Application of the NMR Method in the Study of Simple and Complex Hydrides of Light Metals

G.N.Boiko, Yu.I.Malov, and K.N.Semenenko

The review discusses the results of studies on simple and complex hydrides of light metals by NMR, in particular the relation between the parameters of the NMR spectra and molecular structure, the formation of complexes by the hydrides and the stability of such complexes, as well as the characteristic features of the spectra of hydroborate systems.
The bibliography includes 101 references

I. INTRODUCTION

The results of studies on simple and complex hydrides, in particular boron and aluminium hydrides, by the NMR method are discussed in the present review. In all the tables quoted the spin–spin coupling constants J are expressed in hertz units (Hz), the chemical shifts are given in parts per million (p.p.m.), the δH are relative to $Si(CH_3)_4$, and the $\delta^{11}B$ are relative to $BF_3.(C_2H_5)_2O$. To facilitate comparison, data obtained by different investigators relative to other standards have been recalculated relative to the standards quoted above in accordance with the formulae quoted in the literature[1-10]. The minus sign of δ corresponds to a shift of the signals to low fields relative to the standard. The discrepancies between the chemical shifts found by different workers are most probably due to the use of different solvents (see, for example, Refs. 11–13).

II. COMPOUNDS CONTAINING PYRAMIDAL GROUPS

1. Complexes of the Type $BH_3.L$

Table 1 presents the literature values of the chemical shifts and the constants J_{B-H} for borane complexes with different ligands containing electron donating atoms of Group V and VI elements (O, S, N, and P).

These results make it possible to infer the following changes in the NMR spectra of the donor and acceptor molecules on complex formation.

1. The resonance signals due to the nuclei of the electron-accepting molecules are as a rule displaced towards higher fields relative to the chemical shifts due to the same nuclei in the molecules of the free components. On the other hand, the signals due to the nuclei of the electron-donating molecules shift towards lower

fields. The increase of the shielding of the boron atom on formation of complexes of the type $BH_3.L$ can be explained by a decrease of the paramagnetic contribution to the shielding through the transfer of electrons from the donor to the unfilled p_z boron orbital and the change in the hybridisation of boron from sp^2 to sp^3. This is confirmed also by the value of the spin–spin coupling constant J_{B-H}. It has been shown[7,16] that the J_{B-H} increases from 81 to 136 Hz when boron passes from the sp^2- to the sp^3-state. For the complexes $BH_3.L$, J_{B-H} is in the range 90–106 Hz. On this basis, it was concluded[7,16] that the B–H bonds in the complexes are in a state of hybridisation intermediate between sp^2 and sp^3.

Table 1. The NMR parameters of borane complexes.

2. Changes are observed in the chemical shifts of nuclei not directly involved in the formation of donor–acceptor bonds. These changes are smaller the more remote is the given atom from that involved in the formation of the coordinate bond. One may conclude that the donor–acceptor interaction alters the electronic structure of both donor and acceptor molecules. However, the electron density of the atoms in the α-position relative to those joined by the coordinate bond changes to the greatest extent.

In NMR studies on borane complexes much attention is devoted to the problem of the possible use of ^1H and ^{11}B chemical shifts as characteristics of the relative stabilities of the complexes. For example, the shielding of the boron nuclei in the acceptors and the deshielding of the nuclei forming part of the donor molecules (L) increase in the sequence $BF_3 < BCl_3 < BBr_3 < BI_3$ in the complexes BX_3 (X = halogen) with any ligands L[36–38]. This sequence of electron accepting capacities coincides with the sequence of the enthalpies of formation of boron halide complexes with pyridine[37,38]. It follows from the NMR data that the complex $BH_3.P(CH_3)_3$ is more stable than $BH_3.N(CH_3)_3$. This is explained by a shift[39] of the electrons in the B–H bonds to the 3*d* orbital of phosphorus. The hypothesis of the $d\pi - p\pi$ interaction in complexes with phosphines has not been confirmed. The shift of the electrons localised in the B–H bond should lead to a decrease of the hydrogen atom electron density and hence displace the signal to lower fields. In reality the opposite behaviour is observed in the ^1H spectra of $BH_3.P(CH_3)_3$ and $BH_3.N(CH_3)_3$: the chemical shifts of the protons in the B–H bonds are −0.44 and −1.62 p.p.m. respectively. The sequence of the changes in the NMR parameters is frequently inconsistent with the expectation based on the energy of the donor–acceptor interaction[21,23]. For example, a correlation is observed[21] between the number of methyl groups at the nitrogen atom in the complexes $BH_3.NH_{3-n}(CH_3)_n$ and the ^1H and the ^{11}B chemical shifts. Table 1 shows that, on passing from NH_3 to $N(CH_3)_3$, the signals are monotonically displaced towards lower fields. The change in the proton chemical shifts is evidence for a systematic increase of the *s*-character of the boron orbitals in the direction of hydrogen atoms with increase of the number of methyl groups at the nitrogen atom. The *s*-character of the fourth boron orbital and its capacity for donor–acceptor interaction should decrease in the same sequence. In such a case the ^{11}B chemical shifts should diminish on passing from $BH_3.NH_3$ to $BH_3.N(CH_3)_3$, which does in fact occur. However, this is inconsistent with the finding that borane–amine complexes are more stable than the complexes with ammonia[24].

The change in the electronegativity of the donor and acceptor atoms on complex formation is also indicated by the changes in the internal shifts of the protons of the ethyl groups linked to these atoms. A linear correlation between the electronegativity of X and the internal proton shift, expressed as the difference $\delta CH_3 - \delta CH_2$, has been established[40–43] for $(C_2H_5)_nX$. This correlation is also valid for molecules combined in a complex[22,44–46]. The internal proton shift in compounds of the type $(C_2H_5)_nX$, which behave as donors (X = O, S, N, or P), as a rule increases, while in compounds behaving as acceptors (X = metal) it decreases. Consequently the electronegativity of donor atoms increases on complex formation and that of acceptor atoms diminishes, in agreement with the decrease or increase of electron density at the atom X as a result of charge transfer from the donor to the acceptor. Thus the internal shifts of the protons in the ethyl groups decrease in the complexes $BH_nX_{3-n}.(C_2H_5)_3P$ (X = halogen)[17]. This means that the electron density at the phosphorus atom diminishes on complex formation. The internal shifts give rise to the following sequence of the electron-accepting capacities of boron compounds: $BBr_3 > BCl_3 > BHBr_2 > BHCl_2 > BH_2Br > BH_2Cl > BH_3$.[17] It is significant that this sequence is confirmed by the enthalpies of formation of the BBr_3, BCl_3, and BH_3 complexes with pyridine[37,38]:

Complex	$C_5H_5N \cdot BBr_3$	$C_5H_5N \cdot BCl_3$	$C_5H_5N \cdot BH_3$
$-\Delta H^\circ$ kcal mole^{-1}	32.0	30.8	28.8

Thus the study of the NMR spectra of borane complexes yields information about the nature of the changes in the electronic structures of the components of the complex. Bearing in mind the complexity of the dependence of the chemical shifts on a number of factors, definite $\Delta H^\circ - \delta$ relations can be expected only for series of compounds with similar structures.

2. Complexes of the Type $AlH_3.L$

Table 2 presents data for the proton chemical shifts in several aluminium complexes. Their analysis makes it possible to infer the following changes in the electronic structure of the donor and acceptor molecules on complex formation.

Table 2. The proton chemical shifts in the spectra of coordination compounds of aluminium hydride.

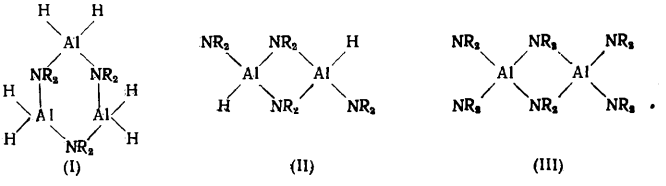
1. With increase of the coordination number (C.N.) of aluminium or with increase of the electron-donating capacity of the ligand for the same coordination number, the chemical shift of the protons linked directly to aluminium increases. This indicates an increase of electron density at the nuclei of the acceptor molecule, caused by charge transfer from the donor.

2. The NMR data for 1 : 1 and 1 : 2 complexes lead to the conclusion that the strength of the bond between aluminium and the ligand $N(CH_3)_3$ is greater than for OC_4H_8†, since the chemical shift of the hydride protons in $AlH_3.N(CH_3)_3$ is greater than in $AlH_3.OC_4H_8$. On formation of mixed 1 : 2 complexes, differences in the shielding of the H–Al protons are not observed. At the same time an excess of tetrahydrofuran (THF) is necessary for the addition of a second OC_4H_8 molecule to the complex $AlH_3.OC_4H_8$.[47]

3. No changes were observed in the chemical shifts of the protons of the CH_3 groups in the NMR spectra of the complex $AlH_3.N(CH_3)_3$ and therefore the state of the $N(CH_3)$ molecule changes only slightly on coordination. The free electron pair of the nitrogen atom in the $N(CH_3)_3$ molecule is involved in sp^3 hybridisation. If a coordinate bond is formed, there is no change in the valence state of carbon. On the other hand, in the complex $AlH_3.2OC_4H_8$ the proton resonance frequency in the α-CH_2 group decreases by 10 Hz, while the resonance frequency for β-CH_3 protons remains unchanged. This indicates alterations in the valence state of the oxygen atom. The NMR spectra of the complexes $H_{3-n}AlX_n.2OC_4H_8$ (n = 1, 2; X = Cl, Br, or I) indicate descreening of the protons in the α- and β-CH_2 groups in THF due to electron withdrawal from the oxygen atom to the aluminium atom[53]. The internal shift of the ethyl protons in the compounds $AlH_nCl_{3-n}.P(C_2H_5)_3$ increases[52] with increase of the degree of substitution of hydrogen atoms by chlorine. This change in the internal shift indicates an increase in electron-accepting capacity in the sequence $AlCl_3 > AlCl_2H > AlClH_2 > AlH_3$. Unfortunately the enthalpies of formation of these complexes are not available, which precludes their comparison with NMR data.

The structures of the above complexes in solution can change markedly as a result of association. The degree of association becomes more marked on passing to complexes with higher dipole moments and also on formation of hydrogen bond bridges of the type Al–H–Al or Al–H_2–Al. The existence of hydrogen bond bridges should have been reflected in the corresponding ^1H NMR shifts or should have given rise to additional signals. For complexes of aluminium hydride with trimethylamine, THF, and dioxane, not more than one signal due to the proton linked directly to the aluminium nucleus was observed[47]. The $R_2AlH.N(CH_3)_3$ and $RAlH_2.N(CH_3)_3$ complexes can undergo a different type of association via the methyl group for R = CH_3 and via the methylene group for R = C_2H_5. This follows from the splitting of the lines in the ^1H NMR spectra of these compounds in cyclohexane[48]. Moreover the formation of the dimer $Al_2(C_2H_5)_6$ does in fact proceed via the CH_3 group, which has also been confirmed by NMR. The ^1H NMR spectra of amino-aluminium hydrides of the type $H_{3-n}Al(NR_2)_n$ (n = 1, 2, or 3; R = CH_3 or C_2H_5) have been investigated[54]. It was shown that in benzene solutions association takes place via the formation of Al–N–Al linkages and the most probable structures (I)–(III) were proposed:



(I) (II) (III)

The formation of bridged structures is confirmed by the presence in the ^1H NMR spectra of two signals due to NR_2 with both R = CH_3 and R = C_2H_5. Infrared spectroscopic data are consistent with those derived from ^1H NMR.[54] The association of complexes of the type $AlF_nCl_{3-n}.THF$ (n = 1 or 2) proceeds via the fluorine atoms[55].

Thus the chemical shifts and the spin–spin coupling constants yield information about the changes in the distribution of electron density, about the capacity for hybridisation, and about the amount of ionic character of the bonds when the molecules are bound in a complex.

III. COMPOUNDS CONTAINING TETRAHEDRAL GROUPS

Table 3 presents the ^{11}B NMR parameters for certain ionic hydroborates.

The ^1H NMR spectrum of an aqueous solution of $NaBH_4$ contains a quartet with the relative intensities 1 : 1 : 1 : 1 and a weak septet[58–61]. In the ^{11}B NMR spectrum there is a 1 : 4 : 6 : 4 : 1 quintet. The fine structure of the spectrum was determined using double resonance. On irradiation of the boron nucleus, the initial quartet is converted into a single line. This indicates the equivalence of all the protons in the BH_4^- anion and their interaction with ^{11}B.

† OC_4H_8 = THF.

Such equivalence is possible if the tetrahydroborate ion has a square planar, pyramidal, or tetrahedral structure. The first two models should lead to relatively more marked variation of the electric field gradients at the boron atom with the angle and this should be reflected in a broadening of the ^1H NMR lines. Narrow lines in the quartet are observed experimentally, which implies that the tetrahydroborate ion is most likely to have the tetrahedral structure. The boron chemical shifts for $LiBH_4$ depend, according to Ehemann et al.,[57] on the concentration of the solution and the type of solvent, i.e. apparently on the degree of separation of the cation and anion due to solvation effects.

Table 3. The ^{11}B NMR parameters of certain ionic tetrahydroborates.

Compound	Solvent	$\delta^{11}B$	J_{B-H}	References
$NaBH_4$	0.1 *N* NaOH	43.8	81	16
$LiBH_4$	Ether	38.2	75	56
$[(C_4H_9)_4N]BH_4$	THF	37.7	82	57
$[(C_{18}H_{17})NC_3H_7]BH_4$	Benzene	36.9	82	57

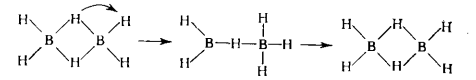
IV. COVALENT HYDROBORATES WITH BRIDGE BONDS

1. Diborane and Its Derivatives

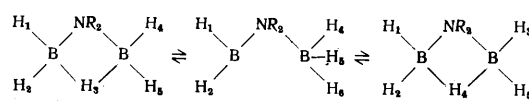
It has been established by electron diffraction[62] and infrared spectroscopy[63,64] that the electron-deficient diborane molecule has a bridged structure:

In this structure four hydrogen atoms are linked directly to the boron atoms by the usual covalent two-electron bonds, while the remaining two hydrogen atoms occupy bridging positions, saturating the remaining valences of the boron atoms. The ^1H and ^{11}B NMR spectra of liquid diborane are consistent with the bridged model[32,37,61,64-67]. Thus the ^{11}B NMR spectrum at $f = 30$ MHz contains one multiplet consisting of a triplet of triplets[32]. The major triplet splitting arises in consequence of the spin–spin interaction of the boron nuclei with the two equivalent terminal protons and the minor splitting is due to the interaction of the boron atom with the pair of bridge hydrogen atoms. An additional confirmation of the bridged structure of B_2H_6 is provided by its ^1H NMR spectrum, from which the existence of two different types of protons follows directly. At a frequency of 30 MHz the ^1H NMR spectrum consists of a complex multiplet. The interpretation of this spectrum shows to a first approximation that the observed component lines have the following origins: a quartet corresponds to the terminal hydrogen atoms linked to one ^{11}B atom ($I = 3/2$) while a septet corresponds to the bridge hydrogen nuclei linked to the two boron nuclei. When the interaction with the boron nuclei is suppressed by double resonance, the two different types of protons are represented in the ^1H NMR spectrum by two singlets with the area ratio 2 : 1. The signals due to the hydrogen nuclei linked to ^{10}B ($I = 3$) form a weak septet. The bridge protons resonate in a higher field than the terminal protons. This shows that the B–H–B linkage is more ionic than B–H. This is also indicated by the ratio of the spin coupling constants. Overall, the NMR parameters show that the electron cloud density at the bridge protons is higher than at the terminal protons. The results of a quantum-mechanical calculation of the magnetic shielding of protons in diborane are consistent with this conclusion[68]. Subsequently the NMR spectra of liquid diborane were investigated on spectrometers with a higher working frequency and with a higher resolving power[66,67]. With increase of the working frequency, the centres of the multiplets are separated and the interpretation of the spectrum is simplified. In addition, the increase in the resolving power of the apparatus made it possible to observe more remote spin–spin interactions of the nuclei in the diborane molecule. According to modern ideas, the spin system of B_2H_6 belongs to the type $A_2A'_2M_2XX'$, in which the two boron nuclei (X and X′) are magnetically nonequivalent owing to the different degrees of spin–spin interaction with the terminal protons (A_2, A'_2).

There are solvents in which the terminal and bridge protons appear to be magnetically equivalent, for example the spectrum of diborane in ethyl ether at −26°C consists of a triplet of triplets, the structure of the spectrum changes with increase of temperature, and at 84°C a septet is observed[69]. In the ^{11}B NMR spectrum of diborane in the dimethyl ether of ethylene glycol a septet is observed at room temperature. The authors explain the equivalence of the protons by rapid intramolecular exchange via the following scheme:



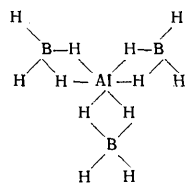
In this scheme the unstable intermediate species may be stabilised by interaction with a solvent molecule, which behaves as an electron donor. The ^{11}B NMR spectra of the products of the reactions of diborane with inorganic and organic anions indicate the formation of substituted hydroborate anions[70-73]. According to Geines and Schaeffer[26], the chemical shifts of the boron nuclei in the aminodiboranes $B_2H_5NH_2$, $B_2H_5NHCH_3$, and $B_2H_5N(CH_3)_2$ are respectively 26.7, 22.7, and 17.0 p.p.m., i.e. the signals shift towards lower fields with increase of the number of methyl groups at the nitrogen atom. Phillips et al.[16] observed that, on raising the temperature from −10° to 40°C, the ^{11}B resonance lines in the $B_2H_5N(CH_3)_2$ spectrum are broadened and the splitting into doublets almost vanishes. The authors explained the breakdown of the spin–spin interaction of boron with the bridge protons by partial dissociation of the B–H–B linkage with subsequent rotation of the BH_3 group about the B–N bond and the formation of a new B–H–B linkage involving a different hydrogen atom. As a result, all the protons become equivalent:



Williams et al.[74] investigated the ^{11}B NMR spectra of various methyldiboranes and their deuterio-derivatives. Their results show that the replacement of hydrogen by a methyl group shifts the ^{11}B signal to a lower field. A more detailed analysis of the ^1H NMR spectra of these compounds is described in the literature[75-77].

2. Aluminium Tetrahydroborate

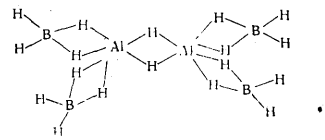
In the aluminium tetrahydroborate structure, proposed on the basis of electron diffraction studies[78] and infrared spectra[79], the aluminium atom is located at the centre of an equilateral triangle formed by the boron atoms. Four hydrogen atoms are linked to each boron atom, so that the latter is in a tetrahedral environment. Two of these hydrogen atoms form bridges between the boron atoms and aluminium, i.e. there are two types of protons in the molecule (bridge and terminal protons):



The ^1H and ^{11}B NMR spectra of aluminium tetrahydroborate were first examined by Ogg and Ray[80]. The ^1H NMR spectrum at a frequency of 30 MHz consists of an unresolved multiplet with a line half-width of about 300 Hz. The spectrum was interpreted using the double resonance of aluminium and boron nuclei. On irradiation of the boron nucleus, the resonance line in the proton spectrum becomes somewhat narrower, although it still remains fairly broad (220 Hz). Irradiation of the aluminium nucleus leads to the appearance in the spectrum of a quartet with a splitting of 87 Hz, as for the BH_4^- ion. The ^{11}B NMR spectrum shows a quintet with the intensity ratios 1 : 4 : 6 : 4 : 1, the splitting and positions of which are characteristic of the BH_4^- ions. In the ^{27}Al NMR spectrum there is an unresolved multiplet due to the spin–spin interaction of the aluminium nucleus with the twelve equivalent protons[81]. Interpretation of the NMR spectra of aluminium tetrahydroborate leads to the following conclusions concerning its structure in the liquid phase. Firstly, all the hydride protons in the molecule have the same electronic environment, i.e. they are "chemically equivalent". Secondly, all the protons are linked to both boron and aluminium. The initial broad line in the proton spectrum can be interpreted as a multiplet consisting of 24 lines due to the spin–spin coupling with boron ($I = 3/2$) and aluminium ($I = 5/2$), the components of the multiplets being appreciably broadened owing to the quadrupole relaxation of the aluminium nucleus. Thirdly, each boron nucleus is linked to four equivalent protons. The narrow lines in the ^{11}B NMR quintet indicate a nearly tetrahedral disposition of the protons around the boron atom. These conclusions do not lead to an unambiguous confirmation of the bridged model of aluminium tetrahydroborate proposed on the basis of infrared spectroscopic and electron diffraction studies. The ^1H NMR spectrum of this structure should contain signals due to two types of protons, while in reality all the protons give rise to one common signal. This apparent contradiction can be eliminated by assuming that there is a dynamic process leading to the exchange and averaging of the bridge and terminal protons over a period of time. To elucidate the mechanism of proton exchange in $Al(BH_4)_3$, Ogg and Ray[80] studied the NMR spectra of liquid specimens at temperatures ranging from −40 to 60°C. The spectra of deuterio-derivatives of aluminium tetrahydroborate were investigated and it was shown that the form of the proton spectrum hardly changes with temperature. Deuteriation leads to a broadening of the quartet components in the ^1H NMR spectrum obtained on single irradiation of the aluminium nucleus. These results led the authors to the conclusion that the proton exchange in aluminium tetrahydroborate is non-classical (there is a tunnel effect)[80]. The same investigators showed that at 80°C $Al(BH_4)_3$ undergoes reversible dissociation:

$$2Al(BH_4)_3 \rightleftharpoons Al_2B_4H_{12} + B_2H_6 .$$

A dimeric structure was proposed for $Al_2B_4H_{12}$:



The ^1H NMR spectrum of $Al_2B_4H_{12}$ contains a quartet, in contrast to the broad signal of $Al(BH_4)_3$. It was suggested that the fine structure of the spectrum is due to the rapid rotation of the BH_4 groups, which interferes with the spin–spin interaction between the protons and the aluminium nucleus. The broad signal in the ^1H NMR spectrum of $Al(BH_4)_3$ is converted into a quartet when the temperature of the liquid specimen is raised from −40 to 90°C; this change can be both reversible and irreversible[81]. The authors attribute the observed changes to exchange between two possible structural models of the $Al(BH_4)_3$ molecule—prismatic and octahedral. However, in order to confirm this conclusion, it is necessary to study the kinetics of the transition from one form to the other and also each of these forms in the solid phase.

Table 4. The ^1H and ^{11}B NMR parameters of certain covalent metal tetrahydroborates.

Williams[82] notes that the occurrence of internal exchange is characteristic not only of aluminium tetrahydroborate but also of many other boron hydrides and their complexes with Lewis bases. The observed equivalence of the protons has been explained by a tautomeric transition in the liquid phase between structures with one and two bridge bonds via hydrogen atoms[82]:

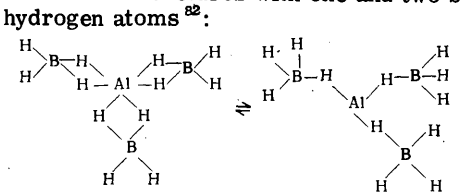

Table 4 presents the results of studies on certain covalent metal tetrahydroborates by NMR.

The observed differences between the ^1H and ^{11}B chemical shifts can probably be explained by differences between the electronic structures of the central atoms. However, the NMR spectra of all these compounds indicate the equivalence of the protons. The disappearance of the fine structure from the ^1H NMR spectrum of $Zr(BH_4)_4$, observed when the temperature is reduced, was explained[88] by the retardation of the intramolecular exchange. However, even at the lowest temperatures it was impossible to ensure the localisation of protons. It has been shown[89] that the observed temperature variation of the spectra of zirconium and hafnium tetrahydroborates is due to the influence of the quadrupole relaxation of the boron nuclei on the resonance of the protons linked directly to these atoms. On the whole, one may say that the studies on covalent tetrahydroborates with bridge bonds by NMR make it possible to draw inferences concerning the bond between the BH_4 group and the central atom and also concerning the mobility of the protons. Diborane is apparently the only example of compounds of this class whose ^1H NMR spectrum shows separate signals due to bridge and terminal protons.

V. COVALENT TETRAHYDROBORATES CONTAINING AN M–L COORDINATE BOND

Table 5 presents the NMR parameters for the $Al(BH_4)_3$ complexes with $N(CH_3)_3$, $P(CH_3)_3$, $As(CH_3)_3$, $O(CH_3)_2$, $S(CH_3)_2$, and $O(C_2H_5)_2$ as well as complexes with hydride derivatives of $Al(BH_4)_3$. The ^{11}B NMR spectra of all these compounds contain a quintet, showing that four identical protons are linked to each boron atom and that all the boron atoms are equivalent in derivatives containing two or more tetrahydroborate groups[84,90]. The presence of four identical protons linked to boron limits the number of possible structures involving the B–N and Al–N–B bridge bonds. The ^1H NMR spectrum of the tetrahydroborate group consists of a broad unresolved signal without the expected fine structure due to the spin–spin interaction of protons with boron and aluminium. However, significant differences between the hydride proton absorption line forms are observed for some of the compounds. For example, the ^1H NMR spectra of the tetrahydroborate group in the complexes with $As(CH_3)_3$ and $S(CH_3)_2$ are split into four lines owing to the spin–spin interaction with boron, while interaction with aluminium is not observed[84]. It has been noted that the proton spectrum of the complex $Al(BH_4)_3.N(CH_3)_3$ contains a multiplet comprising twelve lines, due to the interaction of the protons with boron and aluminium and $J_{B\text{-}H} \simeq 2J_{Al\text{-}H}$.[83,84] There is splitting also in the ^{27}Al NMR spectrum of this compound. The observed differences between the proton spectra of the above compounds can probably be accounted for by the effect of the quadrupole relaxation of the aluminium nucleus. Evidently the electric field gradient at the ^{27}Al nucleus in the complex with $N(CH_3)_3$ is smaller and the rate of relaxation of this nucleus in the compounds with $As(CH_3)_3$ and $S(CH_3)_2$ is much higher than in all the other complexes examined. Thus, using the available information about the absorption line form in the NMR spectra, complexes of the type $Al(BH_4)_3.L$ can be arranged in the following sequence in terms of increasing asymmetry of the electronic environment of the aluminium nucleus:

$$N(CH_3)_3 < P(CH_3)_3 < As(CH_3)_3$$
$$O(CH_3)_2 < S(CH_3)_2$$

At elevated temperatures the signal due to amino-group protons in the ^1H NMR spectrum of $Al(BH_4)_3.N(CH_3)_3$ is split[92], which is associated either with a marked orientation of the ligand in the complex or with the existence of the equilibrium:

$$2Al(BH_4)_3 \cdot N(CH_3)_3 \rightleftharpoons Al(BH_4)_3 \cdot 2N(CH_3)_3 + Al(BH_4)_3 .$$

If it is assumed that there is an equilibrium between the 1 : 1 and 1 : 2 complexes, the singlet at −60°C can be attributed to the undissociated form and the two signals at 60°C to the existence of two equilibrium forms of the complex. With decrease of temperature, the components of the multiplet due to the tetrahydroborate protons are broadened, which has been explained[88] by the retardation of proton exchange. However, such spectral changes can be attributed also to the influence of the quadrupole NMR relaxation of boron and aluminium.

Table 5. The ^1H and ^{11}B NMR parameters of aluminium tetrahydroborate complexes.

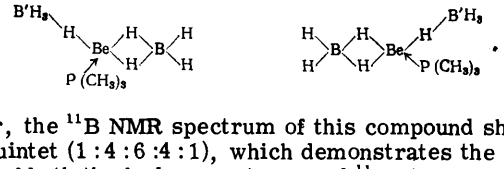
$Al(C_2H_5)_2BH_4 \cdot N(CH_3)_3$	39.4	85	0.08	−2.40 0.91	— 0.10	84	91

Among complexes of aluminium tetrahydroborate with ammonia, a study has been made on the compound with the empirical formula $Al(BH_4)_3.6NH_3$. The ^1H NMR spectrum in ammonia shows[93] a single quartet characteristic of BH_4^-. This spectrum probably agrees best with the ionic structure $[Al(NH_3)_6^{3+}](BH_4)_3^-$. However, the study of ^{11}B NMR spectra suggested another possible structure[94,95]: $AlH_2(NH_3)_4^+BH_2(NH_3)_2^+(BH_4)^-$. The true structure of this compound still has to be determined.

The beryllium complexes $Be(BH_4)_2.L$, where L = $O(C_2H_5)_2$, $P(CH_3)_3$, or $N(CH_3)_3$, were also studied by NMR.[96] The NMR spectra of all these compounds demonstrate the equivalence of both the protons and boron atoms. The following possible structures have been proposed for $Be(BH_4)_2.P(CH_3)_3$ on the basis of infrared spectra[97]:



However, the ^{11}B NMR spectrum of this compound show a single quintet (1 : 4 : 6 : 4 : 1), which demonstrates the equivalence of both the hydrogen atoms and ^{11}B atoms. The authors believe that the above forms can be rapidly interconverted so that average signals due to B and B′ atoms are observed.

The examples discussed show that the occurrence of proton exchange is characteristic not only of free metal tetrahydroborates but also of their neutral complexes.

VI. MIXED METAL HYDRIDES

The NMR method has been widely used to investigate the products of the various double decomposition reactions. For example, the study of the ^1H and ^{11}B NMR spectra of products of the reaction between lithium salts and aluminium tetrahydroborate established[57,93,94] that the complex anion $[Al(BH_4)_4]^-$ is formed. The ^{11}B NMR spectrum of this anion shows a quintet (1 : 4 : 6 : 4 : 1) and the ^1H NMR spectrum consists of a broad unresolved signal. The infrared spectra indicate a bridged structure, while the NMR spectra demonstrate the equivalence of all the protons. There is probably proton exchange in the anion $[Al(BH_4)_4]^-$, as in $Al(BH_4)_3$.

The formation of two complex beryllium anions, $Be(BH_4)_3^-$ and $Be_2(BH_4)_5^-$, has been reported[98]. A structure with a formally tricoordinate beryllium atom was proposed for $Be_2(BH_4)_5^-$:

Table 6. The ^{11}B NMR parameters of certain mixed hydrides.

Compound	Solvent	δ ^{11}B	J_{B-H}	References
$LiTh(BH_4)_5$	Ether	13.4	34.5	100
$LiZr(BH_4)_5$	Ether	13.5	86	100
$LiHf(BH_4)_5$	Ether	15.4	86	100
$[(C_{16}H_{17})_3NC_9H_7][Al(BH_4)_4]$	Benzene	33.1	79	98
$[(C_{16}H_{17})_3NC_9H_7][Be(BH_4)_3]$	Benzene	34.7	80	98
$[(C_{16}H_{17})_3NC_9H_7][Be_2(BH_4)_5]$	Benzene	35.1	83	98
$LiZn(BH_4)_3$	Ether	42.3	84.5	101

The ^{11}B NMR spectra indicate the equivalence of all the tetrahydroborate groups. Table 6 presents the NMR parameters for certain mixed hydrides. The differences between the ^{11}B chemical shifts in the spectra of the above compounds are due to differences between the electronic structures of the central atoms, but all the spectra demonstrate the equivalence of the protons[99].

Kinetic and Thermodynamic Aspects of Catalysis by Immobilised Enzymes

I.V.Berezin, A.M.Klibanov, and K.Martinek

The review deals with a quantitative analysis of the physicochemical characteristics of catalysis by immobilised enzymes. The role of factors such as inhibition by external and internal diffusion and the characteristics of diffusion in polymeric carriers, the nature of the carrier, the changes in the true kinetic parameters of enzymatic reactions after immobilisation, and steric limitation of the rates of reaction of immobilised enzymes with macromolecular substrates are considered. The bibliography includes 152 references.

I. INTRODUCTION

There has been an exponential growth in recent years of the number of studies on immobilised (fixed) enzymes, which has doubled in approximately two years. According to the data of the American Chemical Society[1], research in the field of immobilised enzymes was among the nine most intensely studied topics in chemistry in 1972.

Interest in immobilised enzymes can be explained by two fundamental causes. Firstly, the wide prospects which are opened up by the application of immobilised enzymes in technology and medicine. In this connection we may point out that the unique properties of biological catalysts have been for a long time attracting the attention of workers in different branches of sciences and engineering. These properties include primarily their high catalytic efficiency (i.e. the ability to ensure reaction rates greatly exceeding, sometimes by a factor of 10^{10}—10^{13}, those in the presence of non-biological catalysts), their insurpassable selectivity (not only as regards the type of reaction catalysed but also with respect to the structure of the substrate), and finally the high capacity of enzymes to respond to the regulating action of fine changes in the properties and specific composition of the medium. However, the attempts to use biological catalysts as catalytic or regulating elements in applied chemistry or physics have as a rule encountered a seemingly insurmountable obstacle, involving their exceptionally low resistance to the denaturing influence of the "medium" (the effects of heat and micro-organisms as the principal denaturing factors in protein systems *in vitro* must be mentioned in the first place). On the other hand, the first studies in the field of immobilised enzymes have already suggested a number of ways of improving their stability[2].

1. Covalent attachment of the enzyme to a water-insoluble (or water-soluble) polymeric carrier (such as cellulose, glass, polystyrene, polyaminoacids, etc.).
2. Covalent attachment of enzyme molecules to one another with the aid of an added polyfunctional reagent with formation of water-insoluble (or water-soluble) aggregates.
3. The incorporation of the enzyme in the three-dimensional network of a gel or polymer.
4. The adsorption of the enzyme on water-insoluble carriers (for example on ion-exchange resins).
5. The inclusion of the enzyme in semipermeable microcapsules or polymeric fibres.

Evidently as a result of immobilisation of this kind the enzyme acquires yet another property important for technology—it can be readily separated from the products of the catalysed reaction, which permits its repeated employment or its use under flow conditions[3].

In medical practice immobilisation facilitates the fixation of the enzymes (or other biologically important substances) in specific parts of the organism in addition to increasing its stability[4].

Immobilised enzymes can be regarded as extremely realistic models for biologically active systems acting *in vivo* within membranes or on their surface[2,5].

A number of reviews have already been published on immobilised enzymes[2,3,6-23]. Since a compilation of these reviews has been published in Russia[24], we shall not deal with the methodological aspects of the preparation of immobilised enzymes (see, for example, Crook et al.[10] and Weetall[16]) or the practical aspects of their use in science, engineering, and medicine[3,25]. Attention is concentrated on the kinetic and thermodynamic features which distinguish catalysis by immobilised enzymes from the behaviour of homogeneous (native) systems. These new specific features may include (a) the appearance of external and internal diffusion inhibition in catalysis, (b) factors associated with the distribution of substrates, inhibitors, hydrogen ions, and other effectors between the aqueous solution and the polymeric matrix (as a result of electrostatic or hydrophobic interaction, hydrogen bonds, etc.), and (c) the occurrence of steric hindrance in reactions with macromolecular substrates. In examining these aspects, we shall endeavour to achieve quantitative generalisations, which would make it possible to predict *a priori* in many cases the kinetic and thermodynamic properties of immobilised enzymic systems.

II. THE ROLE OF DIFFUSION IN CATALYSIS BY IMMOBILISED ENZYMES

The principal postulates formulated in the theory of heterogeneous catalysis are essentially applicable to

immobilised enzymes. The effect of diffusion on heterogeneous catalytic processes has been studied in extremely great detail for reactions of different kinetic orders[26-30]. Here we shall consider the influence of diffusion factors on an enzymic reaction whose rate v obeys the Michaelis–Menten equation:

$$v = \frac{V_{max} \cdot C}{K_m + C}, \quad (1)$$

where $V_{max} = k_{cat}[E]$, $[E]$, and C are the initial concentrations of the enzyme and substrate respectively, k_{cat} the catalytic first-order rate constant, and K_m the Michaelis constant. We shall bear in mind that the reacting enzyme is in an immobilised state, being, for example, bound covalently to a water-insoluble porous carrier or incorporated in a gel matrix or within a microcapsule. For the enzymic reaction to occur, it is evidently necessary in the first place for a substrate molecule in solution to approach the surface of the particle containing the immobilised enzymes and in the second place that it can diffuse within the latter. On the other hand, if the reaction in the surface layers of the particle is faster than the supply of the substrate from the solution to the surface, then a zone depleted in the substrate will arise round the particle after a time. As a result, the overall rate of the enzymic process will be determined by the rate of mass transfer of the substrate to the particle. By analogy with heterogeneous catalysis[26], we may say that in this case the process is controlled by external diffusion. On the other hand, we can imagine that the mass transfer of the substrate is faster than the enzymic reaction on the surface of the particle. Then another type of diffusion-dependent inhibition may arise, namely, if the size of the carrier particle is very great or its enzyme is very active, then almost the entire substrate reacts in the part of the carrier near the surface, while its bulk is depleted in the substrate. In such cases one usually says that the process is controlled by internal diffusion[26]. The effects of both diffusion factors on the effective kinetic parameters of an enzymic reaction are analysed below with the framework of the Michaelis equation [Eqn. (1)].

1. EXTERNAL DIFFUSION INHIBITION

Mass transfer takes place as a result of two different processes—convection and molecular diffusion. In liquids the transport of a substance as a result of convection is usually much faster than molecular diffusion[30] and therefore the latter process may be virtually disregarded. However, in examining heterogeneous systems (for example suspended solid particles) one must bear in mind that the boundary between the "phases" is directly adjoined by a layer of unstirred liquid within which the transport of molecules or ions proceeds exclusively via molecular diffusion. Consequently, when an enzymic reaction in which the substrate is consumed takes place on the surface of the particle, a steep reactant concentration gradient may arise within the unstirred layer, because molecular diffusion in liquids is very slow (with a diffusion coefficient of 10^{-5}–10^{-6} cm^2 s^{-1}).[30] As a result, the rate of mass transfer may be limited by the stage involving the heterogeneous catalytic process regardless of the rate of stirring.

We shall consider certain quantitative features of the process for a spherical particle assuming that the enzyme is immobilised either on the surface of a sphere or, if the carrier is porous, also within the sphere, but in the absence of internal diffusion inhibition. We shall assume further that the partition coefficient of the substrate between the solution and the carrier "phase" hardly differs from unity. The surface of the particle may be regarded as equally accessible[26]. Then the rate of supply of the substrate by diffusion j, referred to unit surface area of the particle is †

$$j = \beta (C_0 - C), \quad (2)$$

where C_0 and C are the substrate concentrations in the bulk of the solution and on the surface of the particle respectively, and β is the mass transfer coefficient.

a. In the special case where the enzymic reaction occurring on the surface of the particle follows first-order kinetics we have $K_m \gg C$ in Eqn. (1). Under these conditions, the steady state in the enzymic process is described by the following equation:

$$\beta (C_0 - C) = (V_{max}/K_m) \cdot C, \quad (3)$$

which reflects the fact that the specific rate of supply of the substrate to the surface of the particle with the immobilised enzyme (j) is equal to the rate of the enzymic reaction (v) referred to the unit surface area. From Eqn. (3), we have for the effective substrate concentration in the reaction zone

$$C = \frac{\beta \cdot C_0}{\beta + V_{max}/K_m}. \quad (4)$$

As a result, we conclude that the experimental steady-state rate of the enzymic reaction

$$v = (V_{max}/K_m) \cdot C = k_{eff} \cdot C_0 \quad (5)$$

is characterised by an effective first-order rate constant given by

$$k_{eff} = \frac{(V_{max}/K_m) \cdot \beta}{\beta + V_{max}/K_m} = \frac{1}{\frac{1}{\beta} + \frac{1}{V_{max}/K_m}}. \quad (6)$$

Two limiting cases are possible. When $\beta \gg V_{max}/K_m$, i.e. the mass transfer is much faster than the chemical reaction, we have $k_{eff} = V_{max}/K_m$. On the other hand, when $\beta \ll V_{max}/K_m$, i.e. the chemical reaction is much faster than the mass transfer, then $k_{eff} = \beta$. In the first case we shall say that the reaction proceeds under kinetic conditions and in the second case under diffusion conditions[31].

b. In the general case when the enzymic process is not of first order but of a fractional order (i.e. $K_m \sim C$) the existence of two process conditions (diffusion and kinetic) still remains in force despite the more cumbersome expressions for the reaction rate[26].

c. The second extreme case of the Michaelis equation [Eqn. (1)] when $K_m \ll C$, i.e. the enzyme is saturated by the substrate, constitutes an exception. Since an enzymic reaction is zero order with respect to substrate in the general case, evidently the process cannot in principle be controlled by diffusion and it proceeds under kinetic conditions.

---

† This assertion is approximate. It has been shown[30] that the diffusion flux to the absorbing sphere in a moving liquid is not distributed uniformly on its surface. It is a maximum at the point where the liquid advances to the sphere and diminishes on its rear side.

Theoretical Estimation of the Limits of the Diffusion and Kinetic Regions

Under kinetic conditions, the reaction evidently proceeds in full conformity with the laws specified by its mechanism. The situation is different under diffusion conditions where the reaction kinetics cannot yield information about the chemical mechanism, since they are determined by mass transfer parameters alone. To make a choice between these process conditions, it is necessary to estimate β and compare it, for instance in case (a) (see above), with V_{max}/K_m. For this purpose, we shall show, following O'Neill[32], how this can be done after making certain assumptions. It follows from similarity theory[26] that

$$\beta = \frac{NuD}{d}, \qquad (7)$$

where Nu is the Nusselt number, D the diffusion coefficient of the substance transported, and d the diameter of the absorbing particle. For a laminar flow of the liquid around the spherical particle and low Reynolds numbers, we have[28,28] Nu = 2. As an approximation, we shall assume that this condition holds in our system‡. Then we have from Eqn. (7)

$$\beta = \frac{2D}{d}. \qquad (8)$$

This value constitutes the lower limit. In fact, in consequence of the stirring of the system, β can be higher[26]. However, in studies with enzymes stirring is not usually very fast and therefore this effect is not very significant.

Knowing D and d, it is possible to calculate β by Eqn. (8). By comparing it [case (a)] with V_{max}/K_m, one can in principle deduce the type of conditions governing the enzymic reaction [see Eqn. (6)]. However, V_{max}/K_m must be determined from experimental data, which are already distorted by the influence of diffusion and therefore we shall indicate another, more convenient approach. Having evaluated β, it is possible to calculate the maximum rate of mass transfer and to compare it with the experimental rate of the reaction catalysed on the immobilised enzyme. If these two quantities are similar, the implication is that the reaction proceeds under diffusion conditions. On the other hand, if the observed rate of the enzymic reaction is much lower than the maximum possible rate of mass transfer, the reaction evidently proceeds under kinetic conditions. This approach is valid for any kinetic order of the enzymic reaction and we shall consider it in greater detail.

The rate of mass transfer R to any catalyst particle, which is equal to the diffusion flux multiplied by the surface area of the particle A, is defined by the following expression in accordance with Eqns. (2) and (8):

$$R = jA = \frac{2D}{d} \cdot A(C_0 - C). \qquad (9)$$

Since $A = \pi d^2$ for a sphere, it follows that

$$R = 2\pi Dd(C_0 - C). \qquad (10)$$

‡ Empirical formulae are frequently used in the literature to determine β in various heterogeneous systems under different conditions[33-35]. Our approximation should hold at not unduly high flow rates and has the advantage that β can be readily estimated numerically. In certain studies on immobilised enzymes β is determined from other equations[35,36].

