivity in homolytic reactions, and physiological activity in a series of indane-1,3-dione derivatives. Although the latter two relations could not be established[19,20], examination of the radical reactions of 2-arylindane-1,3-diones was of intrinsic practical and theoretical interest. The first systematic investigation[21] and subsequent work together with researches by other investigators have shown that these are radical-active compounds with a wide range of action. They react vigorously with stable radicals, inhibit liquid-phase oxidations, and stabilise polymers. They have a peculiar influence on radical polymerisation, acting as accelerators and regulators. In several cases 2-arylindane-1,3-diones are more effective than known compounds of other classes in their reactivity.

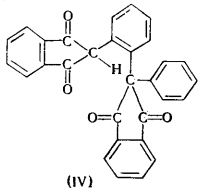
II. OXIDATION OF 2-ARYLINDANE-1,3-DIONES BY OXYGEN



2-Arylindane-1,3-diones are quite easily oxidised by oxygen. The prolonged boiling[22] of an alcoholic solution of 5-methyl-2-phenylindane-1,3-dione in air produces dimerisation. In sodium hydrogen carbonate solution 2-phenylindane-1,3-dione is converted into the dimer—1,2-diphenyl-1,2-diphthaloylethane

(II)

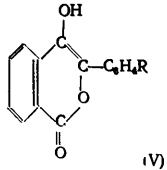
in six weeks; an alcoholic solution of the diketone is decolorised in three weeks[23]. Methanolic solutions of 2-arylindane-1,3-diones are more stable than aqueous solutions[24]. Sodium 1,3-dioxo-2-phenylindane-4-sulphonate(III) is the least stable among these compounds: aqueous solutions of concentration 10^{-4} M at pH 4.3, 10^{-3} M,



and 10^{-2} M undergo 50%, 30%, and 5% decomposition respectively in 1 h. The rate of oxidation of (III) depends on pH: the compound is most stable at pH 0, the rate of oxidation increasing with change in hydrogen-ion concentration in either direction. In strongly alkaline media, containing few hydrogen ions, a 0.001 M solution of (III) is almost unchanged after 1 h. The part played by hydrogen ions in the conversion of sodium 1,3-dioxo-2-phenylindane-4-sulphonate is indicated by the considerable rise in pH observed during the oxidation. It is suggested that the oxidation of 2-phenylindane-1,3-dione to a dimer takes place via a conjugated anion:

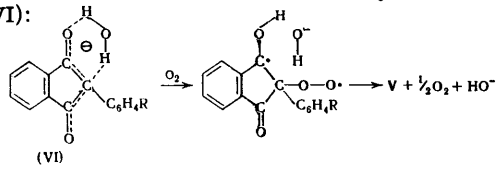
A kinetic study by Sztark[25] has shown that the oxidation of 2-phenylindane-1,3-dione in aqueous solution is a first-order reaction with a rate of 2.45×10^{-4} h^{-1} at 20°C and pH 12. The activation energy is 6.164×10^{-4} J $mole^{-1}$ deg^{-1}. The mean temperature coefficient of the reaction is 1.7. The extrapolated half-decomposition time at 20°C is 164 days.

Fig. 1 shows the pH dependence of the rate of oxidation of 2-phenylindane-1,3-dione. The diketone is seen to be most stable at pH 9.



The oxidation of 2-arylindane-1,3-diones by oxygen can occur in two ways—with the formation of dimers as above and of 4-hydroxyisochroman-1-ones[26,27], which are then converted into acids and derivatives of benzoylphthalide. The dimer (II) is always formed when 2-phenylindane-1,3-dione is oxidised in alcohol, in ether, and also in pyridine in the presence of copper(I) bromide[28,29]. In this case oxidation is rapid, and together with (II) a small quantity of an isomeric dimer

(IV)



2-phenyl-*o*-phenylenebis-2,2′-indane-1,3-dione, is also isolated. The structure and the reactions of the dimer (II) have been studied quite fully[30-33]. 2-*p*-Methoxyphenylindane-1,3-dione in toluene at room temperature is easily dimerised by the action of oxygen[34]; oxidation of 2-*p*-dimethylaminophenylindane-1,3-dione has been observed during synthesis[35].

In an alkaline medium at 60–80°C 2-arylindane-1,3-diones are converted into substituted isocoumarins[27,36-39]

(V)

It has been suggested[38] that the conversion in alkaline aqueous solution involves oxidation of a hydrated diketone anion (VI):

(VI)

The addition of copper salts to an alkaline solution of 2-phenylindane-1,3-dione not only accelerates oxidation but also changes the composition of the products[27]: both 4-hydroxy-3-phenylisochroman-1-one and the dimer (II) are formed. The quantity of dimer increases with increase in the concentration of copper ions. The formation of various acids in the oxidation of 2-phenylindanedione is probably due to further oxidation and conversion of the 3-phenyl derivative (V) in alkaline medium, although this is a matter of controversy[40]. Substituted 4-hydroxy-3-phenylisochroman-1-ones are formed also when 2-arylindanediones undergo oxidation in the presence of amines[34,41]. The oxidation of diketones is accelerated by amines. Vanag and Pilegis[42] noted the formation of complexes of 2-phenylindanedione with amines.

Ozolina and Neilands[43-46] observed the oxidation by atmospheric oxygen of biphenyl and diphenyl oxide analogues of 2-arylindanediones.

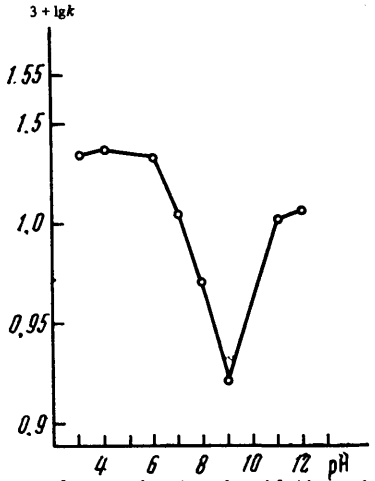


Figure 1. Dependence of rate of oxidation of 2-phenylindanedione on pH of solution.

III. ACTION OF INORGANIC OXIDANTS

In 1893 Nathanson[7] first obtained 1,2-diphenyl-1,2-diphthaloylethane (II) by passing oxides of nitrogen into an alcoholic solution of 2-phenylindane-1,3-dione. The action of pentyl nitrite produced a similar result. Boiling an alcoholic solution of 2-phenylindanedione with sodium nitrite became a simple and convenient method[7,21,23] for obtaining the dimer (II) as well as dimers[22] from substituted 2-phenylindanediones.

Formation of dimers is observed also when substituted indane-1,3-diones are treated with other oxidants. Nitric acid[47] oxidises 2-*m*-tolylindanedione; the dilute acid causes[48,49] dimerisation of the 2-*p*-nitrophenyl and 2-*p*-methoxyphenyl compounds. The nitration of 4,5-dimethoxyindane-1,3-dione produces as byproduct[50] a dimer of 4,5-dimethoxy-2-nitroindanedione. 2-Arylindanediones are easily oxidised by iodine[33,51,52] and by potassium hexacyanoferrate(III)[22,51] in an alkaline medium:

$$\Phi^- + Fe(CN)_6^{3-} \rightarrow \Phi^{\cdot} + Fe(CN)_6^{4-}$$

$$2\,\Phi^{\cdot} \rightarrow \Phi{-}\Phi$$

where Φ^- is the anion of 2-phenylindane-1,3-dione.

2-Methylindane-1,3-dione is oxidised to a dimer by potassium persulphate[53,54]. Substituted 2-phenylindanediones are oxidised to the corresponding dimers by potassium hexacyanoferrate(III), ammonium persulphate, and iron(III) chloride[55,56]. Ethyl 1,3-dioxoindanecarboxylate dimerises under the influence of lead dioxide[57]. Dimers are formed from 2-arylindanediones also in other reactions—in the thiocyanation[58] of the 2-halogeno-derivatives, in the interaction[59,60] of 2-bromo-2-*p*-nitrophenylindanedione with various amines, on treatment[61] of 2-bromo-2-phenylindanedione with alcoholic ammonia and with copper powder, and also on interaction with sodium 2-phenylindanedione. Dimers are formed also[62,63] when 2-aryl-2-iodoindanediones are heated and when 2-nitro-2-*p*-nitrophenylindanedione is boiled in anhydrous carbon tetrachloride or acetic acid[27]. Heating 2-bromo-5-methyl-2-phenylin-

anode both in alkaline[73-77] and in acid[77-82] media. Current–voltage measurements with a controlled current have been successfully applied to the anodic oxidation of β-diketones. In an alkaline medium the 2-arylindanedione anion undergoes oxidation; but in an acid medium the anodic current is maintained by oxidation of the enolic form[82]. In both cases the oxidation products are assumed to be the corresponding dimers. Table 1 lists the oxidation potentials relative to the saturated calomel electrode of the anions $E^{A}_{1/2}$ [74] and of the undissociated enolic forms $E^{E}_{1/2}$ [80] of substituted 2-phenylindanediones. These results clearly show the influence of substituents on the ease of electrochemical oxidation: electron-donating substituents considerably facilitate oxidation; the effect of substituents in the phthaloyl fragment[77] is considerably more complicated.

atom, activation energies E, and pre-exponential factors k_0 for reaction of the radical with the above compounds in dioxan at 20°C. The activation energy could not be determined for 2-naphth-2′-ylindane-1,3-dione, since it is obviously very small. The values found for the rate constants and activation energies for the 2-arylindanediones are close to those for the corresponding reaction of DPPH with phenols[99-101].

Table 2. Rate constants for the reactions of diphenylpicrylhydrazyl with 2-arylindanediones.

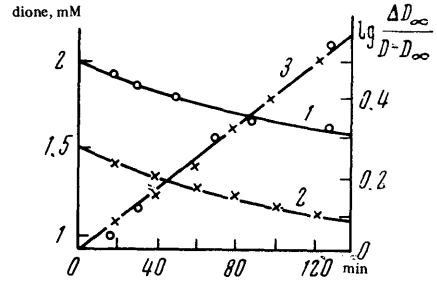
Aryl	a	k_1, M^{-1} min^{-1}	E, kcal $mole^{-1}$	k_0, M^{-1} min^{-1}
Phenyl	1.9	$7.9 \cdot 10^2$	5.5	$1.0 \cdot 10^7$
p-Chlorophenyl	1.7	$16.8 \cdot 10^2$	2.8	$2.0 \cdot 10^5$
p-Bromophenyl	1.7	$17.2 \cdot 10^2$	—	—
Naphth-1′-yl	1.6	$0.41 \cdot 10^2$	7.5	$1.6 \cdot 10^7$
Naphth-2′-yl	1.4	$40 \cdot 10^2$	—	—

The reason for the sharp decrease in reactivity of 2-naphth-1′-ylindanedione (XIX) is the same as in *ortho*-substituted 2-phenylindanediones (XVI and XVII). The nuclear magnetic resonance spectra show[65] that in 2-mesitylindanedione (XVI) the plane of the mesityl ring is perpendicular to that of the indanedione ring, and rotation of the former ring is retarded. The appearance of additional electronic effects in 2-arylindanediones on *ortho*-substitution is confirmed by the ultraviolet spectra[102] and by a change in acidity[17]. Thus the introduction of an *ortho*-substituent disturbs the configuration of the molecule, which leads to a change in mobility of the 2-hydrogen atom in the indanedione ring.

The difference in properties between 1- and 2-substituted naphthalene derivatives attracted attention long ago[103-105] and has been termed an "edge" effect[103], *peri*-interaction[105]. In the field of β-diketones it has been noted that iodo-derivatives[63] of 2-naphth-2′-ylindanedione are thermally less stable than the corresponding naphth-1′-yl derivatives. The construction of Stuart–Briegleb models of compounds (I), (XVI), (XVII), (XIX), and (XX) confirms that, in the *ortho*-substituted derivatives and also in (XIX), the molecular configuration is disrupted by interaction of the substituent and the carbonyl group; the aryl radical in these compounds is unable to rotate freely as in (I) and (XX).

Heating 2-phenylindane-1,3-dione with benzoyl peroxide

constants K determined for azoisobutyronitrile by means of 2-phenylindanedione, and also the initiator efficiencies β in toluene and chlorobenzene at 80°C, show complete agreement with values[109] obtained by other methods. It is interesting that unlike known inhibitors—phenols and amines—the stoichiometric coefficient of inhibition for 2-phenylindanedione is in this case unity. Thus the use of 2-arylindanediones to estimate radicals has certain advantages over such inhibitors as 1-naphthylamine and 1-naphthol in view of the simplicity of quantitative control and the definiteness of the conversion products of the inhibitor. Quantitative determination of 2-phenylindanedione and its analogues can be accomplished also spectrophotometrically[110-114], polarographically[115], bromatometrically[116], by anodic volt–amperometric measurements[76], potentiometrically[117], and by other methods[72].



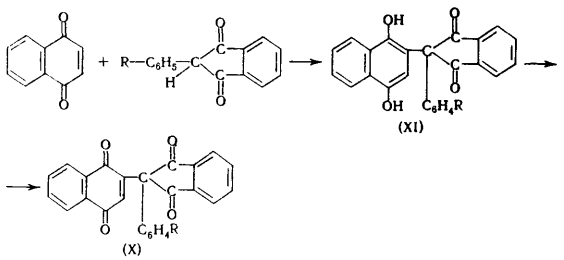


Figure 2. Consumption of 2-phenylindanedione and variation of $\lg [\Delta D\infty/(D - D\infty)]$ with time in experiments on the decomposition of azoisobutyronitrile (0.0005 M) in toluene at 80°C: 1), 2) rate curves; 3) optical density.

VI. 2-ARYLINDANE-1,3-DIONES AS OXIDATION INHIBITORS IN THE LIQUID PHASE

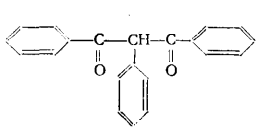
The reaction with radicals such as 2,2-diphenyl-1-picrylhydrazyl suggested that 2-arylindane-1,3-diones would retard the oxidation of alkylarenes by oxygen. An inhibiting effect was shown[118] in the oxidation of *p*-di-isopropylbenzene at 100°C: in the presence of 0.06 mole % of 2-phenylindanedione oxidation was delayed for 25 h.

With substituted indane-1,3-diones the reaction may also go differently: thus the interaction of 2-methylsulphonylindanedione with the quinone involves cross recombination of the 1,3-dioxoindanyl radical and of the semiquinone to form 2-(2,3-dichloro-5,6-dicyano-4-hydroxyphenoxy)-2-methylsulphonylindane-1,3-dione.

2-Arylindane-1,3-diones react with 1,4-naphthaquinone[89] in aqueous acetone solution in the presence of an acetate buffer to form a 2-(2-aryl-1,3-dioxoindan-2-yl)naphthaquinone (X), presumably[89] by the oxidation of the intermediate naphthaquinol (XI) by atmospheric oxygen:

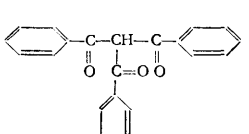
(XI)

(X)



In this case dimers were not isolated. The Reviewers hold a different opinion on the course of the reaction: the first stage is 1,4-addition, the product (XI) is oxidised by the initial 1,4-naphthaquinone, and air oxidises 1,4-naphthaquinol, so that the mechanism is similar to that between quinones and aniline[90].

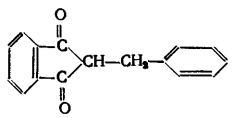
The redox potential of 1,4-naphthaquinone is 0.484 V, whereas those of benzoquinone and of its 2,3-dichloro-5,6-dicyano-derivative are 0.712 and 1.0 V respectively.



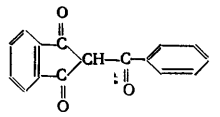
Indane-1,3-dione itself reacts with phenanthraquinone[91] and with nitrophenanthraquinones[92,93] to form 9,9-bis-(1,3-dioxoindan-2-yl)-9,10-dihydro-10-oxophenanthrene and the corresponding nitro-derivative respectively.

V. INTERACTION WITH STABLE RADICALS

The great reactivity of 2-arylindane-1,3-diones towards stable radicals was first observed by Zalukaev and Moiseev[94] in the reaction of diketones with 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2-*p*-methoxyphenyl-2-phenyl-1-picrylhydrazyl[95,96], and 2-*p*-bromophenyl-2-phenyl-1-picrylhydrazyl[21]. With equimolecular proportions of the reactants and an initial concentration of 0.00025 M in toluene at 20°C, the reaction between 2-phenylindanedione and DPPH takes 15–20 s. The reaction of *meta*- and *para*-substituted 2-phenylindanediones with DPPH is equally rapid. This radical detaches the 2-hydrogen atom from the indane ring, as is confirmed by the absence of reaction with 2-methyl-2-phenylindanedione, which does not contain hydrogen in the dione ring. Adding lead dioxide to the 2-arylindanedione system after completion of the reaction regenerates the DPPH radical. Phenyldibenzoylmethane (XII) and tribenzoylmethane (XIII), unlike 2-arylindanediones, do not react with DPPH.

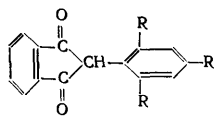


(XII)

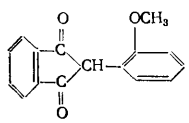


(XIII)

2-Benzyl- and 2-benzoyl-indane-1,3-diones (XIV and XV), in which the dioxoindanyl and phenyl groups are separated by a bridge

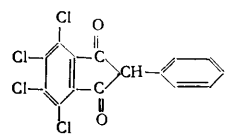


(XIV)



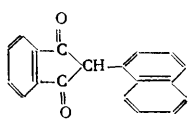
(XV)

also do not react with DPPH under similar conditions. Such diminished reactivity in (XIV) is entirely explicable, since conjugation is considerably weakened by the methylene group[97]. Introduction of an *ortho*-substituent into the phenyl ring produces a sharp decrease in reactivity. No compound of the type

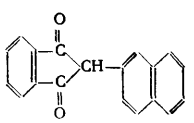


(XVI)
(R=OCH_3, CH_3, C_2H_5, C_3H_7, Br)

reacts either with DPPH or with 2-*p*-methoxyphenyl-2-phenyl-1-picrylhydrazyl in dioxan at 20°C. Even 2-*o*-methoxyphenylindanedione (XVII), which contains one *ortho*-substituent, does not interact with the latter radical. Nevertheless, 4,5,6,7-tetrachloro-2-phenylindanedione (XVIII), which is substituted in the benzene ring of the indanedione system, is highly reactive.



(XVII)



(XVIII)

In order to study the *ortho*-effect[98] a more detailed investigation was made of the reactivity of various substituted indane-1,3-diones—the 2-phenyl (I), 2-*p*-chlorophenyl, 2-*p*-bromophenyl, 2-naphth-1'-yl (XIX), and 2-naphth-2'-yl (XX) derivatives

(XIX)

(XX)

The interaction between 2-arylindanediones and DPPH is a consecutive-parallel reaction:

$$\Phi H + DPPH \xrightarrow{k_1} \Phi\cdot + DPPH - H$$
$$\Phi\cdot + DPPH \xrightarrow{k_2} DPPH - \Phi$$
$$\Phi\cdot + \Phi\cdot \xrightarrow{k_3} \Phi - \Phi$$

Since k_2, $k_3 \gg k_1$, the rate of consumption of DPPH, and hence the rate of detachment of the hydrogen atom from the diketones, are determined by the equation

$$-\frac{d[DPPH]}{dt} = \alpha k_1 [\Phi H][DPPH]$$

where α is the stoichiometric coefficient—the number of radicals that react with one molecule of the dione. The reaction of 2-arylindanediones with DPPH obeys a second-order equation. Table 2 lists the stoichiometric coefficients, the rate constants k_1 of detachment of a hydrogen

atom, activation energies E, and pre-exponential factors k_0 for reaction of the radical with the above compounds in dioxan at 20°C. The activation energy could not be determined for 2-naphth-2'-ylindane-1,3-dione, since it is obviously very small. The values found for the rate constants and activation energies for the 2-arylindanediones are close to those for the corresponding reaction of DPPH with phenols [99-101].

Table 2. Rate constants for the reactions of diphenylpicrylhydrazyl with 2-arylindanediones.

Aryl	a	k_1, M^{-1} min^{-1}	E, kcal $mole^{-1}$	k_0, M^{-1} min^{-1}
Phenyl	1.9	$7.9 \cdot 10^2$	5.5	$1.0 \cdot 10^7$
p-Chlorophenyl	1.7	$16.8 \cdot 10^2$	2.8	$2.0 \cdot 10^5$
p-Bromophenyl	1.7	$17.2 \cdot 10^2$	—	—
Naphth-1'-yl	1.6	$0.41 \cdot 10^2$	7.5	$1.6 \cdot 10^7$
Naphth-2'-yl	1.4	$40 \cdot 10^2$	—	—

The reason for the sharp decrease in reactivity of 2-naphth-1'-ylindanedione (XIX) is the same as in *ortho*-substituted 2-phenylindanediones (XVI and XVII). The nuclear magnetic resonance spectra show [65] that in 2-mesitylindanedione (XVI) the plane of the mesityl ring is perpendicular to that of the indanedione ring, and rotation of the former ring is retarded. The appearance of additional electronic effects in 2-arylindanediones on *ortho*-substitution is confirmed by the ultraviolet spectra [102] and by a change in acidity [17]. Thus the introduction of an *ortho*-substituent disturbs the configuration of the molecule, which leads to a change in mobility of the 2-hydrogen atom in the indanedione ring.

The difference in properties between 1- and 2-substituted naphthalene derivatives attracted attention long ago [103-105] and has been termed an "edge" effect [103], *peri*-interaction [105]. In the field of β-diketones it has been noted that iodo-derivatives [63] of 2-naphth-2'-ylindanedione are thermally less stable than the corresponding naphth-1'-yl derivatives. The construction of Stuart–Briegleb models of compounds (I), (XVI), (XVII), (XIX), and (XX) confirms that, in the *ortho*-substituted derivatives and also in (XIX), the molecular configuration is disrupted by interaction of the substituent and the carbonyl group; the aryl radical in these compounds is unable to rotate freely as in (I) and (XX).

Heating 2-phenylindane-1,3-dione with benzoyl peroxide gives the dimer (II), which is obtained also by interaction of the compound with peroxy-radicals formed on the decomposition of azoisobutyronitrile in the presence of oxygen [21]. The ease with which 2-phenylindanedione can be determined colorimetrically in hydrocarbons [106] has enabled it to be tested in the method of inhibitors. The initiator chosen was azoisobutyronitrile, whose decomposition has been thoroughly studied by various methods [107], including the inhibitor method [108]. Fig. 2 illustrates rate curves for the consumption of 2-phenylindanedione at different concentrations in the presence of azoisobutyronitrile in toluene at 80°C and also the time variation of $\lg [\Delta D\infty/(D - D\infty)]$, where D is the optical density of a sample of the reaction mixture withdrawn during the reaction.

Preliminary results showed that, in chlorobenzene under these conditions, 2-phenylindane-1,3-dione is not consumed by reaction with oxygen. The decomposition constants K determined for azoisobutyronitrile by means of 2-phenylindanedione, and also the initiator efficiencies β in toluene and chlorobenzene at 80°C, show complete agreement with values [109] obtained by other methods. It is interesting that unlike known inhibitors—phenols and amines—the stoichiometric coefficient of inhibition for 2-phenylindanedione is in this case unity. Thus the use of 2-arylindanediones to estimate radicals has certain advantages over such inhibitors as 1-naphthylamine and 1-naphthol in view of the simplicity of quantitative control and the definiteness of the conversion products of the inhibitor. Quantitative determination of 2-phenylindanedione and its analogues can be accomplished also spectrophotometrically [110-114], polarographically [115], bromatometrically [116], by anodic volt-amperometric measurements [76], potentiometrically [117], and by other methods [72].

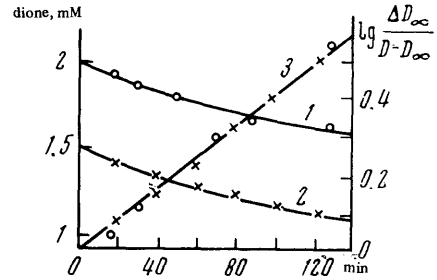


Figure 2. Consumption of 2-phenylindanedione and variation of $\lg [\Delta D\infty/(D - D\infty)]$ with time in experiments on the decomposition of azoisobutyronitrile (0.0005 M) in toluene at 80°C: 1), 2) rate curves; 3) optical density.

VI. 2-ARYLINDANE-1,3-DIONES AS OXIDATION INHIBITORS IN THE LIQUID PHASE

The reaction with radicals such as 2,2-diphenyl-1-picrylhydrazyl suggested that 2-arylindane-1,3-diones would retard the oxidation of alkylarenes by oxygen. An inhibiting effect was shown [118] in the oxidation of *p*-di-isopropylbenzene at 100°C: in the presence of 0.06 mole % of 2-phenylindanedione oxidation was delayed for 25 h. The oxidation of this hydrocarbon is inhibited by 2-*p*-nitro- and 2-*p*-methoxy-phenylindanediones. The causes of the antioxidant power of β-diketones were not elucidated. This problem has been examined in greater detail in a study [21,98] of the oxidation of tetrahydronaphthalene. An active hydrogen atom must be present at the 2-position for inhibiting activity to develop in diketones. Compounds that do not contain such an atom—e.g. 2-ethyl- and 2-methyl-2-phenylindanediones and the dimer of 2-phenylindanedione (II)—do not influence the oxidation. It was found also that the end of the induction period coincided with the instant at which the 2-phenylindanedione was almost completely exhausted. Separate experiments with pure tetralin hydroperoxide in chlorobenzene at 100°C showed that under these conditions decomposition of the hydroperoxide was not affected by 2-phenylindanedione. If a 0.0002 M solution of the latter in tetralin is added before the start of oxidation, an induction period of 100 min is observed.

If the same quantity of this diketone is added during oxidation, no induction period is observed, and the rate of oxidation is almost unchanged. Thus 2-arylindanediones inhibit the autoxidation of hydrocarbons as a consequence of reaction of the active hydrogen atom with peroxy-radicals.

Table 3. Induction periods in the oxidation of tetralin in the presence of substituted indane-1,3-diones.

Substituents	τ, min	Substituents	τ, min
2-Phenyl	100		
2-Naphth-1'-yl	18	4,5,6,7-Tetrachloro-2-phenyl	300
2-Naphth-2'-yl	300		
		2-(2,4,6-Trimethoxyphenyl)	0

A relation has been established between the reactivity of 2-arylindane-1,3-diones towards DPPH radicals and the antioxidant power of the diketones. Thus 2-(2,4,6-trimethoxyphenyl)indanedione (XVI), which does not react with DPPH and the *p*-methoxylated radicals, does not affect the rate of oxidation of tetraline; whereas 4,5,6,7-tetrachloro-2-phenylindanedione, which reacts with these radicals, produces a considerable induction period in the oxidation of tetralin. Table 3 lists the induction periods in the autoxidation of tetralin in the presence of various 2-arylindanediones (0.0002 M) at 100°C. Comparison of the induction period with the behaviour of the 2-arylindanediones towards DPPH shows at least a qualitative parallelism between the antioxidant power of the diketones and the mobility of the 2-hydrogen atom towards the free radical. The lower reactivity of 2-naphth-1'-ylindanedione (XIX) in comparison with 2-phenyl- and 2-naphth-2'-yl-indanedione (XX) is confirmed by its behaviour in the autoxidation of hydrocarbons.

Table 4. Reactivity of phenols.

Compound	k, M^{-1} min^{-1}	τ, min
Phenol	4.3 (19.6°)	75
1-Naphthol	8000 (15.5°)	2250
2-Naphthol	377 (19.0°)	330

It is interesting to draw an analogy between the above compounds and phenols and naphthols. Table 4 lists the rate constants for the reactions of these phenols with DPPH and the induction periods in the oxidation of gasoline in their presence[100]. It is evident that 1- and 2-naphthols are more reactive than phenol in radical reactions. A similar relation should apparently apply to the above 2-arylindanediones. The naphthyl ring system provides greater possibilities for delocalisation of the electron, and the corresponding 2-aryl-1,3-dioxoindanyl radicals should be more stable, so that hydrogen should be more easily detached from diketones containing a naphthyl ring system. However, this is observed only with 2-naphth-2'-ylindanedione: in the case of the naphth-1'-yl derivative the reactivity drops owing to a change in molecular configuration.

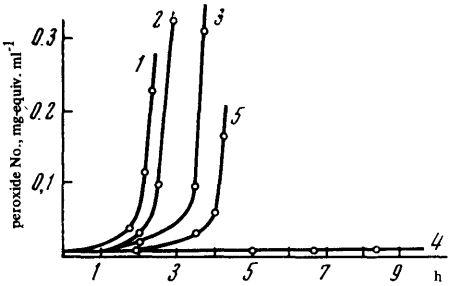

Figure 3. Kinetics of the oxidation of vegetable oil at 120°C in the presence of inhibitors: 1) no antioxidant; 2) 0.01 M ionol; 3) 0.01 M (I); 4) 0.01 M (XXI); 5) 0.001 M (XXI).

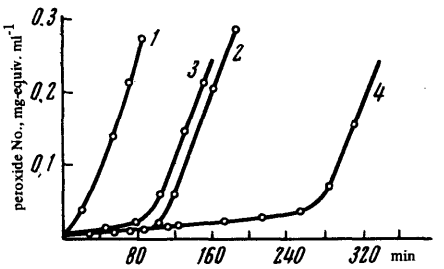

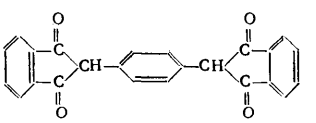

Figure 4. Kinetics of the oxidation of rendered fat at 120°C in the presence of inhibitors: 1) no antioxidant; 2) ionol (0.01 mole kg^{-1}); 3) (I) (0.01 mole kg^{-1}); 4) 2-*p*-hydroxyphenylindanedione (0.01 mole kg^{-1}).

Table 5. Inhibition of the oxidation of sunflower oil at 120°C.

Antioxidant	C, M	τ, min	ε	Antioxidant	C, M	τ, min	ε
None	—	126	—	(XXI)	10^{-2}	>600	19.2
Ionol	10^{-2}	152	1		10^{-3}	186	
(I)	10^{-2}	212	3.3				
				(VII: R = H)	10^{-2}	270	5.5

The antioxidant power of substituted 2-arylindanediones has been examined in detail[119] on the oxidation of sunflower oil and rendered fat. Fig. 3 illustrates the kinetics of oxidation of the oil at 120°C in the presence of equimolar quantities (0.01 M) of ionol, 2-phenylindanedione, and *p*-phenylene-2,2'-bisindane-1,3-dione

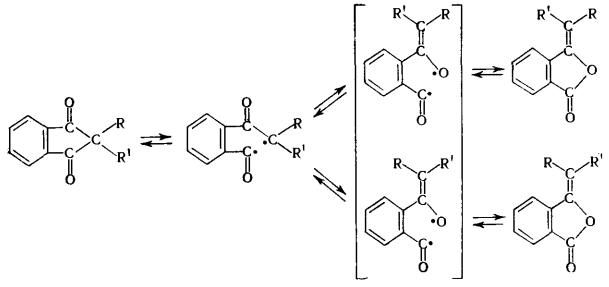
(XXI)

Fig. 3 shows that the substituted indanediones are more effective than the well known antioxidant ionol. Compound (XXI) exhibits an inhibiting effect at a concentration of 0.001 M, at which ionol is completely ineffective.

Hydroxylated 2-phenylindanediones, e.g. the *p*-hydroxy-derivative, were highly effective antioxidants for oils and fats. Fig. 4 illustrates the course of the oxidation of rendered fat at 120°C in the presence of ionol, 2-phenylindanedione, and 2-*p*-hydroxyphenylindanedione (each 0.01 mole kg^{-1}). Table 5 lists the induction periods and the efficiencies of certain diketones in the oxidation of sunflower oil. Antioxidant efficiency was calculated[120] by means of the formula

$$\varepsilon = \left(\frac{\tau - \tau_0}{C}\right)_{\text{init}} : \left(\frac{\tau_1 - \tau_0}{C}\right)_{\text{stand}}$$

where τ, τ_1, and τ_0 are the induction periods during oxidation of the substrate in the presence of the test compound and of the standard (ionol) and in the absence of an inhibitor respectively, and C is the inhibitor concentration.



VII. 2-ARYLINDANE-1,3-DIONES AS STABILISERS FOR POLYMERS

The ability of 2-arylindanediones to inhibit the oxidation of hydrocarbons suggested that they could serve as stabilisers for polymers. The efficiency of several substituted 2-phenylindanediones as stabilisers was investigated in polyethylene and polypropylene[121]. Table 6 shows the dependence of the induction period in the oxidation of low-density polyethylene at 150°C on the structure and the concentration of the diketone (the induction period in the oxidation of unstabilised polyethylene is 105 min). The introduction of methoxy- and hydroxy-groups into 2-phenylindanedione enhances the antioxidant efficiency. Unfortunately, these workers[121] did not measure the change in molecular weight of the polymer during aging as a function of the antioxidant, which would have represented the efficiency of the stabiliser most fully and objectively.

Table 6. Dependence of induction period (min) in the oxidation of polyethylene on the structure and concentration of diketones.

Substituted indane-1,3-dione	Concentration, %		
	0.05	0.1	0.5
	induction period		
2-Phenyl	120	180	900
2-*p*-Methoxyphenyl	300	540	990
2-*p*-Hydroxyphenyl	540	840	2040
2-*p*-Chlorophenyl	110	120	780
2-(3,4-Dimethoxyphenyl)	330	570	1080
2-*p*-Dimethylaminophenyl	200	480	640
4-Hydroxy-5-methoxy-2-phenyl	390	660	1680
4,5-Dihydroxy-2-phenyl	490	840	1530
Ionol		610	

This work showed a slight photostabilising effect of substituted 2-phenylindanediones when polyethylene and polypropylene were exposed at 40°C to a PRK-2 lamp. The absorption maxima in the ultraviolet spectra of 2-arylindanediones are situated approximately in the same regions as in the spectra of known photostabilisers, and a most important practical problem is to select effective compounds and study the mechanism of their action[122]. Under the influence of light 2-phenylindanediones may undergo transitions involving keto–enol tautomerism. Light energy may be absorbed also by a different path. Substituted indane-1,3-diones are isomerised by ultraviolet radiation[123–125] into high yields of phthalide derivatives:

Substituted 2-phenylindanediones prevent the thermo-oxidative degradation and cross-linking of Capron [6-polyamide] film and bristle, largely preserving the physico-mechanical properties of these polymers at 200°C and the specific viscosity of the bristle at 150°C. Diketones containing hydroxy-groups in the benzene rings—2-*p*-hydroxyphenylindanedione and 4-hydroxy-5-methoxy-2-phenylindanedione—possess the strongest inhibiting power.

Although 2-phenylindanedione develops its antioxidant properties in saturated polymers (e.g. polyethylene), the effect is almost completely absent in unsaturated rubbers[68], owing to the relatively high reactivity of 2-aryl-1,3-dioxoindanyl radicals. A mixture of 2-phenylindanedione with 1,2,3,4-tetrahydro-2,2,4-trimethylquinoline was found to exert a certain synergic action in the oxidation of SKS-30 rubber[34]. This effect was assessed merely from the time variation in the relative amplitude of the nuclear magnetic resonance signal, without the application of unambiguous methods for proving synergy[129] and measuring the molecular characteristics of the polymer during aging.

Table 7. Induction periods in the oxidation of SKDL rubber in the presence of ionol and of 2-substituted indane-1,3-diones.

Substituent	τ, min.
Ionol	185
Phenyl	7
p-Hydroxyphenyl	24
4'-Hydroxy-3',5'-dimethylphenyl	230
4'-Hydroxy-3',5'-di-isopropylphenyl	34
4'-Hydroxy-3',5'-di-t-butylphenyl	125
3',5'-Diallyl-4'-hydroxyphenyl	50
4'-Hydroxy-3',5'-dimethoxyphenyl	240
3',5'-Dibromo-4'-hydroxyphenyl	20
4'-Oxocyclohexa-2',5'-dienyl	21
3',5'-Dimethyl-4'-oxocyclohexa-2',5'-dienyl	300
No antioxidant	3

p-Hydroxylated 2-arylindanediones (VII) containing a sterically hindered phenolic fragment are of the greatest interest[68] for stabilising unsaturated rubbers. Table 7 gives the induction periods τ in the oxidation of lithium butadiene rubber SKDL at 130°C in the presence of several diketones (VII) and methylenequinones (VIII) at a concentration of 0.02 mole kg^{-1} polymer.

The above results show that several indane-1,3-dione derivatives surpass the well known stabiliser ionol in efficiency of inhibition.

VIII. EFFECT OF 2-ARYLINDANE-1,3-DIONES ON RADICAL POLYMERISATION

In the presence of atmospheric oxygen 2-arylindane-1,3-diones, in contrast to phenols, accelerate the thermal polymerisation[130] of styrene at 100°C. The ability of substituted 2-phenylindanediones to influence the rate of polymerisation is directly related to their reactivity towards the stable radical 2-*p*-methoxyphenyl-2-phenyl-1-picrylhydrazyl: the highly reactive 4,5,6,7-tetrachloro-2-phenylindanedione (XVIII) has a considerable accelerating effect on polymerisation, but the relatively unreactive 2-(2,4,6-trimethoxyphenyl)indanedione (XVI) does not affect its kinetics. The introduction into the *para*-position of an electron-accepting substituent, e.g. a bromine atom, makes the 2-arylindanedione a stronger accelerator of polymerisation; on the other hand, 2-*p*-methoxyphenylindanedione, which contains an electron-donating substituent, has rather less effect than the unsaturated phenyl derivative on the rate of polymerisation. Like many phenols, 2-phenylindanedione does not change the rate of polymerisation in argon[131]. The polymerisation of styrene is actively initiated by the dimer (II), which breaks down into free radicals when heated in hydrocarbons[33]. The formation of polystyrene has been observed[64] also in the arylation of 2-phenylindanedione with diphenyliodonium chloride in the presence of styrene. Radicals of the triphenylmethyl type also accelerate the polymerisation of styrene[132].

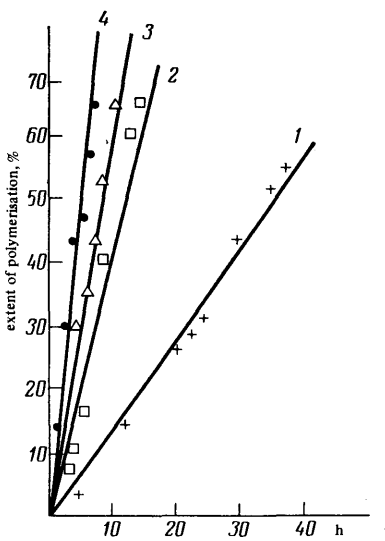


Figure 5. Dependence of rate of polymerisation of SKN-26 rubber on nature and quantity (part by weight) of activator: 1) no activator; 2) 0.2 trihydroxyethylamine; 3) 0.1 (I); 4) 0.2 (I).

The acceleration[133] of emulsion polymerisation in the production of butadiene–nitrile rubbers in the presence of 2-arylindanediones is of practical interest. The use of 0.2 part by weight of 2-phenylindanedione as activator triples the rate of polymerisation observed with the same quantity of trishydroxyethylamine. Fig. 5 illustrates the dependence of the rate of polymerisation on the nature and quantity of activator. In the production of SKN-26 butadiene–nitrile rubber 100% polymerisation is attained in 5 and 20 h respectively in the presence and in the absence of the above quantity of 2-phenylindanedione. The acceleration of emulsion polymerisation is due to the presence of 2-aryl-1,3-dioxoindanyl radicals formed by reaction with the polymerisation initiator—potassium persulphate:

$$2\Phi^- + S_2O_8^{2-} \rightarrow 2\Phi\cdot + 2SO_4^{2-}$$

The formation of dimers of type (II) from 2-arylindanediones has been observed[55] repeatedly in the presence of ammonium persulphate. The increase in the rate of polymerisation of styrene in the presence of 2-arylindanediones in air is also due to radicals resulting[21] from reaction of the β-diketones with oxidation products of styrene.

A second property of 2-arylindanediones of practical importance is their ability to act as chain-transfer agents. Various classes of organic compounds (hydrocarbons, alkenes, thiols, disulphides, amines, phenols, halogenated compounds, etc.) have been investigated[6] in chain-transfer reactions. A few active chain-transfer agents have been widely used in industry under the name regulators or modifiers. In the case of 2-arylindanediones chain transfer can be represented by the scheme

$$RM_n\cdot + \Phi H \xrightarrow{k_s} RM_nH + \Phi\cdot$$
$$\Phi\cdot + M \rightarrow \Phi M\cdot$$
$$RM_n\cdot + M \xrightarrow{k_p} RM_{n+1}\cdot$$

Measurements[134] of chain-transfer constants $C_S = k_S/k_p$ for a series of 2-arylindanediones in the thermal polymerisation of styrene at 100°C were made by Mayo's method[135] from the relation

$$\frac{1}{p} = \frac{1}{p_0} + C_s\frac{[\Phi H]}{[M]}$$

where p_0 and p are the degrees of polymerisation obtained in the absence of a regulator and with a molar ratio $[\Phi H]/[M]$ of regulator to monomer. The results in Table 8 show a fairly wide range of variation—from 0.0001 to 1.05—determined by the structure of the diketone.

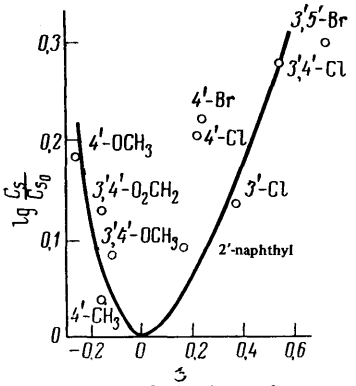
Table 8. Chain-transfer constants of 2-substituted indane-1,3-diones.

Substituent	C_s	Substituent	C_s
	0.0044		
Phenyl	0.53	3',4'-Dimethoxyphenyl	0.64
Benzyl	0.058	*p*-Tolyl	0.57
o-Methoxyphenyl	0.01	*m*-Chlorophenyl	0.73
2',4'-Dimethoxyphenyl	0.01	*p*-Chlorophenyl	0.84
		p-Bromophenyl	0.87
2',4',6'-Trimethoxyphenyl	0.0017	3',4'-Dichlorophenyl	1.00
1'-Naphthyl	0.039	3',5'-Dibromophenyl	1.05
2'-Naphthyl	0.65		
p-Methoxyphenyl	0.80	2-Methyl-2-phenyl	0.0001
3',4'-Methylenedioxyphenyl	0.71	2-(3',5'-Dibromophenyl)2-methyl	0.014

Introduction of a phenyl ring into the indane-1,3-dione molecule increases the chain-transfer constant hundredfold, and produces a considerable change in its reactivity. Thus the half-wave potential of anodic oxidation is lowered[75], which is consistent with calculations of the energy of the highest occupied molecular orbital in the anionic form of β-diketones. Separation of the dioxoindanyl ring system

from the phenyl ring by a methylene bridge reduces the chain-transfer constant to one-tenth of its value. The position of the substituent in the phenyl ring has a considerable effect on the reactivity of substituted 2-phenylindanediones, the chain-transfer constants for the *ortho*-substituted 2-*o*-methoxyphenyl-, 2-(2,4-dimethoxyphenyl)-, and 2-(2,4,6-trimethoxyphenyl)-indanediones being far smaller than that for the unsubstituted phenyl derivative. The results[65,123,136] are consistent with the nuclear magnetic resonance spectra: introduction of a phenyl group into indane-1,3-dione increases the chemical shift of the active proton at position 2; introduction of an *ortho*-substituent into 2-phenylindanedione produces a decrease in the chemical shift.

As in the reaction with diphenylpicrylhydrazyl, 2-naphth-1'-ylindanedione (XIX) and 2-naphth-2'-ylindanedione (XX) exhibit different reactivities: (XIX) is less reactive than (XX) and the 2-phenyl compound.



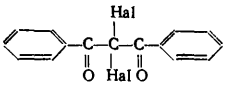


Figure 6. Correlation of chain-transfer constants for substituted 2-phenylindanediones in the thermal polymerisation of styrene, plotted in Hammett coordinates.

It is noteworthy that *meta*- and *para*-substituents in the 2-phenyl ring, independently of whether they are electron-donating or electron-accepting, increase the chain-transfer constant of the compounds in comparison with unsubstituted 2-phenylindanedione. Fig. 6 shows the Hammett plot of the relation obtained. These substituted derivatives have high chain-transfer constants, and surpass several known carriers in activity[6], but are inferior to thiols and certain disulphides[137].

2-Arylindane-1,3-diones containing halogen at position 2 are quite active in chain transfer in the thermal polymerisation of styrene. Compounds of this type have been tested also as modifiers of emulsion polymerisation in the production of polychloroprene[138] and butadiene rubbers[139]. 2-Bromo-2-phenylindanedione (0.6 part by weight) effectively controls the molecular weight of polychloroprene[138] during polymerisation at 50°C. Chain transfer occurs especially efficiently via the bromo-diketone in the initial stages of polymerisation, which is evidently not fortuitous. A disadvantage of 2-halogenated indane-1,3-diones as polymerisation regulators is that the halogen is positive in character[140] and easily detached in weakly alkaline medium, even in sodium hydrogen carbonate solution, for example. They will therefore lose their halogen by this side-reaction during emulsion polymerisation. On the basis of the above researches it has been suggested[141] that dibenzoyldihalogenomethanes

(XXII)

will be more effective regulators of radical polymerisation, free from the above disadvantages.

---o0o---

The work on the radical reactions of 2-arylindane-1,3-diones examined above shows that β-diketones play an active part in reactions of practical interest. The capacity of substituted indane-1,3-diones for keto–enol tautomerism and the formation of intra- and inter-molecular hydrogen bonds makes this class of compounds attractive for the investigation of radical reactivity. There is every reason to suppose that further study of the radical reactions of 2-arylindanediones will give interesting theoretical and practical results.

Advances in the Chemistry of Ethynyl Ketones

R.L.Bol'shedvorskaya and L.I.Vereshchagin

The review deals with problems of the reactivity and the chemical properties of ethynyl ketones. The bibliography includes 201 references.

I. INTRODUCTION

Ethynyl ketones have been attracting increasing interest not only in view of the wide variety of their chemical properties and synthetic possibilities but also owing to their biological activity, particularly their capacity to suppress the growth of various fungi. However, hitherto no reviews have been published on the chemistry of ethynyl ketones with the exception of one [1] on methods of synthesis of these substances. This review is a first attempt at a systematic discussion of the available literature data for the chemical properties of the ketones in which the carbonyl and ethynyl groups are conjugated.

The review covers the periodical literature up to February, 1971.

II. REACTIVITY OF ETHYNYL KETONES

The chemical behaviour of ethynyl ketones is in general determined by the presence in the molecule of three reaction centres—the carbonyl and ethynyl groups and the hydrogen atom involved in the triple bond. The triple bond is known to be less reactive than the double bond in electrophilic addition reactions (addition of halogens, ozone, and peracids [2]) and more reactive in relation to nucleophilic agents (alcohols, amines, thiols, etc.) [2-6].

The reactivity of the ethynyl group in ethynyl ketones is not due solely to the electrophilic properties of the triple bond alone but depends also on the electron-accepting carbonyl group conjugated with it:

As a result 1,2-, 3,4-, and 1,4-addition reactions are characteristic of compounds of this type. Whereas amines, alcohols, and malonic ester add in the 3,4-positions [8-10], hydrazines and semicarbazides (these are much stronger bases and nucleophilic agents than amines) add preferentially in the 1,2-positions. Hydroxylamine, which is a weaker nucleophilic agent than hydrazines and semicarbazides but stronger than amines, can react simultaneously with both electrophilic centres [11].

A wide variety of reactions makes it possible to employ ethynyl ketones as the starting materials for the synthesis of heterocyclic systems. One must note that a particular mode of reaction is determined not only by the basicity of the substance being added but also by the structure of the ethynyl ketone.

III. HYDROGENATION

Depending on the method of hydrogenation, the addition of hydrogen to ethynyl ketones can occur either stepwise with intermediate formation of vinyl ketones and subsequent more far reaching transformation or in a single stage with formation of a reaction product involving the carbonyl group alone. All the methods of hydrogenation of ethynyl ketones described in the literature can be combined in three groups.

1. Catalytic Hydrogenation

Selective hydrogenation of ethynyl ketones depends primarily on the nature of the catalyst. Thus the use of relatively inactive catalysts (colloidal palladium [12], palladium deposited on silica [13] or calcium carbonate [14-17], and Raney nickel [16-18]) makes it possible to stop the hydrogenation process at the stage involving the addition of one mole of hydrogen per mole of the substance hydrogenated. Further saturation with hydrogen leads to the hydrogenation of the double bond and other secondary reactions [19]. The order in which various groups in ethynyl vinyl ketones

of the type $R-CH=CH-CO-C\equiv C-R^1$ (I) are hydrogenated depends mainly on the nature of the substituents R and R^1. The unsubstituted ethynyl vinyl ketone (Ia) and also ethynyl methylvinyl ketone (Ib) are hydrogenated on the $Pd/CaCO_3$ catalyst initially at the triple bond with formation of the divinyl ketone (II) (yield 76%) [20-22]:

$$\underset{\text{(I)}}{R-CH=CH-CO-C\equiv C-R^1} + H_2 \rightarrow \underset{\text{(II)}}{RCH=CH-CO-CH=CHR^1}$$

(Ia, R=R'=H; Iб, R=CH_3, R'=H; Iв, R=H, R'=CH_3)

In the hydrogenation of the ketone (Ic), the first mole of hydrogen adds to approximately equal extents to both triple and double bonds; subsequently $CH_2=CH-CO-CH=CH-CH_3$ (20.6%) and $CH_2=CH-COC_3H_7$ (25.5%) are formed. Moreover, in the first stage, the CO group is also reduced with subsequent isomerisation of the secondary α-ethynylalcohol to the ketone (III):

$$CH_3=CH-CO-C\equiv C-CH_3 \rightarrow \underset{\text{(III)}}{CH_3=CH-CHOH-C\equiv C-CH_3} \rightarrow CH_2=CH-CH=CH-CO-CH_3$$

Isomerisation is observed also in the hydrogenation of disubstituted ethynyl vinyl ketones. Selective hydrogenation of unsubstituted ethynyl vinyl ketone can probably be accounted for by the favourable conditions for the adsorption of the ketone on the catalyst via its triple bond. In this case, steric hindrance results in the reduction of the CO group alone [21].

In the hydrogenation of oct-1-en-3-yn-5-one on $Pd/CaCO_3$, hydrogen adds in the first place to the vinyl group [16]. Unsaturated ketones obtained catalytically have preferentially the *cis*-configuration [16].

2. Chemical Reduction

Ethynyl ketones are readily reduced by nascent hydrogen (zinc + acetic acid) and also by lithium aluminium hydride. The first method is frequently used to reduce the triple bond to a double bond. The reaction takes place in an aqueous alcoholic solution after the addition of catalytic amounts of copper sulphate [23,24]:

$$CH_3-CO-C\equiv C-R \rightarrow \underset{\text{(IV)}}{CH_3-CO-CH=CH-R}$$

$$\rightarrow \underset{\text{(V)}}{R-C\equiv C-C(OH)(CH_3)-C(OH)(CH_3)-C\equiv C-R}$$

(R=CH_3, C_3H_7, C_4H_9)

Together with vinyl ketones (IV), small amounts of ditertiary diethynyl-α-glycols (V) are formed. Aryl-substituted ethynyl ketones are hydrogenated under these conditions to saturated ketones [24]; the vinyl ketones obtained by this method have preferentially the *trans*-configuration.

Lithium aluminium hydride [25] and complexes of the type $Li^+[(RO)_2AlH_2]$ [25,26] reduce ethynyl ketones smoothly to the corresponding ethynylalcohols.

Dibenzoylacetylene (VI) reacts with lithium aluminium hydride in ether or tetrahydrofuran (THF) in different ways at 0-25°C and at −80°C: [27]

$$C_6H_5CHC\equiv C-COC_6H_5 \xleftarrow{-80^\circ} C_6H_5COC\equiv CCOC_6H_5 \rightarrow$$

(VI)

$$\rightarrow C_6H_5-CHC\equiv C-CH-C_6H_5 + \text{(VII)}$$

$$\xrightarrow{0-25^\circ} C_6H_5CHCH=CH=CHC_6H_5 \quad \text{(VII)}$$

$$C_6H_5CHCH_2CH_2CHC_6H_5$$

3. Electrochemical Reduction

The reactivity of ethynyl ketones in electrochemical reduction is determined by the presence of the electron-accepting carbonyl group, which increases the capacity of the triple bond for reduction by an electronic mechanism [28]. Whereas an isolated triple bond combines at a mercury cathode with only one mole of hydrogen, the activated triple bond in diethynyl ketones combines with two moles to form the saturated ketone (VIII): [29,30]

$$(C_6H_5-C\equiv C)_2CO \xrightarrow[\text{Hg cathode}]{H_2} \underset{\text{(VIII)}}{(C_6H_5CH_2CH_2)_2CO}$$

The reduction of disubstituted ethynyl ketones is frequently accompanied by the dimerisation of the vinyl ketone (IX): [30]

$$C_6H_5-CO-C\equiv C-C_6H_5 \xrightarrow{H_2} \underset{\text{(IX)}}{C_6H_5COCH=CH-C_6H_5} \rightarrow C_6H_5COCH=C(C_6H_5)-C_6H_5$$

$$\rightarrow C_6H_5COCH_2-CH(C_6H_5)-C_6H_5$$

The photochemical reduction of 5,5-dimethylhex-3-yn-5-one (X) in isopropyl alcohol has also been described [31]:

$$CH_3-C(CH_3)_2-C\equiv C-CO-CH_3 \xrightarrow[h\nu]{(CH_3)_2CHOH} CH_3-C(OH)(CH_3)-C(OH)(CH_3)-CH_3 + (CH_3)_3C-C\equiv C-C(OH)(CH_3)-CH_3 +$$

(X)

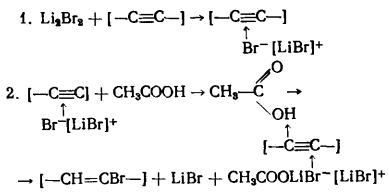
$$+ (CH_3)_3C-C\equiv C-C(OH)(CH_3)-C(OH)(CH_3)-C\equiv C-C(CH_3)_3$$

IV. ADDITION OF HYDROGEN HALIDES

The activated triple bond in ethynyl ketones is capable of combining equally readily with both nucleophilic and electrophilic agents. Whereas the hydrogenation of ethynyl ketones proceeds via consecutive stages involving the addition of initially one and then another mole of hydrogen, the reaction with hydrogen halides terminates in the first stage. The halide ion adds to the β-carbon atom of the triple bond, in agreement with the generally accepted ideas concerning the electron shift in unsaturated ketone molecules [32]. The addition of hydrogen halides to ethynyl ketones usually takes place in chloroform or a mixture of acetic acid and chloroform [33-35]; in some cases, copper(I) chloride was added [33,36]. With strictly equivalent proportions of the starting materials at −40°C, the reaction takes place stereospecifically with formation of the pure *cis*-isomer [34,37,38]. A slight excess of the hydrogen halide or an increase of reaction temperature to 20°C results in the formation either of the sterically pure *trans*-isomer or a mixture of *cis*- and *trans*-isomers (depending on the hydrogen halide used) [34]:

$$p\text{-}R-C_6H_4-CO-C\equiv C-R + HX \xrightarrow{-40^\circ} p\text{-}R-C_6H_4CO-C(X)=C(H)-H$$

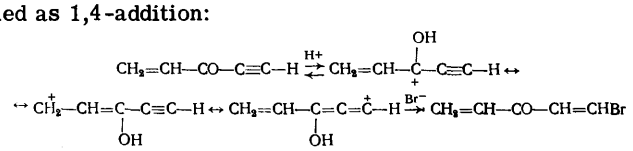
$$\xrightarrow{20^\circ} p\text{-}R-C_6H_4CO-C(H)=C(X)-H$$



(R=H; OCH_3; Cl
X=Cl; Br, I)

Cis- and *trans*-aryl 2-chloro-1-deuteriovinyl ketones were synthesised under analogous conditions [34]:

$$ArCOC{\equiv}CH + DCl \rightarrow ArCOCD{=}CHCl$$



It is believed that the initial reaction stage is nucleophilic attack by the halide ion on the triple bond [34].

Ethynyl ketones are also capable of adding the elements of HBr from LiBr solution in acetic acid [38,39]:

It has been established that the rate of reaction is limited by that of the first stage and depends on the electron-donating properties of the substituents at the triple bond. As the electron-donating properties of the substituent become more pronounced, the reaction rate constant falls, in agreement with the reaction mechanism proposed [39].

In the hydrobromination of the symmetrical ethynyl vinyl ketone, HBr adds to the triple bond only [20,40]. It has been shown [40] that the reaction begins with the protonation of the oxygen atom in the carbonyl group and can be regarded as 1,4-addition:

The reaction takes place stereospecifically in a saturated aqueous solution in the cold with formation of the *cis*-isomer.

V. ADDITION OF HALOGENS

Halogens are added to ethynyl ketones either in ethereal solution [41,42] or in the absence of solvent on heating [37,43]. The reaction with chlorine takes place only when gaseous chlorine is passed through the fused ketone:

$$o\text{-}R{-}C_6H_4{-}C{\equiv}C{-}CO{-}C_6H_5 + X_2 \rightarrow o\text{-}R{-}C_6H_4{-}CX{=}CX{-}CO{-}C_6H_5$$

(R=H, Cl; X=Br, I, Cl)

The addition of a second halogen molecule was not observed under the above conditions.

The bromination of silylethynyl ketones in chloroform leads to a mixture of the *cis*- and *trans*-isomers of $\alpha\beta$-dibromovinyl ketones (XI) (yield 70–75%):

$$R_3SiC{\equiv}C{-}COCH_3 + Br_2 \rightarrow R_3SiCBr{=}CBrCO{-}CH_3$$

(XI)

(R=CH_3, C_2H_5)

When two moles of bromine are allowed to react with the ketone, a mixture of $\alpha\beta$-dibromovinyl ketones and the corresponding tetrabromoketones (yield 15–20%) is formed [44].

Symmetrical ethynyl vinyl ketones are brominated first at the double bond and then at the triple bond with formation of the tetrabromide (XII):

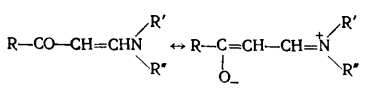
$$R{-}CH{=}CH{-}CO{-}C{\equiv}C{-}R + Br_2 \rightarrow RCHBrCHBrCOC{\equiv}C{-}R \xrightarrow{Br_2} RCHBr{-}CHBr{-}CO{-}CBr{=}CBr{-}R$$

(XII)

(R=H, CH_3)

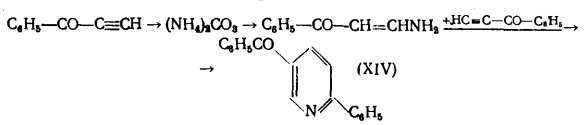
This difference between the reactivities of bromine and HBr can be explained by the different site of electrophilic attack owing to the different nature of the attacking reactant. While the hydrobromination reaction is regarded as 1,4-addition with participation of the CO group, the bromination reaction is regarded as 3,4-addition and the authors believe it to be purely electrophilic [20,40].

Ketones of the type $RCOC{\equiv}CCH{=}CH_2$ are brominated non-selectively at the triple and double bonds simultaneously. The comparatively high rate of addition of bromine to the triple bond, which is usually relatively unreactive in relation to bromine, is striking. Evidently the presence of the carbonyl group increases the reactivity of the triple bond, but this influence is difficult to account for if one regards the addition of bromine as an electrophilic addition reaction. It is more likely that, as postulated by Chelpanova et al.[45], nucleophilic addition takes place in the bromination of ethynyl vinyl ketones.



VI. ADDITION OF AMINES

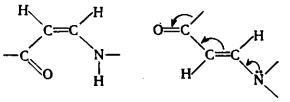
The reaction of amines with ethynyl ketones has been known for a long time. As early as 1904, Watson [46] established that amines add to ethynyl ketones as readily as to vinyl ketones. However, the exact structure of the products was not determined. Somewhat later Andre [47] and then Bowden and coworkers [37,48] and other investigators [49–58] demonstrated that the products of the addition of aliphatic and aromatic amines as well as ammonia to ethynyl ketones have the structure of $\alpha\beta$-unsaturated β-aminoketones (XIII):



(R=H, Alk, Ar; R'=Alk, Ar) (XIII)

The aminovinyl ketones formed are polarised to a very high degree. As a result of the increase of the negative charge on the oxygen atom and of the positive charge on the nitrogen atom, the dipole moments of the aminovinyl ketone increases sharply [59].

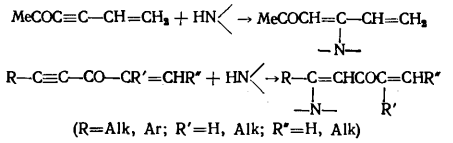
As a result, the reactivity of the double bond relative to nucleophilic agents decreases and a second mole of the amine is not added. Only in a single study by Hoffmann [60], who employed pyrazole and its derivatives as the nucleophilic reactant, diadducts were obtained together with monoadducts. However, the formation of diadducts was demonstrated spectroscopically without their isolation in a pure form.



Ethynyl phenyl ketones react with ammonium carbonate in aqueous alcohol to yield pyridine derivatives (XIV): [61,62]

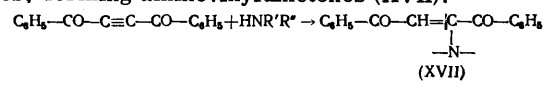
One should note that ethynyl ketones react with amines even at room temperature in the absence of any catalyst in both protic and aprotic solvents. The rate of reaction depends not only on the basicity of the amine [54,58] but also on the structure of the ethynyl ketone involved in the reaction.

The stereochemistry of the addition of amines to ethynyl ketones was studied in only one investigation [63], where it



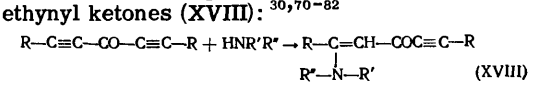
was shown, on the basis of the ^1H NMR data for the reaction mixture, that the reaction of *p*-tolylacetylene with α-phenylethylamine yields the *cis*- and *trans*-isomers of β-(1-phenylethylamino)vinyl-*p*-tolyl ketone [(XV) and (XVI)] with the *cis*-isomer (XV) predominating:

(XV) (XVI)



The stability of the *cis*-isomer can be explained by the formation of an intramolecular hydrogen bond [63].

Conjugated ethynyl vinyl ketones combine smoothly with amines at room temperature via the triple bond only [48,64,65]:

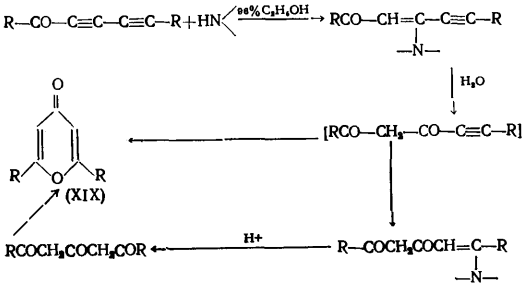


(R=Alk, Ar; R′=H, Alk; R″=H, Alk)

Diketones of the acetylene series readily react with amines, forming aminovinyldiketones (XVII): [66-69]

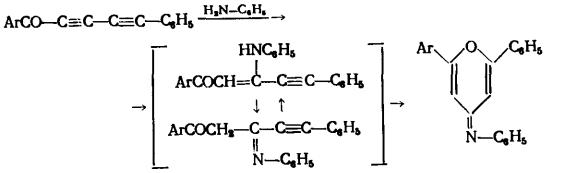
(XVII)

Aliphatic and aromatic amines add to symmetrical diethynyl ketones of the type R−C≡C−CO−C≡C−R′ preferentially at one triple bond with formation of aminovinyl ethynyl ketones (XVIII): [30,70-82]



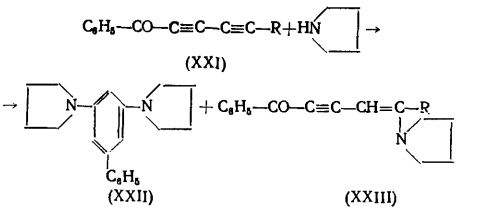
(XVIII)

(R=H, Alk, Ar; R′=R″=H, Alk, Ar)



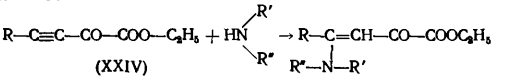
The deactivation of the second triple bond in relation to nucleophilic agents can be explained by the formation of a conjugated system analogous to that in compound (XVI), which evidently greatly weakens the conjugation of the carbonyl group with the second triple bond [80].

The reaction of diacetylenic ketones of the type R−COC≡C−C≡CR′ with secondary aliphatic amines leads to the formation of 2,6-diaryl-4-pyrones (XIX), where R = R′ = Ar: [83]



(R=C$_6$H$_5$)

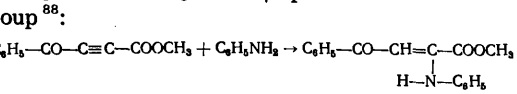
When 1,5-diarylpenta-2,4-diyn-1-ones were allowed to react with aromatic amines, 2,6-diaryl-4-arylaminopyrans (XX) were obtained; it is believed that they are formed via a stage involving the nucleophilic addition of the aromatic amine to the triple bond nearest to the carbonyl group with subsequent cyclisation [83]:



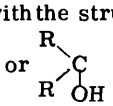
(XX)

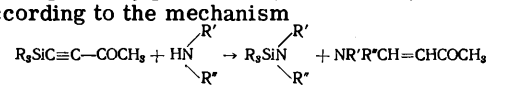
On the other hand, treatment of 4-alkyl-1-benzoyldiacetylenes (XXI) with pyrrolidine leads to the formation of diamino-derivatives of biphenyl (XXII) together with the normal addition products (XXIII): [84]

(XXII) (XXIII)



In α-ketoacid esters of the acetylene series (XXIV) containing in the molecule two adjacent electron-accepting molecules, the triple bond is even more reactive with respect to nucleophilic agents. Secondary aliphatic-aromatic amines, morpholine, piperidine [85], as well as primary aromatic amines [86] and aromatic amines containing other functional groups in the ring (aminophenols, aromatic aminoacids, anisidines, and others) [87] readily add to the triple bond of these compounds even at room temperature:



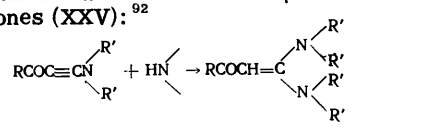


(XXIV)

(R=Alk, Ar; R′=H, Alk, Ar; R″=Alk)

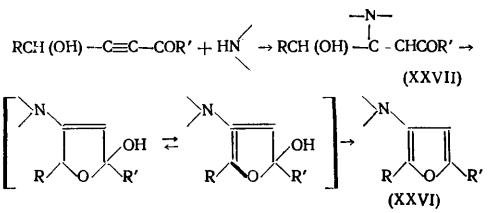
Aniline adds to the triple bond of ketoacids of the type R−CO−C≡C−COO−CH$_3$ in the β-position relative to the keto-group [88]:

Ethynyl ketones with the structure R−CO−C≡CX, where X = SiR$_3$, SR, NR$_2$, or  are of special interest, since the presence of functional group can alter to some extent the mode of addition of nucleophilic agents to the triple bond. When trialkylsilylethynyl ketones react with methyl- and diethyl-amines, only products the formation of which is probably preceded by the cleavage of the Si−C bond according to the mechanism



were isolated instead of the expected compounds. On the other hand, the interaction of the ketones investigated with aniline yields the expected anils R$_3$SiC≡C−C(=NC$_6$H$_5$)−CH$_3$. [89]

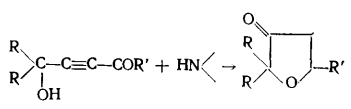
The addition of amines to ethylthioethynyl ketones R−CO−C≡C−SC$_2$H$_5$ can take place in principle in the 2- and 3-positions. It was found that, as for ethylthiopropiolate esters [90], the addition of an amine to ethylthioethynyl ketones [91] in fact takes place in the 2-position:



Ethynyl ketones of the type >N−C≡C−CO−R, where the electrophilic properties of the β-carbon atom are greatly enhanced, behave quite differently. The reaction of such ketones with amines at 20°C leads to αβ-unsaturated β-diaminoketones (XXV): [92]

(XXV)

(R=H, Alk; R′=Alk)



The interaction of secondary α-ethynyl-γ-ketols with primary and secondary amines leads to the formation of β-aminofurans (XXVI): [93]

(XXVII)

(XXVI)

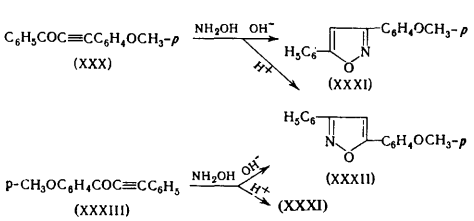
It is believed that initially nucleophilic addition of the amine to the triple bond takes place with subsequent cyclisation of the resulting aminovinylketol (XXVII) to the β-aminofuran (XXVI). When acted upon by secondary amines, tertiary γ-ketols are converted into β-furanones (XXVIII): [93]

(XXVIII)

(R=Alk, R′=Alk, Ar)

Monosubstituted ethynyl ketones react with inorganic salts of tertiary amines, forming quaternary ammonium salts (XXIX) in high yields (87–88%): [94,95]

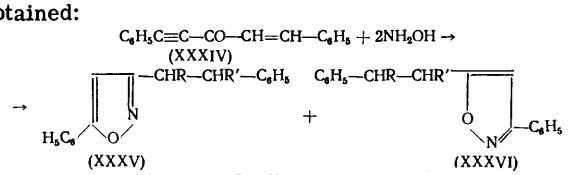
(XXIX)



(R=Alk, Ar; R′=Alk)

According to spectroscopic data, the compounds (XXIX) have the *trans*-configuration [95].

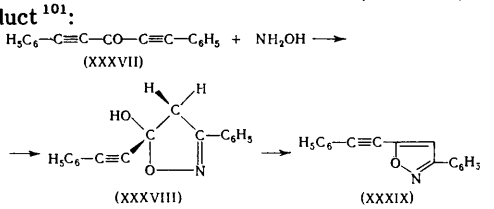
VII. ADDITION OF HYDROXYLAMINE, HYDRAZINES, SEMICARBAZIDES, AND OTHER NITROGEN-CONTAINING COMPOUNDS



As already mentioned, hydrazines and semicarbazides are stronger bases and nucleophilic agents than amines and therefore they react with ethynyl ketones mainly via the carbonyl group. Hydroxylamine occupies an intermediate position and is therefore capable of attacking simultaneously both reaction centres [11].

Thus the reaction of *p*-anisylbenzoylacetylene (XXX) and other substituted benzoylacetylenes [46,62,96] in an alcoholic alkaline solution proceeds with formation of 3-(*p*-anisyl)-5-phenylisoxazole (XXXI). In an acid medium, the attack on the carbonyl group is facilitated and 5-(*p*-anisyl)-3-phenylisoxazole (XXXII) is formed [11,97]. Directly opposite results were obtained when the starting material was *p*-anisoylphenylacetylene (XXXII):

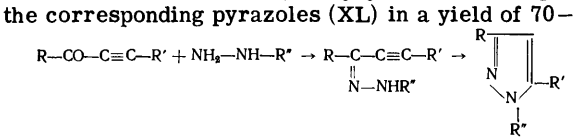
(XXX) (XXXI) (XXXII) (XXXIII) (XXXI)



Ferrocenyl-substituted ethynyl ketones [98] and also esters of $\beta\gamma$-acetylenic α-keto-acids [99] and $\alpha\beta$-acetylenic γ-keto-acids [88] behave similarly in the reaction with hydroxylamine. In the reactions with symmetrical disubstituted ethynyl vinyl ketones (XXXIV), the formation of isoxazole derivatives is accompanied by the subsequent addition of a second hydroxylamine molecule to the double bond and, depending on the reaction conditions, the isomeric isoxazoles (XXXV) [100] and (XXXVI) [101] can be obtained:

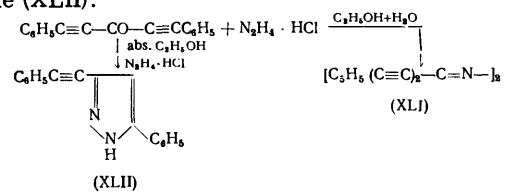
(XXXIV) (XXXV) (XXXVI)

(a) R=NHOH, R′=H; (b) R=H, R′=NHOH)



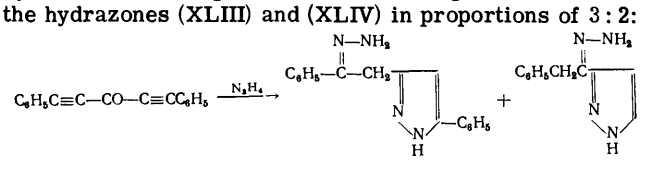
The reaction of 1,5-diphenylpenta-1,4-diyn-3-one (XXXVII) with hydroxylamine in an aqueous alcoholic solution involved the formation of Δ^2-isoxazoline (XXXVIII) as the only product [101]:

(XXXVII) (XXXVIII) (XXXIX)



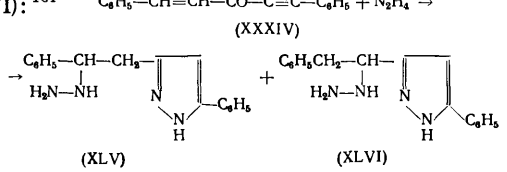
Prolonged heating of the isoxazoline (XXXVIII) in xylene or an aqueous alcoholic solution with distillation of water yields 3-phenyl-5-phenylethynylisoxazole (XXXIX).