The diffusion coefficient of the substrate in the liquid D, entering into Eqn. (10), can be determined experimentally in a separate experiment or estimated from different empirical correlations, provided that the substrate concentration does not exceed 10 mole %.[37] On the other hand, if the particle containing the immobilised enzyme is not spherical, then d is usually assumed equal to the diameter of the sphere whose surface area is equal to that of the particle employed.

The maximum possible rate of mass transfer R_{max} follows from Eqn. (10) for $C_0 \gg C$:

$$R_{max} = 2\pi DdC_0, \qquad (11)$$

where R_{max} is usually expressed in mole per second per particle. According to the recommendations of the International Commission on Immobilised Enzymes, the rate of reaction should be expressed in micromoles of the substrate per minute per milligram of the dry immobilised enzyme preparation[38]. Then Eqn. (11) must be transformed into

$$R^{tot}_{max} = 7.2 \cdot 10^2 \cdot \frac{DC_0}{\rho d^2}, \qquad (12)$$

where ρ is the density of the immobilised enzyme preparation expressed in g cm^{-3}, D is expressed in cm^2 s^{-1}, d in cm, and C_0 is the concentration on the molar scale.

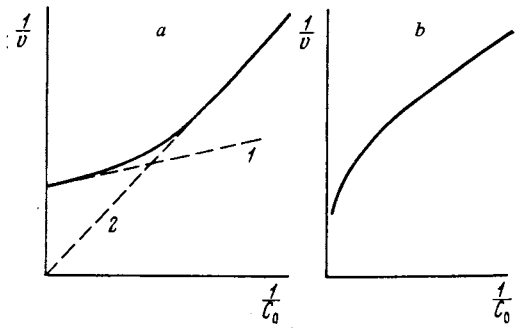

Figure 1. *a*) Theoretical variation of the rate of an enzymic reaction with substrate concentration in terms of the Lineweaver–Burk variables distorted by inhibition due to external diffusion; *b*) experimental curve in terms of the same variables[39,40] apparently corresponding to the presence of two kinetically different forms of the immobilised enzyme.

Certain Experimental Criteria

a. As mentioned above, at sufficiently high substrate concentrations (i.e. when the immobilised enzyme is saturated and the observed rate of reaction is of zero order with respect to the substrate), the enzymic process cannot in principle be controlled by the diffusion of the substrate and therefore the reaction proceeds under kinetic conditions. In its turn the probability of a transition of the reaction system to diffusion-dependent conditions increases with decrease of substrate concentration. This behaviour of the catalytic system is illustrated in Fig. 1, where the theoretical Lineweaver-Burk plot is presented for a reaction occurring at high substrate concentrations (dashed line *1*) under kinetic conditions, where

the experimental results can therefore be described with the aid of Eqn. (1), and at low substrate concentrations (dashed curve *2*) under diffusion conditions, where the variation of the experimental process velocity v with C_0 actually obeys Eqn. (12). On the other hand, if this behaviour of the $1/v-1/C_0$ plot is observed in experiments with an immobilised enzyme (i.e. the plot bends away from the usual linear Lineweaver–Burk relation), then we have the first indication that diffusion plays a significant role in the process. However, here attention should be drawn to the nature of the curvature. Thus a curved Lineweaver–Burk plot of another type, shown in Fig. 1*b*, was obtained in studies[39,40] on the catalytic properties of α-chymotrypsin and glucoamylase immobilised on cellulose derivatives. The authors also explain the observed curvature of the $1/v-1/C_0$ plot from the standpoint of diffusion-dependent inhibition. However, in this case such treatment of the results is incorrect, since it follows from theory that diffusion-dependent inhibition should be manifested particularly strongly at low substrate concentrations (Fig. 1*a*). However, the opposite behaviour actually follows from the experimental data (Fig. 1*b*), namely the process is accelerated at low substrate concentrations. Moreover, from the theoretical standpoint the process controlled by diffusion should follow first-order kinetics with respect to the substrate at low concentrations of the latter [Eqn. (12)] and this too is not observed in the experiment, since (Fig. 1*b*) extrapolation of the linear section of the $1/v-1/C_0$ curve, corresponding to low values of C_0, does not pass through the origin of coordinates. Therefore we believe that the curvature of the $1/v-1/C_0$ relation observed experimentally[39,40] (of the type of the curve in Fig. 1*b*) is probably due to the presence of several kinetically different forms of the immobilised enzyme.

b. Enzymic reactions usually have activation energies of the order of 10–30 kcal mole^{-1}. On the other hand, the rate of an enzymic process occurring under diffusion conditions should depend only slightly on temperature since the only temperature-sensitive parameter (D) in Eqn. (12) is associated with an activation energy of about 4–5 kcal mole^{-1} in water[41]. Consequently it is entirely valid to use the nature of the temperature variation of the reaction rate as a criterion for the determination of the limits of the kinetic and diffusion regions. In this connection one must, however, bear in mind that with increase of temperature the reaction undergoes a transition from kinetic to diffusion conditions [as follows, for example, from an analysis of Eqn. (6), bearing in mind the above differences between the temperature variation of β defined by Eqn. (8) and V_{max}/K_m].

c. Under diffusion conditions the reaction rate should evidently be independent of changes in the specific concentration of the immobilised enzyme [as follows, for example, from Eqns. (5) and (6)] assuming that under such conditions $V_{max}/K_m \gg \beta$. Moreover, if the reaction proceeds under diffusion conditions, its rate should not be affected by specific factors such as a change in pH or ionic strength and the addition of inhibitors or activators; in general these factors are associated with the enzymic mechanism and their influence can in principle be followed for the native catalyst. However, one should bear in mind that, for the same preparation of the immobilised enzyme, the reaction with a highly reactive substrate can proceed under diffusion conditions, while with a less reactive substrate kinetic conditions may obtain. All the postulates discussed in this section follow, for example, from an analysis of Eqns. (5) and (6) bearing in mind that the limits of the diffusion and kinetic regions are defined by the relative values of the parameters β and V_{max}/K_m.

d. Under kinetic conditions, the rate of reaction should be independent of the degree of comminution of the particles containing the immobilised enzyme (provided that there is no internal diffusion inhibition for the substrate). On the other hand, when the reaction proceeds under diffusion conditions its rate increases after comminution of the enzymic preparation, since the decrease in the particle diameter d leads to an increase of the diffusion parameter β [see Eqn. (8)].

e. The influence of diffusion factors may weaken when the rate of mass transfer of the substrate is accelerated by stirring. As already mentioned concerning Eqn. (7), this is because the parameter β depends in principle on the flow rate[30]. A very simple relation between the reaction rate and the rate of stirring can be arrived at from the standpoint of the concept of an unstirred layer, as a physically real feature, to which Fick's first law is applicable. [See, however, the objections to this approach raised by Levin[30] (p. 51) and Ioffe and Pis'men[27] (p. 113).] When the substrate concentration in the diffusion layer decreases linearly, we find that the specific rate of mass transfer $j = (C_0 - C)(D/\delta)$, where δ is the effective thickness of the stationary layer. Comparison of this expression with Eqn. (12) shows that the parameter β, which determines the type (diffusion or kinetic) of Eqn. (16) can be formulated as $\beta = D/\delta$. In its turn, it follows from hydrodynamics that the thickness of the diffusion layer diminishes with increase of the flow rate of the liquid u around the particle[30]:

$$\delta \propto u^{-n}, \qquad (13)$$

where n varies from 1/3 to 1 depending on the conditions (for example $n = 1/3$ for spherical particles or for the flow within a cylinder). This is true not only of an individual particle but also of layers of particles. Thus an increase in the rate of rotation of the stirrer in the reactor or even an increase in the flow rate of the substrate through the column should weaken diffusion-dependent control. In its turn, the dependence of the observed rate of the enzymic reaction on the rate of stirring or on the flow rate demonstrates a significant role of diffusion in this process. Presumably a significant increase in the rate of rotation of the stirrer can cause a transition from diffusion to kinetic conditions. However, the very fact that at low rates of rotation the observed reaction rate depends on stirring while at high rates of rotation such dependence is not observed, cannot alone serve as proof of a transition from diffusion to kinetic conditions, since, as shown in a study of heterogeneous reactions[42], at high rates of stirring the so called slip effect is observed, i.e. the stirrer ceases to drag the liquid with it and therefore the true flux velocities in the system do not change on further increase of the rate of rotation.

The Applications of Theoretical Postulates to the Analysis of Experimental Data

The predicted effects have been confirmed experimentally. It has been shown[39] that, with increase of the rate of stirring in a suspension of α-chymotrypsin bound covalently to KM-cellulose, the rate of enzymic hydrolysis of the ethyl ester of *N*-acetyl-L-tyrosine also increases. In its turn, the catalytic activity of columns with an immobilised enzyme rises with increase of the flow rate of

substrate solutions through them[35,36,40,43]. Fig. 2 illustrates this type of relation for the reaction of trypsin immobilised on porous glass with the *p*-nitroanilide on *N*-benzoyl-DL-arginine[35]. Experiment[40] also confirms the conclusion that there is a high probability that the reaction passes to diffusion conditions at low substrate concentrations: thus at low concentrations of starch (5%) the rate of its reaction with immobilised glucoamylase depends strongly on the flow rate through the column, while at high concentrations (30%) it is almost independent of the flow rate. It has been shown[44] that the reaction of trypsin bound covalently to the inner surface of a nylon tube with the ethyl ester of *N*-benzoyl-L-arginine is fully controlled by diffusion (even for $C_0 > 1000K_m$), the rate of reaction being proportional to the cube root of the flow rate of the substrate through the tube, as predicted by the theory [Eqn. (13)]. Bubbling of the stream of substrate with a gas, which improves the stirring within the tube, greatly increases the observed rate of the enzymic reaction.

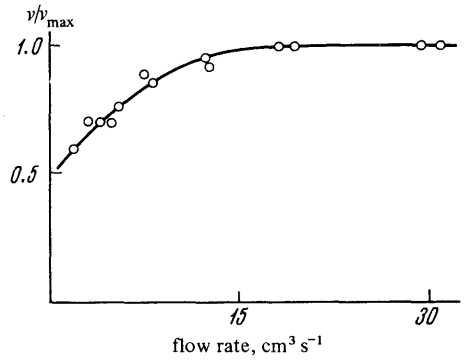

Figure 2. Dependence of the effective catalytic activity of a column filled with immobilised trypsin on the flow rate of the substrate (*p*-nitroaniline of *N*-benzoyl-DL-arginine) solution[35]; v = observed reaction rate at given flow rate Q; v_{max} = maximum reaction rate at fairly high values of Q.

Eqn. (12) can be used not only for qualitative but also for quantitative estimates of the role of external diffusion in catalysis by immobilised enzymes[32]. Thus the reaction of α-chymotrypsin immobilised on KM-cellulose and DEAE-cellulose with the ethyl ester of N-acetyl-L-tyrosine has been studied[39,45]. Table 1 presents the kinetic parameters of these reactions. In both cases the size of the particles containing the immobilised enzyme was about 40 μm and their density can be assumed to be 1 g cm^{-3}. The diffusion coefficient of the substrate, estimated with the aid of empirical correlations[46], will be assumed equal to 5×10^{-6} cm^2 s^{-1}. Then it follows from Eqn. (12) that $R^{tot}_{max} = 2.25 \times 10^2 C_0$. Consequently the maximum rate of mass transfer R^{tot}_{max} for α-chymotrypsin immobilised on DEAE-cellulose becomes lower than the calculated rate of reaction for $C_0 < 5 \times 10^{-2}$ M (as shown by the data in Table 1) and therefore diffusion should become a significant factor in the enzymic process. Indeed experiment shows[45] that the reaction is fully controlled by diffusion for $C_0 < 10^{-2}$ M and that the effect of diffusion is less significant for $C_0 > 10^{-2}$ M. Evidently the agreement between the theory and experiment is satisfactory. As was to be expected, the effect of diffusion disappears with increase of the rate of the enzymic reaction when the experiment is carried out at a pH far from the optimum (at pH < 5). In its turn, comminution of the particles containing the immobilised enzyme also lifts the diffusion-dependent inhibition[45]. The theoretical R^{tot}_{max} for α-chymotrypsin immobilised on KM-cellulose [Eqn. (12)] becomes equal to the theoretical values of v (Table 1) for $C_0 \simeq 10^{-3}$ M. It has been shown experimentally[39] that at such substrate concentrations external diffusion does indeed play an appreciable role.

Table 1. Kinetic parameters of the hydrolysis of the ethyl ester of *N*-acetyl-L-tyrosine catalysed by immobilised α-chymotrypsin.

Carrier	V_{max}, μmole/min mg of preparation	K_m, 10^{-3} M
DEAE-Cellulose (Ref.45)	12	5
KM-Cellulose (Ref.39)	0.5	1

Enzymes are sometimes immobilised in membranes[47-50] or are grafted onto cellulose sheets[51,52]. On the surface of a membrane, there is also a stationary layer, which in some cases can lead to a transition of the reaction to diffusion conditions. Such a system has been analysed in detail by Katchalski and coworkers[48]. The thickness of the diffusion layer (about 50 μm) can be found from the kinetic properties of the system. This value agrees with the earlier determinations of δ from the variation of the permeabilities of various membranes with the efficiency of stirring[53].

We may note that the examples quoted are a sufficient indication that external diffusion factors can indeed play an important role in catalysis by immobilised enzymes. The theoretical relations determined make it possible in turn to outline procedures whereby the experimenter can cause a transition of the reaction from diffusion to kinetic conditions (for example by raising the substrate concentration or conversely by reducing the specific concentration of the immobilised enzyme, or by increasing the rate of stirring, by comminuting the particles containing the immobilised enzyme, etc.).

2. INTERNAL DIFFUSION INHIBITION

The reaction of an enzyme incorporated in the three-dimensional network of a gel or a polymer or joined chemically to a porous carrier can be sensitive to inhibition by internal diffusion, i.e. the diffusion of the substrate within the gel, polymer, or the carrier pores.

We shall consider this problem in relation to a membrane (for example, a polyacrylamide[50] or collodion[47-49] membrane) or a polymeric disc (with a diameter much greater than its thickness) containing an immobilised enzyme. The problem of internal diffusion in such systems was analysed by Katchalski and coworkers[49] for low substrate concentrations and by Laidler and Sundaram[7,54] in the general case.

Here and henceforth we shall base the treatment on Fick's simple diffusion model. If there is an interaction between the membrane and the diffusing substance (for example, an electrostatic interaction[55]), then Fick's first law must be written in the form

$$\frac{dm}{dt} = -D \cdot A \cdot \left[\frac{\partial C}{\partial x} + \frac{C}{kT} \cdot \frac{\partial U}{\partial x}\right],$$

where m and C are the amount and concentration of the substance transferred, t is the time, D the diffusion coefficient, A the area through which diffusion takes place, k the Boltzmann constant, T the absolute temperature, x the coordinate of the direction of diffusion, and U the potential energy of the diffusing species, which depends on its position relative to the membrane. The solution of this equation depends on the type of the function $U(x)$. For a simple electrostatic interaction, $U(x)$ is determined by Coulomb's law.

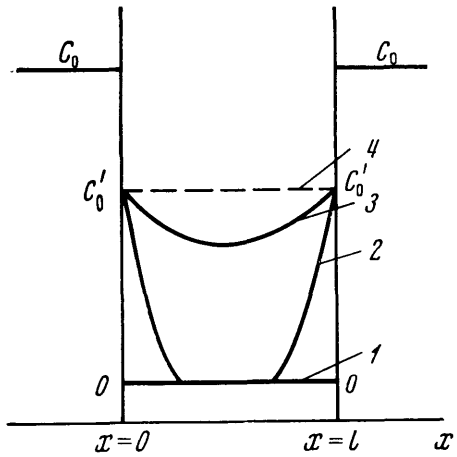

Figure 3. Diffusion of the substrate in the membrane (for explanation, see text): 1) distribution of the substrate for $t = 0$; 2) distribution of the substrate for $t > 0$; 3) steady state in the presence of enzymic reaction; 4) equilibrium state in the absence of enzymic reaction.

We place the membrane with a thickness l, on which the enzyme is immobilised, in a solution of the substrate at a concentration C_0 (Fig. 3).[7] At the initial instant ($t = 0$) the substrate concentration in the membrane is of course zero. Then it increases with time to the equilibrium value, which in the absence of an enzymic reaction is $C_0' = PC_0$, where P is the partition coefficient of the substrate between the membrane and the aqueous "phases" (dashed line in Fig. 3). On the other hand, when an enzymic reaction occurs in the membrane, consuming the substrate, then in the presence of internal diffusion inhibition the steady-state substrate concentration in the membrane may be less than C_0' and should depend on x, as shown in Fig. 3.

Time Required for the Attainment of the Steady State

For practical purposes, it is important to estimate the time required to establish the steady state where the rate of the diffusion flux becomes equal to the rate of the enzymic reaction and therefore the concentration of the substrate diffusing to the enzyme remains constant (steady-state value for C_0 = const.). In general an analytical solution of the problem is impossible and therefore it is necessary to resort to numerical methods. In this connection we shall analyse to a first approximation the case where there is no enzymic reaction in the membrane. Assuming that $P = 1$, the variation of the concentration C in the membrane with time t can be formulated thus[56]:

$$C = C_0\left[1 - \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{1-\cos n\pi}{n} \cdot \sin\frac{n\pi x}{l} \cdot \exp\left(-\frac{Dn^2\pi^2 t}{l^2}\right)\right], \quad (14)$$

where D is the diffusion coefficient of the substrate in the membrane medium. For fairly long times, the sum of the series in Eqn. (14) is determined mainly by the first term ($n = 1$):

$$C = C_0\left[1 - \frac{4}{\pi} \cdot \sin\frac{\pi x}{l} \cdot \exp\left(-\frac{D\pi^2 t}{l^2}\right)\right]. \quad (15)$$

Naturally the substrate concentration is always a minimum in the centre of the membrane ($x = l/2$). It will be assumed that the time τ after the elapse of which the substrate concentration in the centre of the membrane is 90% of its initial concentration in the solution, i.e. $C = 0.9\,C_0$, corresponds to virtual attainment of equilibrium. Then we have from Eqn. (15)

$$\frac{4}{\pi} \cdot \exp\left(-\frac{D\pi^2\tau}{l^2}\right) = 0.9, \quad (16)$$

whence§

$$\tau = 0.035 \cdot \frac{l^2}{D}. \quad (17)$$

The time of the virtual attainment of the steady state can be readily estimated from Eqn. (17). The membrane thickness l can be measured. The diffusion coefficients of different (low-molecular-weight) substances in the membrane D may be assumed to differ little from the diffusion coefficients measured in water, when the polymer content in the gel is not too high (such membranes are in fact used for the immobilisation of enzymes[47-50]). Thus it is shown in Table 2 for sucrose as an example that the diffusion coefficient in a dilute gel is lower only by a factor of 2–3 compared with an aqueous medium. Ultimately, if it is assumed that $D \simeq 3 \times 10^{-6}$ cm^2 s^{-1}, which is typical for substances[57] with molecular weights up to 10^3, Eqn. (17) yields $\tau \simeq 2$ min for a membrane 1 mm thick.

On the other hand, when an enzymic reaction takes place in the membrane simultaneously with diffusion, the substrate concentration at the centre of the membrane may not reach values as high as in the absence of the reaction. Consequently the time required to attain the steady state with respect to the substrate in a membrane with an immobilised enzyme probably should not exceed the value of τ for the state of equilibrium of the membrane without the enzyme¶. Therefore τ found from Eqn. (17) can be regarded as the upper limit to the times of attainment of the diffusion steady state in enzymic membrane systems.

§ There is an arithmetical error in the derivation of Eqn. (16) from Eqn. (17) in publications by Laidler and Sundaram[7,54], which results in an incorrect expression for τ, the true value being exceeded by a factor of 7.3.

¶ Provided that of course the enzyme itself or changes induced by it in the membrane do not exhibit a significant influence on the diffusion coefficient of the substrate.

Determination of the Kinetic Parameters of an Enzymic Reaction in the Absence of Internal Diffusion Inhibition

On the other hand, if the reaction with an immobilised enzyme is slower than diffusion (because the enzyme is not very active or its specific concentration is low) so that the equilibrium distribution of the substrate between the aqueous solution and the carrier particles is not disturbed, the specific rate of reaction referred to unit volume of the carrier should be represented as follows according to Eqn. (1):

$$v_{sp.} = \frac{k'_{cat}[E]_M C'_0}{K'_m + C'_0}, \quad (18)$$

where $C'_0 = PC_0$, $[E]_m$ is the concentration of the enzyme in the bulk of the carrier, and k'_{cat} and K'_m are the true kinetic parameters of the enzymic process within the carrier, which may differ in principle from the corresponding parameters for the reaction in water if only because the enzyme can assume, as a result of being immobilised, a conformation different from that in water or because of the influence of the medium. Hence the overall rate of reaction, referred to the entire bulk of the carrier (v_{tot}, mole s^{-1}), can be formulated as follows:

$$v_{tot} = \frac{k'_{cat.} EC_0}{K_{m(obs.)} + C_0}, \quad (19)$$

where $K_{m(obs)} = K'_m/P$, E is the total amount of the enzyme in the carrier equal to $[E]_M Al$ for a membrane, A is the area of one side of the membrane, and l is its thickness. Eqn. (19) shows that the kinetic parameters k'_{cat} and K'_m can be found by the usual procedure used in enzyme kinetics for the analysis of the Michaelis equation, provided that P is determined in an independent experiment.

Table 2. Diffusion coefficients D of sucrose in different media.

Medium	$10^6 D$, $cm^2 s^{-1}$	Refs.

Effect of Internal Diffusion on the Effective Values of the Kinetic Parameters of an Enzymic Reaction in the Membrane

One can be by no means always certain that the occurrence of the enzymic reaction does not disturb the equilibrium in the distribution of the substrate between water and the carrier. In the general case a substrate concentration C at a specified point in the membrane (with the coordinate x, see Fig. 3) is defined by the equation for the steady-state:

$$D \cdot \frac{d^2C}{dx^2} = \frac{k_{cat.}[E]_M C}{K'_m + C}, \quad (20)$$

which in fact reflects the equality of the gradient of the diffusion flux through unit surface area, defined by Fick's second law, and the rate of the enzymic reaction. The problem consists of finding the form of the function $C(x)$. Generally speaking, Eqn. (20) can be solved only numerically with the exception of two cases.

a. If $C \ll K'_m$ (this is true, for example, at low substrate concentrations when $C'_0 = C_0 P \ll K'_m$), then

$$\frac{d^2C}{dx^2} = \alpha^2 C, \quad (21)$$

where

$$\alpha = \sqrt{\frac{k'_{cat}[E]_M}{K'_m D}}. \quad (22)$$

The solution of Eqn. (21) by Euler's method with the boundary conditions $x = 0$, $C = C'_0$, $x = l$, and $C = C'_0$ yields

$$C = C'_0 \cdot \frac{\sinh \alpha x + \sinh \alpha (l - x)}{\sinh \alpha x}. \quad (23)$$

The steady-state rate of consumption of the substrate in the system must be equal to the diffusion flux through both sides of the membrane, i.e.

$$v'_{tot.} = 2AD \frac{dC}{dx}\Big|_{x=0,l}, \quad (24)$$

where the substrate concentration gradient at the boundary of the membrane follows from Eqn. (23) and is given by

$$\frac{dC}{dx}\Big|_{x=0} = \frac{dC}{dx}\Big|_{x=l} = \pm \alpha C'_0 \cdot \frac{\cosh \alpha l - 1}{\sinh \alpha l}. \quad (25)$$

Then, after simple rearrangement, the overall rate of reaction, referred to the entire volume of the carrier (v'_{tot}) or its specific value (v'_{sp}) per unit volume carrier, can be formulated as follows on the basis of Eqn. (24) and (25):

$$v'_{sp} = \frac{v'_{tot}}{Al} = \frac{k'_{cat}[E]_M C'_0}{K'_m} \cdot F, \quad (26)$$

where

$$F = \frac{2}{\alpha l} \cdot \frac{\cosh \alpha l - 1}{\sinh \alpha l} \equiv \frac{\tanh \gamma}{\gamma}, \quad (27)$$

and $\gamma = \alpha l/2$. Evidently Eqn. (26) differs from Eqn. (18) for the rate of reaction in the absence of diffusion-dependent inhibition (subject to the condition that $C'_0 \ll K'_m$) only by a factor F, which in fact reflects the effect of internal diffusion. F is called the efficiency factor; its properties will be discussed in greater detail below. Here we shall only consider Fig. 4, where F is plotted against αl calculated on the basis of Eqn. (27). When $\alpha l \to 0$ {this holds for a very low enzyme activity $k'_{cat}[E]_M/K'_m$ or for a thin membrane}, we have $F \to 1$, as expected from general considerations. With increase of the thickness of the membrane l or with increase of the activity of the immobilised enzyme {$k'_{cat}[E]_M/K'_m$, see Eqn. (22)}, F falls, which indicates a growing influence of diffusion-dependent inhibition.

b. When $C \gg K'_m$ (this happens when C'_0 is so large that the steady-state substrate concentration at any point in the membrane is much greater than K'_m), we have from Eqn. (20)

$$\frac{d^2C}{dx^2} = \omega, \quad (28)$$

where $\omega = k'_{cat}[E]_M/D$. Subject to the boundary conditions $x = 0$, $C = C'_0$, $x = l$, and $C = C'_0$, the solution of Eqn. (28) becomes

$$C = C'_0 - \frac{1}{2}\omega x(l - x) . \quad (29)$$

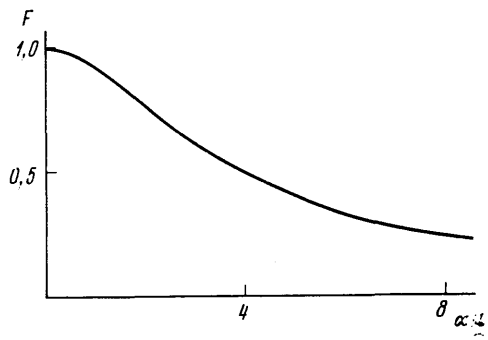

Figure 4. Theoretical variation of the F-factor with αl [Eqn.(27)].

As stated above, under steady-state conditions the overall rate of consumption of the substrate, referred to the entire volume of the carrier, must be equal to the diffusion flux through both sides of the membrane [see Eqn. (24)]. Since the substrate concentration gradient at the boundary of the membrane, derived from Eqn. (29), is

$$\left.\frac{dC}{dx}\right|_{x=0} = \left.\frac{dC}{dx}\right|_{x=l} = \pm\frac{1}{2}\omega l , \quad (30)$$

it follows that Eqn. (24) can be rewritten thus:

$$v'_{tot} = \omega ADl = k'_{cat}[E]_M Al . \quad (31)$$

Evidently the last expression is the same as Eqn. (18) (when $C'_0 \gg K'_m$), which holds for the rate of reaction in the absence of diffusion-dependent rate limitation. This implies that diffusion does not play any role in the enzymic reaction at fairly high substrate concentrations ($C \gg K'_m$).

c. We shall now consider the general case where $C \simeq K'_m$. As already stated, in the general case Eqn. (20) can be solved only numerically. However, the nature of the variation of the rate of the enzymic reaction v'_{tot} with substrate concentration in the solution C_0 can be represented qualitatively on the basis of Eqns. (26) and (31) characterising cases (a) and (b). If the rate of reaction obeys the Michaelis–Menten equation

$$v'_{tot} = \frac{k'_{cat\,(obs.)}EC_0}{K'_{m(obs.)} + C_0} , \quad (32)$$

over the entire experimental range of substrate concentrations, then on the basis of Eqn. (26) and (31) one may assume that

$$k'_{cat\,(obs.)} = k'_{cat} \text{ and } K'_{m\,(obs.)} = \frac{K'_m}{P \cdot F} . \quad (33)$$

Although the above reasoning is not entirely rigorous, the conclusions reached on its basis are satisfactorily confirmed by the results of the numerical integration of Eqn. (20).[7]

It is seen from Eqn. (33) that internal diffusion in no way affects the effective catalytic rate constant and influences only the observed Michaelis constant. The calculation based on Eqn. (27) shows that, when $\alpha l < 1$, F differs from unity by not more than 10%, i.e. $K'_{m(obs)} \simeq K'_m/P$, as predicted by Eqn. (33), and consequently diffusion does not have an appreciable influence on the reaction. On the other hand, when $\alpha l > 1$, F is significantly smaller than unity, i.e. $K'_{m(obs)} > K'_m/P$ and therefore diffusion of the substrate plays a significant role. Thus, in order to estimate beforehand the possible influence of internal diffusion on catalysis by an enzyme immobilised in a membrane, it is useful to calculate F [Eqn. (27)], on which the effective Michaelis constant depends [Eqn. (33)], and to compare it with unity. When $\alpha l > 3$, one can put approximately

$$F \approx \frac{2}{\alpha l} , \quad (34)$$

(see also Fig. 4). For an approximate estimate, it is useful to assume that k'_{cat} and K'_m, which determine the values of α [Eqn. (22)], differ little from the kinetic parameters of the reaction in water. A test of the theory carried out in Laidler's[50] and Katchalski's[49] laboratories fully confirmed this.

Certain Characteristics Distinguishing Rate Limitation by Internal Diffusion from Rate Limitation by External Diffusion

a. For very high values of αl, when $F \ll 1$ [Eqn. (4)] and therefore the reaction is significantly retarded by diffusion [Eqns. (32) and (33)], we have $K'_{m(obs)} \gg C_0$. In this case we obtain the following expression from Eqns. (22), (26), and (34) for the overall rate of the enzymic process referred to the entire volume of the carrier:

$$v'_{tot} = 2PC_0\sqrt{\frac{k'_{cat}[E]_M D}{K'_m}} . \quad (35)$$

It is seen from Eqn. (35) that, in contrast to rate-limitation by external diffusion, where the reaction rate under diffusion conditions is altogether independent of the catalytic properties of the enzyme [see, for example, Eqns. (5) and (6)], when the rate is limited by internal diffusion it is proportional to the square root of the enzyme concentration and enzyme activity.

b. In contrast to rate limitation by external diffusion, where the temperature variation of the reaction rate under diffusion conditions reflects only the activation energy governing the diffusion coefficient (see p. 12), when the rate is limited by internal diffusion [Eqn. (35)], the apparent activation energy ϵ_{app} depends on the temperature variation of not only the kinetic and diffusion parameters ($\sqrt{k'_{cat}/K'_m}$ and $\sqrt{D}$ respectively) but also of the partition coefficient P of the substrate between water and the carrier in the following way: $\epsilon_{app} = \frac{1}{2}(\epsilon + \epsilon_D + 2\Delta H_p)$, where ϵ is the activation energy for the enzymic reaction, ϵ_D the activation energy for the diffusion of the substrate, and ΔH_p the enthalpy of its transfer from water to the carrier.

c. It is interesting to note that the inhibition of the enzymic reaction diminishes the influence of internal diffusion in catalysis[62]. This follows from an analysis of Eqn. (34) bearing in mind that in the inhibition the values

of k'_{cat} and K'_m, which determine α[Eqn. (22)], are in fact effective quantities, which depend on the inhibitor concentration in the usual way.

Dependence of Internal Diffusion on the Geometrical Properties of the Particle

The influence of internal diffusion on the reaction between the substrate and the enzyme immobilised in the membrane was discussed above. However, the particles containing the immobilised enzyme usually have a spherical, cylindrical, or other shape. Naturally it is possible in principle to carry out a similar analysis in each of these instances[62,63]. However, we believe that it is far more useful to consider immediately a more universal case.

Suppose that we have a particle in which the enzyme molecules are distributed uniformly in the matrix (gel, polymer, or porous carrier). The substrate must diffuse into the particle (as before, external diffusion is regarded here as a factor which has been taken into account) and reacts there. The solution of this problem is analogous to that considered by Zel'dovich[64], Thiele[65], and Damköhler[66] for heterogeneous catalysis. They showed that the observed rate of the catalytic reaction controlled by diffusion is

$$v_{obs} = \eta v, \qquad (36)$$

where v is the rate of reaction in the absence of diffusion control, η the efficiency factor[65], which depends on the parameter Φ:

$$\Phi = a\sqrt{\frac{v}{C_0 D}} \qquad (37)$$

(Thiele's modulus), where a is the particle size (the radius for a sphere), C_0 the concentration of the reactant in the bulk phase, and D its diffusion coefficient within the catalyst particle. The specific form of the function η depends on the shape of the particle and the order of the reaction with respect to the substrate†. However, Aris[67] showed that the shape of the particles has only a slight influence on the function η. In all cases the curve relating η to Φ resembles closely the analogous curve for the relation between F and αl (Fig. 4). With increase of the reaction order from zero to third, the $\eta-\Phi$ curve in Fig. 4 is only a little displaced to the left and is slightly deformed. However, the following fact remains unaltered: when $\Phi < 1$, then η is close to unity and therefore diffusion is not important for the process; on the other hand, when $\Phi > 1$, then $\eta < 1$ and the reaction is retarded by diffusion. Therefore presumably the parameter αl, characterising the internal diffusion in the membrane, is a special case of Thiele's modulus. Consequently, in order to estimate beforehand the role of internal diffusion in the immobilised enzyme system[68], it is merely necessary to calculate Φ and compare the corresponding value of η with unity.

In the calculation of Φ [Eqn. (37)] account must be taken of the fact that the substrate diffusion coefficient in the porous particle (for example in porous glass)[28] is $D = D_{true}q$, where D_{true} is the true diffusion coefficient of the substrate in the liquid filling the pores of the particle and q is the fraction of the pore volume (i.e. the space available for diffusion) relative to the total volume of the particle. For example, in the diffusion of oxygen dissolved in water into the pores of porous glass[36] $D_{true} = 2.4 \times 10^{-5}$ cm^2 s^{-1} and $D = 0.93 \times 10^{-5}$ cm^2 s^{-1}, i.e. $q = 0.39$.

† For example, for a unimolecular reaction involving a plate, we have $\eta = (1/\Phi)\tanh\Phi$ and for a sphere we have $\eta = (1/\Phi)(1/\tanh 3\Phi - 1/3\Phi)$.[27,28]

Practical Application of Theoretical Relations

The proposed theory suggests ways of decreasing the rate limitation by internal diffusion in catalysis by immobilised enzymes—see, for example, Eqns. (32)–(34) or (36)–(37). There are two main procedures: the first, which is the most effective, involves a decrease of the particle size of the immobilised enzyme and the second involves a decrease of the specific enzyme concentration in the particle. As an example, Fig. 5 presents the experimental relation between η and Φ for glucose oxidase immobilised on porous glass[36], observed when the particle size is altered. It is found that η reaches about 0.95 only for a particle size of about 30 μm.

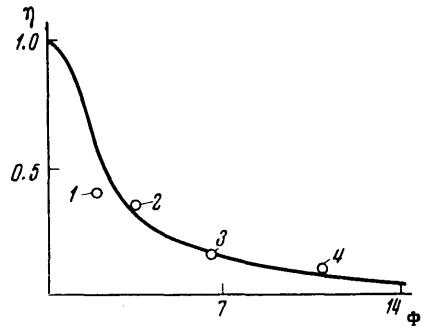

Figure 5. Variation of η with Φ. The curve was calculated theoretically and the circles represent experimental values for the given particle size (μm):[36] 1) 125–250; 2) 250–500; 3) 500–1000; 4) >1000.

With the aid of the theory described above, it is possible to predict the most favourable (from the standpoint of the absence of rate limitation by internal diffusion) immobilisation procedures. Thus analysis showed that[69], for a given particle size of the carrier and a constant amount of the deposited enzyme, Φ is smaller (and therefore η is closer to unity) when the enzyme is not distributed uniformly throughout the bulk of the carrier, but forms instead a surface film on a catalytically inert grain. This method for immobilising enzymes is in fact used successfully[70,71].

It is interesting to note that, as shown theoretically[72,73] and confirmed experimentally[74,75], in immobilised polyenzyme systems, where the reaction product of one enzyme is the substrate of another, the presence of rate limitation by internal diffusion can lead to an increase of the overall rate of reaction. This is because rate limitation by internal diffusion leads to the "concentration of the product" (i.e. of the substrate of the next reaction) in the bulk of the carrier relative to the equilibrium distribution.

3. DIFFUSION IN SIMPLE LIQUIDS AND POLYMERS

When enzymes are immobilised in polymeric carriers and also when they are enclosed in polymeric (usually polyamide) microcapsules[76–86] or in hollow fibres[87–89] there arises the problem of diffusion of the substrate through the polymeric medium.

According to the theory of Lieb and Stein[90-92], developed in recent years, the diffusional behaviour of non-electrolytes in simple liquids and in polymers can differ radically. In the diffusion in simple liquids the particle size of diffusing substances is as a rule greater than the molecular size of the diffusion medium, which therefore may be regarded as continuous and isotropic with respect to viscosity. On the other hand, in the diffusion of molecules into polymers, the molecular size of the diffusing substance is smaller than the molecular dimensions of the diffusion medium. Since diffusion in polymers proceeds via the motion of segments of polymeric molecules of the medium, the latter cannot be regarded as homogeneous and isotropic with respect to viscosity.

For a spherical diffusing species with a radius a in a simple liquid, the diffusion coefficient is defined by the Stokes–Einstein equation:

$$D = \frac{kT}{6\pi a \nu}, \qquad (38)$$

where k is the Boltzmann constant, T the absolute temperature, and ν the viscosity of the diffusion medium. If it is assumed that the diffusing molecules are spheres with a constant density, Eqn. (38) can be transformed into

$$D M^n = \text{const}, \qquad (39)$$

where M is the molecular weight of the diffusing substance and n a numerical coefficient equal to 1/3 for spherical molecules. This approximation is valid for many large protein molecules, although usually the molecules cannot be regarded as spherical and therefore n differs somewhat from 1/3. As an example, Table 3 presents the diffusion coefficients for various non-electrolytes in water[41], $n = 0.43$ follows from a plot of $\lg D$ against $\lg M$ on the basis of these data. Analysis of extensive data[91] has shown that in simple liquids n varies from 0.3 to 0.5, i.e. the diffusion coefficient depends only fairly slightly on the molecular weight of the diffusing substance.

Table 3. Diffusion of different non-electrolytes in water[41].

Diffusing substance	$10^6 D_{25°}$, cm^2 s^{-1}	Activation energy for diffusion ϵ_D, kcal mole^{-1}
Urea, $M = 60$	13.78	4.470
Glycine, $M = 75$	10.55	4.627
Alanine, $M = 89$	9.097	4.783
Glucose, $M = 180$	6.728	4.959
Cyclohepta-amylose, $M = 1134$	3.224	4.931
Bovine serum albumin, $M = 68000$	0.65	4.969

In polymers diffusion proceeds via "holes" formed at random as a result of the thermal motion of polymeric segments[93]. In order that the diffusing substance can pass through the holes, it must evidently have suitable dimensions. Diffusing species comprising very small species can pass through both small and large holes, while those with large species can only penetrate large holes. Since the formation of large holes requires more energy, their number is smaller than that of very small holes; this qualitative reasoning is confirmed by quantitative calculations[91]. Therefore the diffusion coefficients of small and large molecules in polymeric media should presumably differ sharply, i.e. n is large. Indeed, we have, for example, $n = 3.8$ for poly(methyl methacrylate) as a diffusion medium at 65°C.[90,94] Whereas in diffusion in the usual liquids doubling of the molecular weight leads to a decrease of D by a factor of about 1.4,[41] in diffusion in poly(methyl methacrylate) this leads to a 14-fold diminution of D! For different polymeric media, n varies from 2 to 8.[95-97]

Analysis of the effect of molecular shape on the diffusion coefficient showed that, for example, in water when the molecular shape deviates from the sphere, D diminishes and is correlated with the maximum change in the molecule[98]. On the other hand, in polymeric media the diffusion coefficients of substances are correlated with the smallest changes in their molecules (Table 4), which is also apparently associated with the "hole" mechanism of the diffusion process in polymers.

Table 4. Dependence of the diffusion coefficients of hydrocarbons in polyisobutylene on their molecular geometry[99].

Diffusing substance	n-Pentane	Isopentane	Neo-pentane
$10^9 D_{35°}$, cm^2 s^{-1}*	2.64	1.32	0.62

*D was determined by extrapolating the experimental data to zero concentration of the diffusing substance.

It follows from Table 3 and the literature[57,91,100] that, firstly, the diffusion coefficient depends only very slightly on temperature (for example, the activation energy for diffusion $\epsilon_D \simeq 4-5$ kcal mole^{-1} in water) and, secondly, ϵ_D is almost independent of the molecular weight of the diffusing substance. These findings are quite understandable, since the diffusion process in simple liquids is determined mainly by the properties of the diffusion medium and not by those of the diffusing substance itself[101] (see also the Stokes–Einstein equation). On the other hand, in diffusion in polymers the values of ϵ_D exceed significantly those characteristics of solutions[102] and furthermore, ϵ_D increases appreciably with increase of the molecular weight of the diffusing substance (see Table 5). This can also be accounted for within the framework of the "hole" concept of diffusion in polymers, since the formation of large holes, necessary for the diffusion of large molecules, requires more energy than the formation of very small holes. Thus, in contrast to the diffusion in liquids, in polymers D depends strongly on temperature.

Finally, we may note that at not unduly high concentrations of diffusing substances, their joint diffusion in simple liquids is independent. On the other hand, in diffusion in polymers the addition of small amounts of certain substances (called plasticisers) leads to a sharp increase of the diffusion coefficients of other substances[97,103,104], probably in consequence of the improvement of their solubility in the polymer[104]. For example, the addition of 2% of water to a specimen of poly(vinyl acetate) at 40°C leads to an increase of the diffusion coefficient of carbon tetrachloride by a factor of 75.[103]

The data quoted show that diffusion processes in simple liquids and in polymers are fundamentally different. Lieb and Stein[97] suggested that the diffusion in liquids be

assigned to the *s*-type (from the English word 'simple') and that in polymers to the *p*-type (from the English word 'polymer'). As we have already stated, diffusion processes of the *s*- and *p*-types differ significantly in terms of four characteristics, which are compiled in Table 6.

Table 5. Diffusion of different substances into a poly-(vinyl acetate) film[97].

Diffusing substance	$10^{12}D_{40^\circ}$, $cm^2\ s^{-1}$*	ϵ_D, kcal $mole^{-1}$
Water	$1.2\cdot10^5$	15±1
Methanol	$1.5\cdot10^3$	21±2
Acetone	$1.3\cdot10^1$	39±3
1-Propanol	$4.8\cdot10^{-}$	41±4

*D was determined by extrapolating the experimental results to zero concentration of the diffusing substance.

The set of these four characteristics constitutes a criterion for the determination of the type of diffusion in the given medium. It was found[91,92] that non-mediated diffusion of non-electrolytes in biological membranes belongs fully to the *p*-type.

Table 6. Effect of various parameters on diffusion of *s*- and *p*-type[92].

Parameter	Diffusion of *s*-type	Diffusion of *p*-type
Molecular size of diffusing substance	Increase in size entails only a slight decrease of diffusion coefficient (n = 0.3–0.5)	Increase in size leads to a sharp decrease of diffusion coefficient (n = 2–8)
Molecular shape of diffusing substance	Diffusion coefficient is correlated mainly with the maximum dimension of the diffusing molecule	Diffusion coefficient is correlated mainly with the minimum dimension of diffusing molecule
Temperature	Increase of temperature leads to a slight increase of diffusion coefficient for both large and small molecules	Increase of temperature leads to an appreciable increase of diffusion coefficient—greater the greater the molecular size of diffusing substance
Plasticisers	Almost without effect	Their addition to polymeric medium leads to increase of the diffusion coefficients of other molecules

In catalysis by enzymes immobilised in polymeric matrices or microcapsules or in the diffusion of substrates (even low-molecular-weight substrates) through a polymeric medium, there is apparently also a possibility not only of *s*-type but also of *p*-type diffusion. For example, the results obtained by Mogenson and Vieth[105], who found that the permeability of a cellulose nitrate capsule to hydrogen peroxide exceeds the permeability of the same microcapsule to urea by a factor greater than twenty, can be explained only from this standpoint. In this connection we emphasise that in *p*-type diffusion one may expect a sharp dependence of the observed efficiency of catalysis on the molecular weight of the substrate and on temperature.

4. DEPENDENCE OF THE REACTION RATE CONSTANT ON THE DIFFUSION PROPERTIES OF THE MEDIUM

Even if account is taken of external and internal diffusion in an enzymic reaction, its rate may depend on the diffusion properties of the reaction medium. The problem of the effect of diffusion on the rate constants for chemical reactions was solved by Smoluchowski[106], Debye[107], and Noyes[108]. Evidently diffusion should not play any role in unimolecular reactions. For a bimolecular reaction between two uncharged species, the observed rate constant k_{obs} is given by the following general expression:

$$k_{obs} = \frac{k}{1 + \frac{k}{4\pi \cdot D_\Sigma \cdot \sigma}}, \qquad (40)$$

where k is the true reaction rate constant, D_Σ the sum of the diffusion coefficients of the reactants, and σ the equilibrium interaction distance. If $1 \gg k/4\pi D_\Sigma\sigma$, then $k_{obs} = k$ and diffusion is unimportant for the reaction; on the other hand, if $1 \ll k/4\pi D_\Sigma\sigma$, then $k_{obs} = 4\pi D_\Sigma\sigma$ (i.e. is independent of k)‡ and the reaction is fully controlled by diffusion. Eqn. (40) is valid, provided that the molecules do not interact when the distance between them (r) is greater than σ.

In general the Debye equation is valid:

$$k_{obs} = \frac{k}{1 + \frac{k\int_\sigma^\infty \exp\left(\frac{U}{kT}\right)\cdot\frac{dr}{r^2}}{4\pi D_\Sigma}}, \qquad (41)$$

where U is the energy of the interaction between the reactant species. If $U = 0$ when $r > \sigma$, Eqn. (41) becomes identical with Eqn. (40). The form of the function $U(r)$ is usually unknown and therefore Eqn. (41) cannot be put in an analytical form. However, if it is assumed that there is electrostatic Coulombic interaction between the species, then $U = z_1z_2e^2/\kappa\sigma$, where z_1e and z_2e are the charges of the reactant species (e is the electronic charge), and κ the dielectric constant of the medium. In this case we have the following expression for the rate constant for a diffusion-controlled reaction:

$$k_{obs} = 4\pi D_\Sigma \cdot \sigma \cdot \frac{\theta}{\exp\theta - 1}, \qquad (42)$$

where $\theta = z_1z_2e^2/\kappa\sigma kT$. Consequently, knowing the corresponding parameters of the medium and the reaction, it is possible to determine the limits of the region of diffusion control.

The formation of the Michaelis complex must be regarded as the fastest stage of enzymic reactions: the rate constants for this stage sometimes approach the values characteristic of diffusion-controlled processes even in water[109]. Therefore, in very viscous media, where D is exceptionally small, the reaction may be presumably fully diffusion-controlled[110] [it must be emphasised that under these conditions k_{obs} may be very small and k is proportional to D_Σ—see Eqn. (40)].

Consider the reaction of an enzyme and a substrate in the gel, assuming that the process is not controlled by diffusion in solution. With increase of the gel concentration, its pores diminish and a time must come when they

‡ This expression is valid to within the steric factor, since Eqns. (40) and (41) were derived on the assumption that each collision of the reactant leads to chemical reaction.

become comparable to the dimensions of the protein globule of the enzyme, which leads to a sharp fall of its diffusion coefficient (there is a transition from diffusion of *s*-type to *p*-type). The occurrence of this phenomenon has been established experimentally[111]. However, in a reaction with a low-molecular-weight substrate this does not lead to diffusion control even if the enzyme is completely "arrested", since Eqns. (40)—(42) include the sum of the diffusion coefficients and, furthermore, for low-molecular-weight substances D changes little with increase of the gel concentration even to very high values[59]. The situation is different when the substrate is a high-molecular-weight compound. Then an increase in the gel concentration ultimately drives the reaction towards diffusion-controlled conditions and, on further increase of the gel concentration (which entails a decrease of D), there should be a sharp decrease of the observed reaction rate. These effects were predicted and observed experimentally in our laboratory[111,112]. Fig. 6 presents data for the variation of the observed rate of reaction of trypsin with chymotrypsinogen ($M \simeq 25\,000$ for both proteins) in a polyacrylamide gel as a function of the gel concentration[112]. Evidently, with increase of the gel concentration to approximately 32%, the observed rate of reaction actually increases somewhat (which is related to its specific features) and then falls almost to zero on further increase of the concentration by only 2% owing to retardation by diffusion.

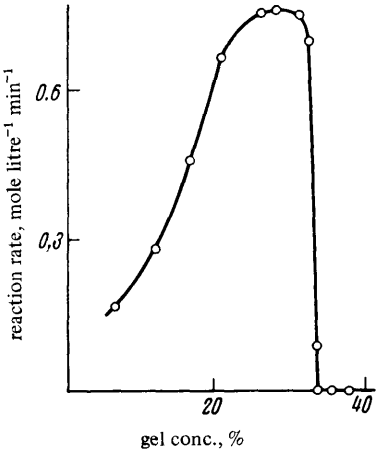

Figure 6. Variation of the observed rate of reaction ($\times 10^6$) of trypsin with chymotrypsinogen in polyacrylamide gel with its concentration[112].

In conclusion we may note that the rate of an enzymic reaction in a polymer may be controlled by diffusion even for a low-molecular-weight substrate, provided that its diffusion is of the *p*-type. In turn one should note that the retardation of enzymic reactions in polymeric (gel) media by diffusion may be used to investigate the fine structure of the polymeric matrix.

III. EFFECT OF THE NATURE OF THE CARRIER ON THE KINETICS OF REACTIONS CATALYSED BY IMMOBILISED ENZYMES

The main idea of this and the next two sections in the present review is that immobilisation of enzymes entails the actual appearance of a new type of specificity of the latter compared with the native biocatalyst. This phenomenon is due to the influence of the carrier on the catalytic process. In the first place one should note that the reaction system [consisting of the enzyme immobilised on (or in) the carrier placed in an aqueous solution] may be regarded as a two-phase system. The fact that the reaction components (substrates, cofactors, inhibitors, hydrogen ions, etc.) are uniformly distributed between the aqueous solution and the effective volume of the carrier (to which an adjacent layer of the solution should be assigned in the general case) is related precisely to the two-phase nature of the reaction system. Naturally such distribution influences the kinetics of the enzymic process. We shall consider this problem in somewhat greater detail.

1. pH EFFECTS

When the enzyme is immobilised on a charged carrier, one may expect that the concentration of hydrogen ions in the carrier phase will be smaller than in the solution if the carrier is charged positively and, conversely, will be greater for a negatively charged carrier. This follows from the quantitative theory developed by Goldstein et al.[113] Thus the ratio of the hydrogen ion concentrations in the carrier $[H^+]'$ and the solution $[H^+]$ is determined by the Boltzmann factor

$$P_{H^+} = \frac{[H^+]'}{[H^+]} = \exp\left(-\frac{e\psi}{kT}\right), \qquad (43)$$

where P_{H^+} is the partition coefficient, e the absolute electronic charge, ψ the electrostatic potential of the charged immobilised enzyme species, k the Boltzmann constant, and T the absolute temperature. As a result, the difference between the pH of the carrier and the solution is

$$\Delta pH \equiv pH' - pH = 0.43 \cdot \frac{e\psi}{kT}. \qquad (44)$$

The resulting pH shift can in turn influence the rate of the enzymic reaction, provided that the mechanism is associated with the dissociation of an ionogenic group in the enzyme or other reaction components (see the general theory of the pH effects in enzymic catalysis[114]). The dissociation constant of the ionogenic group BH^+ of the native enzyme $K = [B][H^+]/[BH^+]$ is by definition the value of $[H^+]$ for which the ionogenic group is half-neutralised. Consequently, on the basis of Eqn. (44), the pK shift due to the carrier is

$$\Delta pK \equiv pK' - pK = -0.43 \cdot \frac{e\psi}{kT}, \qquad (45)$$

where K' is the dissociation constant of the ionogenic group BH^+ in the enzyme joined to the charged carrier. It follows from Eqn. (45) that p$K' <$ pK for a positively charged carrier ($\psi > 0$) and, when the carrier is negatively charged ($\psi < 0$), then p$K' >$ pK.

Experiment confirms the above considerations. Thus at low ionic strengths the pH dependence of the catalytic activity of polyanionic trypsin derivatives is such that its optimum is displaced to the alkaline region and for polycationic trypsin derivatives it is displaced to the acid

region[13,113]. Similarly the pK of the imidazole group of the histidine-57 residue forming part of the active centre of α-chymotrypsin is 6.70 ± 0.02 for the native enzyme, 7.82 ± 0.05 for the polyanionic derivative of α-chymotrypsin, and 6.10 ± 0.05 for the polycationic derivative[115]. The list of similar factors can be extended. Thus when α-chymotrypsin[116,117], phosphatase[118], and urease[119] are immobilised on negatively charged carriers (bentonite or kaolin), the pH optimum shifts to the alkaline region. On the other hand, following immobilisation on positively charged DEAE-cellulose, the pH optima of aminoacylase[120] and invertase[121] are displaced to the acid region. Derivatives of other enzymes (papain[9], ficin[122], and subtilopeptidase A [9]) behave similarly.

The shifts of the reaction rate–pH curves described above become considerable only at a low ionic strength of the solution. This finding is explained by the fact that an increase in ionic strength as well as an increase in the dielectric constant decreases the electrostatic interaction between the charged species and hence the repulsion between the charged carrier and the effector (in the present case hydrogen ions)[123]. Table 7 lists the pK shifts for the ionogenic group controlling the catalytic activity of trypsin immobilised on a polyanionic carrier (a copolymer of ethylene and maleic acid) at different ionic strengths of the solution[113].

Table 7. Dependence of ΔpK and ψ on the ionic strength of the solution for trypsin immobilised on a polyanionic carrier[113].

Ionic strength, M	$\Delta pK \equiv pK' - pK$	Ψ, mV	Ionic strength, M	$\Delta pK \equiv pK' - pK$	Ψ, mV
0.006	−2.4	−150	0.2	−1.3	−80
0.010	−2.0	−120	1.0	−0.4	−30
0.035	−1.6	−100			

pH effects of this type occur also when the enzyme is immobilised on (or in) an uncharged carrier where one may also expect a distribution of hydrogen ions between the solution and the bulk of the carrier, namely $[H^+]' = P_{H^+}[H^+]$. Hence $\Delta pK = -\lg P_{H^+}$. This relation makes it possible to determine beforehand the sign and magnitude of the pH effects in the above systems, provided that the partition coefficient P_{H^+} is known.

The above elementary theory describes the shifts of the pH profiles not only for truly immobilised biocatalysts but also for water-soluble modified enzymes, for example for acetylated and succinylated derivatives of trypsin and α-chymotrypsin, in which the negative charge of the globule has been increased in consequence of the acylation of the amino-groups[13,17,113,124,125]. In certain cases the observed shift of the pH optimum of the reaction catalysed by the immobilised enzyme does not correspond to equilibrium and is due to the fact that there is not sufficient time for the diffusion of the acid or base formed in the reaction away from the carrier[47,49,126].

2. DISTRIBUTION OF THE SUBSTRATE BETWEEN THE CARRIER AND THE SOLUTION

A simple behaviour may be observed in the electrostatic interaction between the substrate and the carrier. Indeed, if the carrier and substrate are both charged, the substrate concentration C_0' on (or in) the carrier is defined by the following relation:

$$P = \frac{C_0'}{C_0} = \exp\left(-\frac{ze\psi}{kT}\right), \qquad (46)$$

analogous to Eqn. (43), where P is the partition coefficient, C_0 the substrate concentration in the solution, and ze the charge of the substrate. Then the rate of the reaction in the carrier phase catalysed by the immobilised enzyme can be represented by Eqn. (19), in which the physical significance of the coefficient P is defined by Eqn. (46). Consequently the effective Michaelis constant observed experimentally is given by the relation $K_{m(obs)} = K_m' \exp(ze\psi/kT)$. Evidently, when the charges of the carrier and the substrate are of the same sign (ze and ψ are of the same sign), $K_{m(obs)} > K_m'$; on the other hand, when they are of different sign (ze and ψ are of different signs), $K_{m(obs)} < K_m'$§. It follows from Eqn. (19) that the electrostatic interaction between the substrate and the carrier is not manifested when $C_0 \gg K_{m(obs)}$.

Table 8. The observed Michaelis constants for different immobilised enzymes[7].

Enzyme	Carrier	Charge of carrier	Substrate	Charge of substrate	$K_{m(obs)}$, M	Refs.
ATP : creatine phosphotransferase	None		ATP	−	6.5×10^{-4}	
	p-Aminobenzylcellulose	0	ATP	−	8.0×10^{-4}	127
	KM-Cellulose	−	ATP	−	7.0×10^{-3}	
Ficin	None		EEBA[a]	+	2.0×10^{-2}	
	KM-Cellulose	−	EEBA	+	2.0×10^{-3}	122
Trypsin	None		BAA[b]	+	6.8×10^{-3}	
	Ethylene–maleic acid copolymer	−	BAA	+	2.0×10^{-4}	113
Papain	None		EEBA	+	1.9×10^{-2}	
	pp-Aminophenylanaline-L-leucine copolymer	0	EEBA	+	1.9×10^{-2}	128
Bromelain	None		EEBA	+	0.11	
	KM-Cellulose	−	EEBA	+	0.049	129

[a] EEBA = ethyl ester of *N*-benzoyl-L-arginine.

[b] BAA = *N*-benzoyl-L-argininamide.

§ One should note that there is an error in the fundamental communication of Goldstein et al.[113], which was unfortunately subsequently transferred to other papers by the same workers and also to certain reviews[8,9]. After deriving correctly Eqn. (44), the authors[113] then adopt as the pH shift between the medium of the carrier and the solution the observed shift of the pH profile of the catalytic activity of the enzyme, which evidently is of the opposite sign. As a result negatively charged carriers would have to be characterised by a positive potential ψ! On the basis of this erroneous postulate, the authors quote an incorrect equation for the distribution of the charged substrate between the charged carrier and the solution [cf. Eqn. (46)]:

$$C' = C_0 \cdot \exp\left(\frac{ze\psi}{kT}\right).$$

We may note that this error is by no means purely terminological, since the last equation and the equation for the pH shift between the carrier and the solution [Eqn. (44)], quoted by Goldstein et al.[113], are mutually exclusive.

Table 8 presents the values of $K_{m(obs)}$ for certain reactions of charged substrates with enzymes immobilised on the charged carrier. Evidently in many systems the electrostatic interactions between the substrate and the carrier may result in a difference between $K_{m(obs)}$ and K'_m greater than by an order of magnitude. As was to be expected, at high ionic strengths of the solution the above effects become insignificant. Thus $K_m = 6.9 \times 10^{-6}$ M was found for the reaction of trypsin with the ethyl ester of *N*-benzoyl-L-arginine in solution; $K_{m(obs)} = 0.2 \times 10^{-6}$ M at an ionic strength of 0.04 M and $K_{m(obs)} = 5.2 \times 10^{-6}$ M at an ionic strength of 0.50 M for trypsin immobilised on a copolymer of ethylene and maleic acid[113].

The interaction between the substrate and the carrier can in principle be other than electrostatic. In the general case, when P cannot be predicted theoretically, it can be measured in a separate experiment (using a carrier without the enzyme). For example, in the case of a hydrophobic substrate $P > 1$ may be expected for a hydrophobic carrier and $P < 1$ for a hydrophilic matrix. In the reaction with a hydrophilic substrate the opposite situation may obtain. The nature of the distribution (the value of P) has in turn a corresponding effect on the observed Michaelis constant [Eqn. (19)]. As an example we may point to the reaction of immobilised cholinesterase with benzoylcholine (a hydrophobic substrate), for which the observed Michaelis constant decreases approximately by a factor of ten on passing from a hydrophilic to a hydrophobic matrix[130]. It has been shown[131] that, in the adsorption of lipase on a hydrophobic carrier (siliconised glass), the rate of its reaction with tripropionin [glycerol tripropionate (Ed. of Translation)] increases sharply owing to the concentration of the hydrophobic substrate at the surface of the carrier.

3. DISTRIBUTION OF INHIBITORS AND COFACTORS BETWEEN THE CARRIER AND SOLUTION

When the enzyme reacts with an inhibitor or a cofactor, their influence on the reaction rate is known to be determined[114] by the product $K_G[G]_b$, where $[G]_b$ is the concentration of the inhibitor or the cofactor and K_G is the constant for its binding to the enzyme. For immobilised enzymes, we have the analogous product $K'_G[G]'_b$, where $[G]'_b$ is the concentration of the effector on (or in) the carrier and K'_G is the constant for the binding of the immobilised enzyme to the effector. However, in a kinetic experiment it is possible to find only the effective factor $K_{G(obs)}[G]_b$, where $K_{G(obs)} = K'_G P_G$ and $P_G = [G]'_b/[G]_b$ is the partition coefficient. Evidently all that has been said above about the distribution of the substrate between the carrier and the solution applies to the partition coefficient P_G.

As an example, we may mention β-fructofuranosidase immobilised on polyaminostyrene (a hydrophobic carrier), where the observed constant for inhibition by aniline is higher by a factor of three compared with the reaction of the native enzyme[132].

IV. THE CHANGE IN THE TRUE KINETIC PARAMETERS OF ENZYMIC REACTIONS AFTER IMMOBILISATION

The true kinetic parameters should be understood as quantities uncomplicated by the influence of diffusion factors or the distribution of the reactants between the carrier phase and the solution. There are at least two main causes responsible for the change in the true kinetic parameters after immobilisation. Firstly, the immobilised enzyme can have a conformation different from that of the native enzyme. This type of explanation can be frequently encountered in the literature. However, in practice it can be neither confirmed nor disproved experimentally. There are at present no reliable experimental data indicating the existence of effects of this kind. The second cause is a possible change in the medium in which the enzymic reaction takes place after immobilisation. In certain instances the effect of the medium on the enzymic process can be satisfactorily accounted for within the framework of the influence of the dielectric constant on the ionic strength, particularly for reactions between charged species[133,134].

According to Laurent's concept[135], when neutral polymers are introduced into the solution the chemical potentials of the macromolecules in it change owing to their exclusion from part of the volume of the solvent. Theoretical analysis (which was confirmed experimentally) showed that this phenomenon can lead to the decrease of the observed Michaelis constant (or of the observed constant for the inhibition by the protein). Possibly similar phenomena occur also when enzymes are immobilised.

V. STERIC RATE LIMITATION IN REACTIONS OF IMMOBILISED ENZYMES WITH MACROMOLECULAR SUBSTRATES

Immobilised enzymes (particularly in porous carriers) as a rule retain a high catalytic activity with respect to low-molecular-weight substrates but in many cases lose at the same time the capacity to catalyse reactions involving high-molecular-weight compounds. Thus it has been found[136] that trypsin immobilised in silica gel reacts with the ethyl ester of *N*-benzoyl-L-arginine almost like the native enzyme but does not hydrolyse casein at all. Water-insoluble derivatives of polytyrosyltrypsin and polytyrosylpapain[138] cleave casein at rates amounting to only 15 or 30% respectively of the values which might have been expected on the basis of their intrinsic activities with respect to the low-molecular-weight substrate. Similar results were obtained also for KM-cellulose derivatives of ficin[43,122], bromelain[139], trypsin[140], α-chymotrypsin[137,140], and also for polyalcohol, polyanionic, and polycationic derivatives of papain[8] and subtilopeptidase A.[9] In all these cases the decrease of protolytic activity is probably related to steric hindrance of the approach of the protein substrate to the immobilised enzyme[13,14,17,137]. The same steric factors are also responsible for another finding, namely that immobilised trypsin is 92% inhibited by the comparatively low-molecular-weight pancreatic protein trypsin inhibitor and is not inhibited at all by the more bulky soya bean inhibitor[141].

Certain quantitative relations have been traced[142]. Suppose that χ is the specific activity of pronase immobilised on a water-insoluble copolymer of *p*-aminophenylalanine and leucine, referred to the specific activity of the native enzyme. It was found that $\chi^{1/3}$ varies linearly with $M^{1/2}$, where M is the molecular weight of the substrate. The authors[142] drew attention therefore to data[143,144] for the distribution of various proteins between the aqueous solution and Sephadex. It was shown for this system that not all the solvent which has diffused into Sephadex is accessible to proteins and that only a fraction $N < 1$ is

available, the relation between N and M being satisfactorily described by the equation

$$\sqrt[3]{N} = \text{const}_1 - \text{const}_2 \cdot \sqrt{M} \quad . \qquad (47)$$

Therefore the authors[140] suggest that in the immobilised enzyme system which they describe a similar effect may occur, i.e. only a fraction of the volume of the porous particle containing the immobilised enzyme is accessible to protein substrates, its value depending on M in the way indicated by Eqn. (47).

Steric hindrance in reactions with immobilised enzymes may be combined with electrostatic interaction between high-molecular-weight substrates and the charged carrier. Trypsin immobilised on an anionic carrier cleaves only ten peptide bonds in pepsinogen (and also in reduced carboxymethylated pepsinogen), while the native enzyme cleaves fifteen such bonds[145]. The same trypsin derivative cleaves myosin approximately fifty times more slowly than the native enzyme and at different peptide bonds[146,147]. Native deoxyribonuclease and the enzyme immobilised on glass cleave DNA into different oligonucleotides[148]. Similar effects were also noted in other studies[149-151].

Summarising, one may conclude on the basis of the data presented in Sections III–V that the substrate specificity of the immobilised enzyme can depend strongly on the nature of the carrier and hence may differ significantly from the specificity of the native biocatalyst.

---o0o---

Only some kinetic and thermodynamic features of catalysis by immobilised enzymes have been explained in the present review from physicochemical standpoints. Many problems remain outside the present discussion. This is because there is so far no quantitative theory in many fields of study involving catalysis by immobilised enzymes. The most important of these are as follows.

1. The study of the dependence of the catalytic activity and substrate specificity of immobilised enzymes on the nature of the carrier (particularly in relation to the individual stages of enzymic catalysis). It is necessary to set up criteria for the choice of the optimal carrier for the given enzyme system.
2. The explanation of the causes of the stabilisation of enzymes on immobilisation. Only the first steps have been taken in this field[152].
3. The development of methods for the immobilisation of enzymes with cofactors and of polyenzyme systems.
4. More attention should be paid in terms of technology to the possibility of the application of "naturally" immobilised systems, in particular micro-organisms.
5. Problems associated with the choice of the optimal reactor for the given process.

In studies on immobilised enzymes efforts should be concentrated on the solution of the above problems.

Energy Transfer Between Organic Molecules and Transition Metal Ions

V.L.Ermolaev, E.G.Sveshnikova, and T.A.Shakhverdov

Modern ideas on radiationless energy transfer in solutions are described briefly. The fundamental formulae for the rates of this process, involving inductive-resonance and exchange-resonance mechanisms, are presented. Studies on the quenching of the fluorescent and triplet states of organic molecules by transition metal ions are surveyed and it is shown that in most cases radiationless energy transfer takes place.

Energy transfer from a fluorescent state to transition metal ions proceeds via a dipole-dipole mechanism and energy transfer from a triplet state involves an exchange-resonance mechanism. Studies on radiationless energy transfer between transition metal ions and molecular oxygen are also considered. The prospects for using energy transfer to elucidate the pathways and mechanisms of photochemical reactions of coordinated transition metal compounds in solutions are discussed.

The bibliography includes 110 references.

I. MODERN IDEAS ABOUT THE MECHANISMS OF THE RADIATIONLESS TRANSFER OF ELECTRONIC EXCITATION ENERGY

In the last decade electronic energy transfer has found increasing applications in the solution of chemical, physical, and biological problems [1-6]. The method of triplet–triplet energy transfer between organic molecules, which is nowadays used in every other study on the mechanisms of photochemical reactions, constitutes the most striking example [1-4].

It has become evident in the last five years [7-9] that there exists yet another large chemical field where the application of energy transfer is extremely promising, namely the coordination chemistry of transition metal ions and lanthanide ions in solution. Radiationless energy transfer methods yield much information about the kinetics and mechanisms of the formation of complexes and photochemical reactions involving coordination compounds. In the present review attention is concentrated on the possibilities arising from the application of energy transfer in the study of interaction between transition metal ions and organic molecules in solution.

The radiationless transfer of electronic excitation energy in solution has been most thoroughly investigated for the interaction between two organic molecules [10,11]. The study of energy transfer from organic molecules to transition metal ions began only in the last few years. Since a review dealing with this field has not so far been published, the present survey is submitted to the reader.

Energy transfer in solution frequently proceeds via one of two fundamental mechanisms: inductive-resonance or exchange-resonance. In the inductive-resonance mechanism the interaction of an excited energy donor species with an unexcited acceptor species takes place via electromagnetic fields. Only interactions between electric dipole transitions in the donor and acceptor (dipole–dipole energy transfer) have so far been observed experimentally in solution. The theory of this type of energy transfer has been fairly thoroughly developed by Förster [10] and Galanin [11]. The expression defining the rate constant for energy transfer by this mechanism between a donor and an acceptor at a distance R is [12]

$$k_n(dd) = 8.8 \cdot 10^{-25} n^{-4} \tau_{0D}^{-1} q_{0D} R^{-6} \Phi^2 \int I_D^n(\nu)\, \varepsilon_A(\nu)\, \nu^{-4}\, d\nu \ (\text{in } s^{-1}), \quad (1)$$

where n is the refractive index of the solution, τ_{0D} and q_{0D} are the decay time and the luminescence quantum yield of the donor in the absence of the acceptor, Φ^2 is a coefficient which depends on the orientation of the dipole moments of the transitions in the donor and the acceptor ($\Phi = \cos\varphi_{D^*A} - 3\cos\varphi_{D^*}\cos\varphi_{A}$), [12-14] $I_D^n(\nu)$ the quantum intensity distribution in the luminescence spectrum of the donor normalised for a unit surface area, $\epsilon_A(\nu)$ the molar decadic extinction coefficient of the acceptor, and ν the wavenumber (cm^{-1}).

The expression for the critical radius of energy transfer (R_0) corresponding to the distance over which energy transfer and intramolecular deactivation are equally probable [i.e. $k_t(R_0) = \tau_{0D}^{-1}$] is:

$$R_0^6 = 8.8 \cdot 10^{-25} n^{-4} q_{0D} \Phi^2 \int I_D^n(\nu) \varepsilon_A(\nu) \nu^{-4} d\nu \ . \quad (2)$$

In the presence of sufficiently rapid molecular rotation the average value $\bar{\Phi} = \sqrt{2}/3$ in the calculation of R_0 for solid solutions by Eqn. (2) becomes $\bar{\Phi} = 0.845 \times \sqrt{2}/3$. [13,14] The phenomenon of singlet–singlet energy transfer between organic molecules, which has been thoroughly investigated, constitutes a typical example of dipole–dipole interaction [15].

The exchange-resonance mechanism of energy transfer becomes of primary importance when the radiative transitions in the donor and acceptor are forbidden by selection rules. Its occurrence requires an overlap of the electron clouds of the energy donor and acceptor. The formula describing the rate of transfer via the exchange-resonance mechanism is [16]

$$k_t(ex) = \frac{2\pi}{\hbar} Y \cdot e^{-\frac{2R}{L}} \int I_D^n(\nu)\, \varepsilon_A^n(\nu)\, d\nu \ , \quad (3)$$

where Y is a constant which cannot be determined from optical experiments, L is the average effective Bohr radius

characterising the rate of decrease of electron density in the peripherial regions of the interacting molecules (ions) of the energy donors and acceptors, and $I_D^n(\nu)$ and $\epsilon_D^n(\nu)$ are the emission spectrum of the donor and the absorption spectrum of the acceptor normalised for a unit surface area. The constant $k_t(ex)$ is also directly proportional in this case to the overlap integral of the normalised spectra and decreases exponentially with the distance between the donor and the acceptor. The exchange-resonance interactions are responsible for the triplet–triplet energy transfer between organic molecules [17].

Formulae for the laws governing the interaction in energy transfer via dipole–dipole (*dd*) and exchange-resonance (*ex*) mechanisms between individual molecules were given above. In a real experiment we do not observe these individual laws but the situation which arises as a result of the averaging of the interaction of unexcited acceptor molecules which have a random distribution in solution relative to the excited energy donor molecules. A number of studies have been devoted to mathematical models of the averaging, starting with those of Förster [10] and Galanin [11].

The following energy transfer parameters in solution are usually observed experimentally: (1) the decrease of the luminescence quantum yield of the energy donor as a function of acceptor concentration C_A: $q_{oD}/q_D = f(C_A)$; (2) the decrease of the average duration of donor luminescence as a function of acceptor concentration: $\bar{\tau}_{oD}/\bar{\tau}_D = f'(C_A)$; (3) the change in the donor luminescence decay law in the presence of the acceptor; (4) the change in these relations when the viscosity, temperature, solvent, and other parameters are varied; (5) the intensity (yield) of sensitised acceptor luminescence as a function of acceptor concentration: $q_{s.a.l.} = f''(C_A)$; (6) the sensitised acceptor luminescence excitation spectra, and many other parameters.

The concentration $(C_A)_e$ for which $q_{oD}/q_D = e$ can be determined from the variation of the degree of quenching of donor luminescence with acceptor concentration in solid (highly viscous) solutions. Hence the experimental critical energy transfer radius can be found† from the formula

$$R_0^{exp} = \frac{7{,}35}{\sqrt[3]{(C_A)_e}} \quad (R_0^{exp} \text{ in Å and } C_A \text{ on molar scale}). \tag{4}$$

Comparison of R_0^{exp} with R_0^{theor} calculated by Eqn. (2) makes it possible to reach a conclusion about the energy transfer mechanism. Another convenient parameter which depends on the transfer mechanism in solid (highly viscous) solutions is the ratio of the slopes of the curves

$$\rho = \lim_{C_A \to \infty} \left[\frac{d(q_D/q_{oD})}{dC_A} \Big/ \frac{d(\bar{\tau}_D/\bar{\tau}_{oD})}{dC_A} \right], \tag{5}$$

which is two for the dipole–dipole transfer, as shown correctly for the first time by Galanin [14]. Later a similar problem for other types of energy transfer was discussed by Sveshnikov and Shirokov [18] and Inokuti and Hirayama [19].

On passing to liquid solutions, it is necessary to take into account the mutual diffusion of donor and acceptor molecules during the lifetime of the excited state of the former. The presence of diffusion increases the degree of quenching of the donor in the presence of a specific concentration of the acceptor, provided that τ_{oD} remains unchanged on passing from a solid to a liquid solution. In the general case of random diffusion, its influence on energy transfer can be taken into account in terms of the theory developed by Rozman and coworkers [20], but only with the aid of computer calculations. An important new parameter in such calculations is the distance R_{min} of closest approach of the excited energy donor and the acceptor. The lack of accurate data for R_{min} may introduce the largest error into the calculations of the parameters of dipole–dipole energy transfer with allowance for diffusion. On the other hand, the marked dependence of energy transfer on R_{min} can yield valuable information about the immediate environment of the interacting species (the energy donor and acceptor). For steady-state excitation, the influence of the diffusion of the donor and acceptor on the energy transfer can be taken into account also by the method which was proposed by Bagdasar'yan and Muler [21]. Their tables make it possible to compare the experimental and theoretical data.

In very fluid (non-viscous) solvents the limiting case of "total mixing" in Galanin's terminology [11] may be attained. Under these conditions, the quenching of donor luminescence remains exponential at all the concentrations of the quenching agent and the decrease of the donor luminescence yield and τ in the presence of the acceptor is the same in each case ($q_{oD}/q_D = \tau_{oD}/\tau_D$) and is a linear function of the acceptor concentration. Tunitskii and Bagdasar'yan [22] showed that the quenching rate constant in this limiting case of "infinite diffusion coefficients" is related by a simple mathematical expression to the critical energy transfer radius and the distance of closest approach:

$$k_t^{theor} = \frac{4}{3}\pi N' \frac{R_0^6}{R_{min}^3} \cdot \frac{1}{\tau_{oD}} \text{ (litre mole}^{-1}\text{ s}^{-1}\text{)}, \tag{6}$$

where $N' = 10^{-3}N$ and N is the Avogadro number. Eqn. (6) is in fact the same as the formula derived earlier by Galanin and Frank [23] using the classical model for energy transfer from an emitting dipole to a continuous absorbing medium. The condition for the applicability of Eqn. (6) is

$$\sqrt{\gamma'/\sigma} \ll 1, \text{ where } \gamma' = \left(\frac{R_0}{R_{min}}\right)^6; \ \sigma = \frac{D\tau_{oD}}{R_{min}^2},$$

$D = D_D + D_A$ is the sum of the diffusion coefficients of the donor and acceptor.

The exponential quenching of donor luminescence and the linearity of the relation $q_{oD}/q_D = \tau_{oD}/\tau_D = \text{const.} C_A$ are maintained also for $(R_0^2/D\tau_0)^{3/2} \ll 1$; alternatively we have approximately $\bar{r} = \sqrt{2D\tau_{oD}} > R_0$, i.e. when the mean square displacement ($\bar{r}$) during the lifetime of the excited state of the donor exceeds severalfold the critical energy transfer radius R_0. On the other hand, for large values of R_0 the last condition cannot correspond to the case of "total mixing" and Eqn. (6) becomes invalid. A fairly complex mathematical expression for k_t under these conditions was derived by Tunitskii [24]. The $D^{3/4}$ law discovered by Yokota and Tanimoto [25] is a special case when $1 \ll 5(D\tau_{oD}/R_0^2)^3 \ll (D\tau_{oD}/R_{min}^2)^2$. Then k_t^{theor} is also described by the simple expression

$$k_t^{theor} = 2\pi^{3/2} N' D^{3/4} R_0^{3/2} \tau_{oD}^{-1/4}. \tag{7}$$

All the above considerations refer to energy transfer between electrically neutral species. However, in many cases the energy donor and acceptor exist in solution as electrically charged species: anions or cations. Thus the theory of radiationless energy transfer must take into account the electrostatic interactions between the energy donor and acceptor and the deviations caused by them from the random distribution of acceptor species around

† In a dipole–dipole energy transfer the concentration $(C_A)_e$, determined from the change of q_D, corresponds to $(C_A)_2$, i.e. to twofold quenching determined from the decrease of τ_D. [19]

the excited donor. This theory was developed by Bodunov [26-28] in terms of the *dd* approximation for solid and liquid solutions. As a result of the electrostatic interaction between the donor and acceptor, the acceptor concentration as a function of the distance from the donor becomes:

$$C_A(r) = C'_A \cdot \exp(-U(r)/kT),$$

where C'_A is the acceptor concentration far from the excited donor and $U(r)$ the electrostatic interaction energy between ions. It has been assumed [26] that $U(r)$ is determined by shielded Coulombic interaction. In his later studies Bodunov [27,28] found the interaction energy as the exact solution of the Poisson equation for the electrostatic potential generated by D* in an electrically neutral solution.

It was shown in the above studies that the effect of electrostatic interaction on *dd* energy transfer for ions bearing charges of the same sign is significant mainly in liquid solutions alone. In solid solutions the contribution of these interactions does not exceed 10–20% and therefore cannot be detected experimentally. For ions bearing charges of different sign, this influence can be manifested also in the absence of diffusion-controlled processes in the solution. The dependence of energy transfer on the electrostatic interaction between ions is determined by many factors, the main ones of which are the dielectric constant of the solvent ϵ and the distance of closest approach between the ions $R\,\mathrm{min}$ (for ions having different charges). For $C_A > C_D$, electrostatic interactions can lead to a curvature (in consequence of the shielding effect of the acceptor molecules) of the relations between q_{0D}/q_D and C_A. The form of this curvature depends on whether the energy donor and acceptor have the same or different charges. The shielding or suppression of electrostatic interaction can also be achieved by adding extraneous electrolytes to the solution.

The number of studies dealing with the theory of analogous problems in relation to the exchange-resonance type of energy transfer is significantly smaller [19]. It has been shown that in a highly viscous solution the energy donor luminescence quantum yield should decrease much faster than the average decay time of donor luminescence. The experimental discrepancy between the ratios q_{0D}/q_D and $\bar{\tau}_{0D}/\bar{\tau}_D$ makes it possible to estimate the average effective Bohr radius L in Eqn.(3).[19] In liquid solutions the exchange-resonance energy transfer obeys in most cases the same relations as other "fast" chemical reactions involving excited species, for example electron transfer reactions and other collision-controlled processes [29,30].

Thus the determination of the rate constants for energy transfer reactions, the ratio of the decrease of the donor luminescence yield to τ, the law governing the decay of donor luminescence in the presence of an acceptor, and the variation of the energy transfer characteristics with the concentrations of the components, the solvent, and the spectral characteristics of the interacting species makes it possible to establish the mechanism of the energy transfer in each specific case. In many instances it is possible to obtain information from energy transfer data about the existence of short-lived unstable complexes, which cannot be detected by other methods.

Below we shall attempt to arrange systematically experimental data which throw light on the mechanism of the interaction in the quenching by transition metal ions of the excited singlet and triplet states of organic molecules and of singlet oxygen. Data concerning the influence of the structure of these molecules and complexes and also of the solvent on the quenching rate constants will be considered. In addition, we shall discuss the applications of energy transfer in the study of the mechanisms of photochemical reactions of transition metal complexes of different types.

II. THE MECHANISM OF THE QUENCHING OF THE FLUORESCENCE OF ORGANIC COMPOUNDS BY TRANSITION METAL IONS

The quenching of the fluorescence of organic compounds by transition metal ions in solution has been known for a long time [31,32], but its mechanism still remains not altogether clear. Weiss [33] rejected the idea that such quenching is related to the intersystem crossing catalysed by the paramagnetism of the quenching agents on the grounds that many paramagnetic ions (for example Mn^{2+}) do not quench the fluorescence of dyes. Linschitz and Pekkarinen [34] also observed only very weak quenching effects due to Mn^{2+} and Zn^{2+} ions. To explain the quenching of the fluorescence of organic molecules by transition metal ions, Terenin [35] and later Linschitz and Pekkarinen [34] proposed a reversible charge transfer mechanism. The latter workers [34] noted a parallelism between the quenching efficiencies for fluorescence and for the triplet state [34,36-38]. However, sufficiently convincing experimental results establishing a relation between the degree of quenching and the redox potentials of the cations were not quoted.

Another concept was put forward by Galanin and Lëvshin [39]. They attributed the pronounced quenching of the fluorescence of quinine sulphate and 3-aminophthalimide by Cr^{3+} in glycerol to inductive-resonance energy transfer from these organic molecules to Cr^{3+}. There is at present a growing interest in the mechanism of the processes involved in the quenching of the fluorescence of organic compounds by transition metal ions. This is related mainly to the recent observation of the sensitising action of organic molecules on photochemical reactions of transition metal complexes. Naphthalene sensitises the photochemical reduction of $[Co(NH_3)_6]^{3+}$ to Co^{2+}.[40] The Stern–Volmer fluorescence quenching (200 litre mole^{-1}) and sensitisation (170 litre mole^{-1}) constants proved to be closely similar in this instance. The quinolinium ion also sensitises this reaction [41] via the excited triplet state (k_T = 36.6 litre mole^{-1}). In the sensitised photochemical reduction of $[Co(Phen)_3]^{3+}$ the fluorescence of free *o*-phenanthroline (Phen) is quenched by the complex [42] with k_T = 600 litre mole^{-1}. The sensitised photochemical aquation of the complex $[Cr(NH_3)_5X]^{2+}$, where $X^- = Cl^-$ or NCS^-, i.e. $[Cr(NH_3)_5X]^{2+} \rightarrow [Cr(NH_3)_4(H_2O)X]^{2+} + NH_3$, has been investigated in solutions containing acridinium ions [43] and riboflavine [44]. The simultaneous quenching of the fluorescence of the latter was observed. The fluorescence of naphthalene is quenched when it sensitises the photochemical reaction of $[Cr(CN)_6]^{3-}$.[45]

Varnes et al.[46] studied the effect of 13 metal ions on the fluorescence of riboflavine. The decrease of the fluorescence yield on quenching is consistent with the decrease of its τ and obeys a linear relation. With increase of temperature, k_T rises, while an increase in viscosity causes its diminution. However, the results obtained do not yield clear-cut conclusions concerning the mechanism of the quenching of fluorescence.

We attempted to revise the above data [40,43,44,46] as well as the results of earlier studies by Weber [47,48] from the standpoint of energy transfer via the dipole (*dd*) mechanism. Table 1 presents the experimental k_T from the

above studies, and our calculated overlap integrals of the spectra (J_O), the critical energy transfer radii (R_0^{theor}), and the theoretical energy transfer rate constants (k_t^{theor}). The k_t^{theor} were calculated by Eqn. (6) assuming infinite diffusion coefficients and $R_{min} = 8$ Å.

Table 1. The quenching of the fluorescence of organic compounds by transition metal ions.

*τ_{fl}^0 and q_{fl}^0 were estimated by the present authors.
**The values of k_q for this compound were estimated by the present authors from the literature data [47,48] on the assumption that the Stern–Volmer relation between q_0/q and C_A holds and that $\tau_{fl}^0 \simeq 20.1$ ns.

We established that the error for $\sigma/\gamma' > 1.5$ arising from the use of this formula does not exceed 10% of the overall error. For systems comprising riboflavine and $[Cr(NH_3)_5X]^{2+}$ (with $X^- = NCS^-$ or Cl^-), $[Cr(H_2O)_6]^{3+}$, and $[V(H_2O)_6]^{3+}$, where $\sigma/\gamma' < 1.5$, calculations of k_t^{theor} were made on a computer by the method of Rozman and coworkers [49] using $D \simeq 1 \times 10^{-5}$ cm^2 s^{-1}.

Examination of the data in Table 1 leads to the following conclusions: (1) in most cases there is a satisfactory correlation between k_q and J_O (except for the Fe^{2+} ion); (2) the experimental quenching rate constants (k_q) are appreciably greater (by a factor of 2–8) than the calculated rate constants for energy transfer via the *dd* mechanism (k_t^{theor}).

In many instances the differences between the above quantities are small and can be entirely due to the inaccuracy of the parameter R_{min}. If the energy donor is charged, one must also consider the influence of the electrostatic interaction of the ions on the fluorescence quenching process.

Thus the parallel variation of k_q and overlap integrals of the spectra and the agreement within an order of magnitude between k_q^{exp} and k_t^{theor}, estimated from the formulae for *dd* energy transfer, demonstrate convincingly that the radiationless energy transfer from excited singlet states of organic compounds to transition metal ions is one of the most likely processes responsible for quenching when the fluorescence spectra overlap with the absorption spectra of transition metal ions.

The marked discrepancy between k_q^{exp} and k_t^{theor} for Fe^{2+} is probably due to the fact that the reversible electron transfer to the excited molecule of the organic compound with formation of Fe^{3+} via Terenin's mechanism [35] is dominant under these conditions.