In most cases the interaction of hydrazines with ethynyl ketones proceeds via the carbonyl group. Mono- [62,92,98] and di-substituted [62,96,98,101,102] ethynyl ketones and α-diketones [68,98] as well as γ-ethynyl-α-ketols [103] give rise to the corresponding pyrazoles (XL) in a yield of 70–80%:



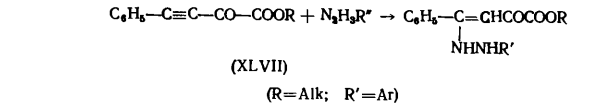
(R = H, Alk, Ar, —COOR; R′=H, Alk, Ar, —COC_6H_5, —C(OH)<, —N(R)$_2$)

Depending on the experimental conditions, the reaction of 1,5-diphenylpenta-1,4-diyn-3-one with hydrazine hydrochloride gives two different products. In aqueous ethanol solution, the azine (XLI) is formed, while in absolute ethanol the product is 3(5)-phenyl-5(3)-phenylethynylpyrazole (XLII): [101]



(XLI) (XLII)

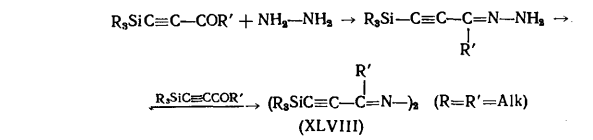
1,5-Diphenylpenta-1,4-diyn-3-one reacts with an excess of hydrazine in boiling absolute alcohol to give a mixture of the hydrazones (XLIII) and (XLIV) in proportions of 3:2:



(XLIII) (XLIV)

The interaction of 1,5-diphenylpent-1-en-4-yn-3-one (XXXIV) with anhydrous hydrazine in absolute alcohol gives rise to a mixture of the pyrazoles (XLV) and (XLVI): [101]

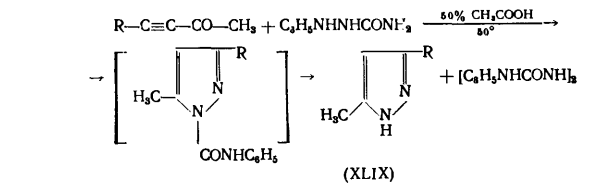
(XXXIV) (XLV) (XLVI)



In contrast to the ethynyl ketones discussed above, esters of phenylethynylglyoxalic acids (XLVII) react with hydrazine derivatives and aromatic acid hydrazides according to the same mechanism [99] as with amines:

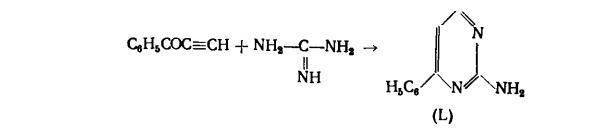
(XLVII)

(R=Alk; R'=Ar)



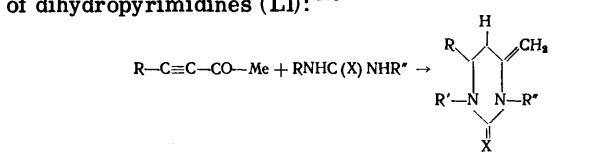
When trialkylsilylethynyl ketones react with hydrazine, the products are not pyrazoles but hydrazones, which are converted in the presence of an excess of the ketone into the azines (XLVIII): [44]

(XLVIII)



The reaction of silylethynyl ketones with 2,4-dinitrophenylhydrazine and 3,5-dinitrobenzoylhydrazine terminates in the hydrazone stage. The hydrazones obtained do not cyclise with the corresponding pyrazoles under the influence of acetic anhydride and acetic acid and char under these conditions [104]. Thus the trialkylsilyl group in the α-ethynylhydrazones is in fact an obstacle to their cyclisation.

In the reaction with ethynyl ketones, semicarbazides behave like hydrazines. Thus phenylsemicarbazide gives rise to pyrazoles (XLIX): [105]



(XLIX)

The only product of the condensation of guanidine with ethynyl phenyl ketone is 2-amino-4-phenylpyrimidine (L): [62]

(L)

Urea and thiourea derivatives react with ethynyl ketones in ethereal solution in the presence of concentrated sulphuric acid to give the corresponding derivatives of dihydropyrimidines (LI): [106]

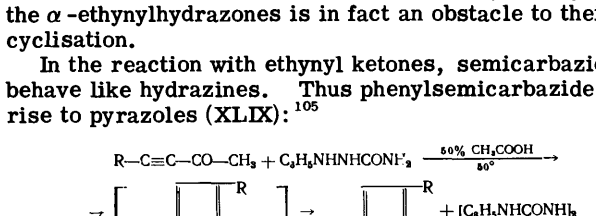
(LI)

(R=Alk; R'=Alk, Ar; R''=Alk; X=O, S)

VIII. ADDITION OF ALCOHOLS, PHENOLS, THIOLS, AND THIOPHENOLS

Whereas the addition of amines to the activated triple bond of ethynyl ketones takes place readily in the absence of catalysts even at room temperature, the addition of alcohols is possible only in the presence of a basic catalyst. The reaction with terminal ethynyl ketones does not stop at the stage involving the addition of one mole of the alcohol but continues until the formation of the acetal of the corresponding β-ketoaldehyde (LII) (yield 60–75%) [37,97]:

(LII)

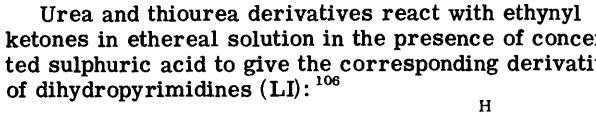


(R=Alk, Ar; R'=Alk)

The reaction was carried out in the presence of sodium alkoxide at 0–5°C. [107] The formation of alkoxyvinyl ketones was not observed under these conditions. Primary, and secondary alcohols add to disubstituted ethynyl ketones in the presence of both alkoxides [9,37,108–110] and tertiary amines [110] with the exclusive formation of the monoadducts (LIII):

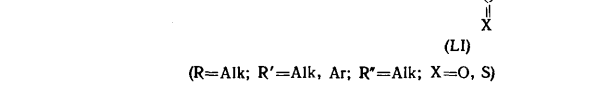
(LIII)

(R=Alk, Ar; R'=Alk, Ar)



The addition of alcohols to phenylbenzoylacetylene in the presence of potassium hydroxide takes place with the cleavage of the initial ketone to acetophenone and potassium benzoate [110]. It is interesting that alcohols add in the presence of BF_3 as the catalyst. Thus dibenzoylacetylene reacts with alcohol in the presence of BF_3, yielding 3-alkoxy-2,5-diphenyldihydrofuranone (LIV) as the sole product [111]:

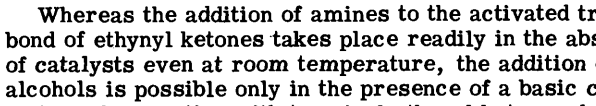
(LIV)



One should note that the addition of alcohols to ethynyl ketones is stereospecific like the addition of amines [33,112,114]. For example, the reaction of isopropyl methylethynyl ketone with methanol in aqueous potassium carbonate solution yielded a pure $\alpha\beta$-unsaturated *cis*-β-methoxyketone, which did not isomerise under the reaction conditions.

The reaction of cyclo-oct-2-ynone with deuteriated aqueous methanol in the presence of potassium carbonate gives 2-deuterio-3-methoxycyclo-oct-2-enone (LV) containing a small admixture (less than 10%) of the non-deuteriated product [113]. There is no doubt about the *cis*-configuration of compound (LV):

(LV)



The addition of phenols to ethynyl ketones in the presence of sodium phenoxide [37] or pyridine [114] takes place sluggishly and always results in the formation of a monoadduct:

(R=H, Ar; R'=Ar)

In the reaction with alcohols and phenols under analogous conditions, silylethynyl ketones are cleaved at the Si–C bond [89].

Thiols and thiophenols add similarly to alcohols and phenols, and in both cases only the monoadducts were isolated [33,37,112,113]:

(R=H, Alk; R', R''=Alk, Ar)

The reaction takes place at room temperature in the presence of alkali metal alkoxides [37,112,113], alkali, and in a few cases also in the absence of the catalyst [65]. Thiols add to symmetrical ethynyl vinyl ketones at the triple bond in the first place and then at the double bond [65]:

$$R{-}CH{=}CH{-}CO{-}C{\equiv}CH + RSH \rightarrow RCH{=}CH{-}COCH{=}CHSR + RCH(SR)CH_2{-}CO{-}CH{=}CHSR$$

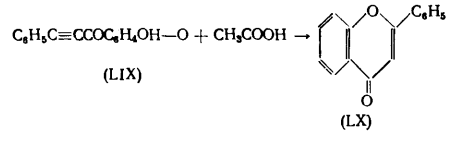
The study of the stereochemistry of the addition of thiols and thiophenols to ethynyl ketones showed that the reaction is rigorously stereospecific and takes place in accordance with the *trans*-addition rule, yielding the *cis*-adducts only [37,112,113].

IX. ADDITION OF ACIDS

As with amines, alcohols, and thiols, the addition of acids to ethynyl ketones is a nucleophilic process; the anionoid fragment of the acid is directed towards the β-carbon atom of the multiple bond. The addition of an arenesulphonic acid to the triple bond of ethynyl ketones was first described by Kohler and Barrett [115], who treated benzoylphenylacetylene with toluene-*p*-sulphonic acid and isolated two stereoisomeric sulphones (LVI). Somewhat later Bowden et al. [37] obtained similar results in the reaction of ethynyl phenyl ketone with the same sulphonic acid:

$$\underset{(R=H,\ C_6H_5)}{C_6H_5COC{\equiv}CR} + p\text{-}CH_3C_6H_4SO_2H \rightarrow \underset{cis\text{- and }trans\text{-}}{C_6H_5COCH{=}C(R){-}SO_2C_6H_4{-}CH_3\text{-}p} \quad (LVI)$$

The addition of acetic and benzoic acids to ethynyl phenyl ketone in the presence of basic catalysts takes place fairly smoothly and yields the acetate (LVIIa) and the benzoate (LVIIb) respectively, which are mixtures of the *cis*- and *trans*-isomers [116]:



$$C_6H_5COC{\equiv}CH \xrightarrow[RCOOH]{RCOONa} C_6H_5COCH{=}CHOCOR \ (LVII)$$

$$C_6H_5COC{\equiv}CH \xrightarrow[N(C_2H_5)_3]{CH_3COOH} C_6H_5COCH_2CH(OCOCH_3)_2 \ (LVIII)$$

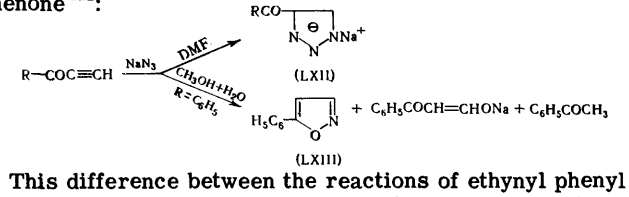
(a) R=CH_3; (b) R=C_6H_5

Treatment of ethynyl phenyl ketone with an excess of acetic acid in the presence of triethylamine yields the diacetate (LVIII).

The addition of acetic acid to 3-(*o*-hydroxyphenyl)-1-phenylprop-1-yn-3-one (LIX) in the presence of polyphosphoric acid at 100°C leads to the flavone (LX): [117]

(LIX) (LX)

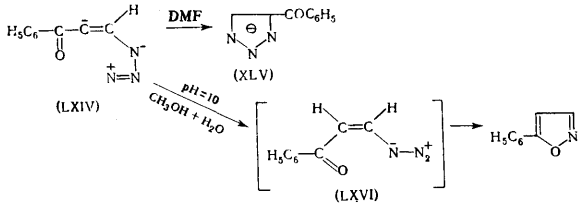
The reaction of hydrogen selenide and also of selenols with ethynyl phenyl ketone takes place successfully without a solvent and a catalyst and also in ether in the presence of catalytic amounts of pyridine. The yield of selenovinyl ketones (LXI) reaches 60–80%: [118]



$$RCOC{\equiv}CH + RSeH \rightarrow \underset{(LXI)}{RCOCH{=}CH{-}SeR}$$

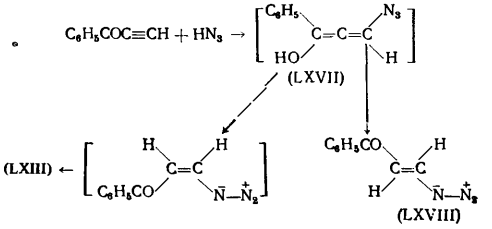
In contrast to the acids discussed above, the addition of diesters of phosphorous and phosphorothious acids to ethynyl ketones takes place only at the carbonyl group without involving the C≡C bond [119,120]:

$$R'COC{\equiv}CR'' + (RO)_2PH \xrightarrow{RONa} (RO)_2P(X){-}CR'(OH){-}C{\equiv}C{-}R''$$



(X=O, S)

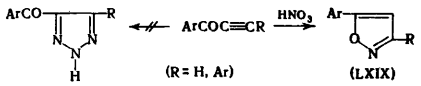
The reaction of ethynyl ketones with sodium azide, investigated by Nesmeyanov and Rybinskaya [121,122], which leads to the formation of either triazoles or isoxazoles depending on the reaction conditions, occupies a special place. Thus ethynyl propyl or ethynyl phenyl ketone reacts with sodium azide in dimethylformamide (DMF) to give the corresponding triazole (LXII). [121] On the other hand, the reaction of ethynyl phenyl ketone with NaN_3 in a proton-donating solvent proceeds with formation of 5-phenylisoxazole (LXIII) and a small admixture of the sodio-derivatives of benzoylacetaldehyde and acetophenone [122]:



(LXII) (LXIII)

This difference between the reactions of ethynyl phenyl ketone with the azide ions in DMF and a protic solvent can be accounted for by a change in the conditions governing the stabilisation of the carbanion (LXIV) formed as a result of the nucleophilic attack by the azide ion on the triple bond. It is suggested that in aprotic solvents the lifetime of the carbanion (LXVII) is long enough for its cyclisation to the stable triazolyl anion system (LXV):

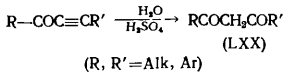
(LXIV) (XLV) (LXVI)



In proton-donating solvents, this carbanion can be protonated, which apparently results in the formation of an unstable intermediate—*cis*-β-azidovinyl phenyl ketone (LXVI), which, owing to the favourable disposition of the carbonyl and azide groups, is converted into the stable heterocyclic system of 5-phenylisoxazole with evolution of nitrogen. However, one cannot rule out the possibility that at low pH ethynyl phenyl ketone reacts with HN_3 to give a 1,4-addition product, from which a mixture of the *cis*- and *trans*-isomers [(LXVII) and (LXVIII) respectively] of azidovinyl phenyl ketone is formed as a result of a prototropic rearrangement:

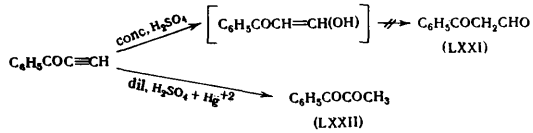
(LXVII) (LXIII) (LXVIII)

trans-β-Azidovinyl phenyl ketone is quite stable under the usual conditions and can be isolated, while the *cis*-form is unstable and decomposes spontaneously with formation of 5-phenylisoxazole (LXIII).



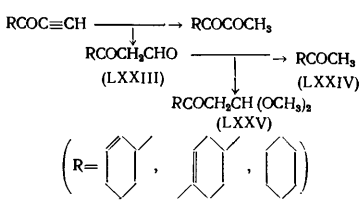
Ethynyl ketones react with NH_3 in chloroform to form isoxazoles (LXIX) and not triazoles [123]:

(R = H, Ar) (LXIX)



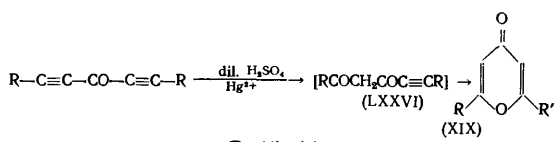
X. HYDRATION

The addition of water to disubstituted ethynyl ketones has been known for a long time. As early as 1899, Nef [41] obtained dibenzoylmethane by treating benzoylphenylacetylene with concentrated sulphuric acid. This method has been used in many other investigations [47,108,109,124-126] and regardless of the nature of the substituent led in all cases to β-diketones (LXX):



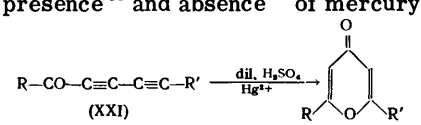
(R, R′ = Alk, Ar)

Monosubstituted ethynyl ketones are not hydrated in concentrated sulphuric acid; in dilute sulphuric acid, the reaction proceeds only on heating in the presence of mercury salts with formation of α-diketones (LXXII) instead of the expected α-ketoaldehydes (LXXI): [37]

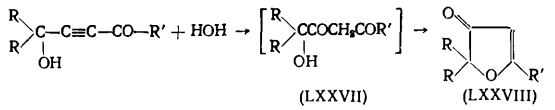


(LXXI) (LXXII)

However, the study of the reactivities of compounds of the Δ^3-cyclohexane series showed that, together with the main products, which are α-diketones, the isomeric β-ketoaldehydes (LXXIII) as well as their conversion products—the methyl ketones (LXXIV) and acetals (LXXV)—are nevertheless formed in comparatively small amounts [127]:



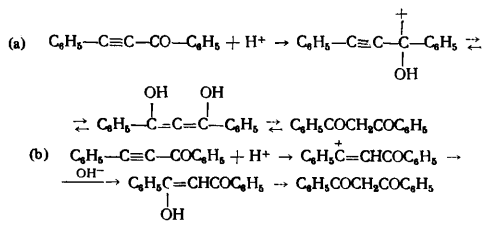
The products of the hydration of symmetrical ethynyl ketones in dilute sulphuric acid on heating in the presence of mercury salts are γ-pyrones (XIX): [70,75,128]



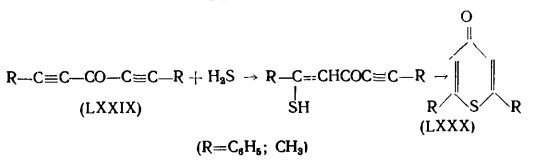
(R = Alk, Ar)

Probably water adds to one triple bond with formation of the intermediate ketone (LXXVI), which then cyclises to (XIX). Similar results were obtained in the hydration of asymmetric diacetylenic ketones (XXI) by dilute sulphuric acid in the presence [83] and absence [84] of mercury salts:

(XXI) (R = C_6H_5; R′ = Alk, Ar)



α-Ethynyl-γ-ketols are fairly readily hydrated in dilute sulphuric acid and in an alkaline alcoholic medium in the presence of mercury salts as well as in the presence of amines in protic solvents [93,103], being converted under these conditions into β-furanones (LXXVIII) in 80–90% yield via the β-diketol (LXXVII) stage. In aqueous dioxan, the yield of furanone is scarcely 50%:



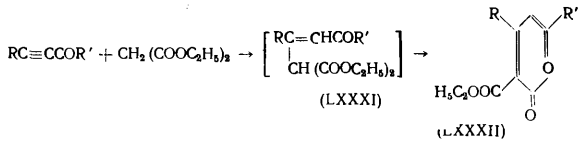
(LXXVII) (LXXVIII)

The addition of water to dibenzoylacetylene in the presence of mercury salts in an acid medium and in the presence of aliphatic amines in an aqueous alcoholic solution results in the formation of 1,4-diphenylbutane-1,2,4-trione [68].

By analogy with the available literature data for the mechanism of the hydration of unsaturated acids [129] and ketones [130-132], two possible mechanisms have been proposed [133] for the hydration of ethynyl ketones in an acid medium:

In the first case, the rate-limiting stage of the process is probably the transformation of the phenylbenzoylacetylene oxonium salt and in the second case a proton adds to phenylbenzoylacetylene. Having measured the rate constants for the hydration of ethynyl ketones of different basicities, Noyce and Debruin [133] showed that the hydration of phenylbenzoylacetylene proceeds via a stage involving proton transfer from the acid medium to the α-carbon atom of the triple bond [i.e. via mechanism (b)]. Probably the interaction of symmetrical diethynyl ketones (LXXIX) with hydrogen sulphide can be interpreted likewise. The reaction in absolute ethanol takes place with formation of 2,6-disubstituted thio-γ-pyrones (LXXX): [128,134]

(LXXIX) (LXXX)



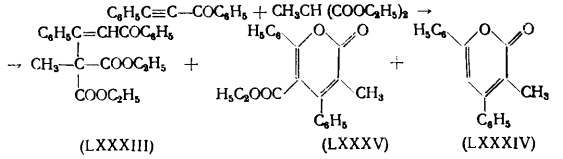
(R = C_6H_5; CH_3)

XI. MICHAEL CONDENSATION AND RELATED REACTIONS

The most typical property of ethynyl ketones is their capacity to undergo the Michael condensation with compounds containing active methylene groups. The nucleophilic agents can be not only carbonyl and carboxylated substances of the type $O{=}\overline{C}{-}CH_2{-}\underset{|}{C}{=}O$, but also the corresponding nitriles, nitro-compounds, and sulphones.

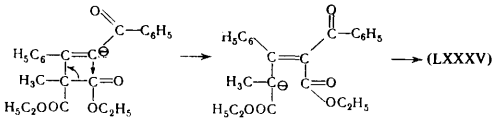
The interaction of ethynyl ketones with malonic ester has been investigated in greatest detail. By analogy with the reactions discussed above, it might have been expected that ethynyl ketones involved in the Michael condensation would form $\alpha\beta$-unsaturated ketones. However, in most

cases cyclisation products—derivatives of α-pyrones (LXXXII)—were isolated and not the open-chain compounds (LXXXI):[10,135-138]



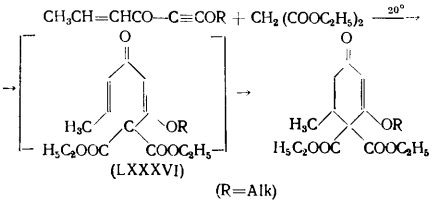
(LXXXI) (LXXXII)

The interaction of ethynyl ketones with malonic ester has been suggested[10] as a method for their identification. However, in studies on ethynyl furyl ketones, it was found that the reaction is not general[139].



Michael condensation involving ethynyl ketones took place smoothly in an alcoholic medium in the presence of traces of the corresponding sodium alkoxides. When the reaction is carried out in the presence of an equimolar amount of sodium alkoxide or metallic sodium, its course changes. Thus the reaction of diethyl methylmalonate with phenylbenzoylacetylene yields under these conditions the "normal" adduct—4,4-diethoxycarbonyl-1,3-diphenylpent-2-en-1-one (LXXXIII) together with 3-methyl-4,6-diphenyl-2-pyrone (LXXXIV) and ethyl 3-methyl-4,6-diphenyl-2-pyrone-5-carboxylate (LXXXV).[140]

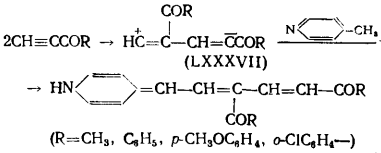
Compound (LXXXIV) is a product of the decarboxylation of the ester (LXXXIII) or (LXXXV):



(LXXXIII) (LXXXV) (LXXXIV)

It is suggested that the pyrone (LXXXV)—the "anomalous" reaction product—is formed from the "normal" adduct (LXXXIII) according to the following mechanism:

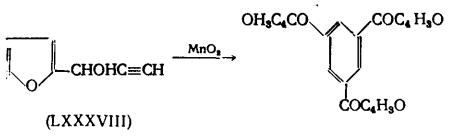
The interaction of malonic ester with the ethynyl vinyl ketone $CH_3CH{=}CHCOC{\equiv}COR$ in absolute t-butyl alcohol in the presence of catalytic amounts of potassium t-butoxide involves the formation of the intermediate open-chain product (LXXXVI) which subsequently cyclises as follows:



(LXXXVI)

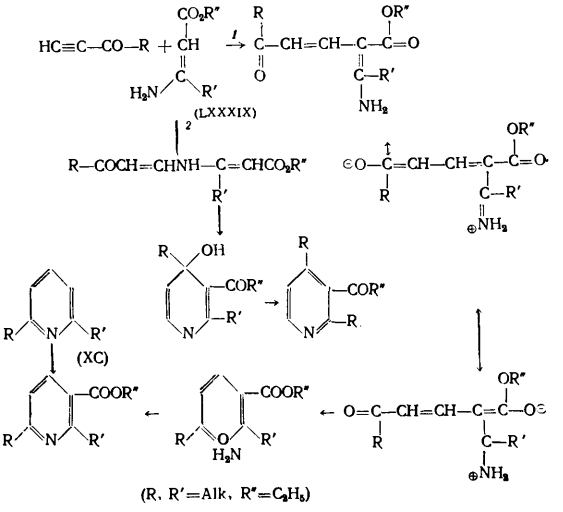
(R=Alk)

The antibiotic griseofulvin was obtained from ethynyl vinyl ketones and coumaranone via this reaction[124].



The intermediate formation of the zwitter-ion (LXXXVII) in reactions of ethynyl ketones with γ-picoline and related compounds has been postulated[141]:

(LXXXVII)



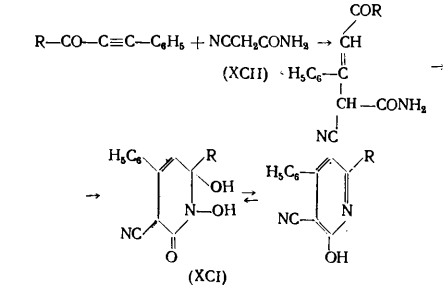
(R=CH_3, C_6H_5, p-$CH_3OC_6H_4$, o-ClC_6H_4—)

Probably ethynylfurylmethanol (LXXXVIII) reacts similarly under the influence of activated manganese dioxide[142]:

(LXXXVIII)

An interesting reaction of ethynyl ketones with esters of α-aminovinylcarboxylic acids (LXXXIX) has been described[61]:

(LXXXIX) (XC)

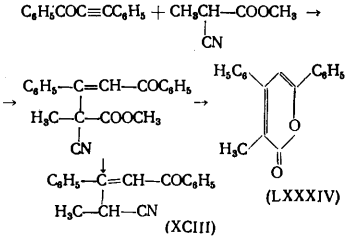


(R, R'=Alk, R"=C_6H_5)

In principle, this reaction can proceed via a mechanism of the type of Michael condensation (*1*) and via a pathway (*2*), where the amino-group adds to the activated C≡C bond. The study of the physical and chemical properties of the final reaction products [pyridine derivatives (XC)] demonstrated unambiguously that the reaction has mechanism (*1*).

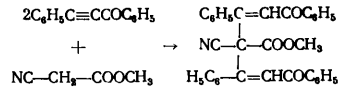
The low probability of the addition of the amino-group of aminovinyl ketones to the triple bond of ethynyl ketones can be accounted for by the reduced basicity of the amino-group owing to the conjugation of the lone electron pair of the nitrogen atom with the carbonyl group[143].

Pyrroles and indoles, which have similar structures, react with ethynyl ketones via the hydrogen atom in the α- or β-position in the ring[141].



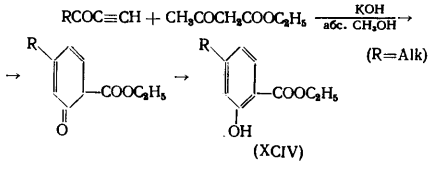
Another characteristic instance of this type of condensation is the formation of pyridones (XCI) by the reaction of ethynyl ketones with cyanacetamide (XCII):[137,144]

(XCII) (XCI)



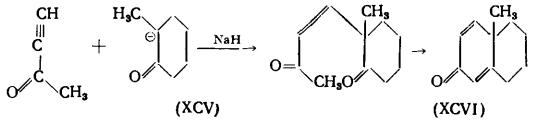
The reaction of phenylbenzoylacetylene with ethyl phenylacetate yielded 3,4,6-triphenyl-2-pyrone[145], while the reaction with methyl α-cyanopropionate in the presence

of an excess of sodium alkoxide gave the α-pyrone (LXXXIV) and a small amount of the unsaturated nitrile (XCIII):[115]



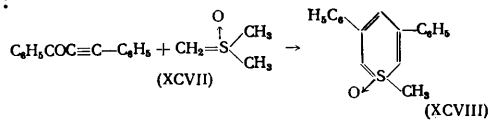
(XCIII) (LXXXIV)

Methyl α-cyanoacetate reacts with phenyl benzoylacetylene via the mechanism



A change in the ratio of the initial reactants does not affect the course of the reaction[115].

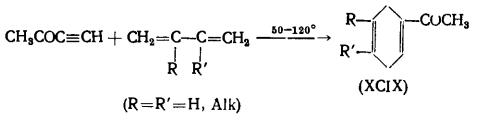
The condensation of unsubstituted ethynyl ketones with acetoacetic ester takes place quite differently. The final product of this reaction is a derivative of ethyl salicylate (XCIV):[146]



(XCIV)

The addition of methylcyclohexanone (XCV) to ethynyl methyl ketone in the presence of sodium hydride proceeds via a stage of internal aldol condensation with subsequent dehydration and formation of 10-methyl-2-oxo-Δ 1,9;3,4-hexahydronaphthalene (XCVI):[147]

(XCV) (XCVI)

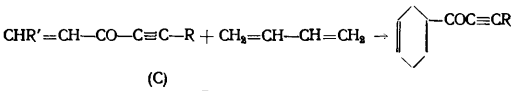


An example of the condensation of ethynyl ketones with compounds containing an active methylene group is provided also by the reaction of phenylbenzoyl acetylene with dimethyloxosulphonium methylide (XCVII), which takes place in dimethyl sulphoxide solution at 20°C with formation of 1-methyl-3,5-diphenylthiabenzene-1-oxide (XCVIII):[148]

(XCVII) (XCVIII)

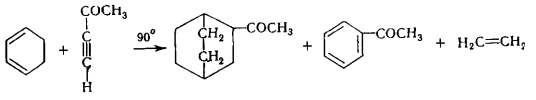
XII. DIELS-ALDER SYNTHESIS

Ethynyl ketones are extremely active dienophiles in Diels-Alder synthesis. Thus butynone, the simplest ethynyl ketone, reacts readily at 50–120°C with butadiene and many of its homologues (isoprene, piperylene, dipropenylene, and di-isopropenylene), yielding dihydrobenzophenones (XCIX):



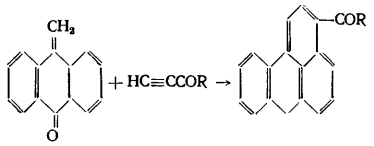
(R=R'=H, Alk) (XCIX)

Ethynyl propyl ketone and ethynyl phenyl ketone enter into a Diels-Alder reaction with butadiene under similar conditions[149,150]. The reactivity of disubstituted ethynyl ketones in this process is somewhat lower[22,100,151].



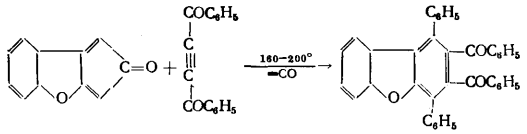
The condensation of ethynyl methyl ketone with chloroprene, bromoprene, and 1-chlorobutadiene at 80–125°C in benzene solution gave high yields of the corresponding halogenodihydrobenzophenones[152,153].

Petrov and coworkers[20,154], showed that in the reactions between butadiene and isomeric hex-2-en-5-yn-4-one and hex-1-en-4-yn-3-one (C, b) the process involves the unsubstituted multiple bond, preferentially in the first case and exclusively in the second, regardless of its nature. The addition of butadiene to pent-1-en-4-yn-3-one (C, a) and hept-2-en-5-yn-4-one takes place exclusively at the double bond:



(C)
(a) R=H; (b) R=CH₃

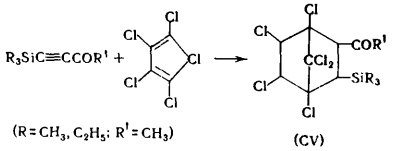
Ethynyl ketones react fairly readily with cyclopentadiene[150,155,156]. The condensation with cyclohexa-1,3-diene takes place with greater difficulty and is accompanied by the splitting off of the endoethylene bridge with formation of acetophenone and ethylene[155]:



On heating in acetic acid solution, ethynyl ketones condense with methyleneanthrone (CI), the final product being 3-substituted mesobenzanthrones (CII):[157]

(CI) (CII)

Dibenzoylacetylene, which readily condenses with dienes in ether or dioxan, is used as a dienophile similarly to ethynyl monoketones[18,158].

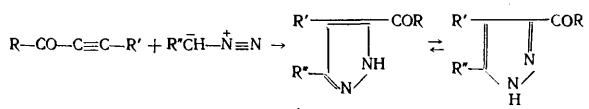


"Indanocyclone" (CIII) reacts with dibenzoylacetylene in ethyl acetate at 160–200°C to form 1,4-diphenyl-2,3-dibenzoylfluorenone (CIV):[159]

(CIII) (CIV)

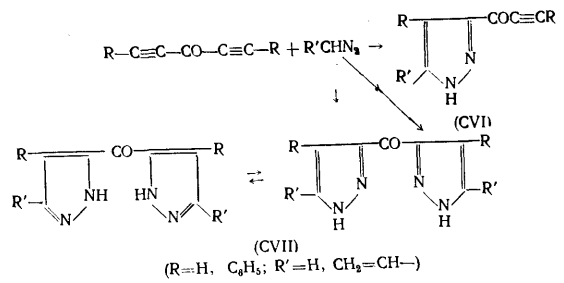
The condensation of diacetylacetylene with butadiene could not be achieved, since the initial diacetylacetylene decomposed under the reaction conditions[160].

Silylethynyl ketones do not react with cyclopentadiene [161], probably owing to the deactivation of the critical bond under the influence of a_π-p_π-conjugation with the silicon atom. However, these studies show at the same time that silylethynyl ketones condense with hexachlorocyclopentadienone at 150–180°C with formation of hexachlorosilylbicycloheptadienyl ketones (CV) in a yield of 15–30%: [161]



(R = CH_3, C_2H_5; R' = CH_3) (CV)

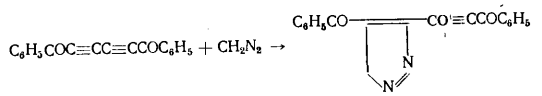
XIII. ADDITION OF 1,3-DIPOLAROPHILES



1. Addition of Diazoalkanes

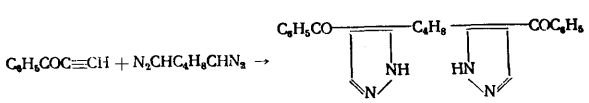
Ethynyl ketones react fairly readily with diazoalkanes, which are powerful nucleophilic agents. The reaction is general for ethynyl ketones and is regarded as dipolar 1,3-addition to the triple bond [62,162–167]:

(R = Alk, Ar; R' = H, Alk, $-COOCH_3$; R'' = H, CH_2=CH–, CH_3)



Ketones of the type RC≡CCOC≡CR react with diazoalkanes to form 1 : 1 and 1 : 2 adducts [(CVI) and (CVII) respectively] [163,168]:

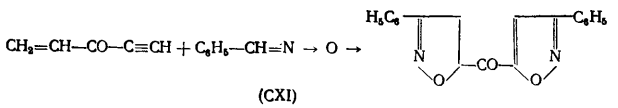
(CVII)



(R = H, C_6H_5; R' = H, CH_2=CH–)

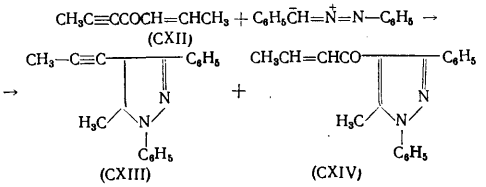
Diazomethane adds to 1,6-diphenylhexa-2,4-diyne-1,6-dione (CVIII) at only one C≡C bond with formation of 4-benzoyl-3(5)-benzoylethynylpyrazole (CIX): [168]

(CVIII) (CIX)



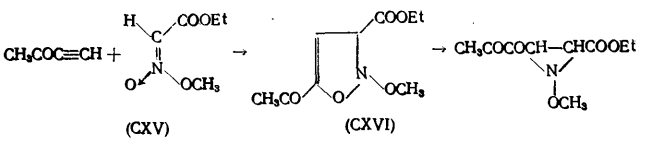
Bisdiazohexane (CX) reacts with benzoylacetylene as follows [169]:

(CX)



2. Addition of Nitrile *N*-Oxides

Like diazoalkanes, nitrile *N*-oxides and nitronic esters react with ethynyl ketones according to the dipolar 1,3-addition mechanisms. Benzonitrile *N*-oxide (CXI) add to unsubstituted ethynyl vinyl ketones at both multiple bonds [170]:

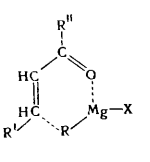


(CXI)

In the interaction of monosubstituted ethynyl vinyl ketones with benzonitrile *N*-oxide, 3-nitrobenzonitrile *N*-oxide, and diphenylnitrylimine, the less substituted multiple bond is the more reactive [170]. Hept-2-en-5-yn-4-one (CXII) reacts with diphenylnitrylimine both via the double bond and the triple bond, forming a pyrazoline (CXIII) and a pyrazole (CXIV): [171]

(CXIII) (CXIV)

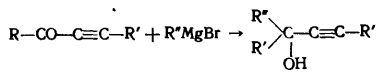
The reaction of butynone with the methyl nitrolic ester of ethyl nitroacetate (CXV) yielded 82% of the corresponding aziridine derivative. Its formation is probably associated with a rearrangement of the substituted 4-isoxazoline (CXVI) obtained in the first stage of the reaction via the general dipolar 1,3-cycloaddition mechanism [172]:



(CXV) (CXVI)

XIV. ETHYNYL KETONES IN ORGANOMAGNESIUM SYNTHESIS

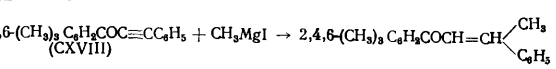
The interaction of vinyl ketones with organomagnesium compounds has been investigated by many Soviet and foreign workers. In particular, special studies have been made on the effect of polar and steric factors on the ratio of the 1,2- and 1,4-addition products [172–174].



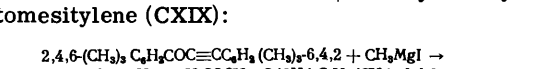
The literature data for the involvement of ethynyl ketones in organomagnesium synthesis are not quite so systematic. It has been suggested [175] that the 1,4-addition of organomagnesium reagents to vinyl ketones proceeds via an intermediate stage involving an unstable chelate complex (CXVII). In ethynyl ketones, this type of steric distribution of reacting molecules is difficult owing to the linear configuration of the –C≡C group and therefore the main reaction pathway should be 1,2-addition to the carbonyl group:

(CXVII)

Indeed, as early as 1907 Kohler [176], showed that phenyl magnesium bromide enters into the 1,2-addition reaction

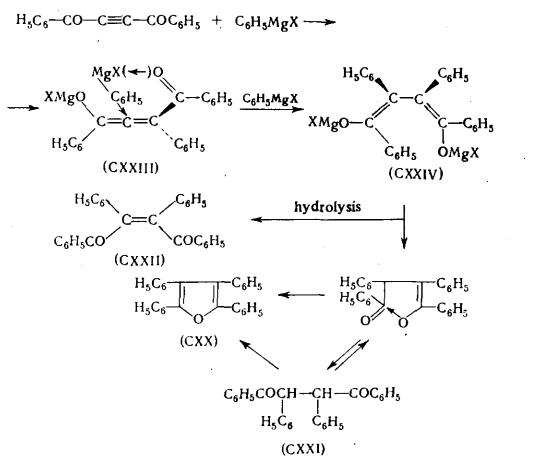


with benzoylphenylacetylene and into the 1,4-addition reaction with its vinyl analogue. Subsequently, studies of the interaction of ethynyl ketones with aromatic [177,178], aliphatic [178,179], and acetylenic [178,180,181] organomagnesium compounds and also of silylethynyl ketones with Iotsich reagents [182] showed that in most cases the main reaction products are tertiary α-ethynyl alcohols (or diethynyl alcohols):



(R=R'=Alk, Ar; R"=Alk, Ar, HC≡C—)

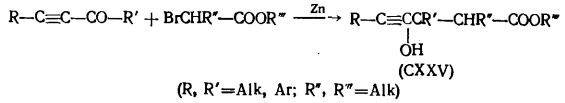
Traces of unsaturated ketones (1,4-addition products) were detected chromatographically in some cases [178].



As a result of the presence of bulky substituents at the carbonyl group, the main reaction pathway becomes 1,4-addition. Thus mesitoylphenylacetylene (CXVIII), in which approach to the carbon atom of the carbonyl group is hindered, readily condenses with methylmagnesium iodide and with phenyl- and mesitylmagnesium bromides via the mechanism [183]:

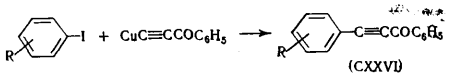
The condensation of mesitoylmesitylacetylene with methylmagnesium iodide yields two isomeric products, namely the *cis*- and *trans*-isomers of β-methylmesitylideneacetomesitylene (CXIX):

Another instance of 1,4-addition occurs in reactions of dibenzoylacetylene [184] which can react, in principle, with Grignard agents via the following pathways: (1) two consecutive 1,2-additions; (2) two consecutive 1,4-additions; (3) a combination of consecutive 1,2- and 1,4-additions. In fact, the reaction with C_6H_5MgX takes place via mechanism (2), since hydrolysis of the reaction mixture yielded tetraphenylfuran (CXX), *meso*-dibenzoyldiphenylethane (CXXI), the thermodynamically unstable *cis*-dibenzoylstilbene (CXXII), and a small amount of *trans*-dibenzoylstilbene [184]. This is probably due to the high reactivity of the allenolate (CXXIII), which is an $\alpha\beta$-unsaturated ketone with a sterically accessible β-carbon atom:



A further 1,4-addition to the allenolate (CXXIII) leads to the saturated diketodienolate (CXXIV), the subsequent hydrolysis of which yields the unsaturated diketone (CXXII), the saturated diketone (CXXI), and tetraphenylfuran (CXX). It is interesting that the main reaction product is *cis*-dibenzoylstilbene (CXXII) when hydrolysis is carried out in effective contact with air. The formation of *cis*-dibenzoylstilbene is minimal if the reaction is performed in an atmosphere of nitrogen.

The differences in the modes of addition of the Grignard reagent to dibenzoylacetylene and phenylbenzoylacetylene cannot be accounted for solely by steric factors. Indeed the electrophilic properties of the triple bond in dibenzoylacetylene are greatly enhanced under the influence of the strong inductive $-I$ effect of the two benzoyl groups. Phenylbenzoylacetylene has only one acetylenic carbon atom in the β-position relative to the carbonyl group, the electrophilic properties of which are somewhat weakened, in relation to dibenzoylacetylene, by the electron-donating influence of the phenyl group [184]:



Mono- and di-substituted ethynyl ketones readily enter into the Reformatskii reaction with α-bromoacetic esters in the presence of metallic zinc, forming β-hydroxyacid esters (CXXV) in a yield of 45–62%: [185,186]

(R, R'=Alk, Ar; R", R"'=Alk)

XV. REACTIONS OF THE ETHYNYL HYDROGEN ATOM

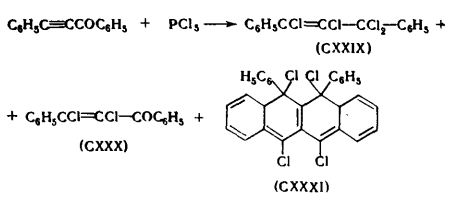
The mobility of the hydrogen atom in monosubstituted ethynyl ketones is due not only to the nature of the triple bond itself but also to the presence of the electron-accepting carbonyl group [187]. Treatment of ethynyl ketones with ammoniacal solutions of silver(I) and copper(I) salts by the usual method yielded the corresponding silver and copper acetylides, which can be used as starting materials for the synthesis of various disubstituted ethynyl ketones (CXXVI) and monosubstituted arylacetylenes [188]:

1,4-Dibenzoylbutadiyne (CVIII) has been synthesised by oxidative dihydrocondensation from benzoylacetylene [168]:

The capacity of ethynyl ketones to give rise to acetylides on treatment with powdered potassium hydroxide permits their employment for the synthesis of the simplest homologues of aliphatic α-ethynylketoalcohols (CXXVII) under the conditions of the Favorskii reaction [189]:

Mercury derivatives of ethynyl ketones can be obtained with the aid of K_2HgI_4 in alcoholic alkali [190]:

The ethynyl hydrogen atom in the ethynyl ketone molecule can be readily substituted by the halogen on interaction with potassium hypobromite [191]:

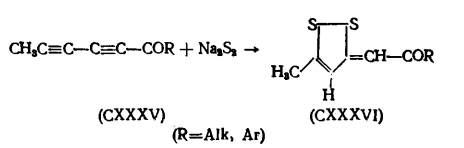


XVI. VARIOUS REACTIONS

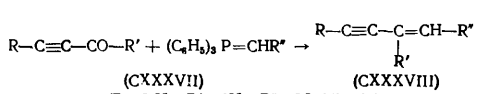
Apart from the reactions already discussed, a number of interactions of a non-general type have been described for ethynyl ketones.

Acetylphenylacetylene readily combines with mercury(II) chloride in saturated aqueous sodium chloride solution to form a crystalline substance (CXXVIII) which is fairly stable in an acid medium but decomposes readily on heating to the initial compounds [192]:

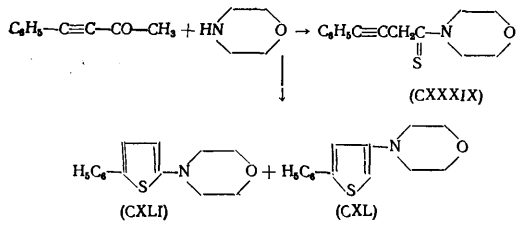
When phosphorus pentachloride is allowed to react with ethynyl ketones, there is both addition of chlorine to the multiple bond and substitution of the carbonyl oxygen by chlorine. The mode of reaction depends on the reactant ratio and on the structure of the ethynyl ketone. Thus the reaction of PCl_5 with benzoylphenylacetylene yields a mixture of products consisting of 1,2,3,3-tetrachloro-1,3-diphenylpropene (CXXIX), 2,3-dichloro-1,3-diphenylprop-1-en-3-one (CXXX), and compound (CXXXI):



With acetylphenylacetylene, two products are formed—3-chloro-1-phenylbut-3-en-1-yne (CXXXII) and 3,3-dichloro-1-phenylbut-1-yne (CXXXIII) in proportions of 3 : 1: [193]

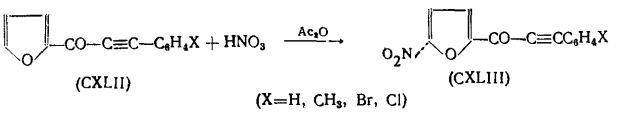


When ethynyl phenyl ketone reacts with sodium thiosulphate in a polar solvent in the presence of acid, the thiosulphate residue adds to the triple bond [194]. The reaction takes place on heating with a 69% yield of the vinyl ketone (CXXXIV):

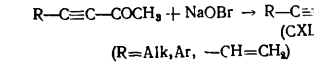


Diacetylenic ketones (CXXXV) react with sodium disulphide in methanol to form cyclic acetonylidenedithiols (CXXXVI) in quantitative yields [195]:

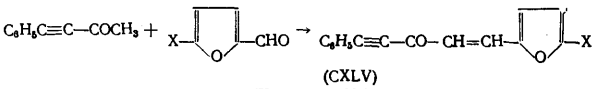
The interaction of ethynyl ketones with phosphorane (CXXXVII) and its derivatives leads to the corresponding ethynyl vinyl compounds (CXXXVIII): [196]



Nightingale and Carpenter [197] carried out the Willgerodt reaction with acetylphenylacetylene using morpholine and sulphur and obtained a 51% yield of a compound to which they attributed the structure of γ-phenylethynylthioacetomorpholide (CXXXIX):



Ozonolysis of the morpholide (CXXXIX) resulted in the cleavage of the molecule to benzoic acid, but the attempt at hydrolysis to phenylacetic was unsuccessful. Later Bacchetti et al. [198] demonstrated by infrared and NMR spectroscopy that the main product of this reaction is 4-(*N*-morpholonyl)-2-phenylthiophen (CXL) with a small admixture of the isomer (CXLI). [198]



Apart from the reactions involving the multiple bond and the carbonyl group, ethynyl ketones can also enter into reactions involving substituents. For example, when furyl phenylethynyl ketones (CXLII) were nitrated in acetic anhydride, 5-nitrofuryl phenylethynyl ketones (CSLIII) were obtained. It was noted that the rate of nitration depends to a considerable degree on the benzene ring substituent conjugated with the furan ring [199]:

The haloform cleavage of ethynyl ethyl ketones takes place fairly smoothly with formation of substituted propiolic acids (CXLIV). [200] The reaction can be used as a method for the synthesis of α-ethynylcarboxylic acids:

The crotonic condensation of ethynyl methyl ketones with aldehydes in an alkaline medium has been used to synthesise symmetrical ethynyl vinyl ketones (CXLV): [201]

Biologically Active Cellulose Derivatives

A.D.Virnik

The review deals with the synthesis and applications of biologically active cellulose derivatives. The synthesis of cellulose derivatives with antimicrobial and haemostatic (arresting blood flow) properties, the possible fields of application of antimicrobial and haemostatic cellulose materials, the synthesis of graft copolymers of cellulose and biologically active proteins (enzymes and antigens), and medical applications of cellulose derivatives containing ionogenic or complex-forming groups are considered.
The bibliography includes 197 references.

I. INTRODUCTION

One of the rapidly developing fields in the chemistry of macromolecular compounds concerns the synthesis of new polymers and the chemical modification of known natural and synthetic polymers carried out to obtain biologically active substances. In particular the use of polysaccharides for such syntheses is of considerable interest. At the present time both insoluble and water-soluble biologically active polymers have been obtained on their basis. For the synthesis of water-insoluble polymers, it is often useful to employ cellulose—a readily available and cheap fibre-forming polysaccharide. The synthesis of biologically active cellulose derivatives and the preparation of biologically active cellulose materials constitutes one of the most interesting and promising aspects of the general problem of the chemical modification of cellulose [1]. The principal types of biologically active cellulose derivatives and their applications are considered below.

II. CELLULOSE DERIVATIVES WITH ANTIMICROBIAL PROPERTIES

The development of methods for the synthesis of cellulose derivatives with antimicrobial properties makes it possible to create a new type of cellulose fibre—antimicrobial fibre; as will be shown below, this can be made into articles which can be employed effectively in medicine and certain branches of industry. Studies on the synthesis of biologically active cellulose derivatives by chemical addition of bactericidal and fungicidal substances to the cellulose macromolecules have developed extensively during the last decade. This method yields fibrous materials, the antimicrobial activity of which is retained after they have been used for a long time. The methods for the determination of the antimicrobial activity of cellulose derivatives (in the form of fibrous materials) have been considered by Virnik and Mal'tseva [2].

One of the main questions arising in the development of methods for the preparation of antimicrobial cellulose fibres containing chemically combined bactericidal substances is that of which type of chemical bond between the bactericidal substance and the polymer ensures an antibacterial activity of the material. To elucidate this problem, a study was made *in vitro* of the antibacterial activity of modified cellulose fibres containing bactericidal substances of the acridine series, halogenophenols, halogens, and silver and copper ions, linked to the functional groups of the modified cellulose macromolecules in different ways [3-7]. Tables 1 and 2 present data for the antibacterial activity of cellulose derivatives with different structures.

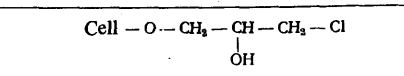
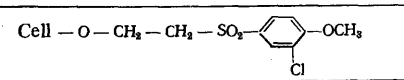
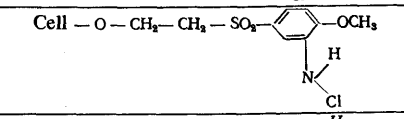
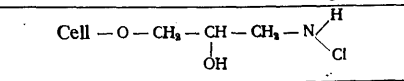
The results show that only those cellulose derivatives in which the bactericidal substance is attached to the polymer by ionic, labile covalent, or coordinate linkages possess antibacterial activity. An example of compounds of this type is provided by cellulose derivatives containing 6,9-diamino-4-ethoxyacridine (Table 1, Nos. 1 and 2) or halogenophenols (Table 1, Nos. 7 and 8). The second type includes cellulose derivatives containing 6,9-diamino-4-ethoxyacridine (Table 1, Nos. 3) or the residue of an *N*-halogenoamino-compound (Table 2, Nos. 5 and 6). Polymers of the third type include complexes of a graft copolymer of cellulose and poly-2-methyl-5-vinylpyridine (or polyvinylpyrrolidinone) with iodine (Table 2, Nos. 7 and 8). Compounds with a stable covalent bond between the cellulose derivative and the bactericidal substance do not exhibit antibacterial activity.

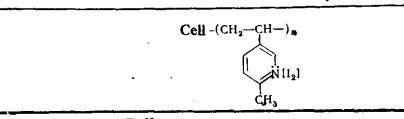
The antibacterial activity of cellulose derivatives in which silver ions are linked to various functional groups increases with the number of silver ions split off from the functional groups of the polymer in an aqueous medium.

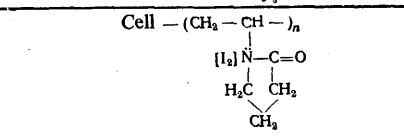












It has been shown [7] that, for the same iodine content, materials obtained from graft copolymers of cellulose and polyvinylpyrrolidinone have more pronounced antibacterial properties than materials obtained from a graft copolymer of cellulose and poly-2-methyl-5-vinylpyridine. This finding can be explained by the fact that owing to the *–I* effect of the carbonyl group in the graft polyvinylpyrrolidinone, the electron density of the nitrogen atom is lower than in the poly-2-methyl-5-vinylpyridine graft copolymer and therefore the stability of the complex formed with iodine by grafted polyvinylpyrrolidinone is also lower.

The sum total of the data quoted above lead to the conclusion that the antibacterial activity of the cellulose derivatives investigated is due to the fact that bactericidal substances interact with the microbial cell after being split off from the polymer carrier.

Cellulose derivatives with antimicrobial properties have been synthesised on the basis of two main principles: (1) by treating cellulose with bactericidal and fungicidal substances containing reactive functional groups capable of interacting with the hydroxy-groups of cellulose or (2) by a preliminary chemical modification of cellulose in order to introduce into its macromolecules reactive functional groups which are subsequently used to combine with bactericidal and fungicidal substances.

The bactericidal and fungicidal substances employed in the synthesis of antimicrobial cellulose derivatives have been mainly (1) metal ions, (2) quaternary ammonium bases, (3) antibiotics, (4) halogens, (5) phenol derivatives,

Table 2. Effect of the structure of the cellulose derivative containing chemically combined halogens on the antibacterial activity of the material [5].

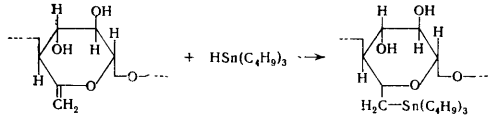
(6) organometallic compounds, and (7) compounds of the nitrofuran series.

It has been suggested [8] that antimicrobial cellulose derivatives containing metal cations and quaternary ammonium bases be obtained by treating cellulose with compounds having the general formula A–B–A, where A $\overset{\oplus}{X}[BC^+]$ are groups capable of reacting with the cellulose hydroxyls (for example, N=C=O, CHO, and ), B is the residue of an aliphatic, aromatic, or heterocyclic compound, X is an ionogenic group, (for example, COO^- and SO_3^-), and $[BC^+]$ is a cation with antimicrobial properties (for example, Ag^+, Hg^{2+}, Cu^{2+}, Zn^{2+}, and R_4N^+). Salts of hydroxymethyl derivatives of levulinhydantoin, *N*-(carboxymethylaminomethyl)melamine, and sulphomethylurea [8] as well as salts of 1,3-di(hydroxymethyl)-5-sulphoethyltetrahydro-1,3,5-triazin-2-one, 5-(*m*-carboxyphenyl)-1,3-di(hydroxymethyl)tetrahydro-1,3,5-triazin-2-one, and 5-carboxymethyl-1,3-di(hydroxymethyl)tetrahydro-1,3,5-triazin-2-one [9] can be used as compounds of this kind. To synthesise derivatives with antimicrobial properties, cellulose (in the form of a fabric) is treated for a short time at 20°C with an aqueous solution of the salt of one of the above compounds containing an acid catalyst, after which the reaction is carried out at 100–150°C.

Antimicrobial derivatives of cellulose containing metal and quaternary ammonium cations and also antibiotics with basic groups have been synthesised from a graft copolymer

of cellulose and poly(acrylic acid) or poly(methacrylic acid)[10,11], a weakly substituted carboxymethyl ether of cellulose[12,13], 2-carboxy-2-chloroethyl ether of cellulose[14], cellulose sulphate[15], cellulose treated with 2,4-dichloro-6-[*N*-(3′,6′,8′-trisulpho-1′-naphthylamino)]-1,3,5-triazine[11,16,17] or dyed with active dyes containing ionogenic groups[17,18] and cellulose phosphate[19] and xanthate[20].
In most of the above studies ionogenic groups were initially introduced into the cellulose macromolecule and then used to combine with the bactericidal substance. An example is provided by the synthesis of antimicrobial cellulose derivatives on the basis of the graft copolymer of cellulose and poly(acrylic acid):

$$\text{Cell}-(CH_2-\underset{\underset{COONa}{|}}{CH}-)_n + [BC^+]\,A^- \rightarrow \text{Cell}-(CH_2-\underset{\underset{COO^-[BC^+]}{|}}{CH}-)_n + Na^+A^-,$$



where $[BC^+] = Ag^+$, Cu^{2+}, R_4N^+, or NH_3^+ - neomycin and $A^- = NO_3^-$, SO_4^{2-}, or Cl^-. The addition of bactericidal cations to the carboxy-groups of viscose fibre has been described[21,22].

Graft copolymers of cellulose with poly-2-methyl-5-vinylpyridine, polyvinylpyrrolidonone, and other polymers containing lactam rings have been used to synthesise antimicrobial cellulose materials containing iodine[6,23,24]. Cellulose derivatives containing chemically combined antimicrobial substances belonging to the group of chlorinated phenols have been synthesised on the basis of the graft copolymer of cellulose and poly-2-methyl-5-vinylpyridine[6,11].

An organotin derivative of cellulose was synthesised for the first time by the reaction of ethynyldeoxycellulose and triphenyltin bromide according to the following scheme[25]:

$$\{C_6H_7O_2(OH)_{3-x}(C{\equiv}CNa)_x\}_n + BrSn(C_6H_5)_3 \rightarrow \{C_6H_7O_2(OH)_{3-x}[C{\equiv}C-Sn(C_6H_5)_3]_x\}_n$$

The synthesis of tin-containing deoxy-derivatives of cellulose, cellulose ethers, and graft copolymers of cellulose has now been achieved[26-28]. Tributylstannyldeoxycellulose has been synthesised by the radical addition of tributyltin hydride to 5,6-celluloseen according to the reaction

and by nucleophilic substitution via the reaction of cellulose iodotoluene-*p*-sulphonate or toluene-*p*-sulphonate with tributylstannyl-lithium[28].

When cellulose toluene-*p*-sulphonate was employed as the starting material, the reaction took place according to the mechanism

$$\{C_6H_7O_2(OH)_{3-x}(O-SO_2-C_6H_4-CH_3)_x\}_n + LiSn(C_4H_9)_3 \rightarrow$$
$$\rightarrow \{C_6H_7O_2(OH)_{3-x}[Sn(C_4H_9)_3]_x\}_n$$

Tributylstannylthiodeoxycellulose has been obtained by treating mercaptodeoxycellulose with bis(tributyltin) oxide[28].

Tin-containing cellulose ethers have been synthesised from trialkyltin oxides and hydroxides and cellulose ethers the functional groups of which contain a mobile hydrogen atom [carboxymethyl, 2-hydroxy-3-mercaptopropyl, 2-(3′-mercapto-4′-methoxyphenyl), sulphonylethyl, and propargyl derivatives] and also by the radical addition of tributyltin hydrides to allyl and propargyl ethers of cellulose[26,28]. The reaction took place according to the following mechanisms:

$$\text{Cell}-O-CH_2-COOH + HOSnR_3 \rightarrow \text{Cell}-O-CH_2-C(=O)-O-SnR_3$$

$$\text{Cell}-O-CH_2-\underset{\underset{OH}{|}}{CH}-\underset{\underset{SH}{|}}{CH_2} + HOSnR_3 \rightarrow \text{Cell}-O-CH_2-\underset{\underset{OH}{|}}{CH}-\underset{\underset{S-SnR_3}{|}}{CH_2}$$

$$\text{Cell}-O-CH_2-CH_2-SO_2-C_6H_3(SH)-OCH_3 + HOSnR_3 \rightarrow$$
$$\rightarrow \text{Cell}-O-CH_2-CH_2-SO_2-C_6H_3(S-SnR_3)-OCH_3$$

$$\text{Cell}-O-CH_2-C{\equiv}CH + HOSnR_3 \rightarrow \text{Cell}-O-CH_2-C{\equiv}C-SnR_3$$

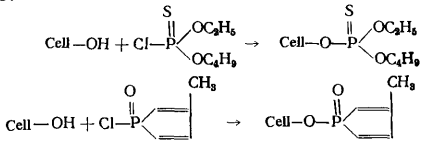
$$\text{Cell}-O-CH_2-CH{=}CH_2 + HSnR_3 \rightarrow \text{Cell}-O-CH_2-CH_2-CH_2-SnR_3$$

$$\text{Cell}-O-CH_2-C{\equiv}CH + HSnR_3 \rightarrow \text{Cell}-O-CH_2-CH{=}CH-SnR_3$$

(R = alkyl residue)

Graft copolymers of cellulose and poly(trialkylstannyl acrylate) or poly(triarylstannyl acrylate) have been synthesised by the reactions of the graft copolymer of cellulose and poly(acrylic acid) with trimethyl-, triethyl-, and triphenyltin hydroxides and also with bis(tributyltin) oxide. The structures of some of the tin-containing cellulose derivatives synthesised were confirmed by Mössbauer spectroscopy[29]. Data on the effect of the structure and amount of the organotin compound chemically combined with cellulose on the antimicrobial properties of the polymer have been published[28,30].

The synthesis of tin-containing derivatives with the general formula cell $-O-SnR_3$ by treating cellulose (or its ether) with alkoxytrialkyltin or the potassium alkoxide derivative of cellulose with trialkyltin chloride has been described[31-33]. However, organotin compounds of the type R_3SnOR' are readily hydrolysed even by atmospheric moisture. It is noteworthy that a high antimicrobial activity of organotin and organomercury derivatives of cellulose can be achieved by introducing into the macromolecules of modified cellulose a very small amount of tin or mercury (0.1–0.2% of the weight of cellulose).



To synthesise organotin derivatives, cellulose ethers and esters containing the residues of unsaturated aliphatic, aromatic, or heterocyclic compounds [2-hydroxybut-3-enyl[34,35], allyl[36], benzyl[37], and 2-(3′-amino-4′-methoxyphenyl)sulphonylethyl[38] cellulose ethers as well as cellulose esters with methacrylic[39,40], sorbic[41,42], oleic[43,44], salicyclic[45,46], furancarboxylic[47,48], and cinnamic[44,47] acids] were mercurated (usually with mercury acetate). As an example one may quote the mercuration of cellulose methacrylate:

$$\text{Cell}-O-\underset{\underset{O}{\|}}{C}-\underset{\underset{CH_3}{|}}{C}=CH_2 \xrightarrow{Hg(OOC-CH_3)_2} \text{Cell}-O-\underset{\underset{O}{\|}}{C}-\underset{\underset{HgOOC-CH_3}{|}}{\overset{\overset{CH_3}{|}}{C}}-\underset{\underset{OH}{|}}{CH_2}$$

Mercury-containing cellulose derivatives have also been synthesised by mercurating with mercury acetate cellulose dyed by active dyes[49], graft copolymers of cellulose with polyacrylonitrile and poly-2-methyl-5-vinylpyridine[50] as well as styrene and benzyl methacrylate[51]. In the preparation of antimicrobial bast fibres, there is no need for a preliminary modification of the fibres; in this case the initial bast fibres can be mercurated to impart to them antimicrobial properties[52,53], since the lignin macromolecules, which enter into the composition of such fibres, contain aromatic residues, which readily interact with mercury salts.

The synthesis of antimicrobial cellulose derivatives containing antimony from cellulose and antimony(III) acid chlorides or esters have been described [54]. The structures of the compounds synthesised may be represented schematically by the formulae Cell–O–$SbCl_2$ and Cell–$OSb(OC_2H_5)_2$. According to patent data [55–57], various phosphorus-containing cellulose derivatives have been synthesised by treating cellulose with phosphorochloridothioates, phosphorochloridothioites, phosphoroisothiocyanatidates, and phosphoroisothiocyanatidites and also with chlorophosphacyclopentenes in organic solvents.

The reactions of cellulose with *O*-n-butyl *O*-ethyl phosphorochloridothioate and 1-chloro-1-oxo-3-methylphosphacyclopentene proceed according to the following mechanisms:

Antimicrobial derivatives of cellulose containing residues of a nitrofuran bactericidal substance have been obtained by the reaction of partly hydrolysed cellulose triacetate with β-(5-nitrofuryl)acrolein [58,59]. According to the literature, esters of cellulose and unsaturated aliphatic acids [60–62] and also 2-carboxy-2-chloroethyl ether of cellulose [14] acquire antimicrobial properties on bromination or substitution with thiocyanate groups [14].

The properties and possible applications of antimicrobial cellulose fibre materials were investigated in detail in recent years. Under practical conditions, the most detailed studies have been made on the antimicrobial cellulose fibre materials containing chemically combined copper or silver ions and also hexachlorophene. It has been shown [30,63–66] that antimicrobial cellulose fibre materials containing various chemically combined bactericidal substances suppress the development of pathogenic microorganisms or postoperative infections. Experiments carried out under the conditions of the surgical clinic of the Antarctic station (Vostok) and also in undertakings of the food industry showed that, when clothing made of antimicrobial fibres containing chemically combined hexachlorophorene and silver or copper ions is used, the population of microorganisms on human skin and on the clothing itself is reduced severalfold compared with the values obtained when ordinary clothing is worn [67–69]. It has been shown [70,71] that, when surgical masks made of antimicrobial muslin containing chemically combined silver ions are worn, the frequency of infection after operative wounds by the microflora from the surgeon's nasopharynx is approximately three times smaller than under the conditions when a mask of ordinary muslin is worn. This suggests that articles made of antimicrobial fibres can be used as a means whereby the microbial population can be reduced and the risks of microbial infection in surgical clinics, in undertakings of various branches of industry, and also in prolonged expeditions can be lowered. Clothing made of antimicrobial fibres can be used not only under specific conditions when the risk of infection by microorganisms is great or the conditions of personal hygiene are difficult but also in ordinary life.

Modified cellulose materials containing chemically combined chlorophenols, organomercury and organotin compounds, or iodine are resistant to the action of mildew and suppress the development of pathogenic fungi causing fungal affections of the feet [30,72,73]. Such fibres can apparently be used to manufacture stockings, socks, and shoe insoles for use in the prophylaxis of common fungal affections.

It has been shown [74] that antimicrobial cellulose fabrics containing chemically combined copper or silver ions can be usefully employed for the packing of sterile surgical instruments. Packing made of antimicrobial fabrics ensures that the surgical instruments remain sterile for several months. The employment of such packing is particularly important for first aid posts and also in rural and mountainous localities.

At the present time antimicrobial materials containing chemically combined hexachlorophene and copper or silver ions have been recommended by the Ministry of Health of the USSR for use in medical practice and their manufacture has begun.

Antimicrobial fibres and non-woven filtering materials made from them can be usefully employed for the sterilisation of air supplied to the fermentation units in the manufacture of antibiotics and in the apparatus for the preparation of blood components [75–78]. In the filtration of air, micro-organisms are not only mechanically trapped by the filtering materials, but also destroyed by the action of the bactericidal substances in the fibres. Non-woven antimicrobial filtering materials ensure the necessary degree of purification and sterilisation of air over a period of several months and their employment increases the reliability of the operation of the filter. In contrast to the filtering materials made of the usual non-antimicrobial fibres, they do not require periodical sterilisation [76,77]. It has been shown [79] that antimicrobial cellulose fabrics containing silver ions bound to the carboxy-groups of grafted poly(acrylic acid) can be used to disinfect river water.

Antimicrobial cellulose materials will presumably prove useful also in other fields.

III. CELLULOSE DERIVATIVES WITH HAEMOSTATIC PROPERTIES

The problem of the arrest of blood flow in surgical operations, particularly of blood flow from small vessels, is important in surgery and still cannot be regarded as finally solved. The use of haemostatic preparations greatly simplifies the technique of the surgical operation and shortens its duration. Despite the positive results achieved when expensive and scarce haemostatic preparations made from donated blood are employed, the search for new haemostatic preparations, based on polysaccharides including cellulose rather than on proteins, is being continued.

Among haemostatic preparations obtained on the basis of cellulose, the so called monocarboxycellulose, synthesised at the end of the 1930's by oxidising cellulose with nitrogen oxides [80], has been investigated in greatest detail. According to the literature [81–84], during the Second World War oxidised cellulose already began to be used in surgical practice as a haemostatic preparation absorbable by the organisms.

Reviews [83,84] and other publications [85–95] have been devoted to monocarboxycellulose. On oxidation by nitrogen oxides, carboxy-groups are formed in the cellulose macromolecule mainly at the sixth carbon atom of the elementary unit. Apart from the main process involving the oxidation of primary hydroxy-groups, secondary hydroxy-groups are also oxidised, which results in the formation of keto- and then carboxy-groups with rupture of the pyran ring [89,90]. Some of the carboxy-groups react with the

hydroxyls in the same cellulose macromolecule (with formation of lactones) or with the hydroxyls of another macromolecule (with formation of esters)[88]. The products always contain a certain amount of nitrate groups. The presence in the oxidised cellulose macromolecule of elementary units containing simultaneously carboxy- and carbonyl groups is responsible for the low resistance of the oxidised cellulose macromolecule to the action of water at an elevated temperature[96]. The sterilisation of cellulose materials oxidised with nitrogen oxides by treatment in an autoclave (this sterilisation procedure is common in surgical clinics) is impossible, since treatment with steam leads to complete degradation of monocarboxycellulose. Haemostatic preparations made from monocarboxycellulose are sterilised by γ-radiation[97,98] or are prepared under sterile conditions[99].

It has been suggested[83,84,96,98] that the calcium salt of monocarboxycellulose, which is prepared by treating oxidised cellulose for a long time with an aqueous solution of calcium chloride, be employed as a haemostatic material. Experiments showed that the calcium salt is an effective haemostatic preparation. During recent years a number of patents and publications have appeared[98,100-104] in which new forms of haemostatic preparations made from oxidised cellulose or various improvements to the technological process for the manufacture of monocarboxycellulose have been proposed. The addition of various antimicrobial substances (tubazid, kanamycin, rivanol, norsulphazol, and streptomycin) to the functional groups of cellulose oxidised by nitrogen oxides and the use of the resulting compounds in surgical operations have been described[97,104-108]. According to the literature, the employment of absorbable haemostatic preparations with antimicrobial activity simplifies the technique of surgical operations and promotes the prophylaxis of post-operative complications. A prolonged action of the above medicinal substances is achieved at the same time.

Nowadays cellulose oxidised by nitrogen oxides is used in surgical practice but the wide-scale employment of this haemostatic preparation which can be absorbed by the organisms is difficult owing to the complicated apparatus required for the technological preparation of monocarboxycellulose and particularly its calcium salt and by the necessity to manufacture the haemostatic material under sterile conditions or the employment of γ-radiation for its sterilisation.

In the patent literature, it has been suggested that haemostatic preparations in the form of tablets consisting of salts of the carboxymethyl ether of cellulose[109] and also salts of cellulose sulphate and ethers of cellulose and aliphatic hydroxyacids be employed to make solutions for the impregnation of bandaging materials[110-112].

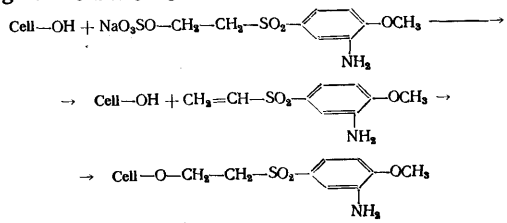
Several years ago, a new haemostatic cellulose material, non-absorbable in the organism, which consists of the calcium salt of the graft copolymer of cellulose and poly(acrylic acid), was proposed[113-117]. In contrast to the haemostatic preparations of monocarboxycellulose, this material is sterilised in an autoclave where its haemostatic properties and stability are hardly altered. The graft copolymer of cellulose and the calcium salt of poly(acrylic acid) was synthesised by three methods[113-117]: (1) by grafting poly(acrylic acid) to cellulose and subsequently treating the resulting graft copolymer with a solution of calcium hydroxide or the calcium salt of a weak acid: (2) by grafting poly(methyl acrylate) to cellulose and then hydrolysing the ester groups of the resulting copolymer with a solution of calcium hydroxide: (3) by grafting the calcium salt of poly(acrylic acid) to cellulose using calcium acrylate as the monomer.

The third method of preparation of the haemostatic material is the most rational, since, in contrast to acrylic acid and methyl acrylate, calcium acrylate is involatile, which greatly simplifies the technology of the synthesis. The synthesis of the graft copolymer of cellulose and poly(acrylic acid) using calcium acrylate as the monomer has been described in a number of studies[118-120]. Wide-scale clinical tests showed that the haemostatic material is useful in surgical practice and it has been recommended by the Ministry of Health of the USSR for use in medicine. Haemostatic muslin is now being manufactured by a continuous process[117].

IV. GRAFT COPOLYMERS OF CELLULOSE AND BIOLOGICALLY ACTIVE PROTEINS

Water-insoluble graft copolymers of cellulose and biologically active protein are of considerable theoretical and practical interest. The synthesis of graft copolymers of cellulose with enzymes and antigens has been most thoroughly investigated. These compounds are obtained by the interaction of cellulose derivatives containing various reactive groups with proteins. However, one must bear in mind that under these conditions several reactive groups of one cellulose macromolecule can interact with several functional groups of one protein macromolecule. There are at present no reliable data concerning the structures of these compounds and therefore we shall henceforth refer to them as graft copolymers.

Water-insoluble graft copolymers of cellulose and enzymes can be used as specific catalysts and can be removed from the reaction sphere at any instant. The employment of these copolymers permits the solution of many problems, which is impossible when the usual water-soluble enzymes are used, such as, for example, the isolation of pure products of the enzymatic decomposition of a substrate, the activation of the enzyme with subsequent complete removal of the activating substance, and sorption with subsequent isolation and investigation of enzyme inhibitors[121]. Water-insoluble graft copolymers of cellulose and antigens, which have been called immunosorbents, are used to sorb antibodies for their quantitative determination and isolation in a pure form with the aim of subsequent investigation of their structures and properties[122,123]. In the synthesis of water-insoluble graft copolymers containing antigens, it is more useful to employ hydrophilic polymers, particularly cellulose, and not hydrophobic synthetic polymers, for example polystyrene, since non-specific sorption of proteins on hydrophilic cellulose materials is much weaker than on hydrophobic synthetic polymers[123].



The initial cellulose derivatives employed in the synthesis of the above graft copolymers are cellulose ethers and esters containing aromatic amino-groups, the carboxymethyl ether of cellulose, the ether of cellulose and cyanuric acid chloride, the 3-chloro-2-hydroxypropyl ether of cellulose, the ester of cellulose and monobromoacetic acid, and cellulose derivatives containing epoxy-rings.

The synthesis of a graft copolymer of cellulose and a protein using as the starting material a cellulose derivative containing aromatic amino-groups was achieved for the first time at the beginning of the 1950's.[124] In this investigation the *p*-aminobenzyl ether of cellulose was diazotised and then introduced into the azo-coupling reaction with the antigen. Subsequently the ester of cellulose and

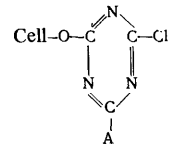
p-aminobenzoic acid and *m*-aminobenzyloxymethylcellulose were used, together with the *p*-aminobenzyl ether, for coupling with enzymes and antigens [124-137]. The cellulose derivatives used in the synthesis of graft copolymers were obtained by treating cellulose with *p*-nitrobenzoyl chloride, *p*-nitrobenzyl chloride, or *N*-(*m*-nitrobenzyloxymethyl)pyridinium chloride followed by reduction of the nitro-groups.

A simpler method for the synthesis of cellulose derivatives containing aromatic amino-groups was proposed in a study [138] where cellulose was treated in an aqueous medium in the presence of sodium carbonate with the sulphate esters of 2-amino-4-(β-hydroxyethyl)sulphonylanisole or 4-(β-hydroxyethyl)sulphonylaniline. 2-(3′-Amino-4′-methoxyphenyl)- and 2-(4′-aminophenyl)-sulphonylethyl ethers of cellulose were synthesised in this way.

The first of the above cellulose ethers was synthesised according to the scheme

The amino-derivatives of cellulose obtained were used to synthesise graft copolymers of cellulose with antigens and enzymes [139-143].

It has been shown [128,129] that the amount of antigen adding to cellulose can be increased sharply by employing a highly dispersed suspension of the cellulose ether containing aromatic amino-groups. The suspension can be obtained by the reprecipitation of the above ether from a cuprammonium solution. Later it was demonstrated [144] that this highly dispersed suspension can also be prepared by substituting the cellulose ether containing aromatic amino-groups with xanthate (in order to obtain a cellulose ether-ester soluble in alkali) with subsequent decomposition of the ester groups in the presence of sulphuric acid. The amounts of antibodies sorbed on the immunosorbents prepared in this way is 500–1000 mg per gramme of immunosorbent and the degree of non-specific sorption of the protein amounts to only 1 mg per gramme of immunosorbent [123].



Recently it has been suggested that graft copolymers of cellulose and biologically active proteins be synthesised from 3-(4′-aminophenoxy)-2-hydroxypropyl [145,146] and *N*-[3′-(*p*-aminophenyl)butyryl]-2-aminoethyl [147,148] ethers of cellulose. However, one should note that these methods for the introduction of amino-groups into the cellulose macromolecule have no advantages over those described above.

One must also note that in immunosorbents where the protein is attached to the polymeric carrier via azo-groups a certain amount of antigen is gradually split off [149]. This is probably due to the formation during the synthesis of diazoamino-compounds, which are gradually cleaved during the storage of the immunosorbent.

The carboxymethyl ether of cellulose was synthesised for the first time for coupling with protein by Michael and Evers [150], the azide obtained from the hydrazide of the carboxymethyl ether of cellulose being introduced into the reaction. Later this method was employed to synthesise the graft copolymers of cellulose with various antigens and enzymes [130,133,151-158]. It was suggested [150-161] that the reaction between carboxymethylcellulose and protein be carried out in the presence of carbodi-imide derivatives. This method of synthesis for graft copolymers, which is simpler than the procedure involving the preparation of the azide of carboxymethylcellulose as an intermediate, has been used recently to synthesise various graft copolymers of cellulose and biologically active proteins [162-165].

The reaction between carboxymethylcellulose and protein can also be achieved in the presence of the Woodward reagent—*N*-ethyl-5-(3′-sulphophenyl)isoxazole [166].

The use of the ester of cellulose and monobromoacetic acid [167-171], the 3-chloro-2-hydroxypropyl ether of cellulose [143,149], and the ester of cellulose and cyanuric acid chloride with the general formula

where A = O–Cell, OH, NH_2, NH–CH_2COOH, etc. [143,149,172-175], as starting materials in the synthesis of graft copolymers of cellulose and biologically active proteins is of considerable interest. The synthesis of these cellulose derivatives is comparatively simple and the reaction between them and proteins can be achieved more simply than with cellulose derivatives containing aromatic amino-groups or carboxy-groups. A cellulose ether containing amino-groups has been treated [176] with an active dichlorotriazine dye (one of the chlorine atoms in the dye molecule reacted with the cellulose ether) and was then allowed to react with the protein (the second chlorine atom in the dye molecule reacted with the functional groups of the protein).

The graft copolymer of cellulose and poly(glycidyl methacrylate) [149], the 3-(4′-isothiocyanatophenoxy)propyl ether of cellulose, and the 3-allyloxy-2-hydroxypropyl ether of cellulose mercurated with mercury acetate [177] were also employed in recent years for coupling with biologically active proteins. In the last case, the mercapto-groups of the protein react with the mercury atoms attached to the alkyl residues of the cellulose ether. Cellulose has been treated [178,179] with cyanogen bromide in an alkaline medium and then a protein was coupled to the iminocarbonate groups formed. The synthesis of a graft copolymer of cellulose and a protein by treating the aminoethyl ether of cellulose and a protein with glutaraldehyde has also been described [180,181].

Likewise, the coupling of enzymes to the carboxymethyl and diethylaminoethyl ethers of cellulose and its phosphate ester via ionic linkages has been achieved [182]. When enzymes are coupled to cellulose by covalent linkages, their activity as a rule decreases. This may be due to the modification of the active centre of the enzyme, a change in the conformation of the enzyme macromolecule, and steric hindrance arising when the enzyme linked to cellulose interacts with the substrate (particularly a high-molecular-weight substrate).

It has been shown [130] that the activity of the graft copolymer of cellulose and its enzymes in relation to a polymeric substrate can be lower than in relation to low-molecular-weight model compounds. This phenomenon can probably be accounted for by steric factors. The same cause may be used to explain the finding [130] that the activity of chymocrypsin linked to carboxymethylcellulose increased with the degree of swelling of the carboxymethylcellulose and reached a maximum when a water-soluble carboxymethylcellulose was employed.

It has been shown in several studies that the addition of enzymes to cellulose not only permits the synthesis of specific catalysts which can be readily removed from the reaction sphere but also reduces the inactivation of the enzyme by external factors and its self-degradation [121,130,145,146,152,154,163]. Interesting results were obtained [137] in the immunisation of animals by the graft copolymer of cellulose and an antigen. In this case a greater amount of antibodies was formed in the animal organism than in immunisation by the soluble antigen. On repeated (after several months) immunisation of animals, to which the graft copolymer of cellulose and the antigen had been administered previously, with the soluble antigen, an extremely intense and prolonged synthesis of antibodies was observed. Their amount exceeded by a factor of 10–20 the amount of antibodies formed on repeated immunisation when the first immunisation was with the soluble antigen. Despite a number of attempts [134,161,167], hitherto it has not been possible to synthesise a graft copolymer of cellulose and an antibody capable of sorbing considerable amounts of the antigen [123].

Graft copolymers of cellulose and enzymes can be used in laboratory practice for preparative and analytical purposes (including clinical analyses), for the simulation of enzymatic processes in living organisms where the enzymes are frequently linked to cellular structures, and in industry and medicine [182]. According to the literature [182], the industrial manufacture of certain cellulose derivatives (bromoacetylcellulose, the *p*-aminobenzyl ether of cellulose, and the carboxymethyl ether of cellulose and its hydrazide), which are employed for coupling to biologically active proteins, has already begun.

As shown above, the synthesis and properties of graft copolymers of cellulose with enzymes and antigens has been investigated in greatest detail. However, bearing in mind that at the present time the advances in the chemistry of macromolecular compounds are being increasingly used for the solution of problems in biochemistry, biology, and medicine, one may expect that in the next few years it will be useful to synthesise water-insoluble graft copolymers of cellulose with other biologically active proteins and polymers incorporating polypeptide chains. The chemical fixation of the above polymers on cellulose should be achieved via functional groups which do not affect their biological activity. Therefore an increase of the number of cellulose derivatives containing various reactive groups, the development of simpler methods for synthesising graft copolymers of cellulose and proteins, and also detailed studies of the interaction of cellulose derivatives with biologically active proteins and of the effect of the structure of graft copolymers on their properties are of great interest.

V. MEDICAL APPLICATIONS OF CELLULOSE DERIVATIVES CONTAINING IONOGENIC OR COMPLEX-FORMING GROUPS

A much smaller number of studies have been made on the possibility of employing in medicine cellulose derivatives containing ionogenic or complex-forming groups. In the middle 1950's, an attempt was made to employ a plasma substitute solution of carboxymethylcellulose polymerised and substituted to different extents [183–185]. The optimum effect in experiments on animals was achieved when a 3% solution of the sodium salt of carboxymethylcellulose (degree of substitution about 0.8, degree of polymerisation 70–100) was used. However, these studies were not developed further because another polysaccharide (dextran) was found to be more useful for the preparation of a plasma substitute.

Cellulose sulphate as well as the sulphates of other polysaccharides are known to have anticoagulant properties (they prevent the clotting of blood); however, owing to its high toxicity, it has not been used for this purpose [186,187]. Cellulose phosphate can be employed as a filtering material for the extraction of calcium ions from the blood of donors for the purpose of its conservation [188–190]. In the presence of an excess of calcium in the organisms of patients, cellulose phosphate can be administered *per os* to sorb calcium ions in the intestine and to remove them from the organism [191–193].

Graft copolymers of cellulose with poly(acrylic acid) and poly-2-methyl-5-vinylpyridine (in the form of fabrics) have been used to prepare radioactive applicators for the treatment of skin diseases [194,195]. These materials are obtained by attaching to the acid and basic groups of the graft copolymers of cellulose the cations and anions of radioactive isotopes respectively. The addition of radioactive isotopic ions to the functional groups of graft cellulose copolymers ensures uniform emission from the entire surface of the radioactive applicator, which enhances its efficiency.

The antithrombogenic cellulose membranes for the dialysis of blood, obtained by coupling heparin to cellulose films with anion-exchange properties, have aroused considerable interest [196,197]. Cellulose materials with anion-exchange properties were obtained in the above investigations by treating cellulose with aziridine.

---o0o---

Thus considerable advances have now been achieved in the synthesis of biologically active cellulose derivatives. Antimicrobial cellulose derivatives containing chemically combined bactericidal and fungicidal substances of different types have been synthesised. The effect of the structure of the cellulose derivatives containing chemically combined bactericidal substances on their antibacterial activity has been investigated. A study has been made of the properties and possible applications of antimicrobial cellulose fibre materials and their manufacture has begun. Methods have been developed for the synthesis of cellulose derivatives with haemostatic properties and their industrial manufacture has been achieved. Various procedures for the synthesis of the graft copolymers of cellulose and biologically active proteins (mainly enzymes and antigens) have been developed and some of the properties of such compounds have been investigated. Cellulose derivatives containing ionogenic or complex-forming groups have been used as independent biologically active compounds or as polymeric carriers for various biologically active substances.

One may expect that further development of studies in this field will yield interesting data and will make it possible to produce new biologically active polymeric materials based on cellulose.

Linear Stoichiometry of Chemical Reactions

G.G.Filippov and M.E.Erlykina

The description of complex chemical reactions in terms of linear algebra (linear stoichiometry) is being increasingly employed in chemical and chemical engineering practice. The review deals with methods for the solution of the most frequently encountered problems in thermodynamics and kinetics involving linear combinations of stoichiometric equations.
The bibliography includes 61 references.

I. INTRODUCTION

Stoichiometry is defined as the "branch of chemistry including the laws of quantitative relations between the reactants, the derivation of chemical formulae, and the derivation of chemical reaction equations".[1] In a wider sense, stoichiometry includes also the application of the laws of conservation of matter and energy to systems in which physical and chemical changes take place[2]. These definitions are formulated regardless of the mathematical procedures for the solution of problems of the above class.

In the present review, linear stoichiometry is understood as the description of complex chemical reactions in terms of concepts of linear algebra. The employment of a unifying procedure involving vectors and matrices permits the maximum enhancement of a characteristic feature of stoichiometry—the derivation of general results without a detailed knowledge of all the characteristics of the phenomenon being investigated.

The language and methods of linear algebra[3-5] are widely employed in applied mathematics[6] and are becoming increasingly necessary in the development of a modern theory of contact and diffusion processes in chemical engineering[7-9]. This review deals with the rules involving linear combinations of stoichiometric chemical reaction equations for which linear or power functions, such as the enthalpy of reaction or reaction rate, have been determined. Topics requiring further research in the field of matrix theory, for example systems of first-order reactions[10] and the design of kinetic experiments[11], have been deliberately omitted.

The rules involving linear combinations of stoichiometric equations were already formulated to some extent by Hess (1840). They are widely employed in chemical thermodynamics albeit without a matrix formulation[12,13]. However, when the problem involves a large number of reactions, the application of linear algebra is both useful and necessary. Moreover, the matrix formulation of the

problem constitutes to some extent the formulation of the algorithm for its solution on a computer.

An interesting set of problems arises likewise in connection with linear combination of stoichiometric equations, which should be regarded also as molecular equations, if the chemical reactions described by them from a kinetic standpoint obey the law of mass action. The study of these problems was initiated by Horiuti [14,15]. A complete and large branch of kinetics—the kinetics of steady-state reactions—has now been established [16-18]. In the theory of steady-state reactions, the methods of linear algebra find the most direct application.

II. ATOMS, MOLECULES, AND REACTIONS

Consider a closed system containing N different substances in equilibrium. The molecular formula of the ith substance consisting of a finite number of B_j atoms† can be expressed in the form

$$A_i = \sum_{j=1}^{n} \beta_{ij} B_j, \tag{1}$$

where B_j is the symbol of an atom or a charge and β_{ij} the number of atoms or charges of type B_j in a molecule A_i. Then the set of molecules A_1, A_2, ..., A_N consisting of atoms B_1, B_2, ..., B_n can be formulated as a system of equations:

$$\begin{aligned} A_1 &= \sum_{j=1}^{n} \beta_{1j} B_j, \\ A_2 &= \sum_{j=1}^{n} \beta_{2j} B_j, \\ A_N &= \sum_{j=1}^{n} \beta_{Nj} B_j \end{aligned} \tag{2}$$

or in matrix form

$$\begin{Vmatrix} A_1 \\ A_2 \\ \vdots \\ A_3 \end{Vmatrix} = \begin{Vmatrix} \beta_{11}\beta_{12} \ldots \beta_{1n} \\ \beta_{21}\beta_{22} \ldots \beta_{2n} \\ \vdots \\ \beta_{N1}\beta_{N2} \ldots \beta_{Nn} \end{Vmatrix} \begin{Vmatrix} B_1 \\ B_2 \\ \vdots \\ B_n \end{Vmatrix} \tag{3}$$

$$A = \beta B \tag{4}$$

The matrix β comprising β_{ij} coefficients with dimensions $N \times n$ is called the atomic matrix. It expresses the composition of a molecular mixture in terms of atomic components.

If one considers a reacting mixture of substances, then using the above concepts, each ith reactant A_i may be associated with a row vector in the β matrix:

$$\vec{\beta}_i = \| \beta_{i1}, \beta_{i2}, \ldots, \beta_{in} \| . \tag{5}$$

We shall suppose that the rank of the β matrix is r and therefore the number of independent $\vec{\beta}_i$ vectors is r. Suppose that these are the first r vectors (i.e. the first r rows of the β matrix). Then each succeeding vector with the indices $r+1$, $r+2$, ..., N can be expressed as a linear combination of the basis vectors

$$\beta_1, B_2, \ldots, \beta_r \tag{6}$$

$$\alpha_{r+1,r+1}\vec{\beta}_{r+1} = \alpha_{r+1,1}\vec{\beta}_1 + \ldots + \alpha_{r+1,r}\vec{\beta}_r \tag{7}$$

or

$$\alpha_{r+1,N}\vec{\beta}_N = \alpha_{N1}\vec{\beta}_1 + \ldots + \alpha_{Nr}\vec{\beta}_r$$

After transferring all the terms of these equations to one side, we obtain the following system:

$$\begin{aligned} &\sum_{i=1}^{r+1} \alpha_{r+1,i} A_i = 0, \\ &\sum_{i=1}^{r+1} \alpha_{r+2,i} A_i = 0, \\ &\vdots \\ &\sum_{i=1}^{r+1} \alpha_{Ni} A_i = 0. \end{aligned} \tag{8}$$

Eqns. (7) and (8) corresponds to chemical reaction equations.

The numbers α_{ki} are called the stoichiometric coefficients of the substance A_i in the reaction ($k = r+1, \ldots, N$; $i = 1, \ldots, r+1$). They are negative if the ith substance is the starting material in the kth reaction and positive for the products. The set of stoichiometric coefficients for the given set of reactions gives rise to the stoichiometric α matrix. In this matrix, each reaction corresponds to a row vector $\vec{\alpha}_k = \| \alpha_{k1}, \ldots, \alpha_{k,r+1} \|$.

Thus the minimum number of reactions required to describe the chemical processes in a system of N reactants is $N - r$, where N is the number of reactants A_i in the given system and r is the rank of its atomic β matrix.

The rank of the atomic matrix determines the number of independent components of the reaction mixture. This concept is used successfully in the study of equilibria. Thus for an equilibrium system in which $N - r$ reactions takes place, one can formulate a system of equations describing the chemical equilibrium conditions (the law of mass action):

$$\begin{aligned} K_1 &= f_1(\eta_1, \eta_2, \ldots, \eta_N), \\ K_2 &= f_2(\eta_1, \eta_2, \ldots, \eta_N), \\ &\vdots \\ K_{N-r} &= f_{N-r}(\eta_1, \eta_2, \ldots, \eta_N), \end{aligned} \tag{9}$$

where η_i are the numbers of models of the A_i reactants. These $N - r$ equations can be solved simultaneously with r conservation equations:

$$\sum_{i=1}^{N} \beta_{ij}\eta_i = 0 \quad (j = 1, \ldots, r) \tag{10}$$

in order to obtain the composition of the equilibrium mixture on the basis of the initial composition. It is then evident that $N - r$ relations (10) are used to determine $N - r$ values of η_i in terms of r values of independent η_i. If these r values of independent η_i are known, the composition of any equilibrium mixture is fully defined.

Key substances, the number of which is equal to the number of independent reactions, i.e. to the rank R of the stoichiometric matrix, should be distinguished from the independent components. Key substances are used as independent variables for an unambiguous description of the kinetics in systems where several reactions take place simultaneously.

The relation between the ranks of the atomic and stoichiometric matrices has been given, for example, by Aris and Mah [22]:

$$R + r \leqslant N. \tag{11}$$

Eqn. (11) is called the Gibbs stoichiometric rule.

The first application of linear algebra to stoichiometric problems involved in fact the theorems of the ranks of the

†Atoms can be understood not only as atoms in the usual sense but also various groups of atoms [19,20] and other structural fragments of the molecule, for example CH_3, $\rangle CH_2$, and $\rangle CH$ in alkanes [21].

atomic β matrix and the stoichiometric coefficient α matrix: Jouguet (1921),[23] Brinkley[24], and Pshezhetskii and Rubinshtein[25]. A convenient numerical method for finding the rank of the atomic matrix was recently described by Hanson[26]. The use of the procedures of linear algebra to give a formalised formulation of the problems arising in the study of equilibria and chemical reaction kinetics was considered by Aris[27].

Since it is frequently difficult to formulate *a priori* a system of reactants $\{A_j\}$ for the chemical reaction under investigation, the problem naturally arises of the experimental determination of the number of independent reactants and hence of the rank of the stoichiometric coefficient matrix[22]. In this case, all the N reactants in the system are determined quantitatively for the chosen initial conditions at $N + 1$ different instants $t_0, t_1, \ldots, t_N$, i.e. the composition matrix is obtained. Such analysis makes it possible to reduce the problem of the determination of the rank of the stoichiometric matrix to the determination of the rank of the composition matrix. Here the necessity to take into account the accuracy of the determination of the composition constitutes a complication.

We may note that a related problem arises also in the interpretation of the results of spectrophotometric analysis of multicomponent systems in solution[28,29].

According to Eqn. (8), any reaction can be formulated thus:

$$R_k \equiv \sum_i \alpha_{ki} A_i = 0, \tag{12}$$

where k is the number of the reaction and i the number of the substance. Here the reactions $\sum_i \alpha_{ki} A_i = 0$ and $\sum_i (\gamma \alpha_{ki}) A_i = 0$ are identical and therefore only the ratios of the stoichiometric coefficients are important. These ratios are rational numbers and for the α_{ki} it is always possible to select integral values. Different conditions which the α_{ki} must obey have been formulated[30-32] but none of these formulations has been adopted. Usually the values of α_{ki} are chosen as the smallest integral numbers compatible with Eqn. (12).

If one remembers that α is the matrix of the stoichiometric coefficients α_{ki} and the column vector of the substances $(A_1, A_2, \ldots, A_N)$ is denoted by A, Eqn. (12) can be written in the form

$$\alpha A = 0. \tag{13}$$

Since according to Eqn. (1)

$$A_i = \sum_{j=1}^{n} \beta_{ij} B_j,$$

the chemical reaction equation can be rewritten in the form

$$\sum_{i=1}^{N} \alpha_{ki} \sum_{j=1}^{n} \beta_{ij} B_j = 0. \tag{14}$$
$$(k = 1, 2, \ldots, m)$$

If the chemical reaction equation (12) is written so that the B_j are linearly independent (i.e. are in the basis of the space to which the reactants A_j belong), then, by interchanging the summation signs, we obtain

$$\sum_{j=1}^{n} \sum_{i=1}^{N} (\alpha_{ki}\beta_{ij}) B_j = 0 \tag{15}$$

and

$$\sum_{i=1}^{N} \alpha_{ki}\beta_{ij} = 0.$$
$$(j = 1, \ldots, n; \quad k = 1, \ldots, m)$$

Having designated the row vector of the elements α_{ki} by $\vec{\alpha}_k$, we obtain

$$\vec{\alpha}_k \beta = 0. \tag{16}$$

Thus for each kth reaction there is a system of n linear homogeneous equations. The coefficient $\alpha_{ki}\beta_{ij}$ must satisfy the valence rules and the laws of conservation of mass and charge.

The system of linear homogeneous equations (16) has been actually employed to find the stoichiometric coefficients α_{ki} in chemical reactions. The numbers $\alpha_{ki}\beta_{ij}$ constitute a matrix $\vec{\alpha}\vec{\beta}$ (rectangular in the general case) with dimensions $n \times N$ (the number of basis elements is smaller than the number of substances in the reacting mixture). Since the rank of this matrix is n, the system of Eqns. (16) is consistent but undetermined. A method for the solution of such systems of equations has been described, for example by Golovina[5].

It may appear strange that the set of reactions occurring in the given system is not unique but has been defined only to within the number of independent reactions. However, for many thermodynamic problems it is unimportant, since the mechanism of equilibration in the system does not affect the thermodynamic functions.

On the other hand, in the study of reaction kinetics, such an approach is unsuitable: if no account has been taken of the mechanism of equilibration, then the rate of equilibration also remains undetermined.

Nevertheless it is found that, with certain assumptions, it is possible to investigate also the problem of reaction rates if one considers stoichiometric equations which reflect the process kinetics. Such equations will be henceforth called molecular-stoichiometric. For molecular-stoichiometric equations, it is possible to define a power function of the reactant concentrations—the reaction rate. However, these equations lose the property of molecularity on being multiplied by a scalar and then added together. An interesting procedure in operations involving such equations consists in their comparison with a system of stoichiometric equations. The problems arising in this connection are considered in Section IV.

The fact that for stoichiometric and molecular-stoichiometric equations it is possible to define certain useful functions, is the reason why linear stoichiometry is of real interest for the chemist.

III. THERMODYNAMIC APPLICATIONS

It is known from thermodynamics that for any chemical reaction it is possible to determine the changes in certain functions of state (thermodynamic functions), such as the internal energy U, the enthalpy H, the Helmholtz free energy F, and the Gibbs free energy G. Since U, H, F, and G are functions of state, then for any chemical reaction under specified external conditions, for example the standard conditions (T = 298°K and p = 1 atm), one can write

$$\Delta P_k^0 = \sum_{i=1}^{n} \alpha_{ij} \Delta P_i^0, \tag{17}$$

where ΔP_k^0 is the change in any thermodynamic function (U, H, F, and G) in the chemical reaction of the number of

moles of reactants corresponding to the stoichiometric reaction equation and the ΔP_i^0 are the changes in U, H, F, and G for the formation of the individual reactants from the elements.

When the thermodynamic functions are introduced in this way, they are not always susceptible to experimental determination. Therefore one frequently employed the method of the algebraic summation of the chemical reaction equations and the corresponding thermodynamic functions. This procedure was employed for the first time by Hess to determine the enthalpies of formation of substances.

As shown in Section II, the set of reactions R_k involving a set of substances $\{A_i\}$ ($i = 1, 2, \ldots, N$) can be regarded as the vector $\vec{\alpha_k}$ in a linear vector space. Since the change in thermodynamic functions is associated with the chemical reaction, each vector $\vec{\alpha_k}$ in the space is associated with a certain number—the change in the thermodynamic function. Thus for a linear combination of vectors (reactions), these numbers obey Eqn. (17), i.e. they form linear functions in the vector space (in the space of chemical reactions) [5].

As stated in Section II, for each system of substances $\{A_i\}$ there is a minimum set $\bar{R}_k$ of reactions describing the chemical processes in the system. If for each reaction $\bar{R}_k$ forming part of the fundamental set the ΔP_k^0 are known, then for any lth linear combination of fundamental reactions,

$$R_l = \sum_{k=1}^{m} \lambda_{lk} \bar{R}_k \left(\bar{R}_k = \sum_{i=1}^{N} \bar{\alpha}_{ki} A_i \right), \qquad (18)$$

it is also possible to find ΔP_l^0 using the properties of the linear functions in the vector space [5]:

$$f(x + y) = f(x) + f(y), \qquad (19)$$

$$f(\lambda x) = \lambda f(x). \qquad (20)$$

Then, if one wants to determine the change in an unknown thermodynamic function ΔP_l^0 for a reaction Rl, one must choose a system of fundamental equations for chemical reactions with known ΔP_k^0. This system must be such that the reaction Rl is a linear combination of the $\bar{R}_k$ i.e. Eqn. (18) holds.

In practice, for example in thermochemistry, the so called thermochemical cycles are set up for this purpose. There are several methods for the determination of the coefficients λ_{lk}, one of which has been described by Luzanov [33].

Substitution of Eqn. (12) in Eqn. (18) yields

$$\sum_{i=1}^{N} \alpha_{li} A_i = \sum_{k=1}^{m} \lambda_{lk} \sum_{i=1}^{N} \bar{\alpha}_{ki} A_i. \qquad (21)$$

By changing the order of the summation and by setting the coefficients of the independent A_i equal to one another, we obtain a system of linear equations in the unknowns λ_{lk}:

$$\alpha_{li} = \sum_{k=1}^{m} \lambda_{lk} \bar{\alpha}_{ki} \quad (i = 1, \ldots, N) \qquad (22)$$

or

$$\begin{Vmatrix} \alpha_{l1} \\ \vdots \\ \alpha_{lN} \end{Vmatrix} = \bar{\alpha}^T \begin{Vmatrix} \lambda_{l1} \\ \vdots \\ \lambda_{lm} \end{Vmatrix}.$$

The number of components A_i entering into the reaction is always greater than or equal to the number of fundamental reactions. Therefore the $\bar{\alpha}$ matrix of the coefficients $\{\bar{\alpha}_{ki}\}$ will have the dimensions $m \times N (N \times m)$ for each reaction with the index l. However, the system obtained is consistent since $N - m$ equations are linearly dependent. Having chosen m independent equations and having solved the resulting system, we obtain λ_{lk}.

After the determination of λ_{lk}, the changes in thermodynamic functions in the lth reaction can be found in accordance with the properties of the linear functions (19) and (20) in terms of

$$\Delta P_l = \sum_{k=1}^{m} \lambda_{lk} \bar{P}_k, \qquad (23)$$

where $\Delta \bar{P}_k$ are the changes in thermodynamic functions for the fundametal chemical reaction equations.

Consider the following simple example from a collection of problems [34]. From a specified system of fundamental reactions for which the enthalpies of formation ΔH^0 are known,

	ΔH^0, kcal mole^{-1}
ZnS(solid) - Zn(solid) - S (orthorhom.) = 0	$\Delta H_I^0 = -44.0$
$2ZnO + 2SO_2 - 2ZnS - 3O_2 = 0$	$\Delta H_{II}^0 = -221.88$
$2SO_3 - O_2 - 3SO_2 = 0$	$\Delta H_{III}^0 = -46.88$
$ZnSO_4 - ZnO - SO_3 = 0$	$\Delta H_{IV}^0 = -55.1$

one is required to find the enthalpy ΔH_V^0 of the reaction

$$ZnSO_4 - Zn - S(\text{orthorhom.}) - 2O_2 = 0 \qquad \Delta H_V^0 = ?$$

We formulate the $\bar{\alpha}$ matrix for this system of chemical equations:

Zn	S	O_2	SO_3	SO_2	ZnO	ZnS	$ZnSO_4$
−1	−1	0	0	0	0	1	0
0	0	−3	2	0	2	−2	0
0	0	−1	−3	2	0	0	0
0	0	0	0	−1	−1	0	1

,

whereupon we have according to Eqn. (22)

$$\begin{Vmatrix} -1 \\ -1 \\ -2 \\ 0 \\ 0 \\ 0 \\ 0 \end{Vmatrix} = \begin{Vmatrix} -1 & -1 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & -3 & 2 & 0 & 2 & -2 & 0 \\ 0 & 0 & -1 & -3 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & -1 & 0 & 1 \end{Vmatrix}^T \begin{Vmatrix} \lambda_1 \\ \lambda_2 \\ \lambda_3 \\ \lambda_4 \end{Vmatrix}. \qquad (24)$$

Having chosen from Eqns. (24) obtained any four which are linearly independent, we find $\lambda_1 = 1$, $\lambda_2 = 2$, $\lambda_3 = 1/2$, and $\lambda_4 = 1$ and we obtain for H_V^0

$$\Delta H_V^0 = \Delta H_I^0 + {}^1/_2 \Delta H_{II}^0 + {}^1/_2 \Delta H_{III}^0 + \Delta H_{IV}^0 =$$
$$= -(1 \times 44.0) - ({}^1/_2 \times 221.88) - ({}^1/_2 \times 46.88) - (1 \times 55.1) =$$
$$= -223.48 \text{ kcal mole}^{-1}.$$

The method of finding the thermodynamic functions for reactions from the known thermodynamic functions for fundamental reactions is suitable also for the determination of the equilibrium constants.

If the equilibrium constants for the fundamental reactions K_{Rk} are known, then since

$$\lg K_R = -\Delta F_R^0/RT, \text{ and } \lg K_{\bar{R}_k} = -\Delta F_{\bar{R}_k}^0/RT,$$

the condition

$$\Delta F_R^0 = \sum_k \lambda_k \Delta F_{\bar{R}_k}$$

leads to

$$\lg K_R = \sum_k \lambda_k \lg K_{\bar{R}_k}.$$

An example of the calculation of the equilibrium constant for the oxidation of arsenic sulphides by nitric acid from the known equilibrium constants for five fundamental reactions is quoted by Luzanov[33].

The efficiency of the method for the calculation of thermodynamic functions described above is illustrated particularly clearly in problems which give rise to large systems of equations, the solution of which requires the employment of a computer. For example, for a certain class of compounds one can consider simultaneously not one thermochemical cycle, but a set of such cycles involving a chosen set of fundamental reactions and one can find all possible linear combinations of the cycles corresponding to the formation of various compounds of the given class. A problem of this kind for boron compounds was formulated and solved by Guest and Pedley[35].

As stated above, the molecular formula of any substance can be written thus:

$$A_i = \sum_{j=1}^{n} \beta_{ij} B_j, \qquad (25)$$

where B_j are structural fragments (atoms, bonds, and groups of atoms) and β_{ij} are their numbers in the molecule. Formally, the formation of a molecule of type A_i from the structural elements can be regarded as a reaction in which the stoichiometric coefficients are β_{ij}. One can show that these "reactions" are vectors in a linear space[27].

Next, if we associate each "reaction" of this kind with a number, for example the enthalpy of formation, evaporation, and fusion or the specific volume, i.e. any extensive property $P(A_i)$ of the substance A_i, and postulate that these numbers obey the conditions

$$P(A_i + A_j) = P(A_i) + P(A_j), \qquad (26)$$

$$P(\gamma A_i) = \gamma P(A_i), \qquad (27)$$

where A_i and A_j are arbitrary substances and γ is an arbitrary real number, then P is a linear function in the given linear space. If the fundamental reaction in this space consists of the $\{B_j\}$, the linear function P can be represented by the linear formula

$$P(A_i) = \sum_{j=1}^{n} \beta_{ij} P_j, \qquad (28)$$

where β_{ij} are the coordinates of the vector A_i in the space and P_j are coefficients independent of β_{ij}.

Then, if we have a series of substances $\{A_1, A_2, \ldots, A_N\}$ for which an experimental property P is known, it is possible to formulate the following equations:

$$P(A_i) = \sum_{j=1}^{n} \beta_{ij} P_j \quad (i = 1, \ldots, N). \qquad (29)$$

These equations are inconsistent, since for real systems Eqns. (26) and (27) hold only approximately and in addition the quantities $P(A_i)$ are themselves not entirely accurate having been determined with an experimental error.

Since the rank of the "stoichiometric" matrix is in this case n, only n of the numbers $P(A_i)$ are linearly independent. The remaining $N - n$ quantities $P(A_i)$ are linear combinations of the chosen n independent $P(A_i)$. For simplicity we shall assume that the first n equations of set (29) are independent. Then any $P(A_s)$ is

$$P(A_s) = \sum_{i=1}^{n} \lambda_i \bar{P}(A_i),$$

where λ_i may be determined by solving equations of type (22). The above equation permits the determination of the unknown quantities $P(A_s)$ having chosen an appropriate system of fundamental equations with experimental $\bar{P}(A_i)$.

However, this method for the calculation of unknown physicochemical properties of substances suffers from two significant disadvantages, namely (1) the experimental errors in the quantities $\bar{P}(A_i)$ in the fundamental equations enter wholely into the required quantity $P(A_s)$; (2) this method permits the calculations of $P(A_s)$ from the given set of fundamental equations for a comparatively narrow range of compounds.

Therefore another procedure, in which the coefficients P_j in Eqn. (28) are evaluated by least squares from experimental points for a large number of compounds, is used much more frequently. Then in principle it is possible to calculate from Eqn. (28), using known values of P_j, a given property P for any compound of the given class. Methods involving this procedure have been called additive. For example, those of Souders et al.[36] and Franklin[37], Laidler[38], Bernstein[39], Allen[40], Benson and Buss[41], Tatevskii[42], and others may be included among them. The methods differ only in the way the basis (structural elements B_j) is chosen and hence have different numbers of terms in Eqn. (28). A detailed analysis of various additive methods for the calculation of the physicochemical properties of compounds and a comparison of the accuracy of the corresponding computational formulae have been carried out[43-45].

Questions relating to the mathematical formulation of the problem and the analysis of the reliability and accuracy of the results obtained by additive methods have been considered[46,47].

IV. KINETICS OF STEADY-STATE REACTIONS

A complex chemical process can be represented by a set of molecular chemical equations (the reaction mechanism) if in addition to the reactants and products one considers also "intermediates".[48,49] It is interesting that, in order to account for chemical changes in a system, it is sufficient to postulate the existence of intermediates in very small amounts. Here the situation is approximately the same as in the boundary layer theory where one introduces the hypothesis of a high property flux gradient in a very thin layer next to the wall.

Together with stoichiometry, molecular equations describe also the kinetics, i.e. they obey the law of mass action on the basis of which it is possible to determine the rate r_s for any molecular equation s included in the mechanism of the complex reaction. For ideal systems r_s is expressed as follows[8]:

$$r_s = k_s \prod_{i=1}^{N} [A_i]^{\theta_{is}} - k'_s \prod_{i=1}^{N} [A_i]^{\gamma_{is}}, \qquad (30)$$

where $\theta_{is} = |\alpha_{is}|$ for the reactants and $\theta_{is} = 0$ for the products, $\gamma_{is} = |\alpha_{is}|$ for the products and $\gamma_{is} = 0$ for the reactants, $[A_i]$ are the concentrations of the products and reactants (these can be both bulk-phase and surface concentrations), and k_s and k'_s are the concentration-independent rate constants for the forward and reverse reactions.

Suppose that the proposed reaction mechanism consists of S stages:

$$\sum_{i=1}^{N} \alpha_{is} A_i = 0 \qquad (31)$$

$$s = 1, 2, \ldots, S,$$

in which N reactants participate, including Q intermediates and $P = N - Q$ reactants and products.

By considering the rate r_i of the disappearance or evolution of the ith substance,

$$r_i = \sum_{s=1}^{S} \alpha_{is} r_s \quad (i = 1, \ldots, N), \tag{32}$$

we can obtain a system of equations describing the local rate of the chemical reaction in terms of the known rates r_s of the individual stages. However, this equation includes also the concentrations of the intermediates, which are not usually measured. The above difficulty can be obviated by adducing the classical hypothesis of the steady-state concentrations of the intermediates, according to which they should obey the following conditions:

$$\begin{gathered} r_q = \sum_{s=1}^{S} \alpha_{qs} r_s = 0, \\ q = P+1, P+2, \ldots, Q. \end{gathered} \tag{33}$$

Here α_{qs} are the stoichiometric coefficients of the intermediates q in the sth stage of the mechanism. Eqns. (33) makes it possible in many cases to express explicitly the concentrations of the intermediates in terms of those of the products and reagents and hence solve the problem. A critical analysis of the steady-state hypothesis has been carried out [50].

Horiuti [14] and also Horiuti and Nakamura [15] showed that there is another method of expressing the steady-state conditions which is more convenient for complex mechanisms than that specified by Eqns. (33). These workers suggested that one should consider linear combinations of stages involved in the mechanism of the complex reaction. The stoichiometric equations resulting from these linear combinations can be called routes. The stoichiometric coefficients of route m are of the form

$$\alpha_{im} = \sum_s \alpha_{is} \nu_{sm}, \tag{34}$$

where ν_{sm} are the so called stoichiometric numbers, i.e. multipliers for stage s, which are introduced before adding to subtracting from other stages.

Formally, we can write, as for the set of stages, an equation of type (32) for a set of routes:

$$r_i = \sum_m \alpha_{im} r_m, \tag{35}$$

where r_m is the rate for route m but the form of r_m is still unknown. By setting equal Eqns. (32) and (35) and taking into account Eqn. (34), we obtain,

$$\sum_s \alpha_{is} r_s = \sum_m \left(\sum_s \alpha_{is} \nu_{sm} \right) r_m.$$

By altering the order of summation, we find

$$\sum_s \alpha_{is} r_s = \sum_s \alpha_{is} \sum_m \nu_{sm} r_m.$$

Assuming that the coefficients of α_{is} are equal, we obtain finally

$$r_s = \sum_m \nu_{sm} r_m \tag{36}$$

Eqn. (36) describes the relation between the unknown rates for different routes and the known rates for different stages. It only remains to decide on the method of choosing the stoichiometric numbers ν_{sm}. According to Horiuti's hypothesis [14,15], the stoichiometric numbers are chosen by solving the homogeneous system of equations

$$\sum_s \alpha_{qs} \nu_{sm} = 0 \quad (q = P+1, P+2, \ldots, Q). \tag{37}$$

It is possible to show that Eqn. (37) is a consequence of the hypothesis that the concentrations of the intermediate correspond to a steady-state. Indeed Eqn. (33) can be put in the form

$$\sum_s \alpha_{qs} r_s = \sum_s \alpha_{qs} \sum_m \nu_{sm} r_m$$

and, by changing the order of summation, we find

$$\sum_m r_m \sum_s \alpha_{qs} \nu_{sm} = 0.$$

This leads to Eqn. (37). Eqn. (37) should in fact be regarded as an expression of Horiuti's steady-state condition but in the literature [17,18] this term is given to Eqn. (36).

Eqns. (37) comprise Q equations in S unknowns ν_s and $Q < S$. The number M of the linearly independent solutions of these equations is equal to the number of routes and is given by the condition $M = S - Q$. Since $Q < S$, some of the ν_s are free variables and must be fixed in order to obtain a solution to Eqn. (37).

Thus each set of molecular equations (mechanisms) can be associated with a set of stoichiometric equations (routes) and Eqns. (36) with the ν_{sm} determined from Eqn. (37) can be used to find r_m and the concentrations of the intermediates.

We shall consider as an example a complex reaction (pyrolysis of ethane) the suggested multiphase mechanism of which is of the following form [51]

$$C_2H_6 = 2CH_3^{\cdot}, \tag{I}$$

$$CH_3^{\cdot} + C_2H_6 = CH_4 + C_2H_5^{\cdot}, \tag{II}$$

$$C_2H_5^{\cdot} = C_2H_4 + H^{\cdot}, \tag{III}$$

$$H^{\cdot} + C_2H_6 = H_2 + C_2H_5^{\cdot}, \tag{IV}$$

$$2C_2H_5^{\cdot} = C_2H_4 + C_2H_6, \tag{V}$$

where C_2H_6, CH_4, C_2H_4, and H_2 are the reactants and reaction products ($i = 1, 2, 3, 4$) and $CH_3^{\cdot}$, $H^{\cdot}$, and $C_2H_5^{\cdot}$ are intermediates ($q = 5, 6, 7$).

Eqns. (37) for mechanism (I)–(V) can be formulated as follows:

$$\begin{aligned} \nu_{1m}(2) + \nu_{2m}(-1) + \nu_{3m}(0) + \nu_{4m}(0) + \nu_{5m}(0) &= 0 \quad E_1, \\ \nu_{1m}(0) + \nu_{2m}(0) + \nu_{3m}(1) + \nu_{4m}(-1) + \nu_{5m}(0) &= 0 \quad E_2, \\ \nu_{1m}(0) + \nu_{2m}(1) + \nu_{3m}(-1) + \nu_{4m}(1) + \nu_{5m}(-2) &= 0 \quad E_3, \end{aligned}$$

This system is reduced to a canomical form by the method of leading operations [52]. The essential feature of the method involves the replacement of the initial equations E_1, E_2, and E_3 by an equivalent system where a variable has a coefficient of unity in one equation and zero in all the others.

In our case the canomical system comprises the equations

$$\begin{aligned} \nu_{1m}(1) + \ldots + \nu_{4m}(0) + \nu_{5m}(-1) &= 0 \quad (E_1 + E_2 + E_3)/2, \\ \nu_{2m}(1) + \ldots + \nu_{4m}(0) + \nu_{5m}(-2) &= 0 \quad (E_3 + E_2), \\ \nu_{3m}(1) + \nu_{4m}(-1) + \nu_{5m}(0) &= 0 \quad E_2, \end{aligned}$$

and we can obtain the complete set of solutions ν_{sm} ($m = 1, 2$) of equations E_1, E_2, and E_3 by assigning any values to the independent variables ν_{4m} and ν_{5m}. We shall now consider the permissible solutions generated by trial and error:

$$\begin{aligned} m = 1: \quad & \nu_{41} = 0; \quad \nu_{51} = 1 \\ m = 2: \quad & \nu_{42} = 1; \quad \nu_{52} = 0. \end{aligned}$$

The route ν_{s1} is of the form

$$\nu_{s1}^T = (\nu_{11}, \nu_{21}, \nu_{31}, \nu_{41}, \nu_{51}) = 1, 2, 0, 0, 1).$$

Similarly

$$\nu_{52}^T = (\nu_{12}, \nu_{22}, \nu_{32}, \nu_{42}, \nu_{52}) = (0, 0, 1, 1, 0).$$

According to Eqn. (34), the stoichiometric equations for the routes are

$$2C_2H_6 = 2CH_4 + C_2H_4,$$
$$C_2H_6 = C_2H_4 + H_2.$$

We shall now find the rates for these routes on the assumption that the reactions occurring in accordance with Eqns. (I), (II), and (V) are irreversible and reactions (III) and (IV) are reversible. Equations of type (36) assume the following form in this case:

$$k_1[C_2H_6] = r_1(1) + r_2(0), \quad \text{(IA)}$$
$$k_3[\dot{CH_3}][C_2H_6] = r_1(2) + r_2(0), \quad \text{(IIA)}$$
$$k_5[\dot{C_2H_5}] - k_5[C_2H_4][\dot{H}] = r_1(0) + r_2(1), \quad \text{(IIIA)}$$
$$k_7[\dot{H}][C_2H_6] - k_8[\dot{C_2H_5}][H_2] = r_1(0) + r_2(1), \quad \text{(IVA)}$$
$$k_9[\dot{C_2H_5}]^2 = r_1(1) + r_2(0). \quad \text{(VA)}$$

We find from Eqns. (IA) and (IIA)

$$[\dot{CH_3}] = 2k_1/k_3.$$

Eqns. (IA) and (VA) yield

$$[\dot{C_2H_5}] = \sqrt{\frac{k_1}{k_9}[C_2H_6]},$$

and from Eqns. (IIIA) and (IV) we obtain

$$[\dot{H}] = \frac{\sqrt{\frac{k_1}{k_9}[C_2H_6]}(k_5 + k_8[H_2])}{k_7[C_2H_6] + k_5[C_2H_4]}.$$

Then, according to Eqns. (IA) and (IIA),

$$r_1 = k_1[C_2H_6],$$
$$r_2 = k_7[C_2H_6][\dot{C_2H_5}]\left(\frac{k_5 + k_8[H_2]}{k_7[C_2H_6] + k_5[C_2H_4]} - k_8[H_2]\right).$$

Knowing r_1 and r_2, it is easy to find the rate of consumption of ethane in the pyrolysis process from Eqn. (32):

$$r_{C_2H_6} = 2r_1 + r_2.$$

If the concentrations of the intermediates are related in some way, as sometimes happens when reactions on the surface are considered, then the above relations must be employed in addition to Eqns. (36). The results obtained, expressed by Eqn. (35), may be compared with experimental data and the adequacy of the mechanism may be tested. For reactions with several routes, a convenient method of comparing theory with experiment involves a comparison of the calculated and experimental selectivities [53, 54].

One should also note the possibility of the occurrence of reactions with several independent mechanisms. A distinctive feature of such reactions is that the number of routes involved is greater than the number of independent reactions which can occur in the given reactant system [18].

In many cases, when the intermediates are excluded, it is convenient to employ the equations proposed by Temkin [55, 56], which are related to Eqns. (36), rather than Eqns. (36) themselves. Finally, it is possible in principle to carry out numerically all the calculations based on Eqns. (36), [57] but in this case we do not have kinetic equations of type (35) in an explicit form.

Apart from facilitating the derivation of kinetic equations on the hypothesis of steady-state concentrations of intermediates, the introduction of routes provides to some extent a basis for the classification of complex reactions. Whereas previously a distinction was drawn between complex consecutive or parallel reactions, when the routes are employed, the difference between them is insignificant and such reactions are simply processes with several routes. An interesting class of complex reactions comprises processes with a single route. These include, for example, the synthesis of ammonia and methanol, the reaction of hydrogen and bromine, etc. A reaction with a single route permits a more detailed theoretical study than reactions with several routes [16, 17]. In particular, the rate of a single-route reaction can be expressed, along the route, as the difference between the rates in the forward (r'_m) and reverse (r''_m) directions and for reversible routes it is possible to find the relation between the equilibrium constant r'_m/r''_m for the route and the rate constants k_s and k'_s for the stages by introducing the so called average stoichiometric number [58, 59], which can be determined experimentally [59-61].

The Use of Proton Magnetic Resonance in the Study of Complexones

N.A.Kostromina

The available literature data for the protonation of complexones and the formation of their complexes with diamagnetic and paramagnetic ions are reviewed. A systematic and general account is given of studies on the equilibria and kinetics of complex formation and of the structures of the complexes. Typical PMR spectra of complexones and their metal complexes are presented; quantitative characteristics obtained from PMR data (chemical shifts, spin-spin coupling constants, stability constants, and reaction rate constants) are tabulated.
The bibliography includes 99 references.

III. PMR study of the formation of metal complexes of complexones 264

I. INTRODUCTION

Complexones are now finding extensive application in various branches of the national economy in view of the high stability and solubility of the majority of complexonates and the characteristic features of the structures of complexones responsible for their selective properties in relation to different metals. Therefore the study of metal complexes of complexones is urgently required in connection with the synthesis of new complexones with specified properties [1].

Proton magnetic resonance	PMR

Infrared spectroscopy has yielded much information about the structures of the protonated forms of complexones and also their metal complexes in the crystalline state but has been much less useful in the study of the structures of complexones in solution. However, owing to the complexity of the spectra and in many cases the ambiguity of the band assignments, the data obtained have to be checked by another method.

The method which yields the most complete information about the structures of compounds in solution is that of nuclear magnetic resonance. Many proton magnetic resonance studies have been made on the protonation of complexones and the structures of complexonates in solution. The present review deals with data obtained by this method for the structures of the complexes and the equilibria and kinetics of complex formation and protonation processes.

Since the research technique is based on a comparison of the spectra of the complexones in bound and free states, in the first section of the review we shall consider the PMR spectra of complexones and data on the structures of the protonated forms of the complexones and on the microequilibria in solution as a function of pH.

II. PMR STUDY OF THE STRUCTURES OF COMPLEXONES

Complexones is the name given to compounds containing a nitrogen atom linked to oxygen-containing groups† which can readily split off and combine with protons. In all complexones there are two types of protons: (1) the labile protons of the functional groups which exchange rapidly with the protons of water and other functional groups; (2) non-labile protons forming part of the CH_2, CH, or CH_3 groups of the complexones.

†In this review only complexones containing methylcarboxyls will be considered since NMR data for other types of complexones are not available.

If the study is performed in aqueous solutions, the resonance signals of protons of the first type merge with the signal of the water protons owing to rapid exchange. In this case, the changes in the PMR spectra on protonation are investigated on the basis of the resonance of the non-labile protons[2]. The number of resonance signals in the spectrum depends on the number of non-equivalent protons in the complexone. The positions of the signals depend on the groups with which the CH, CH_2, and CH_3 groups are linked.

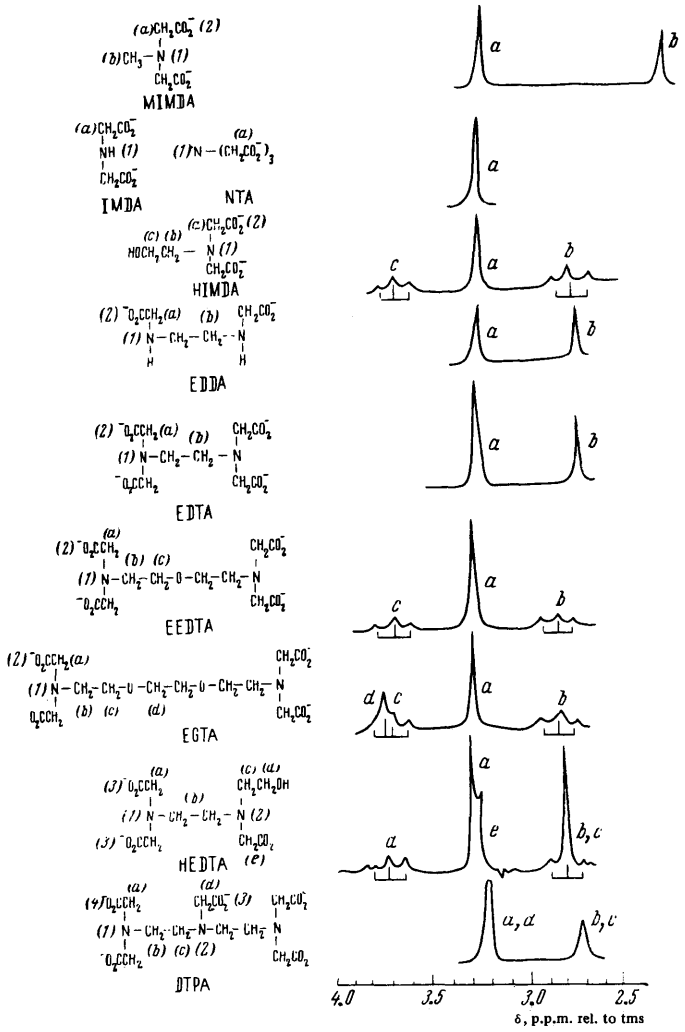

Figure 1. Characteristic proton magnetic resonance spectra of the complexones.

The changes in the position of the CH_2 signal following the addition of electron-donating groups (NR_2, COOH, OH), their protonation, and dissociation have been investigated in detail[2]. The formulae and the designations employed for the complexones investigated, the designations of the non-labile protons (*a*, *b*, *c*, *d*, *e*, ..., *l*) and of the electron-donating groups (1, 2, 3, 4, ..., *L*), and also the PMR spectra of the anions (potassium or tetramethylammonium salts) are presented in Fig. 1. The ratios of the areas and approximate calculations of the signal positions on the basis of the substitution constants carried out by Sudmeier and Reilley[2] were used to assign the signals in the spectra.

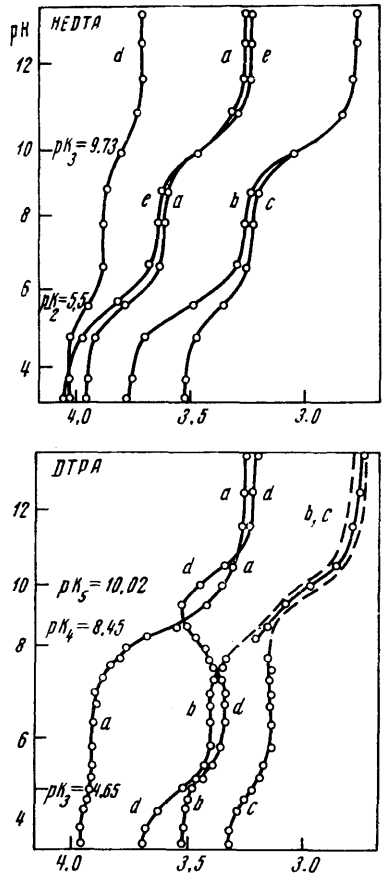

Figure 2. Shifts of the HEDTA and DTPA proton signals as a function of the pH.

If an acid is added to anions with several functional groups capable of combining with protons, microequilibria are established in solution, which include all possible combinations of the protonated and non-protonated forms. Thus, following the addition of one equivalent of acid, each functional group of the complexone may be protonated to a specified degree. This entails the descreening of the methylene protons in the immediate vicinity of the functional group protonated and a shift of their signal to a low field (Fig. 2). The magnitude of the shift depends on the nature of the electron-donating atom, its electronegativity, its position relative to the CH_2 group, and the time during which the proton remains at the electron-donating atom, i.e. on the degree of protonation of each group[2].

In the pH range where signals shifts are observed, there is a mixture of protonated and dissociated forms. The absence of signal splitting shows that rapid proton exchange takes place between these forms.

The position of the signal is defined by the equation

$$\delta_{av.} = N_A\delta_A + N_B\delta_B, \quad (1)$$

where N_A, N_B, δ_A, and δ_B are respectively the mole fractions (N) and the chemical shifts (δ) of the protonated (A) and non-protonated (B) forms. At the point of inflection where $\delta_{av} = (\delta_A + \delta_B)/2$, the concentrations of the protonated and non-protonated forms are equal.

It follows from the dissociation equation

$$\left(K = \frac{N_B[H^+]}{N_A}\right) \quad (2)$$

that, when $N_A = N_B$, the dissociation constant is equal to the hydrogen ion concentration. The dissociation constants determined from the pH–δ relation agree with the literature values [3].

Table 1. Degree of protonation of the electron-donating groups of complexones [2,5].

f_j	MGI^{-}	$IMDA^{2-}$	$MIMDA^{2-}$	NTA^{3-}
	$n=1$	$n=1$	$n=1$	$n=1$
f_1	75±6	93±3	91±5	82±2
f_2	20±5	7±3	6±3	18±2

f_j	$EDTA^{4-}$		$EEDTA^{4-}$	$EGTA^{4-}$		$HEDTA^{3-}$		$DTPA^{5-}$	
	$n=1$	$n=2$	$n=2$	$n=2$	$n=1$	$n=2$	$n=3$	$n=2$	$n=3$
f_1	53±5	96±2	96±11	96±6	42±7	87±6	26±1	85±5	80±11
f_2	−2±3	2±1	2±5	3±3	52±6	97±5	41±1	15±6	64±13
f_3	—	—	—	—	3±18	0±15	7±2	0±16	76±23

Since the addition of a proton causes the greatest shift of the signal of the CH_2 groups linked directly to the electron-donating atoms, the sequence of the protonation of these groups may be established on the basis of the pH–δ relation. The simultaneous shift of the *a* and *b* signals in the spectra of complexones derived from mono- and di-amines following the addition of the first proton to the anion (Fig. 2) shows that the nitrogen atoms are the first to be protonated, in agreement with infrared spectroscopic studies [1]. The study of the spectra of DTPA makes it possible to determine the sequence of the addition of protons to the nitrogen atoms: the middle nitrogen atom is the first to be protonated and is followed by the two extreme atoms, with proton transfer from the middle atom to the extreme atoms and the reprotonation of the middle atom [4].

The PMR method also makes it possible to obtain quantitative data for the degree of protonation of each electron-donating group [2,5]. The calculated degrees of protonation of the electron-donating groups of the complexones are listed in Table 1.

Following the addition of the number of equivalents of acid equal to the number of nitrogen atoms in the complexone, the nitrogen atoms are protonated preferentially in all the complexones investigated. However, partial protonation of the COO^{-} groups is also observed. In the presence of two nitrogen atoms, there is rapid proton exchange between them (HEDTA, EDTA, EGTA, and EEDTA). If there are three nitrogen atoms (DTPA), there is a slow exchange between the middle and extreme nitrogen atoms and rapid exchange between the extreme atoms.

CDTA, a complexone the structure of which is very close to that of EDTA and is distinguished by the presence of the cyclohexane ring, has somewhat unusual properties.

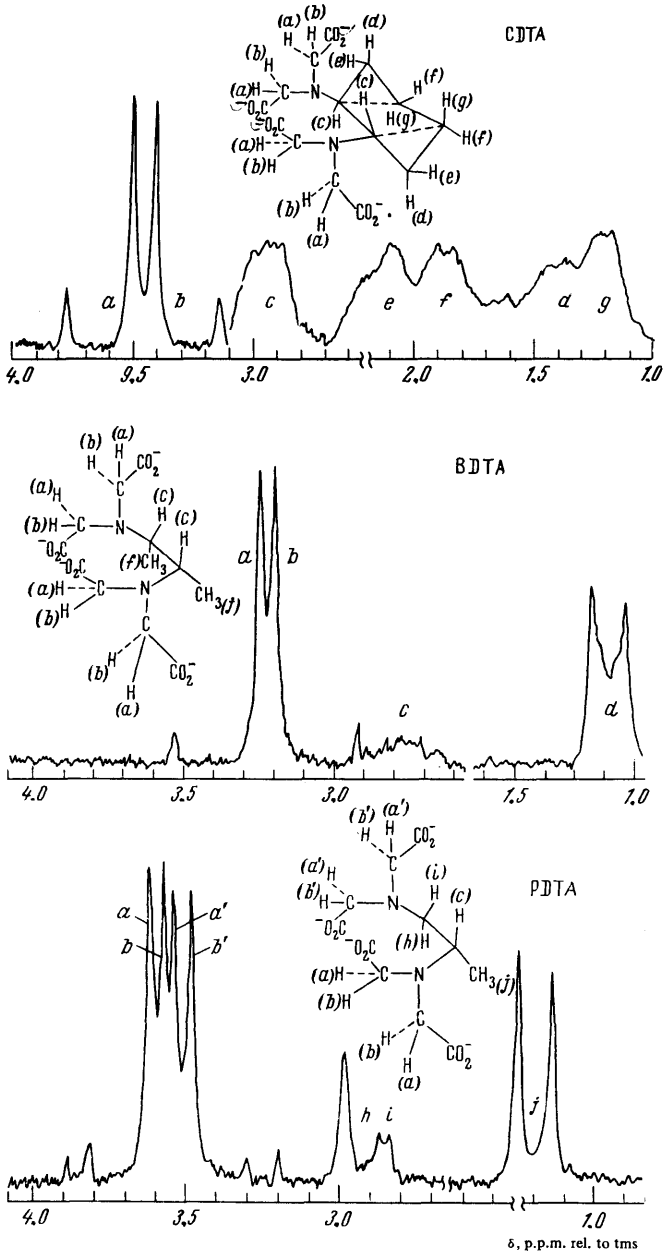

Figure 3. Characteristic spectra of CDTA, BDTA, and PDTA.

The formula of CDTA, the designations of the protons, and the spectrum of the anion are given in Fig. 3. The AB quartet [7], observed in low fields, is due to the protons of

the methylcarboxyls. The two protons in each methylcarboxyl are non-equivalent and give rise to the AB quartet, since the iminodiacetate group is linked to an asymmetric carbon atom [7]‡. The addition of the first two protons causes a shift of the quartet (the *a* and *b* signals) and of the methylidyne proton signals (*c*), the shift of the *c* signals being greater than that of the *a* and *b* signals. Consequently, here too the nitrogen atoms are the first to be protonated. There is further splitting of the *a* and *b* signals after the addition of the first proton, which has been accounted for by the formation of the bridge structure ≥N–H–N<, possibly involving the acetate groups [8].

This difference from EDTA is due to the characteristics of the disposition of the iminodiacetate groups in CDTA. The half-widths of the methylidyne proton signals, which are determined by the spin–spin coupling constant and depend on the positions of the interacting protons, demonstrated that the iminodiacetate groups in CDTA occupy the diequatorial positions. For this disposition, the distance between the nitrogen atoms is 2.2 Å, which favours the formation of a bridge structure. The presence of a linkage with two nitrogen atoms in the monoprotonated form can explain why the reaction becomes much more endothermic following the removal of this proton, in relation to the analogous reaction of EDTA. [6]

III. PMR STUDY OF THE FORMATION OF METAL COMPLEXES OF COMPLEXONES

When complexes are formed, the PMR spectra of the complexones undergo changes which can involve both a shift and a splitting of the bands. To characterise quantitatively the changes occurring in the spectra on formation of complexes with diamagnetic ions, four main parameters are employed: (1) the area of the signal; (2) the chemical shift; (3) the line half-width; (4) the spin–spin coupling constant. For paramagnetic complexes, the main parameters are the relaxation time and the contact and pseudocontact shifts.

Since the methods of investigation and the data obtained for diamagnetic and paramagnetic complexes are significantly different they will be discussed separately.

1. Diamagnetic Complexes

The study of the PMR spectra for the non-labile complexone protons led to the isolation of three groups of complexes: (1) complexes in which the M–N and M–O bonds are labile; (2) complexes in which the M–N bonds are inert and the M–O are labile; (3) complexes in which the M–N and M–O bonds are inert [9]. In the first case, the spectrum of the complex has the same form as that of the free ligand (Fig. 1). Such complexes are formed by the majority of doubly charged metals [except platinum(II) and palladium(II)] with monoamines and EDTA, [10,19] by aluminium and lanthanum with EDTA, [11,17,18] by calcium and lanthanum with HEDTA, [20,21] and by alkali metals with HEDTA. [22]

The signal shifts and the study of the δ –pH relation yielded information in such cases concerning the occurrence of complex formation in the system, and the compositions, stabilities, and structures of the complexes.

‡An analogous splitting into one or two AB quartets is observed in the spectra of other complexones containing an asymmetric carbon atom (Fig. 3).

As an example, Fig. 4 presents δ–pH relations for EDTA complexes with alkali (M : EDTA = 4 : 1) and alkaline earth (M : EDTA = 1 : 1) metals. The δ–pH curve for the potassium salt coincides with the corresponding curve for the tetramethylammonium salt, which implies that potassium does not form a complex with EDTA. The δ–pH relations for sodium, lithium, calcium, strontium, and barium indicate the occurrence of complex formation at pH > 4.

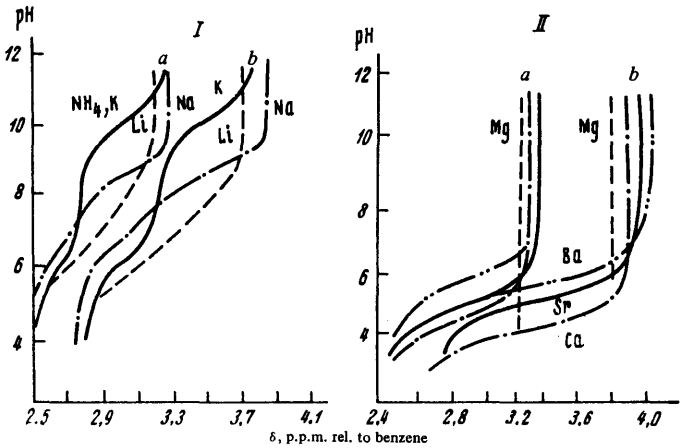

Figure 4. δ–pH relations for the EDTA complexes of alkali (I) and alkaline earth metals (II).

The presence of two rising sections in the curves for the sodium and lithium salts indicates the formation of monoprotonated complexes (in the neutral region). The shift of the signals to low fields in the acid region is due to the decomposition of the complexes. The pH values corresponding to the breakdown of the complexes characterise their stability. The stability constants of the lithium, calcium, strontium, and barium complexes have been calculated [11] from Eqn. (1) in which the subscripts A and B refer to the bound and free ligands. Similar calculations of the constants have been performed for the lanthanum and lutetium complexes of MGl, [14] MIMDA, [12] and DGl [15] and for the cadmium, zinc, and lead complexes of NTA. [16] The calculated stability constants are compared in Table 2 with the values obtained by other methods.

The low stability constants of the lithium, calcium, strontium, and barium complexes of EDTA obtained by the PMR method can be explained by the fact that in the calculation no account was taken of the formation of protonated complexes in the acid region [11].

The formation of a protonated complex in which the proton adds to the carboxy-group (only the *a* signals shift) was observed in a study of the PMR spectra of the lanthanum complex of EDTA at pH < 3. [17] The formation of mixed hydroxo-complexes of zinc and EDTA was established in the alkaline region [25]. The sharp shift of the *d* signal of HEDTA in the lanthanum complex to high fields at the solution pH corresponding to the p*K* for the hydrolysis of the 1 : 1 complex show that in this case a complex is formed in the alkaline region where the hydrogen atom dissociates from the alcoholic group of HEDTA. [21]

The study of the δ–pH relation for stable complexes (the magnesium, calcium, strontium, barium, mercury, aluminium, lead, zinc, and lanthanum complexes of $EDTA^{4-}$, the calcium and lanthanum complexes of HEDTA, and the magnesium, calcium, strontium, and barium complexes with EGTA) yielded information about the regions corresponding to the existence of the complexes: in the pH range where only one complex is present, the positions of the signals remain constant [10,11,17,19,21]. The chemical shifts in the spectra of the 1 : 1 complexes are listed in Table 3, which shows that complex formation entails signal shifts to both low and high fields. The latter are observed for complexes of alkali and alkaline earth metals with large ionic radii [26]. The signal shifts of the CH_2 protons linked to OH groups in DGl and HIMDA indicate the presence of linkages between the metal and the OH group.

*Literature data adjusted to $I = 1$.

The study of the PMR spectra of alkaline earth metal, cadmium, zinc, lead, mercury, aluminium, and lanthanum complexes with different component ratios other than 1 : 1 showed that in the presence of an excess of the metal (2 : 1) calcium and strontium form compounds in which there are two metal ions for each EDTA residue, each being linked to one iminodiacetate group [27]. In the presence of an excess of the ligand (1 : 2, 1 : 3, and 1 : 5 component ratios), the formation of cadmium, zinc, lead, and lanthanum complexes containing two NTA residues per metal atom [13,16] and of a lanthanum complex with two EDTA residues [28] was established. The stability constants of the complexes were calculated (Table 2).

Complexes of metals having coordination numbers not exceeding six (lead, zinc, and cadmium), with two NTA residues can have two structures:

(I) (II).

To elucidate these structures, use was made of the spin–spin interaction between the ligand protons and the magnetic nuclei of cadmium and lead. In the 1 : 1 complexes, such interaction is observed and is reflected by a broadening of the lines in the spectra. In the complexes with two ligand species, the spin–spin interaction is not observed, i.e. the rate of dissociation increases. This can be accounted for by the decrease of the number of binding sites employed on passing from the 1 : 1 to the 1 : 2 complex, i.e. by the formation of structure(I).

The lanthanum complex with two EDTA residues was shown to have an asymmetric structure in which the second EDTA residue adds to one iminodiacetate group, the form of EDTA involved being that which predominates in solution (the protonated residue at pH 6–9 and the quadruply charged ion at pH > 9). [28] For the remaining metals investigated, only 1 : 1 complexes with EDTA have been detected [11].

In this and all subsequent Tables, the chemical shifts for the diamagnetic complexes are given in p.p.m. relative to tms and the designations of the protons in DGl and MGl are the same as for HIMDA and MIMDA (Fig. 1).

In systems containing two polydentate ligands (EDTA and IMDA or NTA) and lanthanide ions, the formation of mixed complexes incorporating EDTA and IMDA or NTA residues was established [29–31]. In the mixed lanthanum complexes, the chemical shifts of the *a* and *b* signals of EDTA remain the same as in the spectrum of the 1 : 1 complex, i.e. the initial complex does not change and the second ligand species entering the complex displaces a water molecule from the inner sphere. In the spectra of the analogous lutetium complexes, the *b* signals of EDTA are displaced to high fields, which can be accounted for by a weakening of the M–N bonds with increase of the coordination number in these complexes compared with the initial $Lu(EDTA)^-$.

In the lutetium complex $Lu(EDTA)(NTA)^{4-}$, there is a slow exchange between the bound and free NTA, while in the $La(EDTA)(NTA)^{4-}$ and $Ln(EDTA)(IMDA)^{3-}$ complexes the exchange is rapid. The formation constants of the mixed complexes were calculated from the relative signal areas in the first case and from the signal shifts in the second (Table 4). For comparison, Table 4 includes the corresponding constants of the neodymium, europium, and erbium complexes evaluated by a spectrographic method [32–34].

The PMR spectra of complexes of Group I metals in the presence of an excess of ligand can be divided into three groups characterised by the rate of exchange between the bound and free ligand. 1. Rapid exchange: the number of signals does not change, the signals are

broadened, and their positions depend on the pH of the solution and are defined by Eqn. (1)—EDTA complexes of barium, strontium, and aluminium at pH < 6 and calcium and mercury in the highly alkaline region, NTA complexes of cadmium, zinc, lead, and lanthanum and IMDA and MIMDA complexes of lanthanum, yttrium, and lutetium. 2. Slow exchange: two sets of broadened signals, one of which refers to the bound and the other to the free ligand—EDTA complexes of magnesium and lead at pH < 11 and calcium, mercury, aluminium, and lanthanum at pH < 9.5, 9, 6.5, and 7 respectively. 3. Intermediate exchange: two sets of broadened signals close to one another with partial overlapping.

Table 4. Stability constants of mixed lanthanide complexes[31] ($I = 1.0$, $t = 25°C$).

Complex	lg$K$*	lg β	Complex	lg K	lg β
La(EDTA)(IMDA)$^{3-}$**	2.5±0.05	16.6	LaY(NTA)$^{4-}$	2.2±0.1	16.3
NdY(IMDA)$^{3-}$	3.8±0.1	19.2	NdY(NTA)$^{4-}$	4.8±0.1	20.2
EuY(IMDA)$^{3-}$	5.0±0.1	21.3	EuY(NTA)$^{4-}$	5.1±0.1	21.6
ErY(IMDA)$^{3-}$	3.4±0.1	20.7	LuY(NTA)$^{4-}$	2.3±0.1	20.4
LuY(IMDA)$^{3-}$	2.2±0.2	20.3			

*K and β are the successive and overall constants respectively.
**Y = EDTA.

In each of these cases the lifetime of the coordinated ligand (τ) can be represented by the following equations.

For rapid exchange:

$$\tau = \frac{\omega_{Y,MY} - N_Y\omega'_Y - N_{MY}\omega'_{MY}}{4\pi^2 N_Y^2 N_{MY}\Delta\nu_0^2}, \quad (3)$$

where ω and ω' are respectively the observed line width and the line width in the absence of exchange, N is the mole fraction, $\Delta\nu_0$ the difference between the positions of the signals due to the free and bound ligand species in the absence of exchange, and MY and Y represent the complex and the free ligand.

For slow and intermediate exchange:

$$1/\tau_{MY} = \pi(\omega_{MY} - \omega'_{MY}), \quad (4)$$

$$1/\tau_{MY} = \pi\sqrt{{}^1/_2(\Delta\nu_0^2 - \Delta\nu^2)}, \quad (5)$$

where $\Delta\nu$ is the difference between the positions of the signals due to the free and bound ligand in the test specimen.

The kinetics of ligand exchange in the systems comprising calcium and strontium with EDTA, calcium with HEDTA, and zinc, lead, and cadmium with NTA have been investigated over a wide pH range[16,20,35]. In systems comprising calcium and strontium with EDTA, the following processes were considered:

$$MY^{2-} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} M^{2+} + Y^{4-}, \quad (6)$$

$$MY^{2-} + \overset{*}{Y}{}^{4-} \underset{}{\overset{k_2}{\rightleftarrows}} \overset{*}{MY}{}^{2-} + Y^{4-}, \quad (7)$$

$$MY^{2+} + H\overset{*}{Y}{}^{3-} \underset{}{\overset{k_3}{\rightleftarrows}} \overset{*}{MY}{}^{2-} + HY^{3-}, \quad (8)$$

$$H^+ + MY^{2-} \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} M^{2+} + HY^{3-}, \quad (9)$$

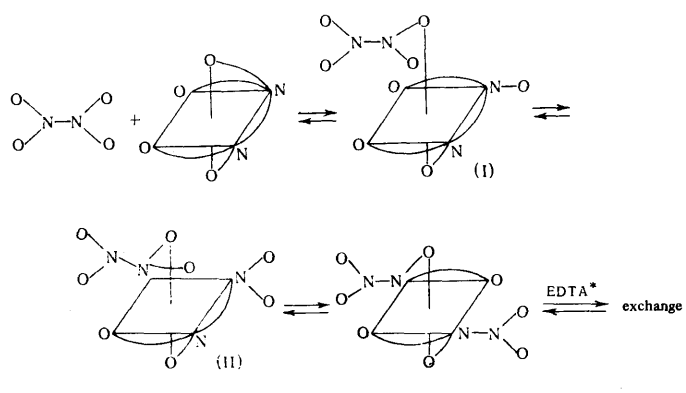
$$HMY^- + H\overset{*}{Y}{}^{3-} \underset{}{\overset{k_5}{\rightleftarrows}} H\overset{*}{MY} + HY^{3-}, \quad (10)$$

$$H^+ + MY^{2-} \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} HMY^-, \quad (11)$$

$$HMY^- \underset{k_{-7}}{\overset{k_7}{\rightleftarrows}} HY^{3-} + M^{2+}. \quad (12)$$

The rate of exchange may be represented by the equation

$$-\frac{d[MY^{2-}]/dt}{[MY^{2-}]} = 1/\tau_{MY} = k_1 + k_2[Y^{4-}] + k_3[HY^{3-}] + k_5[HY^{3-}]\frac{[HMY^-]}{[MY^{2-}]} + k_7\frac{[HMY^-]}{[MY^{2-}]}. \quad (13)$$



The determination of the quantities $1/\tau_{MY}$ as a function of ligand concentration at different pH permitted the calculations of the rate constants k for the reactions. The results are presented in Table 5, which also includes the rate constants for the analogous exchange reactions of the Ca(HEDTA)$^-$ system. The dissociation rate constant for Sr(EDTA)$^{2-}$ is higher than for Ca(EDTA)$^{2-}$, which agrees with the thermodynamic stabilities of the complexes[3]. The association rate constants are consistent with those for the complexes of the corresponding metals with other ligands[37], which confirms Eigen's mechanism[36].

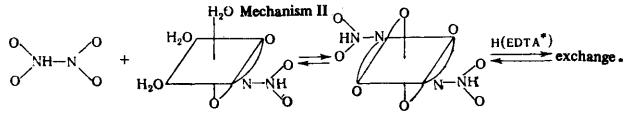


Table 5. Rate constants for exchange in metal complexes of complexones[16,20].