III. THE MECHANISM OF ENERGY TRANSFER FROM TRIPLET STATES OF ORGANIC MOLECULES TO TRANSITION METAL IONS

1. SOLID SOLUTIONS

The mechanism of the quenching of the phosphorescence of organic compounds by transition metal ions has also been inadequately elucidated. In the first studies by Pankeeva [50,51], carried out in solid solutions of ethanol and acetic and formic acid at 90 K, it was postulated that the transition metal ions exhibit a paramagnetic effect on the phosphorescence, i.e. they initiate a radiationless intercombination transition from the triplet to the ground state. She studied the quenching of the phosphorescence of fluorescein and trypaflavine by Ni^{2+}, Mn^{2+}, and Fe^{3+} ions and found that the relations between q_D/q_{oD} and τ_D/τ_{oD} on the one hand and the transition metal concentration on the other differ markedly and the two ratios vary exponentially with the concentration of quenching agents. Smaller et al. [52] studied by ESR the quenching of the phosphorescence of perdeuteronaphthalene (naphthalene-d_8) in a 9:1 mixture of methanol and water at 77 K by Cu^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, Fe^{3+}, and Gd^{3+} ions. They discovered a non-rigorous proportionality between the rate of such quenching and the magnetic moments (in Bohr magnetons) of the transition metal ions, which they regarded as supporting a mechanism of paramagnetic influence of the quenching agents (for a criticism of this study, see below).

Hill and Lin [53,54] used Hoijtink's idea [55,56] about the involvement of exchange interactions in the postulated quenching of the triplet state of organic molecules catalysed by paramagnetic transition metal ions. They compared the experimental parameters of the quenching of the naphthalene-d_8 phosphorescence in ethanol by Co^{2+}, Cr^{3+}, Cu^{2+}, and Ni^{2+} ions (at 77 K) with the theoretical values calculated on the basis of the above model. They were the first to note the non-exponential quenching of the phosphorescence in the presence of paramagnetic substances in addition to the discrepancy between the variations of q_D/q_{oD} and τ_D/τ_{oD} with the concentration of such substances.

Best agreement between theory and experiment was achieved for the parameters γ and C_A^0 quoted in Table 2. The diamagnetic Zn^{2+} ion does not quench the phosphorescence up to $C = 0.25$ M. The experimental data [53,54] do not confirm the exchange mechanism for the interaction of naphthalene with transition metal ions. Thus there are considerable variations in C_A^0 in the series of these ions; it is unlikely that the overlapping of electron clouds of

different transition metal ions and naphthalene-d_8 varies quite so much. The values of R_0^{exp} for the above systems are large, i.e. they exceed considerably the sum of the radii of both components. Table 2 also presents the ratios ρ of the limiting slopes of the degree of quenching–concentration curves, which were calculated by Eqn.(5) from determinations [53,54] of the changes in q_{0D} and τ_{0D}. The Table shows that the ratios are in the range 0.50 to 0.57, i.e. are a characteristic of the dipole–dipole energy transfer.

Table 2. The quenching of the phosphorescence of organic compounds by aquated transition metal ions in solution at 77 K.

Donor	Transition metal ions	R_0^{exp*}, A	ρ	C_A^0, M	ν
Naphthalene-d_8 in 95% ethanol (Refs.53,54)	Co^{2+}	12.4	0.50	0.210	4.4
	Cr^{3+}	24.3	~0.55	0.028	10.0
	Cu^{2+}	17.8	~0.50	0.072	12.0
	Ni^{2+}	11.0	0.57	0.298	7.0
Naphthalene-d_8 in 9:1 methanol–water mixture (Ref.57)	Co^{2+}	14.3**	0.52		
	Ni^{2+}	13.4	0.24		
	Mn^{2+}	14.6	0.13		
Triphenylene in 9:1 methanol–water mixture (Ref.57)	Co^{2+}	15.5**	0.50		
	Ni^{2+}	14.4	0.12		
	Mn^{2+}	14.9	0.10		

*The values of R_0^{exp} were obtained [53,54] on the assumption of an exchange interaction and from the condition of best agreement between the experimental and theoretical values of C_A^0. In another study [57] the R_0^{exp} were obtained from the exponential relations between q_D/q_{0D} and C_A within the framework of the model postulating a limited sphere of quenching action.

**On the assumption of dipole–dipole interaction.

The most clear-cut data were obtained in a recent study by Breuninger and Weller [57], who investigated the quenching of the phosphorescence of triphenylene and naphthalene-d_8 by Co^{2+}, Ni^{2+}, and Mn^{2+} ions. The authors treat the observed quenching of the phosphorescence as a radiationless energy transfer from the triplet states of the molecules with excitation of the transition metal ions. The parameters ρ discussed above [see Eqn.(5)] were calculated in the same study [57] (Table 2). $\rho = 0.50-0.52$ for Co^{2+}, which supports the dipole–dipole mechanism of the interaction. For the remaining ions, the parameter ρ is much smaller (about 0.1–0.2) and much closer to the values for exchange interaction [19]. In the naphthalene-d_8–Ni^{2+} system ($\rho = 0.24$) both types of interaction are postulated. Table 2 also lists the values of R_0^{exp}, which exceed somewhat the R_0 for the triplet–triplet energy transfer [17]. The latter finding is incomprehensible. The reason for the small difference between the R_0^{exp} for the dipole–dipole (transfer to Co^{2+}) and exchange (Mn^{2+}, Ni^{2+}) transfer mechanisms deduced from the parameters ρ is also obscure.

Breuninger and Weller [57] showed that the reduction of the intensity of the ESR signal of the naphthalene-d_8 triplet state by paramagnetic transition metal ions, observed by Smaller et al. [26], is due to the broadening of the ESR lines in the presence of the paramagnetic ions, which increases with the magnetic moment of the ion.

2. LIQUID SOLUTIONS

The quenching of the fluorescence of organic molecules in the triplet state by transition metal ions in liquid solutions was observed in 1958 simultaneously by Porter and Wright [37,38] and by Linschitz and Sarkaninen [36]. In the first investigations [36–38] it was suggested that the quenching is due to the radiationless transition of organic molecules to the ground state catalysed by paramagnetic transition metal ions in accordance with the scheme

$$^3D + {}^nM_j^{k+} \rightarrow {}^1D + {}^nM_j^{k+}, \quad n \geqslant 2 \tag{8}$$

or due to reversible electron transfer reactions:

$$^3D + {}^nM_j^{k+} \rightarrow {}^2D^+ + {}^mM_i^{(k-1)+}, \tag{9a}$$

$$^3D + {}^nM_j^{k+} \rightarrow {}^2D^- + {}^mM_i^{(k+1)+}, \tag{9b}$$

where ^3D is the organic molecule in the triplet state, $^2D^+$ and $^2D^-$ are the radical-cation and radical-anion derived from this molecule, and $^nM_j^{k+}$ is the transition metal ion.

Below we shall attempt to show that the most effective process involved in the quenching of triplet molecules of organic compounds by transition metal ions in liquid and solid solutions is radiationless energy transfer. Most of the studies published on this problem in recent years tend to support this view [58–62]. It is noteworthy that the quenching of the triplet state by transition metal ions in solutions is more closely related to chemical interactions than the quenching of fluorescence. The exchange-resonance mechanism of the process responsible for the "physical" quenching in this case requires the overlapping of the electron clouds of the interacting molecules, which is necessary also for the formation of chemical bonds. However, there is no doubt that the existing relation between complex formation and the quenching of triplet molecules by a transition metal ion has so far been traced less distinctly than in the quenching by lanthanide ions [7–9]. Possibly this is related to the lack of systematic studies on this problem.

a. Direct Evidence for Energy Transfer

The sensitised luminescence of transition metal ions,

$$^3D^* + {}^nM_j^{k+} \xrightarrow{k_t} {}^1D + ({}^mM_i^{k+})^*,$$

$$({}^mM_i^{k+})^* \overset{k_R}{\rightsquigarrow} ({}^lM_k^{k+})^* \xrightarrow{k_{em}} {}^nM_j^{k+} + h\nu_{s.l.}, \tag{10}$$

where $^nM_j^{k+}$, $(^mM_i^{k+})^*$, and $(^lM_k^{k+})^*$ is the complex of the transition metal ion in the non-excited, excited Franck–Condon, and excited resonance states from which emission takes place, constitutes direct evidence for radiationless energy transfer between the triplet molecule and transition metal ions. The sensitised luminescence of transition metal ions was observed experimentally for the first time by Binet et al. [58] They observed the simultaneous quenching of the phosphorescence of benzil‡ and the appearance of the sensitised phosphorescence of the complexes $[Cr(NCS)_6]^{3-}$ and $[Cr(CN)_6]^{3-}$ in a deoxygenated mixture of methanol and water at 160 K (Table 3). Anthracene ($^3\Gamma = 14\,950$ cm^{-1}) also sensitises the phosphorescence of chromium(III) complexes at 160 K in the above mixture [58] and at room temperature in dimethylformamide

‡ The fluorescence of benzil is not appreciably quenched under the experimental conditions by complex chromium(III) ions.

(DMF) [59]§. On freezing the solutions, the quenching and intensity of the sensitised phosphorescence were sharply reduced. The rate constants for energy transfer (k_t) estimated from the decrease of the benzil phosphorescence yield, the decrease of its phosphorescence decay time, and the increase in the intensity of the sensitised phosphorescence of chromium(III) complexes with increase of their concentration are listed in Table 3. Their scatter is small, except for $[Cr(NCS)_6]^{3-}$, where the differences are appreciable. It has been suggested [58] that the maximum value of k_t is close to the rate constant for the diffusion of the solvent under the experimental conditions, although viscosity measurements were not made.

Table 3. The rate constants for energy transfer from triplet benzil molecules ($^3\Gamma$ = 18 800 cm^{-1}, τ_0 = 1.5 ms) to chromium(III) complexes in an 88 : 12 methanol–water mixture at 160°C in the absence of molecular oxygen [58].

Acceptor	$10^{-6}k_t$, litre mole^{-1} s^{-1}	^2E_g, cm^{-1}	$^4T_{2g}$, cm^{-1}
$[Cr(NCS)_6]^{3-}$	5÷18	12 900	17 800
$[Cr(acac)_3]$	10	12 800	18 400
$[Cr(urea)_6]^{3+}$	2.8	14 240	16 300
$[Cr(CN)_6]^{3-}$	1.2÷4.0	12 500	26 700
$[Cr(en)_3]^{3+}$	1.3±0.3	15 000	21 900

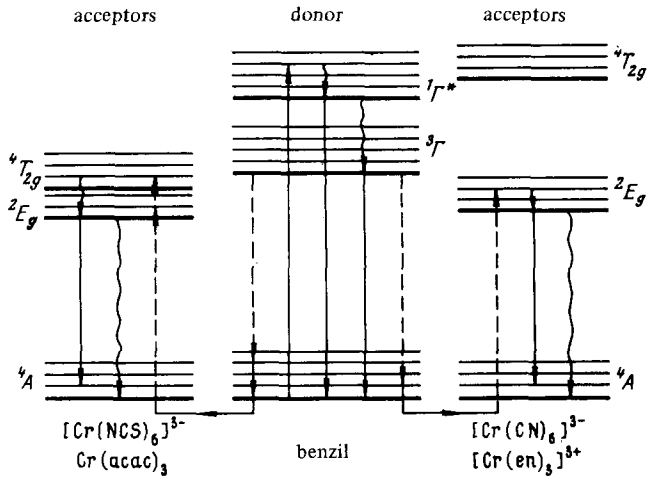

Figure 1. Schematic illustration of the electronic levels in energy transfer from organic molecules (benzil) in the triplet state ($^3\Gamma$) to chromium(III) ions.

If the complex with urea is excluded, then the following observation may be made for the remaining chromium(III) complexes listed in Table 3. The constant k_t decreases abruptly severalfold on passing from complexes where energy transfer to the ^2E_g and $^4T_{2g}$ levels is possible to complexes where energy may be transferred from the benzil triplet level only to the ^2E_g level of Cr^{3+} (Fig. 1).

§ Recently Balzani et al. [60] observed the phosphorescence of $[Cr(en)_3]^{3+}$ sensitised by diacetyl in water at 288 K.

Later Ohno and Kato [61] observed the phosphorescence of chromium(III) complexes sensitised by benzil and erythrosine. They noted that chromium(III) complexes quench effectively the phosphorescence of erythrosine but not its fluorescence. The admission of oxygen does not affect the phosphorescence of Cr^{3+} on direct excitation but fully suppresses its sensitised luminescence. The rate constants for energy transfer from erythrosine to chromium(III) complexes are listed in Table 4. Ohno and Kato [61] attribute the differences between the constants k_t to the aromatic or nonaromatic nature of the ligands in the complexes. However, we believe that the data in Table 4 clearly demonstrate a dependence of k_t on the charge of the complex ion: the higher the negative charge of the complex the smaller the value of k_t¶. This can be understood, since the energy donor (erythrosine) is in all probability present in solution as the dianion.

Table 4. The rate constants for the quenching of the triplet state of erythrosine ($^3\Gamma \simeq$ 14 800 cm^{-1}) in 9 : 1 ethanol–water mixture at 201 K in the absence of molecular oxygen [61].

Ohno and Kato's claim [61] that the constant k_t for energy transfer from erythrosine to [Cr(oxine)$_3$] is equal to the diffusion constant is not altogether correct. The transfer from the excited triplet state of the ligand is indeed endothermic in this case (Table 4)†, but the rate of the triplet–triplet energy transfer is then usually lower than the diffusion rate [63].

A second fairly direct piece of evidence showing that the transfer of electronic excitation energy is in fact usually responsible for the quenching of the triplet state of organic molecules by transition metal ions is the sharp decrease of the quenching rate constant (k_t) when the lower excited resonance level of the transition metal ion in the complex lies above the triplet level, i.e. the energy transfer becomes endothermic. We were able to select from the literature a fairly large number of examples illustrating this postulate. They are presented in Table 5. These data constitute yet another significant confirmation that the quenching of the triplet molecules of organic compounds is caused by radiationless energy transfer.

¶ The chromium(III) and cobalt(III) complexes remain unchanged in solution for a long time, since the rate of exchange of their ligands with the solvent is very low: for example, the rate of thermal exchange between chromium(III) complexes and water is of the order of 10^{-6} s^{-1}. [64]

† The data for the $^3\Gamma$ level of erythrosine listed in Table 1 of Ohno and Kato's paper [61] are erroneous, since they are inconsistent with the Fig. 4 of the same communication and other literature data.

Although the mechanism of the induced catalysis of intersystem crossing in accordance with Eqn.(8), proposed in early investigations [37,38], is in fact possible in the above instances, its probability is lower. Table 5 shows that the rate constants for this process have an upper limit $\leq(0.1-1)\times 10^6$ litre mole^{-1} s^{-1}, which is 1–3 orders of magnitude lower than the rate constants for the energy transfer.

Table 5. The effect of the relative energies of the triplet states of organic molecules and the excited resonance levels of transition metal ions on the rate constants for the quenching of triplet states in solution at 293 K.

***THMF = tetrahydro-2-methylfuran.

An analogy can be drawn with complexes of lanthanide ions. The triplet state of the tris-β-dibenzoylmethanate ($^3\Gamma_{lig} \simeq 20500$ cm^{-1}) of La^{3+} (a diamagnetic ion) has a quenching time $\tau_0 = 0.5$ s for the phosphorescence in an organic glass at 77 K. When La^{3+} is replaced by the paramagnetic Gd^{3+} ion with a high resonance level ($^6P_{7/2} = 32\,000$ cm^{-1}), τ_0 for the ligand decreases to 2×10^{-3} s. [67] On the other hand, τ_0 for the triplet level of the ligand decreases sharply on passing to lanthanide ion complexes with a resonance level below the $^3\Gamma_{lig}$ level of, for example, Eu^{3+} ($^5D_0 \simeq 17\,200$ cm^{-1}) and Sm^{3+} ($^4G_{5/2} \simeq 17\,800$ cm^{-1}). The lifetime of the triplet state of the organic ligand in complexes of this type is shown by the rate of energy transfer to lanthanide ions, to be about 10^{-9} s or less [68,69].

Direct experiments permitting an unambiguous choice between the hypotheses concerning the energy transfer and the catalysis of intercombination transitions as the causes of the quenching of triplet molecules by transition metal ions were described by Allsopp and Wilkinson [70], who showed that the planar diamagnetic nickel(II) and palladium(II) complexes with Schiff bases effectively quench the triplet states of molecules whose triplet level lies above the excited states of transition metal ions in the ligand field (about 2500 cm^{-1} for Ni^{2+} and 16 500 cm^{-1} for Pd^{2+}; see Table 7) but are below the triplet level of the ligand ($^3\Gamma_{lig} \simeq 21\,000$ cm^{-1}). Since the above complexes have a singlet ground state, the possibility of the mechanism involving the spin catalysis of intercombination transitions in accordance with Eqn.(8) is completely ruled out; the only remaining possibility is that these complexes quench via the mechanism involving the heavy atom effect.

b. Effect of the Structure of the Organic Molecule and the Transition Metal Complex and of the Properties of the Solvent on the Rate of Energy Transfer

After the discovery of the method of flash photolysis of Norrish and Porter [71,72], numerous studies were published in which the rate constants for the quenching of triplet molecules by transition metal ions were determined by this procedure. As shown above, in most cases the quenching is due to energy transfer.

Table 6 presents the constants k_t for the transfer of triplet energy from aromatic hydrocarbons at room temperature. It shows that in most cases k_t is around 10^7-10^8 litre mole^{-1} s^{-1}, which exceeds by 1–3 orders of magnitude the analogous constant for the transfer of triplet energy from aromatic hydrocarbons to lanthanide ions [1,7,8,34,38]. The constant k_t increases by a further order of magnitude (to 10^9 litre mole^{-1} s^{-1}) in the quenching of triplet molecules by complexes of transition metal ions with aromatic ligands, as can be seen from the data in Table 7. The quenching is not associated with energy transfer to the triplet level of the ligand, because transfer processes of the latter type are strongly endothermic under the experimental conditions. Table 7 shows that the energy transfer to complexes with aromatic ligands is independent of the structure of the energy donor molecules, in particular of the presence in the latter of active carbonyl and other groups. This shows that the exchange-resonance interactions between the π system of the triplet molecule and the d shell of the transition metal ion takes place effectively via the π system of the coupled ligand. Steric hindrance to the mutual approach of the organic molecule and the π-electron system of the chelate, arising on passing from acetylacetonates to dipivalomethanates, leads to a decrease of k_t by a factor of 2–4 (Table 7).

Table 8. The rate constants for the quenching of triplet naphthalene molecules by transition metal ions in solvents of different viscosities at 293 K in the absence of molecular oxygen [38].

Quenching agent-acceptor	Solvent I and k_d	$10^{-7}k_t^I$, litre mole^{-1} s^{-1}	Solvent I and k_d	$10^{-7}k_t^{II}$, litre mole^{-1} s^{-1}

$[Mn(H_2O)_6]^{2+}$		2.8		1.6
$[Cu(H_2O)_6]^{2+}$		7.5		7.3

The influence of the ligand on the quenching activity of copper(II) chloride has also been studied [77]. The authors observed that ethylenediamine used as a ligand decreases while o-phenanthroline increases the rate of quenching of the triplet state of anthracene.

The effect of complex formation on the quenching of triplet anthracene by Co^{2+}, Ni^{2+}, and Cu^{2+} ions in ethylene glycol at 298 K was studied by Yatsimirskii and Dagaev [79–81]. It was shown that the formation of complexes by the above ions with ethylenediamine, ethylenediaminetetra-acetate, diethylenetriaminepenta-acetate, and cyclohexanediaminetetra-acetate increases the quenching rate constant by a factor of 2–4.

It is at present impossible to reach definite conclusions about the effect of the structure of the complexes and the organic molecules on the rate of energy transfer, since none of the scientific schools have carried out systematic studies on this problem.

The problem of the effect of the solvent on the efficiency of energy transfer from triplet molecules to transition metal ions has also been little investigated. Nevertheless we believe that some data on this problem can be usefully mentioned. Since the rate constants k_t for energy transfer to transition metal complexes with non-aromatic ligands are lower by 1–3 orders of magnitude than the diffusion rate constants k_d, an increase in the viscosity of the solvent should not have an appreciable effect on k_t until k_d becomes smaller than k_t in solvents with a low viscosity. The data of Porter and Wright [38] quoted in Table 8 constitute an experimental confirmation of this conclusion. Evidently the change in viscosity by a factor of 20 on passing from water to ethylene glycol hardly affects k_t. One should bear in mind that an increase in the viscosity of the solvent usually leads to a simultaneous increase of the lifetime of the triplet molecules and is accompanied by an increase in the quantum yield of the energy transfer reaction‡ φ_t at the same energy acceptor concentration. Hence it is possible to increase φ_t by increasing the viscosity of the solvent—by changing it for a related solvent or by reducing the temperature. Admittedly the latter is possible only when the transfer process lacks an appreciable activation energy.

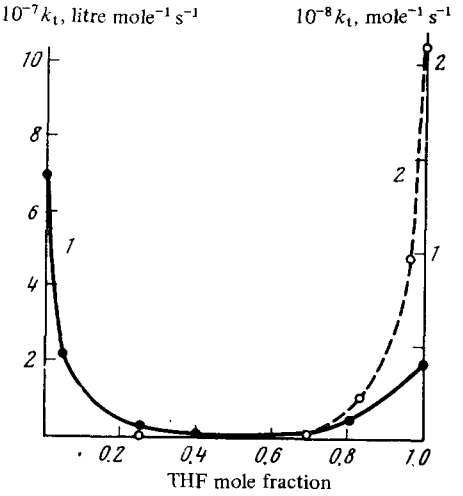

Figure 2. Dependence of the rate constant for the quenching of the triplet state (k_t) of naphthalene by cobalt(II) chloride (curve *1*) and of anthracene by cobalt(II) perchlorate (curve *2*) on the composition of the solvent (water–tetrahydrofuran) [34,73].

Although the rate of energy transfer from triplet molecules to transition metal ions was measured in different solvents (see Tables 3–8), it is at present difficult to

‡ We interpret the quantum yield of the energy reaction φ_t as the ratio of the number of transfer steps to the number of donor triplet molecules formed during the same period under quasisteady-state conditions.

reach any definite conclusions about the role of the chemical nature of the solvent in this process. However, one should note an early study by Linschitz and Pekkarinen [34] in which it was shown that k_t for energy transfer from anthracene and tetraphenylporphin triplets to transition metal ions in tetrahydrofuran and pyridine decreases by 1–3 orders of magnitude after the addition of water to the solvent (Fig. 2). On the other hand, Rogov et al. [73] recently investigated the influence of the addition of alcohols or ethers (Fig. 2) on the rate constant for energy transfer from naphthalene triplet to cobalt(II) complexes. Fig. 2 shows that k_t falls in this case too. There is at present no unambiguous explanation of this interesting phenomenon. Possibly effects associated with the ordering of the solvent molecules in the second coordination sphere of the transition metal ion play a significant role here.

IV. ENERGY TRANSFER BETWEEN TRANSITION METAL COMPLEXES AND MOLECULAR OXYGEN

Studies by Farmilo and Wilkinson [82] and Carlson et al. [83] have now firmly established that transition metal complexes are effective quenching agents for singlet molecular oxygen in solution. It has been shown that the quenching constants are independent of the method of preparation of singlet oxygen. The value of τ for singlet molecular oxygen was estimated by analysing the kinetics of the disappearance of the absorption of 1,3-diphenylazobenzofuran or rubrene in its presence.

Table 9. The constants for the quenching of singlet oxygen by transition metal ions in various solvents at 298 K according to the literature [82,83].

Quenching agent	Solvent	$10^{-8}k_t$, litre mole^{-1} s^{-1}
$Ni^{II}(SB)_2$	Benzene	30
$Pd^{II}(SB)_2$	Benzene	0.6
Di-(2-hydroxy-5-methoxyphenyl-N-n-butylaldimine)-nickel(II)	Iso-octane	35
	Hexadecane	2.0
Nickel(II) di-n-butyldithiocarbamate	Iso-octane	7.0
	Hexadecane	9.0
Nickel(II) n-butylamine[2,2′-thiodi-(4-t-octyl)-phenoxide]	Iso-octane	1.8–2.7
	Hexadecane	0.8
Nickel(II) acetylacetonate	Iso-octane	1.3–2.0
Nickel(II) di(*O*-butyl-3,5-di-t-butyl-4-hydroxybenzyl-phosphonate)	2-Butoxyethanol	0.34
$NiCl_2.6H_2O$	"	3.1
$CoCt_2.6H_2O$	"	0.48
$MnCl_2.4H_2O$	"	<0.01

Table 9 presents the constants for the quenching of singlet oxygen by complexes of different transition metals. The most effective quenching agents are nickel(II) complexes, whose resonance state lies below or possible in some cases at the same energy as O_2 ($^1\Delta g$). The efficiency of quenching by many nickel(II) complexes depends significantly on the ligand. The highest constants are observed for nickel(II) complexes with Schiff bases (SB). The complex $[Mn(H_2O)_6]^{2+}$, the excited resonance state of which is higher than the $^1\Delta g$ state of oxygen, does not quench singlet oxygen. Presumably the main process involved in the quenching of singlet oxygen by transition metal ions is, as for triplet organic molecules, radiationless transfer of electronic excitation energy, which proceeds via an exchange-resonance mechanism, bearing in mind that the $^1\Delta g \rightarrow {}^3\Sigma\bar{g}$ electronic transition in oxygen is forbidden.

Table 10. The rate constants for the quenching of the luminescence of chromium(III) complexes by oxygen extrapolated to 298 K (in the 2 : 1 : 1 mixture of methanol, water, and ethylene glycol as solvent) [84].

Energy donor	$10^{-9}k_t$, litre mole^{-1} s^{-1}	Energy donor	$10^{-9}k_t$, litre mole^{-1} s^{-1}
$[Cr(acac)_3]$	100**	$[Cr(CN)_6]^{3-}$	0.2
$[Cr(NCS)_6]^{3-}$	6	$[Cr(en)_3]^{3+}$	<0.01
{*trans*-$Cr(NH_3)_2(NSC)_4]^{1-}$	2	$[Cr(tmen)_3]^{3+}$ *	<0.01

*tmen = trimethylethylenediamine.

**The values of k_t for $Cr(acac)_3$ at 298 K is unreliable, since it was found by extrapolating to 298 K the values of k_t measured below 180 K.

The quenching of the phosphorescence of excited chromium(II) complexes by molecular oxygen was observed and studied by Pfeil [84]. He assumed that the quenching mechanism involves exchange-resonance energy transfer and explains the marked dependence of the rate constant for the quenching of the phosphorescence of the complexes by oxygen on the nature of the ligand in the complex (Table 10) by the different capacities of the ligands to conduct π electrons and hence by the different overlapping of the electron clouds of the energy donor and acceptor. However, comparison of the data in Table 10 with those in Table 6 makes it clear that σ-binding ligands such as NH_3 or ethylenediamine (en) do not prevent energy transfer from organic molecules to transition metal complexes. We believe that, in discussing the involvement of the ligand in energy transfer between complexes and O_2, one must take into account the possibility of the formation of unstable transition metal complexes with O_2 and the effect of this process on the energy transfer. Transition metals are known to exhibit a tendency to form complexes with O_2. [85]

V. APPLICATIONS OF RADIATIONLESS ENERGY TRANSFER IN THE STUDY OF PHOTOCHEMICAL REACTIONS OF COORDINATION COMPOUNDS OF TRANSITION METAL IONS

The photochemistry of the coordination compounds of transition metal ions has developed very vigorously in recent years. Starting with the pioneer study by Volger and Adamson [86] (1968), the method of radiationless energy transfer from organic molecules began to be used in the investigation of the mechanisms of photochemical reactions. The largest number of studies have been devoted to chromium(III) and cobalt(III) complexes, since the mechanisms of the direct photochemical reactions of such complexes have been investigated in greatest detail. Investigations dealing with certain other ions have also begun to appear in recent years. Brief reviews of the mechanisms of photosensitised reactions are contained in an excellent monograph on the photochemistry of coordination compounds by Balzani and Carassiti [87] and also in other surveys [88–91]. However, they are already obsolete owing to the vigorous development of this field.

1. THE ROLE OF ENERGY TRANSFER IN DETERMINING THE REACTIVITIES OF THE LOWEST EXCITED STATES OF TRANSITION METAL COMPLEXES

The spectroscopy of transition metal complexes has shown that, depending on the strength of the ligand field, the long-wavelength absorption band of the complexes may correspond both to a transition allowed by the spin selection rules and to a forbidden intercombination transition. In the latter case direct selective population of the lowest excited level of the complex by light is difficult, since it is impossible to separate the weak intercombination absorption from the stronger allowed absorption of the adjacent band. In many instances the application of radiationless energy transfer helps in overcoming these difficulties.

It can now be regarded as firmly established that organic molecules are capable of sensitising photochemical reactions of transition metal complexes by energy transfer both from excited singlet [43,44,46] and triplet [92] states.

The processes (for example photochemical aquation processes) occurring in a binary solution {organic sensitiser—energy donor (D) and the transition metal complex $[M^{k+}L_l]$} can be represented schematically as follows (it is assumed that under the experimental conditions the intrinsic absorption of the complex can be neglected compared with the absorption of the sensitiser):

Scheme I

$$^1D + h\nu \rightarrow {}^1D^*, \quad (I\text{-}1)$$

$$^1D^* + {}^n[M^{k+}L_l] \rightarrow {}^1D + {}^n[M^{k+}L_l]^*, \quad k_{ts}\ (I\text{-}2)$$

$${}^n[M^{k+}L_l]^* + H_2O \rightarrow [M^{k+}L_{l-1}H_2O] + L, \quad k_R(I\text{-}3)$$

$$^1D^* \rightarrow {}^1D + h\nu_{fl}, \quad k_{em}(I\text{-}4)$$

$$^1D^* \rightsquigarrow {}^3D, \quad k_{i.c.}(I\text{-}5)$$

$$^3D + {}^n[M^{k+}L_l] \rightarrow {}^1D + {}^m[M^{k+}L_l]^*, \quad k^I_{tT}(I\text{-}6)$$

$${}^m[M^{k+}L_l]^* + H_2O \rightarrow [M^{k+}L_{l-1}H_2O] + L, \quad k^I_R(I\text{-}7)$$

$$^3D + {}^n[M^{k+}L_l] \rightarrow {}^1D + {}^n[M^{k+}L_l]^*, \quad k^{II}_{tT}(I\text{-}8)$$

$${}^n[M^{k+}L_l]^* + H_2O \rightarrow {}^n[M^{k+}L_{l-1}H_2O] + L, \quad k^{II}_R(I\text{-}9)$$

$$^3D \rightsquigarrow {}^1D, \quad k_D\ (I\text{-}10)$$

where ^1D and ^3D are the singlet and triplet states of the sensitiser, M^{k+} is the transition metal ion, L is the ligand, n and m are the multiplicities of the states of the complex, and an asterisk designates electronically excited states.

Whether the photochemical reaction occurs via the singlet or triplet sensitisation channel depends on the ratios of the probabilities of all the processes involving the given excited state of the donor.

It is known from the energy transfer theory that, for effective energy transfer from the donor to the acceptor, two requirements must be met: an energy requirement—the level of the energy donor must lie above the level of the acceptor (the overlapping of the emission spectrum of the donor and the absorption spectrum of the acceptor must be a maximum)—and a spin requirement. For maximum efficiency of the inductive-resonance energy transfer from the excited singlet level of the donor, it is necessary that the multiplicities of the excited and ground states should be identical both in the donor molecule and in the acceptor complex; for exchange-resonance energy transfer, it is necessary that Wigner's rule (the overall spin of the system must remain unchanged) should hold for the transfer process.

The sensitisation of photochemical reactions of transition metal complexes by energy transfer from the excited singlet state of the organic molecule [40] is not of much interest for the elucidation of the mechanisms of such reactions, since it is equivalent (see Scheme I) to direct excitation of the complex in the region of its allowed absorption band.

The study of the dependence of the reactions of the complexes on the height of the triplet level of the sensitiser makes it possible in many instances to reach an unambiguous conclusion about the inertness or reactivity of the lowest excited states of transition metal complexes, i.e. about the energies of the photochemical activated states of non-phosphorescent complexes§.

We shall consider separately two different cases of energy transfer to transition metal complexes.

1. Transfer to low-spin complexes with a set of singlet and triplet energy states. In particular, cobalt(III), rhodium(III), and platinum(II) [94] complexes have zero spin in the ground state. In this case, according to Wigner's rule, of the two processes 6 and 8 in Scheme I only process 6, i.e. triplet–triplet energy transfer to these complexes, is allowed. Consequently the very fact that a sensitised photochemical reaction occurs in this case is unambiguous evidence for the reactivity of the triplet state of the complex. The involvement of the triplet states of the complexes $[Co(CN)_6]^{3-}$, $[Co(CN)_5X]^{2-}$ (where X = Br, Cl, I, or pyridine) [95,96], $[Rh(NH_3)_5X]^{2+}$ (where X = Br, Cl, or I), [92] and $[PtCl]^{2-}$ [97] in their photochemical aquation reactions was demonstrated by this method. In all these studies diacetyl was used as the sensitiser. The quenching of its phosphorescence in the presence of the complexes and the constant intensity of its fluorescence lead to the unambiguous conclusion that the triplet state of diacetyl is responsible for the sensitisation.

2. The transfer of triplet excitation energy to all stable low- and high-spin transition metal complexes with any set of multiplet states other than that considered in paragraph 1 above. In this case both energy transfer processes (processes 6 and 8 in Scheme I) are possible, according to Wigner's rule, for exchange-resonance energy transfer.

If the energy gap between the two lowest excited levels of the transition metal ion is fairly large (>2400 cm^{-1}, see Moggi and Balzani [90]), the reactivity of the lowest excited state of the ion can be determined by studying the dependence of the sensitisation of the photochemical reaction on the height of the triplet level of the sensitiser. This method was used in the investigation of the relative reactivities of the doublet and quartet states of chromium(III) complexes. Diacetyl, acridine, Michler's ketone, and Methylene Blue were used as sensitisers for the complex $[Cr(NH_3)_5NCS]^{2+}$; [43] $[Cr(CN)_6]^{3-}$ was sensitised by pyrazine, xanthone, Michler's ketone, anthracene, and $[Ru(bipy)_3]^{2+}$. [59,98] Among these sensitisers, diacetyl, acridine, pyrazine, and xanthone, i.e. the compounds whose triplet level lies above the $^4T_{2g}$ level of Cr^{3+}¶ show the greatest ability to induce the photochemical aquation of the chromium(III) complexes. This result indicates the photochemical activity of the $^4T_{2g}$ level of Cr^{3+}. The demonstration of the low probability of the aquation reaction via the ^2E_g level follows from a comparison of the

§ Only a few transition metal complexes are phosphorescent in liquid solutions [93].

¶ The failure of Michler's ketone, whose triplet level is also above the $^4T_{2g}$ level, to cause sensitisation is probably due to the short lifetime of its triplet state in solution, i.e. $k_{tT}[M] < \tau_{^3I}^{-1}$.

data for the ability of anthracene and the complex $[Ru(bipy)_3]^{2+}$ to sensitise the phosphorescence of $[Cr(CN)_6]^{3-}$ in dimethylformamide at a reduced temperature with data concerning the absence of the photosensitised photochemical aquation reaction in the systems $[Ru(bipy)_3]^{2+}$ (sensitiser)$-[Cr(CN)_6]^{3-}$ in water and anthracene$-[Cr(CN)_6]^{3-}$ in dimethylformamide. All the considerations adduced here for the photochemical aquation reaction are equally valid for the photochemical isomerisation of transition metal complexes.

The situation is more complex in the sensitisation of the photochemical reduction reaction, for example the photochemical reduction of the amino-complexes of cobalt(III) which takes place on excitation of the triplet states of diacetyl, biphenyl, and quinoline[41,99]. Together with energy transfer and subsequent reduction of cobalt from the tervalent to the bivalent state in the complex itself (see process 1 in Scheme II), type 2 electron transfer is also possible in this system.

Scheme II

$$^3D + [Co(NH_3)_6]^{3+} \rightarrow {}^1D + {}^3([Co(NH_3)_6]^{3+})^* \xrightarrow{+\text{solv.}} {}^1D + [Co(NH_3)_6]^{2+}, \quad (II-1)$$

$$^3D + [Co(NH_3)_6]^{3+} \rightarrow {}^2D^+ + [Co(NH_3)_6]^{2+} \xrightarrow{+\text{solv.}} {}^1D + [Co(NH_3)_6]^{3+}. \quad (II-2)$$

Unambiguous information about the reactivities of the different levels of the cobalt(III) complex can be obtained after eliminating process (II–2). For each specific system, the problem of the relative rates of energy and electron transfer requires special consideration. The same difficulty arises in attempts to investigate the photochemical reduction of Fe^{3+} by the energy transfer method.

2. THE QUANTUM YIELDS OF SENSITISED PHOTOCHEMICAL REACTIONS

Additional information about the pathways followed in photochemical reactions and the probabilities of intercombination transitions in complexes is provided by a comparison of the quantum yields of photochemical reactions in direct photolysis (φ_{ph}^{dir}) and in the sensitisation of the lowest excited state of the complex (φ_{ph}^{sens}).

We shall consider the photochemical aquation reaction.

It is again necessary to deal separately with complexes which have a singlet ground state. For such complexes, the quantum yield of the photochemical aquation reaction in direct excitation $\varphi_{aq}^{dir} = q_{^3\Gamma}(K)\Phi_{aq}(^3\Gamma) + \Phi_{aq}(^1\Gamma^*)$, where $q_{^3\Gamma}(K)$ is the quantum yield in the formation of the triplet state of the complex, $\Phi_{aq}(^3\Gamma)$ the quantum yield in the aquation of the triplet state, and $\Phi_{aq}(^1\Gamma^*)$ the quantum yield in the aquation of the singlet excited state of the complex. Under the conditions of total transfer via triplet levels from the organic sensitiser to the complex, the quantum yield of the sensitised photochemical aquation reaction $\Phi_{aq}^{sens} = q_{^3\Gamma}(D)\Phi_{aq}(^3\Gamma)$, where $q_{^3\Gamma}(D)$ is the quantum yield for the formation of the sensitiser triplets.

In this case comparison of φ_{aq}^{dir} with $\varphi_{aq}^{sens} q_{^3\Gamma}^{-1}(D)$ permits definite conclusions concerning the mechanism of the photochemical process: (1) when $\varphi_{aq}^{dir} = \varphi_{aq}^{sens} q_{^3\Gamma}^{-1}(D)$, then presumably the triplet state of the complex is the only reactive state and $q_{^3\Gamma}(K) = 1$; the alternative hypothesis that $\Phi_{aq}(^1\Gamma^*) = \Phi_{aq}(^3\Gamma)$ is less probable; the yields of the direct and diacetyl-sensitised reactions were found to be the same for the rhodium(III), platinum(II), and cobalt(III) complexes of the type $[Rh(NH_3)_5X]^{2+}$ (X = Cl^-, Br^-, or I^-),[92] $[Co(CN)_5Y]^{2-}$ (Y^- = N_3^-, NCS^-, or CN^-),[95] and $[PtCl_4]^{2-}$;[97] (2) when $\varphi_{aq}^{dir} < \varphi_{aq}^{sens} q_{^3\Gamma}^{-1}(D)$, it follows that $q_{^3\Gamma}(K) \leq \varphi_{aq}^{dir}/\varphi_{aq}^{sens} q_{^3\Gamma}^{-1}(D)$. Assuming that the reaction proceeds only via the triplet state of the complex $[\Phi_{aq}(^1\Gamma^*) = 0]$, it is possible to obtain $q_{^3\Gamma}(K)$ by comparing the yields of the direct and sensitised reactions. Such estimates of $q_{^3\Gamma}(K)$ have been made for $[Co(CN)_6]^{3-}$ [95] and $[PtCl_4]^{2-}$.[97] However, the data of Scandola and Scandola[95] conflict with the results of measurements of Wrighton et al.[96] (Table 11). (3) When $\varphi_{aq}^{dir} > \varphi_{aq}^{sens}$, the implication is that the singlet excited state of the complex is actively involved in the photochemical aquation process and $\Phi_{aq}(^1\Gamma^*) > \Phi_{aq}(^3\Gamma)$.

Among the transition metal complexes which do not have a singlet ground state, chromium(III) compounds were investigated in greatest detail. It was already noted above

Table 11. Comparison of the quantum yields of the direct and sensitised (by energy transfer from the triplet state of organic molecules) photochemical aquation reactions of transition metal complexes.

X = NH_3, en, CN^-

that sensitisation via energy transfer from singlet levels with excitation of the quartet levels of chromium(III) is equivalent to direct excitation and measurement of the quantum yields of photochemical aquation in this case provides no new information about the relative reactivities of the ^2E_g and $^4T_{2g}$ levels of the complex. The observed difference between the yields of the direct and riboflavine-sensitised photochemical aquation of $[Cr(NH_3)_5Cl]^{2+}$ [44] conflicts with data of a study [101] where it was shown that the photochemical aquation quantum yield is independent of the exciting light wavelength and an investigation [43] where the values of φ_{aq}^{sens} and φ_{aq}^{dir} were found to be the same in sensitisation by the acridinium ion.

The quantum yields of the photochemical aquation of chromium(III) complexes with sensitisation via the triplet state of organic molecules were measured in a series of studies [43,60,76,102]. In this case

$$\varphi_{aq}^{sens} = \frac{k_{tT}^{II}}{k_{tT}^{I} + k_{tT}^{II}} \Phi_{aq}\ (^4T_{2g}) + \frac{k_{tT}^{I}}{k_{tT}^{I} + k_{tT}^{II}} \Phi_{aq}\ (^2E_g),$$

where k_{tT}^{I} and k_{tT}^{II} are rate constants for energy transfer from triplets with excitation of the doublets and quartets respectively (see Scheme I).

The presence of so many unknowns precludes a conclusion concerning the reactivities of the $^4T_{2g}$ and ^2E_g states on the basis of data for φ_{aq}^{sens} and φ_{aq}^{dir}. Possibly some information about the reactivities of mixed transition metal complexes can be provided by a study of the dependence of the composition of the products of the reaction of these complexes on λ_{exc}. Martin and Adamson [43] observed differences between the products of the photolysis of $[Cr(NH_3)_5NCS]^{2+}$ with excitation in the region of the $^4T_{2g}$ and ^2E_g bands.

Comparison of the photochemical reaction products of this salt for sensitisation with acridinium ions and diacetyl confirmed qualitatively the differences between the reactivities of the $^4T_{2g}$ and ^2E_g states observed in direct photolysis by light corresponding to the absorption bands for these states (Table 11). The authors conclude that the $^4T_{2g}$ and ^2E_g states are responsible for the photochemical aquation of the NH_3 and NCS^- groups respectively†.

A defect of this and many other studies quoted here is the lack of data for the intensity of the exciting light. On the other hand, the ratios of the rates of the photochemical reaction and the dark forward and reverse reaction depend on the intensity of the exciting light. Since the dark reaction of $[Cr(NH_3)_5(NCS)]^{2+}$ involves the displacement of NCS^- and the photochemical reaction involves predominantly the displacement of NH_3, the ratio of the reaction products should depend on I_{exc}.

3. THE QUENCHING OF THE PHOTOCHEMICAL REACTIONS OF TRANSITION METAL COMPLEXES BY ENERGY TRANSFER FROM THE LATTER

The method of suppressing a photochemical reaction by the introduction of a quenching agent supplements the sensitisation method. Its employment makes it possible to determine the position of the photochemically active state. The combination of the sensitisation and quenching methods yields information about the distortions of this state on excitation. For example, in the absence of sensitisation the *cis–trans* isomerisation of diglycinato-platinum(II) by organic molecules with a triplet state below 22 900 cm^{-1} and the absence of the quenching of the photochemical reaction of Pt^{2+} by Mn_{aq}^{2+} ions (18 900 cm^{-1}), while Ni_{aq}^{2+} ions do cause quenching (8900 cm^{-1})‡ provide information about the shift of the triplet state of platinum(II) on excitation [104].

The quenching method also makes it possible to estimate the contribution of the given state of the overall yields of the photochemical reaction of the complex. As for sensitisation, this method is particularly simple only for transition metal complexes with a set of singlet and triplet levels. In this case the method is analogous to the procedure involving the quenching of the triplet state of organic molecules [2-4].

For other sets of states, the method of quenching the photochemical reactions of transition metal ions by the molecular triplet states is again coupled with the difficulty of separating the processes involving energy transfer from the two lowest excited states of the transition metal ion. The closeness of τ_{fl} and τ_{phosph} for chromium(III) complexes at room temperature aggravates this difficulty still further. For the chromium(III) complexes which phosphoresce in liquid solutions, comparison of data for the influence of quenching agents on photochemical aquation and the phosphorescence of the complexes helps in obviating these difficulties. The employment of this method made it possible to study the pathways in the photochemical reaction of the Reinecke salt in various solvents at reduced temperatures {O_2 [101] and $[Cr(CN)_6]^{3-}$ [81] were used as quenching agents} and in the photochemical aquation of $[Cr(en)_3]^{3+}$ in water at 293 K [cobalt(II) and iron(II) salts served as the quenching agents [105]].

In order to determine the reactivities of the ^2E_g and $^4T_{2g}$ levels of chromium(III), data for the quenching of the phosphorescence of the Reinecke salt and $[Cr(en)_3]^{3+}$, the decrease of the duration of their phosphorescence, and the excitation of the sensitised phosphorescence of $[Cr(CN)_6]^{3-}$ were compared [101,105] with data for the suppression of their photochemical aquation in the presence of quenching agents. It was found that φ_{ph} changes in the presence of $[Cr(CN)_6]^{3-}$ or Ni^{2+} to a lesser extent than q_{phosph} and τ_{phosph} for the Reinecke salt and the complex $[Cr(en)_3]^{3+}$. The incomplete suppression of the photochemical aquation reaction on depopulation of the ^2E_g level of these salts by energy transfer to $[Cr(CN)_6]^{3-}$ is significant evidence in support of the photochemical activity of the $^4T_{2g}$ level of these chromium(III) complexes.

The high reactivity of the $^4T_{2g}$ level of hexacyanochromium(III) was demonstrated by Wasgestian [59], who investigated the effect of O_2 on τ_{phosph} and φ_{aq}^{dir} for the complex $[Cr(CN)_6]^{3-}$ in dimethylformamide at room temperature a and observed that τ_{phosph} for the solution decreases by a factor of 10 after evacuation, but the latter has no influence on φ_{aq}^{dir} for this complex. This result enabled him to claim that the ^2E_g state of $[Cr(CN)_6]^{3-}$ is not reactive. It is still not known whether this claim is true for all chromium(III) complex and whether the hypothesis of Porter et

† No difference in φ_{aq}^{dir} on excitation to the ^2E_g and $^4T_{2g}$ states were noted for the complexes $[Cr(en)_3]^{3+}$, $[Cr(NH_3)_6]^{3+}$, and $[Cr(urea)_6]^{3+}$. [86]

‡ The oxidation-reduction properties of these ions are similar.

al.[101] and Wasgestian[105] that the photochemical activity in the direct population of the ^2Eg level is due to a thermal intersystem crossing to the $^4T_{2g}$ level is correct. If the above conclusion is valid, then the total absence of the photochemical aquation of $[Cr(NH_3)_5(NCS)]^{2+}$ on excitation by sensitiser whose triplet levels lie below the $^4T_{2g}$ level but above the ^2E_g, which was discussed above, can probably be accounted for by the low probability of energy transfer from the sensitisers to the chromium(III) ions and not solely by the height of their levels.

---o0o---

The data described above make it certain that the main cause of the quenching of the fluorescence of organic molecules in solutions by transition metal ions is the inductive-resonance mechanism of energy transfer. The important role of exchange-resonance energy transfer in the sensitisation of the phosphorescence of transition metal ions and of their photochemical reactions has also been convincingly demonstrated. It has been established that the rate constants for the exchange-resonance energy transfer from organic molecules to transition metal ions are lower than those for the energy transfer between organic molecules[2,4] but higher than the rate constants for energy transfer to lanthanide ions[1]. This result is consistent with the decrease of the overlapping of the π-electron clouds of organic molecules in the following sequence: (1) π electrons of another organic molecule > (2) d orbitals of transition metal ions > (3) strongly shielded f orbitals of lanthanide ions.

The application of the exchange-resonance energy transfer in the study of photochemical reactions made it possible to solve unambiguously the problem of the reactivities of individual energy levels of the ions for a number of rhodium(III), cobalt(III), platinum(III), and chromium-(III) complexes§. On the other hand, many problems still await solution: (1) only the first attempts have been made to elucidate the mechanism of the influence of the ligand on the exchange-resonance energy transfer; (2) the role of the solvent in such energy transfer is not clear; (3) the problem of whether several photochemical reactions can occur simultaneously via the same electronic state of the ion remains open; (4) it is not known whether a photochemical reaction involving an excited state of the complex proceeds as the result of the labilisation of the bonds in the latter or whether it proceeds via high vibrational levels of the ground state reached by internal conversion from the quartet state. The latter possibility is inconsistent with the experimental observation that deuteriation of amino-groups has no influence on the φ_{ph} for the complexes[92].

§ The review does not deal with studies on energy transfer involving transition metal complexes whose lowest excited states are singlet and triplet charge transfer states[106–110]. We believe that energy transfer between such complexes and transition metal ions is analogous to the energy transfer between organic molecules and transition metal ions.

The Cleavage of the Carbon-Oxygen Bond by Organomagnesium Compounds

B.A.Trofimov and S.E.Korostova

Studies on reactions involving the cleavage of the C-O bond by organomagnesium compounds (OMC) (Grignard and Norman reagents and Iotsich complexes), including the behaviour of ethers, open-chain acetals, and cyclic acetals in relation to the OMC, are reviewed. The mechanism of the cleavage of the ether linkage by OMC is discussed, attention being concentrated on the reaction of 1,3-dioxacyclanes with OMC, the complex-formation processes in the reaction of 1,3-dioxolans with Grignard reagents and Iotsich complexes, and also the mode of the cleavage of asymmetrically substituted 1,3-dioxacyclanes by these reagents.
The bibliography includes 183 references.

IV. Cyclic acetals (1,3-dioxacyclanes) and their analogues 47

I. INTRODUCTION

Since the publication of the last review[1] on the cleavage of the C-O bond by organomagnesium compounds (OMC) the number of studies in this field has doubled and continues to grow. This is particularly due to the discovery of new preparative syntheses and also the fact that they yield additional information about the structure of OMC and the role of electrophilic catalysis and complex formation in reactions of OMC.

The available information about the chemistry of the O-C bond has been appreciably amplified by studies on the cleavage of cyclic acetals and some of their analogues by Grignard, Iotsich, and Norman reagents carried out in recent years in the USSR[2-27] and abroad[28-34]. Until recently it was not clear whether the Chichibabin-Elgazin-Spath reaction[35-43] can be applied in the series of 1,3-diheterocyclanes. The recommendation[44] that certain cyclic acetals be used as solvents for Grignard syntheses appeared to suggest a high stability of such acetals in relation to OMC. Nevertheless the wide distribution of cyclic acetal systems in nature, the systematic use of acetal protecting groups in carbohydrate and steroid chemistry, and the high and many-sided physiological activities of certain 1,3-dioxacyclanes impart urgency to the solution of these problems: the reactions of the cyclic acetal group leads to new ways of synthesising and modifying important groups of organic compounds. After the development of an industrial method for the synthesis of 2-methyl-1,3-dioxolan[45], the possibility of its employment as a useful chemical starting material became apparent. Against the background of continually expanding research on the polymerisation of trioxan and cyclic acetals and ethers, analysis of the conditions and characteristics of the cleavage of the C-O bond has acquired special importance. Such cleavage is the initial stage in any method of polymerising oxygen-containing heterocycles.

Studies published from 1960 to 1962 and partly in 1973 are discussed critically in the present review. Of the earlier publications, only those which had not been considered in previous reviews[1,46,47] are quoted.

Attention has been concentrated on the reactions of OMC with cyclic acetals, which reflect the trend which is at present dominant in this field. The review does not deal with the behaviour of OMC in relation to 1,4-dioxans, 1,3,5-trioxans, and derivatives of morpholines and orthoesters, since no new data appear to have been published on this subject in the above period. It also seemed undesirable to include in the review the reactions of esters and lactones, since the cleavage of their C-O bonds on interaction with OMC appears to be a secondary process for such compounds, which is not part of the reactions under consideration.

II. ETHERS

1. Reaction Mechanism

In principle, the R'-O-R'' molecule can be cleaved when either of two C-O bonds is acted upon by OMC. If, developing further the ideas described by Houben-Weyl[47], the reaction is regarded as the usual bimolecular nucleophilic substitution (S_N2) at the carbon atom of the group R':

$$R'-OR'' + \overset{-\delta}{R'''}-\overset{+\delta}{M}gX \rightarrow R'-R''' + R''-OMgX, \quad (1)$$

then one must naturally expect that this entails the rupture of the C-O bond where the carbon atom has a lower electron density or there is a greater scope for the distribution of the charge of the attacking anion. Unfortunately, the mode and mechanisms of the cleavage reactions of ethers have not been analysed so far in the literature, although the relevant facts are available (see previous reviews[1,46,47]). If account is taken of all the examples at present available, the conclusion reached is fairly unexpected: the cleavage of asymmetric ethers by OMC involves preferentially the C-O bond in which the carbon atom has the maximum electron density. In other words, the cleavage involves the formation of the most favourable carbonium ion. This is illustrated by examples (2)-(8):[1,48-53]

$$CH_3OC_6H_5 + CH_3MgI \rightarrow C_2H_6 + C_6H_5OMgI, \quad (2)$$

$$C_2H_5OC_6H_5 + C_6H_{11}MgBr \rightarrow C_2H_4 + C_6H_{12} + C_6H_5OMgBr, \quad (3)$$

$$n\text{-}C_8H_{17}OCH_2CH{=}CH_2 + C_6H_5MgBr \rightarrow C_6H_5CH_2CH{=}CH_2 + n\text{-}C_8H_{17}OMgBr, \quad (4)$$

$$C_6H_5OCH_2C_6H_5 + C_4H_9MgBr \rightarrow C_6H_5CH_2C_4H_9 + C_2H_5OMgBr, \quad (5)$$

$$CH_2{=}CHCH_2OC_6H_5 + C_6H_5MgBr \rightarrow CH_2{=}CHCH_2C_6H_5 + C_6H_5OMgBr\ , \quad (6)$$

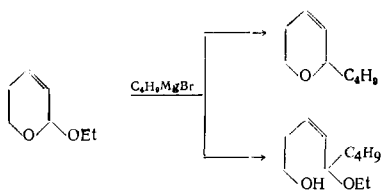
$$C_4H_9OCH_2CH{=}CHC_6H_5 + C_7H_{15}MgBr \rightarrow C_6H_5CH{=}CHCH_2C_7H_{15} + C_4H_9OMgBr\ , \quad (7)$$

$$(C_6H_5)_2COCH_2C \equiv CH + (C_6H_5)_2COCH_2C \equiv CMgBr \rightarrow$$
$$\rightarrow (C_6H_5)_2CC \equiv CCH_2OC(C_6H_5)_2 + HC \equiv CCH_2OMgBr\ . \quad (8)$$

Certain $\alpha\beta$-unsaturated ethers[54-56], which are sometimes cleaved on the side of the double bond, apparently constitute an exception. However, the contradictory information on this problem and also the known specificity of the chemical behaviour of such ethers preclude fairly definite conclusions. Thus it has been reported[55] that the ether $C_6H_5C(OC_2H_5){=}CH_2$ reacts with phenyl- and *p*-methoxyphenylmagnesium bromides, forming respectively $(C_6H_5)_2C{=}CH_2$ and $p\text{-}CH_3OC_6H_4(C_6H_5)C{=}CH_2$. It has also been shown[56] that alkyl vinyl ethers with different alkyl substituents in the α- and β-positions in the vinyl group are cleaved by Grignard reagents (GR) via the reaction

$$RCH{=}C(R')OR'' + R'''MgBr \rightarrow [RCH{=}C(R')OH] \rightarrow RCH_2COR'\ , \quad (9)$$

where R = H, $n\text{-}C_3H_7$, $n\text{-}C_5H_{11}$, or $n\text{-}C_6H_{13}$, R′ = H, $n\text{-}C_4H_9$, $n\text{-}C_5H_{11}$, or $n\text{-}C_6H_{13}$, R″ = C_2H_5 or $n\text{-}C_4H_9$, and R‴ = C_4H_9. Ultimately ketones formed. The reactants are heated in petroleum ether for 12–30 h.[56] For example, 5-undecanone was obtained in 76% yield from $C_5H_{11}CH{=}C(C_4H_9)OC_4H_9$ and butylmagnesium bromide. The results of the study by Quelet and d'Angelo[57] [reaction (10)] are consistent with this finding:



(10)

On the other hand, according to other data[58] β-alkyl-substituted vinyl ethers react with OMC to form primary alcohols and olefins. Similarly the reaction of unsubstituted vinyl ethers, in particular butyl vinyl ether, with phenylmagnesium bromide results in the formation of butanol and styrene in 60 and 30% yields respectively[56]. It has been suggested[56] that the yield of propenylmagnesium bromide, obtained in vinyl ethers, is influenced by its reaction with the solvent.

There are data on the polymerisation of vinyl ethers under the influence of Grignard reagents[59,60] showing that the polymerisation proceeds in the presence of an alkyl vinyl ether[60]. On the other hand, in the presence of an excess of the Grignard reagent, the initial ether is recovered unchanged even after heating and only a small amount of oligomers and products of the hydration of the vinyl ethers are formed under these conditions. Therefore, despite earlier studies[56,58], it was concluded[60] that alkoxy-groups adjoining the double bond are relatively immobile, like a halogen atom, and are not exchanged for the group in the OMC. These results for $\alpha\beta$-unsaturated ethers are nevertheless consistent with the conclusion that the majority of ethers react with OMC apparently via an S_N1 mechanism. However, since spontaneous dissociation of the C–O bond is unlikely under these conditions, the classical S_N1 mechanism must of course be rejected. The following explanation is probable. In all the known cases of the cleavage of the C–O bonds under the influence of OMC the reaction mixture contains Lewis acids (MgX_2 and CoX_2; here and henceforth X is a halogen), which are coordinated to the oxygen atom and probably ultimately cleave the C–O bond. This can occur simultaneously with attack by an anion†, for example R_2Mg:

$$Mg(R)_2 \longrightarrow R\overset{\curvearrowright}{O}{:}\,MgX_2\ . \quad (11)$$

In order to explain the observed mode of cleavage of asymmetric ethers, a decisive role must be attributed to the electrophilic attack $X_2Mg{\rightarrow}{:}O\langle$ in the dissociation of the C–O bond. Thus the process must be classified as nucleophilic substitution with electrophilic catalysis. As will be shown below, the majority of the characteristics of the dissociation of the C–O bond by OMC known at the present time can be explained satisfactorily by the proposed mechanism.

2. Cyclic Ethers

Like open-chain ethers, cyclic ethers are relatively unreactive in relation to OMC. It is not fortuitous that tetrahydrofuran (THF), 2-methyltetrahydrofuran, and tetrahydropyran occupy a special position as solvents for Grignard syntheses[44]. The following new facts can be added to the information available from previous reviews[1,46,47] on the behaviour of cyclic ethers in the presence of OMC. Many reactions involving OMC take place in THF without the cleavage of its ring[28,61,62]. Nevertheless it has been stated[63] that THF is cleaved when butylmagnesium bromide is synthesised in it. On the other hand, according to other data[44,64-67] THF begins to react with Grignard reagents only at about 200°C, forming primary alcohols:

$$+ RMgX \rightarrow R(CH_2)_4OMgX\ , \quad (12)$$

where

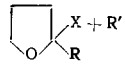
$$R{=}C_2H_5\,(Br),\ C_4H_9\,(Cl),\ (C_6H_5)_3C\,(Br);\quad X{=}Cl,\ Br\ .$$

Chlorotrimethylsilane and magnesium react in THF[68] via the mechanism

$$(CH_3)_3SiCl + Mg + \rightarrow (CH_3)_3Si(CH_2)_4OMgCl\ . \quad (13)$$

The reaction between dihydropyran and OMC leads to the formation of an unsaturated alcohol in 35–40% yield[69].

The reaction of 2-halogeno-substituted cyclic ethers with a Normal reagent can proceed in different ways. Thus, when $CH_3CH{=}CHMgBr$ interacts with 2-chlorotetrahydrofuran and 2-chlorotetrahydropyran, the unsaturated alcohols $CH_3CH{=}CHCH{=}CH(CH_2)_2OH$ and $CH_3CH{=}CHCH{=}CH(CH_2)_3OH$ are formed respectively[70]. On the other hand, another mode of this reaction has been described[71]:



$$+ R'MgBr \rightarrow + MgXBr\ , \quad (14)$$

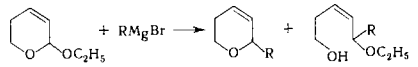
where R = H or CH_3, R′ = $CH_2{=}CH$ or $CH_3CH{=}CH$, and X = Cl or Br. The yield of the reaction products is 50%.

The reaction of 2-alkoxytetrahydropyrans with OMC has been studied[68,72] and the cleavage of the C–O bond in the pyran ring has been reported[69,73-76]. For example,

† One cannot rule out the possibility that this attack occurs in certain cases as a one-electron transfer.

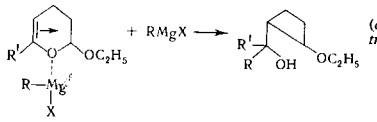
when 2-ethoxy-2,3-dihydro-γ-pyran is heated in toluene (85–90°C, 90 min) with an excess of a Grignard reagent, a mixture of *cis*- and *trans*-alkyl (or aryl)(2-ethoxycyclobutyl)methanols is formed in yields up to 48%.[74] The authors[74] suggest that the reaction proceeds via a mechanism involving cyclic electron transfer.

The reactions of the following cyclic ethers [reactions (15)–(20)] have also been described[28,57,77]:



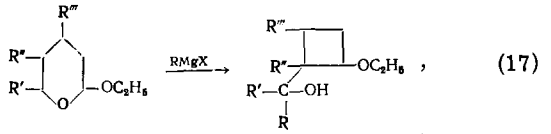
(15)

where R = CH_3, C_2H_5, n-C_4H_9, or C_6H_5;



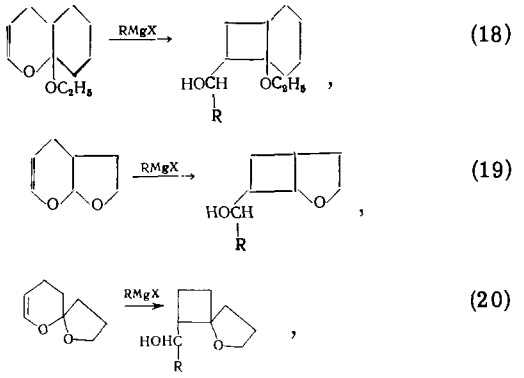
(16)

where R = CH_3, n-$C_4H_9C{\equiv}C$, or t-C_4H_9, R′ = H or CH_3, and X = Br or I;



(17)

where R = CH_3, C_2H_5, or C_4H_9, R′ = R″ = H, R‴ = CH_3 or C_6H_5, and X = Br or I;



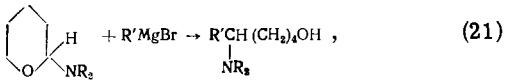
(18)

(19)

(20)

where R = C_2H_5 or C_4H_9 and X = Br.

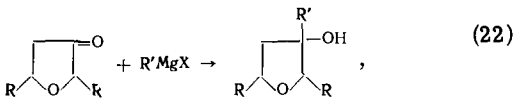
The interaction of 2-dialkylaminotetrahydropyrans with a Norman reagent leads to aminoalcohols[65]:



(21)

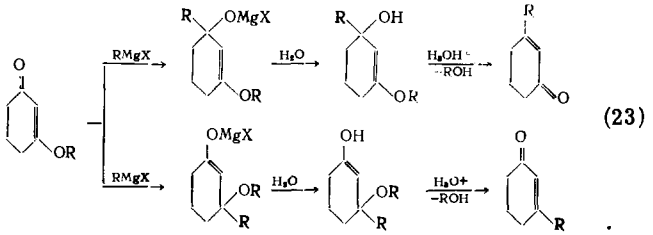
where R = C_2H_5 and R′ = $CH_2{=}CH$ or $CH_3CH{=}CH$.

Cyclic ketoethers react with OMC via the carbonyl group[78–80] [reactions (22) and (23)]:



(22)

where R = H or CH_3, R′ = CH_3, C_2H_5, C_3H_7, C_5H_{11}, or C_6H_5, and X = Br or Cl, and



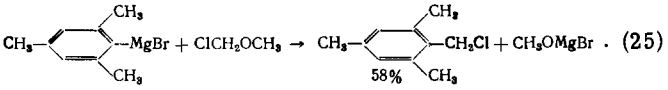
(23)

3. Ethers with Other Functional Groups

Full glycol ethers are fairly resistant to the action of OMC[81–83]. Thus the diethyl and dibutyl ethers of ethylene glycol[82], the diethyl and dibutyl ethers of diethylene glycol[66], and also the ethers of polyethylene glycols of the type $R(OCH_2CH_2)_nOR$ have been suggested[64] as high-boiling solvents for Grignard syntheses. The cleavage of the C–O bond under the influence of OMC was not observed in the dimethyl ether of ethylene glycol[81] even on heating at 70°C for 3.5 h. However, this ether is known to be cleaved appreciably[84] after 3 h at 95°C:

$$CH_3OCH_2CH_2OCH_3 + C_4H_9C{\equiv}CMgBr \rightarrow CH_3OCH_2CH_2C{\equiv}CC_4H_9 + CH_3OMgBr\,. \quad (24)$$

Halogenoethers. Without repeating the references quoted in Pokonova's monograph[85] and Summers' review[86], we shall examine the characteristic reactions of OMC with halogenoethers using some new examples. α-Chloroethers are known[85] to exchange their halogen readily for the hydrocarbon group in OMC, as a rule without the cleavage of the C–O bond. According to Shostakovskii et al.,[87] aryl α-chloroisopropyl ethers behave in this way. The reaction with Norman[88] and Iotsich[89–92] reagents proceeds similarly. Both halogen atoms are substituted without much difficulty in bis-(α-halogenomethyl) ethers[83]. However, under the influence of di-o-substituted arylmagnesium halides, the α-halogenoether is cleaved at the C–O bond[93,94]:



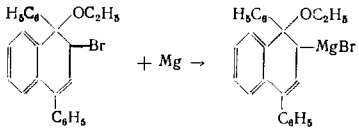
(25)

o-Halogenoethers form Grignard reagents[95]. When an attempt is made to prepare OMC from β-halogenoethers, the C–O bond is usually cleaved with the liberation of an olefin[96]:

$$CH_3O(CH_2)_4Cl + Mg \xrightarrow[THF]{ether} CH_3OMgCl + \rangle C{=}C\langle\,. \quad (26)$$

However, according to Shostakovskii et al.,[61] β-bromoethyl phenyl ether can react normally with magnesium.

Another instance of the formation of OMC from a β-halogenoether is also known[97]:



(27)

A Grignard reagent could not be obtained from γ-bromobutyl vinyl ether (in diethyl ether and THF as solvents), dimerisation and dehydrobromination products being detected[23,98]:

$$CH_2{=}CHO(CH_2)_3CHBrCH_3 + Mg \rightarrow CH_3{=}CHO(CH_2)_2CH{=}CHCH_3 + CH_2{=}CHO(CH_2)_3(CH_3)CHCH(CH_3)(CH_2)_3OCH{=}CH_2\,. \quad (28)$$

Only δ-bromobutyl vinyl ether reacts with magnesium without appreciable complications, forming the corresponding Grignard reagent[23,98].

A Norman reagent does not disrupt the C–O bond in $\alpha\beta$-dibromoethers[99,100] and certain Iotsich complexes behave similarly with respect to β-bromoethyl chloromethyl ether[101].

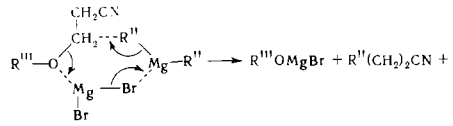
Certain trihalogenoalkyl ethers merely exchange their α-halogen atom for the alkyl group on reaction with a Grignard reagent and the C–O bond remains unaffected[28,102].

Ethers with active functional groups react with OMC in accordance with the general rule, i.e. via the most reactive fragment[28,103-106].

Cyanoethers. In contrast to α-alkoxynitriles, which react with OMC in the usual way, β-alkoxynitriles are wholly cleaved by the latter at the C–O bond[107]:

$$CH_2{=}CHOR'O(CH_2)_2C{\equiv}N + R''MgBr \rightarrow CH_2{=}CHOR'OMgBr\ , \qquad (29)$$

where R′ = $(CH_2)_2$ or $(CH_2)_2O(CH_2)_2$ and R″ = C_2H_5, C_4H_9, or C_6H_5. The reaction proceeds with evolution of heat. It has been suggested[107,108] that it involves the intermediate complex illustrated below:



$$\rightarrow R'''OMgBr + R''(CH_2)_2CN + R''MgBr\ , \qquad (30)$$

where R‴ = CH_2 or CHOR′.

The cyano-product obtained on cleavage of the ether is then converted into a ketiminate and which then polymerises:

$$R''(CH_2)_2CN \rightarrow \left[\begin{array}{c} -C(R')-NH- \\ | \\ (CH_2)_2R'' \end{array}\right]_n^- \ . \qquad (31)$$

When the β-cyanoethyl ether of 2-methyl-4-trimethylsilylbut-3-yn-2-ol reacts with ethylmagnesium bromide[109,110], the main process is the cleavage of the C–O bond:

$$(CH_3)_3SiC{\equiv}CC(CH_3)_2OCH_2CH_2CN + C_2H_5MgBr \rightarrow$$
$$\rightarrow (CH_3)_3SiC{\equiv}CC(CH_3)_2OH + (CH_3)_3SiC{\equiv}C(CH_3)_2OCH_2CH_2\underset{22\%}{\underset{\|}{C}}C_2H_5 \qquad (32)$$
$$O$$

Aminoethers. The exchange of the alkoxy-groups in certain aminoethers for the substituent in Grignard and Norman reagents has been described[111-115] [reactions (33)–(36)]:

$$H_2NOCH_3 + RMgX \rightarrow RNH_2 + CH_3OMgX\ , \qquad (33)$$

where R = C_2H_5, i-C_5H_{11}, i-C_4H_9, or t-C_4H_9 and X = Cl, Br, or I;

$$C_6H_5CH_2ONH_2 + RMgX \rightarrow RNH_2 + C_6H_5CH_2OMgX\ , \qquad (34)$$

where R = C_2H_5, i-C_5H_{11}, cyclo-C_6H_{11}, C_6H_5, $C_6H_5CH_2$, p-BvC_6H_4 or α-naphthyl and X = Cl, Br, or I;

$$R_2NCH_2OR + R''MgCl \rightarrow R_2NCH_2R'' + ROMgCl\ , \qquad (35)$$

$$R_2NCH(R')OR'' + R'''MgBr \rightarrow R_2NCH(R')R''' + R''OMgBr\ , \qquad (36)$$

where R = CH_3, C_2H_5, C_4H_9, C_5H_{11}, R′ = H, R″ = C_2H_5, C_4H_9, or C_6H_5, R‴ = $CH_3CH{=}CH$, $CH_2{=}CHCH_2$; $CH_2{=}CH$, $(CH_3)_2CH$, $(CH_3)_2C{=}CH$, i-C_5H_{11}, C_4H_9, or α-naphthyl, and X = Cl, Br, or I.

III. OPEN-CHAIN ACETALS AND THEIR STRUCTURAL ANALOGUES

Many acetals are very resistant to the reaction of OMC and it is difficult to make them undergo exchange reactions with the latter.

1. Formals

Dimethyl and diethyl formals nevertheless exchange alkoxy-groups for the substituent in the Grignard reagent at high temperatures, forming ethers[116-118]:

$$ROCH_2OR + C_6H_5MgBr \rightarrow C_6H_5CH_2OR + ROMgBr\ , \qquad (37)$$

where R = CH_3 or C_2H_5.

Saturated symmetrical formals derived from alcohols ranging from propanol upwards hardly react with OMC under these conditions. The method of synthesis of a number of OMC[119] in di-isopropyl or di-isobutyl formals is based on this finding. Mixed unsaturated formals[60] are more reactive than saturated symmetrical formals towards Grignard reagents. Alkoxy-groups containing multiple bonds then undergo exchange:

$$ROCH_2OR' + C_6H_5MgX \rightarrow R'OCH_2C_6H_5 + ROMgX\ , \qquad (38)$$

where R = C_2H_5 or C_4H_9 and R′ = $C(CH_3)_2CH{=}CH_2$, or $CH{\equiv}C(CH_3)_2C$.

The above data are consistent with the proposed mechanism (see Section I, 1), since of the two most probable intermediate cations of the type $ROCH_2^+$ the more stable is the one containing a group with more marked electron-donating properties (i.e. in the present case an aliphatic group). When an OMC acts on the diformals $ROCH_2OCH_2OR$, the corresponding formaldehyde acetals are formed in yields up to 50%:[120]

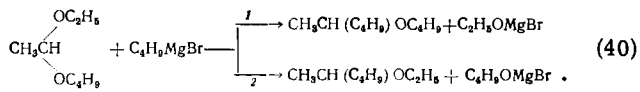
$$ROCH_2OCH_2OR + R'MgX \rightarrow ROCH_2OCH_2R' + ROMgX\ , \qquad (39)$$

where R = C_2H_5, C_4H_9, i-C_5H_{11}, or C_6H_{13}, R′ = $CH_2C_6H_5$ or n-C_6H_{13}, and X = Cl. This reaction proved to be convenient for the synthesis of formals with a β-phenylethyl alcohol residue, which has a flowery scent.

2. Acetaldehyde Acetals

In the reaction of symmetrical dialkyl and di(arylalkyl) acetals[121] with Grignard reagents the alkoxy-groups can be arranged in the following sequence in terms of the ease of their exchange: $OC_6H_5 > OAlk > OCH_2C_6H_5$. This sequence might have been foreseen on the basis of the ideas described in Section I.1. The available data on the reactivities of dialkyl acetals in relation to Grignard reagents are contradictory. Thus as early as 1961 Blomberg and Vrengdenhill[122] observed in the synthesis of Grignard reagents in boiling dialkyl acetals the cleavage of the latter with formation of ethers and alkoxymagnesium halides. However, in 1964 Shostakovskii et al.[123] suggested that diethyl and dibutyl acetals may be used as the medium for the synthesis of OMC, since according to their data, these acetals do not interact with Grignard reagents even at 150°C. Grinberg[124] obtained ethers derived from alkyl(aryl)hexylmethanols and diaryl(alkyl)hexylmethanes by the reaction between the acetal of oenanthaldehyde and OMC. Thus not only the acetal but also the ether formed from it are cleaved in this case.

If the alkyl groups in asymmetric acetals do not differ appreciably in their structures, the reaction proceeds in two ways[59]:



$$\rightarrow CH_3CH(C_4H_9)OC_4H_9 + C_2H_5OMgBr$$
$$\rightarrow CH_3CH(C_4H_9)OC_2H_5 + C_4H_9OMgBr\ . \qquad (40)$$

Pathway *1* is dominant, i.e. the less electron-donating alkoxy-group again undergoes exchange more readily. As expected, in mixed alkyl aryl acetals[59] the aryloxy-group

is split off preferentially. On the basis of the mechanism discussed in Section I.1, the symmetrisation of the mixed acetals in the course of these reactions might have been predicted. Such symmetrisation has in fact been observed in the reaction of ethylmagnesium bromide with butyl ethyl and benzyl ethyl acetals[59]. The reaction of acetals with a Iotsich complex leads to the formation of acetylenic ethers[84,125,126]:

$$CH_3CH(OR)_2 + HC\equiv CMgBr \xrightarrow[1-3\ h]{95^\circ} HC\equiv CCH(CH_3)OR + ROMgBr\,, \quad (41)$$

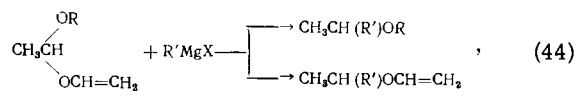
$$2CH_3CH(OC_4H_9)_2 + BrMgC\equiv CMgBr \rightarrow CH_3CH(OC_4H_9)C\equiv CCH(OC_4H_9)CH_3 + 2C_4H_9OMgBr\,. \quad (42)$$

The Iotsich complex obtained from ethynyldimethylmethanol is also reactive[127]:

$$CH_3CH(OC_4H_9)_2 + BrMgC\equiv CC(CH_3)_2OMgBr \xrightarrow{90-95^\circ} \rightarrow (CH_3)_2C(OH)C\equiv CCH(CH_3)OC_4H_9 + C_4H_9OMgBr\,. \quad (43)$$

The reactivity of C–O bonds in relation to the Iotsich complex increases sharply on passing from acetals to ketals[84]. It will be shown below that this rule holds fairly clearly also in other versions of the reaction of OMC with acetals or with their close analogues. This is yet another piece of evidence for the electrophilic nature of the rate-limiting stage in the cleavage of the C–O bond under the influence of OMC. Presumably, the interaction C–O←MgX_2, and not the nucleophilic attack $R^{\ominus}$→C–O, is decisive. Otherwise the enhancement of the electron-donating properties of the group joined to the oxygen atom on passing from acetals to ketals would have reduced the reactivity of the reacting C–O bonds. In reality the C–O bonds in ketals are more reactive than in acetals.

The acetals of unsaturated alcohols react with OMC like the acetals of saturated alcohols. The interaction of alkyl vinyl acetals with Grignard reagents[127,128] leads mainly to the formation of saturated ethers:



$$+ R'MgX \rightarrow \begin{cases} \rightarrow CH_3CH(R')OR \\ \rightarrow CH_3CH(R')OCH=CH_2 \end{cases}, \quad (44)$$

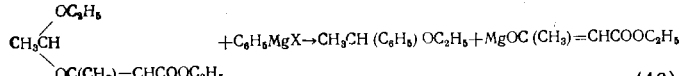
where R = alkyl or CH = CH, R′ = C_6H_5, and X = Br.

The yield of the corresponding alkyl vinyl ethers is about 30%, i.e. as in αβ-unsaturated formals[60], the C–O bond on the side of the more strongly electron-accepting group is the first to be broken, which is equivalent to the formation of the most stable carboxonium ion.

Divinyl acetals[127] involved in an exchange reaction with OMC form vinyl ethers:

$$CH_3CH(OCH=CH_2)_2 + RMgX \rightarrow CH_3CH(R)OCH=CH_2 + CH_2=CHOMgX\,. \quad (45)$$

It is surprising that the reaction of the acetal derived from the β-hydroxycrotonic ester with a phenylmagnesium halide[129] proceeds without affecting the ester group.



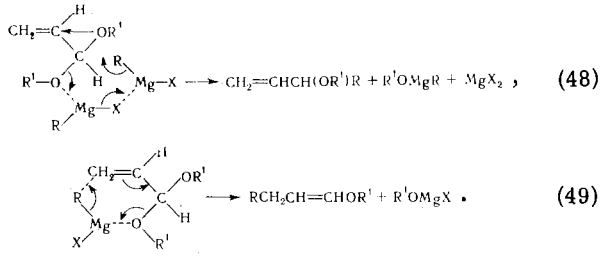
$$+ C_6H_5MgX \rightarrow CH_3CH(C_6H_5)OC_2H_5 + MgOC(CH_3)=CHCOOC_2H_5\,. \quad (46)$$

3. Acetals of Unsaturated Aldehydes

Acrolein acetals[130] give rise to a mixture of allyl and vinyl ethers on reaction with OMC:

$$CH_2=CHCH(OR')_2 + RMgX \rightarrow \begin{cases} \xrightarrow{1} CH_2=CHCH(R)OR' \\ \xrightarrow{2} RCH_2CH=CHOR' \end{cases}, \quad (47)$$

where R = CH_3, C_2H_5, C_3H_7, i-C_3H_7, C_4H_9, i-C_4H_9, $CH_3(C_2H_5)CH$, $(CH_3)_3C$, cyclo-C_6H_{11}, C_6H_5, $CH_3CH=CH$, or $C_4H_9C\equiv C$, R′ = CH_3, C_2H_5, i-C_3H_7, or $CH(CH_3)_2$, and X = Br, Cl or I. At elevated temperatures (100–120°C) pathway *1* predominates (the yield of allyl ether is 93%). The reaction is carried out in ether, THF, toluene, xylene, or decalin in the course of 1.5–2 h. The following reaction mechanisms have been proposed[130]:



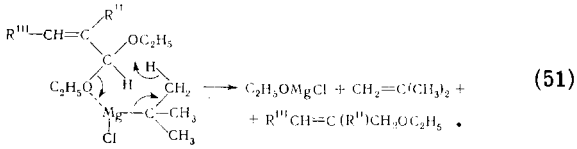
$$\rightarrow CH_2=CHCH(OR')R + R'OMgR + MgX_2\,, \quad (48)$$

$$\rightarrow RCH_2CH=CHOR' + R'OMgX\,. \quad (49)$$

The homologues of the propenal acetal[131] react with OMC as follows:

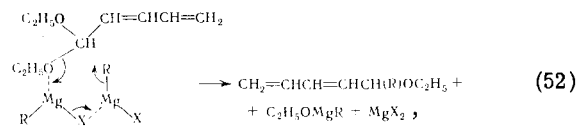
$$R^{IV}CH=CR^{III}CR^{II}(OR^{I})_2 + RMgX \rightarrow R^{IV}CH=CR^{III}CR^{II}(R)OR^{I} + RR^{IV}CHR^{III}C=C(R^{II})OR^{I}, \quad (50)$$

where R = C_2H_5, n-C_4H_9, $(CH_3)_3C$, C_6H_5, $C_6H_5CH_2$, or $C_6H_5CH_2CH_2$, R^I = C_2H_5, R^{II} = H or CH_3, R^{III} = H, C_2H_5, or i-C_3H_7, R^{IV} = H, and X = Br or Cl. The following reaction mechanism is discussed in the same study[131]:



$$\rightarrow C_2H_5OMgCl + CH_2=C(CH_3)_2 + R^{III}CH=C(R^{II})CH_2OC_2H_5\,. \quad (51)$$

Quelet and d'Angelo[57] proposed the mechanism



$$\rightarrow CH_2=CHCH=CHCH(R)OC_2H_5 + C_2H_5OMgR + MgX_2\,, \quad (52)$$

where R = CH_3, n-C_4H_9, or t-$C_4H_9C\equiv C$, and X = Br. Similar reactions are discussed in Normant's review[28].

Ethers with an acetylenic linkage have been obtained from propargyl acetals[132,133].

4. Halogenocetals

The acetals of halogenoaldehydes with a halogen atom in the β-position relative to the ethylidene group undergo an exchange reaction with OMC, forming β-halogenoethers[102]:

$$XCH_2CH(OR)_2 + R'MgX \rightarrow XCH_2CH(R')OR + ROMgX\,, \quad (53)$$

where R = n-C_4H_9, R′ = C_6H_5 or C_4H_9, and X = Br.

Under these conditions, the exchange takes place more readily than for the usual acetals. At first sight this finding is inconsistent with the fact that the C–O bond is ruptured before a new C–C bond is formed. However, when account is taken of the possibility of the anchimeric cooperation by the halogen atom,

$$XCH_2\overset{+}{C}H-OR \leftrightarrow CH_2-\underset{X^+}{CH}-OR\,, \quad (54)$$

the contradiction is removed.

In reactions with Iotsich complexes, bromoacetaldehyde acetals exchange their alkoxy-groups for the ethynyl group[125]. The bromine atom is not substituted under these conditions:

$$BrCH_2CH(OC_4H_9)_2 + HC\equiv CMgBr \rightarrow BrCH_2CH(C\equiv CH)OC_4H_9 + C_4H_9OMgBr, \quad (55)$$

$$2\,BrCH_2CH(OC_4H_9)_2 + BrMgC\equiv CMgBr \rightarrow 2C_4H_9OMgBr + \\ + BrCH_2CH(OC_4H_9)C\equiv CCH(OC_4H_9)CH_2Br. \quad (56)$$

The reactions of chlorodiphenylacetaldehyde with phenylmagnesium bromide, leading to acetals derived from carbon monoxide [$C(OR)_2$] and $\alpha\beta$-unsaturated ethers, have been described[134,135]:

$$(C_2H_5O)_2CHC(C_6H_5)_2Cl + C_6H_5MgBr \rightarrow (C_2H_5O)_2CHC(C_6H_5)_2MgBr + C_6H_5Cl \rightarrow \\ \rightarrow C(OC_2H_5)_2 + CH(C_6H_5)_2MgBr, \quad (57)$$

$$(C_6H_5O)_2CHC(C_6H_5)_2Cl + C_6H_5MgBr \rightarrow (C_6H_5O)_2CHC(C_6H_5)_2MgBr + C_6H_5Cl \rightarrow \\ \rightarrow C_6H_5OCH=C(C_6H_5)_2 + C_6H_5OMgBr. \quad (58)$$

However, studies by other workers[136] failed to confirm the existence of $C(OC_2H_5)_2$.

The interaction of the dibutyl acetal of bromoacetaldehyde with metallic magnesium leads mainly to butyl vinyl ether[60]:

$$BrCH_2CH(OC_4H_9)_2 + Mg \rightarrow CH_2=CHOC_4H_9 + C_4H_9OMgBr. \quad (59)$$

Similar reactions have been reported in other communications[137-139].

When α-bromoacrolein acetals are heated with Grignard reagents at 90–95°C for 3 h, unsaturated bromoethers are formed[131]:

$$CH_2=CHBrCH(OR')_2 + RMgX \rightarrow \begin{cases} \rightarrow RCHCBr=CHOR' \\ \rightarrow CH_2=CBrCH(R)OR' \end{cases}, \quad (60)$$

where R = C_4H_9, R′ = C_2H_5, and X = Br.

When a Grignard reagent reacts with the diethyl acetal of bromoacetaldehyde, β-bromovinyl ethyl ether is formed in 53% yield[28]:

$$Br_2CHCH(OC_2H_5)_2 \xrightarrow{i\text{-}C_5H_{11}MgCl} trans\text{-}CHBr=CHOC_2H_5. \quad (61)$$

The dimethyl acetal of α-bromo-β-chloropropionaldehyde exchanges only the methoxy-group in the cold for the group in the Grignard reagent[102]:

$$ClCH_2CHBrCH(OCH_3)_2 + RMgX \rightarrow ClCH_2CHBrCH(R)OCH_3 + CH_3OMgBr, \quad (62)$$

where R = n-C_3H_7 or n-C_4H_9.