The exchange reaction between the bound and free ligand species in the calcium and strontium complexes can take place either in one stage without the formation of an intermediate or in many stages with formation of an intermediate where both ligand species are linked simultaneously to the metal ion[38]. Mechanisms have been proposed for the exchange reactions (10) and (11), with formation of intermediates as the rate-limiting stage, on the basis of the available data[20,35].

Mechanism I

In mechanism(II), it is postulated that the EDTA residue in the protonated calcium and strontium complexes is linked via one iminodiacetate group. In this case, the exchange rate constants for the protonated EDTA complexes should be the same as for the complexes of the corresponding metals and IMDA. Such agreement has been observed for the strontium complexes[20].

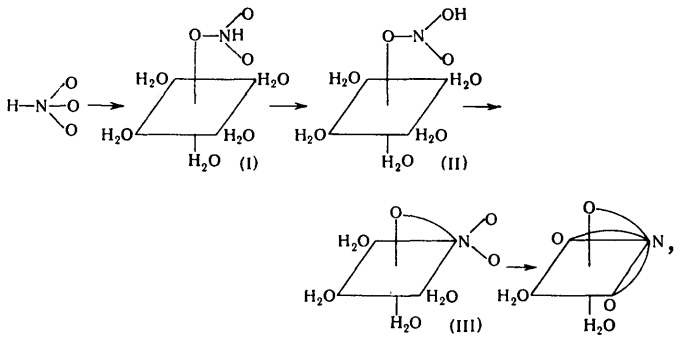
A study has been made[16] of the kinetics and mechanism of the formation of NTA complexes of cadmium and zinc. The exchange rate constants have been determined for the following reactions:

$$M(NTA)^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} M^{2+} + NTA^{3-}, \quad (14)$$

$$H^+ + M(NTA)^- \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} M^{2+} + HNTA^{2-}, \quad (15)$$

$$H^+ + Cd(NTA)_2^{4-} \underset{k_3}{\overset{k_3}{\rightleftarrows}} Cd(NTA)^- + HNTA^{2-}, \quad (16)$$

$$Cd(NTA)_2^{4-} \underset{k_4}{\overset{k_4}{\rightleftarrows}} Cd(NTA)^- + NTA^{3-}, \quad (17)$$



$$N\overset{*}{T}A^{3-} + Cd(NTA)_2^{4-} \underset{k_5}{\overset{k_5}{\rightleftarrows}} Cd(NTA)\,N\overset{*}{T}A^{4-} + NTA^{3-}, \quad (18)$$

$$HN\overset{*}{T}A^{2-} + Cd(NTA)_2^{4-} \underset{k_7}{\overset{k_7}{\rightleftarrows}} Cd(NTA)\,N\overset{*}{T}A + HNTA^{2-}, \quad (19)$$

$$N\overset{*}{T}A^{3-} + Zn(NTA)^- \underset{k_8}{\overset{k_8}{\rightleftarrows}} Zn(N\overset{*}{T}A)^- + NTA^{3-}. \quad (20)$$

The results are compiled in Table 5.

The data obtained demonstrated that in the exchange reaction of Cd^{2+} and Zn^{2+} with H(NTA) the rate-limiting stage is not dissociation of the water in the aquo-ion and that the rate of reaction determines proton transfer from the nitrogen atom to the carboxy-group, which can proceed either via exchange with water molecules or directly from N to O.[39] A mechanism was proposed for the formation of the complexes:

in which the rate-limiting stage is the formation of the intermediate (II).

Lutetium complexes of NTA,[13] molybdenum(V) and molybdenum(VI) complexes of IMDA, MIMDA, and NTA[40-42], cadmium[19], molybdenum[40,43,44], zirconium, hafnium[45], yttrium, and lutetium[17] complexes of EDTA, yttrium and lutetium complexes of HEDTA[21], lanthanum complexes of DTPA[46], and the majority of BDTA and CDTA[26] complexes may be included among compounds with labile M–O and non-labile M–N bonds.

If the nitrogen atom of the complexone is linked to different substituents (IMDA, MIMDA, EDTA, HEDTA, and DTPA), the formation of a non-labile M–N bond makes the two protons of the acetate group non-equivalent (H_A and H_B). The situation remains unchanged on rotation: there are three rotational configurations (Fig. 5) in each of which the H_A and H_B protons have different environments, which lead to the splitting of the signals of the protons of this group into an AB quartet[47]. Owing to the rotation of the $>N-CH_2-CH_2-N<$ group in diamine derivatives, the signals of the ethylene protons are averaged out and a singlet is produced.

A typical spectrum of the protons of the CH_2COO^- group in the EDTA, HEDTA, IMDTA, and DTPA complexes in the presence of inert M–N and labile M–O bonds is presented in Fig. 5. The PMR spectra of such complexes show new features: the spin–spin coupling constant J and the difference between the chemical shifts ($\delta_A - \delta_B$) of the non-equivalent H_A and H_B protons.

A second distinctive feature of the complexes with non-labile M–N and labile M–O bonds is slow interchelate exchange: exchange between the bound and free ligand species or ligand species in complexes with different compositions or structures. This characteristic permits the determination of the number and composition of the complexes formed in metal–ligand systems as a function of the conditions governing complex formation and can yield information about the structures of these complexes.

In the study of the spectra of the molybdenum(VI) complexes of IMDA and MIMDA[41-43], the simultaneous formation of different 1 : 1 complexes (monomers, dimers) in solution was established, the compositions of the complexes corresponding to non-stoichiometric component ratios was determined (from the signal areas), and in some cases the constants were determined and complex formation equilibrium diagrams were plotted (Fig. 6).

Data were obtained for the structures of the complexes. In the MoO_4^{2-}–$IMDA^{2-}$ system, the spin–spin interaction between the CH_2 protons and the NH proton was employed for this purpose. The spin–spin coupling constants (J_{AX} = 7.3 Hz and J_{BX} = 1.0 Hz) show that the H_A protons interact with the NH protons to a greater extent than the H_B protons. A theoretical calculation showed that the

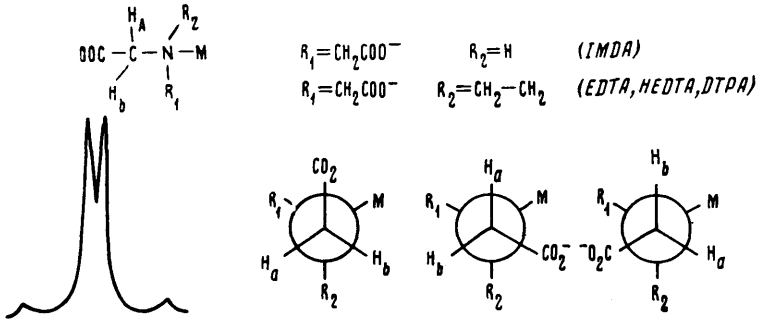


Figure 5. Characteristic spectrum of the CH_2 protons in the presence of non-labile M–N bonds.

7.3 Hz constant corresponds to an angle $\theta AX = 12°$ and the 1.0 Hz constant corresponds to an angle $\theta BX = 110°$.[41,48]

The molybdenum(VI) complexes of MIMDA give rise to a complicated spectrum with spin–spin interaction between the protons of one acetate branch and those of the other. Calculation of the spectra on the hypothesis of such interaction by a standard method[49] agreed with the experimental data[42].

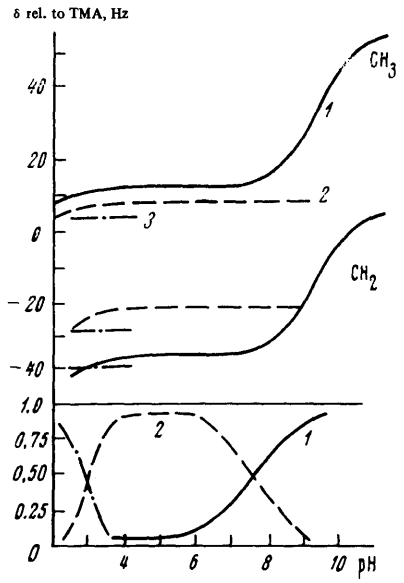

Figure 6. Complex formation equilibrium diagram for the molybdenum–MIMDA system according to PMR data: 1) free complexone; 2) monomeric complex; 3) dimer.

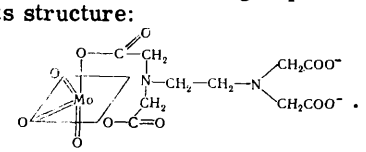


Differences were discovered between the molybdenum complexes of MIMDA and IMDA: (1) the chemical shift difference between the H_A and H_B protons in the IMDA complex is 0.65 p.p.m. in contrast to 0.27 p.p.m. for the MIMDA complex and 0.17–0.30 p.p.m. which is characteristic of all the complexes investigated with NR_3 groups. This can be explained by the fact that the substitution of a proton at the nitrogen atom by an alkyl group reduces the differences between the magnetic environments of H_A and H_B. (2) In molybdenum complexes of IMDA, the rate of exchange is higher [at a high pH the resonance signals of different specimens are averaged out ($k = 1.6 \times 10^2$ mole^{-1} s^{-1})] than for the MIMDA complexes. The reasons for this may be a decrease of steric hindrance, which facilitates attack by the free ligand.

In EDTA complexes with non-labile M–N and labile M–O bonds, the ratio of the signal areas of the bound and free ligands established that in the presence of an excess of the ligand all the metals investigated, except yttrium, form only 1 : 1 complexes. In the yttrium–EDTA system with 1 : 2 and 1 : 5 reactant ratios, a 1 : 2 complex is formed in which the second EDTA residue adds via one iminodiacetate group. This entails an increase of the mobility of the M–N bonds: the AB quartet disappears and the ethylene proton signal (*b*) shifts to a higher field[28].

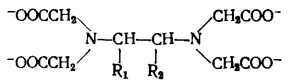
In the lutetium–EDTA, zirconium–EDTA, and hafnium–EDTA systems, only 1 : 1 complexes were detected. The position of the signal of the LuY complex remains unchanged over a wide pH range (from 3 to 12), but above pH 11 a mixed hydroxo-complex is formed. This results in an increase of the mobility of the Lu–N bonds (the AB quartet disappears and the *a* and *b* signals shift to higher fields)[28]. The zirconium and hafnium complexes of EDTA give rise to spectra with signals in different positions depending on the pH of the solution, which corresponds to the two types of complexes formed: one at pH $\leq$ 3.5 (I) and the other at pH $>$ 6 (II). In the intermediate region between pH 3.5 and 6, there is a gradual transition from form (I) to form (II). Comparison with potentiometric titration data[50] established that in the region of pH $\sim$3, a simple chelate is formed and at pH 3.5 an OH group adds to the complex with possible polymerisation.

The complex formation equilibria in the molybdenum(VI)–EDTA system have been investigated as a function of the pH of the solution for Mo : EDTA $\geq$ 1.[40,44] Several complexes are formed in the system, the relative proportions of which and of the free EDTA are variable. The number of complexes in the solution was determined from the number of signals and their variation with the pH of the solution: a 1 : 1 complex, a complex with the ratio Mo : EDTA = 2 : 1, and a polymeric complex in the acid region was detected. A diagram illustrating the distribution of molybdenum among the complexes was plotted on the basis of the relative signal areas as a function of the solution pH and the stability constants of the complexes were determined ($\lg K_{MoO_3Y} = 10.7 \pm 0.3$, $\lg K_{(MoO_3)_2Y} = 19.5 \pm 0.3$).

The presence in the spectrum of the 1 : 1 complex of the signals due to two free acetate groups made it possible to establish its structure:

The complexes are protonated at pH $<$ 8 with formation of MoO_3HY^{3-}. In the complex with two MoO_3 groups, each is linked to an iminodiacetate group.

The molybdenum(V) complexes of MIMDA, NTA, and EDTA were also investigated. The paramagnetic molybdenum(V) ion forms diamagnetic complexes, which can be explained either by the formation of dimers with a linear coordination Mo–O–Mo or by the formation of dioxo-bridge complexes[43].



The study of the yttrium and lutetium complexes of HEDTA revealed two types of complexes with non-labile M–N and labile M–O bonds: complexes with a triply charged HEDTA residue in the pH range between 2 and 6–7 and with a quadruply charged HEDTA residue at pH $>$ 7. As for lanthanum, the formation of a complex in which the hydrogen atom in the alcoholic group has dissociated was indicated by the shift of the signal of the CH_2 group linked to the hydroxyl towards higher fields[21] and in all cases the pH at the point of inflection on the curve corresponded to the p*K* for the formation of the hydroxo-complex[51].

In the lanthanum complex of DTPA, the presence of non-labile equivalent linkages with three nitrogen atoms (C_3 symmetry) and labile linkages with the methylcarboxyls (one signal due to the ethylene proton) was established[46].

The spectroscopic parameters of certain complexes with non-labile M–N and labile M–O bonds are presented

in Table 6, which shows that in all cases where the M–O bonds in the complexes are labile the constant J is close to 17 Hz, which corresponds to unstrained bonds.

Hexadentate ligands with the general formula

(CDTA, PDTA, BDTA; Fig. 3) are very similar to EDTA.

Table 6. Spectroscopic parameters of metal complexes with non-labile M–N and labile M–O bonds.

*If the signals are split, the centre of the multiplet is given (δ in p.p.m. and J in Hz).
**The composition of the complex has not been established.

All these ligands differ from EDTA by the fact that the introduction of substituents into the ethylene chains hinders interconversion which in turn should be reflected in an inhibition of the M–O exchange. This is shown particularly markedly in the presence of the rigid cyclohexane ring (CDTA). Moreover, the presence of the CH_3 groups in PDTA and BDTA can lead to the appearance of isomeric forms of the complexes differing in the positions of these groups. The spectra of the complexes of BDTA with various metals are presented in Fig. 7.[26]

In the spectra of the majority of the bivalent metal complexes§, signals of two types of acetate groups are observed—two AB quartets and a doublet due to the methyl group, which is consistent with the presence of non-labile M–N and labile M–O bonds. Isomeric forms of the complexes were not observed.

Owing to the stereochemical requirements of the ring in CDTA, the methylidyne protons can have only one configuration. The inversion of nitrogen atoms is impossible and therefore the acetate groups are not involved in exchange. If two of these groups are located in one plane and the other two are in a plane at right angles to it, there should be two types of acetate groups regardless of the lifetime of the M–O bond. To obtain information about bond mobility, one can employ the constant J_{AB}: labile bonds are unstrained and J_{AB} is close to 17 Hz. However, unstrained bonds can arise also for long lifetimes. Therefore one employs also an additional method based on the broadening of the lines due to the labile bonds following the addition of a paramagnetic ion[26]. It has been established that Ag^+, all bivalent metals, and lanthanum[26,52] form complexes in which the M–N bonds are inert and the M–O bonds are labile (Fig. 8): $J_{AB} \simeq 17$ Hz.

§Exceptions are the barium and strontium complexes in which the M–N bonds are labile and the cobalt complexes in which the M–N and M–O bonds are non-labile.

The degeneration of the AB quartet to a singlet is observed for strontium, barium, zinc, hafnium(II), and lanthanum, which implies that the difference between the chemical shifts is < 0.1 p.p.m. The spectroscopic parameters of a number of metal complexes of BDTA and CDTA are presented in Table 7.

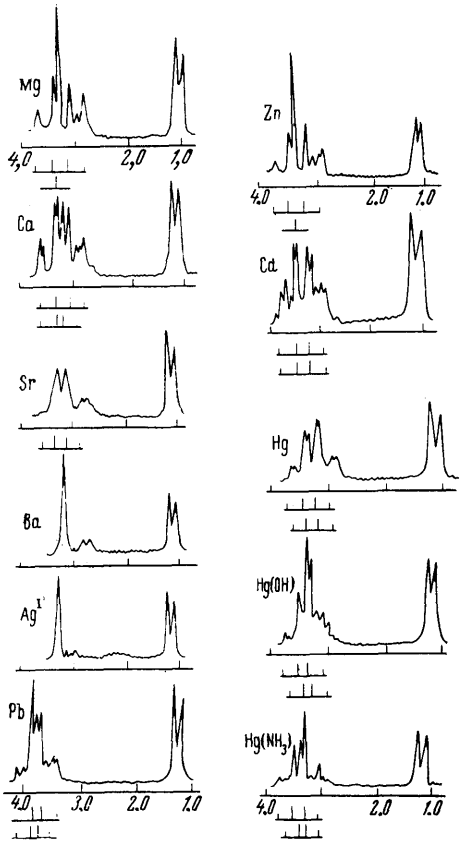

Figure 7. Characteristic spectra of metal complexes of BDTA.

In the third group of complexes (M–N and M–O bonds are inert), there is an additional splitting of the proton signals due to the non-equivalence of the groups and the inhibition of exchange and inversion. The number of AB quartets due to acetate protons varies from one (if all the acetate groups are equivalent) to two, three, or four (if all the acetate groups are non-equivalent). AB or A_2B_2 splitting is also observed.

This group includes the majority of cobalt(III), rhodium(III), platinum(II), and palladium(II) complexes. In all the complexes of the third group, there is a slow exchange between the bound and free ligand species and also between the ligand species bound in different complexes. Therefore when the solution contains two complexes or a complex and a free ligand, the spectrum becomes much more complex. Such spectra yield valuable information about the structure of the complexes, the number of binding sites in the ligand employed, the disposition of the electron-donating

group, the occurrence of *cis–trans* isomerism, and also about the equilibria and kinetics of the exchange between isomeric forms.

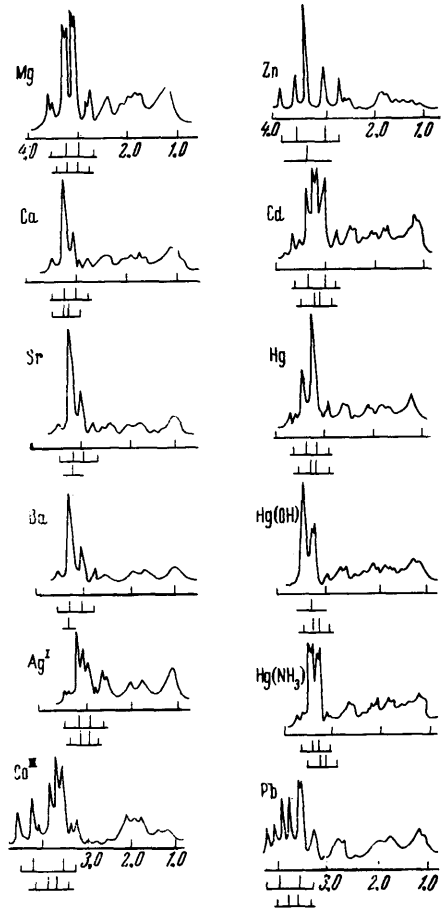

Figure 8. Characteristic spectra of metal complexes of CDTA.

The cobalt(III) and rhodium(III) complexes of monoamine derivatives (MIMDA, IMDA, and NTA) [53–57], diamine derivatives (EDDA, ED3A, HEDTA, EDTA, PDTA, BDTA, and CDTA) [58–67], and DTPA [99] have been investigated. The metals form with each ligand complexes of similar structure. Accordingly, their PMR spectra are also similar.

The spectra of the complexes with monoamine derivatives [53–56] show the AB quartets due to the protons of the acetate groups. In the spectra of the IMDA complexes, the AB quartets are broadened or split owing to the spin–spin interaction with NH protons. The signals of the NH groups are observed immediately after the solutions have been prepared. After the exchange with deuterium (D_2O), the signals disappear and the spectrum becomes simpler.

The formulae of the rhodium and cobalt complexes are isolated and their spectroscopic parameters are given in Table 8. The configurations are designated as follows:

*Here and henceforth J is quoted in Hz.

The spectra of the *trans*-configurations of the 1 : 2 complexes and the s-*cis*-configurations of the 1 : 1 complexes show only one AB quartet and those of the *cis*- and u-*cis*-configurations show two AB quartets. In the spectra of the 1 : 2 complexes, the singlet corresponds to the free-carboxy-group. This is also indicated by the shift of the singlet towards higher fields as the pH of the solution is increased. Complexones with a tertiary nitrogen atom (NTA and MIMDA) give rise only to the *trans*-configurations owing to steric requirements.

The trend in the H_A and H_B proton shifts in the spectra of substituted IMDA can be accounted for on the basis of the magnetic anisotropy of the C–N bonds [57]. In the *trans*-complexes, substitution of the amino-proton by a CH_3 group leads to a greater screening of the H_A proton and to a smaller screening of the H_B proton. The *cis*-complex gives rise to a signal in higher fields than the corresponding *trans*-complexes.

In the cobalt complexes of diamine derivatives, the glycinate rings can be of two types: polar (out-of-plane) and equatorial (in-plane). Depending on this, one or two acetate groups at the nitrogen atom are bound in the complex, being designated by R_1 and R_2 for the polar groups and by G_1 and G_2 for the equatorial groups. The ring in which two nitrogen atoms are linked is designated by the letter E.

Cobalt complexes of ED3A containing a monodentate ligand residue (Cl^- and NO_2) [58], the isomeric forms of complexes containing the EDDA and $AEIDA^X$ residues and bidentate ligand residues [CO_3^{2-}, ethylenediamine (en), oxalate (ox), and malonate (mal) [59-63]], and complexes of the type Co(HY)X and Co(Y)X, where Y =EDTA, PDTA, and HEDTA [26,64], have been synthesised.

The study of the PMR spectra established the number of polar and equatorial glycinate rings on the basis of the number of bands in the spectrum [60,62,65] and proton–deuterium exchange involving the CH_2 group [61] and permitted the assignment of the bands in the spectra.

Table 9 lists the possible forms of the complexes with diamine derivatives, the shifts of the H_A and H_B protons in rings of different types, and the positions of these signals in the spectra of the hexa- and penta-dentate EDTA and HEDTA complexes. Their comparison shows that in the cobalt(III) spectra the H_A and H_B protons in each type of glycinate ring give rise to characteristic band positions, varying in the range 4–4.2 and 3.1–3.4 for R_1, 4.2–4 and 4–3.9 for R_2, and 3.9–4.2 and 3.7–4 for G_2. The differences between the H_A and H_B chemical shifts remain approximately constant: 0.7–0.9 for R_1, 0–0.2 for R_2, and 0–0.2 for G_2. The spectra corresponding to the R_2 and G_2 rings are similar.

These values may be useful for the elucidation of the structure in those cases where isomers can be formed.

Thus two glycinate rings of type G_2 and one ring of type R_2 ($\delta AB = 0$) are observed in the complexes with the pentadentate EDTA and HEDTA residues, which confirms the *trans*-position of the NO_2 groups relative to the acetate group in these compounds. The degeneration of the CH_2 quartet of the R_2 ring to a single is due to the small chemical shift difference between the H_A and H_B protons [66].

Table 9. Positions of the signals due to the CH_2 protons in various rings of the cobalt(III) and rhodium(III) complexes of diamine derivatives*.

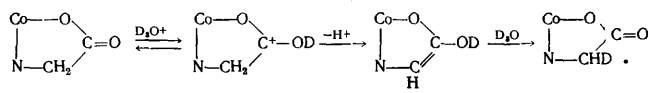
*δ in p.p.m.; J = 11–19 Hz.

**The chemical shifts of the ethylene protons for the remaining complexes are not quoted in the original papers.

In the analogous EDTA complex with a chloride ion, the latter is located in the plane [of the ring ?] (only the R_1 ring is observed).

Complexes of EDDA and its *C*-substituted derivatives with cobalt and neutral ligands have been investigated. For the *trans*-coordination of EDDA, the acetate groups are identical and there is only one AB quartet (due to the R_1 ring), while in the *cis*-isomer there are two types of acetate rings (R_1 and G_1) and the spectrum contains an AB quartet and a singlet.

The E ring of the *trans*-complex has two equivalent proton sets, each of which contains equatorial (eq) and axial (ax) protons giving rise to A_2B_2 splitting. The chemical shifts in the spectra of these compounds have been accounted for on the basis of the magnetic anisotropy of the C–N bond [57]. The application of molecular models to cobalt complexes showed that the angles between the $C-H_{eq}$ and $C-H_{ax}$ bonds on the one hand and the molecular axis on the other are different, varying on alkyl substitution from 80° for H_{eq} and 40° for H_{ax} in the EDDA complex to 65° and 85° for the corresponding protons in the DMeEDDA and DEtEDDA complexes, which leads to a change of the chemical shift of the ethylene protons from 3.10–3.12 p.p.m. to 2.83–2.78 p.p.m.



One can also investigate the effect of C–N bonds on the protons of the glycinate ring. The protons located on the

same side of the ring as the amino-proton or the substituent are designated by H_A and those on the other side by H_B. These protons are symmetrical in relation to the C–N bond in the R ring and are screened by this bond to an equal extent, but H_B is located above the C–N bond in the ring, while H_A is at an angle of 40° relative to the C–N axis. Therefore H_B should be screened more than H_A. Such a situation arises in the EDDA complex. If the proton linked to the nitrogen atom is substituted by an alkyl group, the protons of the R ring are distributed in a different way: H_A at right angles and H_B at an angle of about 35° relative to the bond axis. Under these conditions H_A is screened and H_B descreened. Indeed in the DMeEDDA and DEtEDDA complexes, the signal due to H_A shifts towards higher fields and that due to H_B towards lower fields.

Probably the change in the disposition of the H_A and H_B protons is responsible also for the increase of the difference $\delta A - \delta B$ in the spectra of the cobalt complexes of PDTA, BDTA, and CDTA.

To elucidate the structures of the complexes, one also employs the ability of the acetate group protons located in the vertical planes to undergo exchange with deuterium of heavy water in an acid medium at high temperatures, which leads to a gradual decrease of the intensity and the final disappearance of the signal due to these protons [67].

The study of the kinetics of the exchange of the protons of the acetate groups led to a tentative mechanism of the exchange reaction involving the formation of an intermediate enolic form of the complex:

These investigations also made it possible to determine the relative positions of the CH_2 protons in the complexes [58].

The study of the PMR spectra of rhodium complexes of EDTA established the mechanism of the complex formation process as a function of the solution pH and the number of EDTA binding groups employed in the complexes $Rh(EDTA)(H_2O)$, $RhH(EDTA)X$, and $RhH_2(EDTA)X_2^-$¶, where X = Cl or Br. [68] In the first complex, the composition and the number of EDTA binding sites employed change with increase of the pH:

$$\underset{(I)}{Rh(HY)(H_2O)} \leftrightarrow \underset{(II)}{RhY} \leftrightarrow \underset{(III)}{RhY(OH)^{2-}}.$$

The number of binding sites employed is five in complexes (I) and (III) and six in complex (II); this is confirmed by the presence in the spectra of the first two complexes of signals due to the free acetate group, which are displaced as the pH is varied. The number of free and bound groups was determined from the ratio of the signal areas (1 : 3). Under conditions close to neutrality, the signals of the free acetate groups were not observed.

The signals of the free acetate groups were also noted in the spectra of the complexes $Rh(HY)X^-$ and $Rh(H_2Y)X_2^-$, the ratio of the bound and free groups being 3 : 1 and 2 : 2 in the first and second cases respectively, corresponding to penta- and tetra-dentate EDTA residues. In the last case, the presence of only two AB quartets shows that the EDTA oxygen atoms are in the *trans*-positions, which is consistent with the presence of the R_1 rings in the complexes $[Rh(EDTA)Cl]^{2-}$ and $[Rh(EDTA)Cl_2]^{3-}$.

¶ $RhY(H_2O)$, $Rh(HY)X$, and $Rh(H_2Y)X_2^-$.

Platinum(II) and palladium(II) complexes differ from those of cobalt(III) and rhodium(III) by the fact that the metal coordination number in them is four. In the PMR spectra of the majority of platinum and palladium compounds, AB quartets are also observed [69–71]. The number of binding sites in the complexones (IMDA, MIMDA, and NTA) employed in the 1 : 1 platinum and palladium complexes does not exceed three; the oxygen atoms of the acetate groups are located in the *trans*-positions and are equivalent (one AB quartet). The angles between the C–H_{AB} and C–N bonds were determined from the chemical shifts and the spin–spin coupling constants of the H_A and H_B protons: $\theta_{HA} = 80°$ and $\theta_{HB} = 155°$.

After the addition of ammonia to the palladium complexes of IMDA and MIMDA, initially one water molecule is substituted and then one and two oxygen atoms of the complexone are displaced.

The 1 : 2 complexes were found to have *cis*- and *trans*-isomers for IMDA and only the *trans*-isomers for MIMDA and NTA. The chemical shifts of the platinum and palladium complexes investigated are presented in Table 10, which also includes the constants for spin–spin coupling to the magnetic nuclei of platinum.

Table 10. Spectroscopic parameters of the platinum and palladium complexes of IMDA, MIMDA, and NTA. [69–71]

The PMR spectra of the platinum complexes hardly change with temperature and those of the palladium complexes of NTA show only one signal due to acetate protons, which can be accounted for by the averaging of the signals owing to rapid exchange (lability of M–O bonds). The increase of the lability of the bonds from platinum(II) to palladium(II) is consistent with the known rates of substitution reactions involving the complexes of these metals [72] and may be due to a weakening of the bonds in the palladium(II) complex. The latter is consistent with the shift of the acetate proton signal towards high fields relative to the signals in the spectra of the corresponding platinum complexes.

Mixed cobalt [73–78] and platinum(II) [79] complexes containing an aminoacid as one of the ligands have been studied. The aim of these investigations was to establish the absolute configuration of the complexes and to study the rate of proton exchange and of the mutarotation of the chelated aminoacids.

Some data on the structure of the complexes and the delocalisation of electrons on complex formation may be obtained by analysing the chemical shifts. The chemical

shift is determined by the screening constant, which may be represented by the formula

$$\sigma = \sigma_{dia} + \sigma_{para} + \Delta\sigma + \sigma_{ring} \quad (21)$$

where σdia is the local diamagnetic term, σpara the local paramagnetic term, $\Delta\delta$ represents the effect of the anisotropy of the neighbours, and σring represents the interatomic ring currents [80]. In a study of the proton resonance of acyclic compounds, only the first and third terms should be taken into account.

By considering a series of complexes of various metals with the same ligand, it is possible to distinguish three cases. (1) $\sigma_{dia} > \Delta\delta$; the chemical shift is determined by σ_{dia}, which is a function of electron density. Since complex formation involves the delocalisation of electrons with decrease of electron density at the ligand, a correlation should be observed between z/r or the ionisation potential and the shift towards lower fields. (2) $\sigma_{dia} \simeq \Delta\delta$; the correlation between the chemical shift and the electronegativity breaks down and the signal shift on complex formation may be close to zero if σ_{dia} and $\Delta\delta$ have opposite signs. (3) $\sigma_{dia} < \Delta\delta$; the chemical shift is determined by the symmetry of the complex and is independent of z/r or I for the same symmetry.

Comparison of the chemical shifts of the complexone anions and various complexes shows that in the spectra of certain metal (Li, Na, Mg, Ca, Sr, and Ba) complexonates no signal shift is observed or only a slight shift towards higher fields. This can be accounted for by the fact that the degree of descreening on formation of the metal complexes is caused by the disposition [81] assumed by the complexone atoms on complex formation.

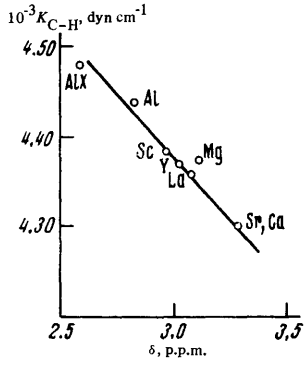

Figure 9. Relation between the chemical shift and the valence-force constant of the C–H bonds for AlX and MX_2 complexes (M = Al, Mg, Ca, Sr, Sc, Y, or La).

In the spectra of the majority of the complexes of the remaining metals, there are signal shifts towards lower fields. If complexes of identical symmetry are formed, the $\Delta\delta$ term will remain approximately constant and the increase of the shift towards lower fields is due to the increase of the delocalisation of electrons on bond formation.

For the NTA complexes, a correlation between the chemical shift and the bond force constant was observed (Fig. 9) [82]. For rhodium and cobalt complexes of the same structure, the chemical shift of the acetate protons in monoamine derivatives and of the ethylene protons in diamine derivatives was found to increase from rhodium to cobalt, which is consistent with the increase of the ionic and ionisation potentials.

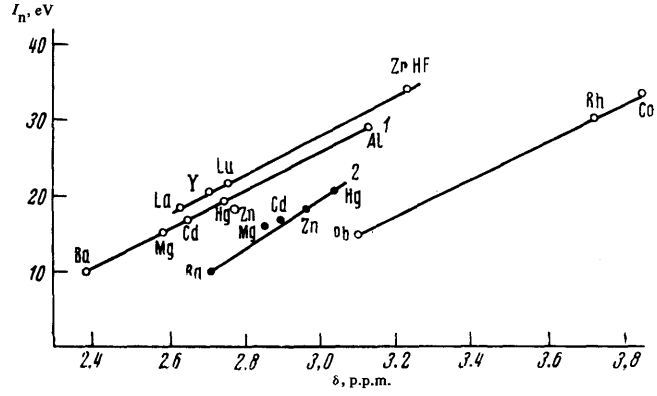

Figure 10. Relation between the ionisation potential of the metal and the chemical shift for EDTA (lines *1*) and BDTA (line *2*) complexes.

Three correlations were found between the ionisation potential I_n, where n is the charge of the metal, and the chemical shift of the EDTA ethylene protons for three groups of metals: (1) lead, rhodium, and cobalt; (2) lanthanum, yttrium, lutetium, zirconium, and hafnium; (3) barium, magnesium, mercury, zinc, and cadmium (Fig. 10). The correlation indicates an identical symmetry of the complexes within the limits of each group and a change in symmetry (with a change in $\Delta\delta$ by a constant amount) on passing from one group of metals to another.

In the first group there is an octahedral symmetry with two nitrogen atoms and two oxygen atoms of the carboxy-groups located in the same plane with the metal atom and two oxygen atoms of the acetate group located in the plane at right angles (a coordination number of six). The formation of polyhedra of lower symmetry (C_1, C_2) with a coordination number greater than six [83,84], in which only the nitrogen atoms are in the same plane as the metal, is characteristic of the second group of metals. The third group includes metals with a noble gas outer shell, in the complexes of which the coordination number may be less than six. These complexes have presumably a *trans*-structure with rapid exchange of the nitrogen atoms along the vertical axis and with the oxygen atoms of the carboxy-groups located in the same plane as the metal ion.

A correlation between the stability constants and the chemical shifts is not always observed. Nor is a linear correlation observed between the stability of the EDTA complexes and the rate of intrachelate and interchelate exchange: with increase of the stability constants, there is both an increase and a decrease of the rate of exchange.

A linear correlation between the stability of bivalent metal complexes and the rate of exchange is observed for the base-catalysed substitution of CH_2 protons in the

acetate residues by deuterium: the rate of proton exchange increases with the stability of the complexes and of the ionisation potential (Fig. 11) [85].

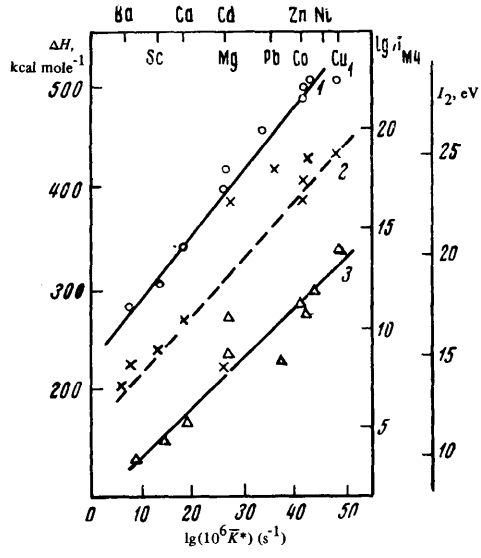

Figure 11. Correlation between the thermodynamic characteristics [1) heat of formation of gaseous MY ions; 2) $\lg K_{MY}$; 3) ionisation potentials] and the rate of proton exchange.

On formation of mixed hydroxo-complexes with substitution of one acetate group by a hydroxide ion, the rate of proton exchange decreases [$Zn(EDTA)(OH)^{2-}$]. If a mixed hydroxo-complex is formed without the dissociation of the linkage with the acetate groups [$Cd(EDTA)(OH)^{2-}$], the rate of proton exchange remains unchanged. Thus the rate of proton exchange serves as an indicator whereby it is possible to establish the structure of the mixed hydroxo-complexes.

The chemical shifts of the acetate protons and their variation in a series of BDTA complexes with various metals are approximately the same as for the EDTA complexes (Fig. 10).

In the CDTA complexes, the chemical shift is almost independent of the metal (apart from the lead complexes). The absence of a dependence on z/r or the metal ionisation potentials can be explained by approximately equal contributions of inductive (σ_{dia}) and long-range ($\Delta\delta$) effects. This is confirmed by similar differences between the chemical shifts of the H_A and H_B protons, the latter being determined by long-range screening [26].

2. Paramagnetic Complexes

The paramagnetic complexes differ from the diamagnetic complexes by higher contact and pseudocontact shifts and considerable changes in the relaxation times on complex formation [47]. Nickel(II), cobalt(II), and copper(II) complexes of aminoacids and complexones and EDTA complexes of uranium(IV) and paramagnetic lanthanide ions have been investigated.

The spectra of complexes with ligands containing NH_2 and NH groups, show lines in the region of high fields (between +50 and +200 p.p.m.), which are attributed to the protons of these groups. It has been shown that these protons exchange with the water protons at the rate of 1×10^3 s^{-1}. The water molecules bound to the ion do not give rise to a separate line (rapid exchange). The majority of lines in weak fields are attributed to the protons of the CH_3, CH_2, and CH groups bound to the nitrogen atom.

The signals of the protons in the CH_2 groups bound to COO^- groups are displaced towards higher fields. The observed directions of the shifts can be accounted for by a contact interaction on formation of the covalent bond [47,86].

However, pseudocontact interaction (the effect of anisotropy) also plays a considerable role. The presence of the CH_3 group in the sarcosine complexes of nickel leads to a disposition of the chelate ring such that the two C–N bonds involving methylene groups form different angles with the Ni–N–C plane, which results in a splitting of the methylene proton signal into two lines (–100 and –40 p.p.m.). In the corresponding glycinate complex there is only one resonance of CH_2 groups, which can be explained by the planarity of the glycinate ring [86].

In complexes with polydentate ligands, a rigid structure may be formed, incorporating several rings which are not planar, which should lead to a splitting of the CH_2 proton signals.

Proton resonance of the nickel(II) complexes of tridentate complexones and nickel(II) and cobalt(II) complexes of tetra- and hexa-dentate complexones has been investigated [86,87]. 1 : 1 complexes with iminodiacetic acids and NTA were shown to have the *cis*-configuration. The following ratios of the *cis*- and *trans*-configurations were found in the complexes with two ligand species: 80 : 20 for IMDA, 40 : 60 for MIMDA, and < 10 : 90 for NTA. [88]† In complexes with two tetradentate ligand species (HIMDA and NTA), the number of binding sites of the ligand employed decreases to 3. The lifetimes of the Ni–N and Ni–O bonds have been determined. In complexes with one NTA residue, the exchange is faster than in the complexes with two NTA residues, which can be explained by the fact that the substitution of water molecules is faster than the substitution of the acetate group. The rate constant is of the order of 10^5 s^{-1}. In $Ni(IMDA)_2^{2-}$ and $Ni(MIMDA)_2^{2-}$, the rate of exchange is lower than in the NTA complex, owing to the absence of a free acetate group [56] ($\bar{k} < 10^3$ s^{-1}) [88].

The spectra of the nickel(II) and cobalt(II) complexes of hexadentate ligands depend on the pH of the solution: the bands are displaced and their width changes. The spectra of the cobalt complexes contain sharper lines and their structure is more complicated, which can be explained by a lower rate of exchange in these complexes [86].

In the spectra of all the metal compounds with complexones investigated, the signals of the CH_2 group linked to a nitrogen atom are split into two components, which can be accounted for by the anisotropy of the linkage (different angles between the Ni–N–C plane and the CH_2 protons). The difference between the chemical shifts of the CH_2 protons increases in the spectra of complexes with six-membered rings compared with complexes having five-membered rings. The explanation may be that the angles between the Ni–N–C plane and the C–H vector

† *cis*- and *trans*- in relation to the oxygen atoms.

differ more on formation of six-membered rings. All these conclusions are consistent with X-ray diffraction studies [89,90,91] and with studies on the PMR spectra of the diamagnetic complexes (see p. 271). The shift of the N–CH_2 protons and the angle between the Ni–N–C plane and the C–H vector have been found to be correlated (Fig. 12).

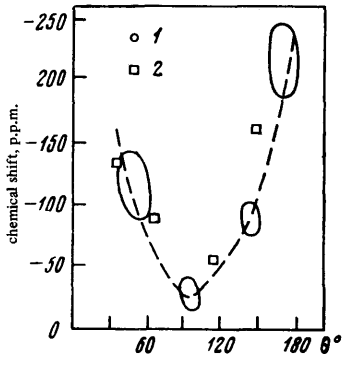

Figure 12. Correlation between the shift of the CH_2 proton signals and the NiNC–H angle: 1) angles determined from the model; 2) X-ray diffraction data.

The study of mixed complexes containing an EDDA residue and an aminoacid established the conformation of the glycine ring in the unsubstituted and methyl-substituted glycinate complexes: the number of binding sites of the tridentate aminoacids employed in the mixed complexes was found to be reduced, the stereochemistry of the mixed complexes was established, and stereoselective coordination of the aminoacids in the mixed complexes was found [92].

Mixed complexes of asymmetric aminoacids give rise to diastereoisomers, which can be detected in the PMR spectra.

Interesting studies have been made on complex-formation equilibria with simultaneous investigation of the structure of the complexes in the cobalt(II)–histidine system [93]. Fig. 13 illustrates the variation of the contact shift of the protons in water and histidine,

$$(\overset{+}{N}H_3\text{—}\underset{\displaystyle COOH}{\underset{|}{C}}H(\alpha)\text{—}CH_2(\beta)\text{—}),$$

as the pH of the solution is varied. At a low pH, there is a greater contact shift of the water protons, while the histidine protons do not exhibit a shift relative to the free ligand, i.e. there is no complex formation. With increase of the pH, the signals of the $H\alpha$ and $H\beta$ histidine protons are displaced, which indicates coordination via the nitrogen atom and the COO^- group. At pH > 4, the contact shift of the water proton signals decreases with a simultaneous increase of the contact shift of the signals due to the protons in the imidazole ring and at pH > 6 the position of the water proton signal becomes the same as in pure water. This shows that under these conditions water does not enter the inner sphere of the complex.

Four complexes were discovered in the system, in which the linkages are formed either with the COO^- group alone or with the COO^- group and one or two nitrogen atoms. In the latter case, there is a transition from octahedral to tetrahedral configuration [93].

The hydration and structures of certain copper(II) aminoacid complexes have been investigated [94]. The hydration numbers of copper and the distances between the copper atom and the oxygen atoms of water in complexes with aminoacids and in the normal and protonated EDTA complexes were determined from the relaxation time of the water protons (Table 11).

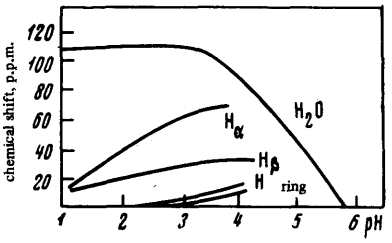

Figure 13. Variation of the contact shifts of the proton signals of water and histidine ($H\alpha$, $H\beta$, H_{ring}) with the pH of the solution.

The spectra of EDTA complexes with paramagnetic lanthanide ions (cerium, neodymium, praseodymium, and samarium) show one AB quartet due to the methylene protons and a singlet due to the ethylene protons. The presence of one AB quartet can be accounted for either by the equivalence of the methylcarboxyls or by a rapid exchange between them. The latter is more likely. In a mixture of complexes of two lanthanides, two sets of signals due to these complexes are observed. The relative concentrations of the complexes were determined from the relative intensities and the stability constants were calculated from the exchange equilibrium constants [97]. The constants obtained agree with the values quoted in the literature [3].

Table 11. Cu–OH_2 distances in complexes with aminoacids and EDTA.

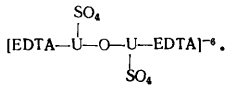
*Refs. 95 and 96.



**In $Ni(H_2EDTA)H_2O$ which is isomorphous with the copper(II) complex [89].

In the uranium(IV) complex of EDTA in the presence of sodium sulphate above 27 °C, the U–O bonds are labile and the U–N bonds are non-labile, while below 27 °C the U–O

bonds also become non-labile [98]. This is reflected in an additional splitting of the signals due to the methylene and ethylene protons. Measurements of the rate of exchange and inversion at different temperatures and of the activation parameters for these processes showed that the ethylene ring undergoes inversion without dissociation of the metal–ligand bonds ($\Delta G = 10.22$, $\Delta H = 10.8$, and $\Delta S \simeq 0$).

The study of the spectra at different pH revealed two types of complexes (at pH 0–3 and at pH > 6). At lower pH values, the signals due to free EDTA are also observed.

The complex formed in the acid region is a monomer with a distorted cubic structure. At pH > 6, dimeric species with an oxygen bridge and incorporating sulphate groups are formed:

The structure of the monomeric complex was deduced by analysing the chemical shifts on its formation [92].

Chemical Reactions of Cobaltocene and Nickelocene

E.V.Leonova and N.S.Kochetkova

This review deals with the comparative chemical characteristics of metallocenes containing Group VIII metals in the Third Period of the Periodic System, namely cobaltocene, nickelocene, and their derivatives. The common features of their chemical properties and the differences between them have been elucidated. The capacity of cobaltocene and nickelocene to form complexes with electron-accepting agents is discussed.
The bibliography includes 200 references.

I. INTRODUCTION

π Complexes with a sandwich structure, the first representative of which is ferrocene, have been a truly inexhaustible store of interesting problems and puzzles for a generation of investigators. The similarity of the structures and similar principles of the formation of chemical metal – cyclopentadienyl (CP) ligand linkages are responsible for the similarity of the physicochemical properties of metallocenes. However, the nature of the central metal atom should have a significant influence on the metal – ligand bond, causing a corresponding change in the properties of the "sandwich".

In the Third Period, Group VIII of the Periodic System contains three elements (iron, cobalt, and nickel) each of which forms the corresponding "sandwich" compound. The variation of the physicochemical properties of these complexes on passing from iron to nickel is interesting. In view of the large number of reviews and monographs on the chemistry of ferrocene and other π complexes with a sandwich structure[1–10], this review deals mainly with experimental studies on the chemistry of nickelocene, cobaltocene and the cobalticenium cation (up to 1972), the chemical properties of ferrocene being considered only for the purposes of comparison.

The review does not discuss the catalytic properties of these metallocenes and their other possible applications.

II. SUBSTITUTION REACTIONS OF THE CARBON ATOMS OF COBALTOCENE AND NICKELOCENE.

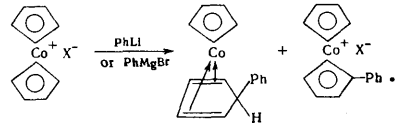
One of the simple chemical proofs of the non-benzenoid aromatic nature of metallocenes is the absence of Diels – Alder reactions with maleic anhydride and reactions with iron(II) chloride as well as the resistance of these compounds to hydrolysing agents. Another important piece of chemical evidence for the aromaticity of these systems is the capacity to undergo substitution reactions.

Neither cobaltocene nor nickelocene form ferrocene by reacting with $FeCl_2$.[11] However, nickelocene is not decomposed by water and cobaltocene is converted into the stable cobalticenium cation[11]. However, whereas electrophilic substitution reactions are typical for ferrocene[1–10], all attempts to acylate, arylate, and metallate nickelocene[10] and also to sulphonate, nitrate, acylate, and arylate cobalticenium picrate[10] under conditions close to those of the analogous ferrocene reactions were unsuccessful. Hitherto, the only known substitution reaction involving the hydrogen atoms of the cyclopentadienyl rings of the cobalticenium cation and nickelocene is the protophilic hydrogen isotope exchange reaction[12]:

$$(C_5H_5)_2M \rightarrow (C_5D_5)_2M\ (M=Fe;\ Co;\ Ni).$$

When nickelocene is treated with *N*-deuteriodiethylamine in the presence of lithium diethylamide, hydrogen isotope exchange takes place with the cyclopentadienyl ring of nickelocene[13, 14]. The rate of hydrogen isotope exchange involving nickelocene depends on the concentration of lithium diethylamide and, when the latter is 0.09 *N* in solution in *N*-deuteriodiethylamine at 25°C, the isotope exchange rate constant is 6×10^{-5} s^{-1}:

$$(C_5H_5)_2Ni \xrightarrow[Et_2NLi]{Et_2ND} (C_5D_5)_2Ni.$$



It is noteworthy that the protophilic hydrogen isotope exchange in ferrocene takes place under more severe conditions — in liquid ammonia in the presence of potassamide[15]. The rate constant for the replacement of deuterium in deuterioferrocene by protium in 0.02 *N* potassamide solution in liquid ammonia at 13°C is 9×10^{-4} s^{-1}. Under the same conditions, the rate constant for the exchange of deuterium in benzene is 3×10^{-5} s^{-1}. The data quoted show that in ferrocene and in benzene hydrogen atoms possess a much lower protophilic mobility than in nickelocene[12].

The kinetics of hydrogen isotope exchange between cobalticenium hydroxide and 10% sodium methoxide solution in *O*-deuteriomethanol at 50°C were also investigated and it was established that the rate constant for this reaction is 6.4×10^{-5} s^{-1}.[16] The degree of exchange is 80 – 90% of equilibrium value:

$$(C_5H_5)_2Co^+X^- \xrightarrow[MeONa]{MeOD} (C_5D_5)_2Co^+X^-.$$

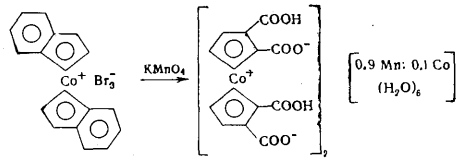
The fact that a substitution and not an addition reaction occurs follows from a comparison of the ^1H NMR and infrared spectra of the initial and deuteriated compounds. The ^1H NMR spectrum shows in both cases a singlet with δ = = 5.85 p.p.m., and the infrared spectra of the deuteriated and the initial compounds are extremely similar[16].

It was also shown that in the reaction with phenyllithium or with phenyl-magnesium bromide, cobalticenium salts form, together with addition products, also a certain amount of a phenyl-substituted product[17]:

Other cobalt-containing metallocenes exhibit the chemical properties of aromatic systems. These compounds include cyclopentadienyl(tetraphenylcyclobutadienyl)cobalt[18, 19] and its unsubstituted analogue[20]. While the acylation reactions of these compounds have low yields (less than 1%[18, 19] and 5%[20] respectively), mercuration[20], the Mannich and Vilsmeier reactions[20], and substitution with lithium[20] take place readily. It is noteworthy that substitution of $C_5H_5CoC_4H_4$ takes place preferentially in the cyclobutadienyl ring[20].

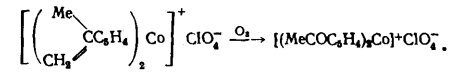
The krypton electronic configuration obtains in these compounds. Analogous organonickel compounds, in particular (cyclopentadienyl-R_3-cyclopropenyl)nickel, exist. The three-membered ring can contain both aromatic[21] and aliphatic substituents[22]. An X-ray diffraction study of the compound $C_5H_5Ni(C_3Ph_3)$ has been carried out[23]. Possibly these compounds, like the cobalt-containing metallocenes, will show a tendency to undergo electrophilic substitution reactions.

III. REACTIONS IN THE SIDE CHAINS OF SUBSTITUTED COBALTICENIUM SALTS



The possibility of carrying out reactions involving the side chains of substituted metallocenes (cobaltocene and nickelocene), other conditions being equal, arises primarily from the strength of the metal – ring bond. Nickelocene is known to enter readily into ligand exchange reactions. On the other hand, the nickelicenium cation and dication are extremely labile and are readily decomposed by atmospheric oxygen. No ligand exchange in aqueous solution at pH 1.99 takes place between cobalticenium perchlorate $(C_5H_5)_2CoClO_4$ and $^{60}Co(ClO_4)_2$.[24]

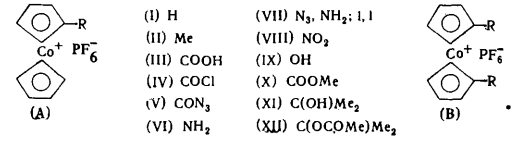
The cobalticenium cation is not decomposed by concentrated sulphuric and nitric acids[25, 26], but is ozonised when ozone is passed through its solution in acetic acid over a period of many hours[27]. These factors permitted a series of side chain reactions of substituted cobalticenium cations. Similar reactions are not known for the cation and dication derived from nickelocene.



1, 1′-Dimethylcobalticenium perbromide was oxidised at 100°C with an aqueous alkaline solution of potassium permanganate[28]:

$$[Co(C_5H_4Me)_2]^+Br_3 + MnO_4^- \rightarrow [Co(C_5H_4COOH)_2]^-Br^+.$$

The dicarboxylic acid formed in this process was isolated as the bromide. A similar reaction was carried out with bis(indenyl)cobalt(III). 1, 2, 1′, 2′-Tetracarboxycobalticenium has been obtained as a mixed salt:



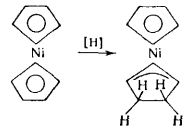
1, 1′-Di-isopropenylcobalticenium perchlorate has been ozonised[29]:

1, 1′-Diacetylcobalticenium has been characterised as the tetraphenylborate and the derivative with the anion of the Reinecke salt.

A mixture of cobalticenium (Ia), methylcobalticenium (IIa), and 1, 1′-dimethylcobalticenium (IIb) has been oxidised[30] with an alkaline solution of sodium permanganate to the corresponding carboxylic acids (III, A, B). The carboxy group was further converted into the acid chloride group (IV, A, B), an ester, an amide, and finally an acid azide (V, A, B). The Curtius rearrangement of the azide gave an amine (VI, A, B) and the 1-amino-1′-azido-compound (VII, B). Similar reactions are also known for ferrocenes[31]. However, in contrast to ferrocenylamine, the aminocobalticenium salt can be oxidised to the nitro-derivative (VIII, A)[30]. Moreover, the aminocobalticenium salt can be diazotised and azo-coupled[30]. Under these conditions, aminoferrocene is converted into the corresponding arylferrocenes[1].

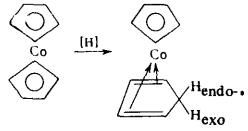
The reaction of dicarboxycobalticenium hexafluorophosphate with alcohol in an acid medium leads to the corresponding ester (X, B)[30]. Moreover, 1,1′-di-(α-hydroxy-α-methylethyl)cobalticenium hexafluorophosphate (XI, B)[32] and the corresponding diacetate (XII, B)[32] were obtained from 1, 1′-di-isopropylcobalticenium hexafluorophosphate:

The infrared spectra of mono-substituted cobalticenium salts with the COOH, CON_3, and NO_2 substituents do not contain frequencies in the region of 1000 and 1100 cm^{-1},[30] while homoannular homologues of cobalticenium salts have spectra with frequencies in this region, resembling in this respect ferrocene derivatives[33].



IV. REACTIONS INVOLVING ADDITION TO THE CYCLOPENTADIENYL LIGAND OF COBALTOCENE AND NICKELOCENE

1. Reductive Addition of Hydrogen.



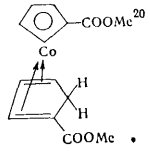
Ferrocene does not react with maleic anhydride[34] and is not hydrogenated in the presence of platinum[27] and Raney nickel[27, 35]. The hydrogenation of ferrocene was achieved under very severe conditions — in the presence of Raney nickel at 280 atm and 340°C,[36] but the iron—cyclopentadienyl ring bond was cleaved. For nickelocene †, this process takes place at 50°C in tetrahydrofuran (THF)

† The calculated standard free energies of formation of the biscyclopentadienyl compounds of iron, ruthenium, nickel, and manganese show that the reduction of these metallocenes by hydrogen with formation of the free metal and cyclopentadiene (CPH) or its hydrogenation products is more typical for nickelocene and ruthenocene than for ferrocene[37].

at 27 atm.[38] The reduction results in the formation of cyclopentadienylcyclopentenylnickel:

Nickelocene can also be reduced by sodium amalgam in ethanol[39,40]. Cobaltocene is reduced under similar conditions[41] with formation of cyclopentadienylcyclopentadienecobalt:

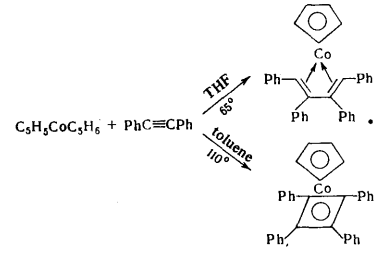
Its polarographic study showed[42] that cobaltocene is reduced more readily than nickelocene (-1.92 and -1.74 V respectively). It was established that the above electrochemical reaction of the π complexes is irreversible and that solvent protons are involved in it.



The conversion of $[(C_5H_5)_2Co]^+$ into $C_5H_5CoC_5H_6$ cannot be achieved by electrolysing neutral or alkaline aqueous solutions of a cobalticenium salt or by reduction with sodium amalgam, Devardov's alloy, and sodium dithionite[43]. $LiAlH_4(LaAlD_4)$ or $NaBH_4$ have been used for this purpose[43-47]. Probably attack by the hydride ion is a necessary condition for the conversion of the cobalticenium cation into cyclopentadienylcyclopentadienecobalt. Further interaction of cyclopentadienylcyclopentadienecobalt with lithium aluminium hydride does not entail a change in the structure and properties of the organocobalt compound[44]. It has been shown[42] that the reduction of the cobalticenium cation involves the initial reversible addition of an electron:

$$[(C_5H_5)_2Co]^+X^- + e \rightleftarrows (C_5H_5)_2Co,$$

and then the irreversible addition of hydrogen:



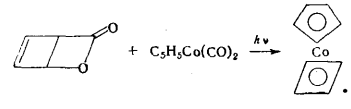
$$(C_5H_5)_2Co + \bar{e} + H^+ \rightarrow C_5H_5CoC_5H_6.$$

All the foregoing considerations apply to substituted cobalticenium salts. Treatment of 1, 1′-dimethoxycarbonylcobalticenium with $NaBH_4$ resulted in the formation of the corresponding organocobalt compound[20]:

If the last compound is not isolated and the reaction mixture formed is sublimed over a period of five days after removing the solvent, it is possible to isolate 1, 1′-dimethoxycarbonylcobaltocene in 47% yield[20]. By treating cyclopentadienylcyclopentadienecobalt with *N*-bromosuccinimide or benzaldehyde, it is possible to obtain cobalticenium salts[44]. The possibility of similar reactions involving nickelocene has not been investigated.

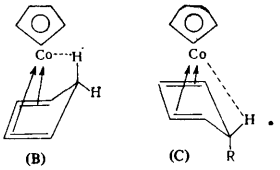
$C_5H_5CoC_5H_6$ and $C_5H_5NiC_5H_7$ are relatively unstable diamagnetic crystalline compounds. $C_5H_5NiC_5H_7$ decomposes on heating in nitrogen. The C_5H_6 group in $C_5H_5CoC_5H_6$ does not enter into the ligand exchange reaction with the cobalticenium cation in acetone solution[24]. When $C_5H_5CoC_5H_6$ is treated with diphenylacetylene[48] in THF at 65°C, the product is cyclopentadienyl-1, 2, 3, 4-tetraphenylbutadienecobalt, while in toluene at 110°C cyclopentadienyltetraphenylcyclobutadienylcobalt ‡ is formed[48,49]:

It is interesting to compare the results of the study of $C_5H_5CoC_5H_6$ and $C_5H_5NiC_5H_7$ by the ^1H NMR method.



The authors[38] believe that the *endo*-protons are located in the region of the *d* orbitals of the nickel atom, so that they are strongly screened and there is a shift towards high fields (δ = 0.67 p.p.m.). The validity of this assignment has been confirmed by the appreciable broadening of the signal in a high field, which cannot be a consequence, as believed by the authors, of only the spin – spin splitting but suggests an interaction between the *endo*-protons and the nickel atom. If the suggested assignments are adopted, the disappearance of the 0.67 p.p.m. signal from the ^1H NMR spectrum of $C_5H_5NiC_5H_5D_2$ is evidence that the hydrogen adds to the cyclopentadienyl ligand and occupies the *endo*-position[38].

Green et al.[43], who were the first to analyse the ^1H NMR spectrum of $C_5H_5CoC_5H_6$, concluded that the signal in a higher field should be assigned to protons in the *endo*-position. The absence of this signal from the ^1H NMR spectrum of $C_5H_5CoC_5H_5D$ was regarded as evidence supporting the *endo*-addition of the hydrogen atom to the cyclopentadienyl ligand in the reduction of cobaltocene. This assignment is not inconsistent with the analogous interpretation of the infrared spectrum of this compound. The infrared spectra of compounds with similar structures ($C_5H_6CoC_5H_5$, $C_5H_6RhC_5H_5$, and $C_5H_6IrC_5H_5$) have an intense band due to the stretching vibrations of the CH group in the region of 2750 cm^{-1}. Such marked decrease of the frequency is caused, as suggested by Green et al.[43], by the interaction between the metal atom and a hydrogen atom in a favourable position, i.e. in the *endo*-position relative to the metal. The second absorption band of the CH group at 2950 cm^{-1} was assigned to an *exo*-hydrogen atom. The disappearance of the low-frequency band from the infrared spectra of substituted $R-C_5H_5CoC_5H_5$ derivatives was regarded as another piece of evidence supporting the above assignments.



However, X-ray diffraction studies on benzoyl[52] and phenyl[53] derivatives of the above organocobalt compound showed that the group added occupies the *exo*-position, which the authors believe is not in conflict with the above interpretation of the infrared and ^1H NMR spectra[43].

The changes in the infrared and ^1H NMR spectra of $R-C_5H_5CoC_5H_5$ are associated with the differences in the

‡ The corresponding unsubstituted compound was obtained in a moderate yield on photolysing solutions of 2-oxabicyclo[2, 2, 0] hex-5-en-3-one and cyclopentadienyldicarbonylcobalt[20, 50]:

direction in which the methylene group deviates from the plane of the cyclopentadiene ligand. Whereas in the unsubstituted complex the methylene group is bent towards the metal (C), in the substituted derivative it is ben in the opposite direction[54] (D), The angular position of the CHR group greatly increases the distance from the metal to the formally *endo*-hydrogen atom (about 3.0 Å) and the Co – H interaction is weakened:

(B) (C)

Table 1. Parameters of the ^{1}H NMR Spectra of $C_5H_5CoC_5H_6$ and $C_5H_5NiC_5H_7$.

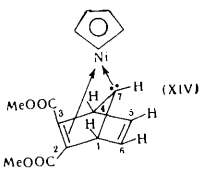
[a] 100 MHz.[38]
[b] There is no signal in the $C_5H_5NiC_5H_5D_2$ spectrum[38].
[c] 40 MHz.[43]
[d] The assignment has been made by analogy with that in Fischer's monograph[51].
[e] There is no signal in the $C_5H_5CoC_5H_5D$ spectrum.[43]

However, an alternative solution of the problem is possible. The methylene group in the substituted and unsubstituted compounds can deviate in the same direction (away from the metal) but to different extents from the plane of the butadiene fragment of the cyclopentadiene ligand. Then the ^{1}H NMR signal of $C_5H_6CoC_5H_5$ in a high field may be a consequence of the screening of one of the protons of the aliphatic group by the π electrons of the cyclopentadiene ligand in the complex[55]. In this case the high-field doublet should correspond to the *exo*-methylene hydrogen atom. The changes in the infrared spectra of the substituted and unsubstituted compounds are then determined by the changes in the angle between the plane of the butadiene fragment and the plane of the methylene group in the ligand. However, all these hypotheses require further X-ray diffraction study.

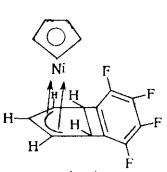


2. Addition of Alkyls, Alkenes, and Alkynes

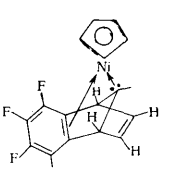
The capacity of cobaltocene and nickelocene to add one and two hydrogen atoms respectively to the cyclopentadienyl ligand determines the type of interaction between these metallocenes and saturated and unsaturated compounds. Similar reactions are unknown in the chemistry of ferrocene. The degree of electronic unsaturation of the diene has a significant influence on the nature of its interaction with nickelocene.

The interaction of nickelocene with ethylene led to the isolation of cyclopentadienylcyclopentenylnickel[56]. Subsequent introduction of fluorine into the ethylene molecule reduces the yield of $C_5H_5NiC_5H_7$. The reaction with tetrafluoroethylene gives rise to a compound with the general formula $C_{10}H_{10}NiC_2F_4$, [56] to which structure (XIII) was attributed[56, 57]:

(XIII)



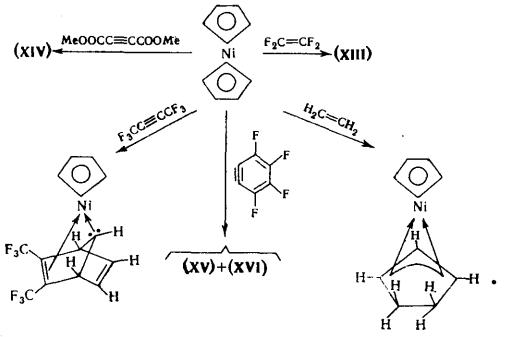
(XIV)



When the dimethyl ester of acetylenedicarboxylic acid is employed as the dienophile, its electron-withdrawing groups favour the addition of the ester via a Diels – Alder reaction, which results in a 68% yield of [2, 3-bis-methoxycarbonyl)-2 π, 5-norbornadien-7-yl](π-cyclopentadienyl) nickel (II) (XIV)[58].

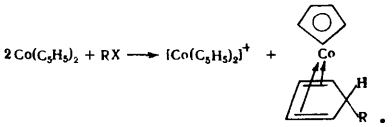
Its structure was confirmed by X-ray diffraction analysis[59]. ^{1}H NMR spectra are also satisfactorily consistent with the proposed structure. Apart from the singlets due to the protons in the cyclopentadienyl ring and the methoxycarbonyl group, the spectrum of (XIV) contains three groups of signals two of which have equal intensities and the third has an intensity smaller by a factor of two. This last signal is in the region of the highest field, which can be accounted for have an effect of the anisotropy of the central metal atom (nickel) on the single proton of the 7-C carbon atom of the norbornadiene ligand[57, 59]. The ^{1}H NMR spectrum of compound (XIII) also has three groups of signals with intensity ratios of 2 : 2 : 1, but the signal with the lowest intensity is observed in the region of the lowest field. This is evidence for the presence of a π-allyl system in the molecule[40, 57, 60]. All these hypotheses have not so far been confirmed by X-ray diffraction studies.

When nickelocene was allowed to react with tetrafluorodehydrobenzene[61], different amounts of both structural isomers with the general formula $(C_5H_5)_2NiC_6F_4$ were isolated:



(XV)

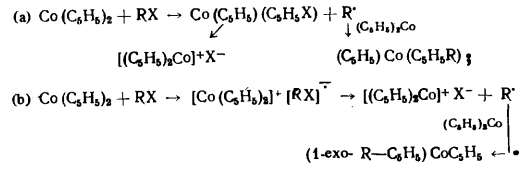
(XVI)



Thus the cyclopentadienyl ligand can combine with olefinic and acetylenic derivatives having electron-accepting groups

in the 1, 2- and 1, 4-positions. This results in the formation of a π-allyl or pseudobutadiene system: §

The addition of olefins, alkyl halides, polyhalogenoalkanes, acyl halides, α-halogenoketones, etc, to cobaltocene takes place with retention of the diene system of the cyclopentadiene fragment. Cobaltocene reacts with tetrafluoroethylene[62]. The infrared spectrum of the products contains ν_{C-H} bands at 3085 and 2940 cm^{-1}. The ^1H NMR spectrum of the compound shows four signals with intensity ratios of 5 : 2 : 2 : 1. On the basis of a detailed analysis of these data[63], the authors concluded that the compounds formed have the structure $C_5H_5CoC_5H_5(CF_2)_2C_5H_5CoC_5H_5$.



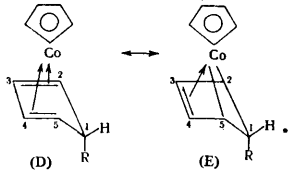
The reaction of cobaltocene and the cobalticenium cation with different organohalogen compounds takes place similarly[43, 64]:

(XVII)

The products have the structure (XVII), where R = CH_2Cl, CH_2Br, $CHCl_2$, $CHBr_2$,[65] etc.[55]. The interaction of cobaltocene with allyl, benzyl, and propargyl halides (R = = $C_6H_5CH=CHCH_2$, $C_6H_5CH_2$, and $C_6H_5C\equiv CCH_2$) was also investigated[66]. Benzoyl chloride[28], α-halogenoketones, and α-halogeno-esters react similarly[65, 67]. Cobaltocene dissolves in chloroform and chlorobenzene without change[65]. However, when the reaction is carried out in the presence of oxygen, a high yield of a compound (XVII), where R = = CCl_3, is formed[68]. Under these conditions, cobaltocene also reacts with acetonitrile, propionitrile, phenylacetylene, and acetone[68], forming the corresponding compounds (XVII). The reaction with acetone gives rise to the dinuclear complex $(C_5H_5CoC_5H_5CH_2)_2CO$.[68]

Two alternative mechanisms of the reaction between cobaltocene and organohalogen compounds have been considered[65, 66, 69]:

§ Nickelocene reacts with perfluorobutyne not only by an addition mechanism but also via a ligand exchange mechanism. A small amount of $(C_5H_5Ni)_2(C_4F_6)$ was isolated[56].



A kinetic study of the reaction did not permit an unambiguous choice. However, the authors are inclined to favour the second mechanism[69] in view of the following qualitative findings: firstly, the rate of reaction of benzyl bromide derivatives is much higher for electron-accepting substituents (p-CN, p-COOEt) and, secondly BBr_3 is known to react with cobaltocene at a temperature as low as -80°C, while $(CH_3)_3NBBr_3$ does not react at 60°C. BBr_3 has more pronounced electron-accepting properties and a higher B – Br bond energy than $(CH_3)_3NBBr_3$. Evidently the reactivity is determined by the electron-accepting properties and not the dissociation energy of the B – Br bond. This conclusion is confirmed also by the finding that the reactivity of $CHBr_3$ in relation to cobaltocene is much lower than that of boron bromide, while the energy of the C – Br bond is also significantly lower than that of the B – Br bond [D(B – Br) = 87.4 kcal $mole^{-1}$; D(C – Br) = 55.5 kcal $mole^{-1}$][69].

The data for the decomposition of azoisobutyronitrile in the presence of cobaltocene are consistent with the proposed radical reaction mechanism[70]. The product is compound (XVII), where R = $C(CH_3)_2CN$. On the other hand, the reaction of chlorotriphenylmethane with cobaltocene results only in the oxidation of the latter to cobalticenium ions[71]. It was suggested that the reaction proceeds according to the equation:

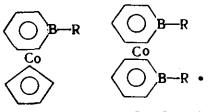
$$(C_5H_5)_2Co + Ph_3C^+ \rightarrow [(C_5H_5)_2Co]^+ + [Ph_3C^\cdot].$$

It is believed[71] that the reaction of nickelocene with the carbonium ion also results in the formation of the nickelicenium cation. However, the low stability of this compound and its paramagnetic properties give rise to the possibility of further interaction between $[(C_5H_5)_2Ni]^+$ and the $(C_6H_5)_3C\cdot$ radical with formation of the complex. $C_5H_5NiC_5H_5C(C_6H_5)_3$. By virtue of its instability, the latter decomposes into $NiCl_2$ and $C_5H_5-C(C_6H_5)_3$.[71]

The study of *exo*-phenylcyclopentadienecyclopentadienylcobalt[53] showed that the $C_{(1)}$ carbon atom deviates from the plane of the cyclopentadiene ligand by 36° and the bond lengths in the "butadiene" fragment are non-uniform (the $C_{(3)}-C_{(4)}$ distance is a minimum, amounting to 1.38 Å):

(D) (E)

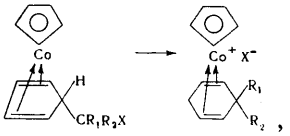
Therefore it was suggested that the carbon atoms in the 2- and 5-positions be regarded as sp^3-hybridised, which would imply that the complex is predominantly in form (F). However, X-ray diffraction study of *exo*-benzoylcyclopentadienecyclopentadienylcobalt showed that the bond order in the "butadiene" system of cyclopentadiene is relatively constant[53]. The authors are inclined to attribute these contradictions to differences between the inductive effects of the benzoyl and phenyl substituents.



The bond between the substituent and the cyclopentadiene fragment of an *exo*-substituted organocobalt compound is known to be fairly labile. *Exo*-(trichloromethyl)cyclopentadiene(cyclopentadienyl)cobalt splits off a CCl_3 group and is converted into the cobalticenium cation on acid hydrolysis or on standing in acetone. $C_5H_5CoC_5H_5CCl_2COOCH_3$ behaves similarly[67]. On the other hand, although chlorine exchange between LiCl and $(exo\text{-}CCl_3-C_5H_5)Co(C_5H_5)$ is not observed, the C – X bond in compounds of the type $(exo\text{-}XCH_2-C_5H_5)Co(C_5H_5)$[55, 72, 73] or the B – X bond in the

compound (*exo*-$C_6H_5BXC_5H_5$)CoC_5H_5 (Herberich et al.[74]) is thermally unstable and undergoes heterolysis extremely readily.

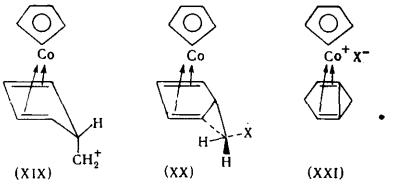
Thus whereas $(C_5H_5)Co(C_5H_5CF_2CF_2C_5H_5)Co(C_5H_5)$ sublimes *in vacuo* at 125°C and $C_5H_5CoC_5H_5 - CHCl_2$ and $C_5H_5CoC_5H_5 - CH_2Cl$ are still stable at 70°C, the bromo-compounds decompose appreciably already at room temperature and $C_5H_5CoC_5H_5CH_2I$ decomposes in the solid state at 0°C. The heterolysis of the C – X bond in these compounds terminates in a ring expansion reaction and the formation of cyclohexadienylcyclopentadienylcobalt halide. The reaction with the pseudocarbonium ions derived from organocobalt compounds leads to the formation of a new class of paramagnetic cobalt complexes[75]. The unsubstituted borabenzene



is unknown. However, the reaction of cobaltocene with substituted boron dibromide and subsequent heterolysis of the C – B bond in the resulting compound [*exo*-Br(R)BC_5H_5] CoC_5H_5 and then the formation of a six-membered ring leads to cobalt complexes of substituted borabenzene ¶ [74, 75]:

The compounds have one unpaired electron, the magnetic moment of which is 1.8 ± 0.1 Bohr magnetons[75]. The ionisation potentials of these compounds are higher than that of cobaltocene, which indicates more pronounced electron-accepting properties of the group C_5H_5BR compared with C_5H_5.

The reaction of the pseudocarbonium cation,



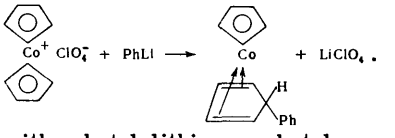
(XVIII)

discovered by Herberich and coworkers[55, 65, 72] resembles the solvolysis of alkyl halides.