The halogen in the acetals of chloropropiolaldehyde may be substituted by the group of the Grignard reagent with formation of acetals of $\alpha\beta$-acetylenic aldehydes in 40–70% yield[139]:

$$ClC\equiv CCH(OR)_2 + R'MgX \rightarrow R'C\equiv CCH(OR)_2 + MgXCl, \quad (63)$$

where R = C_2H_5 or C_4H_9, R′ = n-C_3H_7, i-C_3H_7, n-C_4H_9, i-C_4H_9, n-C_6H_{13}, n-C_9H_{19}, C_6H_5, or α-$C_{10}H_7$ and X = Br.

The acetals of halogenoalcohols as a rule exchange their halogen atom for the group of the OMC in the first place. Thus the reaction

$$CH_2CH(OR)OCH_2CH_2Cl + R'MgX \rightarrow \begin{cases} \rightarrow CH_2CH(R')OCH_2CH_2Cl \\ \rightarrow CH_2CH(OR)OCH_2CH_2R' \\ \rightarrow CH_2CH(R)OCH_2CH_2R', \end{cases} \quad (64)$$

where R = C_2H_5 or C_4H_9, R′ = C_6H_5 or $C_6H_5CH_2$, and X = Cl or Br, has been described[140]. The reaction temperature is higher than the boiling point of β-chloroethyl acetal.

When di-(β-chloroethyl) acetal reacts with benzylmagnesium chloride, both chlorine atoms are substituted by benzyl residues with formation of di-(γ-phenylpropyl) acetal[141-143]:

$$CH_3CH(OCH_2CH_2Cl)_2 + 2\,RMgX \rightarrow CH_3CH(OCH_2CH_2R)_2 + 2MgClX, \quad (65)$$

where R = C_6H_5 or $C_6H_5CH_2$ and X = Br or Cl.

Asymmetric alkyl β-chloroethyl acetals react similarly with Grignard reagents[141], but the yield of substitution products does not exceed 8%. The authors[141] note that chlorine in the β-position relative to the alkoxy-group makes the latter relatively immobile.

After prolonged heating with magnesium in ether, alkyl β-chloroethyl acetals give rise to a mixture of three products[60]:

$$2CH_3CH(OC_4H_9)OCH_2CH_2Cl + Mg \rightarrow \begin{cases} 1 \rightarrow CH_3CH(OC_4H_9)OCH_2CH_2CH(CH_3)OCH_2CH_2Cl \\ 2 \rightarrow CH_3CH(OC_4H_9)OCH_2CH_2CH_2CH_2OCH(OC_4H_9)CH_3 \\ 3 \rightarrow ClCH_2CH_2OCH(CH_3)CH(CH_3)OCH_2CH_2Cl. \end{cases} \quad (66)$$

The third pathway predominates.

5. Acetals with Other Functional Groups and Heteroatoms

The acetals of methoxyacetaldehyde[106] form glycol ethers with OMC:

$$CH_3OCH_2CH(OCH_3)_2 + RMgCl \rightarrow CH_3OCH_2CH(R)OCH_3. \quad (67)$$

The reaction of the ethoxyacetals $C_6H_5[CH(OC_2H_5)CH_2]_n.CH(OC_2H_5)_2$ with $ArCH_2MgCl$ has been discussed[144,145] as a possible pathway to the synthesis of arylated polyene hydrocarbons, which are used as organic phosphors.

Carbamoyl- and cyano-acetals react with OMC via their functional groups[106,129,146]:

$$R_2NCOCH(OC_2H_5)_2 + CH_3MgI \rightarrow R_2NC(OH)(CH_3)CH(OC_2H_5)_2 \rightarrow (C_2H_5O)_2CHCCH_3, \quad (68)$$

$$CNCH(OR)_2 + R'MgX \rightarrow R'COCH(OR)_2, \quad (69)$$

where R = C_2H_5 or C_6H_5 and R′ = C_2H_5, i-C_3H_7, n-C_5H_{11}, n-C_7H_{15}, C_6H_5, or cyclo-C_6H_{11}. The yield of ketoacetals in the latter reaction is 79–95%.

At 36°C 1-acetoxy-1-butoxyethane reacts with Grignard reagents primarily via the ester group[140,147], which is ultimately exchanged for the group attached to the Grignard reagent.

Mono- and di-thioacetals can be involved in exchange reactions with OMC[148,149] [reaction (70)]. Monothioacetals initially split off the alkoxy-group under the influence of the Grignard reagent:

$$CH_3CH(OR')(SR'') + RMgX \rightarrow CH_3CH(R)SR'' + R'OMgX, \quad (70)$$

where R = C_4H_9 or C_6H_5. The reaction of dithioacetals with Grignard reagents is much more difficult.

The reaction of organosilicon acetals with OMC has been described[110,140,150]. The alkoxy-group containing the silicon atom is exchanged regardless of whether it is linked to oxygen directly or is more remote. This mode of reaction is difficult to explain. The corresponding ethers are usually obtained in yields up to 70%.

The capacity of organosilicon groups in acetals for exchange decreases in the sequence[150] $OSi(CH_3)_3 > OSi(C_2H_5)_3 > OCH(CH=CH_2)CH_2Si(CH_3)_2C_2H_5$.

In organogermanium acetals the germanium-containing groups are also exchanged for the group of the Grignard reagent[60].

IV. CYCLIC ACETALS (1,3-DIOXACYCLANES) AND THEIR ANALOGUES

Cyclic acetals play an important role in synthetic organic chemistry. The protection of vicinal hydroxy-groups of carbohydrates and sugars by acetal groups is widely known. The protection of the carbonyl group by the acetal group has been used successfully in the industrial synthesis of steroids and terpenoids.

Although 1,3-dioxacyclanes do not differ in principle in any way from open-chain acetals, nevertheless their cyclic structure is responsible for one characteristic feature which justifies the consideration of the reactions of 1,3-dioxacyclanes with OMC in a separate section. This feature is that 1,3-dioxacyclanes do not lose their oxygen-containing fragment on cleavage of the C–O bond by OMC in the way that open-chain acetals do.

As shown above, the exchange reactions of acyclic acetals with OMC have been investigated in fair detail. On the other hand, systematic studies on the analogous reactions of 1,3-dioxacyclanes began only recently. It appeared for a long time that 1,3-dioxacyclanes are fully resistant to the action of OMC. This was indicated by many facts. Thus 1,3-dioxolans with methyl substituents at $C_{(4)}$[44] or at $C_{(4)}$ and $C_{(5)}$[34] were suggested as solvents for Grignard syntheses. According to Nazarov[151], a bicyclic acetal with a complex structure, consisting of two 1,3-dioxolan fragments, does not react with OMC under the usual conditions. Many examples are known in which 1,3-dioxacyclanes containing functional groups react with OMC only via these functional groups without the cleavage of the C–O bonds in the acetal ring. In particular, the methylation of the terminal acetylenic group in 2-but-3-ynyl-2-methyl-1,3-dioxolan by ethylmagnesium bromide and methyl iodide in THF has been described[152]. The cleavage of the C–O bond has not been observed either in reactions of various carbonyl derivatives of 1,3-dioxolans with OMC[31,153-155].

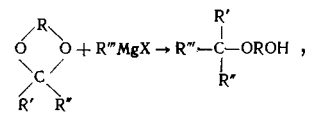
The interaction of 2-methoxy-1,3-dioxolans with OMC on heating leads to 2-alkyl(aryl)dioxolans[156]. The formation of OMC from cyclic five-membered acetals derived from saturated and unsaturated halogenoketones, including aromatic and heteroaromatic ketones, has been described[99,144,157].

The ethylene acetal of chloral is reduced by Grignard reagents to the dichloroacetaldehyde acetal in 74% yield[28].

When cyclic acetals of certain dihalogenoketones are treated with metallic magnesium, a three-membered ring is formed. The C–O bonds are not then affected[106]. All the data quoted above appear to have created a psychological barrier to studies on the cleavage of 1,3-dioxacyclanes by OMC. A few early studies[158-161] at the beginning of the century, in which the formation of the monoethyl ether of catechol from its formal on prolonged heating with methylmagnesium iodide was mentioned, were not developed further and were undeservedly essentially forgotten until the 1960's.

1. The Cleavage of 1,3-Dioxacyclanes by Grignard Reagents

Reactions involving the opening of the ring in various cyclic acetals by OMC [reaction (71)], leading to glycol monoethers (cellosolves), have been described almost simultaneously and independently by two research teams[2,34]:

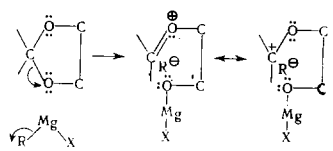


(71)

where R = $(CH_2)_2$, $(CH_3)CHCH_2$, $(CH_3)CHCH_2CH_2$, R′ = H, CH_3, or C_2H_5, R″ = H, C_2H_5, C_3H_7, or n-C_4H_9, R‴ = CH_3, C_2H_5, n-C_4H_9, C_6H_5, or CH_2=$CHCH_2$, and X = Br or I.

Cellosolves are usually obtained by the addition of alcohols to epoxyalkanes. The reaction is carried out in the presence of various catalysts[162] or by heating in an autoclave[163]. A mixture of ethers of mono-, di-, and tri-alkylene glycols, which are capable of interconversions under the reaction conditions, is as a rule formed[163]. The reaction of 1,3-dioxacyclanes with Grignard reagents made it possible to develop a fundamentally new method[5,6] for the preparation of a wide variety of glycol monoethers. The reaction is carried out at 60–130°C in solvents (benzene, toluene, or xylene) or in an excess of the acetal itself. The yield of hydroxyalkyl ethers depends on the structure and nature of the initial reactants, their proportions, the duration of heating, and the medium, reaching 82%.

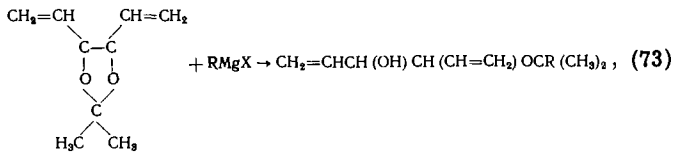
More than 30 different glycol monoethers obtained in this way have been described[22-24]. Cyclic formals are resistant to the action of Grignard reagents under the conditions investigated. As alkyl substituents accumulate in the 2-position, the reaction accelerates and the yield of cellosolves increases[22-24]. This behaviour is consistent with data for the influence of substituents on the hydrolysis[164,165] of 1,3-dioxacyclanes and also on their cleavage by halogenoacyls[166-170] and is probably due to similar causes: a change in electron density at the oxygen atoms which are the object of the primary electrophilic attack and in the stability of the intermediate carboxonium ion[24]. This finding conflicts with the concept of the primary nucleophilic attack on the $C_{(2)}$ atom, since under such conditions the electron-donating substituents in the 2-position should have retarded the process. The facilitation of the reaction with increase of the electron-donating capacity of substituents in the 2-position shows that the $C_{(2)}$–O bond dissociates before the formation of a new $C_{(2)}$–R bond (R is the group attached to OMC). The following mechanism has been proposed for the opening of the 1,3-dioxolan ring by OMC[34]:



(72)

According to mechanism (72), an increase in the electron-donating influence of the alkyl substituents in the 2-position should facilitate the cleavage of the acetal ring. The results of Blomberg at al.[34] indicate that ethylmagnesium bromide hardly reacts at room temperature with 2-methyl-1,3-dioxolan, while 2-ethyl- and 2-n-propyl-1,3-dioxolans form hydroxyethers under these conditions in yields of 39 and 78% respectively. The bulk of the alkyl groups in the Grignard reagent is reflected in the course of the reaction only when the dioxolan ring contains fairly bulky substituents[34]. The corresponding hydroxyethers have been obtained from the ethylene ketal of cyclohexanone on treatment with two equivalents of a Grignard

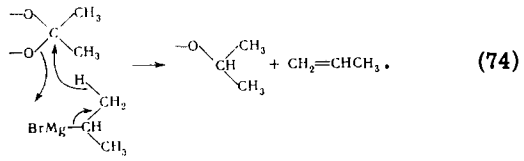
reagent in 91% yield (75°C, 16 h, benzene).[33] The reaction of 4-alkoxymethyl-2,2-dialkyl-1,3-dioxolans with ethylmagnesium bromide leads to the corresponding glycerol ethers[171]. The reactions of 2,2,4,4-substituted 1,3-dioxolans with various Grignard reagents [reactions (73)–(76)] have been described[29]‡:



(73)

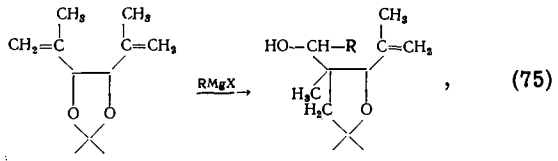
where R = CH_3 (X = I), C_2H_5, i-C_3H_7, or C_6H_5 (X = Br).

When R = i-C_3H_7, a reduction takes place:



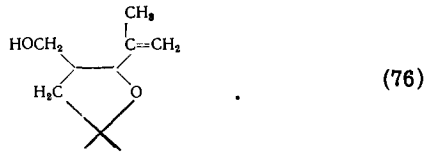
(74)

cis-Isomers undergo isomerisation:



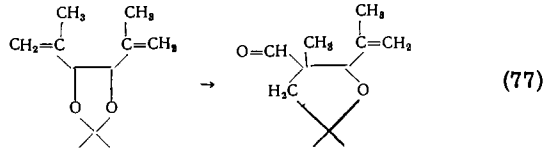
(75)

a primary alcohol being obtained with i-C_3H_7MgBr:



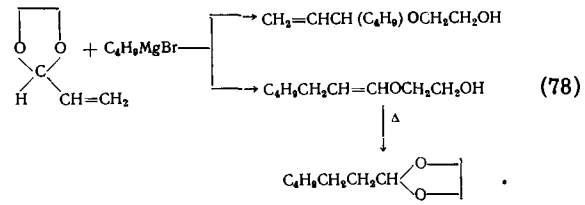
(76)

A rearrangement of similar acetals to furan aldehydes is known[173]:



(77)

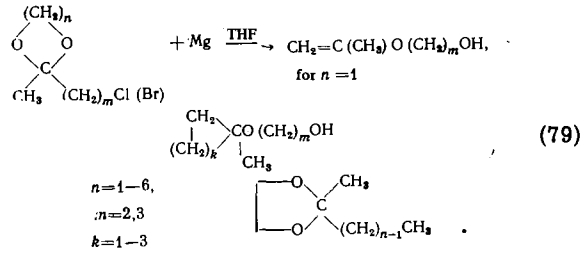
The latter are probably intermediates in the isomerisation described by Mousset[29]. When butylmagnesium bromide reacts with the cyclic acrolein acetal, the vinyl group is alkylated in addition to the normal mode of reaction [reaction (78)]. The process is accompanied by a prototropic rearrangement[130]:



(78)

‡ These problems are discussed in greater detail by Mousset[172].

The reactions of ω-halogenoalkyl-1,3-dioxolans with metallic magnesium have been considered[28,96,174]:

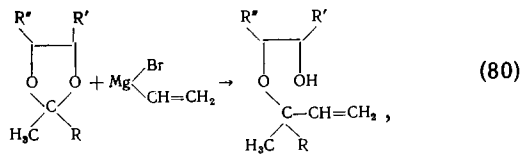


(79)

When $n = 3$, the formation of hydroxyethers is already accompanied by the reduction of the ω-halogenoalkyl substituent, which leads to the appearance in the reaction mixture of the corresponding 2-alkyl-2-methyl-1,3-dioxolans; when $n = 5$ or 6, the reduction becomes the only pathway followed in the process.

2. The Cleavage of 1,3-Dioxacyclanes by Vinylmagnesium Bromide and the Iotsich Reagent

Compared with saturated OMC, which readily rupture the C–O bonds of cyclic acetals and ketals, vinylmagnesium bromide is much less reactive in relation to these compounds[14]. Thus 2-ethyl-2-methyl-1,3-dioxolan begins to react with vinylmagnesium bromide only under relatively severe conditions (120°C, xylene):

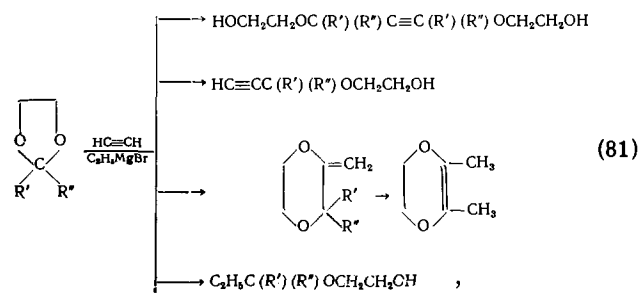


(80)

where R = H, C_2H_5, C_3H_7, or C_4H_9, R′ = CH_3, and R″ = CH_3.

β-Hydroxyalkyl ethers of ethylenic alcohols are obtained in yields of about 10%. 2-Butyl-2-methyl-, 2-ethyl-2,4-dimethyl-, and 2-ethyl-2,4,5-trimethyl-1,3-dioxolans were introduced into the reaction. Unsaturated β-hydroxyalkyl ethers could not be isolated in the case of 2-methyl- and 4-methyl-2-propyl-1,3-dioxolans, i.e. here too the conclusion that the reactivity of 1,3-dioxolans is reduced as the electron-donating properties of the substituents in the 2-position are weakened remains valid.

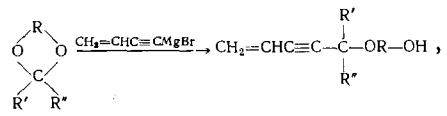
The cleavage of cyclic acetals by ethynylmagnesium bromide [reaction (81)] is accompanied by side reactions. A complex mixture containing, according to gas–liquid chromatographic and infrared spectroscopic data, various cyclisation products of the expected ethynyl ethers in addition to the ethers themselves as well as saturated hydroxyethers corresponding to the opening of the dioxolan ring by the initial Grignard reagent, is formed as a rule[19,22–24]:



(81)

where R′ = H or CH_3, R″ = CH_3 or C_2H_5, and R′,R″ =  or .

A number of hydroxyalkyl ethers derived from vinylethynylmethanols have been obtained in yields up to 80% by the reaction of various 1,3-dioxolans with vinylethynylmagnesium bromide (VEMB)[4,6,8,10,15,16]:



(82)

where R = $(CH_2)_2$ or $CH_2CH(CH_3)$, R′ = H or CH_3, and R″ = H, CH_3, C_2H_5, C_3H_7, or C_6H_{13}. In this process too the reactivity of 1,3-dioxolans increases somewhat with increase of the number and electron-donating capacity of substituents in the 2-position. Thus, whereas the yields of the hydroxyethyl ethers from 2-methyl- and 2-ethyl-2-methyl-1,3-dioxolans were 44.3 and 58.3% under comparable (but not optimal) conditions, unsubstituted 1,3-dioxolan could not be cleaved at all by VEMB.

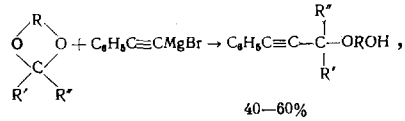
The introduction of the methyl group in the 4- or 5-position does not affect the reactivity of 1,3-dioxolan quite so significantly, although the latter is also apparently somewhat activated. One of the most important factors affecting the yields of hydroxyalkyl ethers derived from vinylethynyl alcohols is the reactant ratio[10] (see Table).

Variation of the yield of the vinyloxyethyl ether derived from methylvinylethynylmethanol with the initial reactant ratio.

Molar ratio 2-methyl-1,3-dioxolan : VEMB	Yield (w.r.t. VEMB), %
1:2	80
1:1	39.2
2:1	21.9

The yield of hydroxyethers depends no less significantly on the solvent. In ethyl ether the yield does not exceed 10%. When all the stages of the synthesis, including the preparation of the Grignard reagent, are carried out in the reacting acetal, it was possible to obtain the hydroxyether in yields up to 45%.[10] The effect of the halogen entering into the composition of the Iotsich complex on the yield of hydroxyethers has not been studied systematically. In the only relevant study[10] the use of $CH_2{=}CHC{\equiv}CMgI$ instead of VEMB (reactant ratio 1 : 1, benzene, 56–66°C, 2 h) was unsuccessful. The addition of catalytic amounts of $CoCl_2$ for an equimolar reactant ratio increases the yield to 57% compared with 39% (benzene, 80–90°C, 1.5 h). Higher $CoCl_2$ concentrations do not favour the reaction[10].

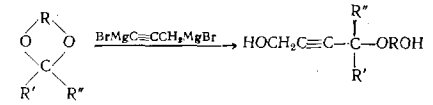
A number of β-hydroxyethyl ethers derived from secondary and tertiary phenyl-substituted acetylenic alcohols were obtained[7] from 1,3-dioxolans and phenylethynylmagnesium bromide:



40–60% (83)

where R = $(CH_2)_2$ or $(CH_2)_3$, R′ = H or CH_3, R″ = CH_3, C_2H_5, or C_3H_7, and R′ = R″ = . The reaction proceeds at 60–80°C. Iotsich complexes can be used under these conditions in the form of ether adducts with subsequent distillation of the ether, but they can be formed just as conveniently directly in the reacting cyclic acetal. To prevent the competing process, involving the saturated organomagnesium compound used to prepare the Iotsich complex, the intermediate Grignard reagent must then be synthesised at the lowest possible temperature (not above 40°C). Unsubstituted 1,3-dioxolan is resistant to the action of phenylethynylmagnesium bromide even at 100–120°C (xylene).

β-Hydroxyalkyl ethers of asymmetric acetylenic glycols were obtained by the reaction of certain 1,3-dioxolans with propynylenedimagnesium dibromide[3,24]:

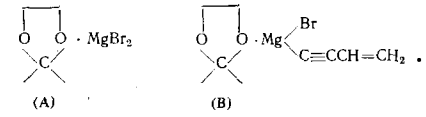


(84)

where R = $(CH_2)_2$ or $CH(CH_3)CH(CH_3)$, R′ = H or CH_3, and R″ = CH_3, C_2H_5, or C_3H_7.

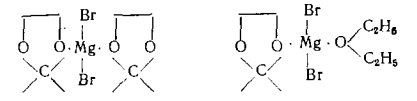
3. Complex Formation Processes

Like 1,4-dioxan, 1,3-dioxolans[175,176] can precipitate MgX_2 and RMgX from OMC solutions[8,10]. In the case of VEMB[8,10] the precipitate consists mainly of a mixture of the dioxolanates (A) and (B) in proportions of approximately 2 : 1:



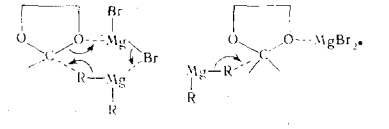
(A) (B) (85)

Small amounts of solvates of the type



(86)

were detected in the precipitate in addition to the complexes (A) and (B).[8,10] Thus ether adducts of Iotsich complexes probably have the same structure as the ether adducts of saturated magnesium halides and can be regarded as a mixture of $(CH_2{=}CHC{\equiv}C)_2Mg$ (40%), $MgBr_2$ (40%), and $CH_2{=}CHC{\equiv}CMgBr$ (20%). The reaction most probably proceeds via a synchronous electron transfer in cyclic or linear complexes[8,10]:



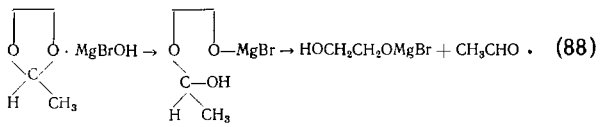
(87)

In such concerted nucleophilic substitution, the coordination O → $MgBr_2$ should play the most significant role. If the nucleophilic attack C_2 ← R were the most important factor, then electron-donating substituents at $C_{(2)}$ would hinder the reaction. The proposed mechanism gives a completely natural explanation of the requirement of at least a twofold excess of the Iotsich complex for the attainment of the maximum yield of hydroxyethers. A similar mechanism has been proposed for the cleavage of certain unsaturated acetals by OMC.[130]

Insoluble complexes with certain 1,3-dioxolans are also formed by ethylmagnesium bromide. The principal components of the complexes are $MgBr_2$, C_2H_5MgBr, and

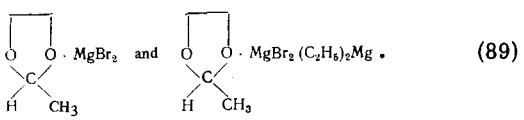
the corresponding dioxolan. The composition of the complexes is not constant and depends on the structure of the initial acetal, the reactant ratio, temperature, and the time of contact between the solid phase and the solution. It has been established for unsubstituted 1,3-dioxolan[10,11] that a decrease of temperature reduces the content of OMC in the precipitate. Gradual binding of 2-methyl-1,3-dioxolan by anhydrous $MgBr_2$ was observed[11]. The infrared spectrum of this complex hardly differs from that of the complex obtained from ethylmagnesium bromide at −20°C.

Basic magnesium salts are also capable of coordination interaction with cyclic acetals. However, the resulting complexes are unstable and tend to undergo further reactions (particularly on heating) with ring opening:



(88)

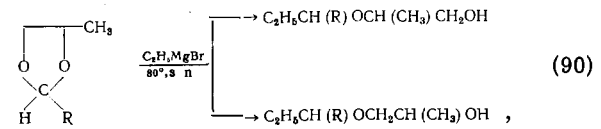
The rate of change of the OMC concentration in solution in the reaction between ethylmagnesium bromide and 2-methyl-1,3-dioxolan at 18°C has been measured[11]. The sharp decrease of the OMC concentration at the beginning of the reaction corresponds to the precipitation of the complex [the OMC concentration probably falls not only as a result of the binding of C_2H_5MgBr but also as a result of the adsorption of $(C_2H_5)_2Mg$ at the instant of the formation of the precipitate]; subsequently the OMC concentration over the precipitate changes much more slowly. Presumably the consumption of the OMC in this stage is due to the ring opening reaction itself. However, gas–liquid chromatographic analysis of the products of the hydrolysis of the reaction mixture failed to reveal even traces of the expected β-hydroxyethyl ether. The results correspond to the consecutive formation of complexes of two types:



(89)

4. The Mode of Cleavage of Asymmetrically Substituted 1,3-Dioxacyclanes

When 4-alkyl- and 2,4-dialkyl-1,3-dioxolans react with Grignard reagents[9], the products may be two structurally isomeric β-hydroxyalkyl ethers differing only by the position of the hydroxy-group—at the first carbon atom in one and at the second carbon atom in the other:

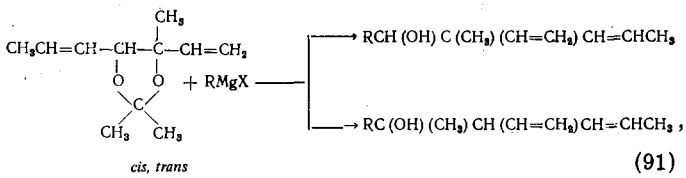


(90)

where R = CH_3 or C_3H_7.

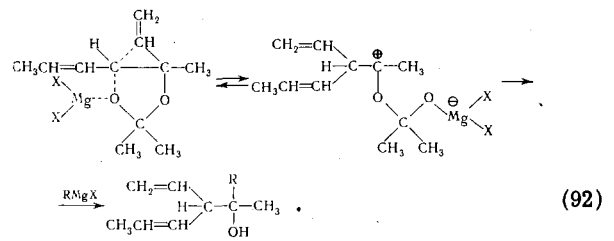
However, it was found[9] that the reaction results in the almost exclusive formation of 2-hydroxy-1-methylethyl ethers. The admixture of the second isomer is slight, amounting to about 4% of the first.

Interesting rearrangements were discovered[30] in the following reaction:



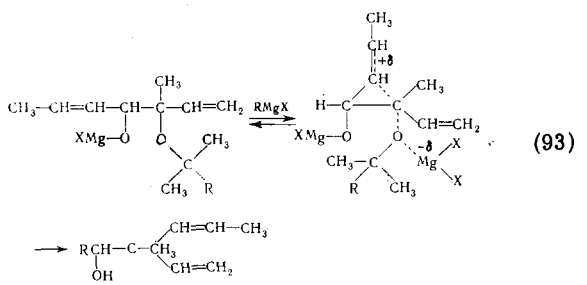
(91)

where R = CH_3 (X = I), C_2H_5, or C_6H_5 (X = Br). The formation of the tertiary alcohol begins with the rupture of the $O_{(1)}-C_{(5)}$ bond:



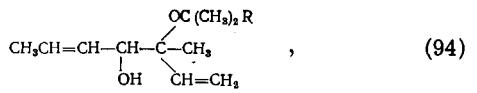
(92)

The cleavage of the $O_{(1)}-C_{(2)}$ bond leads to a secondary alcohol:



(93)

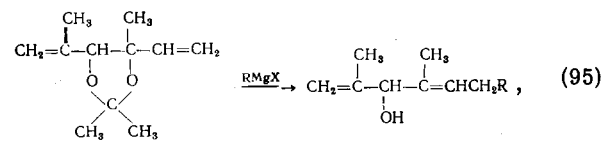
Thus both the tertiary and secondary alcohols are products of the attack by the OMC on the $O_{(1)}$ oxygen atom. The formation of hydroxyethers with the ether function at the tertiary carbon atom having the structure



(94)

which should have been obtained as a result of attack on the $O_{(3)}$ atom, was never observed in these reactions[30].

The cleavage of the C–O bond under the influence of a Grignard reagent in another 1,3-dioxolan with a structure very similar to that considered above was accompanied by the alkylation of one of the double bonds and its subsequent migration to the centre of the molecule[30]:



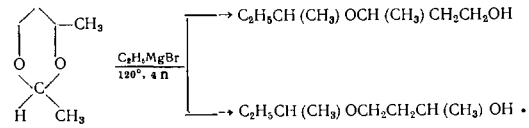
(95)

where R = CH_3 (X = I), C_2H_5, or C_6H_5 (X = Br).

The *cis*- and *trans*-isomers of 2,3-dimethyl and 4-methyl-2-propyl-1,3-dioxolans are cleaved by Grignard reagents at different rates[9]. The *cis*-isomers proved to be more reactive. This shows that the $O \rightarrow MgBr_2$ bond is oriented in space at a certain angle to the plane of the dioxolan ring, since otherwise the isomers of 2,4-dialkyl-1,3-dioxolans would be sterically indistinguishable in the formation of the intermediate complex[9]. These data, demonstrating a lower reactivity of 1,3-dioxolans with the

trans-disposition of the substituents with respect to the Grignard reagent, were subsequently confirmed in another study [30].

In contrast to asymmetrically substituted 1,3-dioxolans, 2,4-dimethyl-1,3-dioxan is cleaved by ethylmagnesium bromide with formation of two possible isomeric hydroxyethers in proportions of approximately 1 : 1 [17]:



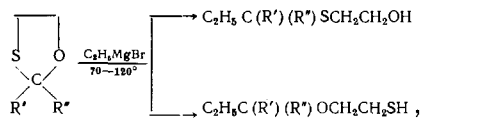
(96)

The change in the structural specificity of the cleavage of acetal rings on passing from five- to six-membered rings is associated with the conformations of the compounds. In contrast to the almost planar 1,3-dioxolans, 2,4-dimethyl-1,3-dioxan has the chair conformation with the *cis*-equatorial disposition of the CH_3 groups [17]. The 1 : 1 ratio of the isomeric hydroxyethers formed from this acetal shows that the *cis*-*e*,*e*-conformation to a large extent eliminates the steric hindrance to the interaction $O \rightarrow MgBr_2$, which is the initial stage in the cleavage of the 1,3-dioxacyclane.

However, the degree of structural specificity of the reaction depends on the bulk of the OMC molecules. When branched groups and bulky halogen atoms are present, the above effect of steric descreening of the $O_{(3)}$ atom in the 1,3-dioxan ring is insufficient for a preferential cleavage of the $O_{(1)} - C_{(2)}$ bond, of the kind observed in the cleavage of 2,4-dimethyl-1,3-dioxan by isobutylmagnesium bromide [17]. Thus the mode of cleavage of asymmetrically substituted 1,3-dioxolans and 1,3-dioxans is determined not only by the ring conformation but also to a similar extent by the steric characteristics of the OMC components [17].

5. The Cleavage of 1,3-Oxaheterocyclanes by OMC

1,3-Oxathiolans are cleaved by ethylmagnesium bromide with formation of 2-ethylthioethanols only [18,24]:

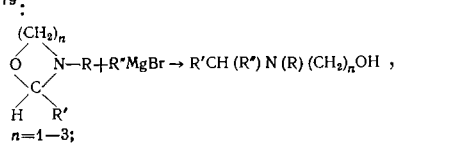


(97)

where R′ = H or CH_3 and R″ = H, CH_3, C_2H_5, or C_3H_7.

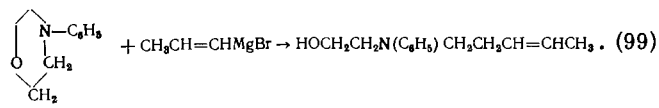
The unsubstituted ring is stable in the experimental temperature range (70–120°C). Compared with the corresponding 1,3-dioxolans, 1,3-oxathiolans are less reactive with respect to OMC [18]. Yet another feature of the reaction has been noted [18,23,24]: in contrast to 1,3-dioxolans, the introduction of two alkyl groups in the 2-position increases the stability of the 1,3-oxathiolan ring. 2-Monoalkyl-1,3-oxathiolans are the most reactive. This influence of substitution is evidence that in this instance the dissociation of the C–O bond does not precede appreciably the formation of the C–R bond, i.e. the reaction approaches the S_N2 type [18].

1,3-Oxazolidines are also cleaved by OMC at the C–O bond [115,177–179]:



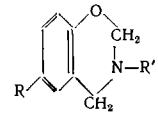
(98)

where R = H, CH_3, n-C_4H_9, i-C_4H_9, $(CH_3)_2CHCH_2$, or C_6H_5, R′ = H, CH_3, i-C_3H_7, or C_6H_5, and R″ = CH_3, $C_6H_5CH_2$, $(CH_3)_2CH$, CH_2=CH, or CH_3CH=CH_2. The yield of amino-alcohols reaches 80% in some cases. The reaction between 1,4-oxazolidines and propenylmagnesium bromide proceeds similarly [115]:



(99)

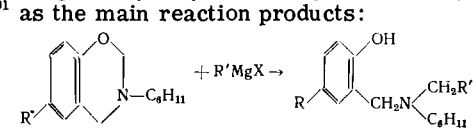
It has been found [180] that 2-oxazolidines of the type



(100)

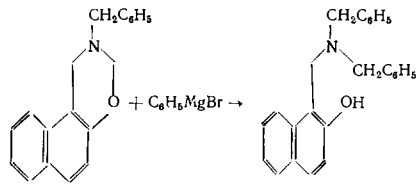
unsubstituted in the 2-position, do not react with CH_3MgI. However, later it was observed [181] that, when oxazines of similar structure are acted upon by a large excess of C_6H_5MgBr, the cleavage products are nevertheless formed in 8% yield.

When OMC interact with certain 1,3,2-dibenzoxazines, the benzoxazine ring is ruptured with formation of the corresponding 4-alkyl(aryl)-2-dialkylaminomethylphenols [74,101] as the main reaction products:



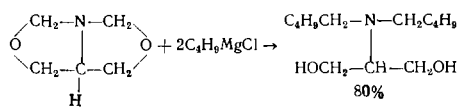
(101)

where R = $C(CH_3)_3$ or C_6H_5, R′ = CH_3, $(CH_3)_2CHCH_2$, C_6H_{11}, $C_6H_5CH_2$, or CH_2=$CHCH_2$ and X = Br, Cl, or I. The reaction is carried out in the presence of an excess of OMC. A similar reaction



(102)

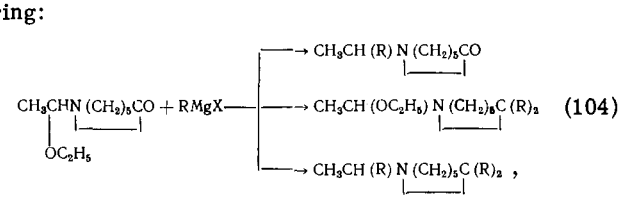
has been described [181]. The reaction



(103)

takes place at room temperature in the course of 24 h. [177]

N-(1-Ethoxyethyl)lactams [182,183] initially exchange preferentially the ethoxy-group for the group in the OMC and then the reaction involves the C=O bond with retention of the ring:

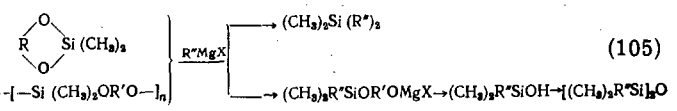


(104)

where R = C_3H_7, C_4H_9, or i-C_5H_{11} and X = Br.

1,3-Dioxa-2-silacyclanes and their oligomers [20,25] readily undergo ring opening under the influence of alkyl-(aryl)magnesium halides at a temperature as low as 30–40°C with formation of trialkyl(diaryl)silylglycol monoethers. In addition, the second Si–O bond is also ruptured with formation of tetra-alkyl(trialkylaryl)silanes, whose yields increase in the presence of an excess of the

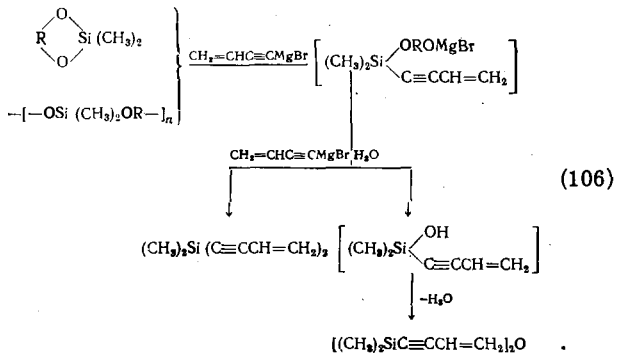
Grignard reagent and on raising the reaction temperature to 70–80°C:



(105)

where $R' = (CH_2)_2$, $(CH_2)_2O(OCH_2)_2$, or $(CH_2)_4$ and $R'' = C_6H_5$, C_3H_7, C_4H_9, or C_6H_5.

The cleavage of cyclic alkoxysilanes or the elementary units in the corresponding oligomers by VEMB proceeds as follows:[22,25]



(106)

The reaction occurs at 60–90°C. The above examples show that the Si–O bond is more reactive with respect to OMC than the C–O bond.

Specific Complex Formation in Aqueous Solutions Involving Mononucleotides and Oligonucleotides

N.I.Sokolova, V.K.Kagramanova, and N.G.Dolinnaya

Data on complex formation between synthetic polynucleotides and complementary oligo(mono)nucleotides are reviewed and analysed. The principal methods for the investigation of complexes are examined and the limits of their applicability are estimated. Attention is concentrated on the complex formation conditions (temperature, ionic strength, pH, concentration, component ratio, etc.). The influence of the nature of the heterocyclic base and the sugar and of the length of the oligonucleotide chain on the stoichiometry and thermal stability of the complexes is discussed.
The bibliography includes 150 references.

CONTENTS

I. Introduction 56
II. Fundamental principles of formation of oligomer (monomer)-polymer and oligomer-oligomer complexes 56
III. Complexes of monomers with polynucleotides 60
IV. Complexes of oligonucleotides with polynucleotides 63
V. Interaction of complementary oligonucleotides 67

I. INTRODUCTION

Numerous studies have been made in recent years on the interaction between complementary mononucleotides, oligonucleotides, and polynucleotides in connection with the expansion of research on the secondary structure of nucleic acids and on the relation between the structures of native macromolecules and their biological functions.

One of the approaches used to elucidate the causes and characteristics of the formation of involved native nucleotide complexes is based on the study of simpler synthetic systems. Recent studies have shown that such systems are convenient models for the investigation of many problems in molecular biology (codon–anticodon interactions[1], the problem of protein biosynthesis[2], DNA replication[3,4], etc.).

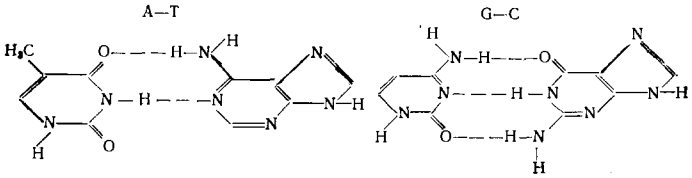
The study of the ability of mononucleotides, oligonucleotides, and polynucleotides to form DNA-like complexes in aqueous solution is also important from the standpoint of bio-organic chemistry in connection with the development of new approaches to non-enzymatic oligonucleotide synthesis on matrices[5-7].

Data published up to 1973 on specific interactions in simplest nucleotide systems are arranged systematically in the present review. Studies on monomer–polymer, oligomer–polymer and oligomer–oligomer complexes are considered, but problems of polynucleotide–polynucleotide interaction, which have been examined in a number of papers and monographs[8-10], as well as certain general problems such as theoretical consideration of the nature of the forces involved in complex formation[11-13] and the modern treatment of the "helix–coil" transition[14-16] are not discussed.

II. FUNDAMENTAL PRINCIPLES OF THE FORMATION OF OLIGOMER(MONOMER)–POLYMER AND OLIGOMER–OLIGOMER COMPLEXES

The capacity for the formation of specific intermolecular complexes in aqueous salt solutions is not characteristic solely of polynucleotides. It has been shown that short oligomers can also form under appropriate conditions ordered intermolecular structures with one another and with polymer molecules[17-25]. The formation of complexes by oligonucleotides and polynucleotides as well as native nucleic acid macromolecules is determined by three fundamental factors: the interaction of the heterocyclic bases (complementary and interplanar), the effect of the solvent, and the electrostatic effects of the phosphate groups.

Complementary (tranverse) interactions result in specific binding to one another of definite heterocyclic bases in adjacent polymeric (oligomeric) chains: adenine interacts with uracil (thymine) and guanine interacts with cytosine[26]:



The theoretical aspects of the problem of the stability of hydrogen-bonded pairs of bases are considered in the monograph of Kochetkov and Budovskii[10].

Interplanar longitudinal "stacking" interactions play an important role in creating a specific conformation of the mononucleotide, oligonucleotide, and polynucleotide chains involved in complex formation and ensure stability of the complex. By virtue of hydrophobic forces, the heterocyclic bases of each chain are arranged in a stack, in an attempt to avoid contact with water molecules; this is caused by the energy gain as a result of the entropy factor associated with the change in the number of structured water molecules around the dissolved substance when its molecules are associated to form a complex. Furthermore, the process is accompanied by a decrease in the surface tension energy due to the change in the surface area of the molecules on passing from the hydrated bases to their association complexes.

Using gel chromatography in conjunction with thermodynamic calculations, Bresler et al.[27] showed that the total

energy of the hydrogen bonds is much higher than the energy of the stacking interaction. On the other hand, it was believed previously that hydrogen bonds do not contribute significantly to the stabilisation of the complex[23].

Apart from the interaction between the bases and the influence of the solvent, the charges of the phosphate groups are an important factor. Whereas the binding of the heterocyclic bases to one another and to water molecules stabilises the complex, the repulsion of the negatively charged phosphate groups destabilises it.

A distinctive feature of the complexes considered in the present review is their marked dependence both on the overall concentration of the nucleotides and on the excess energy of the oligo(mono)nucleotide component in relation to the polymeric matrix[28]. A qualitative explanation of the latter has been given by Pitha and Ts'o[29] and by Uhlenbeck et al.[30] These workers showed that the local concentration of the monomeric units of two polynucleotides of comparable length in the interaction volume is fairly high. Under such conditions, the degree of complex formation is independent of the polymer concentration in solution.

On the other hand, when one of the chains forming the helix consists of mononucleotides or short oligonucleotides, the degree of complex formation is consistent with the law of mass action.

In an oligomer–polymer system the overall concentration of the oligonucleotide affects significantly its local concentration near the polymeric molecules and for this reason the degree of complex formation depends on the overall nucleotide concentration in accordance with the law of mass action.

In monomer–polymer systems the local concentration of the monomeric units is determined directly by the overall concentration of the monomer. Thus the concentration variation of the degree of complex formation in these systems should be most pronounced. The study of various oligonucleotide–polynucleotide complexes revealed a linear relation between $1/T\mathrm{m}$ and $\lg c$ (c is the concentration of the oligomer calculated in terms of the base and $T\mathrm{m}$ is the melting point)[28]. The slope of the experimental straight line depends on the length of the oligonucleotide chain. A general property of complementary complexes is the dependence of their stability on the ionic strength of the solution.

The contribution of electrostatic forces to the free energy of the "helix–coil" transition is specified by the equation[31]

$$\Delta E_{el} = RT(C_1 - C_2 \lg I),$$

where C_1 and C_2 are empirical constants and I is the ionic strength of the solution.

A linear relation between the melting point and $\lg I$ has been found for polymer–polymer systems[31,32]. It has been shown that the melting point of the complex increases with ionic strength. The same behaviour is characteristic of the oligo A-poly U system[33]. The stability of monomer–polymer complexes depends particularly strongly on the concentration of salts.

The presence of Mg^{2+} ions stabilises appreciably oligomer(monomer)–polymer complexes[34]. For example, an increase of the Mg^{2+} concentration in the $(pA)_4$–poly U system by a factor of 4 (from 10^{-3} M to 4×10^{-3} M) increases the melting point of the complex by 6.5 deg C.[35]

The most important property common to specific intermolecular complexes formed from both short and long nucleotide chains, is the cooperative nature of the decomposition of such structures, which is reflected in a comparatively narrow range of temperatures separating the ordered complex from the disrupted structure. At present the problem of the cooperative nature of the "helix–coil" transition is being solved within the framework of theories in which this process is considered from the standpoint of statistical physics. The essential feature of the cooperative transition is that its different stages do not occur independently but are interrelated and that the disruption of even one section of the helix leads to rapidly progressing breakdown of the entire structure. The cause of cooperative fusion is the breakdown of the interplanar interaction between pairs of bases[36]. The extent of the cooperative transition can be different for different systems and is characterised by the cooperativity factor $\sigma = e^{-E/RT}$, where E is the free energy of the stacking interaction of two isolated pairs of bases linked by hydrogen bonds.

1. Methods for the Investigation of the Complexes

The formation of helical nucleotide complexes in solution is accompanied by a significant change in their properties compared with those of the free components—an increase in molecular weight and rigidity of the structures, an increase in optical activity, the occurrence of hyperchromic and hypochromic effects in the absorption region, etc. This makes it possible to record and investigate the complexes by a number of physicochemical methods: infrared and ultraviolet spectroscopy[5,37], optical rotatory dispersion and circular dichroism[38,39], sedimentation analysis[40], viscometry[34], proton magnetic resonance (^{1}H NMR),[41] calorimetry[42], etc. In studies on oligomer–oligomer and oligomer(mono)–polymer systems optical methods are most widely used and these will be considered in somewhat greater detail.

Ultraviolet spectroscopy. Under complex formation conditions, the ultraviolet absorption intensity changes relative to the overall absorption intensity of the individual components. Depending on the wavelength of the absorbed light, the molar extinction coefficient of the complex can then be smaller (hypochromic effect) or greater (hyperchromic effect) than the sum of the corresponding extinction coefficients of the components or it can be equal to this sum. In the region of the absorption maximum the absorption intensity usually decreases on formation of the complex (Fig. 1). In certain cases where the initial components have an intrinsic secondary structure the formation of the intermolecular complex is accompanied by an increase in absorption[43].

The hypochromic effect is characterised by the percentage of hypochromicity ($\%h$) and reflects the degree of the stacking interaction between the bases in the complex. The temperature variation of the absorption of the solutions at a specified wavelength is usually determined by ultraviolet spectroscopy and the "melting" curves are plotted[9]. A number of thermodynamic characteristics can be calculated from the variation of the thermal stability of the complex ($T\mathrm{m}$) with the chain length of the oligomers and their concentration[33].

In the interaction between homo-oligonucleotides and polynucleotides the wavelength at which the molar extinction coefficient of the complex is equal to the sum of the extinction coefficients of the components serves as a characteristic from which one can infer the approximate

stoichiometry of the complex. The relation between the isochromatic wavelength and the stoichiometry of the complex was established by Stevens and Felsenfeld[44]. Subsequently Blake et al.[45] showed that this characteristic wavelength is 280 nm for 1A.1U double helices and 283.5 nm for the three-chain complex 1A.2U.

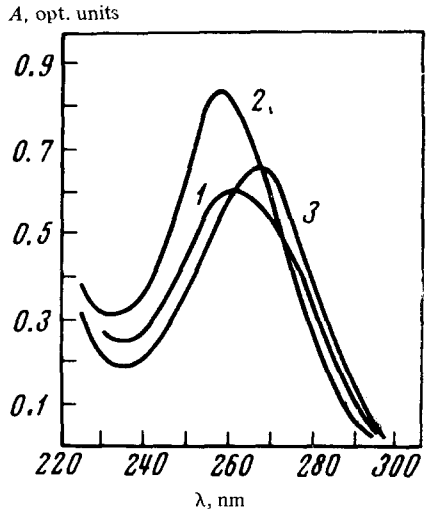


Figure 1. Ultraviolet spectra: 1) of the complex $A(pA)_7 \cdot d(pT)_8$; 2) of the component $A(pA)_7$; 3) of the component $d(pT)_8$ (9.4×10^{-6} M nucleotides, 1 M NaCl, pH 7.0, −5°C).[36]

Thus ultraviolet spectroscopy can yield all the necessary information about the interaction in the given system and its only disadvantage is that it is inconvenient for the investigation of solutions with a high concentration of nucleotides.

Optical rotatory dispersion (ORD) and circular dichroism (CD). In the formation of complexes of synthetic oligonucleotides and polynucleotides appreciable changes are observed in ORD and CD spectra: the shift of the 0–0 transition point to the short-wavelength region and the change in the amplitude of the Cotton effect[46–48]. The ORD or CD curve for the complex is usually compared with the overall curve obtained by adding together the curves for the individual components (taking into account their mole fractions in the complex) or with the ORD or CD curve for the mixture of the components at a temperature greater than the melting point of the complex. Useful information about complex formation is also provided by the "melting" curve reflecting the temperature variation of the molar ellipticity of the molar rotation measured at a specified wavelength. It is noteworthy that a hypsochromic shift of the ORD and CD spectra, a change in optical activity, and hypochromic effects in ultraviolet spectroscopy can be caused not only by the formation of specific complexes but also by the formation of various homoassociation.complexes. As a result, the experimental data for systems where a specific interaction is accompanied by the homoassociation of the components must be corrected[39].

Infrared spectroscopy. The stretching vibration wavenumbers of the NH_2, HN, and O=C< groups of the pyrimidine and purine bases change when these groups are involved in the formation of hydrogen bonds[49,50]. This is the basis of the method for the investigation of complex formation by infrared spectroscopy, whereby one can detect the occurrence of complementary interactions in the system.

The structure of the complex can be determined in two ways: (a) by comparing its infrared spectrum with that of a complex of known stoichiometry (the infrared spectra of polymer–polymer complexes with an appropriate nucleotide composition are usually employed as standards)[51]; (b) by measuring the variation of the intensity of the characteristic absorption band of the complex with mixture composition for a constant overall concentration of both components[10].

Infrared spectroscopy makes it possible to estimate quantitatively the degree of complex formation from the intensities of the bands appearing as a result of the interaction and the plot of this intensity against temperature constitutes the melting profile of the complex[52,53].

Infrared spectroscopy has many advantages over the methods discussed above. Since the infrared spectra of the individual components, their complexes, and self-aggregates as a rule differ from one another, this makes it possible to distinguish the interaction products and to infer the occurrence of non-specific interactions in this system[52]. An important advantage of the method is that it permits the employment of high nucleotide concentrations and complex formation can be studied under conditions which rule out the application of other optical methods. This is particularly valuable in the study of monomer–polymer systems where the concentration of the components plays a decisive role in the complex formation process[53]. A disadvantage of the method is the low intensity of the absorption bands arising as a result of the formation of hydrogen bonds.

2. The Stoichiometry of the Complexes

The most important characteristic of the complex is its stoichiometry. For synthetic homo-oligonucleotides and polynucleotides, there is a possibility of the formation, apart from the usual double helix, of a triple helix, the second polynucleotide (pyrimidine) chain being incorporated into the complex evidently via the formation of hydrogen bonds with the imidazole rings of the purine bases. Such structures are known for the A-U(T) pair in the crystalline state[54,55].

Studies in recent years showed that the stoichiometry of oligomer–polymer complexes is not determined unambiguously by the component ratio on mixing, but depends on a number of factors (temperature, ionic strength of the solution, bivalent metal ions, oligomer chain length, etc.).

The most common method for the determination of the stoichiometry of complexes involves the plotting of mixing curves (the so called Job method of continuous variations)[56]. For example, the ultraviolet absorption of mixtures containing different proportions of the reactants at a fixed overall concentration is measured and the optical density of the mixture is plotted against the mole fraction of one of the components. The extremum on the mixing curve indicates the stoichiometry of the complex. ORD,[57] CD,[48] and infrared spectroscopy[34] are also used to plot mixing curves.

The stoichiometric ratio of the bases interacting in the complex can be determined directly from the mole fraction of one of the components at which the extremum is observed:

$$r = \frac{(1-x)}{x},$$

where x is the mole fraction of one of the components and $1-x$ is the mole fraction of the other component.

When the extremum is broad, the stoichiometry of the complex is found by determining the point of intersection of the straight lines obtained by producing the linear sections of the mixing curve. However, when the curve is asymmetric (for example on formation of a three-chain complex) the extrapolation can lead to a gross error [58,59]. If self-aggregation of the components takes place in the system together with complex formation, additional terms taking into account the change in absorption and concentration due to self-aggregation, are introduced into Job's formula [47]. The calculation of the stoichiometric ratio is extremely difficult. In some cases it is possible to select the wavelength at which the self-aggregation process does not significantly influence the ultraviolet absorption of the system, whereupon the extremum on the mixing curve coincides with the maximum concentration of the complex, as in the absence of aggregation. For example, the stoichiometry of the complexes involving guanylic acid oligonucleotides is usually studied at 275 or 290 nm. [60]

The method based on mixing curves is used in the study of oligomer–oligomer and oligomer–polymer complexes. In the monomer–polymer interaction the complex formation depends very markedly on the concentration of the monomeric component, although in most cases there is no correlation between the component ratio in solution and the stoichiometry of the complexes [39]. The stoichiometry of the interaction is then determined directly by the ratio of the amount of monomer bound in the complex to the total amount of polymer in the solution (when the polymer molecules are completely bound in the complex). This ratio can be found by plotting the Ts'o isotherm [34] or the Scatchard diagram [61]. The interaction energy between nearest neighbours and the binding constant of the bases can be calculated from such graphs [62]. The stoichiometry of the complexes is also determined by viscometry, gel filtration [28], and equilibrium dialysis [63].

3. The Stability of the Complexes. Thermodynamic Parameters

The thermal stability of the complex is one of the main characteristics derivable directly from the experiment. Fig. 2 illustrates the thermal melting curve for the complex obtained by ultraviolet spectroscopy. If it is assumed that the optical density at a low temperature (below the plateau) corresponds to the completely helical structure and the optical density at the end of melting corresponds to the free components, then the proportion θ of the bases interacting in the complex can be calculated at any point in the transition range from the formula

$$\theta(t) = \frac{A_\infty - A_t}{A_\infty - A_0},$$

where A_∞ is the optical density of the solution of the fully denatured complex and A_0 is the optical density of the solution under optimal complex formation conditions.

The thermal stability of the complex is characterised by two parameters—the melting point (T_m) and the width of the transition range (ΔT_m) [64]. The melting point is the midpoint on the transition curve defined as the temperature at which the fractions of the helical and non-helical sections are equal, i.e. $\theta = 1/2$. For a given complex under constant external conditions, the melting point is constant. The width of the transition range is determined by the difference between the temperatures at which the tangent to the $(1-\theta)$–$t°$ fusion curve at the melting point intersects the lines corresponding to $1-\theta = 0$ and $1-\theta = 1$. ΔT_m reflects the cooperative nature of the transition, i.e. the degree of synchronisation of the breakdown of all the units of the helical structure with increase of temperature. For synthetic homopolynucleotides, the width of the transition range is related to the cooperativity factor σ as follows:

$$\Delta T_m = 12.4\, R \frac{T_m^2}{\Delta H} \sigma^{1/2},$$

where ΔH is the enthalpy of the transition.

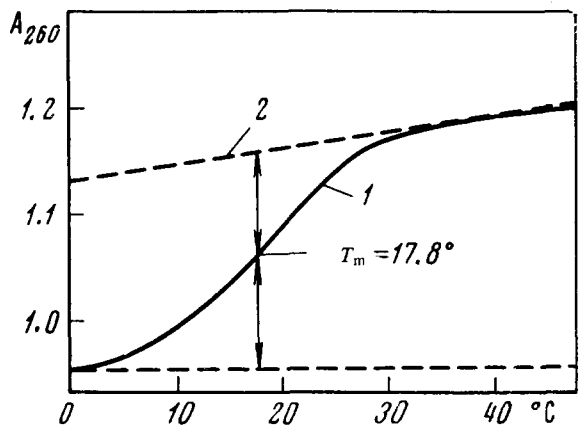

Figure 2. Temperature variation of the optical density A_{260} of the intermolecular complex $(Ap)_5U(pU)_4$ (1 M NaCl, pH 7.4): 1) experimental curve; 2) calculated absorption of the solution in the absence of interaction [63].

The theory of the cooperative "helix–coil" transition, developed in terms of modern statistical physics for polynucleotide models [65–67], is also applicable in the study of oligomer–oligomer and oligomer(monomer)–polymer interactions [68–72]. According to this theory, the first base pair formed in the oligomer–polymer (oligomer) interaction is much less stable than the subsequent pairs. The formation of each successive base pairs is associated with a specific stability constant, which rapidly approaches a limit in the transition range. It has been established that in most cases the differences between the stability constants of all the base pairs, other than the first, are insignificant and the cooperative transition can be described in terms of a model with two parameters.

Accordingly, the formation of a double oligomer–oligomer helix is represented schematically as follows:

$$A + B \overset{\beta S}{\underset{k_{10}}{\rightleftarrows}} D_1 \overset{S}{\underset{k_{21}}{\rightleftarrows}} D_2 \overset{S}{\underset{k_{32}}{\rightleftarrows}} \cdots \overset{S}{\underset{k_{N(N-1)}}{\rightleftarrows}} D_N,$$

where A and B are the interacting oligomers (oligomer and polymer), N is the length of the oligomer chain, D_i the partly helical structure with i pairs of bases, βS the stability constant of the first pair of bases, and S the stability constant of any of the succeeding pairs.

Statistical analysis of this scheme, taking into account the possibility of the existence of partly bound structures D_i, showed that β is extremely small ($\beta \ll 1$) and the constant S is very large ($S \gg 1$).[68-70] For relatively short oligomers, this makes it possible to neglect the concentrations of the partially bound structures $[D_i]$ and to treat complex formation in real systems in accordance with the "all or nothing" model:

$$A + B \overset{\beta S_N}{\rightleftarrows} D_N .$$

According to Applequist and Damle[68,69], this assumption does not introduce a significant error into the calculation of the thermodynamic parameters and ensures a simple quantitative relation between the thermodynamic parameters and the melting point, the slope of the fusion curve, length of the oligonucleotide, and its concentration in solution.

Table 1. Thermodynamic parameters of the "helix-coil" transition for a number of oligomer(monomer)–polymer systems[66].

Complex	Complex formation conditions	ΔH_1, kcal mole^{-1}	ΔS, kcal mole^{-1} deg^{-1}	β, mole^{-1}	Refs.

To simplify the calculations, it is assumed that ΔH_1 and ΔS_1 (the molar enthalpy and entropy of formation of a pair of bases), are the same for all the pairs and that β is independent of temperature. Then the enthalpy and entropy of the transition are proportional to the oligomer chain length:

$$\Delta H = N\Delta H_1, \quad \Delta S = N\Delta S_1 .$$

Damle[70] calculated a number of thermodynamic parameters for several oligomer(monomer)–polymer systems from the experimental data of other investigators. The results of these calculations are presented in Table 1.

A monomer–polymer system, for which thermodynamic calculations can be made even when the monomers are aggregated in solution, constitutes a real system most closely corresponding to the "all or nothing" model[71].

Later investigations of a number of oligomer–oligomer complexes showed that in real systems β is a function of temperature and the enthalpy of formation of the first base pair is significantly different from the molar enthalpy of formation of the subsequent pairs[36,71,76-78]. Thus, although the simplified theory of Applequist and Damle does in fact make it possible to estimate to a first approximation the thermodynamic characteristics of complex formation in the system as a whole, it does not reflect quite correctly the thermodynamics of the individual stages of this process.

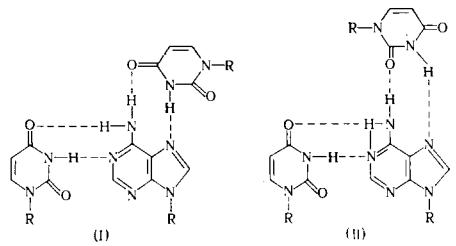
III. COMPLEXES OF MONOMERS WIT H POLYNUCLEOTIDES

The formation of complexes of monomers with complementary polynucleotide with rigorous structural specificity has been observed for only one combination of components: a purine monomer and a pyrimidine polymer[34,39,41,50,53]. It has not so far been possible to obtain the corresponding complexes involving pyrimidine monomers[50]. This is probably because the smaller surface area of the pyrimidine base compared with that of the purine base leads to a smaller degree of their overlapping in the formation of a pseudopolymeric structure in the complex and therefore to a lower stabilisation of the complex via the stacking interactions of the covalently non-bonded monomers. For this reason, such complexes should be significantly less stable, if they are formed at all, than the complexes of purine monomers.

A characteristic feature of the monomer–polymer complexes is their marked dependence on the concentration of the monomeric component. The polymer concentration does not actually influence the stability of the complexes—a tenfold increase of the amount of poly U did not affect the stability of the poly U-2-aminoadenine system[63].

Stoichiometry of monomer–polymer complexes. Among the monomer–polymer systems, the interactions of adenosine or its derivatives with 2 poly U have been most widely investigated[34,50,78-80]. Whereas oligomer–polymer or polymer–polymer systems lead to the formation of double and triple helical structures[28], the formation of triple-stranded complexes consisting of two polynucleotide chains and one pseudopolymeric chain formed by the monomers is prefered in the monomer–polymer interaction. The stoichiometry of these complexes (1Pu-2Py) can probably be accounted for by the thermodynamics of the complex formation process. The formation of an ordered secondary structure is as a rule associated with a decrease of entropy which is unfavourable for the process. In this case the heat of reaction should provide the driving force for the process. According to the results of Ross and Scruggs[81], the formation of a triple-stranded complex involving the monomer is accompanied by a large entropy change (about −42 cal mole^{-1} deg^{-1}) compared with the entropy of formation of the triple polymer–polymer helix (about −32 cal mole^{-1} deg^{-1}). Evidently the heat of formation of the double-stranded complex is insufficient to compensate such a high entropy change and in a monomer–polymer system the addition of another chain, which ensures a further enthalpy gain, is necessary. The authors attribute the differences between the entropies of formation of monomer–polymer and polymer–polymer complexes to a greater degree of disorder in the monomer in solution compared with the rigid molecules of polynucleotides. Felsenfeld and Miles[53]

proposed two possible structures for the monomer–polymer complexes A.2U, differing in the disposition of the poly U chains: the chains are antiparallel and parallel in the first and second structures respectively (see below).



(I) (II)

Both structures satisfy the requirements of stoichiometry. However, the study of the infrared spectra of the complex A.2poly U showed that the poly U chains are linked to the adenine residues by different carbonyl oxygen atoms[37]: one of the chains forms pairs of hydrogen bonds via $-C_{(4)}=O$ and $N_{(3)}-H$ and the other via $-C_{(2)}=O$ and $N_{(3)}-H$. This finding supports structure (II), in which the second polynucleotide chain is linked to the adenine bases in accordance with the scheme of Haschemeyer and Sobel[55].

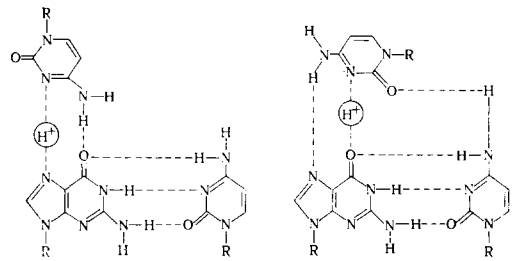
The structure with the antiparallel disposition of chains is also entirely likely for the monomer–polymer complex. In this complex the polynucleotide chains can belong to the same poly U molecule folded in two and are linked to one another via the adenine monomers.

On the basis of the results of sedimentation analysis, Huang and Ts'o[34] suggested the formation of a double-stranded complex of adenosine with poly U at 20°C. However, this conclusion was not confirmed by CD [79] and equilibrium dialysis[63] studies on the system. Damle[80] believes that the triple-stranded complexes 1A.2poly U constitute the only form of interaction between adenosine and poly U regardless of the concentrations of the components and temperature. It should also be noted that the infrared spectra and the melting curves obtained by Howard et al.[50] indicate the complete dissociation of the triple-stranded complex, $A.U_2 = A + 2U$, without the intermediate formation of the complex 1A.1U, The formation of the complex 1A.1U instead of 1A.2U should be reflected in a change in the infrared spectra—the appearance of an intense absorption band at 1672 cm^{-1}, while the 1657 cm^{-1} band is characteristic of the 1A.2U structure[53].

As a result of the presence of substituents in the purine base in the positions responsible for the binding of the second polynucleotide chain, the complex either does not form at all (for example in the case of tebericidin) or a very high concentration of the reactants is required. Thus Huang and Ts'o[34] failed to detect the formation of the complex of $N_{(6)}$-methyladenosine and poly U. On the other hand, Howard et al.[50] discovered the formation of a 1 : 1 complex of 9-methyl-6-methylaminopurine with poly U after increasing the concentration of the reactants.

The interaction of guanine monomers with poly C depends to a large extent on the pH of the solution. Thus at pH 7.8, where the protonation of poly C is impossible, guanosine 5'-phosphate forms the complex 1G.1C with poly C.[52] In the range pH ≤ 7, the complex has the structure 1G.2C, although in this case the formation of a triple-stranded helix requires the presence of the protonated form of poly C^+ at a fairly high pH. However, potentiometric titration has shown that the protonation of polycytidylic acid is facilitated in the present of guanosine, the pK of poly C being displaced towards the neutral region[39].

Among all the schemes proposed at present for the binding of 1G.2C,[74,79] most workers give preference to structure (A) (see below).



(A) (B)

One should note that melting of the triple-stranded complexes 1G.2C takes place in different ways in neutral and acid solutions[39]. At pH 6.4 the complex decomposes to the initial components as the temperature increases, while at pH 4.5, the guanine monomers are "melted out" and the double-stranded structure of poly C and poly C^+ remains. Such denaturation of the complex is more likely for structure (B), in which the parallel poly C and poly C^+ chains are linked. Evidently one can not rule out the possibility that different structures exist at different pH.

The study of the role of substituents in the heterocyclic ring of the purine component involves in most cases attempts to a quantitative estimation of the individual contributions of hydrogen bonds to the stabilisation of the complex. Evidently the contributions to the interaction energy due to other forces involved in the formation of the structure also vary on formation of a new hydrogen bond. For this reason, it is sometimes difficult to determine the main cause of stabilisation[42,50].

It has been observed that the introduction of substituents in the 1-, 6-, and 7-positions prevents the interaction of the monomer with the corresponding polynucleotide[34,39,82–84] Thus $N_{(1)}$-methyladenosine, where the introduction of the methyl group effects simultaneously the two sections responsible for the binding, is incapable of interacting with poly U.[42,50] Sarocchi et al.[39] also note that poly C does not form a complex when guanosine is replaced by 7-methylguanosine, 6-chlororibosylpurine, 6-thioguanosine and 2,6-diaminoribosylpurine.

Howard et al.[50] observed that complexes of 2-aminoadenosine and 2-aminoadenosine 5'-phosphate with poly U are more stable than the corresponding complexes of adenosine and 5'-AMP. The 2-amino-group participates in the formation of an additional hydrogen bond with one of the poly U chains, which results in the formation of a system resembling 1G.2C. The stoichiometric formula of the complexes of 2-aminoadenosine with poly U is 1A.2U.[63]

Substituents which do not prevent the formation of hydrogen bonds have hardly any influence on the capacity of the monomer for complex formation and on the stability of the complex. For example, the stability of complexes of poly U with various 3- and 9-alkyl-substituted adenines is close to that of complexes with unmodified adenine[34]. The formation of a complex of poly U with 8-aza-2,6-diaminopurine instead of adenine has been observed[50].

The sugar residue in the monomer molecule is not involved in the formation of the sugar phosphate skeleton which strengthens the chain, as happens in polynucleotides. For this reason, the replacement of the purine base by the appropriate nucleoside does not as a rule have a significant

influence on the stability of the complex, although Ts'o noted in a number of cases some stabilisation by the carbohydrate group. The nature of the sugar residue (ribose or deoxyribose) and its configuration (D- or L-ribose) is apparently unimportant at the level of monomer–polymer interactions[34]. A comparative study has been made of a number of systems of homopolymers and copolymers (poly AC, poly UC, poly UG) with monomers by equilibrium dialysis in combination with ultraviolet spectroscopy[63]. The authors established that the copolymer systems obey the same relations as the homopolymer systems. The employment of a mixture of monomers made it possible to compare the strength of the complementary interaction of individual monomers. For example, a study of the formation of complexes by poly UC with a mixture of dG and dA or dG and 2-aminoadenosine revealed a greater degree of binding in the second case.

Effect of the terminal phosphate group. Complexes of mononucleotides with polynucleotides have been least thoroughly investigated among the monomer–polymer systems, although they are of considerable interest from the biological point of view.

The first study in which mononucleotides were detected and investigated was carried out by Howard et al.[82] At high nucleotide concentrations (0.10–0.25 M) the presence of double- and triple-stranded structures, formed by guanylic acid mononucleotides (5'-GMP and 5'-dGMP) with polycytidylic acid, was established by infrared spectroscopy. It was noted that at pD 7.8 the infrared spectrum of the complexes is similar to that of the complex GpGpGp. .poly C, the stoichiometric formula of which is 1G.1C according to Lipsett[74]. At pD ≤ 7 new absorption bands appeared in the spectra of the mononucleotide–polynucleotide complexes, indicating the formation of triple-stranded helices containing the protonated form poly C^+.

Guanylic acid monomers, which are known to show a tendency towards self-aggregation and the formation of gels, sometimes precipitate from a nucleotide concentration of 0.01 M even in solutions at low ionic strength[39]. It is extremely likely that at this high nucleotide concentration the investigators observed the interaction between poly C and complex guanylic acid gels. Sarocchi et al.[39] investigated mixtures of guanylic acids with poly C in weakly acid dilute (overall nucleotide concentration 0.002 M) solutions. The formation of the complex 1G.2C noted under these conditions depends on the pH of the solution: complex formation was observed only at pH ≤ 6. In all probability this upper pH limit to the stability of the complexes is caused not only by the necessity for the protonation of poly C to form a triple-stranded complex but also by the need to suppress the dissociation of the secondary phosphate groups of the mononucleotide. The difference in the behaviour of the complexes of 5'-GMP and 3'(2')-GMP with poly C merits special attention: the latter complex is stable over a wider pH range. Guanylic acids with a phosphate group in the 5'- or 3'(2')-position are known to exhibit different tendencies towards self-aggregation and form gels of different structures[85–87]. However, the differences between their complexes with poly C have not so far been explained.

The study of Ts'o and Huang[40] occupies a special place among those dealing with the interaction of nucleoside mono-, di-, and tri-phosphates with polynucleotides. In solutions with a moderate concentration of the components in the presence of $MgCl_2$ the authors observed that the formation of complexes by purine nucleotides with the corresponding polynucleotides entails the precipitation of the complex. It was not possible to detect complexes in the supernatant. On the basis of these observations, the authors suggested that complex formation of mononucleotide–polynucleotide systems requires an additional driving force, which may be a phase transition. Complexes of monomer triphosphates proved to be less stable than complexes of monophosphates. Studies on the formation of complexes by cyclophosphates[88] showed that they give rise to more stable complexes with polymers than nucleotides. This can probably be explained by the decrease of the charge of the phosphate, which is particularly important for mononucleotides. The conditions governing the complex formation and the characteristics of a number of monomer–polymer complexes are given in Tables 2 and 3.

Analysis of studies of the dependence of monomer–polymer systems on the monomer concentration leads to the conclusion that the interaction requires a definite minimum monomer concentration (the "lower threshold"), which depends on the nature of the monomer, the pH of the solution, ionic strength, and the presence of Mg^{2+} ions. On further increase of the monomer concentration, the thermal stability of the complexes rises, but, after the attainment of a concentration characteristic of the given conditions, saturation takes place, the degree of complex formation reaching a limit and not changing further. Graphically the process can be represented by the Ts'o isotherm[39]. According to Huang and Ts'o, the existence of the "lower concentration threshold" can be accounted for by the fact that the interaction of monomers with polymers is preceded by the self-association of the monomeric molecules in solution:

$$nM \rightleftarrows M_n,$$

where M is the monomer molecule and n the number of monomeric units in the aggregate ($n = 1, 2, 3, \ldots$).

The aggregates formed (stacks) then interact with the polymer to form the corresponding complexes. The formation of the stacks initiates the complex formation process and determines the minimum monomer concentration in solution.

There exists also another point of view. Felsenfeld and Miles [53] believe that the self-aggregation of monomers must be regarded as a process competing with specific complex formation. The mutual orientations of the purines in the stacks and in an ordered complex are probably different, since in the former case the orientation is determined mainly by the hydrophobic interaction of the aromatic rings and in the second by the action of stereospecific forces. Since there is no rigorous mutual orientation of the monomers in the stacks (this is indicated by the ORD and CD spectra of the monomer solutions), the interaction of the stacks with the polynucleotide should involve their decomposition and the rearrangement of the monomers in accordance with the stereochemical requirements of the helix.

There is at present no reliable information about the involvement of the monomer–polymer complexes in natural biological processes. However, the inhibition of the peptide synthesis directed by the polynucleotide matrix in a cell-free system in the presence of complementary monomers, observed by Maxwell et al. [2], suggests that the monomer–polymer interactions can control the transfer of genetic information in the cell. Such control can occur at different levels of information transfer—in both transcription and translation stages.

IV. COMPLEXES OF OLIGONUCLEOTIDES WITH POLYNUCLEOTIDES

Oligomer–polymer complexes are more stable than the monomer–polymer complexes, which makes it possible to use them as convenient models for the investigation of complex formation. Oligomers containing not only purine bases (as happens in monomer–polymer interactions) but also pyrimidine bases [3,34,81,89] take part in the complex formation process. The structures and physical properties of the oligomer–polymer complexes are close to those of the polymer–polymer association complexes.

The stoichiometry of the A—U(T) complexes is not determined unambiguously by the component ratio in solution, but does depend on a number of factors, one of which is the nature of the oligonucleotide. Thus, according to Cassani and Bollum [28], at a moderate ionic strength the oligomers of thymidylic acid forms a complex 1T.1A with poly dA even in the presence of Mg^{2+}, while the structure 1A.2T is produced in the system of short dA oligomers and poly dT. The reason for the different stoichiometries is probably that in the 1Pu.2Py triple helix, formed with participation of oligo dA, there are breaks in the adenylic acid chain alone. In the triple-stranded complex oligo dT–poly dA, two chains of the helix consist of oligomers. Other conditions being equal, the stability of the latter complex should be much lower than that of the former [81].

The effect of the nature of the sugar residue on the structure of the polynucleotide chains and helices has been discussed in the literature for several years [90–95]. Marked differences have been observed between the CD spectra of the complexes poly-(A-A-U).poly-(A–U-U) and their deoxy-analogues, which may be due to the difference between their carbohydrate components [91].

It has been shown for polymer–polymer systems that the stability of the complexes of deoxypolynucleotides and mixed complexes is lower than that of the corresponding ribopolynucleotide systems [90]. The same behaviour is observed for oligomer–polymer complexes, the nature of the sugar residue of the polynucleotide component playing a particularly important role. The two-chain structure characteristic of the complex $d(pT)_{10}$.poly dA gives way to a triple-stranded structure when poly dA is replaced by polyrA (Fig. 3). [28]

Possibly the role of the 2′-OH group in the stabilisation of the triple-stranded helix is associated with the formation of additional hydrogen bonds in which the hydroxy-group can be involved as a proton acceptor [92] or donor [93]. Ts'o et al. [94] suggest the formation of intramolecular hydrogen bonds between 2′-OH and the $N_{(3)}$ atom of purine, the $O_{(2)}$ atom of pyrimidine, or the phosphate group. However it is still not clear how this can promote the introduction of a second polynucleotide chain into the complex.

A number of other investigators [90,92] suggested that the effect of the 2′-OH group on the structure and stabilisation of the helices is due to a change in the conformation of the sugar ring and the interaction of the ribose 2′-hydroxyl with solvent molecules. There is as yet no sufficiently convincing evidence in favour of a particular point of view.

By varying the chain length of the oligonucleotide in the system d(pA)m–poly dT, it has been shown that there is a critical value of m (characteristic of the given ionic strength of the solution) at which the interaction of an equimolar mixture of the oligomer and a polymer begins to form a double-stranded complex [28]. The formation of

a triple-stranded helix is characteristic of all oligo dA whose length is smaller than this value, regardless of the component ratio in solution. The authors noted that, near the critical value of m-, an equilibrium is established in the equimolar mixture of the components between the double- and triple-stranded complexes: there is a two-stage melting curve, the optical density at 260 nm in the first fusion stage and the decrease of the optical density at 284 nm being due to the complex 1A.1T, while the optical density at 260 nm in the second fusion stage indicates the decomposition of the complex 1A.2T (Fig. 4). A true equilibrium is probably observed in the system: the ratio of the double- and triple-stranded complexes did not change even on incubating the solution (5°C) for three months.

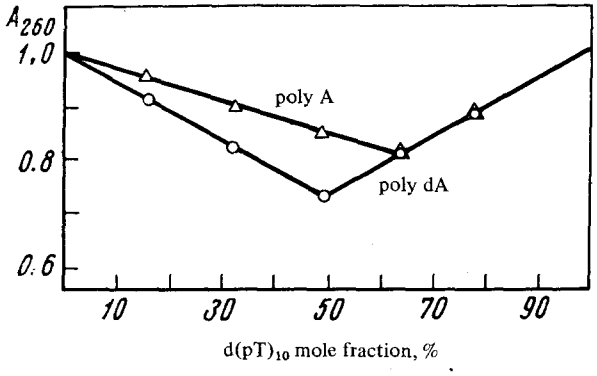

Figure 3. Mixing curves for complexes of $d(pT)_{10}$ with poly A and of $d(pT)_{10}$ with poly dA (1 M NaCl, pH 6.8, 23°C).[28]

As in the interaction of polynucleotides[96,97], an increase in ionic strength promotes the formation of triple-stranded oligomer–polymer helices. Thus Rich[89] observed a change in the stoichiometry of the two-helix oligo dT. .poly A complex and the formation of a triple-stranded structure with increase of the concentration of LiCl. Certain bivalent metal ions play an even more effective role in the stabilisation of triple-stranded complexes. For example, in order to obtain the complex 1A.2U in the system $(pA)_4$–poly U, the 1 M NaCl solution can be replaced by 0.001 M magnesium chloride solution[35]. The main function of the salts introduced into the solution is to shield the charged phosphate groups of oligo- and polynucleotides. The greater effectiveness of bivalent cations compared with univalent cations is a consequence, according to Michelson[9], of the differences between the dissociation constants of the corresponding metal phosphate salts. One cannot rule out the possibility that polyvalent cations can bind simultaneously the phosphate groups in different chains, which should also promote the formation of triple-stranded complexes.

The influence of ionic strength and bivalent metal ions on the interaction of polyanions such as oligo- and polynucleotides is very great. This factor sometimes plays a decisive role in the formation of the complex and with the given stoichiometry. Thus the interaction of oligo A with poly U in the presence of Mg^{2+} leads to the formation of the triple-stranded complex 1A.2U regardless of the component ratio in solution[98].

Some data on the stoichiometry of oligomer–polymer complexes formed with participation of the oligonucleotides of adenylic, deoxyadenylic, and thymidylic acids are presented in Table 4.

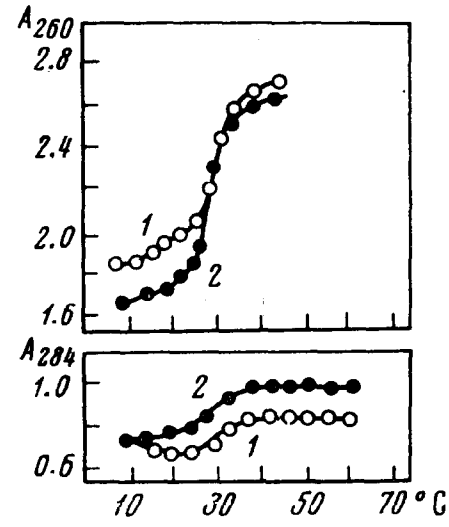

Figure 4. The melting of the structures formed by $d(pA)_8$ with poly dT for different component ratios in solution: 1) 1A–1T; 2) 1A–2T (0.15 M NaCl, pH 7.0).[28]

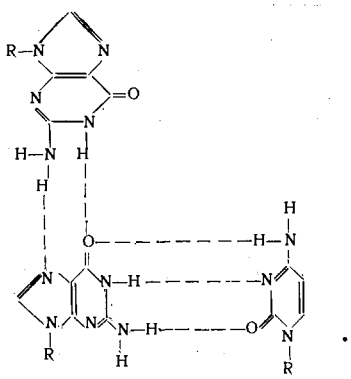
Table 4. Effect of various factors on the stoichiometry of A–U(T) complexes.

System	Component ratio in solution	Complex formation on conditions	Stoichiometry of complex	Refs.
$(pA)_m$—poly U	1A-2U	1*M* NaCl, 0.001*M* $MgCl_2$, 0.002*M* phosph. buffer, pH 7.4	1A-2U	35
$m \geqslant 3$	1A-1U	ditto	1A-2U	35
	1A-2U	0.001*M* MgCl, phosph. buffer, pH 7.2	1A-2U	35
	1A-2U	0.1*M* NaCl, 0.01*M* $MgCl_2$, 0.05*M* cacodylate buffer, pH 7.0	1A-2U	99
	1A-1U	0.1*M* NaCl, 0.002*M* phosph. buffer, pH 7.4	1A-2U	35
$A(pA)_m$—poly U				
$m \geqslant 2$	1A-2U	0.5*M* NaCl, 0.04*M* phosph. buffer, pH 7.3	1A-2U	81
	1A-1U	0.1*M* NaCl, 0.002*M* phosph. buffer, pH 7.4	1A-1U	35
$m=1$	1A-1U	0.001*M* $MgCl_2$, 1*M* NaCl, 0.002*M* phosph. buffer, pH 7.4	1A-1U	35
$d(pA)_m$—poly dT	1A-2T	0.04*M* phosph. buffer, pH 7.0	1A-2T	28
$m \leqslant 12$	1A-1T	ditto	1A-2T	28
$m > 12$	1A-1T	»	1A-1T	28
$m = 4 - 25$	1A-1T	0.008*M* $MgCl_2$, 0.04*M* phosph. buffer, pH 7.0	1A-2T	28
$m \leqslant 16$	1A-1T	0.15*M* NaCl, 0.015*M* citrate buffer, pH 7.0	1A-2T	28
$m > 16$	1A-1T	ditto	1A-1T	28
$d(pT)_m$—poly dA	1A-1T	0.04*M* phosph. buffer, pH 7.0	1A-1T	28
	1A-2T	0.008*M* $MgCl_2$, 0.04*M* phosph. buffer, pH 7.0	1A-1T	28
$d(pT)_m$—poly A	1A-2T	1.0*M* LiCl, 0.01*M* cacodylate buffer, pH 6.8	1A-2T	28

Stoichiometry of G–C complexes. The study of the formation of complexes involving G–C pairs is made extremely difficult by the tendency of guanylyl derivatives to undergo self-association. Numerous studies[99–102] have shown that, under conditions favourable for complex

formation (low temperature, high ionic strength), polyguanylic acid exists in the form of stable aggregates. For this reason, it has not so far been possible to obtain complexes of poly G with cytidylyl oligonucleotides. With decrease of the degree of polymerisation, the tendency towards self-aggregation falls appreciably (but does not disappear altogether), which makes it possible to detect the G–C interaction in the systems oligo G.poly C.

The first data on the stoichiometry of such complexes were obtained by Lipsett[60,74], who investigated the formation of complexes by short guanylic acid oligomers (GpG, GpGp, and GpGpGp) with poly C. On the basis of mixing curves, she concluded that, depending on the temperature and the incubation time, these oligonucleotides can form two types of complexes in a neutral medium: 1G1C (see p. 56) and 2G.1C, in which the guanine bases are linked:



The author believes that the two-stage melting of the complex confirms this structure (Fig. 5).

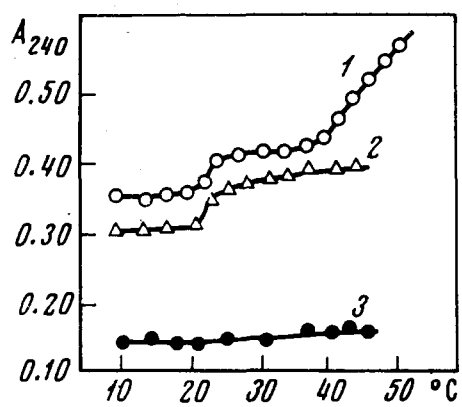


Figure 5. Melting curves: 1) for the complex GpGpGp. .poly C (2G.1C); 2) of the self-association complex GpGpGp; 3) of poly C (0.2 M NaCl, pH 6.2).[74]

However, the mixing curves, which do not have a distinct extremum, show that complex formation in the system is complicated by other, secondary processes, possibly the formation of the self-aggregate GpGpGp. One cannot rule out the possibility that the first stage in the melting profile (Fig. 5) is due to the melting of the self-aggregate GpGpGp, while the second reflects the decomposition of the double-stranded complex 1G.1C.

In the region pH < 6 the oligo G-poly C mixing curve has a distinct minimum at a cytidine mole fraction of 0.66, which indicates the presence of a triple-stranded complex 1G.2C.[74] The formation of a structure of this type was discussed earlier in connection with complexes of guanosine monomers with poly C and is associated with the protonation of polycytidylic acid. Possible schemes for the binding of the bases in the 1G.2C structure were presented above (p. 61).