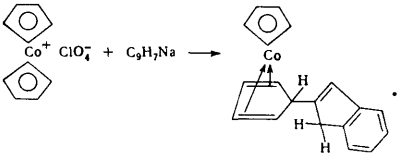
Compounds (XVIII) react under very mild solvolytic conditions[72], such that their structural analogues isobutyl and neopentyl halides hardly ionise. The rate of reaction depends on the medium and the positions of the substituents in the cyclopentadiene ligand (*endo*- and *exo*).

In non-polar solvents, the rate is insignificant, while in acetone, methanol, or their mixture with water the reaction proceeds smoothly and virtually without side products. The reactivity of compounds (XVIII) decreases in the series I > Br > Cl. The effect of substituents on the rate of reaction is the same as for the solvolysis of alkyl halides which has an S_N1 mechanism. Thus the bromo-derivative (XVIII), where $R_1 = R_2 = CH_3$, is much more labile than the secondary bromo-substituted derivative (XVIII), where $R_1 = CH_3$ and $R_2 = H$. Moreover, this reaction is observed only when the substituent occupies the *exo*-position[77].

Thus the authors believe that the order of the reaction (S_N1), the solvolytic effect, which is somewhat weaker than in the solvolysis of t-butyl halides[78], and the entropy of activation[72] indicate the heterolysis of the C – X bond in compounds (XVIII) as the rate-determining stage of the reaction. It is noteworthy that the reaction of primary alkyl chlorides (XVIII) ($R_1 = R_2 = H$, X = Cl) in methanol is faster than the solvolysis of t-butyl chloride[79]. This enhanced reactivity of primary alkyl halides is believed[72] to be evidence in support of the stabilisation of the intermediate ion (XIX) by the entire electron system of the $C_5H_5CoC_5H_5$ group. It is suggested that two processes take place synchronously — heterolysis of the C – X bond and rearrangement of the cyclopentadiene ligand. The authors believe [72] that the six-membered ring is formed either via the complex (XX) or via a short-lived intermediate (XXI):

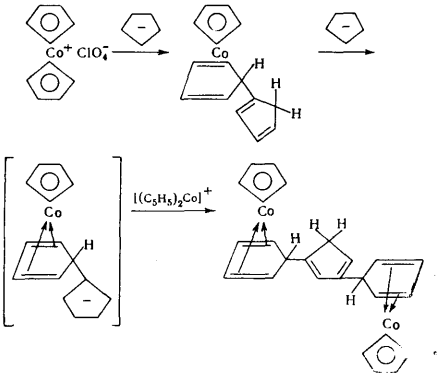


(XIX) (XX) (XXI)



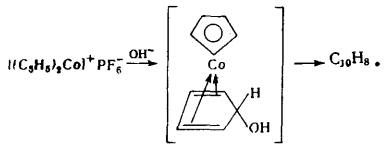
The kinetic study of the process is consistent with either of the two mechanisms proposed.

3. Reactions with Nucleophilic Agents

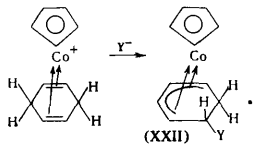


Reactions involving nucleophilic addition to the cyclopentadienyl ligand of nickelocene, where organometallic compounds are employed as the attacking agents, are so far unknown. The cobalticenium cation readily reacts with organolithium or organomagnesium compounds[28] and also with sodium hydroxide and sodamide[80]:

The reaction with n-butyl-lithium, n-butylmagnesium bromide, and methylmagnesium iodide takes place similarly. The reaction of cobalticenium perchlorate with indenylsodium also gives rise to a "normal" addition product — indenylcyclopentadienecyclopentadienylcobalt[81]:



Sodium cyclopentadienide and its methyl derivative react with cobalticenium salts to form dinuclear complexes[81]. The suggested reaction mechanism can be represented as follows in a general form:



¶ 1, 1'Bis(methoxyborabenzene)cobalt has been investigated by X:ray diffraction[76].

The central ring may be hydrogenated. Initially two hydrogen atoms are added readily and then a further two but with greater difficulty. The compound does not react with maleic anhydride, probably owing to steric factors[81].

The reaction between the cobalticenium cation and sodium hydroxide with formation of azulene has been carried out[80]. The authors believe that it proceeds via the following mechanisum:

Nucleophilic agents such as sodium borohydride[72], ammonia, aliphatic amines, and sodium methoxide[82] add readily to the cyclohexadienyl ligand of the cyclohexadienylcyclopentadienylcobalt cation; the product is cyclopentadienylcyclohexa-1, 3-dienecobalt (XXII):

(XXII)

There is an analogous reaction of the cyclohexadienyltricarbonyliron cation[83, 84].

Thus the numerous addition reactions characteristic of cobaltocene and nickelocene distinguish these compounds from ferrocene. The ferrocene system, like the benzene system, is extremely passive in relation to reactions involving the addition of hydrogen, alkyl halides, alkenes, alkynes, and other reagents[1, 2].

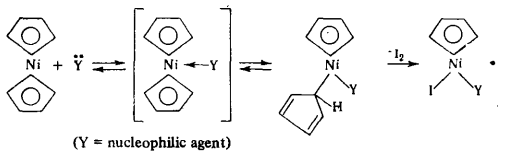
V. LIGAND EXCHANGE REACTIONS IN COBALTOCENE AND NICKELOCENE

The ligand exchange reaction is characteristic of all three types of sandwich compounds discussed in the present review. However, the nature of the ligand capable of replacing the cyclopentadienyl group in ferrocene, nickelocene, and cobaltocene is different. In the first case the ligands can be benzene[85-87], cyclopentadiene[88], their substituted derivatives, and many others. The ligand exchange reaction has been investigated most extensively in nickelocene. The cobalticenium system is more passive in ligand exchange processes.

The reaction of cobaltocene with $Fe(CO)_5$ gives rise to dicobalticenium tridecacarbonylferrate[89]. Under analogous conditions, nickelocene enters into a ligand exchange reaction and is converted into (cyclopentadienyliron)cyclopentadienylnickel tricarbonyl[90, 91]. This is not fortuitous either. Whereas ligand exchange reactions are extremely characteristic of nickelocene and many experimental data have been accumulated in this field, under these conditions cobaltocene is usually converted into a cation or undergoes no change whatever. Similarly, when a triphenylphosphonium halide is allowed to react with nickelocene, the phosphine ligand is coordinated to the nickel atom and a cyclopentadienyl fragment is split off[92], while cobaltocene is oxidised with formation of cobalticenium halide[93]. Mass-spectrometric studies on the dicyclopentadienyl compounds of cobalt and nickel[94, 95] have shown that the energy required to form metallocenium ion $[(C_5H_5)_2M]^+$ is much lower for cobaltocene than for nickelocene (6.21 eV and 7.16 eV † respectively). The stability of the cobalt–cyclopentadienyl linkage in the cobalticenium cation is well known[11, 24-27]. Moreover, the formation of the $[C_5H_5M]^+$ fragment takes place more readily in the case of nickelocene. The energies of ionisation of cobaltocene and nickelocene, resulting in the formation of $[C_5H_5M]^+$, are 14.00 and 12.59 eV respectively. Probably this can explain the finding that nickelocene reacts readily with various nucleophilic agents under mild conditions, exchanging one or two cyclopentadienyl rings. Thus, whereas nickelocene reacts with PF_3 at 60°C and normal pressure to form tetrakis(trifluorophosphine)nickel[98], the complex $(C_5H_5)Co(PF_3)_2$ was obtained from cobaltocene and PF_3 at 170°C and a pressure of 300 atm.[99]. Under analogous conditions, cobaltocene and its derivatives react with carbon monoxide, which results in the isolation of the extremely labile cyclopentadienylcobalt dicarbonyl[20, 100]:

$$(RC_5H_4)_2Co \xrightarrow{CO} RC_5H_4Co(CO)_2.$$

[R = H (Fischer and Jira (Ref.100) or $COOCH_3$ (Rosenblum et. al. (Ref.20)]



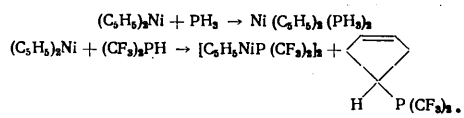
1. SUBSTITUTION OF BOTH CYCLOPENTADIENYL LIGANDS

The capacity of nickelocene to exchange readily a cyclopentadienyl ligand resulted in the formation under mild conditions of various nickel complexes. The analogous reaction with $Ni(CO)_4$ or nickel halides takes place under more severe conditions. Various phosphorus- and nitrogen-containing nickel complexes were obtained in this way[101-103]. The substitution of both cyclopentadienyl ligands in the cobaltocene molecule take place under more severe conditions (on refluxing in dioxan for a week)[104]. The product is formed in low yield:

$$(C_5H_5)_2Co + P(OPh)_3 \rightarrow (Co[P(OPh)_3]_4)_n.$$

2. SUBSTITUTION OF ONE CYCLOPENTADIENYL LIGAND

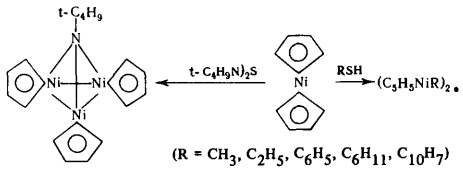
When equimolar amounts of nickelocene and triphenylphosphine react in benzene at 50°C, one cyclopentadienyl ring is substituted. Further treatment with iodine or hydrogen chloride leads to the formation of $(C_5H_5)Ni(R_3P)X$, where X = Cl or I.[105]. It is believed[105] that the nucleophilic agent is initially coordinated to the nickel atom. Simultaneously with or after the coordination, a $\pi-\sigma$ rearrangement of one of the cyclopentadienyl rings takes place. The final stage of the process involves the stabilization of the unstable σ complex by the substitution of the σ-linked cyclopentadienyl ligand:



(Y = nucleophilic agent)

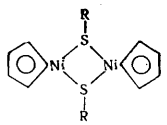
The results obtained in the study of the kinetics of the reaction of nickelocene with mercaptans are consistent with the mechanism proposed[106]. Reactions of nickelocene

† The ionisation potential quoted is consistent with other published values: 6,8 eV,[96] 7.06 eV,[94] and 6.75 eV.[97]



with phosphine[107] and bis(trifluoromethyl)phosphine are known[108]:

In both cases the ease with which the phosphine forms a cluster or interacts with unsaturated hydrocarbons is striking. It is interesting that the reaction between an olefin and a phosphine takes place only following irradiation with ultraviolet light[108]. Therefore it has been suggested [108] that the nickel atom behaves at a catalyst in the addition of a phosphine to the cyclopentadienyl ligand. On heating a 4 – 6-fold excess of $P(OR)_3$ (R = C_6H_5, CH_3, or C_2H_5) with cobaltocene for 3 – 7 days at 100°C, one cyclopentadienyl ligand is also exchanged[104]. The stability of the product $C_5H_5CoL_2$ depends on the nature of the substituent in the ligand L. Analysis of the complexes known so far makes it possible to arrange these compounds in the following series in terms of the decrease of their resistance to the action of oxidising agents: L = $P(OC_6H_5)_3$ > > $PF_3 \simeq P(OCH_3)_3 \simeq P(OC_2H_5)_3 > CO > P(C_6H_5)_3$.[104]

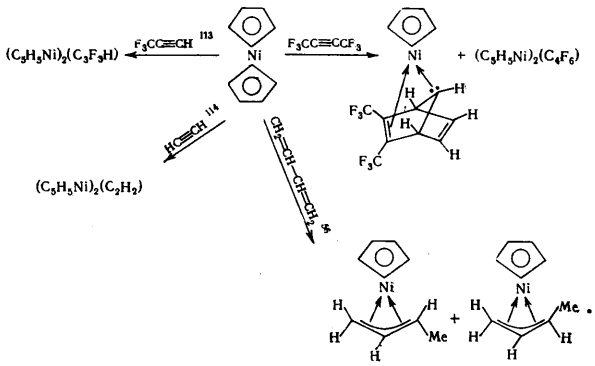


a. Reactions Yielding Polynuclear Complexes

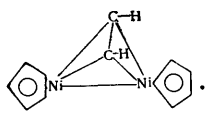
Reactions of nickelocene and 1, 1′-dimethylnickelocene with thioalcohols[106, 109, 110] and the di-imide of sulphurous acid[111] are known. They result in the formation of organonickel compounds containing sulphur[109, 110] or nitrogen[111] bridge atoms:

(R = CH_3, C_2H_5, C_6H_5, C_6H_{11}, $C_{10}H_7$)

The reactions have been carried out with equimolar amounts of the initial compounds in benzene at room temperature. The dark-brown compounds are diamagnetic and stable in air. It has been suggested[109] that the sulphur atoms are sp^3-hybridised and the compounds have the following structure:



In a study of the polymerisation of cyclohexyl isocyanide in the presence of catalytic amounts of nickelocene, the compound $(C_5H_5NiCNC_6H_{11})_2$ was isolated[112]. $(C_5H_5NiCO)_2$ and $(C_5H_5Ni)_2C_2H_2$ were also used as catalysts. It was shown that nickelocene is the most effective catalyst of the process[112].

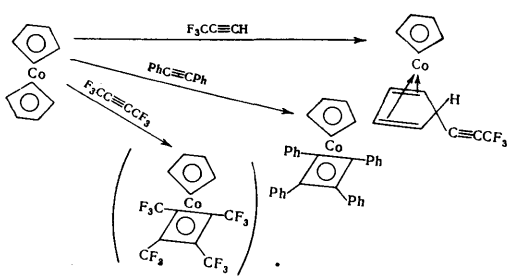


b. Reactions with Unsaturated Compounds

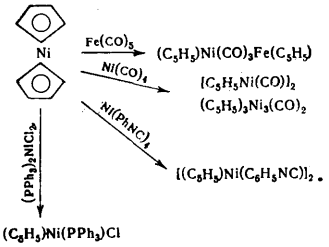
Earlier it was noted that, depending on the electron-accepting properties of the substituents at the unsaturated carbon atom, the reactions of nickelocene with unsaturated hydrocarbons involve addition to the 1, 2- or 1, 4-positions. As the triple bond becomes more nucleophilic, the ligand exchange becomes the dominant process in the reactions of nickelocene with unsaturated compounds.

Thus, whereas the reaction of nickelocene with perfluorobut-2-yne[56] leads to a mixture of products of addition to the 1, 4-positions and of ligand exchange, the reaction with trifluoropropyne[113] results in the formation of a green complex the elemental analysis and mass spectra of which correspond to the formula $(C_5H_5Ni)_2(C_3F_3H)$. A compound of a similar type was obtained from nickelocene and acetylene[114]:

X-ray diffraction analysis of $(C_5H_5Ni)_2(C_2H_2)$ showed[115] that acetylene occupies a bridging position between two nickel atoms:



It is noteworthy that cobaltocene can also react with trifluoropropyne[113], but this leads to the formation of a compound with the general formula $(C_5H_5)Co(C_5H_5C \equiv CCF_3)$. ^1H and ^{19}F NMR spectra showed that this is a product of the "normal" addition to the cobaltocene molecule[113]. The reaction of perfluorobut-2-yne with cobaltocene results in the formation of traces of the stable complex $(C_5H_5)CoC_8F_{12}$,[116] and the reaction with tolane terminates with formation of a high yield of the aromatic complex $(C_5H_5)Co[C_4(C_6H_5)_4]$[116] (see scheme on p. 286). The complexes $(C_5H_5)Co(C_4R_4)$, where R = $Si(CH_3)_3$, CoCh3, etc, can be obtained similarly[145].

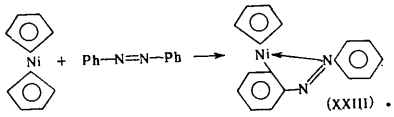


c. Disproportionation Reactions

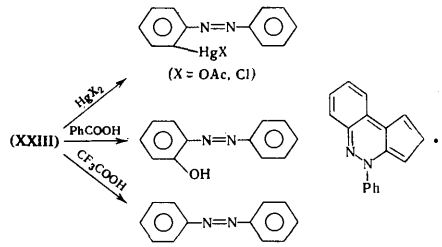
The ease with which nickelocene exchanges its cyclopentadienyl rings promotes its involvement in disproportionation reactions. Reactions with $Fe(CO)_5$,[90, 91] $Ni(CO)_4$,[117–120] $Ni(C_6H_5NC)_4$,[121] and $[(C_6H_5)_3P]_2NiCl_2$[121, 122] are known.

Schematic representation of the interactions of cobaltocene with unsaturated compounds.

The disproportionation and synproportionation reactions of ferrocene homologues take place in the presence of aluminium chloride[88]:

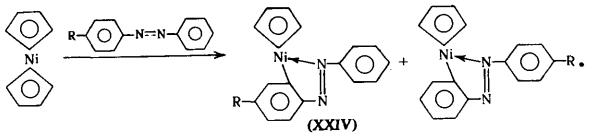


The only disproportionation reaction of cobaltocene known hitherto is the reaction with cyclobutadienyltetraphenylpalladium dibromide[123]:

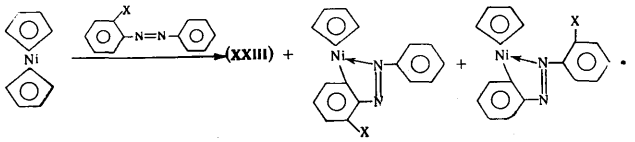


$$(C_5H_5)_2Co + (C_4Ph_4)\,PdBr_2 \rightarrow (C_5H_5)\,Co\,(C_4Ph_4).$$

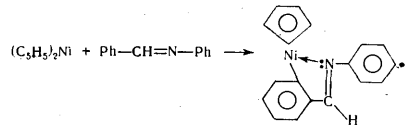
d. Reactions Involving the Formation of Complexes with an M – C σ Bond.



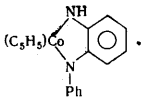
The reaction of nickelocene with azobenzene was described for the first time by Kleiman and Dubek[124]:



The study of the reactions and the ^1H NMR spectra of (2-azophenyl)phenylcyclopentadienylnickel (XXIII) demonstrated the existence of an Ni – C σ bond with the *ortho*-carbon atom of one of the benzene rings[125]:



Examination of the influence of various *ortho*- and *para*-substituents in azobenzene on the nature of the compounds formed in the reaction[126] showed that *para*-substituted azobenzenes [$(CH_3)_2N$, CH_3O, CH_3, F, Cl, $COOCH_3$, CN, or NO_2] react with nickelocene to form the complexes (XXIV):



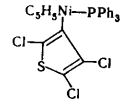
The reaction of ortho-substituted halogenoazobenzenes with nickelocene takes place anomalously:

The rate of formation of compounds (XXIII) increases in the series azobenzene < *o*-chloroazobenzene < *o*-bromoazobenzene. Benzylideneaniline reacts with nickelocene like azobenzene[127]:

Cobaltocene also reacts with azobenzene[128]. However, here the product is a complex to which the following structure has been assigned:

The yield of the reaction is 2.4%.

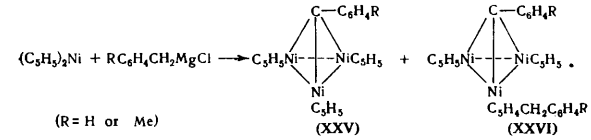
When nickelocene is treated with an alky- or alkynylmagnesium iodide in the presence of triphenylphosphine[129], nickel complexes also containing an Ni – C σ bond are formed:



$$(C_5H_5)_2Ni + Ph_3P \xrightarrow{RMgI} C_5H_5Ni\,(Ph_3P)\,\sigma\text{-}R.$$
$$(R‡=Me \quad or \quad C\equiv CR').$$

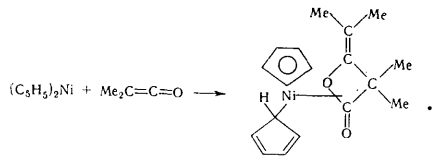
Another convenient procedure for the preparation of these compounds involves the reaction between $(C_5H_5)Ni[(C_6H_5)_3P]Cl$ and various organolithium or organomagnesium compounds[122, 131, 132]:

$$C_5H_5Ni\,(Ph_3P)\,Cl + RMgX \rightarrow C_5H_5Ni\,(Ph_3P)\,\sigma\text{-}R,$$



where R = aliphatic and aromatic substituents.

The above organonickel compounds consist of dark-green diamagnetic crystals which are fairly stable in air. The stability of complexes of the type $(PR_3)_2NiR'_2$ or $(PR_3)_2NiR'X$ is known to increase in the following sequence depending on the nature of the substituent: alkyl < ethynyl or substituted ethynyl ≃ *o*-aryl[133]. This sequence is probably determined by the possibility of the formation of a $d_\pi - p_\pi$ bond between the nickel atom and σ - R and also by the inhibition of the rotation of the *ortho*-substituted phenyl group about the Ni – C bond, which likewise promotes the interaction of the ligand π orbitals with the *d* orbitals of the nickel atom[133]. In this connection, it is interesting to note that, in contrast to the stable complex



a thiophen derivative without chlorine atoms has not been isolated at all[132].

‡ On the other hand, the reaction of nickelocene with benzylmagnesium chloride at room temperature results in the formation of nickel cluster compounds[130]:

It is suggested[130] that compound (XXVI) is formed owing to an unusual alkylation process: (XXVI) + $RC_6H_4CH_2MgCl$ → (XXVI), which has been confirmed experimentally.

The interaction of a ketone with nickelocene[134] gives rise to a compound in which one of the cyclopentadienyl ligands is linked to the nickel atom via a σ bond:

VI. ELECTRON-DONATING PROPERTIES OF COBALTOCENE AND NICKELOCENE

Analysis of the chemical reactions of cobaltocene and nickelocene reveals significant differences between the chemical behaviour of each compound. This is a consequence of the electronic structures of these π complexes. Moreover, the different stabilities of their cations, $[(C_5H_5)_2CO]^+ > [(C_5H_5)_2Ni]^+$ and $[(C_5H_5)_2Ni]^{2+}$, play a significant role.

1. CONDITIONS GOVERNING THE FORMATION OF THE METALLOCENIUM CATION.

The oxidation-reduction potentials of the metallocenes (Fe, Co, Ni) were determined initially in 90% ethanol using 0.1 M sodium perchlorate solution as the electrolyte. The results were $E_{1/2}$ = +0.30 V for ferrocene, $E_{1/2}$ = = -1.16 V for cobaltocene[135], and $E_{1/2}$ = -0.08 V for nickelocene[136]. Further studies in this field led to a revision of these values[42, 45].

The polarographic reduction of substituted cobalticenium salts at a mercury electrode in an aqueous alcoholic medium was also investigated[32]. The half-wave potentials $E_{1/2}$ are independent of the pH of the medium. The effect of substituents on $E_{1/2}$ is of the usual type[32]. Table 2 lists for comparison the oxidation-reduction potentials of the unsubstituted metallocenes and certain π acceptors.

Table 2. Oxidation-reduction potentials of the metallocenes (Fe, Co, Ni) and certain π aceptors*.

Donor	$E°$, V	Refs.	π Acceptor	$E°$, V	References
$(C_5H_5)_2$ Fe	+0.30	137	*p*-benzoquinone	−0.50	138
	+0.42	42	*p*-chloranil (CA)	+0.01	138
			tetracyanoethylene (TCE)	+0.15	139
$(C_5H_5)_2$ Co	−0.98	42			
$(C_5H_5)_2$ Ni	+0.01	42	2,3-dichloro-5,6-dicyanoquinone (DDQ)	+0.51	138

* All the E values were determined in acetonitrile.

The metallocenes exhibit a high electron-donating capacity, which is reflected in their tendency to form readily salts and charge-transfer complexes.

Interaction with Strong Oxidising Agents (Halogens, Thiocyanogen, and Picric Acid)

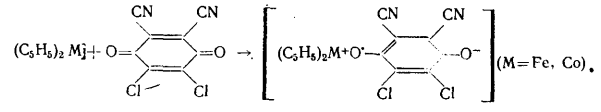
The electron deficiency of the π acceptor and the electron-donating properties of the metallocene determine the type of the charge-transfer complex formed. Partial charge separation between the components, $(\text{Don.})^{+\delta}$ $(\text{Acc.})^{-\delta}$, leads to the formation of a π complex of the dative type[140]. In this case the infrared and ultraviolet spectra of the π complex exhibit all the features characteristic of the metallocene and the π acceptor. When the charge separation is more complete, a charge-transfer complex of the ionic type is produced[141]. Further development of this process terminates with the formation of a salt in which the metallocene is converted into the metallocenium cation and the π acceptor behaves as the anion. Treatment of ferrocene with chlorine[142] or bromine[143] is known to result in the formation of a ferricenium halogenoferrate (III) salt $[(C_5H_5)_2Fe]FeX_4$. Thiocyanogen, the oxidising capacity of which is intermediate between those of bromine and iodine, forms the salt $[(C_5H_5)_2Fe]_2Fe(NCS)_4$, but in this case the metal in the anion is in a lower state of oxidation[144]. The series is terminated by iodine[146, 147], which forms polyiodides with ferrocene. When thiocyanogen is allowed to react with cobaltocene, the latter does not decompose like ferrocene. The product is cobalticenium thiocyanate $[(C_5H_5)_2Co](NCS)$.[144]

Iodine reacts similarly with cobaltocene[148], forming cobalticenium tri- or octo-iodide. When iodine reacts with nickelocene, the latter is decomposed[148]. According to its chemical properties, bis(tricarbonylcyclopentadienylchromium) is an analogue of iodine. Its reaction with cobaltocene gives rise to the cobalticenium salt $[(C_5H_5)_2Co][C_5H_5Cr(CO)_3]$.[149] Treatment of cobaltocene with HX (X = Cl, Br, or I) in ether results in the formation of cobalticenium tetrahalogenocobaltates $[(C_5H_5)_2Co]_2CoX_4$.[93] The authors believe[93] that the reaction proceeds in several stages:

$$(C_5H_5)_2Co^{\cdot} + HX \rightarrow [(C_5H_5)_2Co]^+X^- + H^{\cdot}, \quad (1)$$

$$[(C_5H_5)_2Co]^+X^- + HX \xrightarrow{\text{slow}} C_5H_6 + C_5H_5^{\cdot} + CoX_2^{\cdot}, \quad (2)$$

$$2[(C_5H_5)_2Co]^+X^- + CoX_2 \xrightarrow{\text{rapid}} [(C_5H_5)_2Co]_2^+[CoX_4]^-. \quad (3)$$



Hydrogen fluoride, being a weak acid, cannot decompose the cobalticenium ion [Eqn. (2)] and therefore the reaction results in the formation of the complex $[(C_5H_5)_2Co]HF_2$.[93] The reaction of the hydrogen halides HX (X = Cl, Br, or I) in the presence of triphenylphosphine with cobaltocene in ethereal solution leads to the formation of $[(C_5H_5)_2Co]^+X^-$ (X = Cl, Br, or I) as the main product and as well as small amounts of $[(C_5H_5)_2Co]_2^+[CoX_4]^-$ and $[(C_5H_5)_2Co][Co(PRh_3)X_3]$.[150, 151] Trichloroacetic acid reacts with ferrocene to form a paramagnetic compound with reducing properties[152]. The authors believe that an electron of the ferrocene molecule is bound by the acid proton, as happens in the reaction between an alkali metal and ammonia or an amine[153]. The interaction between trichloroacetic acid and cobaltocene takes place similarly. The product is the paramagnetic compound $[(C_5H_5)_2Co]^+(BH^-)(BH)_2$, where B = CCl_3COO.[154] However, the usual cobalticenium salt is also formed in this case together with the charge-transfer complex, which is fully consistent with the electron-accepting properties of cobaltocene.

Picric acid reacts with ferrocene to form a charge-transfer complex[155, 156], while its reactions with cobaltocene[148] and nickelocene[148] give rise to salts §.

§ However, it has been shown that in the reaction between picric acid and cobaltocene, a charge-transfer complex is formed together with the cobalticenium salt[154].

2. CHARGE-TRANSFER COMPLEXES

Treatment of ferrocene[157] or cobaltocene[157,158] with 2, 3-dichloro-5, 6-dicyanoquinone (DDQ) or 7, 7, 8, 8-tetracyanoquinodimethan results in both cases in the formation of stable complexes with a 1 : 1 component ratio. The infrared spectra of the complexes with DDQ do not contain the ν_{CO} band (1680 cm^{-1}), but a new band appears at 1590 cm^{-1}, which has been assigned to the vibrations of the phenoxy-group[159]; this suggests that these compounds are ionic π complexes[157]:

It is noteworthy that only the addition of a solution containing a 40-fold molar excess of $AgClO_4$ relative to the DDQ – cobaltocene and DDQ – ferrocene complexes results in the appearance in the ultraviolet spectra of these compounds of the band which has been assigned to absorption by the metallocenium cations. It has been shown experimentally[157] that the component ratio in the DDQ – nickelocene complex is not 1 : 1 and the infrared spectrum of this compound differs significantly from those of the corresponding ferrocene and cobaltocene π complexes. It is most probable that, by virtue of its electron-donating properties, nickelocene forms a mixture of salts of the singly and doubly-charged cations, $[(C_5H_5)_2Ni]^+$ and $[(C_5H_5)_2Ni]^{2+}$, in its reaction with DDQ.

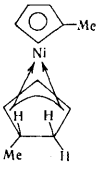
Tetracyanoethylene (TCE)[157] and *p*-chloranil (CA)[160] form charge-transfer complexes with cobaltocene and nickelocene, which differ significantly in stability. As a stronger electron acceptor, TCE forms unstable compounds with cobaltocene and nickelocene, which can be kept in an atmosphere of nitrogen or at a low temperature (-80°C). The interaction with CA, which is a weaker electron-acceptor than TCE, leads to the formation of stable complexes. This anomaly can probably be accounted for by the lower "electron capacity" of the tetracyanoethylene system compared with the CA aromatic molecule and also by the higher electron-donating capacity of cobaltocene and nickelocene compared with ferrocene. This explanation has been confirmed by the properties of the TCE–ferrocene[161] and TCE – bis(tetrahydroindenyl)iron[157] complexes. The introduction of an alkyl substituent is known to enhance the electron-donating properties of the ferrocene system, increasing thereby the likelihood of the transfer of electron density to the π acceptor. Presumably the π complex of substituted ferrocene with TCE is less stable than the complex with an aromatic π acceptor. Indeed the TCE–bis(tetrahydroindenyl)iron complex is labile, while the complex with DDQ is quite stable[157]. On the basis of ultraviolet and infrared spectroscopic data, the TCE–ferrocene complex was assigned to the dative type[157,161-163] and the TCE–cobaltocene complex was assumed to be ionic[157], CA, the electron-accepting properties of which differ only slightly from those of TCE, forms similar complexes with ferrocene[157], cobaltocene[157,164], and nickelocene[157,160].

The data presented show that, depending on the relative contributions by the electron-donating and electron-accepting properties of both components of the charge-transfer complexes, the degree of charge separation between the components may be various. Dative complexes are usually formed by ferrocene. The interaction with cobaltocene and nickelocene leads to the formation of ionic complexes.

The capacity to form complexes with electron acceptors is a general property of the three types of compounds considered.

* * *

In conclusion we shall consider the properties of the metallocenes which must be taken into account in their synthesis. The metallocenes can be obtained in the gas phase[165,166] by the reaction between metal salts and cyclopentadiene. However, the yield is not always quantitative. Cyclopentadiene or its dimer are used as the starting materials for the synthesis of the metallocenes by reaction with the corresponding metal carbonyls[136,167]:



$$C_5H_6 + M_n(CO)_m \rightarrow (C_5H_5)_2M + CO$$

for M=Fe, m=5, n=1; for M=Co, m=8, n=2).

The main product of this type of reaction with nickel carbonyl is cyclopentadienylcyclopentenylnickel. Nickelocene is formed as a side product in an amount not exceeding 5%[136,168,169]:

$$C_5H_6 + Ni(CO)_4 \rightarrow C_5H_5NiC_5H_7 + (C_5H_5)_2Ni.$$

The interaction of $CH_3C_5H_5$ with $Ni(CO)_4$ led to the isolation of a red diamagnetic compound to which the following structure was attributed on the basis of ^1H NMR spectra[170]:

When cyclopentadiene is introduced into the reaction in the form of the anion, the dimer of cyclopentadienylnickel carbonyl $(C_5H_5NiCO)_2$ is isolated[171]:

$$C_5H_5Na + Ni(CO)_4 \rightarrow (C_5H_5NiCO)_2.$$

Probably this compound is obtained by a ligand exchange reaction between the nickel carbonyl and the nickelocene formed, which is extremely typical for the chemistry of the latter[117-120]. It is noteworthy that the interaction of di-μ-carbonyldi(cyclopentadienyl)dinickel(0) $(C_5H_5NiCO_2)$ with a monodentate ligand L {L = CO, $(C_6H_5)_3As$, $(C_6H_5)_3P$, $C_2H_5(C_6H_5)_2P$, $[(CH_3)_2N]_3P$, etc.} leads to the formation of a nickelocene in 30 – 70% yield[172-173]:

$$(C_5H_5NiCO)_2 + 2L \rightarrow Ni(CO)_2L_2 + Ni(C_5H_5)_2.$$

The amount of ionic character of cyclopentadiene or its substituted derivative is also significant in the formation of nickelocene. One can employ different bases, the nucleophilic properties of which are sufficient for the formation of the ionised form of cyclopentadiene. A fairly wide range of amines, with $pK_a < 9$, is usually employed for unsubstituted cyclopentadiene[174]. The so called "amine method" was found to be valid in all three cases. Ferrocene[175,176], cobaltocene[176], its cation[175], and nickelocene[176] were obtained in high yields. More powerful nucleophilic agents can also be used. Among these mention may be made of sodium methoxide[177], potassium hydroxide[178], ethylmagnesium bromide[26,136,179,180], and thallium(I) hydroxide[181-183]. In all these cases, the metallocenes were obtained in high yields. Sodium cyclopentadienide can also be employed as a cyclopentadienylating agent. It is synthesised by metallating cyclopentadiene with metallic sodium[184], sodamide[185,186], sodium hydride[187], or sodium acetylide[188].

It is noteworthy that in the synthesis attention should be concentrated on the choice of the transition metal salt. When nickel chloride is replaced by its acetylacetonate in the reaction with cyclopentadienylmagnesium bromide, the yield of nickelocene increases from 8 to 60%.[136] If cobalt chloride is replaced by the bromide, the reaction of the latter with cyclopentadienylthallium results in a quantitative isolation of the cobalticenium salt instead of the 25% yield in the case of cobalt chloride[181]. On the other hand, the yield of nickelocene increases from 0 to 25 and 70% as nickel(II) chloride is replaced in succession by its bromide[181] and then by hexamminenickel(II) chloride[182]. Cobalticenium salts can be obtained in high yields also by the disproportionation reaction of dihalogenocyclopentadienylcobalt[189]:

$$[C_5H_5CoX_2]_n \rightarrow [C_5H_5)_2Co]^+.X^- + CoX_3,$$

where X = I, Br, or Cl. The π complexes of cobalt can be arranged in the following sequence in terms of the decrease of their resistance to disproportionation: $[Co(C_5H_5)I_2] > [Co(C_5H_5)Br_2] > [Co(C_5H_5)Cl_2]$.[189]

Ferrocene derivatives are usually obtained by an electrophilic substitution reaction[1-10]. The direct introduction of a substituent into cobaltocene and nickelocene molecules is complicated by the ready oxidisability of the compounds and their tendency to undergo addition and ligand exchange reactions. This was discussed above in detail. Therefore cobaltocene and nickelocene derivatives can be obtained either from fulvenes[29, 32, 190] or from substituted cyclopentadienes[33, 191-193, 200] and cyclopentenones[30, 194]. Members of the homologous series of metallocenes [29, 32, 191, 193], polysubstituted heterohomologous series of metallocenes[192, 193], chlorometallocenes[200], homoannular homologues of metallocenes[33, 195], and also hydroxy-derivatives of ferrocene and cobaltocene[30, 194] have been obtained in this way. An interesting method involving the employment of ferrocene derivatives, which are widely available, as the starting materials for the synthesis of other metallocenes, in particular cobalticenium salts, has been described[196]:

$$(RC_5H_4)_2Fe \xrightarrow[2.CoCl_2,\ THF]{1.LiEtNH_2} [(RC_5H_4)Co]^+X^-,$$

(a) R = Et; X = $^1/_2PtCl_6$; (b) THF = Pr; X = $HgCl_3$).

If the substituted cyclopentadiene obtained by the reductive cleavage of ferrocene is isolated as an organothallium derivative, it can be converted into other metallocenes[181, 197, 198]:

$$(R_1R_2C_5H_3)_2Fe \xrightarrow[2.\ TlOH,\ H_2O]{1.\ LiEtNH_2} R_1R_2C_5H_3Tl \xrightarrow{MX_2} (R_1R_2C_5H_3)_2M.$$

(M = Co, Ni).

In addition, nickelocene has been converted into ferrocene[199], which may be important for the identification of nickelocene and its derivatives. Thus interconversions of the dicyclopentadienyl derivatives of the metals in the Fe, Co, Ni triad are possible.

Examination of the chemical behaviour of nickelocene and cobaltocene (substitutions, addition, and ligand exchange reactions) showed that information about the reactions of the first type is comparatively scanty. Therefore in the future the efforts of investigators will probably be directed towards research in this field.

Electrochemical Alkoxylation of Organic Compounds

M.Ya.Fioshin, L.A.Mirkind, and M.Zh.Zhurinov

The review considers current problems of the electrochemical alkoxylation of heterocyclic compounds, unsaturated and aromatic hydrocarbons, carboxylic acids, amines, and ethers. Certain alkoxydimerisation reactions are also discussed. The methods used to carry out alkoxylation reactions are considered. Much attention is given to the present state of studies on the kinetics and mechanism of electrochemical alkoxylation.
The bibliography includes 120 references.

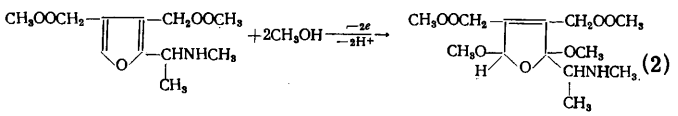
I. INTRODUCTION

The results of the first experiments on the electrochemical alkoxylation of organic compounds were published at the beginning of the 1950's[1,2]. Over a comparatively short period, numerous studies designed to develop effective electrochemical methods for synthesising a wide variety of alkoxy-derivatives were carried out. Interest in electrolysis as a method for the preparation of compounds of this class is due to the importance of alkoxy-derivatives and also the disadvantages of the chemical methods for their synthesis. Alkoxylated aliphatic and alicyclic organic compounds can be used to synthesise polymers and plasticisers[3-5], valuable lubricating oils[6], emulsifying agents[7], perfumes[8], extractants[9], inhibitors of the oxidation of petroleum products[7], and biologically active preparations[6,10-13].

II. ELECTROCHEMICAL ALKOXYLATION OF HETEROCYCLIC COMPOUNDS

The electrochemical alkoxylation, mainly methoxylation, of furan and its derivatives has been investigated in greatest detail:



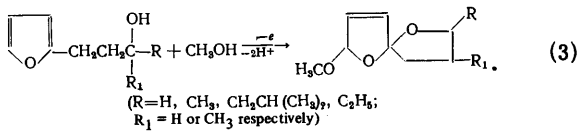
(1)

The electrolysis of a methanol solution of furan (R_1 = R_2 = H) containing ammonium bromide as an electrolyte results in the formation of 2,5-dimethoxy-2,5-dihydrofuran[1,2,14-19], in 92% yield with respect to current, the hydrolysis of which gives a high yield of maleic dialdehyde, a valuable intermediate in the manufacture of synthetic fibres[20].

The electrochemical methoxylation of many α-alkylfurans[21,22], for example silvan (R_1 = H, R_2 = CH_3), and also of disubstituted derivatives such as 2,5-dimethylfuran (R_1 = R_2 = CH_3), which can be converted by methoxylation into a mixture of *cis*- and *trans*-isomers of 2-5-dimethoxy-2,5-dimethyldihydrofuran[22,23], has been studied. The corresponding dimethoxy-derivatives can be obtained by the electrochemical methoxylation of 5-ethyl-2-methylfuran and 2,5-diethylfuran[22].

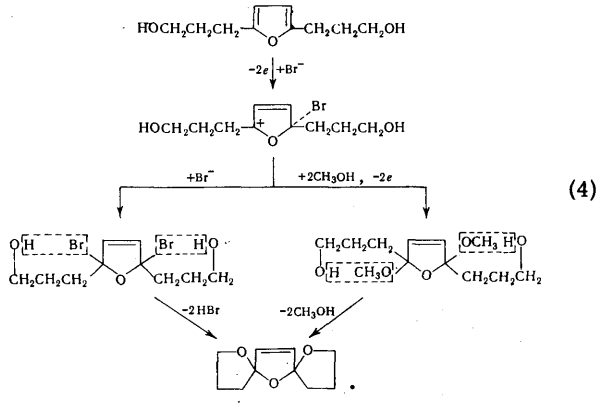
Electrochemical methoxylation can occur not only as a result of the addition of a methoxy-group, but also as a result of substitution. A characteristic example of reactions of this type is the methoxylation of chloro- and bromo-furans[24]. Apart from reaction (1), substitution by a methoxy-group takes place. The electrochemical methoxylation of 2-bromo- and 2-iodo-furans (R_1 = Br or I; R_2 = H), 5-bromo-, 5-chloro-, and 5-iodo-furfurals (R_1 = Cl, Br, or I; R_2 = CHO), and the methyl ester of 5-bromopyromucic acid (R_1 = Br; R_2 = $COOCH_3$) has been achieved. In all cases the reaction yields trimethoxy-derivatives.

Electrochemical methoxylation takes places with a fairly high efficiency also in the electrolysis of certain other furan derivatives. For example, 2,5-dimethoxy-2,2-dihydrofurfuryl alcohol[21] and 2,5-dimethoxy-2,2-dihydrofurfuryl acetate[18,19,21] can be obtained from furfuryl alcohol (R_1 = H; R_2 = CH_2OH) and furfuryl acetate (R_1 = H; R_2 = CH_2OOCH_3) in yields of 77 and 81—86% respectively. Similarly methoxylation of furfural dimethylacetal [R_1 = H; R_2 = $CH(OCH_3)_2$] at the anode gives a high yield (with respect to the current), of 2,5-dimethoxy-2,5-furfural methylacetal[21]. Methyl pyromucate[25] and some of its derivatives[26-28], for example compounds with R_1 = CH_2NH_2 and R_2 = $COOCH_3$ or with R_1 = $(CH_3)_2CH$ and R_2 = $COOCH_3$, are methoxylated selectively with formation of the corresponding dimethoxy-derivatives. The presence of substituents in the 3- and 4-positions does not hinder the addition of methoxy-groups in the 2- and 5-positions, as can be seen from the following example:



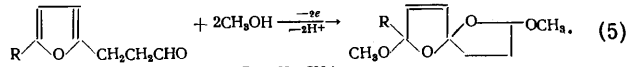
(2)

although the yield in this case does not in fact exceed 50%.[29]



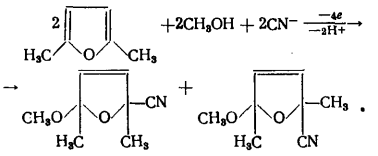
Ponomarev and Markushina[18,19,30-37] investigated the electrochemical alkoxylation of a large group of γ-furylalkanols and showed that, together with the usual addition

of the methoxy group, there is an intramolecular reaction accompanied by cyclisation:



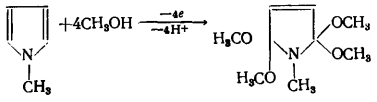
(R=H, CH_3, $CH_2CH(CH_3)_2$, C_2H_5; R_1 = H or CH_3 respectively) (3)

Thus the final products are the corresponding derivatives of 2-methoxy-1,6-dioxaspiro[4,4]non-3-ene. The electrochemical methoxylation of 1-(α-furyl)-3-propanol, 1-(α-furyl)-3-butanol, 1-(α-furyl)-5-methyl-3-hexanol, and a tertiary alcohol—1-(α-furyl)-3-methyl-3-pentanol—has been investigated. Polycyclic spirans are formed on electrochemical methoxylation of mono- and bi-cyclic alcohols[32,36,37]. An attempt at the electrochemical methoxylation of 2,5-di-(3′-hydroxyalkyl)furans led to interesting results[33]. For example, the methoxy-derivative could not be obtained at all from 2,5-di-(3′-hydroxypropyl)-furan. The anodic product of the electrolysis of the compound in methanol containing sodium bromide as the electrolyte is the *trans*-form of 1,6,8-trioxadispiro-[4,1,4,2]-tridec-12-ene.



Intramolecular cyclisation is probably due to the involvement in the reaction of bromide ions and of the hydroxy-group of the initial alcohol. The intramolecular cyclisation reaction may proceed via the following mechanism:

(4)



The electrochemical methoxylation of β-carbonyl derivatives of furans is extremely interesting. For example, the electrochemical methoxylation of aldehydes containing the furan ring makes it possible to obtain high yields of derivatives of 2,7-dimethoxy-1,6-dioxaspiro[4,4]non-3-ene[38]:

(R = H, CH_3) (5)

The yields of heterospirans vary from 53 to 76%. These products are of interest as biologically active preparations, in particular some of them exhibit a tranquilising activity[38]. If the methanol solution of the heterocyclic compound contains a readily oxidised anion, the electrolysis may be accompanied by the formation at the annode of a product containing two different substituents. For example, the electrolysis of a methanol solution of 2,5-dimethylfuran containing sodium cyanide gives a 74% yield of *cis*- and *trans*-2-cyano-5-methoxy-2,5-dimethyl-2,5-dihydrofurans[39]:

(6)

Whereas in the electrochemical methoxylation of furan derivatives two methoxy-groups add on as a rule, in the electrolysis of methanol solutions of *N*-methylpyrrole a tetra-substituted derivative is formed at the anode—2,2,5,5-tetramethoxy-1-methyl-3-pyrroline[40]:

(7)

2,6-Dimethoxypyridine undergoes electrochemical methoxylation whereby it is converted into 2,3,5,6-tetramethoxypyridine and 2,3,3,5,6-pentamethoxyazocyclohexa-1,4-diene[40,41].

Several studies have been made on the electrochemical alkoxylation of thiophen and its derivatives[42-44]. The alkoxylation of thiophen is accompanied by the formation of γ-dicarbonyl compounds[42], although in certain cases it is in fact possible to preserve the five-membered heterocycle. For example, 2,5-dimethoxy-2,5-dihydrothiophen can be obtained in 36% yield by the electrochemical methoxylation of thiophen[45]. The methoxylation of methyl 3-(5-methyl-2-thienyl)propionate also involves ring rupture and the formation of a sulphur-free product, which does however contain a methoxy-group: methyl 4,7-dioxo-uct-5-enoate[43]. The electrochemical methoxylation of 1-(3-thienyl)ethyl acetate also involves the removal of sulphur and the formation of 4-acetoxy-3-dimethyoxy-methylpent-2-ene-1-al dimethylacetal (46% yield)[44].

In conclusion, we must consider the alkoxylation of hydrogenated furan and thiophen derivatives—tetrahydrofuran and tetrahydrothiophen[46]. Methoxylation takes place in both cases with formation of α-methoxytetrahydrofuran and α-methoxytetrahydrothiophen in yields of 26 and 8.5% respectively on electrolysis of methanol solutions containing sodium methoxide.

The conditions governing the electrochemical ethoxylation of heterocyclic compounds probably do not differ significantly from those for methoxylation. This is indicated by experiments on the electrochemical oxidation of furan in ethanol[47].

III. ELECTROCHEMICAL ALKOXYLATION OF UNSATURATED AND AROMATIC HYDROCARBONS

Electrochemical alkoxylation of unsaturated hydrocarbons is more selective than the reactions involving heterocyclic compounds. The electrochemical methoxylation of aryl-substituted unsaturated hydrocarbons—styrene and its derivatives[48,49] and stilbene[49,50]—has been investigated in greatest detail. The electrochemical methoxylation of styrene gives a 20% yield of dimethoxyphenylethane[48]:

(8)

α-Methylstyrene and 1,1-diphenylethylene are converted respectively into the dimethyl ether of 1-methyl-1-phenylethylene glycol (15%) and the dimethyl ether of 1,1-diphenylethylene glycol[48] in 23% yield.

The electrochemical ethoxylation of styrene resulted in the formation of methane, ethane, the diethyl ether of styrene glycol, *meso*-1-4-diethoxy-2,3-diphenylbutane, and condensation products of acetaldehyde which the authors[49] believe to be formed as a result of decomposition of ethoxy-radicals. Studies on the electrochemical alkoxylation of stilbene[49,50] indicate the possibility of obtaining a satisfactory yield of dimethoxydiphenylethane.

Benzene does not undergo electrochemical alkoxylation, while its derivatives are methoxylated on electrolysis[51-56]. Benzyl methyl ether, 1-methoxy-1-phenylethane, and α-methoxyisopropylbenzene have been obtained in low yields by the electrochemical methoxylation of toluene, ethylbenzene, and cumene respectively[51]. The reactivity of alkylbenzenes in the alkoxylation reaction decreases in the sequence $C_6H_5CH(CH_3)_2 > C_6H_5C_2H_5 > C_6H_5CH_3$.

Interesting data have been obtained on the electrochemical methoxylation of 9,10-disubstituted anthracene derivatives[53]. On methoxylation of anthracene and 9,10-dimethylanthracene, the ratios of the *cis*- and *trans*-dimethoxy-derivatives are respectively 3:1 and 5:1. If diethyl-, dipropyl-, and diphenylanthracenes are methoxylated, the ratio of the *cis*- and *trans*-isomers changes in favour of the latter, approaching 1:1.

Reactions involving tetralin, indan, and diphenylmethane lead to the formation of the corresponding α-methyl ethers in low yields[55,57]. If the methanol solution of tetralin contains cyanides, then at anodic potentials of about 2.5 V electrochemical cyanation products[54], for example 6-cyanotetralin[56], appear in solution in addition to the methoxy-derivatives.

The electrochemical methoxylation of cycloalkenes yields the corresponding mono- and di-substituted derivatives[58]. For example, 1-methoxycyclohex-2-ene, 1,1-dimethoxycyclohexene[58], and in some cases 3-methoxycyclohex-1-ene[59] may be obtained from cyclohexene, while 1-ethylcyclohex-1-ene can give rise to 1-(1′-methoxyethyl)cyclohex-1-ene, 1-ethyl-3-methoxycyclohex-1-ene, and 2-ethyl-1-methoxycyclohex-2-ene[58]. The methoxylation of 2-methylpent-2-ene gives rise to three products: 3-methoxy-2-methylpent-1-ene, 2,3-dimethoxy-2-methylpent-1-ene, and 2,2-dimethoxypent-2-ene in an overall yield of 71%.[58] 3,4- and 3,6-dimethoxycyclohex-1-enes are formed as a result of the electrochemical methoxylation of cyclohexadiene[60]. A certain amount of the products of the addition of the methoxy-radical in the 1- and 4-positions are observed on electrolysis of the methanol solution of buta-1,3-diene[61,62], although in this case the methoxy-dimerisation reaction, which will be discussed below, is more typical.

As in some of the examples discussed previously, electrochemical methoxylation may result in the formation of bifunctional compounds owing to the addition of two different substituents to the hydrocarbon molecule. For example, electrolysis at the anode of methanol saturated with hydrogen chloride and ethylene results in the formation of chloromethoxyethane together with dichloroethane[63,64]:

$$C_2H_4 + CH_3OH + Cl^- \xrightarrow[-H^+]{-2e} CH_3OCH_2CH_2Cl. \qquad (9)$$

1-Hydroxy-4-methoxybut-2-ene can be synthesised by the electrolysis of a methanol solution of potassium hydroxide containing buta-1,3-diene[62,65].

IV. ELECTROCHEMICAL ALKOXYLATION OF COMPOUNDS WITH FUNCTIONAL GROUPS

A number of studies have been devoted to the electrochemical alkoxylation of organic acids. For example, electrochemical oxidation of *exo*- and *endo*-norbornane-3-carboxylic acid in methanol solution yielded methyl *exo*-norbornyl ether, while *exo*- and *endo*-5-norbornenecarboxylic acids give rise to 3-methoxynonatricyclene[66]. Methoxy-derivatives of hydrocarbons are formed in the electrolysis of methanol solutions of organic acids as a result of the replacement of the carboxy-group by a methoxy-group. For example, in the oxidation at the annode in methanol solution of acids with the general formula $o\text{-}XC_6H_4(CH_2)COOH$, where X = Cl, Br, or O_2, the methoxy-derivative $o\text{-}XC_6H_4(CH_2)_nOCH_3$ was detected together with the products of the anodic Kolbe condensation and certain other derivatives[67]. The yield of ether diminishes with increase of *n*. The substitution process can involve also the hydrogen atoms in the side chain. This is characteristic of phenylacetic acids[66]:

$$RC_6H_4CH_2COOH \xrightarrow[-CO_2,\ -H^+]{-2e,\ +CH_3OH} RC_6H_4CH_2OCH_3$$
$$\xrightarrow[-CO_2,\ -3H^+]{-3e,\ +2CH_3OH} RC_6H_4CH(OCH_3)_2$$
$$\xrightarrow[-CO_2,\ -H^+]{-4e,\ +3CH_3OH} RC_6H_4C(OCH_3)_3. \qquad (10)$$
(R=CH$_3$O, N(CH$_3$)$_2$)

The electrochemical alkoxylation of adamantane-1-carboxylic acid in a methanol solution of sodium methoxide results in the formation of 1-methoxyadamantane in 65% yield[68]. Under the same conditions, the methoxylation of adamantane-1-acetic acid leads to 3-methoxyhomoadamantane[69]. If the methanol solution of an unsaturated acid contains hydrogen chloride or bromide, then chlorine or bromine adds to the double bond together with the methoxy-group. Thus α-chloro- or α-bromo-β-methoxyphenylpropionic acid can be obtained from cinnamic acid[70]. Methoxylated products were detected also in the anodic Kolbe condensation of ω-hydroperfluorovaleric and ω-hydroperfluorooenanthic acids[71]. The principal products of the anodic oxidation of certain α-ketoacids RCOCOOH in methanol solutions are the methyl esters $RCOOCH_3$ (R = CH_3, C_2H_5, or n-C_3H_7), which are formed in yields of 65—81.5%.[72] The yield of esters increases in the following sequence in terms of R: $CH_3 > C_2H_5 >$ n-C_3H_7.

The possibility of the methoxylation [part of the Russian text is missing at this point (Ed. of Translation)].....the yield of methoxydioxan is 28%.[46]

Among nitrogen-containing organic compounds, most attention has been devoted to the alkoxylation of amines[17,40,73,74]. Electrochemical methoxylation of *NN*-dimethylaniline gave a mixture[46] of *N*-methoxymethyl-*N*-methylaniline and the product of more extensive alkoxylation—*NN*-(dimethoxymethyl)aniline—in proportions of 6:1:

$$C_6H_5N(CH_3)_2 \xrightarrow[-H^+]{-e,\ +CH_3OH} C_6H_5N(CH_3)(CH_2OCH_3) \xrightarrow[-H^+]{-e,\ +CH_3OH} C_6H_5N(CH_2OCH_3)_2. \qquad (11)$$

Similarly one can synthesise α-methoxy-*NN*-dimethylbenzylamine and *N*-methoxymethyl-*N*-methylbenzylamine from *NN*-dimethylbenzylamine and 3-methyl-2-phenyloxazolidine, 3-benzyloxazolidine, and *N*-methoxymethyl-*N*-methylbenzylamine from *N*-benzyl-*N*-methylethanolamine[40,74]. The electrochemical methoxylation of

cyclohexyl isocyanate takes place with a low yield of methoxylated products (20%) and seven different compounds, five of which proved to be methoxides, were identified in the mixture[74].

A few studies have been made on the electrochemical methoxylation of ethers. For example, in the electrochemical methoxylation of the dimethyl ether of resorcinol, 2,3,3,6,6-pentamethoxycyclohexa-1,4-diene is formed in 61% yield[76]. However, veratrol is methoxylated at the anode with a lower selectivity and yields four substances, including hexamethyl *cis,cis-o*-muconate—the product of the opening of the benzene ring[76]. In the electrochemical methoxylation of anisole[41,77] in an alkaline solution, *o*-, *m*-, and *p*-dimethoxybenzenes are formed in proportions of 39 : 3 : 58.[41] The reaction in an acid medium takes place in a more complex manner[77]. In this case, the electrolysis products are the methyl esters of *p*-methoxybenzoic (45.3%) and *o*-methoxybenzoic (4.5%) acids as well as the dimethyl esters of maleic (15.5%) and succinic (23.8%) acids.

The electrochemical alkoxylation of trimethylsilane has also been described[78]. The yield of alkoxytriethylsilane in the electrolysis of an ethanol solution of triethylsilane varies in the range 30—80%. Attempts at electrochemical alkoxylation in *t*-butyl alcohol were unsuccessful.

V. ELECTROCHEMICAL ALKOXYDIMERISATION

In some cases electrochemical alkoxylation is accompanied by dimerisation with formation of dimethoxy-derivatives of compounds with twice as many carbon atoms as the starting material. For example, a dimeric product—*meso*-1,4-diethoxy-2,3-diphenylbutane—is formed in the electrolysis of an ethanol solution of styrene at the anode together with the ethoxylation product (the diethyl ether)[49,79]:

$$2C_6H_5CH{=}CH_2+2C_2H_5OH \xrightarrow[-2H^+]{-2e} C_6H_5CH(OC_2H_5)-CH_2CH_2-CH(OC_2H_5)C_6H_5. \qquad (12)$$

The electrolysis of a methanol solution of *cis*-cyclopropane-1,2-dicarboxylic acid results in the formation of a mixture of dimeric products—dimethyl ester of bicyclopropyl-2,2-dicarboxylic acid and the methyl ester of cyclopropane-1,2-dicarboxylic acid[80]. A number of studies in recent years were specially undertaken to investigate the conditions governing the alkoxydimerisation reaction and the methods for the electrochemical synthesis of alkoxydimers[61,62,65,79,81,82].

Electrochemical methoxylation of buta-1,3-diene can give rise under certain conditions to three isomeric dimethoxyoctadienes[79,83]: *trans, trans*-1,8-dimethoxyocta-2,6-diene, *trans*-1,6-dimethoxyocta-2,7-diene, and 3,6-dimethoxyocta-1,7-diene. In other investigations[61,62,65], 1,6-dimethoxy-2-vinylhex-4-ene was detected in addition to the first isomer. However, the product yields do not exceed 15%. Apart from the products mentioned, two isomeric dimethoxydodecatrienes were detected in an overall yield of 11%.[83] Methoxydimers are obtained in somewhat higher yields in the electrolysis of arylated olefins—styrene, α-methylstyrene[83], and isoprene[84]—as well as vinyl ethers[81,85]. In the last case, the reaction has been investigated for a fairly large number of systems:

$$2R_1O-\underset{R_3}{\overset{}{C}}=\underset{R_4}{\overset{}{C}}-R_2+2R_5OH \xrightarrow[-2H^+]{-2e} R_1O-\underset{R_3}{\overset{OR_5}{C}}-\underset{R_4}{\overset{R_2}{C}}-\underset{R_4}{\overset{R_2}{C}}-\underset{R_3}{\overset{OR_5}{C}}-OR_1, \qquad (13)$$

where $R_1,\ldots,R_5$ are C_nH_{2n+1} groups with $n = 1-8$ for R_1, $n = 0-8$ for R_2-R_4, and $n = 1-4$ for R_5; R_1 can also be a five- or six-membered cycloalkyl group.

Together with dimerisation, there is simple addition of alkoxy-groups to the double bond. The yield of products then exceeds the yield of methoxydimers, although in some cases, for example, for ethyl vinyl ether, it reaches 51%.[83]

A methoxydimer—1,1-dimethoxy-2,2′-bisindanyl—can be obtained in 38% yield by the anodic oxidation of indene in methanol[83].

Finally, we must consider the anodic coupling reaction with formation of dimethoxy-derivatives occurring when alcoholic solutions of two different unsaturated hydrocarbons are electrolysed[82]. For example, the electrolysis of a methanol solution of styrene and ethyl vinyl ether results in the formation of a methoxydimer—4-ethoxy-1,4-dimethoxy-1-phenylbutane:

$$C_6H_5CH{=}CH_2+H_2C{=}CHOC_2H_5+2CH_3OH \xrightarrow[+2H^+]{-2e} C_6H_5CH(OCH_3)-CH_2CH_2-CH(OCH_3)OC_2H_5, \qquad (14)$$

1-Ethoxy-1,4-dimethoxy-4-phenylpentane has been synthesised in this way from α-methylstyrene and ethyl vinyl ether.

VI. CONDITIONS GOVERNING THE ALKOXYLATION AND ALKOXYDIMERISATION REACTIONS

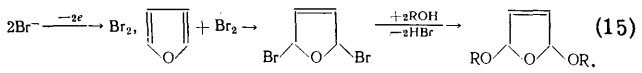
The mode of the alkoxylation reaction and the nature and yields of products depend largely on the nature of the anode material, the electrolyte, the concentrations of the initial organic compounds, the current density, the anode potential, and the solution temperature. Systematic studies designed to compare the roles of these factors have not been made. However, certain largely qualitative generalisations can be made from the available data.

Electrochemical alkoxylation and alkoxydimerisation have been carried out at anodes made of platinum[17,22,23,40,48-50,52,54,55,57,58,60-62,65,68,73,74,76,85] and charcoal or graphite[5,18,19,24,30-38,43-46,75,79,82,83]. Platinum[66,74], graphit[82], nickel[18,19,40,43,61,62,65,47] or mercury[22,60] have been used as the cathode materials. Probably in the electrochemical alkoxylation of heterocyclic compounds, fairly high yields of products may be achieved at both platinum and graphite anodes. On the other hand, in the vast majority of the experiments on the electrochemical alkoxylation of hydrocarbons and organic compounds with functional groups platinum anodes were used.

The choice of electrolyte constitutes a very important problem. Electrochemical alkoxylation of heterocyclic compounds takes places most efficiently in alcoholic solutions of bromides, mainly ammonium bromide. Attempts to employ as electrolytes alcoholic solutions of nitrates, carboxylic acid salts, and sulphuric acid inevitably resulted in a lower yield of alkoxy-derivatives. The specific role of bromide in the electrochemical alkoxylation of heterocyclic compounds has been discussed by a number of workers[2,24,33,41]. Alcoholic solutions of alkalis and alkoxides can be recommended for the electrochemical alkoxylation of hydrocarbons[49,61,62,65] and tertiary amines[17]. Attempts to employ bromides as electrolytes in the electrochemical alkoxylation of unsaturated hydrocarbons lead to the formation of bromo-derivatives.

An important process parameter is the anodic current density. Electrochemical alkoxylation is carried out over

a fairly wide range of anodic current densities—from 1 to 10 A dm^{-2}. The ratio of the alkoxylation and alkoxydimerisation products depends to a considerable degree on the anodic current density when these reactions can occur simultaneously. Experimental data show that the yield of alkoxydimerisation products as a rule increases with decrease of anodic current density. Anodic current density can also influence the proportions of the isomers of the alkoxydimers. For example, in the electrochemical methoxylation of buta-1,3-diene an increase of anodic current density entails an increase in the yield of the linear dimer 1,8-dimethoxyocta-2,6-diene in a mixture with the branched isomer 1,6-dimethoxy-2-vinylhex-4-ene[62].



The mode of reaction is influenced significantly by the concentration of the initial organic compound. As a rule, when the alkoxylation reaction is accompanied by alkoxydimerisation an increase in the concentration of the initial organic compound tends to increase the rate of the latter[62].

Finally, we must consider the effect of the temperature of the solution electrolysed. In most cases, it is recommended that the electrolytic alkoxylation of heterocyclic compounds be carried out at low temperatures ranging from −20°C [1,14] to 25°C.[43] It is also useful to maintain low temperatures (between −10° and −15°C) when low-boiling reagents (for example buta-1,3-diene) are involved in the reaction in order to reduce their volatility and increase their solubility. It is not recommended that the alkoxylation and alkoxydimerisation reactions be carried out above 20—25°C, although the methoxylation of cyclohexyl isocyanate in the electrolysis of boiling methanol containing sodium methoxide has been described[75].

VII. THE MECHANISMS OF THE ALKOXYLATION AND ALKOXYDIMERISATION REACTIONS

The number of studies on the mechanisms of the alkoxylation and alkoxydimerisation reactions is much smaller than on their preparative applications. In the published studies, the mechanism of electrochemical alkoxylation is generally regarded as an aspect of the electrode processes (the nature of the primary stage, the adsorption of the reactants, etc.) or is treated from the standpoint of secondary chemical reactions (the mode of addition and substitution, structural effects, etc.). Studies dealing in detail and systematically with the problems of the secondary and primary reactions in electrochemical alkoxylation and alkoxydimerisation have not yet been made. The literature data on this question are often highly contradictory. This is largely caused by experimental difficulties, which are inevitable when electrochemical methods are employed to investigate the kinetics of electrode processes in non-aqueous media. Significant difficulties arise also owing to changes in the surface of the anode over a period of time—a specific deactivation effect is characteristic of many anodic alkoxylation processes[44,62,80]. Electrochemical measurements are limited as a rule to the recording of polarisation curves[17,74,86,87]. On the other hand, the interpretation of the mechanism solely on the basis of an analysis of stable electrolysis products, which is done in the majority of investigations[41,88], makes the reaction mechanisms thus devised somewhat arbitrary[88,89]. As a result the mechanisms of the alkoxylation and alkoxydimerisation reactions remain on the whole to a considerable degree controversial. We shall consider certain modern ideas in this field.

The generally accepted view is that the alkoxylation reaction proper is the secondary chemical reaction which follows the discharge of the electrochemically active species at the electrode. However, different investigators hold divergent views concerning the nature of this species. As already mentioned, in the first studies on the methoxylation of furan, it was established that the reaction takes place most efficiently when bromide salts are employed as the electrolytes. On this basis, it was concluded in a number of investigations[2,5,15,19,24,33], that the initial reaction stage is the discharge of the bromide ion. This view is held, for example, by Ponomarev and Markushina[9,33], who suggest that the alkoxylation of furan derivatives proceeds via three stages. The first involves the oxidation of the bromide ion with formation of molecular bromine, in the second bromine undergoes 1,4-addition to the ring, and in the third dibromohydrofuran is alkoxylated chemically with elimination of HBr:

(15)

Kochetkov et al.[90] assume an analogy with chemical alkoxylation in the presence of bromine, where the initial stage is two-step electrophilic addition of Br_2. Sokolov and Giller believe that the primary step in the electrochemical methoxylation of furans in the presence of ammonium bromide is the formation of atomic bromine and its subsequent recombination to molecular bromine, which is in fact responsible for the methoxylation proper in the bulk of the solution[24]. A similar point of view has been largely adopted in studies by certain Japanese investigators[52], who assume that the discharge of the anion, regardless of its nature, is the initial reaction step. In contrast to the previous mechanism, Japanese investigators believe that the process may be described by the following consecutive reactions:

$$X^- \rightarrow X^\cdot + e\,(A);\ RH + X^\cdot \rightarrow HX + R^\cdot \qquad (B) \qquad (16)$$
$$CH_3OH \rightarrow CH_3O^\cdot + H^+ + e\,(C);\ R^\cdot + CH_3O^\cdot \rightarrow CH_3OR\ (D).$$

It is suggested that reaction (16B) is rate-determining. A characteristic feature of this mechanism is the electrochemical step involving the anodic oxidation of an alcohol molecule with formation of a $CH_3O\cdot$ radical. Methoxylation takes place homolytically as the recombination of $CH_3O\cdot$ and a radical formed from the substrate molecule via reaction (16B). Possibly in some cases, for example in halogen-containing electrolytes, this mechanism is acceptable but it can hardly be general. In fact the yield of methoxy-derivatives of furan is higher in solutions of bromide salts, but these derivatives are formed also in electrolytes containing NH_4NO_3, $NaNO_3$, sodium formate[17,91], sulphuric acid[61,62,91], alkalis[52,65,84], boron trifluoride-ether[91], cyanides, perchlorates[39,52,74], and other compounds[52]. The discharge of the anions of such electrolytes, for example ClO_4^-, F^-, etc., requires much higher positive potentials than those which actually obtain in the alkoxylation or alkoxydimerisation reactions. Naturally the step (16C) is ruled out when the electrolyte is a methoxide. Thus the mechanisms postulating as the initial step the direct electrochemical oxidation of the alcohol at very low positive potentials are more acceptable and undoubtedly more general.

Regardless of the conflict between the views concerning the nature of the electrochemical stage, the involvement of the methoxy-radical in the reaction is postulated by the

vast majority of investigators. However, the assertion that the electrochemical oxidation of alcohols generates the corresponding alkoxy-radicals is frequently made without sufficient evidence, solely on the basis of the observed formation of ethers. An attempt at a quantitative approach to this problem was made by Tsutsumi and coworkers[51], who showed that the relative reactivities of many aromatic compounds in electrochemical alkoxylation is fully consistent with Szwarc's observations[92] on their behaviour in free-radical reactions. A further development of this approach, within the framework of mechanism (16), is illustrated by the work of Sasaky et al.[52], who investigated the reactivity of alkylbenzenes in the electrochemical synthesis of α-substituted methyl ethers under various conditions. They established a linear relation between the current yield and the heat of reaction (16B) (rate-limiting step) calculated from thermochemical data. They believe that this finding is consistent with Semenov's law of the proportionality between the activation energy and enthalpy[93] for radical reactions and therefore confirms the validity of the homolytic mechanism. Since such views have gained wide acceptance recently[55,94], note should be taken of the methodological error which they involve.

In the first place the current yield of methoxy-derivatives in various electrolytes cannot be regarded as equivalent to the relative reactivity (the rate constant for the reaction between X· and RH), since the rate of formation of X· and their "actual" concentration determined by the partial oxidation current [stage (16A)] are not taken into account. Since the potential was not measured in the electrolysis and the reaction was carried out galvanostatically, the feasibility of reaction (16A) in all the cases investigated (X^- = F^-, ClO_4^-, OH^-, Cl^-, etc.) becomes doubtful. The application of concepts of homogeneous kinetics to this reaction, which the authors themselves regard as heterogeneous[52], also appears incorrect.

It is not the first time that attempts have been made in the literature to employ thermochemical data in order to establish the mechanisms of electrode reactions. The error of this approach has been demonstrated by Conway and Vijh[95]. Moreover, the validity of the "Semenov—Polanyi rule" cannot alone be regarded as a criterion of the validity of the homolytic mechanism, since it is a special case of the Brønsted equation or "the principle of the linearity of free energies", which is valid for many classes of chemical reactions regardless of their mechanism[96]. The above critical comments do not, however, refer to the actual conclusion that the stage involving the formation of the ether is homolytic. This conclusion is adhered to by the majority of investigators of this reaction. According to Inoue and Tsutsumi[48], only homolytic substitution can result in the formation also of certain side products of the oxidation of alkylbenzenes in alcoholic media, for example dimeric compounds.

The possibility of forming alkoxy-radicals was confirmed in a study[97] of the oxidation of tertiary alcohols of the type $R_1R_2(C_6H_5)COH$ (R_1 and R_2 = CH_3, C_2H_5, and iso-C_3H_7). The authors of this investigation, who carried out the electrolysis in aqueous dioxan solutions of the alcohols, observed a high yield of ketones (80—90%) and detected dimeric gaseous products. These products were interpreted as resulting from the formation of t-alkoxy-radicals by the reaction

$$R_1R_2PhCOH \xrightarrow[-H^+]{-e} R_1R_2PhCO^{\cdot}. \qquad (17A)$$

Next, decomposition into ketone molecules and aliphatic radicals takes place:

$$R_1R_2PhCO^{\cdot} \begin{cases} \longrightarrow R_1COPh + R_2^{\cdot} \\ \longrightarrow R_2COPh + R_1^{\cdot}, \end{cases} \qquad (17B)$$

which then recombine or disproportionate according to the equations

$$R_1^{\cdot} + R_2^{\cdot} \begin{cases} \longrightarrow R_1R_1 + R_2R_1 + R_2R_2 \\ \longrightarrow R_1H + R_2H + \text{olefins}, \end{cases} \qquad (17C)$$

The intermediate formation of an alkoxy-radical in the reaction involving furan is also postulated in the electrolysis of solutions containing non-halide electrolytes[22,60].

Despite the fact that a homolytic mechanism is assumed in most investigations, there are also discrepancies as to the details of the process (if these are considered at all). Thus in many studies it is assumed that, under the conditions of electrolytic alkoxylation, the alcohol is oxidised in the molecular form[51,52,76,94]. However, comparative analysis of polarisation measurements and of the composition of the electrolysis products in the anodic methoxylation of tertiary amines in various electrolytes led to the conclusion[74] that the active species in the electrochemical stage proper is only the methoxide ion. The possibility of oxidising the alcohol at the anode in both molecular and anionic forms, depending on the acidity of the medium, is indicated by experiments on the alkoxylation of 1,3-dienes[84,98].

In early and also in certain recent investigations, the problem of whether the reaction is homogeneous or takes place on the surface of the electrode was ignored. Recently several special investigations on this question were made[17,40,52].

Sasaky et al.[99], who investigated the oxidation of methanol in the presence of $NaClO_4$, NaOH, and $NaOCH_3$ as supporting electrolytes, concluded that the methoxy-radical may diffuse far from the surface of the anode. This conclusion is based on the finding that the electrochemical oxidation is accompanied by the evolution of gas at the porous diaphragm separating the cathodic and anodic compartments. This fact is interpreted as follows:

$$CH_3OH_{ads} \rightarrow CH_3O^{\cdot}_{ads} + H^+ + e, \qquad (18A)$$

$$CH_3O^{\cdot}_{ads} \rightarrow CH_3O^{\cdot}_{bulk}, \qquad (18B)$$

$$2CH_3O^{\cdot} \xrightarrow{\text{disproportionation}} CH_3OH + HCHO. \qquad (18C)$$

However, these results were not confirmed by any other investigator. The mechanism proposed by Sasaky et al. can hardly be regarded as probably bearing in mind the instability of free $CH_3^{\cdot}$ radicals. The fact that the reaction

$$CH_3O \rightarrow HCHO + H \qquad (18D)$$

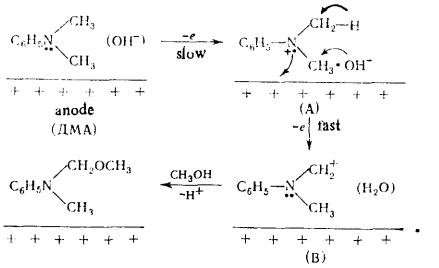
is endothermic [q = (−20)—(−40) kcal mole^{-1}] [93] is hardly an unambiguous indication that CH_3O· has sufficient stability for reactions (18B)—(18C), to occur as suggested by Sasaky et al.[99] Indeed, mechanism (18) itself shows that reaction (18D) does not constitute the only pathway for the removal of methoxy-radicals.

Many data indicating the formation of intermediate adsorbed radical products in the electrochemical oxidation of alcohols have been published[100-102]. The problems of the structure of these species have been the subject of special investigations in recent years by potentiostatic, galvanostatic, potentiodynamic, and radiochemical measurements[88,101-103]. However, these measurements were

made mainly in dilute aqueous solutions which precludes an unambiguous extrapolation of the results to alkoxylation conditions. This problem requires special consideration.

The oxidation of lower aliphatic alcohols in aqueous solutions up to high concentrations[100] has been intensively investigated in recent years in connection with the problem of fuel cells. As emphasised previously[88], the results of these investigations probably cannot be used for an unambiguous interpretation of the electrode processes in alkoxylation owing to the significant differences in reaction conditions. However, it would also be a mistake to ignore them completely (as is done in many investigations of the electrochemical alkoxylation), particularly since electrochemical synthesis of alkoxy-derivatives can take place also in aqueous alcoholic media[98].

A unanimous view on the mechanism of the anodic oxidation of alcohols in aqueous solutions does not exist either[101-103]. Electrochemical measurements at the electrode—alcohol solution boundary indicate the possible adsorption on the surface of the anode of a whole range of carbon-containing species characterised by different bonding energies with the surface. (For example: $\cdot C\begin{matrix}OH\\ \\ O\end{matrix}$, $\ddot{C}{=}O$, $\ddot{C}-OH$, and $\cdot CH_2OH$ in the oxidation of methanol and $CH_3\dot{C}HOH$ and $CH_3CH_2O\cdot$ for ethanol[104]). Some investigators[102] believe that in acid solutions methanol is oxidised via a stage involving the formation of the species $[COH]_{ads}$. Without special assumptions, such ideas are inconsistent with, for example, the results of the preparative electrolysis of acid alcoholic, including aqueous alcoholic solutions, which unambiguously demonstrate the homolytic addition of $CH_3O\cdot$ to the substrate molecule. According to the data of Podlovchenko et al.[105], the oxidation of methanol includes several parallel stages:

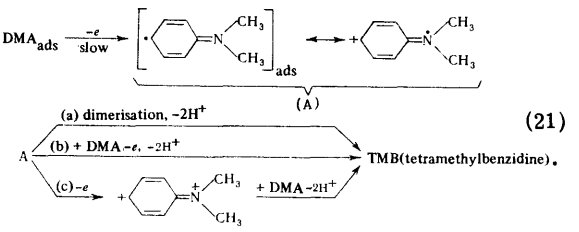


$$CH_3OH \rightarrow CH_3OH_{ads}\begin{cases}\longrightarrow SCS \rightarrow CO_2\\ \longrightarrow A_1 \rightarrow CO_2\\ \longrightarrow A_2 \rightarrow HCOOH\,(HCOO^-),\\ \longrightarrow A_3 \rightarrow H_2CO\end{cases} \qquad (19)$$

where SCS is a strongly chemisorbed substance and A_1, A_2, and A_3 are relatively weakly adsorbed species, whose composition has not been specified precisely. Analogous ideas were developed later by Breiter[106]. Although such mechanisms do not specify the nature of the adsorbed intermediates in the oxidation of the alcohol, they evidently allow a compromise with the results of electrochemical synthesis within the framework of the heterogeneous mechanism. Sasaky et al., who carried out the study on the electrochemical synthesis of alkoxybenzenes mentioned previously[52], also concluded that the reaction is heterogeneous. This conclusion is based on an analysis of kinetic data for the relation (which passes through a maximum) between the yield of the methoxy-derivative and the alcohol concentration.

In the study quoted previously[55], it was established that the products of the electrochemical synthesis of methoxy-derivatives of certain aromatic compounds differ significantly from the products of chemical methoxylation in the thermal decomposition of dimethyl peroxide (in particular, benzyl dimers, found among the products of the chemical synthesis, are not formed in the electrochemical synthesis). This anomaly can be readily explained if one postulates that the reaction layer is localised near the electrode (the high concentration of $CH_3O\cdot$ then prevents the dimerisation of benzyl radicals, promoting the formation of methoxy-derivatives).

The results of a study of the reaction involving amines lead to the conclusion that anodic alkoxylation is a heterogeneous process[17,40,73,74]. In particular, according to the data of Weinberg et al.[17,40], the adsorption of the substrate is an essential stage in the methoxylation of tertiary amines. Initially this conclusion was based on the structure of the electrochemical oxidation product of *NN*-dimethylaniline[40]. Subsequently it was confirmed by kinetic data[74]. The authors observed a fractional reaction order with respect to the amine, which is characteristic of the adsorption of substrate molecules in accordance with the Temkin or Freundlich isotherm[107]. Convincing evidence in support of the adsorption of the 1,3-diene under the conditions of anodic alkoxylation was also obtained by Zhurinov et al.[98]



A number of studies carried out in recent years[88,103] also involved the investigation of the electrochemical behaviour of the substrate at the anode. The half-wave potentials for the oxidation of substances used in the alkoxylation reactions demonstrate the possibility, in principle, of oxidising many of them in the range potentials in which electrochemical synthesis is usually carried out. The results of studies by Eberson and coworkers[108-111] and also other workers[112-114] show that many electrochemically generated radicals may be oxidised further at their formation potentials. These data have led some investigators to hypotheses concerning the involvement of the substrate, including its ionised form, in the reaction[17,40,73,74]. For example, according to Weinberg and Reddy[17], the alkoxylation of tertiary amines proceeds via a stage involving the oxidation of the adsorbed amine molecules. Analysis of the Tafel sections of the polarisation curves and also of the potential—time relations under galvanostatic conditions led the authors to the conclusion that the molecule is oxidised electrochemically in steps. In the first, rate-limiting stage, one electron is abstracted with formation of a radical-cation. This is followed by a rapid stage with further one-electron oxidation of the radical-cation A and solvolysis with formation of the methoxy-derivative:

(20)

The wide variety of reaction products can be accounted for within the framework of this mechanism taking into account the pH of the electrolyte. The basicity of the solution promotes the deprotonation of the adsorbed radical-cation A.

In the absence of deprotonation facilitated by the hydroxide ion, the radical-cation A can enter only into the dimerisation reaction according to the equations

(21)

Kinetic data do not allow a choice between the three versions (a), (b) and (c). Other workers who investigated this reaction[74] also postulate the involvement of ionised intermediates in it, but they assume that the adsorbed radical and not the aniline molecule is oxidised. Smith and Mann[74] believe that the initial stage is the electrochemical oxidation of the methoxide anion to $CH_3O\cdot$, which dehydrogenates the amine moiety in the side chain:

$$CH_3O^- - CH_3O\cdot + e;\ 2CH_3O\cdot + 2PhCH_2N(CH_3)_2 \xrightarrow{-2CH_3OH} \underset{(I)}{PhCH_2-\overset{\cdot}{\underset{|}{N}}(CH_2)-CH_3} + \underset{(II)}{PhCHN(CH_3)_2}.$$

Methoxylated products are obtained as a result of the solvation of the radical-cations (III) and (IV) formed in the oxidation of the radicals (I) and (II) at the electrode:

$$\text{(I) or (II)} \xrightarrow[\text{anode}]{-e} \underset{(III)}{PhCH_2\overset{+}{\underset{|}{N}}(CH_2)-CH_3} \text{ or } \underset{(IV)}{PhCH\overset{+}{N}(CH_3)_2},$$

$$\text{(III) or (IV)} + CH_3O^- \rightarrow \underset{(V)}{PhCH_2\underset{|}{N}(CH_2OCH_3)-CH_3} \text{ or } \underset{(VI)}{PhCH\underset{|}{N}(OCH_3)(CH_3)_2}. \qquad (22)$$

The preferential formation of compound (V), which was also noted by Weinberg and Reddy[17], is attributed to the higher stability of compound (II) compared with (I). The hypothesis of the electrochemical oxidation of the substrate as a necessary stage in alkoxylation has also been adopted by certain investigators for furan derivatives[22,60]. This pathway is adopted, as an alternative to the purely homolytic mechanism, for the reaction with aromatic compounds[55]. The mechanism is analogous to that discussed above and involves the oxidation at the electrode of the radical generated in the homolytic deprotonation of the substrate molecule by the electrochemically generated methoxy-radical:

$$RH \xrightarrow{CH_3O\cdot} R\cdot \xrightarrow[\text{anode}]{-e} R^+ \xrightarrow{CH_3O^-} ROCH_3. \qquad (23)$$

Similar views have gained acceptance for the mechanism of the formation of ethers. This process is frequently accompanied by the Kolbe reaction[67,115-119] and proceeds as follows[18]:

$$RCOO^- \xrightarrow{-e} RCOO\cdot \xrightarrow{-CO_2} R\cdot \xrightarrow{-e} R^+ \xrightarrow[-H^+]{CH_3OH} ROCH_3. \qquad (24)$$

Wladislaw and Viertler, who investigated the successive anodic oxidation of certain phenylacetic acids, arrived at the same conclusion. They believe that the acid molecule undergoes two-electron oxidation at the anode[119].

However, it should be noted that in many studies the formation of carbonium ions is postulated only on the basis of the formal possibility of the oxidation of substrate molecules. For a correct solution of this problem, it is necessary to carry out electrolysis in each case at a measured potential in combination with the study of the electrochemical behaviour of the substrate itself. This problem has been discussed in greater detail in two reviews[88,103].

Chemical Defects in Macromolecules of Heterounit Polymers

V.V.Korshak

This review discusses reasons for the appearance of chemical faults in macromolecules during the preparation of polymers by addition polymerisation or polycondensation and as a result of substitution, oxidation, and other reactions of polymers. The presence of anomalous monomer units in chemically imperfect macromolecules leads to the formation of heterounit polymers, and their presence in the latter exerts a great influence on the chemical and physical properties of the polymers. A list of 198 references is included.

CONTENTS

I. Chemical defectiveness of macromolecules 303
II. Modes of appearance of anomalous monomer units in macromolecules of heterounit polymers 304
III. Effect of anomalous monomer units on chemical properties of heterounit polymers 315
IV. Effect of anomalous monomer units on physical properties of heterounit polymers 318

I. CHEMICAL DEFECTIVENESS OF MACROMOLECULES

The dependence of the properties of polymers on their structure is one of the most important problems of polymer science, to whose solution a large number of investigators—both chemists and physicists—have directed their efforts. The Reviewer has adduced many examples of quite clear relations between structure and such properties of polymers as heat resistance and thermal stability[1]. It was found that, although the structure of a given polymer and its inherent combination of chemical and physical properties are determined by the fundamental structure of the monomer unit, a significant influence is exerted by the presence of anomalous units, which are responsible for the "chemical defectiveness of the macromolecular structure"[2-5]. This exhibits some analogy with the physics of solids, where the currently favoured theory is that the imperfection of the physical structure is the most important factor determining the real strength of any solid, including of course polymers[6,7].

The present Review aims to assess the significance of the chemical imperfection of macromolecules as a factor in determining the dependence of the properties of polymers on their structure. The Reviewer would also like to direct the attention of research workers to the finer details of the structure of macromolecules, and to show their value in establishing the dependence of the properties of polymers on structure.

The method generally adopted at present for representing polymer macromolecules indicate the structure only of the main component, whose repetition leads to formation of the macromolecular chain, as shown for instance by the formula of poly(vinyl chloride) $-[CH_2-CHCl]-$. All other structural features, usually designated the microstructure of the polymer—the nature of the end groups, the presence of branches and their number and size, the presence of abnormal monomer units differing in some way from the main units forming the polymer chain, the sequence of alternation of abnormal and normal polymer units, the spatial arrangement of the units and groups (the stereochemistry of the monomer unit and of the macromolecule), etc.—are incapable of representation by this method. This is probably one reason for the disregard of many important structural details of macromolecules, which are extremely significant for an understanding of the relation between the structure of polymers and their properties.

The importance of establishing the structure of the monomer unit and the relative arrangement of units in the macromolecule for an understanding of the properties of polymers was first appreciated by Harries[8] and Lebedev[9], and was systematically explored for a large number of polymers by Staudinger[10], Marvel[11], and other workers. Staudinger showed that the monomer units in the polystyrene macromolecule are linked in a uniform sequence[12]. Marvel[11] showed, with many different polymers as examples, that the same regular arrangement of monomer units is the fundamental law of the construction of macromolecules by polymerisation.

Further development of methods of investigation and a deepening knowledge of polymers led to our realisation that, together with the regular sequence of monomer units, there are several stereochemical and structural factors that are important for an understanding of the structure and the properties of polymers. Present-day methods of synthesising polymers are always accompanied by various types of side-reactions, leading to the formation in the polymer chain of a larger or smaller number of abnormal monomer units of various kinds, differing in some way from the main units. Cases have recently become more and more frequent in which certain apparently minor structural details of a polymer molecule actually have a very significant effect on the whole set of physical and chemical properties characterising the given polymer. Close study reveals that this is due to chemical defects in the macromolecules resulting from the presence of abnormal monomer units[2-5].

Abnormal monomer units influence the properties of the polymer as structural components of the macromolecule, their presence leading to a change in the polar effects between atoms both in this unit and in adjacent and sometimes even fairly remote neighbours, which influences the chemical properties of the polymer; they also make their contribution to the flexibility of and intermolecular interaction between the macromolecules, either weakening or strengthening it, but also influencing the character and degree of order of the macromolecules, which affects the physical properties of the polymer. Ideas based solely on the study of homopolymers are therefore no longer adequate for a proper understanding of the relations between the properties and the structure of polymers. A new approach is required, which would take into account all the aspects of the structure of polymeric molecules. In this connection with concept of "heterounit" polymers is of

fundamental significance, being the main type of polymeric structures which arises from the introduction of abnormal units into the macromolecule.

The chemical defectiveness of the macromolecular structure characteristic of heterounit polymers can be produced intentionally, as in all kinds of copolymerisation and polycondensation, as well as by substitution in a polymeric molecules, which are widely used for modifying the properties of polymers. In these cases, where we control the processes and can choose a desired extent of change in the polymer, the equivalent degree of chemical imperfection can vary within very wide limits.

Cases in which chemical imperfection arises spontaneously, contrary to our wishes, during the synthesis or the modification of a polymer, are far more important. Chemical defectiveness of a macromolecular structure usually results from the inclusion in the polymer chain of abnormal monomer units, having some kind of structural difference from the chief units. In several cases very reliable evidence has been obtained of the presence of abnormal units in polymer macromolecules. Still more cases are known in which there are weighty grounds for assuming their presence.

In every chemical reaction the main product is accompanied by a larger or smaller quantity of secondary products. The yield of the main product usually shows the proportion of the main reaction. The secondary products are removed on purification, and thus do not affect the quality of the main product, merely diminishing its yield. In the formation of polymers, however, all secondary products remain as an integral part of the polymer in the form of abnormal units, and this is one reason for its chemical defectiveness. Therefore, although we write the general formula for a polymer as $[M]_x$, where M represents a monomer residue, this is an idealised formula. It would actually be more correct to represent the structure of a real polymer by a formula such as $[-[M]_m-[A]_n-]_x$, where A is an abnormal unit and M a normal unit [3,5].

The types of chemical defectiveness of macromolecules and the ways in which the corresponding abnormal monomer units arise can be indicated briefly.

1. Abnormal units resulting from cross-links, side-chains, branches, and other abnormal structures.
2. Differences during addition polymerisation or polycondensation in the coupling of units "head to head" or "head to tail".
3. Isomerisation of monomer units during addition polymerisation and polycondensation.
4. Appearance of abnormal units owing to differences in the configuration of asymmetric carbon atoms forming the macromolecular chain ("tacticity").
5. Formation of abnormal units resulting from differences in the configuration of groupings having central, axial, and planar asymmetry.
6. Differences in geometrical isomerism of units formed by the polymerisation of dienes, and also those containing disubstituted rings.
7. Differences in the structure of monomer units resulting from conformational asymmetry and hindered rotation of the units.
8. Abnormal units resulting from incomplete trimerisation in the polycyclotrimerisation of diynes.
9. Abnormal units as the residue of incomplete formation of a carbocyclic or a heterocyclic ring during polycyclisation or polycyclocondensation.
10. Appearance of abnormal units as a result of copolymerisation and copolycondensation.
11. Abnormal monomer units resulting from chemical reactions of units in the macromolecule (chlorination, oxidation, dehydration, etc.).

The abundance of published data more or less closely connected with the present problem does not permit a complete review of the whole literature on this question, and only individual researches can be mentioned below as examples illustrating the principles under discussion.

II. MODES OF APPEARANCE OF ANOMALOUS MONOMER UNITS IN MACROMOLECULES OF HETEROUNIT POLYMERS

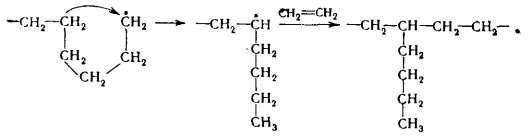
All the known syntheses and transformations of polymers are accompanied by various side-processes leading to the appearance of abnormal monomer units and the formation of heterounit polymers. Among reactions leading to the appearance of abnormal units are the recombination of macroradicals, intra- and inter-molecular chain transfer, formation of an atactic chain structure, isomerisation of monomer units, various types of copolymerisation and copolycondensation, various substitutions in the chain, and also various secondary processes occurring during polymerisation and polycondensation [3,5]. We use individual examples to examine the ways in which chemical imperfection appears in macromolecules during the synthesis and the transformation of polymers.

1. Appearance of Abnormal Monomer Units during Polymerisation

The polymerisation of unsaturated compounds by a radical or other mechanism is accompanied by such reactions as the recombination of macroradicals and also intramolecular and intermolecular chain transfer, isomerisation of the monomer unit, etc., leading to the formation of abnormal units. In the first case the recombination

$$(-CH_2CHX)_m-CH_2CHX^{\cdot} + {}^{\cdot}CHXCH_2-(-CHXCH_2-)_n- \rightarrow (-CH_2CHX-)_m-CH_2CHX-CHXCH_2-(-CHXCH_2-)_n$$

results in the appearance of the anomalous group $-CHX-CHX-$ in the chain. In the second case branches and side-chains of various lengths appear as a result of chain transfer.



The simplest example of such a polymer containing abnormal monomer units formed during polymerisation is high-pressure (low-density) polyethylene, in which the presence of a considerable number of small, and a small quantity of large, side-chains has been reliably demonstrated. As a result, of course, the macromolecule of such a polymer contains a considerable quantity of units having the structure

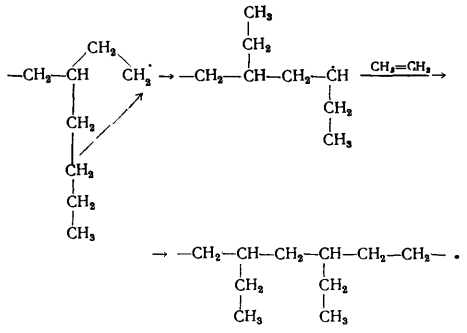
$$\cdots-CH_2-\underset{\vdots}{CH}-\cdots \quad \text{or} \quad \cdots-CH_2-\underset{R}{CH}-\cdots .$$

Such units arise from chain transfer, and their presence must therefore be assumed in all polymers obtained by radical polymerisation. The presence of such units in some polymers of this type has been proved experimentally [13]. The formation of long side-chains is a result of intermolecular chain transfer:

$$-CH_2-CH_2-CH_2-CH_2- \xrightarrow{R^{\cdot}} -CH_2-CH_2-\dot{C}H-CH_2- \longrightarrow$$
$$\xrightarrow{CH_2=CH_2} -CH_2CH_2-\underset{\displaystyle CH_2-CH_2-}{\overset{\displaystyle |}{CH}}-CH_2- .$$

Short branches are formed by intramolecular chain transfer [14]:

Butyl side-chains are formed in this way. Ethyl groups, however, are produced by the reaction



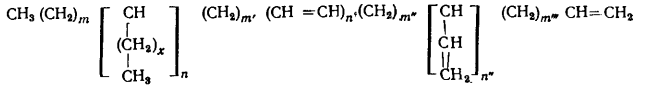


Table 1. Presence of abnormal groups in polyethylene [15].

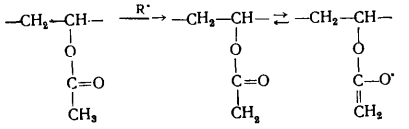

Abnormal group	Abnormal groups per 1000 carbon atoms in	
	low-density (high-pressure) polyethylene	high-density (low-pressure) polyethylene
Methyl (total content) including end-groups	21.5	3.0
Methyl (in side-chains)	4.6	~2.0
Ethyl (in side-chains)	2.5	—
Ethylenic bonds including (% of bonds)	14.4	1.0
$R-CH=CH_2$ type	0.6	0.7
$RR'C=CH_2$ type	15.0	43.0
$R-CH=CH-R'$ type	68.0	32.0
	17.0	25.0

As a result of this, polyethylene obtained by radical polymerisation (low-density polyethylene) contains such groups as ethyl and butyl, together with long side-chains [13]. Furthermore, its macromolecule contains double bonds both in the main chain and in side-chains. Table 1 gives the results of an investigation of the structure of polyethylene [15]. Consequently the actual structure can be represented by the formula

where in low-density polyethylene $n = 20-40$, $n' = 1$ or 2, $n'' = 1$ or 2, and $x = 0-1000$; and in high-density polyethylene $n = 1$ or 2, $n' = 1$ or 2, $n'' = 1$ or 2, and $x = 0-10$. Determination of the presence of side-chains in several samples of high-pressure polyethylene showed that the relative degree of branching decreased as the chain grew, although the content of methyl groups per macromolecule increased (Table 2) [16].

Investigation of the copolymerisation of ethylene with vinyl acetate [14] showed that the degree of branching of the copolymer increased with rise in temperature (Fig. 1). In the case of poly(vinyl acetate) branchings of the polyethylene type may be accompanied by branchings as a consequence of chain transfer via the acetyl group [17]:

which leads to the formation of readily hydrolysable units having the structure

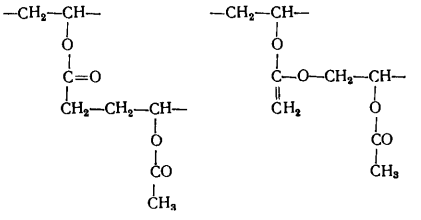

Table 2. Content of methyl groups in various specimens of high-pressure polyethylene.

Mol. wt.	No. of CH_3 per		Mol. wt.	No. of CH_3 per	
	1000 C	macromolecule		1000 C	macromolecule
1700	48	5.5	24000	31	52.0
2400	44	7.1	28000	28	54.0

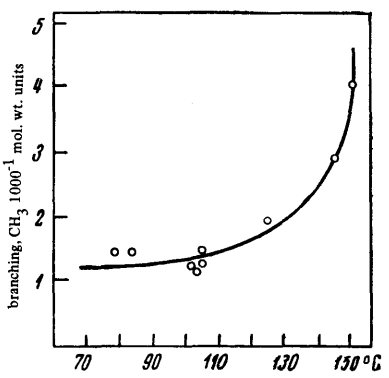
6600	38	17.5	53000	18	67.5
19000	37	48.5	76000	18	93.5
21000	33	48.5			



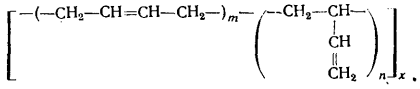


Figure 1. Effect of temperature of polymerisation on branching of a copolymer of ethylene with vinyl acetate.

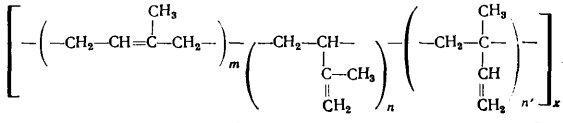
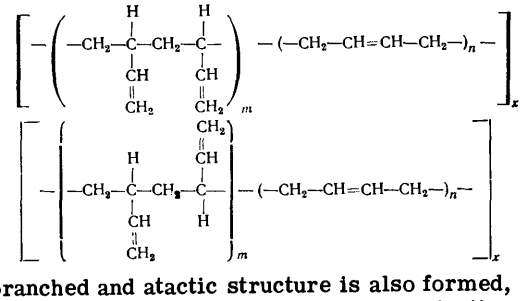
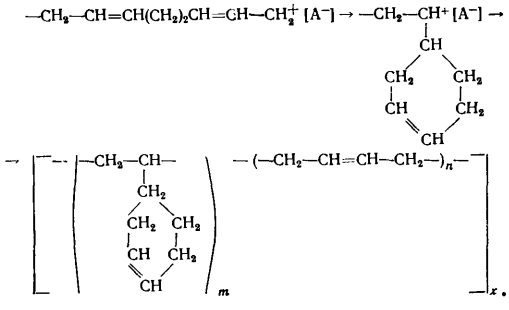


A similar branching reaction is possible also with other esters of poly(vinyl alcohol), as also with polyacrylic and polymethacrylic esters.

The polymerisation of dienes is extremely sensitive to conditions, so that polymers of varied structure can be obtained. Dolgoplosk and Tinyakova[18] examined the mechanism of the polymerisation of dienes and the microstructure of the resulting polymer chain, and showed that the polymerisation of butadiene may lead to the formation of polymers containing monomer units linked together at the 1,2- and 1,4-positions, of *cis*- and *trans*-configuration, and also cyclic units and other structures. With polymers of isoprene 3,4-units may also appear[19].



We thus meet a very large variety of abnormal units in the polymers of dienes. The first type of synthetic rubber, obtained by Lebedev's method[20] of polymerising butadiene by the action of metallic sodium, were polymers containing butadiene units linked together at the 1,2- and 1,4-positions in both *cis*- and *trans*-configurations[21]

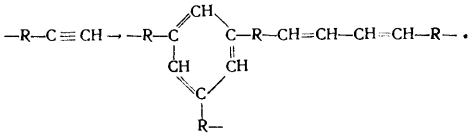


Polymers of butadiene and isoprene obtained in the presence of organometallic catalysts contain far fewer abnormal units. Thus polyisoprene contains 96% and 92% of *cis*-1,4-units when prepared in the presence of a complex of titanium(IV) chloride and triethylaluminium[22] and in the presence of alkyl-lithium catalysts[22,23] respectively. The isoprene polymer obtained in the presence of π-allylnickel iodide contains 95% of 1,4-*trans*-units, 1% of 1,2-units, and 4% of 3,4-units, and its structure can be represented by the formula[24]

Butadiene and isoprene 1,2-polymers containing predominantly isotactic or syndiotactic units were obtained in the presence of a Ziegler–Natta catalyst[25]. The structure of these heterounit polymers can probably be represented

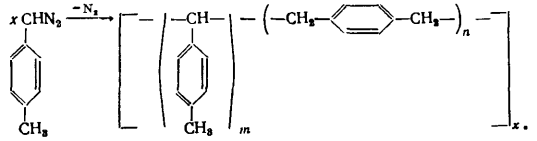
A branched and atactic structure is also formed, though to a less extent, in the case of ionic polymerisation, as we have already seen in the case of low-pressure (high-density) polyethylene. In the cationic polymerisation of butadiene Dolgoplosk et al.[18,26] observed the formation of six-membered rings by the reaction

The polymerisation of cyclohexa-1,3-diene yields polycyclohexene having different degrees of chemical imperfection depending on the nature of the catalyst: in the presence of organometallic and Ziegler catalysts a polymer containing 1,2- and 1,4-units and having the structure[27]



is formed; with π-allylnickel iodide as catalyst the resulting polymer contains 83% of 1,4-units[24].

Atactic polymers, which are formed both in radical and in ionic polymerisation, also represent a case of the presence of randomly arranged foreign *laevo*-units in a chain of *dextro*-units, which is in general characteristic of polymers obtained by radical polymerisation[28]. Natta showed[29] that in this case the difference in structure of the units is stereochemical. Atactic polymers are in general more correctly regarded as random copolymers of *dextro*- and *laevo*-forms, in contrast to a regular copolymer of these forms, represented by the corresponding syndiotactic polymer.

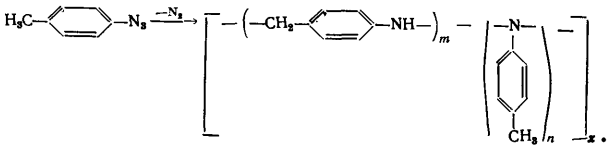


Polymerisation in the presence of oxygen leads to the formation of polymers containing anomalous peroxy-units[30] $CH_2.CHX.O.O$ or ether links $CH_2.CHX.O$ arising from the breakdown of these peroxides. Similar abnormal units appear when polymerisation is initiated by polymeric acyl peroxides, e.g. terephthaloyl peroxide[31]. The initiation of polymerisation by radiation leads to the formation of branched or cross-linked polymers containing abnormal units[32].

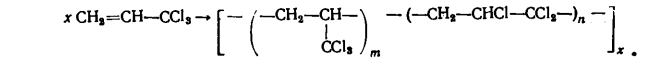
In the polycyclotrimerisation of diacetylenic derivatives with the formation of polyphenylenes defective units are produced as residues of incomplete cyclisation[33]:

2. Abnormal Units Resulting from Isomerisation of Units During Polymerisation

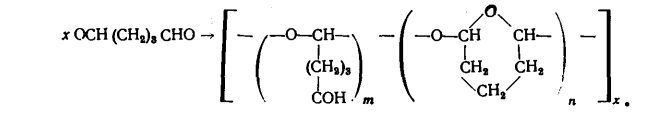
In several cases of polymerisation the resulting units undergo isomerisation, so that heterounit polymers are formed containing two or more types of units. Isomerisation occurs mostly as a result of hydrogen migration, but cases are known of the migration of chlorine, e.g. in the polymerisation of 3,3,3-trichloropropene, or even rearrangement of the electronic structure of the monomer without the migration of hydrogen, as with acrylonitrile, dimethylketen, glutaraldehyde, and other dialdehydes. Thus Korshak et al. showed[34] that the polymerisation of *p*-tolyldiazomethane involved not only formation of the normal *p*-methylbenzylidene units but also isomerisation with the appearance of an appreciable quantity of *p*-ethylenephenylene units. As a consequence the structure of the resulting polymer corresponds to the formula



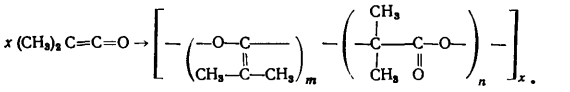
Similar isomerisation was observed in the polymerisation of diazoethane, with the formation of a heterounit polymer



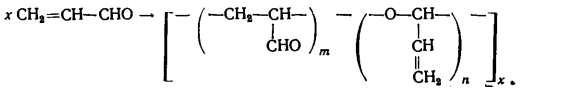
containing ethylene units [35]:



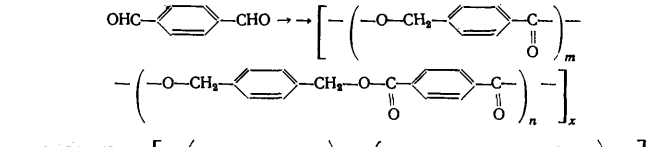
A heterounit polymer with isomerised units probably having the following structure was formed [36] in the catalytic decomposition of *p*-tolyl azide in the presence of sulphuric acid:



Suprun et al. found [37] that the polymerisation of 3,3,3-trichloropropene, owing to isomerisation involving migration of a chlorine atom, yields a heterounit polymer:

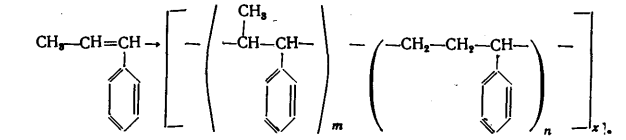


The polymerisation of glutaraldehyde occurs in two ways, with formation of a heterounit polymer [38]:



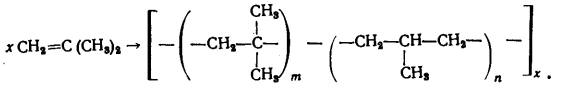
According to Natta et al. [39] dimethylketen polymerises in the presence of triethylaluminium to a polyketone–polyacetal, which is a heterounit polymer:

The polymerisation of acrylaldehyde in the presence of weak ionic catalysts lead to the formation of a heterounit polymer containing both ether and carbon–carbon links [40]:



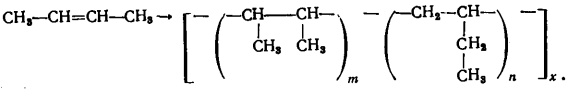
The polymerisation of terephthalaldehyde and of biphenyl-*pp'*-dialdehyde in the presence of organoaluminium or organozinc compounds also shows an unusual course, leading to the formation of heterounit polymers [41,42]:

where

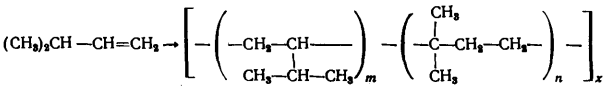


The ionic polymerisation of certain vinyl compounds, substituted styrenes, and vinylpyridines often occurs as migration polymerisation with hydrogen transfer and the formation of heterounit polymers containing in the main chain carbocyclic and heterocyclic rings together with other abnormal units [43,44]. The first case of this type of isomerisation polymerisation with migration of hydrogen [45,46] was probably the polymerisation of anethole [46] and β-methylstyrene [45] studied by Staudinger, which in the latter case gave a heterounit polymer of probable structure

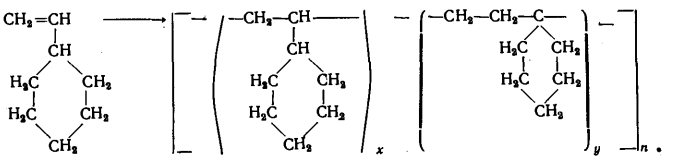
Kennedy showed [48] that an analogous polymer is obtained by the cationic polymerisation of allylbenzene.



Topchiev et al. [47] showed that in the case of isobutene isomerisation polymerisation led to the formation of a heterounit polymer:

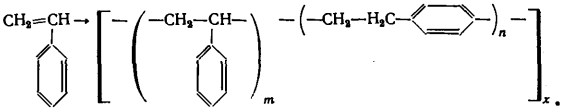


Isomerisation polymerisation with hydrogen transfer has been observed also with many other alkenes [43]. Thus propene gives a heterounit polymer corresponding to a copolymer with ethylene [49,50]:

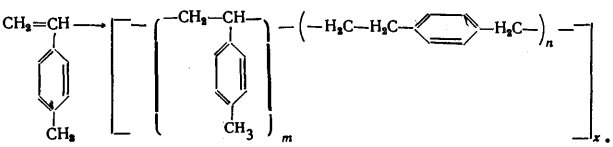


But-2-ene also forms a heterounit polymer [51]:

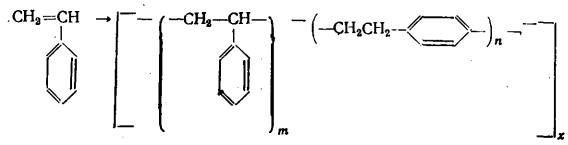
Isopentene yields a polymer of the following structure [52]:



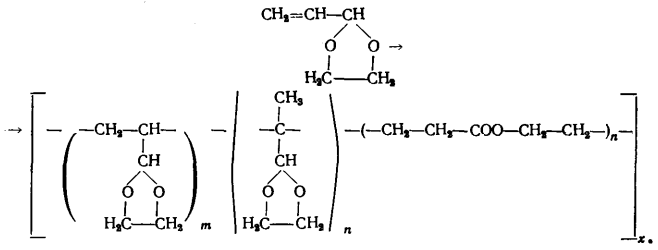
The ionic polymerisation of vinylcyclohexane produces a heterounit polymer containing, together with normal units, abnormal units in which the cyclohexane ring enters the polymer chain [53]:



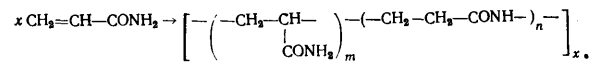
Abnormal monomer units of this type are characteristic of "card" polymers.



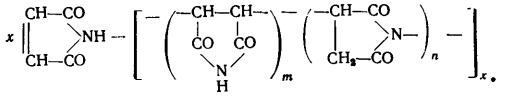
Styrene as a result of isomerisation polymerisation forms a polymer containing not only styrene but also *p*-ethylenephenylene units [54]:



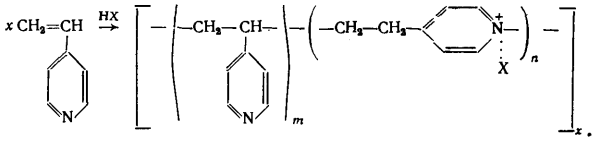
An analogous result was obtained also by the polymerisation of *p*-methylstyrene [55]:



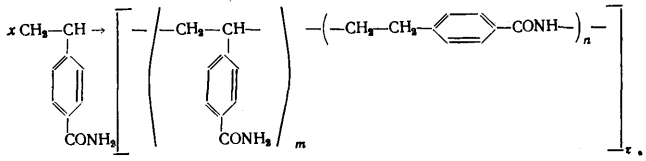
In the case of allylbenzene the resulting polymer has the following structure[56]:



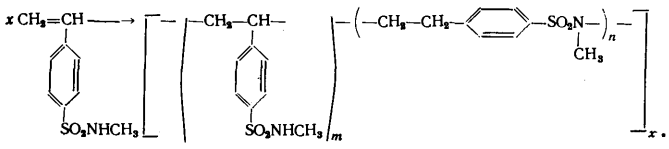
In the case of 2-vinyl-1,3-dioxolan the polymer may have a still more complicated structure[57]:



Acrylamide in the presence of basic catalysts undergoes isomerisation to form a heterounit polymer[44,58]:

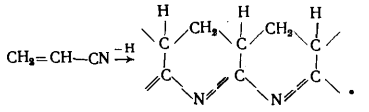


The anionic polymerisation of maleimide in dimethylacetamide similarly yields a heterounit polymer containing not only normal units but also abnormal units formed by the migration of hydrogen[44,59]:



Migration of hydrogen takes place in the polymerisation of 4-vinylpyridine in the presence of acids with the formation of ethylenepyridinium units[60]:

Under conditions of anionic polymerisation *p*-vinylbenzamide forms a heterounit polymer containing different proportions of normal and abnormal units[44,58,59,61-63]:



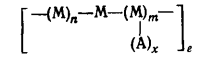
N-Substituted *p*-vinylbenzenesulphonamides behave similarly, forming heterounit polymers by the reaction[44,64,65]

The polymerisation of acrylonitrile under the influence of X-rays[66], γ-rays[67], or fast electrons[68] produces a heterounit polymer containing up to 10% of ketenimine structures:

Nevertheless, the radiation polymerisation of acrylonitrile in the solid phase at low temperatures leads to formation of a syndiotactic polymer, wnereas at high temperatures fused nitrogen-containing rings are obtained[68,69]:

3. Appearance of Abnormal Units during Copolymerisation

Copolymerisation leads to the formation of copolymers containing various quantities and proportions of foreign units, which are therefore heterounit polymers. In this case not only the quantity but also the arrangement of foreign units is especially important. Thus with a regular alternation of the different units we no longer have a copolymer but a true homopolymer having a long repeating unit, as occurs e.g. in the copolymerisation of sulphur dioxide with unsaturated compounds to form polysulphones



or in the migration copolymerisation of diols or diamines with di-isocyanates to form polyurethanes or polyureas

The concept of the defectiveness of macromolecules is of practical value, of course, only when one type of unit predominates. When the two types of units are present in equal quantities, the concept obviously loses the meaning in which it is used in the present paper.

Simultaneous polymerisation may lead to the formation of different types of copolymers, which may even have the same elementary composition. Thus at present we are acquainted with such different types as block copolymers (in particular polyallomers), graft copolymers, random copolymers, and also diagonal or insymmetrical copolymers and copolymers with a regular alternation of different units[70-72]. The introduction of one or more other types of copolymers into a particular type will undoubtedly yield a "copolymer of copolymers", which may be a polymer with chemically defective macromolecules.

Among the above types of copolymers those with a regular alternation of units must be regarded as homopolymers. Their structure can be represented by the general formula $[M.A]_x$, whereas in the case of statistical copolymers, which are heterounit polymers, the general formula expressing their structure will be $[[M]_n.[A]_m]_x$, where $n = 1, 2, 3, \ldots$, $m = 1, 2, 3, \ldots$, and $n \neq m$. Hence we should again have a regular copolymer when $n = m$. A block copolymer will be represented by the same general formula but with $n \neq m$, $n > 10$, and $m > 10$. In the case of a graft copolymer the general formula will be

in which $n + m > 1000$, $x > 10$, and $e = 1-10$ and above.

The copolymerisation of styrene with divinylbenzene by Staudinger [73] was the first case in which a branched and cross-linked polymer was obtained. This type of imperfection is met widely in ion-exchange resins, since in this way insoluble granules of limited swelling can be obtained. The "copolymerisation" of styrene with ϵ-caprolactam also yields a graft copolymer with a chemically imperfect macromolecular structure [74].

The peculiar polymers known as "diagonal" or "unsymmetrical", obtained by the copolymerisation of a mixture of two monomers of variable composition, should also be regarded as heterounit polymers. They differ from the other examples in the variation in structure of the units along the length of the macromolecule [71].

A more detailed description of copolymerisation and the properties of copolymers lies outside the scope of the present paper. The account will therefore be confined to the above examples, illustrating the fact that most copolymers are heterounit polymers.

4. Formation of Abnormal Units during Polycondensation

Two groups of polycondensation processes, differing significantly in reaction mechanism and termed respectively "equilibrium" and "non-equilibrium" polycondensation, have been distinguished. We must therefore take into account their differences in considering individual examples of reactions of each type [75-83]. Heterounit polymers can also be formed in various ways during polycondensation.

As in the various cases of polymerisation discussed earlier, polycondensation may also involve reactions leading to the formation of various abnormal units—containing side-chains and branches, cross-links, anomalous groups in the main chain—as well as all kinds of stereochemically distinguishable units yielding macromolecules having structures similar to those in atactic, isotactic, and syndiotactic polymers obtained by stereospecific polymerisation. The concept of "tacticity" has a specific sense when applied to polycondensates [84]: it covers units containing carbon atoms with two different substituents, *cis*- and *trans*-isomers with multiple bonds and with a disubstituted ring, and also groups with central, axial, and planar asymmetry. In complicated polymers stereoregular structures may be formed also as a result of the appearance of stable conformations [85]. Another important source of abnormal units is the residue of incompletely cyclised units remaining during polycyclisation or polycyclocondensation.

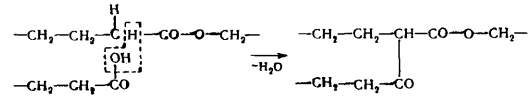
Let us cite a few examples of the formation of heterounit polymers during equilibrium polycondensation. Thus the polycondensation of dicarboxylic acids with glycols in the presence of mineral acids is accompanied by the formation of ethers:

$$HOR—OH+HO—R—OH \xrightarrow{-H_2O} HO—R—O—R—OH.$$

As a consequence, abnormal units containing an ether bond

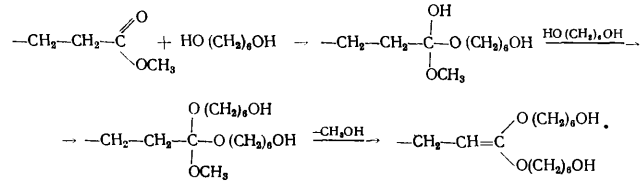
$$—O—R—O—R—O—CO—R'—CO—$$

appear in the polyester macromolecule [86]. In the polycondensation of glycerol this reaction leads to the formation of units containing biglycerol



$$—O—CH_2—\underset{\displaystyle OH}{CH}—CH_2—O—CH_2—\underset{\displaystyle OH}{CH}—CH_2—O—$$

and polyglycerols [87,88].



The equilibrium polycondensation of ethylene glycol with terephthalic acid or its dimethyl ester in the presence of most catalysts leads to the formation of poly(ethylene terephthalate) melting at 256°C. [89] However, the use of sulphuric acid as catalyst yields a polyester of lower melting point, owing to the formation of a heterounit polymer containing ether bonds

$$[—(—OCH_2CH_2OCOC_6H_4CO—)_m—(—OCH_2CH_2OCH_2CH_2OCOC_6H_4CO—)_n—]_x.$$

The formation of branched polyesters on prolonged heating of the reaction mass was observed by Staudinger and Schmidt [90], who explained this result by dehydration

or by formation of a keten acetal

When unsaturated monomers such as maleic and fumaric acids are used in polycondensation, polyesterification is accompanied by secondary addition of the glycol to the double bond with the formation of hydroxyethoxysuccinic esters [91,92]:

$$—CO—CH=CH—CO—O—CH_2CH_2—O— \xrightarrow{HOCH_2CH_2OH} \rightarrow —CO—CH_2—\underset{\displaystyle O—CH_2—CH_2—OH}{CH}—CO—O—CH_2CH_2—O—.$$

At the later stages of conversion this reaction leads to branching and cross-linking of the polymer. During polycondensation with the glycols investigated in detail by Petrov [93] and by others [94] maleic acid isomerises into fumaric acid, to yield polyesters which are heterounit polymers, and can be regarded also as copolymers of the two acids. The degree of conversion may reach 70–90% depending both on the nature of the glycol and on the conditions of polycondensation.

Polyamides prepared by prolonged heating in the molten state form branched products having the structure

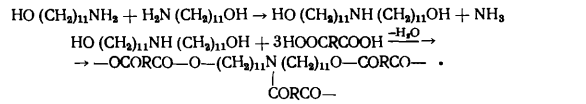
$$\begin{matrix}—NH(CH_2)_6NH—CO(CH_2)_8CO \\ —NH(CH_2)_6NH—CO(CH_2)_8CO\end{matrix}\!\!>\!N(CH_2)_6NH—CO(CH_2)_8CO—.$$

Such observations were made by Champetier [95,96] and by other workers [97-99] on both aliphatic and aromatic polyamides. According to Meacock [100] as well as Kamerbeek et al. [101] heterounit polyamides result from the formation of secondary amino-groups by the reaction

$$—CO(CH_2)_4CO—NH(CH_2)_6NH_2 + H_2N(CH_2)_6NH—CO(CH_2)_4CO— \xrightarrow{-NH_3} \rightarrow —CO(CH_2)_4CO—NH(CH_2)_6NH(CH_2)_6NH—CO(CH_2)_8CO—.$$

These groups react with terminal carboxy-groups of other macromolecules to produce branched polyamides

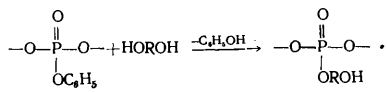
$$—CO(CH_2)_4CO—NH(CH_2)_6\underset{\displaystyle CO(CH_2)_4CO—NH(CH_2)_6NH—}{N}(CH_2)_6NH—CO(CH_2)_4CO—.$$



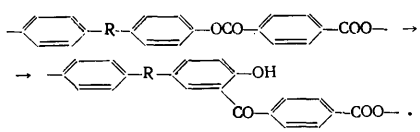
Thomas showed [102] that, when polyamides are prepared from diamines and dicarboxylic esters at high temperatures, the diamine may undergo alkylation

$$H_2NRNH_2 + 2R'COOCH_3 \rightarrow CH_3NHRNHCH_3 + 2R'CO[illegible]$$

with the formation of methyl side-groups in the polyamide

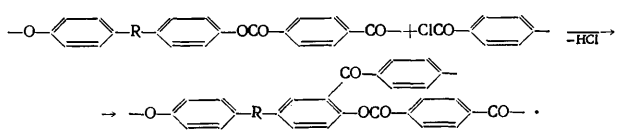


The formation of branched and three-dimensional poly(amide–esters) by the polycondensation of ω-amino-alcohols with dicarboxylic acids results from the elimination of ammonia and the formation of amino-glycols [103]:

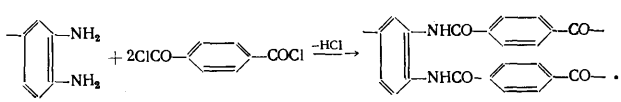


The presence of different functional groups in the initial monomers, and subsequently in the polymer macromolecule, may lead to branching and ultimately to the formation of three-dimensional polymers, as has been shown with *N*-cyanoethylated polyamides [104].

The synthesis of poly(ethyl ethylene orthophosphates) is accompanied by transesterification with the formation of branches [105]:

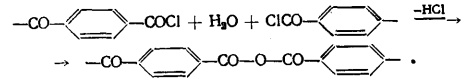


Formation of branched polyesters in the polycondensation of a glycol with an unsaturated acid, e.g. fumaric or maleic, may result also from the dimerisation or the polymerisation of the acid during the reaction [106]. Lavalou [107] observed cross-linking also in the polycondensation of ω-aminoundecanoic acids containing such *N*-substituents as allyl, undec-10′-enyl, and 2′-hydroxyethyl. Cross-linking of polyesters may result also from their oxidation by oxygen during preparation [108].

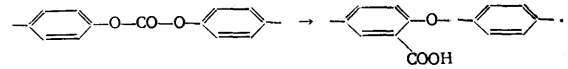


Although the laws of non-equilibrium polycondensation, like the structure of the polymers obtained, have been investigated less thoroughly, we shall consider some examples showing that heterounit polymers are formed in this process. Branched polymers may be produced by direct acylation or by a rearrangement analogous to the Fries rearrangement. Thus in the synthesis of polyarenoates branching may occur in conformity with the equation [109]

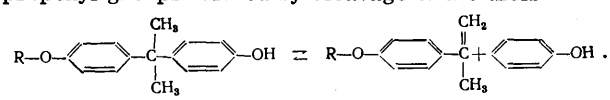
The resulting phenolic hydroxyl in then able to react with an acid chloride to form a branch. Acylation can cause branching as a result of the reaction



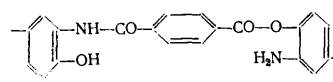
Branching can occur in the reactions of the dichlorides of dicarboxylic acids with tetramines, bis-*o*-amino-phenols, and bis-*o*-amino-thiols:



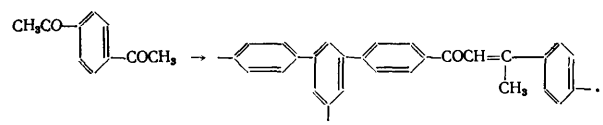
The action of water on a solution of such a dichloride in triethylamine yields a polyanhydride of terephthalic acid [110]:



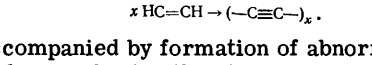
Therefore the presence of traces of moisture in the low-temperature polycondensation of acid chlorides with dihydric phenols may lead to the appearance of anhydride groups in the macromolecule by the reaction



Schnell [111] considered it possible that a Kolbe type of side-reaction leading to the formation of branched and cross-linked structures may occur in the preparation of polycarbonates from diphenyl carbonate:

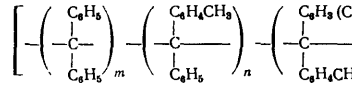


He also considers [112] that branching may result from the polymerisation of polycarbonates involving terminal isopropenyl groups formed by cleavage of the diols



When dichlorides of dicarboxylic acids undergo polycondensation with biaminophenylmethanediols or bisaminophenylmethanedithiols (in which the amino-group is *ortho* to the hydroxy- or mercapto-group), their analogues and homologues, reaction can occur in two directions with the formation of abnormal units of isomeric structure, e.g.

In the polycyclocondensation of diketones the phenyl rings may be accompanied by aliphatic units remaining from incomplete cyclisation [113]:



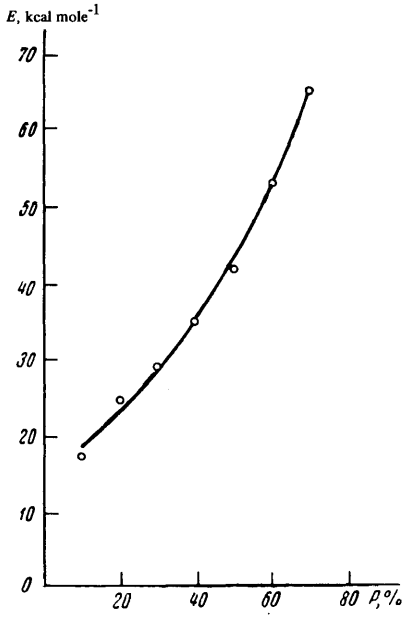
The oxidative dehydropolycondensation of acetylene yields a linear form of polymeric carbon, which is a third allotropic modification of carbon termed "carbyne" [114]:

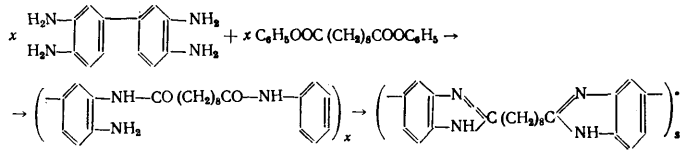
This is accompanied by formation of abnormal units and block copolymers having the structure

A side-reaction in the polyrecombination of diphenylmethane is methylation of the benzene rings by the action of methyl radicals, so that the resulting polymer contains tolyl and xylyl groups [115]

Polycyclisation is one of the most important types of reactions in non-equilibrium polycondensation [116]. It occurs in two stages: the linear polymer formed initially then undergoes cyclisation, and is thus converted into a

ring–chain polymer. However, several examples have shown that the second stage is almost always incomplete. One reason is increasing rigidity of the chain causing steric hindrance to cyclisation. This is shown in an increase in the activation energy of cyclisation during the process, as illustrated by Fig. 2, in which are plotted results of the cyclisation of a polyhydrazide [117]. The reason for this increase in activation energy and consequent decrease in rate of polycyclisation is the stiffening of the polymer macromolecules caused by the formation of oxadiazole rings, since this diminishes the mobility of the units necessary for them to overcome the stereochemical obstacles to cyclisation. Therefore the macromolecules of the resulting ring–chain polymer always retain some proportion of uncyclised units as a residue of incomplete cyclisation: i.e. these are abnormal units in the resulting heterounit polymer.





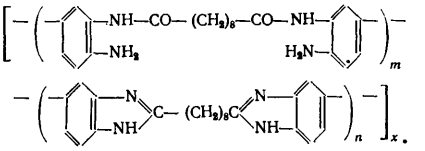


Figure 2. Variation of activation energy for the cyclodehydration of a polyhydrazide of diphenylphthalidedicarboxylic acid with completeness of conversion P.

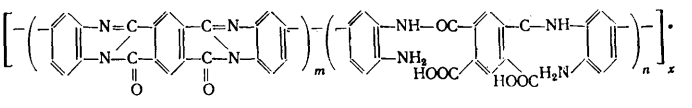
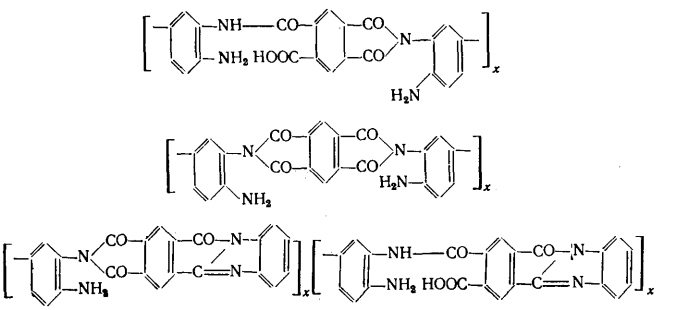
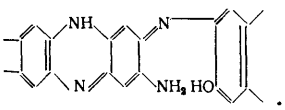
Thus the polycondensation of aromatic bis-*o*-diamines with diphenyl esters of aromatic dicarboxylic acids leads to the formation of polybenzimidazoles:



At any stage in this reaction, however, the product is a heterounit polymer containing amino-amide and benzimidazole units in the macromolecule, so that its structure is more correctly represented by the formula [118,121,122]

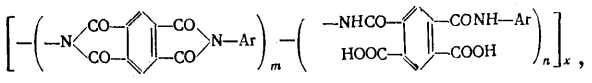


Examination of polybenzimidazoles which have been dehydrated at 270°C showed that they contained about 69% of benzimidazole and 31% of amino-amide units [121].



The structure of pyrrones—products of the reaction between tetracarboxylic anhydrides and bis-*o*-diamines—has also been studied very carefully in view of the especially high thermal stability expected [123–129]. Application of a thermodynamic method by Rabinovich et al. [123] established that the pyrrone macromolecule contains 66% of benzoylenebenzimidazole and 34% of amino-amide units, the latter remaining from incomplete cyclisation. Their structure is therefore represented more accurately by the formula

It must be borne in mind, of course, that this formula contains only the two extreme structures: several intermediate structures may also be present, formed in the passage from the amido-amino-acid to the benzoylenebenzimidazole, e.g.

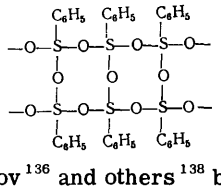


Incomplete cyclisation has also been suggested in the ladderlike polyquinoxalines obtained by Stille and Mainen [130] from 2,5-dihydroxy-*p*-benzoquinone and benzene-1,2,4,5-tetra-amine, so that the chain should contain units of the two types

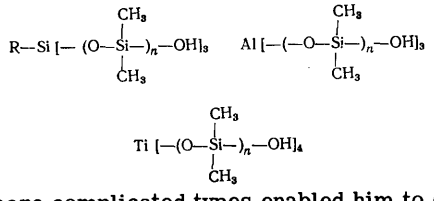
A similar hypothesis was put forward by Okeda and Marvel for polyquinoxalino-oxazines [131] and polyquinoxalino-thiazines [132].

Polypyromellitimides also contain a considerable quantity of uncyclised units. Thus Bruck [133] found that the polypyromellitimide obtained from bis-*p*-amin[illegible]yl ether contained only 78% of imide units, with 22% of

amido-acid units remaining uncyclised, so that a more correct formula for this heterounit polymer is



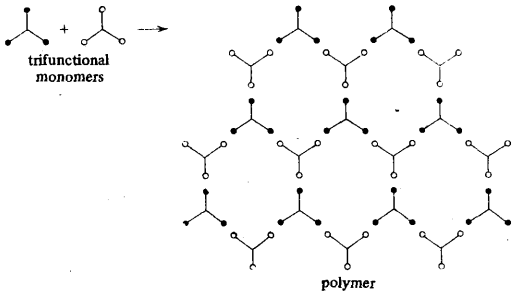
where



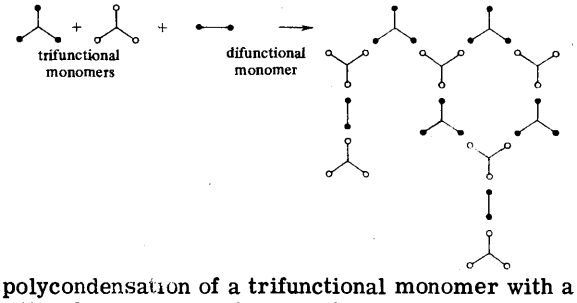
Investigation of several polyheteroarylenes obtained recently has revealed the presence of a considerable quantity of uncyclised units also in polyquinoxalines [130], polybenzoxazoles [134], polyoxadiazoles [117], polypyridines [135], etc.

Thermal dehydrocyclisation—a process widely applied to the synthesis of various thermostable polymers—represents a novel type of pyrolysis involving the elimination only of water. Genuine pyrolysis is often a polycondensation process occurring with the elimination of volatile products—water, carbon dioxide, carbon monoxide, hydrogen, methane and other saturated and unsaturated hydrocarbons, and benzene and other aromatic compounds—the composition of which varies with the temperature and the conditions of pyrolysis. The non-volatile product of pyrolysis is coke or graphite, whose structure and properties also depend on the structure of the starting materials and the conditions of pyrolysis.

The polycondensation of monomers containing three or more functions leads to the formation of branched and cross-linked polymers containing abnormal units. Andrianov [136,137] showed with several polymers that the functionality and the structure of the initial monomers play a very important role. Thus a three-dimensional polymer with a regular arrangement of rings can be obtained [137] by the polycondensation of cruciform polytitano-organosiloxane oligomers. An especially detailed investigated was made of the ladderlike polymer of structure

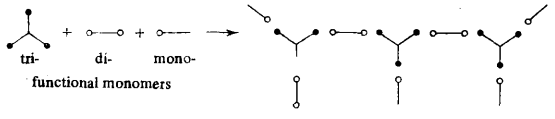


obtained by Andrianov [136] and others [138] by the hydrolysis of phenyltrichlorosilane. Its macromolecule contains defects consisting in incomplete ring closure [139]. In the case of three-dimensional polymers it is very important to ensure maximum regularity of the network structure, which is achieved by using tri- and tetra-functional oligomers having the same side-chains [137]. Thus Andrianov's use of oligomers of the type

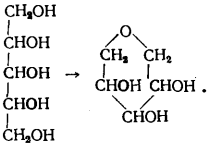


and also more complicated types enabled him to obtain polymers having a regular network structure [137].

Defects of two kinds—rings (loops) and long side-chains attached at only one end to branch points of the network—may appear on formation of a network structure [140]. The structure of the initial substances is evidently of especial importance. Thus an extremely regular network could probably be obtained by the polycondensation of two trifunctional monomers [141]:

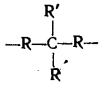


In the work cited above Andrianov proved experimentally the possibility of obtaining such regular structures [136,137].

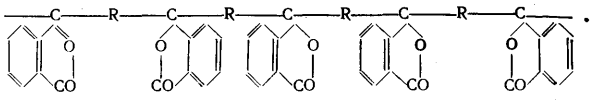


The regularity of the three-dimensional framework undoubtedly breaks down in the polycondensation of trifunctional with difunctional and especially with monofunctional monomers, which makes such a system chemically imperfect owing to the appearance of many abnormal units, as shown below. The picture for the polycondensation of trifunctional monomers when one of them has been replaced by a difunctional monomer will be

The polycondensation of a trifunctional monomer with a difunctional monomer and a monofunctional monomer can be depicted



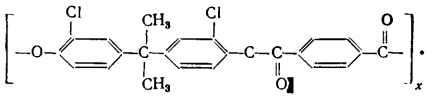
The polycondensation of polyhydric alcohols with dicarboxylic acids will be accompanied by the side-reactions considered above, together with substitution, cyclisation, etc. leading to the formation of abnormal units [142]. An interesting case of the formation of heterounit polymers was observed by Kiselev and Lubman [143] in the polycondensation of xylitol with phthalic anhydride, when abnormal units resulted from secondary dehydration with the formation of cyclic ethers:



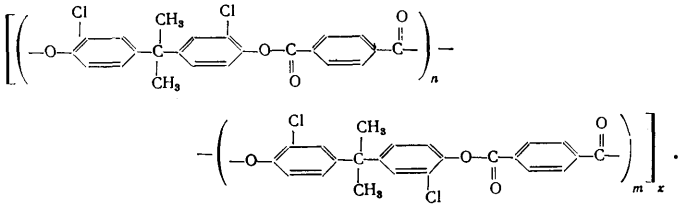
Most polymers obtained by polycondensation methods contain symmetrical units, so that the stereoregularity of their structure does not attract the attention of investigators. As with polymerisation methods, however, it must be envisaged that stereoregular polymers can be prepared by polycondensation. The first necessary condition for achieving this aim is, of course, the use of polymers capable of forming asymmetric units. This has already

been realised in practice by starting with optically active monomers, which enable polymers to be obtained with a sterically regular alternation of units.

Use is generally made of monomers having two different and two identical substituents of the type



but this yields polymers having a structure analogous to that of atactic polymers, i.e. with sterically non-equivalent units. Consequently these units can also be regarded as abnormal relative to each other, and such polymers as heterounit. An example of this type is supplied by the "atactic" polyarenoates of phenolphthalein and various dicarboxylic acids, which have the schematic formula

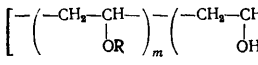


As we shall see later, this view of its structure is supported by its physical properties [144].

When bulky substituents are present, polyarenoates are produced having different crystal forms depending on the nature of the solvent. Thus the polyarenoate of 2,2-bis-*m*-chloro-*p*-hydroxyphenylpropane and terephthalic acid obtained in the presence of pyridine is crystalline and gives narrow signals in the nuclear quadrupole resonance spectrum, indicating the predominance of one crystalline form [85], so that this polymer can be regarded as stereoregular. It probably has the structure

When this reaction is conducted in dioxan and other solvents, a heterounit polymer is formed containing both crystallographic conformations, which can be represented by the formula

Thus this reaction is an example of the synthesis of a stereoregular polymer by stereospecific polycondensation.



5. Appearance of Abnormal Units during Copolycondensation

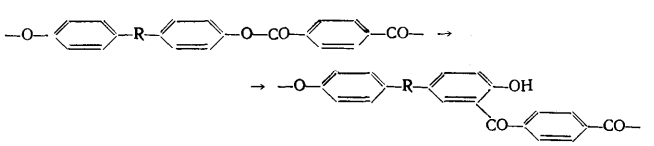
Copolycondensation, like copolymerisation, results in the formation of "heterounit polymers" containing units differing in structure. Polymers having macromolecules of varying degrees of imperfection are obtained depending on the nature and the quantity of the monomers taken. The use of monomers having three or more functions enables polymers to be obtained containing substituent groups and side-chains, as well as cross-linked three-dimensional structure. A more detailed description of the structure of the copolymers obtained is outside the scope of the present paper, so that reference will be made to the monograph on this topic [75].

6. Formation of Various Abnormal Units during the Substitution, Oxidation, and other Reactions of Macromolecules

Heterounit polymers can be obtained also as a result of substitution in the macromolecule of hydroxy-groups, hydrogen atoms, halogen atoms, and other atoms or groups by halogenation, oxidation, metallation, and other reactions. Since such reactions never go to completion, a heterounit polymer is obtained containing the initial units, together with the final and intermediate substitution products. The distribution of substituents resulting from substitution is usually random.

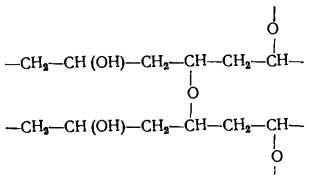
An extremely clear example of reactions of this kind is the polymerlike substitution in the hydroxy-groups of cellulose, polyvinyl alcohol, starch, and other polymers containing easily replaceable hydrogen atoms, which are usually only partly replaced by various groups. As a result of this, polyvinyl alcohol forms a heterounit polymer having the structure [145]

A still more complicated situation is found in cellulose ethers, which may contain four types of units [146]

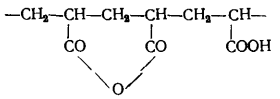


The same consideration applies to the huge number of heterounit polymers of various types, whose chains may contain two, three, or more different units in various proportions. They include both copolymers obtained by the copolymerisation of different monomers, which we have discussed previously, and heterounit polymers formed by the replacement in a homopolymer of hydrogen or other atoms or even whole groups as a consequence of such reactions as oxidation, chlorination, hydrochlorination, dehydrochlorination, esterification, alkylation, acylation, sulphonation, nitration, metallation, etc. These reactions yield heterounit polymers containing, together with the original monomer units, irregularly arranged mono- and di-substituted units, which can be represented for a substituted polyethylene by

where X = Cl, Br, I, F and E = O, S.

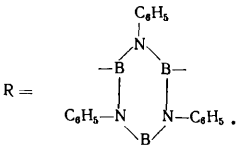


Abnormal units and consequent chemical imperfection may result also from various reactions leading to the formation of heterounit polymers—the Fries rearrangement in polyarenoates, the elimination of hydrogen chloride from poly(vinyl chloride) and other halogenated polymers, the removal of water from polyvinyl alcohol and from polymethacrylic acid, etc. The Fries rearrangement



takes place when polyarenoates are exposed to ultraviolet radiation or are treated with aprotic acids [147]. The elimination of a hydrogen halide from halogenated polymers results in the appearance of double bonds [148,149]:

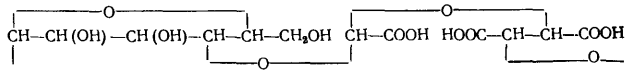
Dehydration of polyvinyl alcohol leads to cross-linking by ether bonds



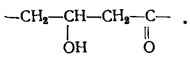
and the polymer becomes insoluble [150]. Elimination of water from polymethacrylic acid converts it into the cyclic anhydride [151]

An interesting and very peculiar case of the formation of a heterounit polymer is the isomerisation of polyethers containing bishydroxymethyl-*o*-carborane residues into polyethers of bishydroxymethyl-*m*-carborane, which occurs on prolonged heating in an inert atmosphere [152]:

where



Marvel's synthesis of polyphenylene [27] involves a stage of polymerisation of cyclohexa-1,3-diene followed by dehydrogenation of the resulting polycyclohexene. The latter reaction is incomplete, so that actually the product is not poly-*p*-phenylene but the heterounit polymer



containing phenylene and cyclohexene units.

The oxidation of polymers results in the formation of heterounit polymers whose macromolecules contain carboxyl, ketone, alcohol, and other groups formed by oxidation of a monomer unit. Thus oxidised cellulose

comprises [146] units containing carboxy-groups formed both by oxidation of terminal primary alcohol groups and by cleavage of a pyran ring. Marvel and Denoon [153] showed that oxidised polyvinyl alcohol contains keto-groups

Oxidised polyethylene contains peroxy- and keto-groups together with double bonds [154]:

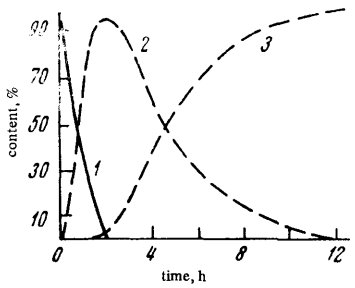
Nearly every polymer is oxidised on standing in air for a long time, and therefore contains aldehyde and ketonic groups, carboxyls, and peroxy-groups [155].

Marvel and Sampel [156] showed that dehydrochlorination of poly(vinyl chloride) leads to the formation of double bonds in the chain and the appearance of a dark colour in the polymer [156].

An immense number of heterochain polymers of varying structure—e.g. polyamides, polyesters, poly(amide–esters), etc.—have quite polar bonds in their chain, and therefore readily undergo exchange reactions with analogous heterochain polymers to form heterounit polymers. The products have the same structure and properties as copolymers synthesised from the corresponding initial monomers [157].

Heating a mixture of polyhexamethylenedipamide and poly-6-hexanoamide yields mixed polyamides having the same properties as those obtained by the reaction of hexamethylenediammonium adipate with ϵ-caprolactam [97]. In the same way, heating a mixture of three polyamides—polyhexamethylenedipamide, polyhexamethyleneazelaamide, and poly-ϵ-caproamide—results in a mixed polyamide with the properties of the polymer obtained by polycondensation of the corresponding starting materials [157]. When a mixture of two polyesters is heated, a heterounit polymer is formed with the same properties as in the corresponding copolymer obtained from the initial monomers [158,159]. Similarly, a poly(amide–ester) was obtained by heating a mixture of a polyamide and a polyester [160].

Another interesting feature of exchange reactions between two heterochain polymers is that, together with the statistical copolymer which is the final result of such a process, block copolymers appear in the early stages [97]. We obtain a mixture of various copolymers with abnormal units depending on the stage at which the reaction is halted, as shown in Fig. 3.



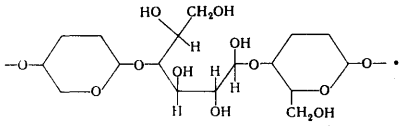


Figure 3. Variation in composition of a mixture of two heterochain polymers during heating: 1) homopolymers; 2) block copolymers; 3) random copolymer.

The formation of cross-linked polymers by various types of vulcanising reactions also produces chemically defective macromolecules [73,161,162]. Thus polyethylene, when heated with a peroxide [161], exposed to radiation [162], or treated with other chemical reagents becomes initially branched, and then an insoluble, infusible, cross-linked three-dimensional product. This type of imperfection resulting from chemical or radiation treatments occurs in many polymers, and is widely used in technology. The network produced in vulcanising and similar cross-linking processes is in most cases irregular, and usually results in chemically defective heterounit polymers.

7. Natural Polymers containing Abnormal Units

The examples we have been considering have been drawn mainly from synthetic polymers. In conclusion, therefore, we will cite examples of chemically imperfect macromolecules in natural polymers. Pacsu [163] and Strepikheev [164] showed that such an important natural polymer as cellulose contains, together with cyclic units, abnormal, acyclic units, as in the formula

Natural rubber contains 97–98% of *cis*-1,4-units and a small quantity (2–3%) of *trans*-units with units of different structure [22]. Deoxyribonucoeic acid, which plays such an outstanding part in the transmission of inherited characters, can also contain abnormal units in the chain, whose presence leads to the appearance of mutations and inherited diseases [165,166]. Thus abnormal units appear in appreciable quantities even in the synthesis of polymers in living organisms.

The above examples show that almost all known methods for synthesising and modifying polymers result in the formation of compounds that are heterounit polymers and contain chemically defective macromolecules. In practice, therefore, we are always dealing with heterounit polymers whose macromolecules contain abnormal units.

III. EFFECT OF ANOMALOUS MONOMER UNITS ON CHEMICAL PROPERTIES OF HETEROUNIT POLYMERS

The presence of abnormal units in the chain of a heterounit polymer should undoubtedly have a significant influence on the whole complex of its inherent chemical and physical properties. Primary importance will, of course, attach to the nature and number of abnormal units and their arrangement in the polymer chain. Very little information is yet available which could clearly illustrate the details of such effects, but the general picture has become quite distinct.

Let us consider individual examples of how the chemical properties of a polymer may vary under the influence of abnormal units. The differences between the chemical properties of heterounit polymers and those of the ideal polymer containing only one type of unit, taken as the initial standard for comparison, is larger the more the abnormal units differ from the main units constituting the macromolecule. Thus the formation of a branch in the radical polymerisation of vinyl compounds leads to the appearance in the macromolecule of units containing tertiary hydrogen atoms and side-chains, which are anomalous for this structure. The consequence is diminished resistance to oxidation, since tertiary hydrogen atoms are oxidised very easily, and therefore become points from which chain oxidation reactions begin, leading to degradation of the polymer [167].

Investigation has in fact shown that the thermal degradation of branched polyethylenes is initially considerably more rapid than that of the linear polymers (Fig. 4) [168]: only at 60% breakdown of the polymer do the rates of degradation of the two polyethylenes become equal. It is interesting that the rate of degradation of branched polyethylenes increases with increase in the degree of branching, i.e. in the content of side-chains, as is evident from Fig. 5. [169] Similarly, the branching of polymers containing aromatic rings diminishes their thermal stability, since benzene rings containing three substituents are more easily oxidised, being weak spots in the macromolecule.

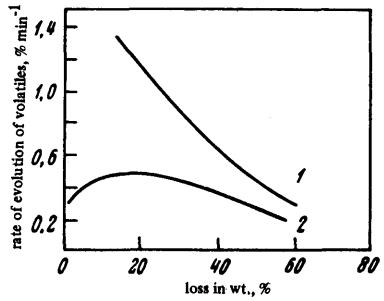

Figure 4. Rate of evolution of volatile products during the heating at 400°C of polyethylene: 1) branched; 2) linear.

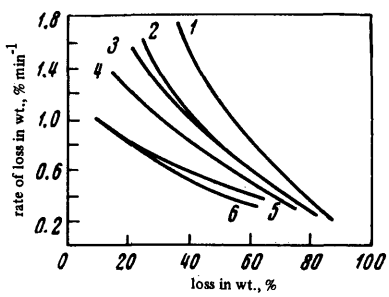
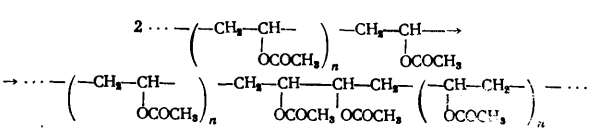
The presence of monomer units linked "head to head" in vinyl polymers results in the appearance of anomalous groupings containing adjacent halogen atoms or hydroxy-groups, as e.g. in poly(vinyl chloride) or polyvinyl alcohol [153]





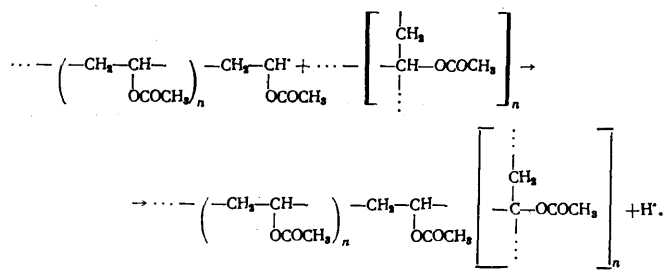


Figure 5. Rate of loss in weight at 400°C for specimens of branched, high-pressure polyethylene having different contents of side-groups (CH_3 per 100 CH_2): 1) 8.7; 2) 6.9; 3) 6.0; 4) 5.6; 5) 3.9; 6) 3.7.

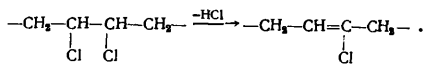
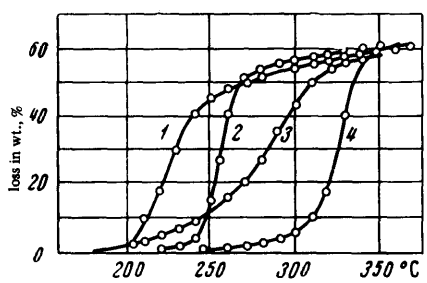


The latter polymer is found to contain ~1% of 1,2-groupings [170], which differ in chemical properties from 1,3-groupings typical of these polymers [153,170]. Such 1,2-groupings may be formed [170] as a result both of the recombination of macroradicals

and of chain transfer

The effect of such anomalous units was shown very clearly in an investigation of the thermal stability of two polymers of vinyl chloride and of vinylidene chloride, in which the units were arranged "head to head" and "head to tail" [171]. Fig. 6 shows that decomposition was slower in the former than in the latter case. The explanation is that, although the first stage in the reaction is more rapid for a "head to head" polymer, it leads to the formation of a stable structure resembling chloroprene, by the reaction



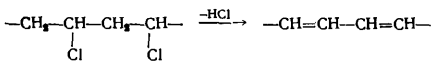


Figure 6. Thermal breakdown of:
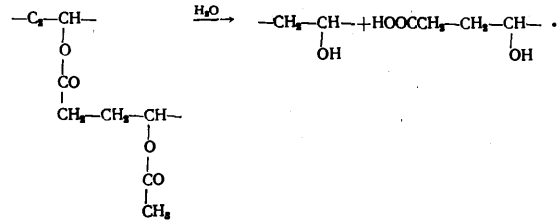
1) "head to tail" poly(vinylidene chloride);
2) "head to tail" poly(vinyl chloride);
3) "head to head" poly(vinyl chloride;
4) "head to head" poly(vinylidene chloride).



Chain dehydrochlorination is therefore unable to develop further along the macromolecule. In a "head to tail" structure, however, dehydrochlorination

proceeds along the chain until complete. Nevertheless, if abnormal units containing chlorine atoms in the 1,2-positions are present in such a chain, dehydrochlorination will be interrupted.

Examination of poly(vinylidene fluoride) by nuclear magnetic resonance spectroscopy showed that the content of units linked "head to head" varied between 8.6% and 10.6%. [172]

The presence of abnormal units in poly(vinyl acetate) (Section II, 1) results in a decrease in molecular weight on hydrolysis, owing to saponification of the ester bonds [17]:

The polymers of methyl α-chloroacrylate and α-bromoacrylate contain predominantly monomer units linked "head to head" [173]. Monomer units are assumed to be linked in different ways also in polystyrene [54].

Stereochemical relations in the structure of the units in polysaccharides influence their chemical properties especially strongly. Thus natural cellulose and its modification containing 3,6-anhydroglucose as well as glucose units differ in their liability to acid hydrolysis, which according to Rogovin et al. [174] is appreciably lower in cellulose. Similarly, the acetylation of cellulose is slower than that of modified cellulose containing altropyranose units [175]. The presence of anomalous groupings in the cellulose macromolecule, which are more easily hydrolysed than the principal units, facilitates its degradation on hydrolysis, as was shown by Pacsu [163] and by Strepikheev [164]. The increased rate of hydrolysis of cellulose in the first stage is explained by the fact that the abnormal units are "open" structures (Section II, 7), which are less resistant than cyclic structures to acid hydrolysis.

The chemical imperfection of the macromolecules of atactic polymers is shown also in a marked difference in rates of reaction from those of stereoregular polymers [176]. The temperatures at which half the weight of the polymer is lost on heating for 35 min (including heating to this temperature in 15 min) are 295° and 312°C for atactic and isotactic poly(propylene oxide) respectively, and the corresponding activation energies are 20 and 45 kcal mole^{-1}. [176] Similarly, atactic and isotactic polystyrene have activation energies for pyrolysis of 24.5 and 42 kcal mole^{-1}. [177]

The temperature characteristics—primarily the thermal stability—are among the most important indications of the chemical stability of a polymeric structure. The presence of defective units resulting from incomplete cyclisation diminishes the thermal stability of polymers [1,2]. Fig. 7 illustrates the results of a dynamic thermogravimetric analysis showing that a pyrrone is more thermostable than the corresponding poly(amide–aminoacid). However, the observed difference may depend on the dominant importance of dehydration in the acid. Fig. 8 therefore shows the quantities of water and carbon dioxide evolved at various temperatures. Differences are observed not only for water but also for carbon dioxide [127]. Evolution of the latter from the polymeric acid not only begins at a lower temperature than in the case of the pyrrone (200° and 300°C) but also occurs in far larger quantity. It can thus be accepted that defectiveness of the polymer structure consisting of the presence of abnormal units is one cause of the diminution in the thermal stability of polymers [1,127,178].

Polyphenylene, obtained by Marvel's method [27] of dehydrogenating poly-1,4-cyclohexene, has low thermal stability, which is explained by the presence of incompletely aromatised cyclohexene units in its macromolecules.

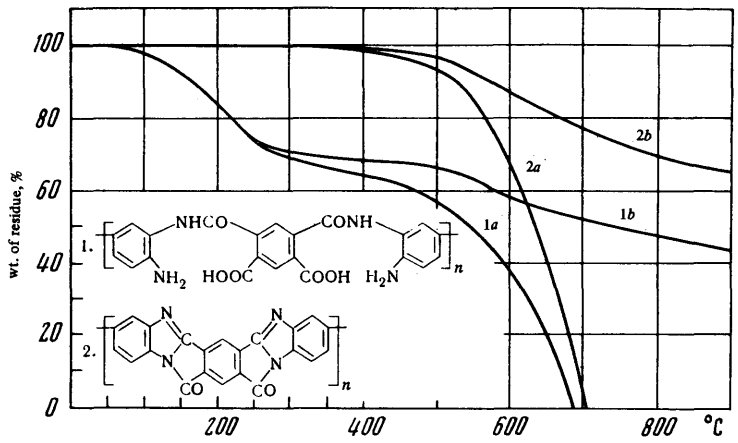


Figure 7. Dynamic thermogravimetric analysis (rate of heating 5 deg min^{-1}) of:
1*a*) poly(amide–amino acid) in air; 1*b*) poly(amide–amino acid) in helium;
2*a*) polybenzoylenebenzimidazole in air; 2*b*) polybenzoylenebenzimidazole in helium.

Hitherto we have been seeing in most cases examples in which the presence of abnormal units impairs the properties of the polymer and is therefore undesirable. However, as we shall see below, there are also cases in which abnormal units improve the thermal, thermo-oxidative, and chemical stability of a polymer.

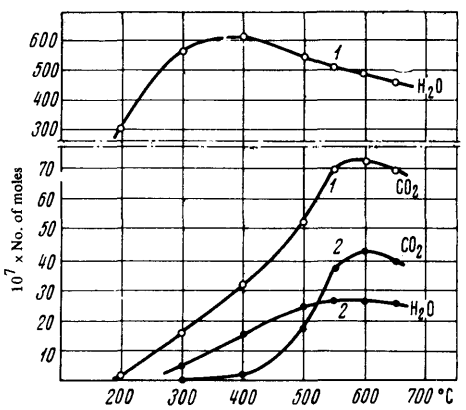

Figure 8. Evolution of water and carbon dioxide in the pyrolysis (15 mg in argon for 8 min) of:
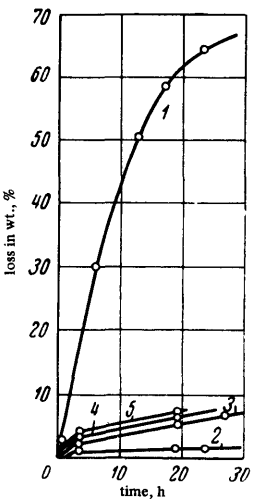
1) poly(amide–amino acid); 2) pyrrone.

The presence of anomalous groupings has a very significant effect on the rate of the thermal depolymerisation of polyvinyl compounds, in most cases slowing it down significantly, as Dolgoplosk and other investigators have shown [179] on several polymers. This self-inhibition of the thermal decomposition of copolymers was shown by Dolgoplosk et al. [179,180] to be due to the difference in activity of the free radicals formed at the end of the chain. If if the radical ...–B· is more reactive, detachment of an A unit will require the consumption, not only of the energy evolved on addition of the monomer A, but also additional energy equal to the difference in energy between the two radicals, i.e. the energy of ...–B· minus the energy of ...–A·; breakdown is then retarded at the stage –A–B–A–A–A–.... If, however, the radical ...–B· is the less reactive, the slowing down occurs at the stage ·B–A–A–A–.... The depolymerisation rate curves in Fig. 9 support this deduction [180].



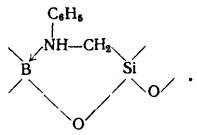


Figure 9. Kinetics of the degradation in air at 200 °C of copolymers of methyl methacrylate with:
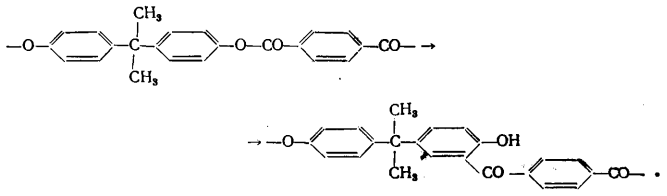
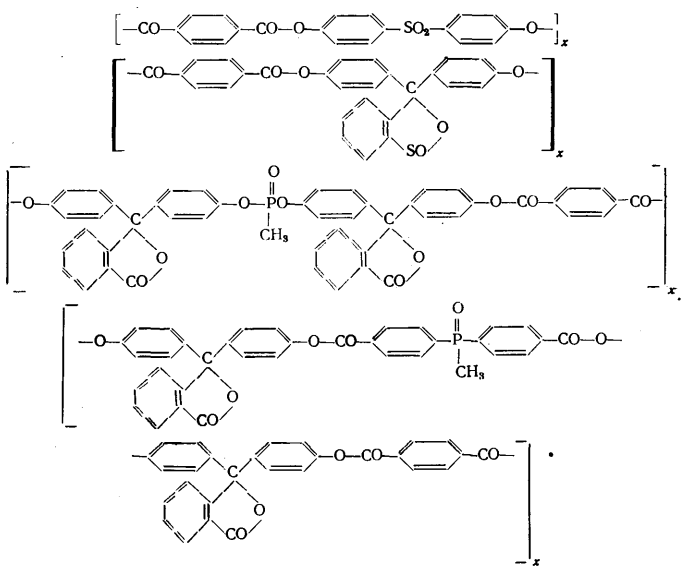
1) poly(methyl methacrylate) alone; 2) citraconamide (40%); 3) methylmethacrylamide (40%); 4) hydroxymethylmethacrylamide (7%); 5) methacrylic acid (15%).



Because of this, copolymers of formaldehyde are also more thermostable than the homopolymer [181]. For the same reason polysilaphenylenesiloxanes are thermally more stable than polysiloxanes [182]. In these cases the

presence of foreign units has a favourable effect, by improving the thermal stability of the polymers.



Andrianov's work [183], showing the substantial change in the properties of polymers produced by the introduction of small quantities of "alloying" additives, is most valuable for an understanding of the role of abnormal units. Thus he showed [184] that the presence of anilinomethyl groups attached to silicon greatly increases the hydrolytic stability of polyboraorganosiloxane copolymers, owing to formation of a donor–acceptor bond between boron and nitrogen

We find a similar situation in "self-protecting" polymers [147]. Under the influence of radiation or catalysts, self-protecting polyarenoates undergo the Fries rearrangement, with the formation [109,147] of hydroxybenzophenone units:

The presence of such groupings enhances appreciably the photochemical and the thermal stability of the polymers. A similar improvement in thermal stability is observed on the introduction into polyarenoates of units containing sulpho-groups and phosphine groupings, as in the compounds

Rafikov et al. [185,186] showed that the presence of such groups in these polyarenoates greatly increases their resistance to the action of light and heat.

IV. EFFECT OF ANOMALOUS MONOMER UNITS ON PHYSICAL PROPERTIES OF HETEROUNIT POLYMERS

The physical properties of polymers are also extremely sensitive to the presence of abnormal units, since the latter usually disturb the packing of the polymer chains, which interferes with their crystallisation and the formation of the most compact structures. This is very significant, since structure is a factor governing the physical and especially the mechanical properties of polymers [187]. The presence of abnormal units therefore diminishes the mechanical strength of fibres, films, and other articles made from a given polymer, and conversely raises the solubility and lowers the melting and softening points: i.e. their presence diminishes the heat resistance of polymers. In contrast to this, flawless polymers, containing no abnormal units, should obviously ensure denser packing of the chains, easy crystallisation of the polymer, very strong fibres, films, and other goods, high heat resistance, and sparing solubility.

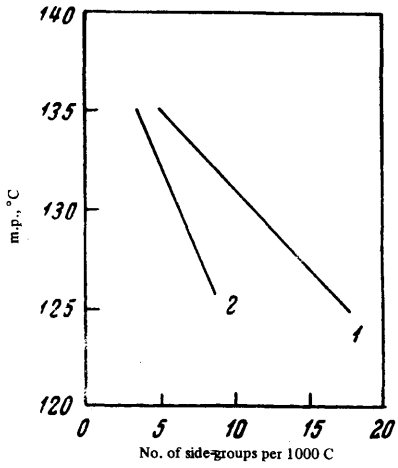


Figure 10. Melting-points of polymethylenes containing different quantities of alkyl groups: 1) methyl; 2) ethyl.

Some support for this suggestion may be found in Preston's work [188], which showed that fibres made from ordered copolymers have higher mechanical strength than fibres made from disordered copolymers with more imperfect heterounit macromolecules. This is suggested also by the effect of side-chains on the properties of polymers. Fig. 10 shows that increase in the content of methyl and ethyl groups lowers the melting point of copolymers [189], ethyl groups being the more effective.

The physical properties of three types of polyethylene (Table 3) show a fall in melting point and decreases in density and crystallinity with increasing degree of branching. The effect of abnormal units is exhibited especially clearly in polymers of butadiene and isoprene: *cis*-1,4-polymers possess the greatest elasticity; the presence of *trans*-1,4- and 1,2-units has an adverse influence on their properties.

Further support may be obtained from data on the effect of the relative imperfection of the structure of a polymer on its temperature characteristics, i.e. its heat resistance and thermal stability. Thus the glass and melting points of copolymers vary significantly with the quantity of the second monomer added [191-193]. Figs. 11 and 12 show a quite clear regularity for copolymers containing only small quantities of the second monomer. Fig. 11 shows the dependence of the glass point of vinyl polymers on the content of a second monomer [191]; Fig. 12 shows the composition dependence of the melting point of mixed polyamides [192,193]. In most cases both glass and melting points fall with increasing content of the second monomer, i.e. with increase in the number of abnormal units in the polymer chain. Since these temperatures depend on the strength of intermolecular forces, and hence on the degree of ordering of the macromolecules, their fall indicates that the second monomer diminishes the degree of order in the polymer and hence the forces of interaction between the macromolecules.

Table 3. Physical properties of various polyethylenes [190].

Property	Polymethylene	High-density polyethylene	Low-density polyethylene
Melting-point, °C	135	125	105—115
Density at 20°C, g cm^{-3}	0.97	0.95	0.92
Crystallinity, %	95	85	60—70

As we have seen, chemical defectiveness of the polymer structure may have a twofold effect on the physical properties: it may either weaken or strengthen intermolecular forces. This applies also to the rigidity of the macromolecules. In this case both the size and the polarity of a substituent are obviously significant. Fig. 13 shows how an abnormal unit containing a side-group or a branching affects the ordering of the macromolecules. The steric effect of a substituent will be in some measure proportional to its size. The final effect should depend also on the quantity of abnormal units. The influence of polarity will obviously be more clearly developed the more polar is the abnormal substituent in comparison with the main substituents, as is evident in a copolymer of vinyl chloride with acrylonitrile.

A clear example of the immense influence of the stereochemistry of units on the properties of a polymer is provided by the polyamides obtained from *cis*- and *trans*-cyclohexane-1,3-diamines with dicarboxylic acids. Fig. 14 shows the variation in melting point of the mixed polyamides containing various quantities of the *cis*- and *trans*-isomers [194]. The effect of the stereoisomerism is very clearly evident: polyamides obtained from the *trans*-diamine have higher melting points.

Chemical imperfection of the macromolecules is also an important factor governing the ability of polymers to crystallise. The more imperfect is a given heterounit polymer, i.e. the more abnormal units it contains and the more disordered their arrangement, the less is the tendency to crystallise under otherwise similar conditions.

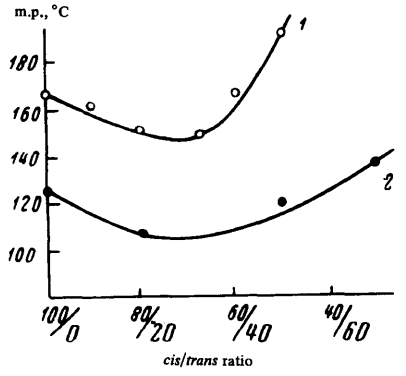

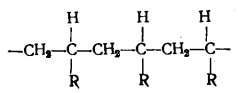

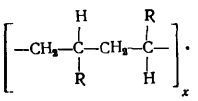

Figure 14. Variation of melting-point with ratio of *cis*- and *trans*-forms of cyclohexane-1,3-diamine for polyamides with: 1) adipic acid; 2) azelaic acid.

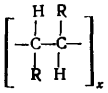
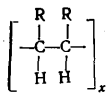
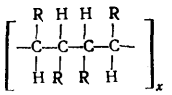


There are several polymers which it has not yet proved possible to obtain in a crystalline state. Among them must first be mentioned the atactic polymers of styrene, methyl methacrylate, propene, vinyl chloride, etc., which are amorphous owing to the disordered arrangement of *dextro*- and *laevo*-units in their macromolecules. In this sense they are also copolymers of the stereoisomeric *dextro*- and *laevo*-forms of the units. When arranged with some regular alternation, however, these same monomer units give readily crystallisable homopolymers—the isotactic polymers

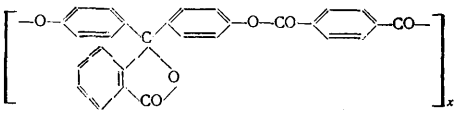


and also a regular copolymer of *dextro*- and *laevo*-forms—a syndiotactic polymer—which, however, can be regarded also as a homopolymer having the longer unit

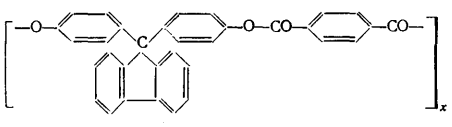


Similarly, the di-isotactic *threo*-polymer

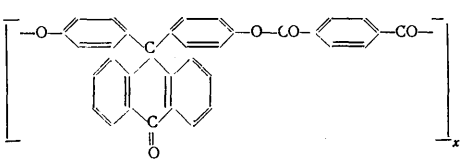
and the di-isotactic *erythro*-polymer



are homopolymers, whereas the disyndiotactic polymer can be regarded either as a copolymer of two different units or as a homopolymer having the longer unit



Several polycondensation polymers exhibit a similar effect of monomer structure on ability to crystallise. Thus polyarenoates that are polyesters of dihydric phenols and dicarboxylic acids containing rings and a central carbon atom, of the type



are among the most interesting "card" polymers. They are constructed on the necklace principle: i.e. each unit contains a carbon atom forming part both of the polymer chain and of a side-ring. These polyarenoates are either crystalline or amorphous depending on their structure. Polyarenoates of phenolphthalein having the structure

are non-crystallisable, amorphous polymers [144]. This was explained on the hypothesis that their structure resembles that of atactic polymers: i.e. they have a statistical distribution of an asymmetric substituent (phthalide group) in the repeating unit of such a polyarenoate, which is a heterounit polymer (Section II, 4). Under certain conditions a stereoregular distribution of this substituent could probably be achieved, which would lead to the formation of a crystalline polyarenoate of phenolphthalein. This suggestion is supported by our observation [144] that polyarenoates of card type having a symmetrical cyclic side-substituent are able to crystallise. Examples are the polyarenoates based on 9,9-bis-*p*-hydroxyphenylfluorene (I) and 10,10-bis-*p*-hydroxyphenylanthrone (II)

(I)

(II)

These polyarenoates are crystalline substances, in contrast to those of phenolphthalein.

Similarly, as Batzer showed [195], poly(hexamethylene 2,9-dibutyldecanedioate) does not crystallise, in contrast to the crystalline poly(hexamethylene decanedioate). The reason is that the former polyester is also an atactic heterounit polymer, because the racemic form of the initial acid was taken, so that the polymer has an irregular distribution of butyl groups. The copolymer obtained from decanedioic and 2,9-dibutyldecanedioic acids begins to crystallise only when their proportions are 5 : 1, which corresponds to a content of one butyl group for every 54 atoms in the polymer chain [195]. In this case the presence of abnormal units becomes sufficiently minor not to prevent crystallisation of the polyester.

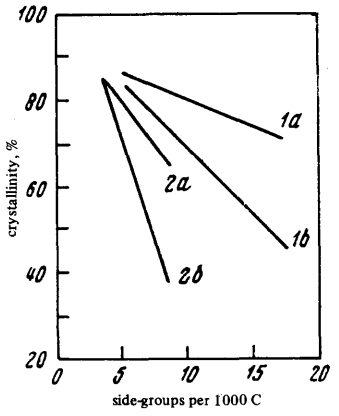


Figure 15. Crystallinity of branched polymethylenes determined by different methods:
1*a*) methyl groups by X-ray examination;
1*b*) methyl groups by differential thermal analysis;
2*a*) ethyl groups by X-ray examination;
2*b*) ethyl groups by differential thermal analysis.

We may recall also that, when carbyne is heated to 1000°C, the abnormal units

$$-C\equiv C-CH=C=C=,$$

split off hydrogen

$$-C\equiv C-CH=C=C= \xrightarrow{-H} -C\equiv C-C\equiv C-C\equiv C-$$

which results in conversion of the polymer into a crystalline form [114]. As a consequence of this reaction, the heat-treatment of carbyne enhances its crystallinity.

A detailed investigation of the dependence of crystallinity on the number of abnormal groups has been made on polymethylenes containing various quantities of methyl or ethyl groups, obtained by copolymerising diazomethane with diazoethane or diazopropane [189]. Fig. 15 shows that ethyl groups have a stronger effect than methyl groups in diminishing crystallinity. The amorphous content is greatly increased by the presence of branching in the polyethylene macromolecules (Fig. 16) [196].

The density of polymers changes significantly with increasing imperfection of the macromolecules: it usually decreases with increase in the content of abnormal units. The presence of branches has a similar effect: thus unbranched polymethylene has a density of 0.971, slightly branched low-pressure polyethylene 0.95–0.96, and strongly branched high-pressure polyethylene 0.92 to 0.93 (Table 4). The densities of copolymers obtained from diazomethane and other diazoalkanes [189] are also given in Table 4, from which it is evident that increase in the number and length of the side-chains diminishes the density of the polymer. The variation in the density of polyethylene with degree of branching illustrated in Fig. 17 shows a decrease in density with increase in content of methyl groups [197].

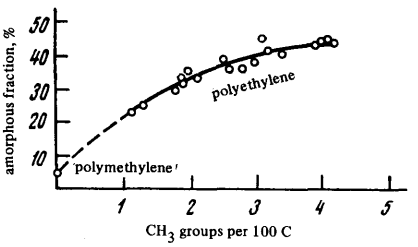

Figure 16. Dependence of content of amorphous material on degree of branching of polyethylene macromolecules.

The solubility of polymers also is extremely sensitive to the presence of abnormal units in the macromolecule: it is usually increased by increase in their content and their disordered arrangement. This is illustrated (Fig. 18) by the dependence of the temperature of dissolution of polymethylenes containing branched macromolecules on the number of branches [16].

Table 4. Properties of copolymers.

Polymeric material	Mode of preparation	Density
Polymethylene	polymerisation of diazomethane	0.971
Polymethylene with side-groups:		
methyl	diazomethane–diazoethane copolymer	0.939
ethyl	diazomethane–diazopropane copolymer	0.952
Polyethylene with ethyl side-chains	ethylene–but-1-ene copolymer	0.957
Crystalline ethylene–propene block copolymer	copolymerisation of ethylene and propene	0.917

Enhancement of solubility is observed also in many copolymers. Homopolyamides usually dissolve only in acids, phenols, and amides, whereas their copolymers and mixed polyamides dissolved even in aqueous alcohol. Fig. 19 shows how the solubility of mixed polyamides varies with their composition [198].

We have thus been considering many of the methods for synthesising polymers known at the present time, and have shown that they are all accompanied by various side-reactions. These result in the formation of abnormal units in the macromolecule, and the consequent chemical defectiveness characteristic of heterounit polymers. Abnormal units appear not only during polymerisation and polycondensation but also in the course of copolymerisation and copolycondensation.

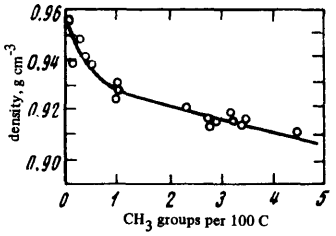

Figure 17. Dependence of density of polyethylene on degree of branching.

Various reactions involving substitution in the polymer chain also lead to the appearance of abnormal units and the formation of heterounit polymers. It is undoubtedly possible to influence the number and distribution of the abnormal units thus formed, which is an important task of synthetic polymer chemistry. The significance of studying the chemical imperfection of the macromolecule structure is that it has a great influence on the chemical and physical properties of polymers, as has been illustrated by the series of examples of heterounit polymers given here.

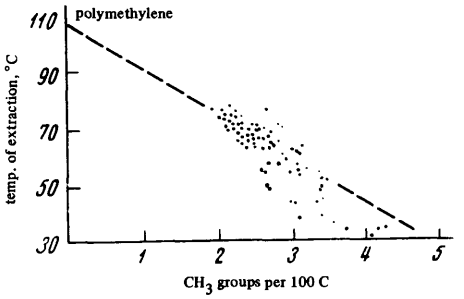

Figure 18. Dependence of temperature of dissolution on degree of branching of polyethylene macromolecules.

Finally we conclude that these examples quite clearly illustrate the effect of various reactions leading to the formation of abnormal units and hence the production of heterounit polymers of general formula $[[M]_m-[A]_n]_x$.

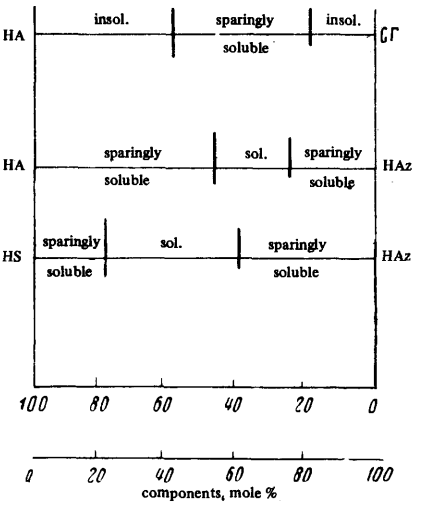

Figure 19. Effect of composition of copolymers on their solubility in ethanol: HA = hexamethylenediammonium adipate; HS = hexamethylenediammonium sebacate; HAz = hexamethylenediammonium azela-ate.

This feature of polymerisation and polycondensation processes, and also of substitution in polymer chains, has not yet been investigated systematically, so that our knowledge in this field is still largely haphazard. However, it can be concluded from the above results that almost all real polymers comprise heterounit macromolecules, while homounit polymers, containing no abnormal units, are rare exceptions. Hence this must be taken into account in considering the problem of the relation between the structure and the properties of polymers, since the concept of heterounit polymers as the main type of polymeric structure acquires fundamental importance for polymer chemistry.

U.D.C. 547.933:

Degradation of Cellulose by Alkaline Oxidation

O.P.Golova and N.I.Nosova

Investigations on the alkaline and oxidative-alkaline degradation of cellulose by molecular oxygen are reviewed, and the reaction mechanisms are surveyed. The effect of the supermolecular structure of cellulose on the rates of these processes is examined. A list of 136 references is included.

IV. Effect of supermolecular structure of cellulose on its alkaline and oxidative-alkaline degradation 335

I. INTRODUCTION

The problem of the oxidative degradation of cellulose embraces a very wide range of scientific and practical questions—oxidising reactions, the effect of chemical and supermolecular structure on the oxidation of cellulose, the changes in chemical, physical, and mechanical properties of cellulose produced by oxidants, etc. The present Review discusses aspects of the alkaline and oxidative–alkaline degradation of cellulose and the mechanisms of the reactions involved.

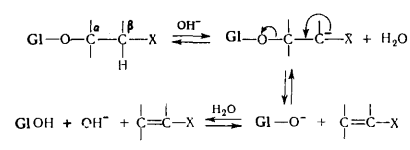
II. ALKALINE DEGRADATION OF CELLULOSE AND OXIDISED CELLULOSES

The oxidation of cellulose by molecular oxygen in alkaline media is a very complicated process, involving genuine oxidation reactions and also reactions undergone by the initial cellulose and its oxidation products under the influence of alkalis. In order to obtain a better understanding of this complicated question, it is advisable firstly to consider the reactions occurring during the alkaline degradation of cellulose and oxidised cellulose.

The reactions involved in the degradation of carbohydrates under the influence of alkalis are also very complicated, and have been discussed in detail in several review papers and monographs [1-8]. We therefore give only the principal experimental results together with modern views on the mechanism of the reactions involved.

1. Alkaline Degradation of Cellulose

The main processes occurring in the alkaline degradation of cellulose are the so called degradation of cellulose from the reducing end of its molecule and the alkaline hydrolysis of glycosidic bonds. The former process is observed almost exclusively at temperatures up to 150°C; the two processes occur simultaneously above this temperature.

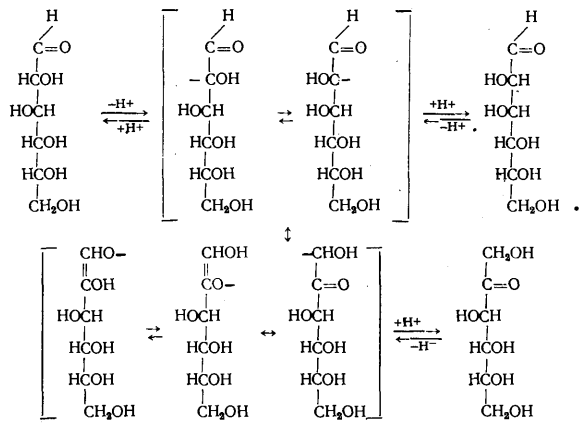


(*a*) Degradation of cellulose from the reducing end

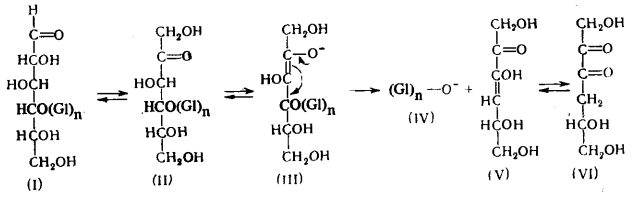
The action of alkalis on cellulose at temperatures up to 150°C produces losses in weight without any considerable change in the degree of polymerisation [9,10]. Native cotton cellulose reacts slowly with a hot alkali solution, but the rate increases when the degree of polymerisation is lowered by hydrolysis, with a resulting increase in the number of aldehyde groups. On the basis of these observations Davidson suggested [11] that degradation consists in the successive detachment of units from the end of a molecular chain possessing reducing properties. The validity of this hypothesis has since been confirmed by numerous experimental data. It has been shown that hydrocelluloses are degraded more rapidly than cotton cellulose, though having the same chemical structure but a lower degree of polymerisation; the rate of degradation of hydrocelluloses increases as the degree of polymerisation falls, and hence as the content of reducing terminal groups decreases [10,12]. The stability of hydrocellulose towards hot dilute alkali is sharply improved when the aldehyde end-groups are eliminated by being oxidised to carboxy-groups with chlorous acid [13], bisulphite solutions at high temperatures [14], or cuprammonium solutions [15], reduced with sodium tetrahydroborate in weakly alkaline medium [10,16], dehydrated by heating [17], or even modified by glycoside formation [18].

Breakdown from the reducing end is indicated also by data suggesting that acids of approximately the same composition are formed by the action of alkalis on hydrocellulose and on 4-*O*-substituted monosaccharides and 1,4-disaccharides [19].

(*b*) Mechanism of degradation from the reducing end



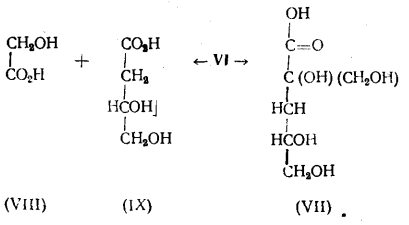
The most widely accepted explanation of the alkaline degradation of cellulose from the reducing end is based on Isbell's theory of β-elimination [20], which he proposed to explain the previously observed [21,22] instability towards alkalis of glycosides of alcohols containing electronegative groups in the β-position. The reaction is represented by



This theory is widely used at the present time to explain the sensitivity to alkalis of unsubstituted and substituted monosaccharides and also of di-, oligo-, and polysaccharides [19,23-35].

According to Isbell's theory an alkoxy-group should be present in the β-position relative to the aldehyde group. In the reducing terminal unit of cellulose the alkoxyl is in the γ-position to the aldehyde group. Detachment of the reducing terminal glucose unit will become possible after isomerisation into a fructose unit [9,23]. The possibility of the conversion of monosaccharides into their epimers and the corresponding ketoses by the action of alkalis had already been shown at the end of the nineteenth century by Lobry de Bruyn and van Ekenstein [36]. Not only monosaccharides but also the reducing units of disaccharides, oligosaccharides [37-40], and cellulose [23] are able to undergo similar transformations.

The most probable mechanism of this rearrangement [36] involves elimination of a proton and formation of a carbanion in equilibrium with enolate ions; the latter have a planar configuration and are converted with almost equal probability into three epimers [41]:



The degradation of cellulose by the action of alkalis is regarded [23] as involving conversion of a reducing terminal unit (I) of cellulose into a fructose unit (II), which is detached as the enolic form (V) of a dicarbonyl compound:

This liberates a reducing group in the adjacent glucose unit, which in turn undergoes the same changes. Thus a stepwise process of alkaline degradation takes place, beginning from that terminal unit of the cellulose molecule that possesses reducing properties.

The eliminated enol (V) undergoes further changes, the composition of the products depending on the nature of the alkali and the reaction conditions. Calcium hydroxide yields mainly D-glucoisosaccharinic acid (VII), whose formation results from rearrangement of 4-deoxy-D-*glycero*-2,3-hexodiulose (VI), which has been isolated from and identified in the products of the alkaline degradation of cellobiose [31] and maltose [32]:

Treatment with caustic soda favours conversion of (VI) into a mixture of $\beta\gamma$-dihydroxybutyric (IX), glycollic (VIII), formic, and lactic acids [19,32].

(*c*) "Stopping" reactions

The alkaline degradation of cellulose never goes to completion, and the final polysaccharide becomes stable towards alkali [10]. This stability is due to conversion of the usual reducing terminal glucose units into non-reducing units containing carboxy-groups [42,43]. Richtzenhain and Abrahamsson [44] considered that the reducing terminal units might rearrange into saccharinic acids, whereas Lindberg [45] assumed that the carboxyls were formed either by oxidation of the reducing groups by traces of oxygen or as a consequence of a Cannizzaro reaction between aldehyde groups of the terminal unit and those of soluble decomposition products.

The nature of the stabilising reaction was investigated by Machell and Richards [9,35], who subjected alkali-stabilised hydrocellulose to acid hydrolysis and isolated the acidic products. The main product was identified as D-metasaccharinic acid, whose formation during alkaline treatment might be a consequence of β-elimination of the 3-hydroxyl in the terminal glucose unit followed by rearrangement of the resulting enol. Because of the absence of a carbonyl group, hydrocellulose molecules containing metasaccharinic acid as terminal unit are stable towards alkali.

Alkaline-earth metal ions—Ca^{2+}, Sr^{2+}, Ba^{2+}—are evidently more effective than sodium ions in catalysing the conversion of reducing terminal units in cellulose into metasaccharinic acid redidues [12,33,46]. Stabilisation is usually slower than degradation from the reducing end. The activation energies for the degradation of hydrocellulose from the reducing end by the action of 5% sodium hydroxide solution (in the absence of oxygen) and for the formation of stable terminal metasaccharinic acid units are 24 and 32 kcal mole^{-1} respectively [47].

It is interesting that the 3-deoxy-D-*erythro*-hexulose postulated by Isbell's theory as an intermediate in the formation of metasaccharinic acids has been isolated and identified by Machell and Richards [34] on treating 3-*O*-benzyl-D-glucose with 0.04 *N* sodium hydroxide. On treating with calcium hydroxide solution the isolated reaction intermediate was converted almost quantitatively into D-glucometasaccharinic acid [34].

(*d*) Alkaline hydrolysis of glycosidic bonds

Solutions of alkalis at 170°C and above cause the direct hydrolysis of cellulose, which is indicated by a rapid drop in degree of polymerisation and considerable weight losses [48,49]. This reaction is due to the action of hydroxide

ions, not to oxidation by traces of oxygen or to a purely thermal effect [49]. Brooks and Thompson [50] used methyl β-glucoside to show that 10% sodium hydroxide solution produces a very low rate of rupture of glycosidic bonds (after 5 h only 0.3%, 0.9%, and 5.5% of glycosidic bonds broken at 140°, 150°, and 170°C respectively).

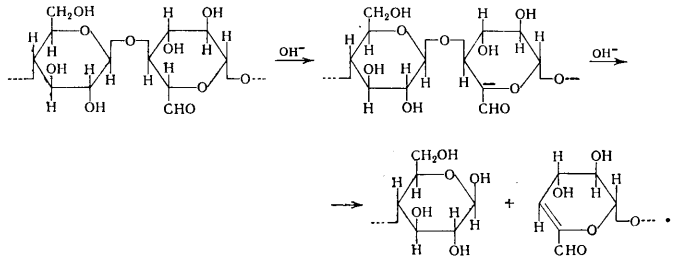
Investigation of the alkaline hydrolysis of glycosides by Lindberg and his coworkers [45, 51-54] on numerous model compounds showed the simultaneous occurrence of several reactions. Thus the action of 10% sodium hydroxide solution on 4-*O*-β-D-glucopyranosyl-D-sorbitol yields 1,6-anhydro-β-D-glucopyranose, D-sorbitol, 1,4-anhydro-D-sorbitol, and acidic products. Formation of the first two products necessitates rupture of the bond between the glycosidic oxygen and the $C_{(1)}$ atom of the glucose residue; formation of the third product requires rupture of the corresponding bond with the $C_{(4)}$ atom of the sorbitol residue. Direct attack by a hydroxide ion on these carbon atoms may give glucose and sorbitol respectively. Under the experimental conditions glucose rapidly forms acidic products.

The alkaline hydrolysis of cellulose forms new reactive groups for ensuring degradation from the reducing end, which occurs by the same mechanism as at lower temperatures. The soluble breakdown products obtained when cotton cellulose is treated with 0.5 *N* sodium hydroxide solution at 170°C include the same compounds as produced by treating hydrocellulose with a 0.5 *N* solution of the alkali at 100°C. [49]

2. Alkaline Degradation of Oxidised Celluloses

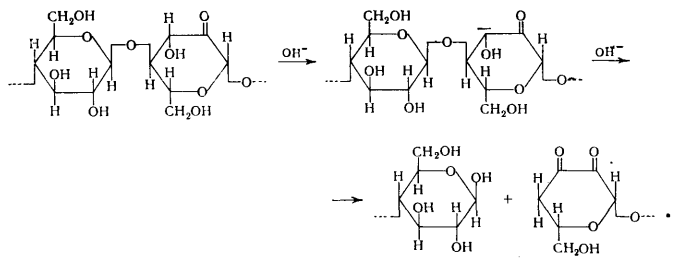
Since oxidation and alkaline degradation occur simultaneously, it is useful first to examine the alkaline degradation of already oxidised cellulose. Alkalis break down the structure of oxidised celluloses. Davidson investigated the oxidation of cellulose with potassium dichromate in an acid medium, and found that the viscosity of a solution of oxidised cellulose nitrate is far higher than that of oxidised cellulose in cuprammonium solution. This difference disappears after treatment of the oxidised cellulose with alkali [55]. Furthermore, oxidised celluloses lose weight when heated with weak solutions of alkalis [56]. Staudinger and Sohn [57] attributed the lowering of the degree of polymerisation of cellulose to the presence of ester bonds in its chain, which are cleaved by the action of alkalis. They also discussed the ways in which ester bonds are formed on oxidation.

Somewhat later, investigators came to link the degradation of oxidised celluloses by the action of alkalis with the formation of carbonyl groups, which facilitate the rupture of glycosidic bonds [58, 59]. Oxycelluloses obtained by periodate oxidation, and hence containing aldehyde groups at positions 2 and 3 of the repeating unit of cellulose [60], are easily degraded by alkalis [13, 56, 61-63], the sensitivity to which increases with increase in the content of aldehyde groups [61, 63]. According to Kaverzneva and Ivanov the fall in the viscosity of cellulose when oxidised with air in cuprammonium solution is due to rupture of glycosidic bonds caused by the presence of aldehyde groups formed by the oxidation of primary alcoholic groups [64].



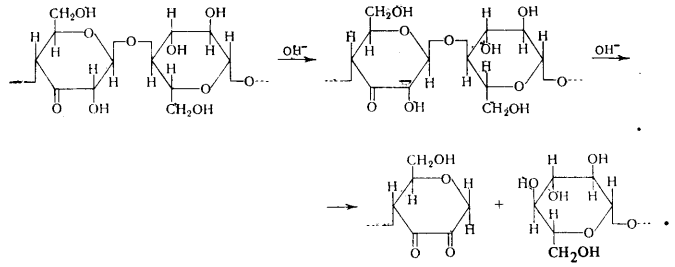
The influence of ketonic groups on the stability of cellulose oxidised with dichromate was referred to by Meller [13]. Kaverzneva and Kist' [65] showed that the presence of a considerable quantity of ketonic groups in cellulose oxidised with nitrogen dioxide is the main reason for its degradation in alkaline media.

The dominant effect of carbonyl groups on the degradation of oxidised cellulose in an alkaline medium is evident also from the conversion of alkali-unstable oxidised celluloses into stable materials by reduction with sodium tetrahydroborate in a weakly alkaline medium, i.e. under conditions such that aldehyde groups are converted into alcoholic groups [61-63, 66]. The stability of oxidised celluloses is considerably enhanced also when carbonyl groups are oxidised to carboxy-groups [13, 62].



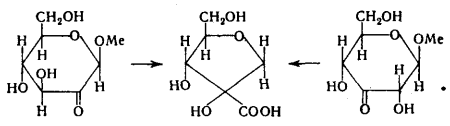
(*a*) Mechanisms of the degradation of oxidised celluloses

Several reaction mechanisms have been suggested [58, 64, 67, 68] to explain the alkaline degradation of oxidised celluloses, but investigations during recent years of the degradation of these materials, as well as of monosaccharides, disaccharides, and their derivatives, have shown that, when a carbonyl group is present in the β-position relative to a glycosidic bond, degradation takes place mainly by Isbell's mechanism [69].

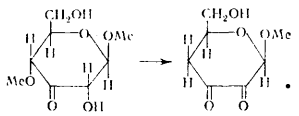


This hypothesis was first put forward by Haskins and Hogsed [59], who gave the following scheme for the alkaline degradation of cellulose containing units with a 6-aldehyde group

When the alcoholic group at $C_{(2)}$ of the repeating unit of cellulose is oxidised, the mechanism of cleavage of the glycosidic bond under the influence of alkali will be



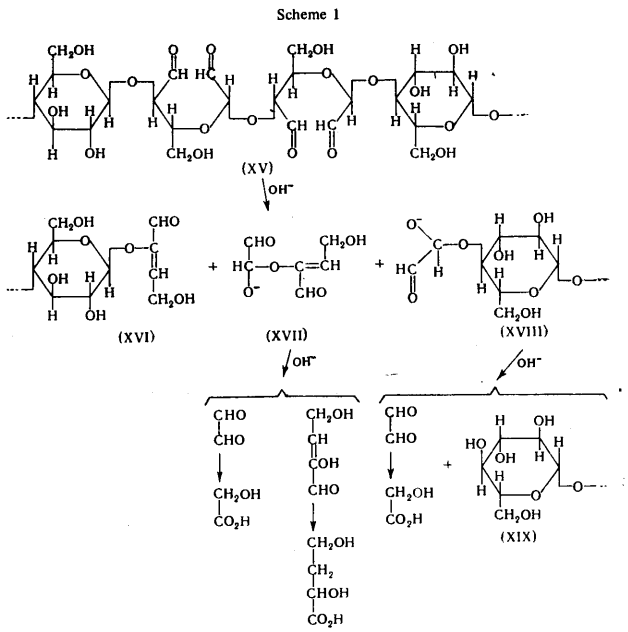
The action of alkali on cellulose containing units with a 3-keto-group should be represented by



A later investigation of the action of alkali on model compounds having a keto-group at the $C_{(2)}$ and $C_{(3)}$ atoms—methyl β-D-*arabino*-hexulopyranoside (X) and methyl

β-D-*ribo*-3-hexulopyranoside (XI)—showed [70] that they rapidly split off the methoxy-group under the influence of weak solutions of sodium or calcium hydroxide at room temperature. The same final product (XII) is obtained in the two cases, whence it follows that the intermediate product is the same in the two reactions:

(X) (XII) (XI)



In order to determine whether, in the alkaline treatment of cellulose containing glucose units with a keto-group at $C_{(2)}$or $C_{(3)}$, elimination occurs at the glucosidic carbon atom or at the $C_{(4)}$ atom, the alkaline degradation of methyl 4-*O*-methyl-β-D-*ribo*-3-hexulopyranoside (XIII) was examined [71]. This compound is degraded almost five times as rapidly as (XI). The chief intermediate product is isolated in the degradation of (XIII) was the 4-deoxy-compound (XIV):

(XIII) (XIV)

From this the author concluded that the alkaline degradation of oxidised cellulose of this type involves the cleavage mainly of bonds between the $C_{(4)}$ atoms of the glucose units and the oxygen of the glycosidic bonds.

Scheme 1

Model compounds—methyl 4-*O*-methyl-β-D-*arabino*-hexulopyranoside, methyl 4-*O*-methyl-β-D-*ribo*-3-hexulopyranoside, and methyl 6-formyl-4-*O*-methyl-β-D-glucopyranoside—were used to study the effect of different positions of the carbonyl group in the oxidised glucose unit. The glycosidic bond was found to be most labile in compounds containing a carbonyl group in position 2 or 3. It was more stable in compounds containing a 6-aldehyde group [71].

O'Meara and Richards [69] examined the initial and final products of the alkaline degradation of periodate-oxidised cellulose, and concluded that degradation occurs mainly by Isbell's β-alkoxy-carbonyl mechanism. When periodate oxycellulose is treated with calcium hydroxide solution the chief products are glycollic and αβ-dihydroxybutyric acids, the relative proportion of the former acid diminishing with increasing degree of oxidation of the cellulose. These workers give Scheme 1 for the degradation of periodate-oxidised cellulose.

Three cleavage products (XVI)–(XVIII) are formed initially. The first of these is fairly resistant to the further action of alkali. Products (XVII) and (XVIII) are glyoxal hemiacetals, and are rapidly cleaved by lime-water at room temperature: (XVII) gives equivalent quantities of glycollic and αγ-dihydroxybutyric acids; and (XVIII) yields glycollic acid and a normal, non-reducing terminal glucose unit (XIX). The possibility of such breakdown is supported by a study of the properties of glyoxal hemiacetals [69] and of the alkaline decomposition of model compounds [72]. The ratio of the quantities of glycollic and αγ-dihydroxybutyric acids for cellulose preparations of different degrees of oxidation also supports reaction in this direction, since only the product (XVII), which is formed at a high degree of oxidation of the cellulose, is a source of αγ-dihydroxybutyric acid.

III. OXIDATION OF CELLULOSE BY MOLECULAR OXYGEN IN ALKALINE MEDIA

In the preceding Sections of the Review we have isolated and examined aspects of the alkaline degradation of cellulose and oxycelluloses. We now give an account of published information on the simultaneous oxidative and alkaline degradation of cellulose. The oxidation of cellulose by air in alkaline media can take place both under heterogeneous and under homogeneous conditions. Processes involving the heterogeneous oxidation of cellulose are especially widespread, taking place both in the isolation and processing of cellulose and during the functioning of goods made from it. The Review will be confined to aspects of the heterogeneous oxidation of cellulose.

Most of the many publications on the oxidation of cellulose by molecular oxygen in an alkaline medium are concerned with the investigation of oxidation under the conditions of ripening in the manufacture of viscose rayon. We shall first give the experimental results obtained by various investigators on the oxidation of cellulose by molecular oxygen in alkaline media, and then consider views on the chemical changes undergone by the cellulose macromolecule and the suggested reaction schemes.

1. Process Characteristics of the Oxidation of Cellulose

The autoxidation of cellulose in alkaline media has been followed experimentally by examining the rate of absorption of oxygen, the variation in degree of polymerisation and in functional groups, and the chemical composition of the resulting cellulose and decomposition products of low molecular weight. The first fact to emerge from an examination of these results is that the rate and several features of the oxidation depend in considerable measure on whether the cellulose has been squeezed free from

excess of alkali or whether oxygen is passed through caustic soda solution containing cellulose in suspension. For the sake of brevity we shall henceforward term the former process the "oxidation of alkaline cellulose", and the latter the "oxidation of a cellulose suspension". When discussing the autoxidation of alkaline cellulose the alkali concentration will not be indicated if 18–20% solutions of caustic soda were used for impregnation. The oxidation of a suspension of cellulose is slower than that of alkaline cellulose.

Mention should be made of the difficulties of comparing results obtained by different workers, resulting from the use of different samples of cellulose, obtained not only from different types of raw material but also by different methods of isolation and purification, and resulting also from the use of different methods for determining functional groups and different degrees of polymerisation of the cellulose. Different methods often give different results.

Here we shall not consider the defects of methods for determining functional groups in cellulose, but merely cite the literature on this problem. Critical surveys of such methods will be found in monographs[3,73,74]. Analytical results for carbonyl groups obtained by various methods have been compared by the Sihtola[75], Strole[76], and Gunne and Samuelson[77]. Different methods for determining the copper numbers of cellulose were compared by Bethge and Nevell[78], and copper numbers have been compared with the content of carbonyl groups determined by the hydroborate method[79]. Various methods have been given[80,81] for determining carboxy-groups.

(*a*) Absorption of oxygen

The chief parameter indicating the rate of autoxidation of cellulose is the rate of absorption of oxygen. It must be borne in mind, however, that the oxygen absorbed is consumed not only in the primary oxidation of cellulose macromolecules but also in the oxidation of secondary products of low and high molecular weight, formed as a result of oxidative–alkaline degradation. The rate curves for the absorption of oxygen during the oxidation of alkaline cellulose comprise three portions: the rate varies during the first period, after which it remains constant, and during the third period it falls[82–84].

For any given type of cellulose the initial rate of absorption of oxygen during oxidation of the alkaline material is proportional to the copper number of the regenerated cellulose. The same dependence is shown by cotton cellulose bleached with hypochlorite, hydrocellulose obtained from cotton cellulose, and various wood celluloses. The initial rate of absorption of oxygen by periodate-oxidised cellulose is about half the rate for cotton cellulose and other celluloses having the same copper numbers as the periodate-oxidised sample. A diminished initial rate of absorption of oxygen was observed also for cellulose that had first been subjected to oxidation by molecular oxygen in an alkaline medium. If oxidation was interrupted during the constant-rate period, and the regenerated cellulose was again subjected to oxidation, the rate of absorption of oxygen was very low, far below the steady rate, although the regenerated cellulose had a high copper number. The explanation offered was that probably not all, only a proportion, of the reducing groups of cellulose are capable of initiating its oxidation[84].

In some cases oxidation progresses autocatalytically during the first period: i.e. the rate of absorption of oxygen increases with the duration of oxidation. Purified cotton cellulose, of low reducing power, is oxidised autocatalytically. In other cases the rate of absorption of oxygen gradually decreases, as in the oxidation of wood celluloses of higher reducing power[84]. Sometimes the rate of absorption of oxygen remains constant from the start of oxidation, as with alkaline purified beechwood cellulose[82].

During the second period of oxidation the rate of absorption of oxygen is constant and about the same for different alkaline celluloses, in spite of differences in reducing power[84]. The rate remains constant until the total absorption is ~0.6 oxygen atom per anhydroglucose unit of the cellulose[84].

With increase in the alkali concentration the rate of absorption of oxygen by alkaline cellulose increases, passes through a maximum, and decreases with further increase in concentration. Weltzien and Tobel[85] observed the maximum rates at alkali concentrations of 6.5 *N* and 8.5 *N* for cotton cellulose and for cellulose hydrate regenerated from cuprammonium solution respectively, and Davidson[83] found the optimum for cotton cellulose to be 10 *N* caustic soda. With wood cellulose the maximum rate of absorption of oxygen is found at a concentration of the impregnating alkali of 10–12.5 *N*.[84]

Not only the rate of absorption of oxygen but also the character of the rate curves changes with the alkali concentration for the same cellulose preparation. At alkali concentrations below 8 *N* the initial rate exceeds the steady value in the oxidation both of alkaline cellulose and of a suspension of cellulose; above 8 *N*, however, the initial rate is lower than the steady rate[84,86]. In the oxidation of a suspension of cellulose, in contrast to that of alkaline cellulose, the rate of absorption of oxygen increases continuously with increase in the alkali concentration[86].

A rise in temperature produces an increase in the rate of absorption of oxygen[83–85]. According to Davidson[83] the rate increases approximately ninefold when the temperature of the oxidation of alkaline cotton cellulose is raised from 20° to 40°C. Entwistle et al.[84] calculated the activation energy as ~21 kcal mole^{-1} for sulphite wood cellulose during the period of a steady rate of absorption of oxygen by the alkaline material at temperatures from 5° to 80°C. This value corresponds roughly to a threefold increase in reaction velocity for a 10-deg rise in temperature.

Increase in the oxygen pressure from 25 to 700 mmHg produces an increase in the rate of absorption. At higher alkali concentrations the rate is more strongly dependent on pressure[84,86].

Salts of various metals present in low concentrations in cellulose have an appreciable catalytic effect on its rate of oxidation. Those of iron[87], copper[83], nickel[83], cobalt[86], and manganese at a manganese concentration of 0.002% (on the cellulose)[87,88] are positive catalysts. The greatest effect is exerted by salts of cobalt, followed by manganese, iron, nickel[88], and copper[89]. Gold and silver salts are inhibitors, as also manganese salts at manganese concentrations exceeding 0.05%.[88] Neither catalytic nor inhibiting metal salts have any appreciable effect on the initial rate of absorption of oxygen, but affect it during subsequent stages of the reaction[88].

The addition of substances that form free radicals increases the initial rate of absorption of oxygen[88].

Addition of 0.1% of a typical antioxidation to the impregnating alkali lowers appreciably the steady rate of absorption of oxygen. 1,4-Naphthaquinone and magnesium diphenylamine-*p*-sulphonate were most effective[88].

These antioxidants did not influence the initial rate of absorption.

The initial rate is increased by adding to the impregnating alkali substances capable of autoxidation, such as glucose, formaldehyde, sodium dithionite, etc.[88]

If oxidation is interrupted by removing oxygen from the reaction space, and is then renewed, the original rate of absorption of oxygen is re-established[82,83].

(*b*) Variation of degree of polymerisation of cellulose during oxidation in alkaline media

The degree of polymerisation of cellulose usually drops sharply at the beginning of oxidation, but the rate of depolymerisation then diminishes[84,90-93]. A high rate of depolymerisation during the initial period is observed[94-96] in celluloses having a comparatively high content of carbonyl groups and hence high copper numbers (0.58 to 1.04 according to Brady). In celluloses having low contents of carbonyl groups (Brady copper numbers 0.10–0.18) the rate of depolymerisation remained constant for 24 h. Reduction with sodium tetrahydroborate to diminish the content of carbonyl groups in wood celluloses only slightly decreases the rate of depolymerisation during the first period of oxidation. During the following period the rates for reduced and unreduced cellulose converge, with the rate for celluloses in which the carbonyl groups have been reduced remaining constant[94].

Good agreement was shown[84] between the initial rate of absorption of oxygen by alkaline wood celluloses and the rate of decrease in viscosity, as well as the same ratio of change in viscosity to quantity of oxygen absorbed by alkaline cotton cellulose of varying reducing power. Schulz and Mertes[82] compared their kinetic data on oxygen absorption with the variation in degree of polymerisation during the oxidation of alkaline cellulose at 20°C. They observed a rapid fall in degree of polymerisation at the start of the oxidation of alkaline cotton cellulose, after which depolymerisation slowed down, and a constant rate was established after about 15 h. The rate of absorption of oxygen became constant 100 h after the start of oxidation. In the oxidation of beechwood cellulose under the same conditions the rate of depolymerisation was constant from the very beginning.

The rate of depolymerisation of cellulose during oxidation depends on the caustic soda concentration. At low alkali concentrations cellulose is depolymerised very slowly. For example, the degree of polymerisation hardly changes during the oxidation of a cellulose suspension in 1% and 2% caustic soda solution at 40°C,[97] and varies very slightly during oxidation at 85–86°C.[98] With alkali concentrations up to 80 g litre^{-1} no change in degree of polymerisation occurs for 2 h during the oxidation both of alkaline cellulose and of a cellulose suspension at 50°C. With increase in the caustic soda concentration the rate of depolymerisation of cellulose passes through a maximum according to some investigators[86,99,100] but exhibits a continuous increase according to others[83,89]. The reasons for the discrepancies are obscure.

The rate of depolymerisation of cellulose increases with rise in temperature[99,101,102]. It has been suggested that the mechanism of degradation in the oxidation of alkaline cellulose is probably the same at different temperatures (25° and 50°C), a difference being observed only in the rate of degradation[103].

Catalysis of the oxidation of alkaline cellulose by transition-metal compounds or free radicals is accompanied by increase in the degree of depolymerisation for a given absorption of oxygen[83,88]. In the presence of silver and organic antioxidants the degree of depolymerisation at a given oxygen absorption decreases[83,88]. The introduction of hydrogen peroxide considerably accelerates the rate of depolymerisation during oxidation by molecular oxygen both of alkaline cellulose[104-106] and of a cellulose suspension[107]; the rate of depolymerisation increases with increase in the hydrogen peroxide concentration. Additions to cellulose of sodium sulphide[104], sodium hypochlorite[104,108], and ammonium persulphate (in amounts of 1–8%)[104] accelerate the depolymerisation of alkaline cellulose. The presence in the impregnating alkali of 1% of substances capable of autoxidation, such as glucose and sodium dithionite, has little effect on the rate of depolymerisation of cellulose.

(*c*) Change in functional groups during oxidation of cellulose

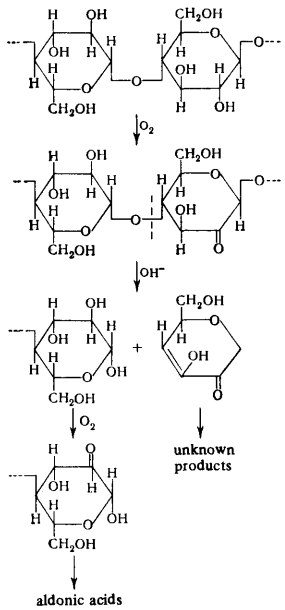
An important feature of the oxidation of cellulose is the formation of carbonyl and carboxyl groups in the macromolecules.

According to Davidson[83] and to Entwistle et al.[84] the reducing power of cellulose, as measured by the copper number, increases continuously during the oxidation of alkaline cellulose by molecular oxygen. According to other workers[81,94,109] the reducing power increases only during the first few hours of oxidation, after which it remains almost unchanged. For a given oxygen absorption the content of aldehyde groups is larger with higher alkali concentrations and in the presence of oxidation catalysts[83,88]. Only a slight change in copper number was observed[97] during the oxidation of a suspension of cellulose.

Both aldehydic and ketonic groups are formed in the oxidation of alkaline cellulose[77]. It is not surprising that the reducing power of cellulose observed during oxidation is slight, since in alkaline media the carbonyl groups undergo further oxidation or the other reactions described earlier. The content of carboxy-groups gradually increases with increasing duration of oxidation[81,84,88,109,110]. At a given oxygen absorption the carboxyl content is greater in the presence of cobalt[88].

The oxidation of alkaline cellulose by molecular oxygen involves the formation of peroxides[84,99,111], the quantity of which diminishes in the presence of traces of salts of metals that catalyse oxidation (cobalt, manganese) and also metals that inhibit oxidation (silver). No peroxide at all could be detected in the presence of 0.0006% of cobalt or 0.0032% of silver[84,88].

(*d*) Chemical composition of products of the oxidative–alkaline degradation of cellulose



Examination of the changes in functional groups and degree of polymerisation during oxidation by molecular oxygen still does not provide an accurate idea of the chemical changes undergone by the cellulose molecule. It is true that the fact that a small quantity of absorbed oxygen produces a considerable change in degree of polymerisation indicates that oxidation occurs throughout the length of the cellulose molecule, not only at its ends. It was suggested that oxygen would attack preferentially carbon atoms carrying the most ionised hydroxy-groups, i.e. the second carbon atom in the repeating unit[84].

However, a more exact picture of the reaction mechanism can be obtained only from a study of the structure of the oxidation products—both those of low molecular weight, which pass into solution, and those of high molecular weight, remaining in the solid phase.

The chemical composition of cellulose remaining after oxidation with molecular oxygen in an alkaline medium depends on the conditions. The only acid found after the oxidation of cellulose hydrate suspended in 1% caustic soda solution in air at 100°C was erythronic acid [112]. Arabonic acid was found, with smaller quantities of erythronic and mannonic acids, in the oxidised cellulose formed from alkaline cellulose at 33°C; small quantities of gluconic and ribonic acids were also detected [113].

According to a hypothetical scheme to explain the formation on erythronic acid [112] the main reaction involves oxidation of the secondary alcoholic groups at $C_{(2)}$ and $C_{(3)}$ to keto-groups with subsequent oxidation to the dicarboxylic acid, which in turn is oxidised to a carbonic ester. Hydrolysis of the ester in an alkaline medium results in cleavage of the macromolecules to give an erythronic acid residue at the end of one newly formed cellulose molecule, and a non-reducing anhydroglucose unit at the end of the other molecule [112].

Scheme 2

Another series of reactions (Scheme 2) has been suggested for the oxidative degradation of alkaline cellulose by workers [113] who found that the oxidised cellulose contained as terminal units arabonic, erythronic, mallonic, gluconic, and ribonic acids in roughly the same proportions as are formed in the oxidation of glucose and cellobiose under similar conditions [114]. On the basis of this observation it was suggested [113] that the terminal aldonic-acid units were formed by the oxidation of reducing terminal glucose units in the cellulose.

2. Mechanism of the Oxidation of Cellulose by Molecular Oxygen in Alkaline Media

(*a*) Radical-chain mechanism of the oxidation of cellulose

During the past two decades investigators have begun to work on elucidating the mechanism of the oxidation of cellulose by molecular oxygen in alkaline media. The first papers on this problem were published in 1949 by Entwistle, Cole, and Wooding [84,88], who suggested a radical-chain mechanism analogous to that of the autoxidation of alkenes. They based it on kinetic data on the absorption of oxygen by alkaline cellulose during oxidation, observations on the catalytic action of transition-metal ions, inhibition by silver and organic antioxidants, the increase in the initial rate of oxidation on the addition of substances that dissociate to form free radicals, and the relation between the initial rate of oxidation and the content of reducing groups. This mechanism includes the stages indicated in the subheadings below.

Chain initiation. The autoxidation of alkaline cellulose begins by the detachment of an active hydrogen atom by molecular oxygen. In cellulose the hydrogen of an aldehyde group (perhaps enolised) is active:

$$R_{cell}-\underset{\underset{H}{|}}{\overset{\overset{O}{\|}}{C}} + O_2 \rightarrow HOO^{\cdot} + R_{cell}-C^{\cdot}=O \quad (1)$$

The resulting cellulose radical then reacts as follows:

$$R_{cell}-C^{\cdot}=O + O_2 \rightarrow R_{cell}-CO(OO^{\cdot}) \quad (2)$$

$$R_{cell}-CO(OO^{\cdot}) + R_{cell}-H \rightarrow R_{cell}-CO(OH) + R^{\cdot}_{cell} \quad (3)$$

Entwistle and his coworkers put forward the hypothesis that the allylic hydrogen in an enolised reducing thermal unit of cellulose should be especially labile, and removable by molecular oxygen:

$$R_{cell}-\underset{\underset{CH_2OH}{|}}{\overset{\overset{CHOH}{|}}{OCH-CHOH-C(OH)=CHO^-}} \xrightarrow{+O_2} R_{cell}-\underset{\underset{CH_2OH}{|}}{\overset{\overset{CHOH}{|}}{OCH-\dot{C}(OH)-C(OH)=CHO^-}} + HOO^{\cdot}$$

These workers assume [84] that oxidation is facilitated by ionisation of the hydroxy-groups of cellulose. The presence of an ionised hydroxyl on a carbon atom attached to hydrogen may strongly polarise and weaken the carbon-hydrogen bond. Oxidising attack in an unchanged repeating unit of cellulose probably takes place at the carbon atom having the most ionised hydroxyl, and hence primarily at the second carbon atom of the anhydroglucose unit.

Chain propagation. Subsequent oxidation of the cellulose takes place by alternation of the reactions

$$R^{\cdot}_{cell} + O_2 \rightarrow R_{cell}-OO^{\cdot} \quad (4)$$

$$R_{cell}-OO^{\cdot} + R_{cell}-H \rightarrow R_{cell}-OOH + R^{\cdot}_{cell} \quad (5)$$

and the hydroperoxy-radical detaches a hydrogen atom from a carbon atom of a repeating unit. In an alkaline medium the resulting hydroperoxides are usually hydrolysed to form hydrogen peroxide:

$$R_{cell}-OOH + H_2O \rightarrow R_{cell}-OH + H_2O_2 \quad (6)$$

After the hydrolysis of hydroperoxides formed on the second, third, or sixth carbon atom of the repeating unit, hydrated forms of the ketone or aldehyde are produced, which immediately lose water to give a keto- or aldehydo-cellulose. If the hydroperoxide has been formed on the

fourth or fifth carbon atom, hydrolysis yields a hemiacetal, which is rapidly hydrolysed with cleavage of the cellulose molecule. Hydrolysis of a hydroperoxide on the first carbon atom produces an orthoester, which in an alkaline medium is also rapidly hydrolysed with rupture of the chain.

The hydroperoxide formed may also undergo homolytic decomposition to give a free radical on the cellulose and a free hydroxy-radical, so that chain branching occurs:

$$R_{cell}\cdot OOH \rightarrow R_{cell}-O^{\cdot} + HO^{\cdot}. \qquad (7)$$

Homolytic decomposition of hydroperoxides is accelerated in the presence of catalytically active metals:

$$R_{cell}-OOH + M^{2+} \rightarrow R_{cell}-O^{\cdot} + HO^{-} + M^{3+}. \qquad (8)$$

Thus the catalytic effect of metals emphasises the radical-chain character of the reaction, although oxidation may take place in their absence. When transition-metal ions are not present, a cellulose hydroperoxide will break down mainly with the liberation of hydrogen peroxide by reaction (6).

Chain termination. Termination may be caused by the association of radicals or by the reaction of radicals with impurities. Since alcohols and carbohydrates can be active inhibitors of chain reactions, it was assumed [84] that the reaction chains might be relatively short.

A weighty argument in favour of the formation of free radicals in the macromolecule in the oxidation of alkaline cellulose is Schurz's observation of the formation of a graft copolymer by the action of styrene on the spontaneously oxidising alkaline cellulose system: a homopolymer is not formed. However, the life of the radicals is very brief, especially at high temperatures. In this worker's opinion the long-lived groups initiating the graft copolymerisation after oxidation has ceased are peroxy-groups in the cellulose, which on heating give free radicals [115]. However, Mottor's attempts to detect free radicals by electron spin resonance were unsuccessful [116]. Determination of the quantity of hydroxyl radicals by a chemical method based on the convertion of benzene into phenol showed their almost complete absence.

(*b*) Ionic mechanism for the oxidation of cellulose

In view of his finding that hydroxyl radicals are absent, Mottor assumes [116] that the autoxidation of alkaline cellulose takes place by an ionic mechanism. Oxygen is regarded as reacting initially with reducing functional groups in the cellulose, probably aldehyde groups, which in an alkaline medium behave as Lewis acids and form the anions (XX) and (XXI):

$$R_{cell}-\underset{\underset{H}{\diagdown}}{\overset{\overset{O}{\diagup}}{C}} \underset{\rightleftharpoons}{\overset{HO^-}{\rightarrow}} R_{cell}-\underset{OH}{\overset{O^-}{\underset{\diagdown}{\overset{\diagup}{C}}}}-H \underset{\rightleftharpoons}{\overset{HO^-}{\rightarrow}} R_{cell}-\underset{O^-}{\overset{O^-}{\underset{\diagdown}{\overset{\diagup}{C}}}}-H + H_2O \quad . \qquad (9)$$

(XX) (XXI)

These anions are able to donate a hydride ion to an oxygen molecule to form a hydrogen peroxide ion:

$$R_{cell}-\underset{O^-}{\overset{O^-}{\underset{\diagdown}{\overset{\diagup}{C}}}}-H + O_2 \rightarrow R_{cell}-\underset{O^-}{\overset{O}{\underset{\diagdown}{\overset{\diagup}{C}}}} + HOO^-, \qquad (10)$$

which oxidises the cellulose.

The ability of hydrogen peroxide to oxidise cellulose is well known [105,117,118]. Kleinert showed that the changes occurring in the oxidation of alkaline cellulose are analogous to those accompanying the oxidation of cellulose by hydrogen peroxide in 18% caustic soda [105].

(*c*) Ion–radical chain mechanism for the oxidation of cellulose

MacDonald [107] combined the two views on the autoxidation of alkaline cellulose and suggested that the initial stages take place by an ionic mechanism, and later stages by a radical mechanism. On the basis of Mottor's results showing the absence of hydroxyl or perhydroxyl radicals during the autoxidation of alkaline cellulose, those of other workers on the effect of transition-metal ions on the formation of hydrogen peroxide and the fall in the viscosity of cellulose, and also his own results on the inhibition of autoxidation by sulphur and on the quantity of hydrogen peroxide formed during the autoxidation of cellulose suspended in caustic soda solution [107], MacDonald considers that at the start of the process, when the reducing groups of the cellulose are undergoing oxidation, hydrogen peroxide can be formed only by Mottor's ionic mechanism (reactions 9 and 10). In the presence of metal catalysts the resulting hydrogen peroxide would form cellulose free radicals but not hydroxyl or perhydroxyl radicals. MacDonald considers that the cellulose radicals are formed by detachment of a hydrogen atom from cellulose by means of complexes of hydrogen peroxide ions with tervalent iron ion. Such complexes had been described by Kremer in a study of the decomposition of hydrogen peroxide by iron(III) salts [119]. The cellulose radicals then react by the chain mechanism suggested by Entwistle et al. (reactions 4–6). The oxidation products $R_{cell}OH$ undergo the further reactions described earlier.

A rather different mechanism was suggested by Michie and Neale [86] for the oxidation of cellulose in an alkaline medium. On the basis of their kinetic data on the absorption of oxygen by cellulose suspended in caustic soda solution, and also data obtained by other investigators on the autoxidation of alkaline cellulose, glucose, and α-ketols, they considered direct initiation of autoxidation by radicals formed by interaction between oxygen and reducing groups in the cellulose to be impossible. They assumed that initiation is effected by monomeric radicals formed by decomposition of hydroperoxides, the latter produced by the reducing groups at the start of the process. Transition-metal ions play an important part in the decomposition of the hydroperoxides. Oxidation then proceeds as in most cases of autoxidation. Formation of a cellulose radical is followed by absorption of oxygen with formation of the corresponding peroxy-radical. The latter radical would be extremely unstable, because hydroperoxides are hydrolysed rapidly in alkaline solution, and also because of the instability of compounds containing a peroxy- and a hydroxy-group attached to the same carbon atom. This radical may therefore be expected to break down rapidly to give an $HO_2^{\cdot}$ radical and a carbonyl group. Under alkaline conditions the $HO_2^{\cdot}$ radical will be almost completely dissociated into the radical ion $O_2^{\cdot -}$. The hydroperoxy-radical $HO_2^{\cdot}$ is known to be far less reactive than the hydroxyl radical $HO^{\cdot}$, [120] so that the ionised form of the former radical will probably be a still weaker oxidising agent. But these workers consider that the radical ion $O_2^{\cdot -}$ is nevertheless able to oxidise a cellulose molecule ionised in strongly alkaline medium.

Michie and Neale give the following scheme for the oxidation of cellulose:

(i) chain initiation

$$HO_2^- \rightarrow O_2^- \quad , \tag{11}$$

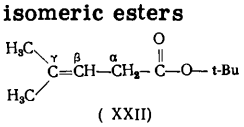
(ii) chain propagation

$$O_2^- + R_{cell}\text{—}\overset{|}{C}HO^- \rightarrow R_{cell}\text{—}\overset{|}{C}\cdot\text{—}O^- + HO_2^- \tag{12}$$

$$R_{cell}\text{—}\overset{|}{C}\cdot\text{—}O^- + O_2 \rightarrow R_{cell}\text{—}\overset{|}{C}\text{=}O + O_2^- \quad , \tag{13}$$

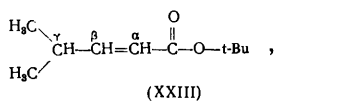
(iii) chain termination

$$R_{cell}\text{—}\overset{|}{C}\cdot\text{—}O^- + O_2^-(H^+) \rightarrow R_{cell}\text{—}\overset{|}{C}\text{=}O + HO_2 \quad . \tag{14}$$



$$2\,O_2^- + H^+ \rightarrow HO_2^- + O_2 \tag{15}$$

Ionisation of the hydroxy-groups of cellulose and of a cellulose radical are represented by the equations



$$R_{cell}\text{—}\overset{|}{C}HOH + HO^- \rightarrow R_{cell}\text{—}\overset{|}{C}HO^- + H_2O \tag{16}$$

$$R_{cell}\text{—}\overset{|}{C}\cdot OH + HO^- \rightarrow R_{cell}\text{—}\overset{|}{C}\cdot\text{—}O^- + H_2O \quad . \tag{17}$$

Thus no generally accepted view has yet emerged on the mechanism of the oxidation of cellulose by molecular oxygen in alkaline media, as on the mechanism of the oxidation under analogous conditions of many compounds of low molecular weight. It may be supposed that, besides the above possible mechanisms of oxidation, some part in these processes will be played by the reactions of carbanions formed under the influence of the alkali. A basis for such a hypothesis is provided by data on the oxidation of esters and ketones in alkaline media with the formation of α-hydroxyperoxides [121,122]. This possibility is demonstrated still more clearly by results for the oxidation of the isomeric esters

(XXII)

(XXIII)

which in an alkaline medium give a considerable quantity of α-oxidised products, but only γ-hydroperoxides by true free-radical oxidation in benzene solution [123].

One possible oxidation mechanism involving carbanions is represented by the scheme [124-127]

$$\rangle C^- + O_2 \rightarrow \rangle C\cdot + O_2^- \tag{18}$$

$$\rangle C\cdot + O_2 \rightarrow \rangle COO\cdot \tag{19}$$

$$\rangle COO\cdot + \rangle C^- \rightarrow \rangle COO^- + \rangle C\cdot \quad . \tag{20}$$

In the classical free-radical mechanism of oxidation, initiation is effected by the detachment of a hydrogen atom from the oxidisable compound (e.g. Eqn. 1), but in the present case it occurs by electron transfer (Eqn. 18). If such a mechanism is accepted, the great ease of oxidation in the presence of alkalis compared with oxidation in neutral medium can be explained. Another mechanism is also possible for the oxidation of carbanions:

$$\rangle C^- + O_2 \rightarrow \rangle CO_2^- \quad . \tag{21}$$

However, there are grounds for thinking that this process is improbable [128].

Whatever the mechanism of oxidation, its result is always the formation of hydroperoxides (or hydroperoxy-radicals) as reaction intermediates. In alkaline media the hydroperoxides are hydrolysed with the formation of hydrogen peroxide, which is able to oxidise cellulose. Further support for this is given by Müller's results [99] showing that the degree of polymerisation of cellulose remains completely unchanged when alkaline cellulose is oxidised by molecular oxygen in the absence of water, whereas with an insufficient quantity of water it changes more slowly than during the oxidation of cellulose in the presence of a sufficient quantity. The absence of water probably slows down not only the rate of formation of hydroperoxides, owing to the diminished degree of ionisation of the cellulose hydroxyls, but also terminates the formation of hydrogen peroxide, because of the impossibility of the hydrolysis of hydroperoxides under anhydrous conditions.

Unfortunately, the mechanism of oxidation by hydrogen peroxide in an alkaline medium has not yet been accurately established. Most investigators adhere to a radical reaction mechanism: they consider that the active oxidising agent is the hydroxyl radical, formed by the decomposition of hydrogen peroxide in the alkaline medium. Kazarnovskii and Neiding [129] assume that the decomposition of hydrogen peroxide in alkaline solutions is caused by reaction between products of its electolytic dissociation and the undissociated molecules:

$$\left.\begin{aligned} H_2O_2 &= H^+ + HO_2^- \\ HO_2^- &= H^+ + O_2^{2-} \end{aligned}\right\} \text{electrolytic dissocation}$$

$$O_2^{2-} + H_2O_2 = O_2^- + OH^- + OH\cdot \quad \text{(chain initiation)}$$

$$\left.\begin{aligned} H_2O_2 + OH\cdot &= H_2O + HO_2\cdot \\ HO_2\cdot &= H^+ + O_2^- \\ H_2O_2 + O_2^- &= OH^- + O_2 + OH\cdot \end{aligned}\right\} \text{reaction chain} \quad .$$

Several investigators, however, hold a different view on the mechanism of the oxidising action of hydrogen peroxide, regarding the active agent as the anion HO_2^-. [130-132]

It must be supposed that further investigations on the mechanism of the oxidative-alkaline breakdown of cellulose under the influence of molecular oxygen in various media will establish the actual mechanism of these processes.

IV. EFFECT OF SUPERMOLECULAR STRUCTURE OF CELLULOSE ON ITS ALKALINE AND OXIDATIVE-ALKALINE DEGRADATION

The reactivity of cellulose, as of other biopolymers, is greatly dependent on its supermolecular structure. The ordered "crystalline" portions of cellulose must be supposed to be less reactive than the disordered "amorphous" portions, which are more easily accessible to chemical reagents. Structure may affect both the rate of depolymerisation and the nature of the processes involved, by changing the relative reactivities of atoms and groups in the repeating unit.

Few data are available on the effect of the supermolecular structure on alkaline degradation, but they are consistent with the above view. Thus Meller [133] noted the effect of the structure of the cellulose fibre on the rate of the changes occurring from the reducing end, and suggested [4,133] that intramolecular and intermolecular hydrogen bonds play a part in the reactivity of celluloses.

Colbran and Davidson [12] showed that hydrocelluloses obtained from mercerised cotton cellulose are more stable to the action of hot dilute alkalis than are those obtained from unmercerised cotton cellulose of the same reducing power. The alkali-insoluble cellulose had considerably lower copper numbers and contained a greater quantity of carboxy-groups in the case of degradation of the hydrocelluloses obtained from mercerised cellulose.

The difference was explained by the effect of the supermolecular structure on the stabilising reaction, which is evidently favoured by the structure of cellulose II. Evidence of the greater resistance of this form to hot dilute alkalis is provided also by Machell and Richards' results [134] showing that pretreatment of hydrocellulose with 5 *N* sodium hydroxide solution increases its stability to the subsequent action of the 0.5 *N* alkalis at 100°C and by the enhanced stability [135] of unbleached sulphite pulp to the action of hot dilute alkalis resulting from its mercerisation.

Swelling and "decrystallisation" of cellulose diminish its resistance to hot dilute alkalis [133].

Machell and Richards [134] and Colbran and Davidson [12] observed that only certain molecules in the residue resistant to further degradation, obtained when hydrocellulose was treated with hot dilute alkali, contained metasaccharinic acid as terminal unit. These workers assumed that degradation ceased not only when the reducing terminal unit of cellulose was converted into a metasaccharinic acid residue but also when the reactant end of the molecule reached inaccessible (crystalline) regions of the cellulose fibre. Richtzenhain et al. [10] found no significant differences in the X-ray patterns or in the distribution curves for the degree of polymerisation of hydrocellulose before and after treatment with hot dilute alkali. The explanation offered was that only that part of the material located in disordered regions and on the surface of ordered regions of the cellulose suffered breakdown.

Very few results have been published on the effect of the supermolecular structure of cellulose on its oxidation by molecular oxygen in alkaline media. However, the available data indicate that the less ordered portions of cellulose are the more reactive. Thus the rate of oxidation of alkaline cellulose is considerably increased if the cellulose has first been swollen in alkali [83,99]. The X-ray patterns of cellulose oxidised after swelling are typical of cellulose hydrate, whereas the interference pattern obtained after oxidation without preliminary swelling is identical with that of native cellulose [99]. Preswelling obviously increases the proportion of amorphous regions in the supermolecular structure. As Brassard suggested [100], this process may be responsible for the increase in the rate of oxidation of alkaline cellulose with increase in the caustic soda concentration (see Section III, 1*b*).

A fairly recent investigation [136] of the effect of the supermolecular structure of cellulose on its oxidative degradation by the action of molecular oxygen on a suspension in 1% caustic soda solution at 100°C has shown a marked difference in rate of oxidation between natural cotton cellulose and cellulose hydrate obtained from cotton cellulose. After the carbonyl groups had been reduced, the hydrate was degraded at a greater rate, whereas natural cotton cellulose underwent only slight degradation. The structure of cellulose hydrate differs from that of natural cotton cellulose in the type of packing of molecules in the ordered ("crystalline") regions, in the size of the densely packed regions, and in the degree of ordering (crystallinity) of the cellulose. The influence of these structural features on the rate of oxidative-alkaline degradation was investigated.

This work showed that, after the carbonyl groups had been reduced, oxidative-alkaline degradation occurred at the same rate in densely packed regions of native cotton cellulose and in the cellulose hydrates isolated from them by hydrolysis. Thus the difference in the rates of oxidation of the two materials can be explained only by different degrees of ordering, which was confirmed by examining the oxidation of specimens of cellulose differing in this parameter. It should be mentioned in this connection that cellulose undergoes oxidation even in the absence of carbonyl groups [136]. Cellulose hydrate, which X-ray examination showed to possess a lower degree of ordering, is then oxidised especially intensely. It was concluded from the experimental results that the oxidising process can be initiated not only by carbonyl groups but also by hydroxyls situated in disordered regions.

The constancy of the degree of polymerisation during the oxidation of hydrocelluloses, obtained both from native cotton cellulose and from cellulose hydrate, implies [136] that the oxidative-alkaline degradation of hydrocelluloses takes place only from the ends of macromolecules and on the surface of ordered regions.

The above survey of the literature shows that processes involved in the degradation of the cellulose molecule and oxidised celluloses have been studied in detail, whereas the reaction mechanism of the oxidation of cellulose by molecular oxygen in an alkaline medium had not yet been adequately elucidated. These processes are of the utmost importance in the technology of cellulose and other polysaccharides, and further research is needed in order to control them.

Dynamic Nuclear Magnetic Resonance

N.M.Sergeev

Nuclear magnetic resonance spectroscopy has been widely used in recent years to investigate the kinetics of chemical reactions. Dynamic nuclear magnetic resonance spectroscopy covers the investigation of temperature-dependent n.m.r. spectra and the calculation of rate constants and Arrhenius parameters from these spectra. The present Review describes the principles of d.n.m.r. spectroscopy, methods of recording the spectra, and their processing by exact and approximate methods. The theoretical and experimental foundations are illustrated by many examples of the investigation of hindered rotations, inversions, and rearrangements in various organic and organometallic systems. A list of 81 references is included.

I. INTRODUCTION

The most diverse physicochemical methods have been used to investigate the kinetics of chemical reactions[1-4]. Recently nuclear magnetic resonance (n.m.r.) spectroscopy has found wide application. Dynamic nuclear magnetic resonance (d.n.m.r.) spectroscopy involves observing the changes with temperature in n.m.r. spectra and hence calculating reaction rate constants and the corresponding Arrhenius parameters. Dynamic effects in n.m.r. spectra were first detected by Gutowsky and his coworkers in 1953.[5,6] Since then various investigations have been made in this field, and several reviews have been published[7-13] on the theory and applications of d.n.m.r. spectroscopy.

At the present stage in the development of the technique and applications of d.n.m.r. spectroscopy several new and original methodological principles have been suggested which broaden significantly the possibilities, and among which carbon-13 n.m.r. spectroscopy may be the most promising approach. Secondly, the abundance of experimental data and the inadequacy of procedures for their analysis demand a critical assessment of the accuracy with which activation parameters are measured. Thirdly, the application of d.n.m.r. has led to the discovery of a completely new class of fluctuating or stereochemically non-rigid molecules, i.e. compounds capable of degenerate intramolecular rearrangements. The present Review discusses these problems as illustrated by various organic and organometallic systems.

II. ELEMENTS OF THE THEORY OF DYNAMIC NUCLEAR MAGNETIC RESONANCE

Dynamic n.m.r. data are usually analysed in terms of the theory of rate processes, clear and detailed accounts of which can be found in monographs[3,4]. Only the main formulae are given below.

The reaction A ⇌ B can be represented most simply by a plot of free energy against the generalised reaction coordinate (Fig. 1), where the state of maximum energy is termed the transition state (Tr). The rate constant of the change from state A to state B is given by the formula

$$k_{AB} = \varkappa \frac{k_{Bol}T}{h} \exp(-\Delta G^{\neq}_{AB}/RT) , \quad (1a)$$

$$\Delta G^{\neq}_{AB} = \Delta H^{\neq}_{AB} - T\Delta S^{\neq}_{AB} , \quad (1b)$$

where $\varkappa$ is the transmission coefficient, $\Delta S^{\neq}$, $\Delta H^{\neq}$, and $\Delta G^{\neq}$ are the entropy, enthalpy, and free energy of activation respectively, T is the temperature, and the remaining symbols represent fundamental constants. In view of the slight temperature dependence of the pre-exponential factor, use is often made of the Arrhenius equation

$$k = A \cdot \exp(-E_a/RT) , \quad (2)$$

where A is the frequency factor and E_a is the activation energy. Comparison of Eqns. (1) and (2) gives

$$\Delta H^{\neq} = E_a - RT ,$$

$$\Delta G^{\neq} = E_a - RT - T\Delta S^{\neq} , \quad (3)$$

$$A = \varkappa \frac{k_{Bol}T}{h} \cdot e \cdot \exp(\Delta S^{\neq}/RT) .$$

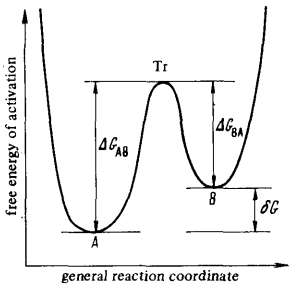

Figure 1. Form of potential-energy surface for exchange between two states.

The activation energy is determined experimentally from the dependence of $\ln k$ on $1/T$ by means of the equation

$$E_a = -R \cdot \frac{\partial(\ln k)}{\partial(1/T)} . \quad (4)$$

Under equilibrium conditions we can determine the equilibrium constant for the reaction A ⇌ B

$$K = p_A/p_B = k_B/k_A = \exp(-\delta G/RT) , \quad (5)$$

where p_A and p_B are the populations (or concentrations) of states A and B, and $\delta G = \Delta G^{\neq}_{AB} - \Delta G^{\neq}_{BA}$.

If the reaction rate constant k_{AB} is considerably smaller than 0.01 s^{-1}, the reaction is slow. The n.m.r. method can then be used to monitor the changes in concentration of the states with time by measuring the integral intensities of the corresponding signals. In spite of the triviality of such measurements, there are an immense number of examples where n.m.r. is used in this way, including extremely complicated coupled reactions in multicomponent systems. Several examples can be found in Ionin and Ershov's book[13].

The concept of the lifetime τ of a state[11-13] is often used in d.n.m.r. spectroscopy. For complex reactions the lifetime τ_{ij} of a state i with respect to transition to state j is defined by the formula

$$\tau_{ij} = 1/k_{ij} . \quad (6)$$

The lifetime may vary within wide limits depending on the temperature (Eqns. 1 and 2). The choice of method for recording a rate process is determined by the ratio of the lifetime of the state to the characteristic time of the method τ_m. The latter quantity is a time constant characterising the processes of energy dissipation (relaxation) in the corresponding frequency range (Table 1). Intermittent processes in a molecular system that are more rapid than the dissipation (relaxation) processes in the corresponding frequency range cannot be recorded, and such a system appears static (averaged over the states involved) when the given method is used.

Table 1. Characteristic times of some physical methods used in chemistry.

Method	Time, s	Method	Time, s
Electron diffraction	10^{-20}	Electron spin resonance	10^{-4}—10^{-8}
X-Ray diffraction	10^{-18}	Nuclear magnetic resonance	10^{-1}—10^{-7}
Ultraviolet (electronic) spectra	10^{-14}—10^{-15}	Molecular beams	10^{-6}
Vibrational spectra	10^{-11}—10^{-13}	Visual methods (separation of isomers)	10^{2}
Ultrasonic absorption	10^{-5}—10^{-9}		

It is interesting that the characteristic time constant of the n.m.r. method covers a very wide range (Table 1). The reason is that various methods are used in n.m.r. spectroscopy, which permit the recording of processes ranging from rapid ($k \simeq 10$ s^{-1}) to very rapid ($k \simeq 10^7$ s^{-1}). This range of reaction velocities is usually inaccessible to other methods[12-15]—a fact responsible for the widespread interest in d.n.m.r. spectroscopy.

The discovery of dynamic effects on n.m.r. spectra[5,16] was followed by theoretical descriptions of this phenomenon by Gutowsky and Holm[16], Hahn and Maxwell[17], and McConnell[18] based on Bloch's phenomenological equations for the nuclear magnetisation vector[19]. This work has been analysed in reviews[7,8], so that we shall merely give the equation for the complex magnetisation G in exchange between two positions A ⇌ B

$$G = i\omega_1 M_0 \frac{[(\tau_A + \tau_B) + \tau_A\tau_B(\alpha_A p_A + \alpha_B p_B)]}{(1+\alpha_A\tau_A)(1+\alpha_B\tau_B)} \quad (7)$$

where $\omega_1 = \gamma H_1$ (in which γ is the gyromagnetic constant and H_1 the amplitude of the high-frequency field), M_0 is the equilibrium intensity of magnetisation,

$$\alpha_i = \frac{1}{T_2} + i(\omega_i - \omega)$$

τ_A and τ_B are the lifetimes in states A and B,

$$p_A = \frac{\tau_A}{\tau_A + \tau_B} , \qquad p_B = \frac{\tau_B}{\tau_A + \tau_B} , \quad (8a)$$

$$\tau = p_A\tau_B = p_B\tau_A . \quad (8b)$$

T_2 is the spin–spin relaxation time, and ω_i and ω are the resonance and instantaneous frequencies respectively.

The complex magnetisation G is defined as $u + iv$, where in particular the component v perpendicular to the field vector H_1 is termed the absorption signal[7,11,12,19], while the component u is the dispersion signal. The v components are usually recorded. The form of the absorption signal for a two-position exchange can be obtained from the imaginary part of Eqn. (7):

$$v = \omega_1 M_0 \frac{[(1+\tau/T_2)P + QR]}{P^2 + R^2} \qquad (9)$$

where

$$P = \tau\left\{\frac{1}{T_2^2} = \left[\frac{1}{2}(\omega_A + \omega_B) - \omega\right]^2 + \frac{1}{4}(\omega_A - \omega_B)^2\right\} + \frac{1}{T_2} ,$$

$$Q = \tau\left\{\frac{1}{2}(\omega_A + \omega_B) - \omega - \frac{1}{2}(\omega_A - \omega_B)(p_A - p_B)\right\} ,$$

$$R = \left\{\frac{1}{2}(\omega_A + \omega_B) - \omega\right\}(1 + 2\tau/T_2) + \frac{1}{2}(\omega_A - \omega_B)(p_A - p_B).$$

Analysis of Eqn. (9) enables two regions of values of τ to be isolated, for which quite accurate calculations can be made by means of simplified formulae[16,18].

1. Approximation of Slow Exchange $\tau \gg (\nu_A - \nu_B)^{-1}$†

Two signals are observed corresponding to the two states with their statistical weights p_A and p_B. The signal from A in particular has a Lorenzian profile, and the line width $\delta\nu_A$ (in c/s) at midheight is given by

$$\delta\nu_A = \frac{1}{\pi T_{2A}} + \frac{1}{\pi\tau_A} \quad . \qquad (10)$$

2. Approximation of Rapid Exchange $\tau \ll (\nu_A - \nu_B)^{-1}$

Only one signal is observed, having the resonance frequency $\nu = p_A\nu_A + p_B\nu_B$. Its width is given approximately by Meiboom's formula[20]

$$\delta\nu = \frac{p_A}{\pi T_{2A}} + \frac{p_B}{\pi T_{2B}} + 4\pi^2 p_A^2 p_B^2 (\nu_A - \nu_B)^2(\tau_A + \tau_B) \quad . \qquad (11)$$

Computers are generally employed to calculate the complete line shape of the signal of the v component for any values of τ_A and τ_B, owing to the cumbersome computations involved, although a few other approximate methods have been suggested (nomograms[12,21], ratio of maxima and minima in the absorption spectrum[22]).

Fig. 2 illustrates the changes undergone by the spectrum in a two-position exchange. When the populations of the states are equal $p_A = p_B = \frac{1}{2}$, the separate stages in the dynamic process are easily detected. When $\tau >$ 100 s, no appreciable broadening of the lines is observed, and exchange cannot be detected. With slow exchange $\tau \simeq 1$ s, each component of the spectrum becomes wider and moves towards the centre (Fig. 2*a*). The signals coalesce at values of $\tau = \sqrt{2}/2\pi(\nu_A - \nu_B)$. On subsequent increase in the rate of exchange the line again narrows. Finally, with $\tau < 10^{-5}$ s (with $\Delta\nu = 100$ Hz—Eqn. 11), the broadening becomes so small ($\sim$ 0.1 c/s) that the exchange process can no longer be reliably recorded. Exchange effects are similar in the case of unequal populations (Fig. 2*b*), the only difference being that they are more significant for the less populated state (B in Fig. 2*b*). It is easily seen that, if the difference in free energies δG exceeds 3 kcal mole^{-1} (Fig. 1), which corresponds to $p_B < 10^{-2}$, the exchange effects become so small that it becomes difficult to record the actual fact of exchange.

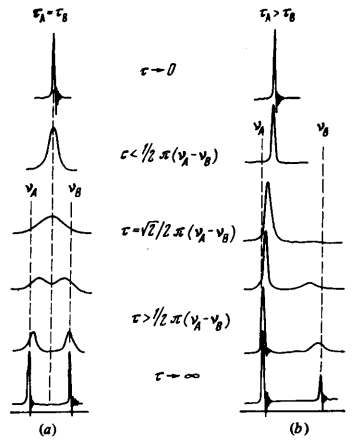

Figure 2. Qualitative shapes of n.m.r. signals for two-position exchange with spectra obtained under the conditions: a) $\tau_A = \tau_B$; b) $\tau_A \neq \tau_B$.

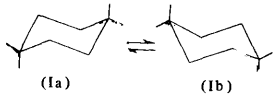
These conditions impose evident limits to the applicability of the d.n.m.r. method to the investigation of rate processes.

III. TECHNIQUE FOR THE ANALYSIS OF DYNAMIC NUCLEAR MAGNETIC RESONANCE SPECTRA



In practice the dynamic effects in n.m.r. spectra described in Section II are always complicated by several additional factors. The greatest difficulties arise from the multiplet structure of the spectra due to indirect spin–spin interaction, in which two cases must be distinguished. (i) The n.m.r. spectra for weakly coupled spin systems ‡ can be regarded as a superposition of d.n.m.r. spectra analogous to those shown in Figs. 2*a* and 2*b* for $p_A = p_B$ and $p_A \neq p_B$ respectively. Simple graphical methods of calculating rate constants have been developed[24,25] to analyse multiplet d.n.m.r. spectra. Relations have also been suggested[26,27] enabling several more complicated situations to be analysed, in which methods of subspectral analysis make it possible to isolate simple subspectra. (ii) With strongly coupled spin systems a complete description of the high-resolution spectra is impossible on the basis of the Bloch equations, and methods of quantum mechanics must be used. A complete description of the effects in systems with strong coupling of the spins was first given by Kaplan[28] using the

† Here and subsequently it is convenient to use angular frequencies $\nu = \omega/2\pi$.

‡ This term is applied to systems[23] in which any pair of nuclei with resonance frequencies ν_A and ν_B and a spin–spin interaction constant J_{AB} conforms to the relation $J_{AB}|\nu_A - \nu_B| \ll 1$.

density matrix. This method was later developed by Alexander[29] for the interchange of spins. Work on these lines was reviewed by Johnson[8] and by Lynden-Bell[9]. In recent years Binsch has put forward a general theory of line shape in high-resolution n.m.r. spectra based on Liouville's theorem[30,31].

The multiplet character of the signals in d.n.m.r. spectra must be taken into account because the most widely used method for analysing dynamic effects is proton magnetic resonance (p.m.r.) spectroscopy[12,13]. The investigation of inversion in cyclohexane

provides a typical example of the procedure for allowing for such multiplets[11-13,32-37]. At room temperature the p.m.r. spectrum is a narrow singlet, so that cyclohexane can be used as a standard of resolution. As the temperature falls the signal begins to broaden, and at −50°C its width is ~ 20 Hz (for a proton resonance frequency of 60 MHz [32]). With further drop in temperature the signal divides into two multiplets separated by 0.5 ppm and having a complicated structure[32]. Below −100°C the width of the lines of the doublet is maintained. The changes observed in the spectrum are interpreted as due to inversion of the ring (Ia ⇌ Ib). With such inversion each proton is sometimes in an axial position and sometimes in an equatorial position: i.e. it is "exchanged" between the two positions.

One of the most important stages in the investigation of dynamic effects is calculation of the spectrum in the absence of exchange. It is easy to see that in the case of cyclohexane such calculation is impracticable, since we need to analyse very complicated n.m.r. spectra (the p.m.r. spectrum of cyclohexane under these conditions can be described as an A_6B_6 system with magnetic nonequivalence).

These difficulties can be avoided to a certain extent by the use of deuteriated compounds[33,34,38]. Isotope effects due to the introduction of heavy hydrogen are assumed to be small and to have no significant effect on the barrier to inversion of the ring. Bovey et al.[33] investigated the proton spectra of undecadeuterocyclohexane. Since $J_{HH}/J_{HD} = \gamma_H/\gamma_D \simeq 7$, the width of the multiplet in the p.m.r. spectra of strongly deuteriated compounds should decrease significantly. Further narrowing of this signal is achieved by the use of $^1H-\{^2D\}$ heteronuclear double resonance. In this case observation of the proton signals at the ^1H frequency (60 MHz) is accompanied by exposure to a second frequency (9.2 MHz), corresponding to ^2D resonance in the same external magnetic field. Use of this technique enabled quite narrow lines (Fig. 3), corresponding to the equatorial and axial positions, to be obtained at low temperatures[34].

The spectra in Fig. 3 already permit approximate methods to be used to calculate rate constants. These methods, based on Eqns. (10) and (11), are often termed *parameter analysis* (Table 2). Many uncertainties generally arise from the use of approximate methods, so that the accuracy of the determination of activation parameters is no better than 10%. Among such uncertainties are the effect of the instrument line width, the temperature dependence of relaxation times and chemical shifts, and the presence of weak spin–spin interactions leading to broadening of the signal. More detailed information on the procedure for correcting for these factors can be found in several published sources[26,27,34,35,40,41].

In some cases it is advisable to simplify the d.n.m.r. spectra by the "fluorine label" method[36] together with the use of deuteriated compounds. The basis of this method is that fluorinated model compounds usually give ^{19}F spectra which are simpler than the proton spectra of the corresponding initial compounds. In particular Roberts[36] suggested that the inversion of cyclohexane (I) should be simulated by that of 1,1-difluorocyclohexane. At +35°C the ^{19}F n.m.r. spectrum of this compound consists of one multiplet (a quintet) due to spin coupling with neighbouring protons. On cooling to −40° the signal broadens, and at −110°C a spectrum of type AB appears, corresponding to two ^{19}F nuclei in a stereochemically rigid structure. The signals of one nucleus are further split into triplets as a result of spin coupling with a pair of neighbouring protons.

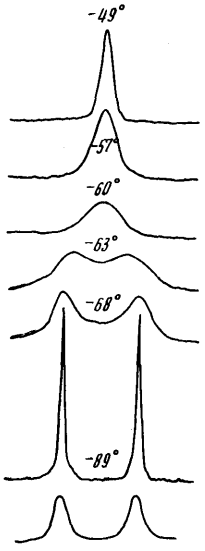


Figure 3. Proton magnetic resonance spectra of C_6HD_{11} with uncoupling from deuterons[34]; the bottom spectrum has been recorded at low temperatures without such uncoupling.

In the temperature range between −100° and +40°C quite complicated changes are observed in the ^{19}F spectrum, owing to mixing of A and B states both as a result of exchange and because of strong coupling between the spins[41]. Nevertheless, the fluorine-19 spectra permit quite accurate analysis of activation parameters by $^{19}F-\{^1H\}$ double resonance.

Dynamic processes can be investigated also by means of non-stationary n.m.r. techniques[35,37,40], for which purpose spectra can be recorded under conditions of rapid flow or pulse methods can be used[42]. Information on rate constants can also be obtained from measurements of relaxation times T_1 (or T_2). In the Carr–Purcell method[37,42], which is most convenient for measuring times T_2, the magnetisation vector M is first subjected to a 90° pulse, i.e. a pulse which turns the vector through 90° and brings it into the xy plane. This is followed by

a series of 180° pulses at intervals of time t_p, $3t_p$, $5t_p$, etc.; as a result of the action of each such pulse the "warmed up" magnetisation vector begins to "run down" and will give spin echo signals at times $2t_p$, $4t_p$, $6t_p$, etc.

Table 2. Approximate methods of calculating rate constants in d.n.m.r. spectroscopy.

Type of method	Basic information	Ref.
Approximation of slow exchange	line width of components $\Delta\nu_{1/2}$ and distance between them $\Delta\nu$ used	7, 18, 34
Approximation of rapid exchange	line width of signal after merging $\Delta\nu_{1/2}$ used	7, 20, 34
Temperature of collapse T_c	temp. determined at which signals merge	7, 34
Temperature of stereochemical rigidity T_r	temp. determined at which appreciable broadening of lines observed at stage of slow exchange	7.39

Because of the occurrence of transverse relaxation processes with time T_2, however, a successive weakening of these signals is observed, which enables T_2 to be measured. If we choose $t_p \ll \tau$, the system will be perceived as static, and damping will correspond solely to dipole–dipole relaxation. If, however, $t_p > \tau$, damping will include a contribution by the exchange process. Equation (10) shows that the contribution by the dynamic process will shorten the effective relaxation time.

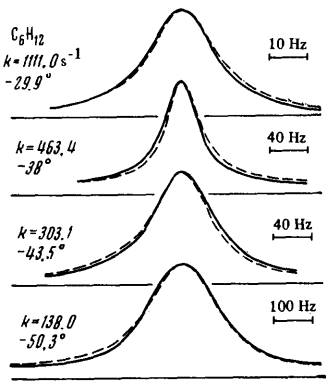

Figure 4. Line-shape analysis in p.m.r. spectra of cyclohexane (100 MHz) at various temperatures[21]: full curves obtained experimentally; broken curves theoretically.

The spin echo method is convenient for investigating rapid dynamic processes. It has been used in particular to measure the time T_2 in cyclohexane (C_6HD_{11}) in the high-temperature range (up to 312°K)[35,37], where continuous n.m.r. methods are ineffective.

It is interesting that spin–spin multiplicity in the region of high-temperature narrowing can be allowed for classically in terms of the Bloch equations[8], which enables methods of *complete line shape analysis* to be applied on the basis of an equation of type (7)§. Calculations by this method are made on an electronic computer[45–48], and sometimes include a stage in which experimental and theoretical spectra are matched by means of special iterative procedures[26,27,49]. The method has been applied to cyclohexane by Inglefield et al.[35] Fig. 4 shows the theoretical spectra having the smallest standard deviation from the corresponding experimental spectra for cyclohexane C_6H_{12}. Satisfactory agreement between the line shapes is evident. Such comparison enables a derived parameter—the rate constant k—to be correlated with an experimental parameter—the temperature.

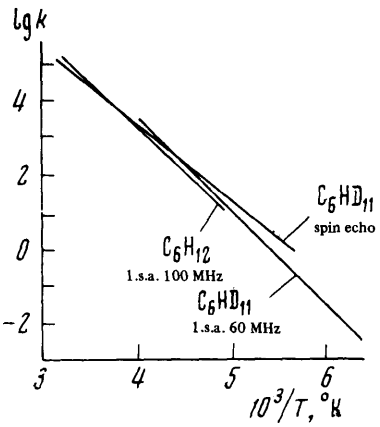

Figure 5. Comparison of various results for the dependence of $\lg k$ on $1/T$ for cyclohexane[35].

Fig. 5 illustrates the variation in $\lg k$ (the rate constant of the inversion of cyclohexane) for three different methods—(a) spin echo[37] and complete line shape analysis at (b) 100 MHz (Fig. 4)[35] and (c) 60 MHz [34] for C_6HD_{11}.

Table 3. Activation parameters for the inversion of cyclohexane and related compounds*.

Compound	Method	Temp. range, °C	E_a, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	$\Delta G^{\neq}$, kcal mole^{-1}	Ref.
C_6H_{12}	l.s.a., 100 MHz	223—263	10.8±0.2	—3.6	10.8	35
C_6HD_4	spin echo	178—312	9.5	—5.8	10.6	37
$C_6D_{11}H$	l.s.a., 60 MHz	156—256	11.24	+2.8	9.8	35
$C_6D_{11}H$	p.a., 60 MHz	198—226	10.9±0.5	+1.4	10.0	12, 33

* l.s.a. = line-shape analysis; p.a. = parameter analysis.

The results of the various investigations of the inversion of cyclohexane (Table 3) enable certain comments to be made on the accuracy of the measurements of activation parameters. Interest in this question has arisen from

§ Dynamic n.m.r. spectra under conditions of multiposition exchange have been considered in Refs. 43 and 44.

the fact that, despite the wide application of d.n.m.r. spectroscopy in various kinetic investigations, the accuracy of the measurement of activation parameters is small. As a consequence, the analysis of dynamic effects is restricted in many cases to a qualitative picture (establishment of the actual fact of exchange, determination of the approximate temperature range, estimation of the free energy of activation). Recent detailed analyses of the errors involved in the use of various forms of d.n.m.r. [21,26,27,35,39,40,49] lead to certain conclusions.

Approximate methods of analysis (Table 2) yield activation parameters with an accuracy of at best 10%. In principle an accuracy of 2–3% can be achieved by line shape analysis, provided that several conditions are observed, primarily careful experimental recording of the spectra. Important factors are slow passage, absence of phase distortions and amplitude non-linearities, control of resolution throughout the temperature range, and accurate measurement of temperature [39]. Experimental data can be compared only if conditions (solvent, concentration) are fully adequate [11,26]. On the other hand, methods of line shape analysis should be adequate in allowing for relaxation, the temperature dependence of the resonance frequencies, and the character of the iteration procedures [27,49].

In the analysis of complicated spectral systems (e.g. cyclohexane) it is possible to use simpler model systems. It must always be borne in mind that the model may not be adequate to the system. In particular, when strongly deuteriated models are used (C_6HD_{11} in the case of cyclohexane), the total secondary isotope effect may exceed the error of measurement [4]. Fluorinated models (systems with a fluorine label), while being attractive experimentally, must be all the more inadequate models.

Investigations of the activation parameters for inversion in cyclohexane show that the possibility of making measurements over a wide temperature range is an important factor.

It is interesting that, in spite of the poor accuracy with which the activation functions E_a and $\Delta S^{\neq}$ are determined (especially by approximate methods), the free energy of activation can be determined very accurately [10,11,39,49] (Table 3). The reason is that the value of $\Delta G_T^{\neq}$ is obtained directly from data on rate constants (Eqn. 1), whereas E_a is evaluated as the difference between two sometimes closely similar values of $\lg k$ (Eqn. 4). Kessler [10] gave a curious graph for the activation functions of rotation in dimethylformamide: a plot of E_a against $\Delta S^{\neq}$ showed that values of E_a obtained experimentally in various studies cover a range of 8–28 kcal mole^{-1}. [1] However this variation is almost linear, so that values of $\Delta G_T^{\neq}$ differ by at most ±1 with a mean value of 21.5 kcal mole^{-1}.

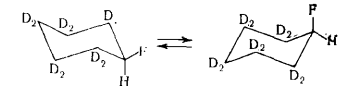
Summarising, we can say that d.n.m.r. spectroscopy at present has diverse ways of recording spectra and techniques for analysing the data, which permits both the rapid and straightforward estimation of free energy of activation and also the accurate determination of activation parameters.

IV. CLASSIFICATION ACCORDING TO TYPE OF SPECTRA OF THE EXCHANGEABLE SPIN SYSTEMS

Where spin multiplicity is present the d.n.m.r. spectra can be classified in conformity with the type of n.m.r. spectra (according to Pople's nomenclature [12,13,23] characteristic of the separate instantaneous structures.

1. The ^{19}F spectrum of 1,1-difluorocyclohexane, under conditions of uncoupling from the protons [41] at sufficiently low temperatures, is of type AX, where A is a ^{19}F nucleus in an axial position, and X a ^{19}F nucleus in an equatorial position, which can be denoted as the A(1)X(2) type. As a result of inversion of the ring the fluorine atoms exchange positions. Thus the whole spectrum under conditions of exchange is described by the relation

$$\begin{array}{c} A(1)\,X(2) \rightleftarrows X(1)\,A(2), \\ \text{or}\quad AX \rightleftarrows XA\ . \end{array} \qquad (12)$$



In principle this case of exchange is described more rigorously by the equation

$$AB \rightleftarrows BA \qquad (13)$$

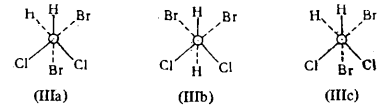
which takes into account the mixing of the eigenfunctions of nuclei A and B due to strong spin coupling. In the limit of rapid exchange (i.e. as $\tau \to 0$) the spectrum is a singlet in both cases (12) and (13). In systems with strong mixing of the spin functions of the nuclei the lifetime of a state at the instant of collapse of the signals in the spectrum can be estimated [50] by means of the formula

$$\tau_c = \frac{2}{\pi}[(\nu_A - \nu_B)^2 + 6J^2]^{-1/2}\ . \qquad (14)$$

2. In contrast to the exchange described by Eqns. (12) and (13), corresponding to so called interchange [11,31], cases are theoretically possible in which the individual structures are not identical. Let us examine in particular the d.n.m.r. spectra of decadeuterofluorocyclohexane (II) under conditions of conformational mobility [51]

$$\text{or}\quad F_{eq}\,H_{ax} \underset{k_1}{\rightleftarrows} F_{ax}\,H_{eq}$$

$$A_1X_1 \underset{k_2}{\rightleftarrows} A_2X_2\ . \qquad (15)$$



The different subscripts for AX systems in this case show that the spectral parameters of the systems are different. Processes of type (15) are in general non-degenerate ($k_1 \neq k_2$). In the case of rapid exchange the spectrum corresponds to a system of type AX with the average parameters

$$\begin{aligned} \langle\delta_A\rangle &= p_1\delta_{A_1} + p_2\delta_{A_2}\ , \\ \langle\delta_X\rangle &= p_1\delta_{X_1} + p_2\delta_{X_2}\ , \\ \langle J_{AX}\rangle &= p_1J_{A_1X_1} + p_2J_{A_2X_2}\ , \end{aligned} \qquad (16)$$

where

$$p_1 = \frac{k_2}{k_1+k_2};\quad p_2 = \frac{k_1}{k_1+k_2}\ .$$

3. A system of two nuclei with slightly non-equivalent instantaneous structures is illustrated by 1,1,2,2-tetrasubstituted ethanes, e.g. HCl_2C-CBr_2H. [51] Rapid rotation about the carbon–carbon bond usually occurs in these molecules, which is clearly depicted by Newman projections as the three structures

(IIIa) (IIIb) (IIIc)

Two of them (a and c) are gauche (or skew) forms, and one a *trans*-form. In the absence of exchange the spectra of structures (IIIa), (IIIb), and (IIIc) are of types A*B*, A**B**, and A*B* respectively, where it is implied that the gauche isomers are spectrally indistinguishable.

Rotation about the carbon–carbon bond is described by the equations

$$A^*B^* \underset{k_2}{\overset{k_1}{\rightleftarrows}} A^{**}B^{**} \underset{k_1}{\overset{k_2}{\rightleftarrows}} A^*B^* \qquad (17)$$

where in general $k_1 \neq k_2$, since the statistical weights of forms (a) and (b) may differ.

A more complicated situation was examined by Newmark and Sederholm [52,53] for the case of completely non-degenerate exchange (rotation about the carbon–carbon bond in fluorinated ethanes)

$$A_1B_1 \rightleftarrows A_2B_2 \rightleftarrows A_3B_3 . \qquad (18)$$

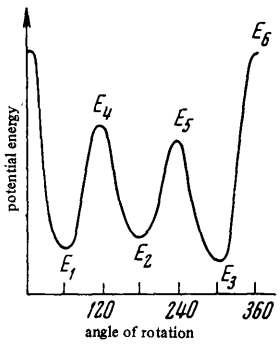


Figure 6. Form of the potential-energy surface for rotation about carbon–carbon bond in unsymmetrically fluorinated ethanes.

The potential-energy curve for such a process is characterised by three maxima E_4, E_5, E_6 and three minima E_1, E_2, E_3 corresponding to three stable rotamers (Fig. 6). Analysis of the stereochemically rigid case will give the populations of the states, i.e. the values of E_1, E_2, and E_3. Determination of the activation barriers E_4, E_5, and E_6 involves analysis of the complete kinetic scheme [52].

4. The most complicated type of system comprising three nuclei with interchange [30] involves exchange among six possible states—ABC, ACB, BAC, CBA, BCA, and CAB—in particular the cyclic exchange

$$ABC \rightleftarrows BCA \rightleftarrows CAB \qquad (19)$$

or exchange between two positions

$$ABC \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} BAC . \qquad (20)$$

The latter type of exchange process can be illustrated by the spectra calculated by Binsch [30] (Fig. 7). With very slow exchange the spectrum is described by the parameters (all in Hz) $\nu_A = 19.6$, $\nu_B = 22.9$, $\nu_C = 52.7$, $J_{AB} = 12.3$, $J_{BC} = 7.3$, and $J_{AC} = -17.7$. The spectrum is quite complex, and combination transitions are observed. Increase in the rate k is accompanied by complicated changes in the spectrum, not susceptible to simple analysis. When sufficiently high rates are reached the system passes into an effective A_2B type (the spectrum at k = 10 000 s^{-1} in Fig. 7). Results of an analysis of d.n.m.r. spectra have been published for complete interchange in a system of three spins [31].

5. A system of four spins is represented by the spectrum of formamide $H_2{}^{15}NCHO$, [54] described in general as an ABCX system (where X is the ^{15}N nucleus and C the formyl proton). Here rotation about the partly double carbon–nitrogen bond leads to an exchange process of the type

$$ABCX \rightleftarrows BACX . \qquad (21)$$

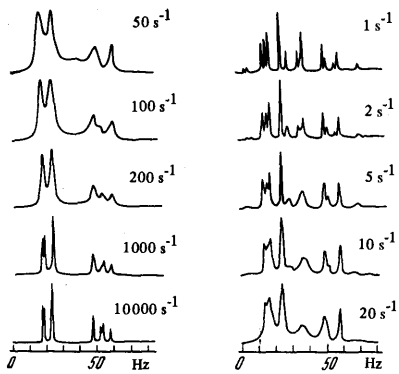

Figure 7. Theoretical spectra [30] calculated for various rate constants by means of a d.n.m.r. programme for exchange of the type ABC ⇌ BAC.

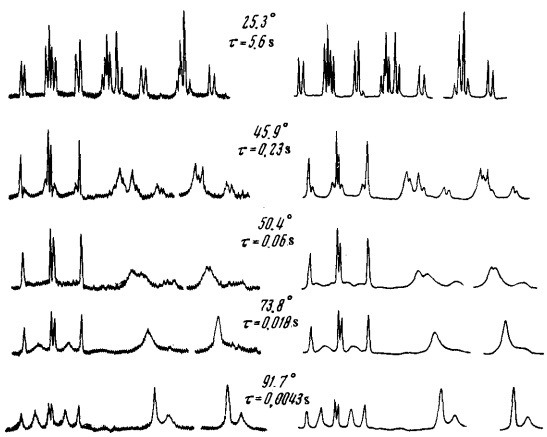

Figure 8. Experimental (on left) and theoretical spectra in formamide $H_2{}^{15}NCOH$ (exchange of type ABCX ⇌ BACX) at various temperatures and rate constants [54].

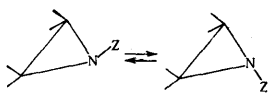


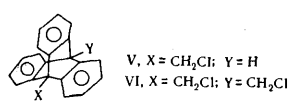
Experimental investigations of this spectrum made at various temperatures by Drakenberg and Forsen [54] are illustrated in Fig. 8. Rate constants were calculated by line shape analysis. A necessary first stage in the calculation was to analyse the ABCX spectrum in the absence of exchange. This gave values of chemical shifts and bond constants (δ_H, J_{HH}, J_{NH}), which were then used in calculating the spectra during exchange by means of a DENSMAT programme [54,55]. A theoretical spectrum characterised by a definite value of k was then selected

by comparison with the experimental spectrum (Fig. 8), after which the activation parameters were calculated (Table 4). This rigorous approach permitted a significant improvement in the accuracy of determination of the activation parameters in comparison with previously published values.

Table 4. Activation parameters in formamide.

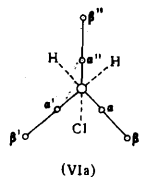
Solvent	E_a, kcal mole^{-1}	lg$A$	$\Delta H^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	$\Delta G^{\neq}_{300°}$, kcal mole^{-1}	Ref.
Pentan-2-one	19.2±0.2	13.2	18.2±0.2	2.7±0.6	17.55±0.2	54
Acetone	13±8	—	—	—	—	55

Another example is provided by inversion in substituted aziridines[57,58]



(IVa) (IVb)

The p.m.r. spectrum of the four protons in this compound is described as the AA'BB' system. As a result of rapid inversion at the nitrogen atom, represented by the equation



$$AA'BB' \rightleftarrows BB'AA', \qquad (22)$$

the spectrum is converted into a singlet.

6. Rather complicated spin systems have been examined theoretically by Binsch and Kleier[31] (including $A_3B_3 \rightleftharpoons C_3D_3$, $A_3B_3 \rightleftharpoons B_3A_3$, and $AA'BB' \rightleftharpoons CC'DD'$) using symmetry properties. These systems correspond to the upper limit of the possibilities of the best modern electronic computers[30,31]. The investigation of dynamic effects in complicated spin systems is therefore usually based on a series of simplifying assumptions. A very instructive example is the study of hindered rotation about $C_{(9)}$–CH_2Cl bonds in chloromethyltriptycenes[59] substituted at positions 9 and 10 (V, VI)

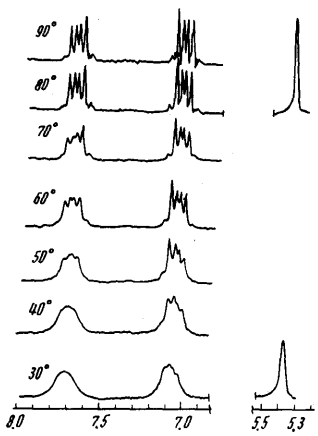
V, X = CH_2Cl; Y = H
VI, X = CH_2Cl; Y = CH_2Cl

(VIa)

The spectrum of the initial compound (triptycene) consists of two groups of signals with their centres at 5.50 (bridge protons) and at 7.50 and 7.00 ppm (aromatic protons). The spectrum of the latter is quite simple and of type AA'BB' owing to the high symmetry ($C_{(9)}$–$C_{(10)}$ is a threefold symmetry axis). Replacement of the 9- and 10-protons by chloromethyl groups produces significant changes in the spectrum: both parts become notably broader (part A to a greater extent) in the spectrum measured at room temperature. The symmetry of the system may be assumed to be diminished by the hindered rotation of the chloromethyl group; the individual structure is shown as a Newman projection (VIa). On heating, the spectrum becomes narrower, and passes into type AA'BB' at 100°C (Fig. 9). Estimates of the barrier to rotation in this system yielded the value $\Delta G^{\neq}_{300°} = 16$ kcal mole^{-1}.

Similar changes are observed with the monosubstituted 9-chloromethyltriptycene[60], where rapid rotation transforms an extremely complicated superposition of ABCD spectra characteristic of each ring into a comparatively simple spectrum of ABCD type. In this latter case the exchange process is degenerate, and can be represented by a scheme involving all twelve [aromatic] protons in the molecule:

$$A_1B_1C_1D_1A_2B_2C_2D_2A_1B_1C_1D_1 \rightleftarrows A_1B_1C_1D_1A_1B_1C_1D_1A_2B_2C_2D_2 \rightleftarrows \rightleftarrows A_2B_2C_2D_2A_1B_1C_1D_1A_1B_1C_1D_1 . \qquad (23)$$



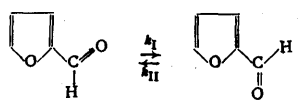


Figure 9. Proton magnetic resonance spectra of 9,10-bischloromethyltriptycene at various temperatures[59].

The exchange scheme for the disubstituted compound will be still more complicated owing to interaction of the chloromethyl groups lowering the symmetry of the system. It is significant that in these examples the spectra are almost incapable of analysis under conditions of stereochemical rigidity.

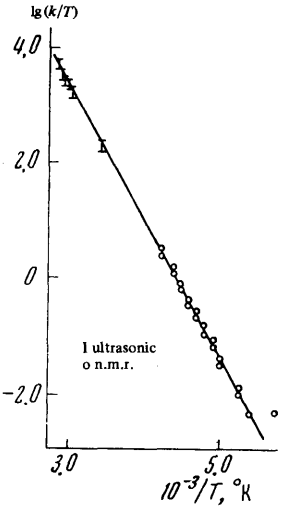
V. COMBINATION WITH OTHER METHODS OF INVESTIGATION OF THE KINETICS OF CHEMICAL REACTIONS

In several cases the accuracy of the measurement of activation parameters can be significantly improved by combining d.n.m.r. with other methods of determining rate constants[15]. An instructive example is provided by hindered rotation in 2-furaldehyde

(VIIa) (VIIb)

In the p.m.r. spectrum of this compound at room temperature the aldehydic proton is observed as a doublet of doublets with constants $J_{CHO(H_{(4)})}$ and $J_{CHO(H_{(3)})}$ of 0.3 and 0.77 Hz. When the temperature is lowered to −115°C two signals are observed in the region of aldehydic protons, the intensity ratio being 1 : 10. These signals are doublets with separations of 0.85 and 1.10 Hz (low- and high-field signals). The chemical shifts showed that the

isomer (VIIa) is present in higher concentration: i.e. $k_{II} > k_I$ and $\delta G = \Delta G_I^{\neq} - \Delta G_2^{\neq} > 0$. The activation parameters for processes k_I and k_{II} were calculated from the temperature-dependent p.m.r. spectra by means of McConnell's modification of Bloch's equation for unequal p_A and p_B.[61]



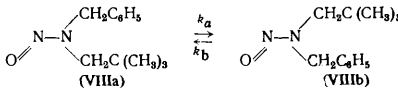


Figure 10. Dependence of lg (k/T) on $1/T$ for rotation in 2-furaldehyde from n.m.r. and ultrasonic relaxation data[62].

The same system has since been investigated by means of ultrasonic relaxation[15], which permits study of equilibria established with rates of 10^5–10^6 s^{-1}. Fig. 10 illustrates the dependence of $\lg k_A/T$ on $1/T$ based on the combined results of n.m.r. and ultrasonic relaxation[62]. Use of an extended temperature range (from −100° to +90°C) enables extremely reliable values to be obtained: E_a = 11.5 ± 0.5 kcal mole^{-1} and the frequency factor $A = 2 \times 10^{13}$ s^{-1}.

In many cases d.n.m.r. can be combined with "visual" kinetic methods (Table 1). Only the isotopic labelling version of these methods is applicable to degenerate exchange processes[1]. The usual methods for measuring concentrations of states (including n.m.r. with integration of the signals) can be applied to non-degenerate exchange processes. We shall examine an investigation of a dynamic process using both n.m.r. methods (in the corresponding temperature range, of course).

Jaeschke et al.[63] have examined equilibrium and exchange in benzylneopentylnitrosamine and detected rotation about the partly double bond:

In the temperature range 0–50°C the rates of both processes are small ($< 10^{-4}$ s^{-1}), so that the slow establishment of equilibrium in the system can be investigated by integration in the n.m.r. spectra, for which purpose a pure rotamer is isolated and appearance of the second rotamer is observed. Above +100°C a gradual broadening of the signals in the nitrosamine spectrum is observed, which enables d.n.m.r. spectroscopy to be used in this range.

These workers[63] concluded from a complete survey of various methods for calculating rate constants from n.m.r. spectra that closely similar results are obtained by parameter analysis and by line shape analysis. In view of the diversity of initial line shapes and the uncertainties in the procedure for matching experimental and theoretical spectral curves, parameter-analysis methods (line widths, distance between signals) were mostly used.

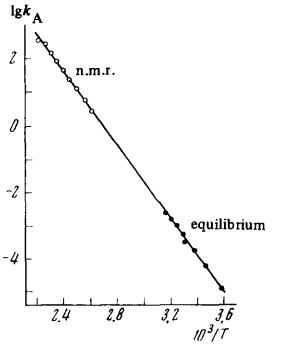

Figure 11. Dependence of $\lg k$ on $1/T$ for the isomerisation of benzylneopentylnitrosamine[63].

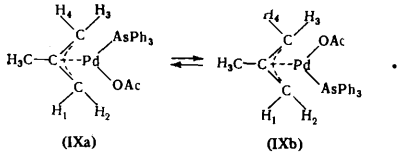

Fig. 11 illustrates the dependence of $\lg k_a$ on $1/T$ based on both equilibrium (integration at low temperatures) and d.n.m.r. (at high temperatures) data. The linearity of this relation enables the two methods to be compared (Table 5), with the following significant conclusions: (*a*) the accuracy of the determination of activation energy from d.n.m.r. spectra is ±10%; (*b*) this is substantially inferior to the accuracy obtained by the equilibrium method (±1.5%); (*c*) use of data from both methods yields an improvement to 0.5%; and (*d*) in all cases the determination of $\Delta G^{\neq}$ is more accurate than that of E_a.

Table 5. Comparison of activation parameters for the process (VIIIa) → (VIIIb) in benzylneopentylnitrosamine obtained by equilibrium method and from n.m.r. spectra[63].

Method	E_a, kcal mole^{-1}	lg A	$\Delta G^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	Temp., range, °C
Dynamic n.m.r.	25.3±2.2	14.8±1.2	22.0	+6.7	112—182
Equilibrium (integration)	24.2±0.3	14.1±0.2	22.1	+3.5	0—50
Mean	24.7±0.1	14.5±0.1	22.0	+5.2	0—182

Furthermore, the temperature range of the measurement of rate constants can be extended by applying various modifications of d.n.m.r. Mention has already been made

of spin echo methods, useful in the investigation of rapid dynamic processes. Double magnetic resonance (saturation transfer effect) has recently been used to investigate exchange processes where rates of exchange are not too high[64]. An example is the study of pseudorotation in a π-allylpalladium complex[65], sometimes termed *π-rotation*[65]

(IXa) (IXb)

As a consequence of such rotation the spectrum, originally consisting of individual signals $H_1H_2H_3H_4$ somewhat broadened by spin–spin interactions, is averaged out on heating, with the proton H_1 exchanging with H_4, and the proton H_2 with H_3. The occurrence of exchange in the slow stages was proved in this case by the use of double resonance methods, the most detailed description of which has been given by Hoffman and Forsen[64] in a survey of various applications of double resonance.

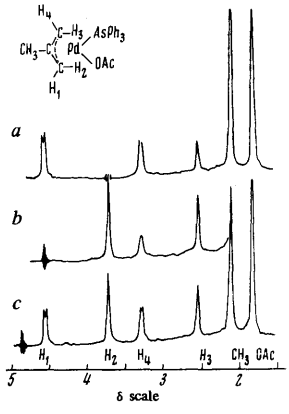

Figure 12. Proton magnetic resonance spectra of π-allylpalladium complex: a) single resonance; b) exposure of signal of proton H_1; c) exposure of signal of proton H_2.[65]

If we imagine a system in which a nucleus can occupy positions A and X, application of the Bloch–McConnell equations gives for the longitudinal magnetisation of nucleus A the formula

$$\frac{dM_z}{dt} = \frac{M_0^A - M_z^A}{T_{1A}} - \frac{M_z^A}{\tau_A} + \frac{M_z^B}{\tau_B} \qquad (24)$$

where M_0 is the equilibrium magnetisation and τ_A the lifetime of state A. If the signal of nucleus B is saturated by means of a second high-frequency field (i.e. $M_z^B \to 0$), we obtain

$$\frac{dM_z}{dt} = \frac{M_0^A}{T_{1A}} - \frac{M_z^A}{\tau_{1A}} \qquad (25)$$

where

$$\frac{1}{T_{1A}} = \frac{1}{\tau_A} + \frac{1}{T_{1A_0}} \quad .$$

The solution of this equation for the equilibrium case is given by

$$M_z^A(t \to \infty) = M_0^A \frac{\tau_{1A}}{T_{1A}} \quad . \qquad (26)$$

Thus the magnetisation in state A falls with increase in the rate of exchange ($\tau/T_{1A} \to 0$). This has been termed the saturation transfer effect. If the signal of the proton H_1 is now exposed to the second high-frequency field, the signal intensity of the proton H_4, bound to H_1 by exchange, becomes weaker. Similarly, exposure of the signal of proton H_2 produces a fall in signal intensity of the proton H_3 (Fig. 12). Thus proof of the occurrence of a dynamic process has not required the measurement of a temperature dependence.

Equation (26) can in principle be used to measure the lifetime τ (from the relative fall in intensity of the signal of state A). However, such measurements encounter certain difficulties (incomplete saturation of signal of state B, allowing for the relaxation time T_{1A}). Use of the saturation transfer effect makes it possible in principle to measure slower processes than in the case of single resonance, since as a rule $T_1 > T_2$, so that the effect can be expected to be appreciable at earlier stages of exchange than can the line-broadening effect (τ/T_2).

The temperature range over which rate constants can be measured can be extended also by the use of carbon magnetic resonance (c.m.r.) spectroscopy. Such spectra are usually recorded under conditions of uncoupling from protons, with a consequent significant improvement in the signal/noise ratio both as a result of collapse of the multiplet structure and because of the Overhauser effect. This is responsible for the first advantage of c.m.r. over p.m.r. spectroscopy, since there is no need to correct for the multiplet character of the spectra. Furthermore, the range of chemical shifts of carbon nuclei is about thirty-fold the range for protons. Equation (11) shows that, for the line width in the case of rapid exchange, it becomes possible to measure faster processes. We have in fact, for rate constants measured at the upper limit of rapid exchange, the ratio

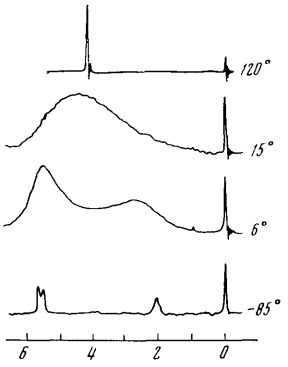
$$k_C/k_H = (\Delta\nu_C)^2/(\Delta\nu_H)^2 \simeq (30)^2\gamma_C^2/\gamma_H^2 \simeq 45$$

where $\Delta\nu_C$ and $\Delta\nu_H$ (Hz) are the ranges of chemical shifts for ^{13}C and ^{1}H spectra respectively. This usually enables rate constants to be measured from c.m.r. spectra at temperatures 50–60 deg higher than in the case of p.m.r. spectra. An example of the use of carbon magnetic resonance for this purpose will be given in Section VI.

VI. FLUCTUATING OR STEREOCHEMICALLY NON-RIGID SYSTEMS

Two main groups—intermolecular and intramolecular processes—can easily be distinguished from the range of dynamic phenomena studied by d.n.m.r. spectroscopy. Intermolecular processes are not discussed in the present Review: references are merely given to sufficiently comprehensive and competent reviews on general[7,8] and special aspects (proton exchange in alcohols, acids, etc.[66], dissociation–recombination processes in organometallic compounds[67]). Several examples of intramolecular processes have been given in Sections III–V. A number of up-to-date reviews have been published on rotations about various types of partly double or sterically hindered bonds[10] and on inversions of various cyclic organic molecules[68].

Recent years have seen a widening use of d.n.m.r. spectroscopy for the investigation of various rearrangements, i.e. processes in which, in contrast to rotations and inversions, some bonds are broken and new bonds are formed. Degenerate intramolecular rearrangements, during which the molecule passes "into itself", are of especial theoretical interest. The individual structures formed during such rearrangements are termed instantaneous structures. In contrast to the classical method of examining rearrangements—isotopic labelling—d.n.m.r. spectroscopy involves considerably fewer technical difficulties and also enables rapid processes to be examined (Table 1). Examples of degenerate rearrangements are extraordinarily varied and are encountered in organic [69], inorganic [70], and organometallic [71] systems. Several terms have been suggested to denote systems capable of degenerate processes—stereochemically non-rigid systems (Muettertis [70]), fluctuating molecules (Doering and Roth [69], Cotton [71]).



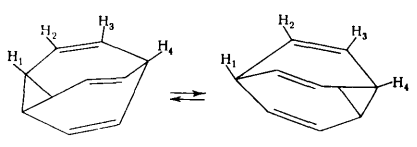


Figure 13. Proton magnetic resonance spectrum of bullvalene measured at various temperatures.

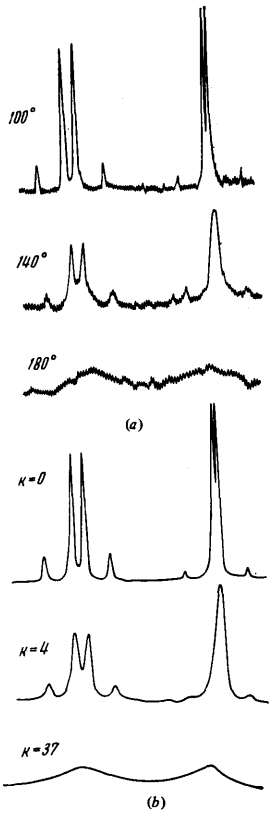
Perhaps the most impressive fluctuating molecule is that of bullvalene, whose existence was predicted by Doering and Roth [69]. The compound itself was prepared and described by Schröder [72]. At sufficiently low temperatures its spectrum consists of two poorly resolved multiplets (Fig. 13): the signal at 5.65 ppm corresponds to the six olefinic protons, and that at 2.08 ppm to the remaining four protons. It is interesting that the proton attached to the tertiary carbon atom gives resonance in the same region as those of the three-membered ring, probably as a result of the magnetically anisotropic effect of this ring. Broadening of both groups of signals is detected on heating above 0°C, the change occurring more rapidly in the high-field signal. On further heating (to 100°C) a singlet appears for all the protons (Fig. 13) with a shift of 4.42 ppm.

Exchange involving all positions is obviously occurring in this system. One step in such exchange is

in which the proton H_1 "rearranges" into H_4, proton H_3 into H_2, proton H_4 into H_1, and H_2 into H_3. At the next stage in the rearrangement the olefinic protons H_2 and H_3 may change positions with those attached to the extreme carbon atoms, and so on. The multiplicity of paths in such a dynamic process and of individual instantaneous structures (computed [69] as 1 209 600) led Doering [69] to introduce the term "fluctuating" molecules. Saunders and Hagen [46] used a programme for multipositional exchange to calculate the activation energy of degenerate rearrangement in bullvalene as $E_a = 11.8$ kcal mole^{-1}, while the entropy of activation is close to zero.



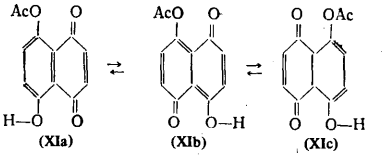


Figure 14. Experimental (a) and theoretical (b) p.m.r. spectra of monoacetatonaphthazarin at various temperatures [73].

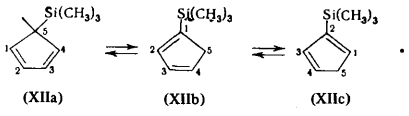
An interesting rearrangement has been discovered by Calder et al. [73] in an investigation of the temperature-dependent spectra of acetatonaphthazarin (XI)



The p.m.r. (100 MHz) spectrum of this compound measured at 100°C (Fig. 14) exhibits two groups of signals

giving spectra of type AB—at 6.70 and 6.67 ppm with a constant J_{HH} = 10 Hz, and at 7.20 and 7.10 ppm with J_{HH} = 8.1 Hz—from which the high-field signals can be assigned to protons of the quinonoid ring. On heating above 140°C the signals begin to broaden, which indicates the occurrence of a dynamic process on the pattern $A_1 \rightleftharpoons A_2$, $B_1 \rightleftharpoons B_2$. The dynamic process may be assumed to involve formation of the product (XIb), which is intermediate (but not transitional) and corresponds to a "jump" by the proton in the hydrogen bond. However, the p.m.r. spectra do not reveal the presence of (XIb), and hence the acetyl rearrangement and the proton shift take place synchronously.

In order to estimate the parameters of the rearrangement theoretical spectra were calculated by the use of a d.n.m.r. programme. The free energy of activation of this process proved to be 22.5 kcal mole^{-1}. Conditions of rapid exchange could not be attained even at 180°C, but available data suggest that the acetyl exchange occurs intramolecularly. It may be supposed that a single spectrum of type AB should be observed at high temperatures.

An example of a fluctuating organometallic molecule is the cyclopentadienylsilicon compound $C_5H_5Si(CH_3)_3$.[39,74] As a consequence of prototropic rearrangement—characteristic also of cyclopentadiene itself[75] and of its alkyl derivatives[76]—this compound may be present in one of the forms (XII):

(XIIa) (XIIb) (XIIc)

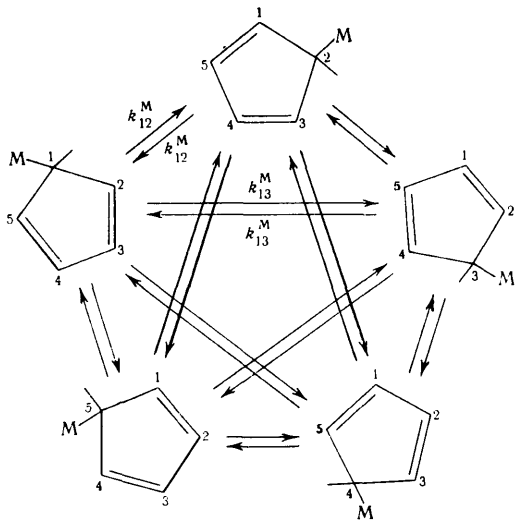


Figure 15. Scheme of degenerate metallotropic rearrangement in cyclopentadienyl derivatives of metals C_5H_5M.

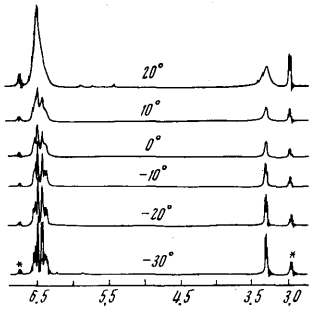
This process is non-degenerate, and is characterised in general by complicated kinetic and equilibrium parameters. Up to temperatures of 100°C, however, the rate constants of prototropic rearrangement are small, so that the process remains slow on the n.m.r. time scale.

The p.m.r. spectrum at room temperature exhibits signals from all three isomers (XII) (a solution of the compound in benzene gives three signals due to the methyl groups with the intensity ratio A : B : C = 90 : 9 : 1). Integral measurements indicate that equilibrium in the compound is displaced towards the isomer (XIIa). Furthermore, a second dynamic process—metallotropic rearrangement, shown diagrammatically in Fig. 15—has been noted with this isomer. The p.m.r. spectrum at −20°C and below includes the AA'BB'X type (Fig. 16) corresponding to the isomer (XIIa), where X is a methine proton (at 3.00 ppm). The following stages of the dynamic process are observed on heating—broadening of the multiplet structure, coalescence of the signals in the AA'BB' part, collapse of all signals, and the appearance of one signal (a singlet) at 5.87 ppm¶.



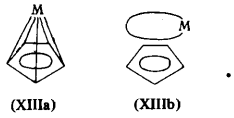


Figure 16. Proton magnetic resonance spectra (100 MHz) of $C_5H_5Si(CH_3)_3$ at various temperatures[39]. Signals marked with an asterisk (*) correspond to contamination with vinyl isomers.

Slow migration of the heavier metals (tin, mercury, gold) in cyclopentadienyl compounds can be achieved only at very low temperatures (around −150°C), and it becomes difficult to choose between alternative structures—true (XIIIa) and effective (XIIIb) centrosymmetric complex

(XIIIa) (XIIIb)

In such cases ^{13}C n.m.r. is useful (Section V), which can be illustrated by a specific example. Migration of the metal across the ring in cyclopentadienyltrimethylstannane $C_5H_5Sn(CH_3)_3$ has such a low activation energy (~ 6 kcal mole^{-1} [77]) that the line width in the proton spectra remains < 1 Hz right down to around −80°C (the most practicable temperatures when carbon disulphide is used as solvent). In the carbon spectra[78] (Fig. 17) significant broadening is already observed at −45°C.

In certain cases accurate line-shape analysis in the n.m.r. spectrum during exchange enables the mechanism of the process to be determined. In cyclopentadienyl

¶ The latter stages of the dynamic process are not shown in Fig. 16, since at high temperatures cyclopentadienyl compounds of silicon dimerise quite rapidly.

derivatives of metals, in particular, it is theoretically possible to choose one of the mechanisms[79] (Fig. 18)—(*a*) 1,2-migration of the metal, (*b*) 1,3-migration, and migration to any position in the ring equally probable, either via a centrosymmetric transition state (*c*) or by intermolecular exchange (*d*). Until quite recently it was both experimentally and theoretically problematical to separate these mechanisms. Experimental determination of the predominant migration was first achieved by Cotton et al.[79] from the unsymmetrical collapse in the d.n.m.r. spectra. This idea has since been used in many studies[39,48,77,78] of the fluctuating behaviour of the cyclopentadienyls of various metals.

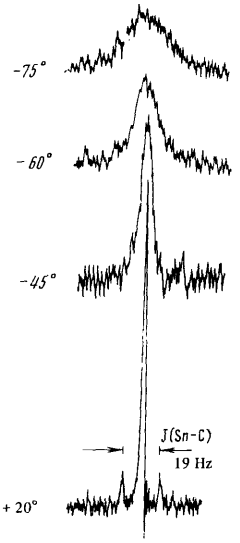

Figure 17. Carbon-13 n.m.r. spectra of trimethylstannylcyclopentadiene at various temperatures[78].

It can be postulated[79,78] that the assignment of the lines in the scheme illustrated by Fig. 15 is such that the low-field signal in the general spectrum AA'BB'X is due to the 1,4-protons of the isomer (XIIa). In a single act of migration the frequencies of the protons will then undergo different changes for the different mechanisms of migration (Table 6). Thus in the case of 1,2-migration the signal A merges with B and X, while signal B merges with A and with the other B (null exchange) (Table 6). The signals of protons A will therefore undergo greater broadening than those of protons B. Thus unsymmetrical broadening of the signals in the olefinic region may be observed at the stage of exchange at which the migration rate constant is comparable with the shift $\Delta\nu_{AB}$ (expressed in frequency units Hz). In the case of the alternative assignment $\delta_A = \delta_{2,3}$ and $\delta_B = \delta_{1,4}$ the signal B will obviously undergo greater broadening.

Examination of the p.m.r. spectra of cyclopentadienyltrimethylsilicon at temperatures near 0°C (Fig. 16) reveals greater broadening of the up-field signal in the AA'BB' part. Unfortunately, *a priori* assignment of the signal in the olefinic part of the spectrum is not possible. Detailed analysis of the spectrum by double resonance under conditions of stereochemical rigidity[39] shows that $\delta_A = \delta_{2,3}$ and $\delta_B = \delta_{1,4}$. Thus silicon undergoes 1,2-migration in its cyclopentadienyl compounds. Correct assignment of the signals is of decisive importance in selecting the predominant mechanism of migration.

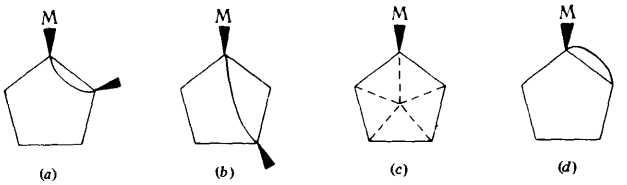

Figure 18. Possible modes of migration of metal in cyclopentadienyl compounds (intramolecular): a) 1,2-displacement; b) 1,3-displacement; c) through a centrosymmetric transition state; d) intermolecular migration.

There is usually no difficulty in eliminating the remaining mechanisms of migration. Unsymmetrical broadening is not observed when migration takes place through a centrosymmetric state or by intermolecular exchange. These two mechanisms can be distinguished by the use of additional data, in particular on the dependence of the rate of migration on the solvent and on the concentration of the solution.

Table 6. Transpositions of nuclei in exchanges involving 1,2- and 1,3-migration.

Position of proton	Position of signals in spectrum ($\delta_A > \delta_B$)		
	initial	final	
		1,2-shift	1,3-shift
5	X	A	B
1	A	B	B
2	B	B	A
3	B	A	X
4	A	X	A

In calculating the activation parameters of metallotropic rearrangement we encounter difficulties that are sufficiently common not to receive special mention. These difficulties arise primarily from the presence of strong spin coupling, which is apparent in the complicated multiplet structure of the signals in the absence of exchange (spectra of type AA'BB'X). Certain technical difficulties connected with the great size of the computations derive from the multipositional character of the exchange (five-position exchange allowing for magnetic non-equivalence—Section IV). In the limit of slow exchange the line width of the methine proton can be used to calculate the rate

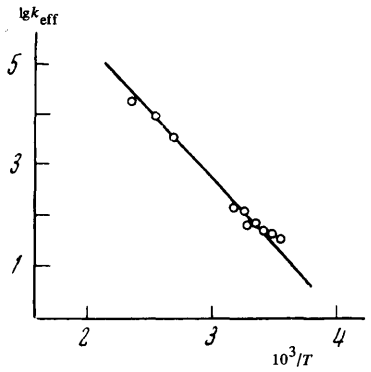
constants. On the assumption of a mechanism of 1,2-migration we can write for the line widths of signals A, B, and X[39]

$$\pi\delta\nu_A = \left(\frac{1}{T_2}\right)_A + \frac{1}{\tau}\ ,$$
$$\pi\delta\nu_B = \left(\frac{1}{T_2}\right)_B + \frac{1}{2\tau}\ , \qquad (28)$$
$$\pi\delta\nu_X = \left(\frac{1}{T_2}\right)_X + \frac{1}{\tau}\ .$$

In the region of rapid exchange we can start from the approximations $\delta_A = \delta_B$, $p_A = 4/5$, $p_X = 1/5$. From Eqn. (11) we can obtain

$$k_{eff} \approx \frac{1.61 \cdot (\Delta\nu)^2}{\Delta\nu_{1/2} - (\Delta\nu_{1/2})^0} \qquad (29)$$

where $\Delta\nu$ (in Hz) is the distance between the AB and the X parts of the spectrum, and $\Delta\nu_{\frac{1}{2}}$ is the line width with infinitely rapid exchange.



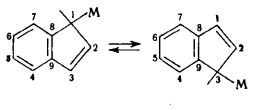


Figure 19. Dependence of lg$k$ on $1/T$ for metallotropic rearrangement in $C_5H_5Si(CH_3)_3$.[39]

Fig. 19 illustrates the dependence of lgk_{eff} on $1/T$ for migration in cyclopentadienyltrimethylsilicon. At low temperatures values of k_{eff} somewhat exceed k_{true}, since initial dipole–dipole relaxation and the multiplet structure make a contribution to the line width. At high temperatures, on the other hand, values of k_{eff} are rather lower than k_{true} owing to neglect of the relaxation term $(1/T_2)$ in Eqn. (28). Extrapolation from each section thus leads to underestimates of the activation energy E_a. A linear approximation to the dependence of lg$k$ on $1/T$ yields for the activation energy E_a and the entropy of activation $\Delta S^{\neq}$ values of 13 kcal mole^{-1} and −9.2 e.u. respectively[39].

Migration of the metal is detected also in indenyl derivatives of Group IVb elements[80,81]:

(XIVa) (XIVb)