Thus the results concerning the stoichiometry of oligomer–polymer complexes lead to the following conclusions. Complementary oligo- and poly-nucleotides with a monotonic sequence can form in aqueous solutions double- and triple-stranded helices. The stabilities of the complexes are not the same and are determined in many respects by the structure of the oligomer (the nature of the heterocyclic bases, chain length, etc.). However, with an appropriate choice of conditions (component ratio, pH, ionic strength), it is possible to obtain complexes having the required stoichiometry. In this connection we may recall that the formation of triple-stranded structures is promoted by the presence of purine groups in the oligomer, the presence of ribose residues in the polynucleotide chain, a high ionic strength, and the presence of Mg^{2+} ions. The formation of double-stranded complexes is as a rule observed at a low concentration of salts in the absence of bivalent metal ions. The pH of the solution plays an important role in the stoichiometry of the complex formed in the G–C interaction.

The stability of oligonucleotide–polynucleotide complexes. Thermodynamic parameters of the systems. Triple-stranded polynucleotide complexes can give rise to single-stage or two-stage melting depending on the ionic strength of the solution[90]. The effect of the concentration of the salts on the fusion curves for oligomer–polymer complexes was not specially studied. However, in most of the oligonucleotide–polynucleotide systems the thermal melting profiles are single-stage regardless of ionic strength[35,81,98]. This implies that triple-stranded complexes of oligomers with polymers dissociate, like double-stranded complexes, directly to the initial components without passing through a double-stranded intermediate.

The presence of G–C pairs stabilises the native DNA helices[103]. This is also characteristic of oligomer–polymer systems and is reflected by an increase in the melting points of the complexes containing the G–C pairs. Thus the melting point of the complex of GpG with poly C is 26°C, while that of the complex of ApA with poly U is only 6°C under analogous conditions[35,60].

The thermal stability of the complexes depends on which type of oligomer (purine or pyrimidine) is involved in complex formation. It has been observed that the complexes oligo Pu–poly Py are more stable than oligo Py–poly Pu. For example, the melting point of the complex $(pA)_8$.poly U is 52.8°C, while that of the complex $(pU)_8$. .poly A is 20°C.[104] The reason for the difference between the thermal stabilities of such structures is probably the greater strength in the case of the purine derivatives of the interplanar interactions stabilising the oligomers–polymer helices.

Lipsett et al.[35] showed that, under optimal complex formation conditions, the percentage of hypochromicity in the oligo A-poly U system is 35 for all oligomers, starting

with the trinucleotide, i.e. corresponds to the hypochromic effect of the formation of a triple-stranded helix poly A. .2poly U. Consequently the chain formed by adenylyl oligomers in the complex can be regarded as a continuous pseudopolymeric chain, in which the individual units (oligomers) are linked by vertical interactions.

The situation is different for pyrimidine oligonucleotides. The hypochromic effect observed in the formation of a complex of oligo dT with poly A is smaller than the hypochromic effect for the corresponding polymer–polymer complex. Rich and Tinoco[105] suggested that thymidylic acid oligomers interacting with a polynucleotide are not linked to one another and form independent short helices.

The values of the hypochromic effect for the complexes formed by oligo dT with poly A were calculated for oligomers of different lengths with the aid of the quantitative theory of the hypochromic effect developed by Rich and Tinoco[106].

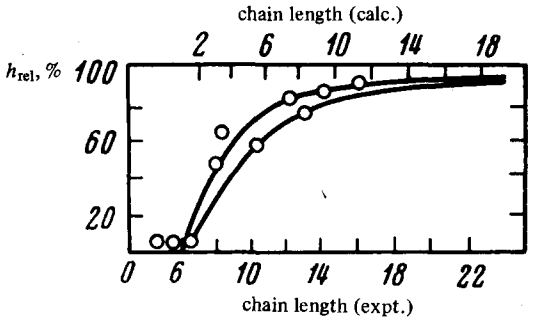

Figure 6. Variation of the hypochromic effect of the complex oligo dT.poly A as a function of the oligomer chain length at 262.5 nm ($h$rel, % is the percentage of hypochromicity calculated in relation to the hypochromicity of the complex poly A.poly U at pH 6.9).[105]

Fig. 6 shows calculated plots (continuous curve) of the relative hypochromic effect as a function of the length of the oligomer chain, the circles representing the experimental hypochromic effects. The experimental hypochromic effect for the heptamer corresponds to the theoretical value calculated for the dimer. This difference does not change with increase in the oligomer chain length up to the eicosanucleotide and makes it necessary to conclude that for any oligo dT 4–6 bases (probably 2–3 at each end) are not included in the stacking interaction, which probably results in a less ideal and stable structure than for the complex oligo A.2poly U.

With increase in the oligomer chain length, the stability of oligonucleotide–polynucleotide complexes rises[60,74,88,103]. A linear relation between the melting point and lg m (or $1/m$), where m is the oligomer chain length, has been established both theoretically[28] and experimentally[85]. The relation shows that the melting points of complexes of short oligomers differ very appreciably from one another, but for longer oligomers the differences between the melting points of the complexes become insignificant. The observed relation is consistent with the statistical-mechanical treatment of cooperative oligomer–polymer interactions described by Magee et al.[67] and Damle[70]. Michelson and Monny[89,104] studied the thermal stabilities of complexes as a function of the oligomer chain length (m) and established that, for a given series of oligomers, the plots of the reciprocals of the melting points against lg m are parallel, i.e. their slope is independent of the nature of the polynucleotide involved in the formation of the complex. It is determined by the structure of the oligomer (the nature of the heterocyclic bases, the presence of terminal phosphate groups, the type of internucleotide bond, etc.). There is a possibility of a break in the $1/T$m–lg m relation, indicating a change in the stoichiometry of the interaction. Indeed, since double- and triple-stranded complexes have different thermal stabilities, the slopes of the plots for these complexes should be different.

The system oligo I–poly C is convenient for the investigation of oligomer–polymer interactions[107]. The stoichiometry of the resulting complexes is always 1I.1C and their optical properties are similar to those of the poly I. .poly C systems[8,59]. However, the stability of the oligo I. .poly C complexes is much lower than that of oligo A.2poly U. Thus the complex ApA.2poly U is not difficult to obtain, while the complex IpI.poly C could not be detected and the minimum length of the inosine oligomers forming complexes with poly C was 5–6 monomeric units depending on the conditions[104].

The variation of the stability of the oligomer–polymer complexes with oligomer concentration, which decreases with increase in the oligomer chain length, has been determined. Thus the melting point of the complex $A(pA)_6$.2poly U decreases by 13 deg on 1000-fold dilution of the solution, while the melting point of the complex $A(pA)_4$.2poly U, containing a shorter oligoadenylate, decreases by 14 deg on 100-fold dilution[29]. Blake[33] confirmed this behaviour in a study of the stability of the complexes $(Ap)_4$.2poly U as a function of the tetramer concentration. Cassani and Bollum[28] noted an appreciable influence of the oligomer concentration on the width of the thermal transition ΔTm.

It was noted in a number of cases that the stability of the oligomer–polymer complexes depends on the nature of the sugar ring. The complexes of the ribo-series apparently have a higher thermal stability than those of the deoxyribo-series, which is largely consistent with the characteristics of the polymer–polymer interaction[95,108]. Knorre and coworkers[109] showed that, when the sugar residue of the terminal nucleoside in the oligomeric component is modified, the capacity of the latter for complex formation persists. Thus 2′,3′-*O*-benzylidene derivatives of oligoadenylates give rise to complexes whose properties are identical to those of the complexes of unmodified oligomers, the benzylidene group being displaced from the helix.

The available data about the influence of the terminal phosphate group on the stability of the complex are fairly contradictory. Uhlenbeck et al.[30], who investigated the thermal stabilities of the complexes formed by (Ap)mA and $(Ap)_{m+1}$ with poly U, noted the destabilising effect of the 3′-phosphomonoester group. Thus the introduction of a terminal 3′-phosphate into the tetramers and pentamers reduces the melting points of the complexes of these oligomers with poly U by 8 deg, which the authors believe can be explained by the increased electrostatic repulsion between the oligomers and the polymer chains in the presence of a terminal phosphomonoester group. A similar effect, decreasing appreciably with increase in chain length, has been observed for the system oligo G–poly C.[74]

However, according to Lipsett's data[35], only the terminal 5'-phosphate group has a destabilising effect, while the 3'-phosphomonoester group increases the thermal stability of the complex (Table 5). The author does not explain this fact satisfactorily. Presumably the presence of the phosphomonoester groups should destabilise the complex regardless of their positions in the oligomer chain and the degree of destabilisation can be different for the 3'- and 5'-phosphates, since these groups are known to have different effects on the secondary structures of the oligonucleotides themselves[110].

Table 5. Effect of the terminal phosphate group on the melting points of the complexes oligo A.2poly U (0.18×10^{-3} M nucleotide, 1 M NaCl, 0.001 M $MgCl_2$, pH 7.4).[35]

Position of terminal phosphate	Oligomer chain length			
	2	2	4	5
5'-Phosphomonoester group	7	17	29.5	37
3'-Phosphomonoester group	5	23	33.2	40.5
Without phosphomonoester group	6.2	17.4	31.3	

The formation of complexes by poly U with 5'-oligodeoxyadenylate amides, differing in the structure of the amide fragment and the length of the nucleotide chain, has been investigated by ultraviolet spectroscopy[111]. It was observed that the amide group does not alter the symmetry of the complex (1A.2U), but reduces somewhat its melting point. The destabilising influence of the amide group depends on its structure and decreases with increase in the oligomer chain length.

The nature of the internucleotide linkages in the oligomer molecule has a definite influence on the thermal stabilities of the complexes. It has been noted that the fusion of complexes of isomeric oligonucleotides with the 2'-5'-phosphodiester linkage in the systems oligo A–poly U and oligo G–poly C gives rise to a transition of the same width as complexes of the oligomers with the natural internucleotide linkage, but their melting points are somewhat lower[35,74].

The influence of the defects in the nucleotide sequence of the complementary oligomer on the stability of the oligonucleotide–polynucleotide complexes is of great interest. It has not been established unambiguously whether the non-complementary bases are incorporated into the helix or whether they form loops with breakdown of the stacking interaction between adjacent heterocyclic bases. A study of polynucleotide complexes revealed that the steric disposition of the non-complementary bases in the helix depends on their nature and number[30,112–115].

When the content of the non-complementary base is above a critical value, which depends on the type of system, a complex is not formed[114,115]. Only the frequency and length of the non-complementary sections of the chain are important[59], while the requirements which must be met by their positions in the chain as well as the steric requirements for the formation of complementary pairs at the ends of the helical section are less rigorous than within the section[82].

Uhlenbeck et al.[30] investigated the influence of terminal non-complementary bases in the oligomer on complex formation in the systems X(pA)m–poly U and (Ap)mX–poly U (X = C, U, or G) and reached the following conclusions.

1. The presence of a non-complementary base at one of the ends of the oligonucleotide lowers the stability of the complex.

2. The non-complementary base is displaced from the helix and the polymer is filled without gaps, for example in the interaction between poly U and the oligomers $C(Ap)_4$ and $(Ap)_4C$ the minimum on the mixing curve should occur at a uridine mole fraction of 0.667 if all the oligomer bases interact with the uracil residues, while the experimental curve has a minimum at a uridine mole fraction of 0.612. This means that the cytosine residues do not occupy any sites on the matrix.

3. The introduction of a cytosine residue in the middle of the oligomer has a weaker distabilising effect. The authors believe that this is largely due to the greater degree of solvation of the non-complementary cytosine ring, which has a higher dipole moment than the guanine and uracil rings.

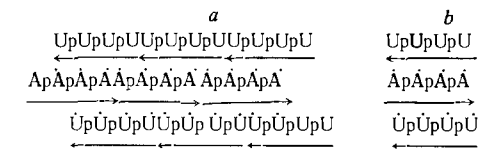
4. A non-complementary base at the 3'-end of the oligomer molecule destabilises the complex to a greater extent than the same base at the 5'-end.

V. INTERACTION OF COMPLEMENTARY OLIGONUCLEOTIDES

The study of complexes of complementary oligonucleotides is particularly important, since it yields information about the stability of short helices, which appear to be important structural elements in ribonucleic acids[53]. However, heterogeneous oligomers with a complex nucleotide sequence are so far almost inaccessible to study owing to the difficulty of their synthesis. Oligomeric complexes formed by oligonucleotides with a monotonic sequence have been most thoroughly studied. The kinetics of complex formation involving flow and relaxation (temperature jump) methods have been studied recently in systems of this kind[36,57,116–118].

Complexes of oligonucleotides with a monotonic nucleotide sequence are apparently not truly oligomeric. These are the so called "concatomers" having a structure similar to that of polymer–polymer complexes and differing from the latter only by the presence of breaks in the chains of the helix.

For example, the triple-stranded complex 1A.2U, formed by the tetranucleotides ApApApA and UpUpUpU, can be represented by the following concatomeric scheme (a):



The formation of such structures rather than dimeric or trimeric complexes is confirmed by the higher molecular weight of the complexes, greatly exceeding three times the molecular weight of the oligomer[48,81]. The formation of concatomeric structures in those cases where it is possible is probably thermodynamically more favourable than the formation of individual short helices of type *b*.

The stoichiometry of concatomeric complexes has been inadequately studied. It has been shown for the interaction of short oligo A oligomers with oligo U by CD, infrared, and ultraviolet spectroscopic methods[53,81] that the stoichiometric formula of these complexes is 1A.2U regardless of the component ratio and the ionic strength of the solution.

Pörschke[23] determined the critical oligomer chain length ($n = 7$) above which the formation of double complexes is possible. The author believes that for shorter oligomers ($n \leq 7$) both double and triple helices are formed.

On the basis of the ultraviolet spectrum of the complex oligo A.oligo dT, Hoggett and Maass[36] suggest the stoichiometric formula 1A.1T. Complexes of oligo G with oligo C have not so far been studied.

The thermal stabilities of the concatomeric complexes formed by adenylic acid oligomers with oligo U or oligo dT have been studied in fair detail[5,36,81]. The stability of such complexes greatly depends on the length of the oligomers and their concentration in solution. Thus the complex $A(pA)_3.3U(pU)_3$ (nucleotide concentration 0.12 M; 0.04 M $MgCl_2$; pH 7.0) melts at 17°C, while $A(pA)_5.2U(pU)_5$ has a melting point of 27°C under these conditions[53]. The shorter the oligomers the higher should be their concentration for complex formation to be appreciable. Thus the complex formation reaction between $A(pA)_7$ and $d(pT)_8$ takes place even at a nucleotide concentration of 8.5×10^{-6}, while the trinucleoside diphosphates ApApA and UpUpU interact only at a concentration of 0.12 M.[53]

The problem of the minimum oligomer size necessary for complex formation has been discussed in the literature for a long time[5,48,103]. Studies by Brahms et al.[119] showed that, at an overall nucleotide concentration of 10^{-4} M, the smallest oligomers are the heptamers. Felsenfeld and Miles[53], who increased the nucleotide concentration by a factor of 1000, demonstrated the existence of complexes of tri- and tetra-mers. The interaction between the complementary mono- and di-nucleotides in aqueous solutions has not so far been observed, although it does apparently occur in organic solvents (chloroform, dimethyl sulphoxide)[120,121].

Complex formation depends on the nature of the oligomers. Thus the formation of a complex in the system oligo dT–oligo dA at a nucleotide concentration of 0.001 M is observed starting with the pentamer of thymidylic acid and the tetramer of adenylic acid[5]. Maurizot et al.[122] observed a relation between complex formation and the structure of the sugar. Thus a comparative study by the CD method of the oligomer mixtures dA_n–dT_n and rA_r–rT_n ($n = 3$–8) in 4.7 M KF solutions at −20°C and a nucleotide concentration of 0.001 M established that deoxyribo-oligomers begin to form a complex starting with trimers, while their ribose analogues begin to form complexes starting with hexamers.

The effect of the ionic strength of the solution on complex formation in the majority of oligomer–oligomer systems has been studied as a rule at high ionic strengths (0.5–1.0 M NaCl) and in the presence of $MgCl_2$.[5,36,48,81] It was noted that, when oligo dT reacts with oligo A, the relation between the melting point and $\lg I$ (I is the ionic strength of the solution) deviates somewhat from linearity[36], in agreement with the behaviour of the system poly dT–poly A.

The formation of concatomers[108] is probably favourable also in this case, when the oligomers have an alternating nucleotide sequence. For example, oligo (CA) likewise forms overlapping structures with oligo (TC).[123]

However, when the oligomer has a self-complementary alternating sequence, intermolecular complex formation is not observed. Studies by Scheffler and coworkers[124,125] showed that the structure formed on folding the oligomer chain in two is more favourable for the oligonucleotide $d(TA)_m$. The melting point of the complex then also increases with the oligomer chain length, but is independent of the oligomer concentration.

Complexes of oligonucleotides with a non-monotonic nucleotide sequence were begun to be studied only in the last few years when considerable advances were made in chemical methods for the synthesis of oligomers with a specified sequence[126]. It was established that the interaction of non-monotonic oligonucleotides, uncomplicated by self-aggregation, involves the binding of two (or three) molecules of complementary oligomers with formation of short oligomer–oligomer helices[48,63,127,128]. In this case the general rules are approximately the same as for the formation of concatomeric structures.

The thermal stabilities of a number of complexes of nucleotides with a fairly wide variety of compositions were studied by Khorana and coworkers[127,128], who established that in the presence of Mg^{2+} there is a possibility of complex formation involving relatively short oligonucleotide blocks. Thus complexes of tetranucleotides with deca- and eicosa-nucleotides were obtained at a low temperature (0–5°C).[123] It was noted that, with increase of the content of G–C pairs, the oligomer–oligomer helices are stabilised. A similar behaviour was discovered also in a study by Martin et al.[129]

The attempt to obtain shorter oligomer–oligomer helices was unsuccessful. Jaskunas et al.[47], who investigated by the ORD method a large number of systems consisting of complementary trinucleoside diphosphates, found complexes only for the GpGpG–GpCpC pair (at a nucleotide concentration of 0.01 M in the presence of 0.001 M $MgCl_2$ at pH 7 and 1°C). However, the complex formation process is complicated so much by the self-aggregation of the trimers GpGpC that it is impossible to infer the stoichiometry of the interaction.

If the oligomer chain length is equivalent to 8–10 nucleotides, it is possible to obtain fairly stable complexes also from oligomers without guanylic and cytidylic acids[116]. Martin et al.[129] studied the capacity for complex formation of the self-complementary oligonucleotides $(Ap)_mU(pU)_{n-1}$, in which m and n were varied from 3 to 7. The marked concentration variation of the degree of complex formation for such oligomers suggests the formation of intermolecular complexes and rules out the possibility of intramolecular interactions. It was established that the structure of the complex formed is determined by the ratio A/U in the oligomer chain. A double helix is formed for $m \geq n$ but, when $m < n$, the results of sedimentation analysis and the ultraviolet spectra indicate the formation of larger aggregates, probably containing triple-stranded sections. For identical lengths of the A and U blocks in the oligomer ($m = n$), the melting point of the complex increases appreciably with chain length $N = m + n$ (Table 6).

The enthalpies ΔH_1 quoted in Table 6 refer to the formation of 1 mole of A–U pairs and were calculated from the slopes of the concentration variation of the melting point of the complex. The absolute value of ΔH_1 increases with increase in chain length. This deviation from Applequist's ideal model[68], for which ΔH_1 is independent of the oligomer chain length and the overall heat of reaction is defined by the expression $\Delta H_N = N\Delta h_1$, is not surprising, since it is clear that the contributions to the stabilisation of the helix are by no means the same for all the base pairs. Hoggett and Maass[36] showed that, in the interaction of oligo T with oligo A, the enthalpy of formation of the first base pair $\Delta H\beta S$ is positive although low. The enthalpies of formation of terminal base pairs can also differ significantly from the enthalpies of formation of the base pairs within the oligomer chain.

The stabilities of the oligomer–oligomer complexes having the same length and nucleotide composition but different nucleotide sequences are evidently not the same. Indeed, the oligonucleotides $(Ap)_6C$ and $G(pU)_6$ form a more stable complex (m.p. 25°C) than $C(pA)_6$ and $(Up)_6G$ (m.p. 19°C),[48] which may be due to a difference between the stacking interactions of the bases in the isomeric structures[130]. Differences have also been observed in the stabilities of the series of complexes $A_nCG.CGU_n$ (n = 6 or 8), $AnG_2.C_2U_n$ (n = 4 or 5), and $AnG_3.C_3U_n$ (n = 4 or 5) differing in the positions of the G–C pairs, which the authors attribute to differences in the entropy changes[131].

Table 6. Certain characteristics of the complexes formed by the oligonucleotides $(Ap)_mU(pU)_{n-1}$ (10^{-4} M nucleotide, 1 M NaCl, pH 7.0).[129]

Oligonucleotide	$N=(m+n)$	$-N\Delta H_1$, kcal mole^{-1}	$-\Delta H_1$, kcal mole^{-1}	M.p., °C
$(Ap)_3U(pU)_2$	6	—	—	—13
$(Ap)_4U(pU)_3$	8	51	6.4	12
$(Ap)_5U(pU)_4$	10	72	7.2	23
$(Ap)_6U(pU)_5$	12	85	7.1	32
$(Ap)_6G(pU)_4 \cdot (Ap)_4C(pU)_5$	14	107	7.6	40
	10	—	—	29*
				33**
$(Ap)_4CpG(pU)_4$	10	76	—	42.6

*The melting point of the complex calculated for a nucleotide concentration of 0.5×10^{-4} M.
**ditto for a nucleotide concentration of 2×10^{-4} M.

The introduction of a non-complementary nucleotide into the oligomer molecule hinders the formation of a complex and lowers its stability. Thus a study has been made of the capacity for interaction of the two oligomers $(Ap)_mC(pU)_n$ and $(Ap)_mG(pU)_n$, but in separate solutions and not in a mixture as in the previous study[132]. The cytidine and guanosine monomers disturb the self-complementarity of these oligomers and the destabilisations of the complexes due to them are not the same. The oligomer containing cytidylic acid forms a less stable intermolecular complex than the oligomer with guanylic acid (Fig. 7).

For comparison, the same figure presents the melting profile for the complex formed by $(Ap)_5U(pU)_4$ under analogous conditions. Analysis of the melting points of these complexes for different m and n showed that the introduction of the cytosine residue into the oligomer molecule lowers the stability just as much as the removal of two A–U pairs. The cytidylyl nucleotide probably forms a loop in the structure and displaces from the helix at least a pair of nucleotides adjoining it in the chain. The higher stability of the complex formed by the oligomer $(Ap)_mG(pU)_n$ compared with that of the oligomer $(Ap)_mC(pU)_n$ can be explained on the assumption that the guanylyl residue is not displaced from the helix, like the cytidine residue, but is incorporated in it, forming a G–U pair. The oligomeric molecules should then be displaced relative to one another:

ApApApApGpUpUpUpU
UpUpUpUpGpApApApA .

This structure is confirmed by the fact that its stability is close to that of the complex

ApApApApApUpUpUpU
UpUpUpUpApApApApA .

If 4–6 cytidylyl residues are inserted in the oligomer between homogeneous blocks, the molecule folds in two with formation of a single-stranded cytidylyl loop and a structure simulating the tRNA fragments[133]. Complexes of oligomers, in which not all the bases are paired have also been studied, in particular those formed by deca- and nona-nucleotides or deca- and hepta-nucleotides[127]. It has been noted that the thermal stabilities of these complexes decrease with the increase of the non-complementary backbone. For example, the complex of two eicosanucleotides, forming a helix from ten nucleotide pairs.

GTACCCTGTCAGAGGCCAAC
GCTCCCTTAGCATGGGACAG ,

has no cooperative melting profile at all[128], while the complex of a deca- and nona-nucleotide (GAACCGGAGA and TCTCCGGTT) melts over a fairly narrow temperature range (m.p. 40°C).[227] The destabilisation of the eicosanucleotide complex is due to the absence of an ordered steric structure from the single-stranded section of the helix. The inclusion of the single-stranded section in the complex with another oligomer leads to a sharp increase of the stability of the structure[127, 128].

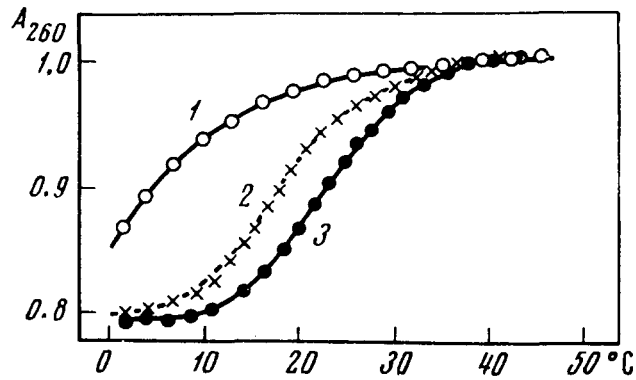


Figure 7. Melting curves for intermolecular oligomer complexes: 1) $(Ap)_5C(pU)_5$; 2) $(Ap)_5G(pU)_5$; 3) $(Ap)_4ApU(pU)_4$ (2.5×10^5 nucleotide, 1 M NaCl).[132]

Analysis of the fundamental relations established in the study of the complementary properties of mono- and oligonucleotides will undoubtedly help in predicting, in a broad outline, the behaviour of systems which have not so far been investigated and in assessing the scope of the complex formation, the stoichiometry of the interaction, etc. However, these characteristics of comparatively simple synthetic systems cannot be applied mechanically to oligomer–oligomer interactions involving native macromolecules with a complex steric structure. Complexes of synthetic oligonucleotides with native polymeric molecules or their fragments, studies on which began recently[134–139], are probably more useful models.

A number of new publications appeared recently. Studies on monomer–polymer [140–143] and oligomer–polymer complexes [144–146] are being continued. Oligomer–oligomer systems which both monotonic [147] and non-monotonic sequences of bases [148–150] are being investigated vigorously.

The Structural Chemistry of Organic Compounds of Mercury and Its Analogues (Zinc and Cadmium)

L.G.Kuz'mina, N.G.Bokii, and Yu.T.Struchkov

Information on the structure of organometallic compounds of zinc, cadmium, and mercury published up to 1973 is summarised. Detailed consideration is given to true organometallic compounds, containing a metal-carbon bond. Compounds in which a carbon atom (hydrocarbon radical) is separated from the metal atom by a heteroatom are mentioned only for comparison, and no systematic description of their structures is given. The Review covers results obtained by X-ray and neutron diffraction, gas-phase, electron diffraction, and in part microwave and Raman spectroscopy. A list of 90 references is included.

I. INTRODUCTION

Structural examination of compounds of zinc, cadmium, and mercury—members of subgroup II*b* of Mendeleev's Periodic System and having outer electron shells of similar structure—reveals significant differences in their stereochemistry: whereas a tetrahedral bond configuration is more characteristic of zinc and cadmium, mercury prefers a linear configuration with two short bonds, and this geometry of mercury compounds is little distorted by additional coordination interactions. Orgel[1,2] explained the structure of this type of mercury compound with strongly electronegative ligands in terms of their conferring a high positive charge (formally +2) on its atom: transition from the $5d^{10}$ (Hg^{2+}) electronic configuration to $5d^{9}6s^{1}$ followed by d_z2s hybridisation requires relatively little energy (5.3 eV), considerably less than for zinc and cadmium. Such hybridisation presupposes the existence either of two stable bonds in the *z* direction and four weak bonds in the *xy* plane or four stable bonds in the *xy* plane and two weak bonds in the *z* direction. The former alternative is preferred, although this cannot be explained in terms of Orgel's concepts.

In compounds with less electronegative substituents, in which the mercury atom has a small positive charge (formally +1) and the $5d^{10}6s^{1}$ configuration, the energy necessary for the transition $5d^{10}6s^{1} \rightarrow 5d^{10}6p^{1}$ is really not so small (~ 6 eV).[2,3] Linear *sp* hybridisation is therefore most favourable, with the use of only one higher *p*-level. In zinc and cadmium the energy difference between *s* and *p* levels is smaller, which facilitates sp^3 hybridisation.

Since the structure of organomercury compounds differs from that of organozinc and organocadmium compounds, they are discussed in different Sections. The stereochemistry of organomercury compounds is dealt with in Section II, where ideas put forward by Grdenić[2] are used. Subsections II, 1 and II, 2 examine the structures of aliphatic and aromatic organomercury compounds respectively. The presence of intramolecular coordination is discussed in subsection II, 3, and finally crystal structures with intermolecular coordination of the mercury atom are described in II, 4. However, assignment to a particular subsection is often difficult, both owing to the impossibility of establishing coordination on the basis of available data and because the original paper lacks the appropriate information (in particular no analysis of intermolecular distances is given, and sometimes even the atomic coordinates are missing). Structures of organomercury compounds determined by X-ray diffraction are usually not very accurate, owing to the great difference in atomic number between mercury and the other atoms present in the molecule. Section III deals with the structures of organozinc and organocadmium compounds, which have been little studied.

II. ORGANOMERCURY COMPOUNDS

1. Aliphatic Derivatives

The first information on the structure of dimethylmercury was obtained during 1936-1937, when gas-phase electron diffraction gave values of 2.20 and 2.23 Å[4,5] for the mercury-carbon bond length in this molecule. However, 2.094(5) Å has since been obtained[6] from the Raman spectra. This value has recently been confirmed by a second electron diffraction investigation: the internuclear distance in the linear CH_3-Hg-CH_3 molecule is 2.083 Å.[7]

Compound	Hg-C, A	Hg-X, A	Ref.
CH_3HgCH_3	2.083 (5); 2.094 (5)	—	6,7
CH_3HgCl	2.061 (20)	2.282 (5)	8
CH_3HgBr	2.074 (15)	2.406 (5)	8
CH_3HgI	2.087 (10)	2.528 (5)	9

Closely similar values have been obtained by microwave spectroscopy for the methylmercury halides (Table). It is evident that the presence of a halogen atom in the molecule shortens the mercury-carbon bond, an effect which diminishes in the sequence Cl > Br > I, so that the bond length in methylmercury iodide is the same as in dimethylmercury.

X-Ray examination of several alkylmercury halides—methylmercury, ethylmercury, propylmercury, and butylmercury chlorides and ethylmercury bromide—by means of projections[10] gave values of 2.06(3), 2.50, and 2.51 Å for the bonds between mercury and carbon, chlorine, and bromine respectively. The mercury–halogen bond lengths differ significantly from the above values, probably because of the lower accuracy of X-ray examination. This method gave 2.43 Å for the mercury–bromine bond length in *trans*-2-chlorovinyl mercury bromide ClCH:CH.HgBr.[11]

From the bond lengths in the above compounds and in those of type HgX_2 investigated by electron diffraction in the vapour phase, with the Schomaker–Stevenson correction for the electronegativity difference, Grdenić proposed[2] the value 1.30 Å for the covalent radius of mercury with a linear bond configuration. This value corresponds satisfactorily to the additivity rule for free molecules of the types HgX_2 and $HgXX'$. This rule is not always satisfied in crystalline structures, owing to the influence of surrounding molecules.

sp-Hybridisation of the mercury atom presupposes that these dihalide molecules have a linear structure, but it is interesting to trace to what extent linearity is preserved in organomercury compounds. From the vibrational spectra of methylmercury cyanide CH_3HgCN it was concluded[12] that linearity of the C–Hg–C(N) fragment was disturbed in this compound. Examination of crystals by X-ray and neutron diffraction[13,14] showed in both cases that the angle at the mercury atom was 180 ± 2°. The Hg–CH_3 and Hg–CN bond lengths were 2.15(5) and 2.01(5) Å according to the X-ray results, and 2.08(2) and 2.05(1) Å respectively according to neutron diffraction. It is interesting that the latter method distinguished between the nitrogen and carbon atoms, and showed that mercury was attached to the carbon atom of the cyano-group.

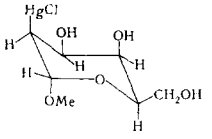

Figure 1.

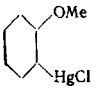
X-Ray examination of DL-penicillaminatomethylmercury[15] indicated that the methylmercury group is attached to the amino-acid through a deprotonated mercapto-group $CH_3.Hg.S.C(CH_3)_2.CH(NH_3^+).COO^-,H_2O$. The CH_3–Hg–S fragment is nearly linear (176(2)° and 179(1)° in two independent molecules). The mean Hg–C and Hg–S bond lengths are 1.90(6) and 2.38(1) Å, and the angle at the sulphur atom is 109°.

A linear configuration has been found for mercury also in methoxycarbonylmercury chloride Cl–Hg–$COOCH_3$ (X-ray examination by projections).[16] The Hg–C and Hg–Cl bond lengths of 1.96 and 2.35 Å differ from those found in methylmercury chloride[8] and in mercury(II) chloride[2], but the poor accuracy makes the reality of these differences dubious.

X-Ray investigation[17] of two diastereomers—(I) $\alpha(dd,ll)$ and (II) $\beta(dl,ld)$—of 2-methoxycyclohexylmercury chloride



showed that in (I) the Hg–C and Hg–Cl bond lengths were 2.34 and 2.53 Å, with the ClHgC angle 178°; the corresponding values in (II) were 2.15, 2.50, and 180°. The molecules differ in the relative orientation of the substituents about the cyclohexane ring. Thus the intramolecular Hg...O distances in (I) and (II) are 4.06 and 3.06 Å.

Structure determination by means of X-rays showed[18] that the Hg–Cl bond length in methyl 2-chloromercury-2-deoxy-α-D-talopyranoside (Fig. 1) is 2.38(10) Å. Preliminary examination of dibenzylmercury crystals[19] established only the partial position of the mercury atom in the cell (space group $P4_2/n$, $z = 4$).

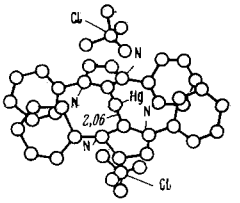


Figure 2.

The mercury–carbene complex $[Hg(C_{15}H_{12}N_2)_2](ClO_4)_2$ possesses an interesting structure (Fig. 2).[20] The cation is located at the centre of symmetry, so that the configuration of the mercury bonds is strictly linear. The Hg–C bond length of 2.06(1) Å coincides within the limits of accuracy with the sum of the covalent radii of mercury and sp^2 carbon (1.30 + 0.74 Å).

2. Aromatic Compounds

Measurements of the dipole moments of diarylmercury compounds indicate significant polarity[2,21,22], which might be explained by non-linearity of the C–Hg–C fragment. It was therefore of interest to undertake structure determinations on these compounds.

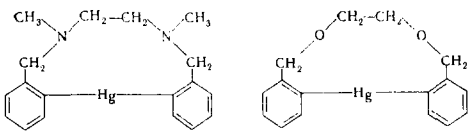
Two methods—X-ray structure determination[23–25] and gas-phase electron diffraction[26]—have been used to examine diphenylmercury. This planar molecule is situated at a centre of symmetry in the crystal, so that the C–Hg–C fragment is strictly linear. The structure was refined on the assumption that the Hg–C bond length was 2.10 Å: i.e. this parameter was not objectively determined. Electron diffraction in the gas phase led to the fairly accurate value of 2.092(5) Å for the Hg–C internuclear distance. The CHgC angle was not determined experimentally, but was assumed to be 180°.

Comparison of the mercury–carbon bond length thus obtained with that found in aliphatic organomercury compounds reveals no contraction on passing from sp^3 to sp^2 hybridisation of the carbon. On the other hand, it was of interest to ascertain the extent to which the state of

hybridisation of the carbon atom attached to mercury in organomercury halides affects the mercury–halogen bond length. Examination of phenylmercury bromide vapour by electron diffraction[27] showed, on the assumption that the C–Hg–Br fragment was linear, that the Hg–Br bond length was 2.435(4) Å, rather longer than the 2.40 Å in methylmercury bromide (see above): i.e. it was established that the organic substituent attached to the mercury atom influences the length of the mercury–halogen bond.

X-Ray structure determination on di-*p*-tolylmercury established that the mercury–carbon bonds were collinear[28,29] (the planar molecule was located at a centre of symmetry). The Hg–C bond length of 2.08 Å coincides within the limits of accuracy with the sum of the covalent radii. The great scatter in the carbon–carbon bond lengths and angles in the phenyl rings (1.39–1.44 Å and 116–124°) is an indication of the difficulty of locating light atoms in the structures of organomercury compounds.

In most of the symmetrical mercury compounds examined by X-ray diffraction the mercury atom is situated at a centre of symmetry, so that the C–Hg–C fragment has a strictly linear structure in the crystal. In bispentafluorophenylmercury $(C_6F_5)_2Hg$, in whose crystal structure the molecule is located at a common position [sic: the molecular crystal has four molecules in the unit cell (Ed. of Translation)], the CHgC angle is 176.2(1.2)°.[30] This value probably represents the limits within which linearity of X–Hg–X bonds can be disturbed by the packing of molecules in the crystal. It is noteworthy, however, that the distances between mercury and the *ortho*-fluorine atoms—3.32, 3.25, 3.22, and 3.14 Å—are fairly short. The possibility of specific Hg...F interaction is therefore not excluded; this would be analogous to (but weaker than) the coordination interaction of the mercury atom with the *ortho*(2,2′ and 6,6′)-chlorine atoms in bispentachlorophenylmercury[31] indicated by the nuclear quadrupole resonance spectrum. Such interaction may disrupt the linearity. In contrast to diphenyl- and di-*p*-tolyl-mercury, moreover, the $Hg(C_6F_5)_2$ molecule is non-planar in the crystal, with an angle of 59.4° between the planes of the benzene rings.



(I) $HgC_{18}H_{22}N_2$ (II) $HgC_{16}H_{16}O_2$

Figure 3.

The angle at the mercury atom also differs from 180° in the crystal structures of *NN*′-dimethylethylenediamine-ωω′-di-*o*-tolylmercury (I) and ethylenedioxy-ωω′-di-*o*-tolylmercury (II) (Fig. 3),[32] being respectively 172.3(9)° and 173.6(2.1)°. The Hg...O distances of 3.01(4) and 3.19(3) Å in (II) and the Hg...N distances of 2.92(2) and 2.97(2) Å in (I) were regarded as excluding coordination between the atoms, which might have led to some disturbance of bond linearity. Thus these disturbances are probably due to steric stresses.

X-Ray examination of 1-naphthylmercury iodide[33] revealed only the heavy atoms—mercury and iodine—separated by the bond length 2.61 Å.

Thus these subsections 1 and 2 show that a linear bond configuration is most common in organomercury compounds, with the mercury–carbon bond length generally within the range 2.06–2.10 Å.[34] Other bond configurations are rare and atypical in organomercury compounds.

3. Compounds with Intramolecular Coordination of Mercury with a Heteroatom

Coordination between the mercury atom and a heteroatom in the same molecule has recently been increasingly used to explain several anomalies in the physical properties of organomercury compounds, as well as to interpret many of their reactions[27]. In particular, special features of the infrared, nuclear magnetic resonance, and nuclear quadrupole resonance spectra and the dipole moments, as also anomalous effects of *ortho*-substituents, are explained by such coordination interaction[35–37].

X-Ray structure determination and electron diffraction are often used to ascertain the possible presence of intramolecular coordination interaction. The sole geometrical criterion of such interaction is the shortening of the distance between the atoms in comparison with the sum of their van der Waals radii. The presence of interaction can be deduced unambiguously from this criterion only if the contraction exceeds those which may arise from packing effects (~ 0.2 Å). Grdenić[2] suggested 1.50 Å, half the shortest interatomic distance in metallic mercury, as the van der Waals radius; and to allow for several specific coordination interactions he proposed the value 1.73 Å (half the next larger interatomic distance in metallic mercury). These recommendations were based on the intermolecular mercury–halogen distances in the structures of organomercury halides[10]. Since the minimum van der Waals radius proposed by Grdenić exceeds the covalent radius of mercury by only 0.2 Å, it is difficult in several cases to reach, on the basis of the above geometrical criterion, an unambiguous conclusion on the presence of weak coordination interaction. Additional criteria must therefore be adduced in order to establish such interaction.

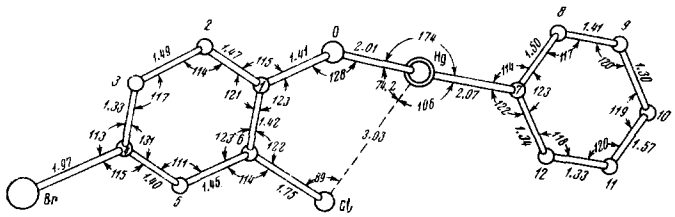


Figure 4.

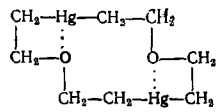
X-Ray examination of phenylmercury 4-bromo-2-chlorophenoxide (Fig. 4) was undertaken[38] to establish the possibility of intramolecular interaction of the *ortho*-chlorine with the mercury. Such interaction is possible on appropriate rotation of the phenyl ring about the C–O single bond. The angle between the HgOC ω plane and the plane

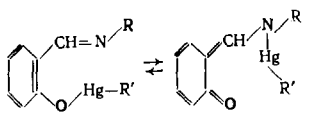
of the benzene ring $C_{(1)}...C_{(6)}$ is found experimentally to be 17°, when the molecule acquires a cisoid conformation, in which mercury and chlorine atoms approach to 3.03(2) Å. This distance is 0.3 Å shorter than the sum of the van der Waals radii of chlorine (1.8 Å) and mercury if the minimum 1.5 Å is adopted for the latter, and 0.5 Å shorter if 1.73 Å is used. It should be noted also that the OHgC angle away from the chlorine atom has diminished to 174(1)°, while the location of the chlorine atom relative to the C–Hg–O fragment is roughly symmetrical (to the extent that this is permitted by the geometrical rigidity of the "metal ring" HgOCCCl): the ClHgO and ClHgC angles are respectively 74° and 106°. All this is evidence of the presence of intramolecular Hg...Cl coordination. The Hg–C and Hg–O bond lengths are respectively 2.07 and 2.01 Å. Thus such interaction does not cause elongation of valency bonds and produces no significant change in hybridisation.

X-Ray structure determination on "diethylenemercury oxide" established [39] that the molecule was dimeric



with strong Hg...O coordination interaction at 2.21(10) Å (sum of covalent radii 1.96 Å) in a twelve-membered ring arranged about a twofold axis. It is strange, however, that such strong interaction barely disturbs the hybridisation of the mercury atom (CHgC angle 176°), which probably indicates the poor accuracy of the work (the structure was determined from projections). The length of the Hg–C bonds in this molecule is 2.14 Å.

An intensive study of metallotropic rearrangements, including metallotropic tautomerism, has begun recently. In particular, electron spectroscopy has provided evidence that phenyl- and methyl-mercury derivatives of *o*-iminomethylphenols are present in solution as equilibrium mixtures of metallotropic benzenoid and quinonoid tautomers, whose proportions vary with the temperature and the polarity of the solvent [40]:



(I) (II)

Transfer of the phenylmercury residue from one reaction centre to the other is facilitated by intramolecular coordination, which is possible if the molecule has a *cis*-conformation relative to the exocyclic carbon–carbon bond. X-Ray structure determination has shown [41] that phenylmercury *o*-methyliminomethylphenoxide is an *N*-derivative of *o*-methyliminomethylphenol with the *cis*-conformation. The triclinic cell contains two independent molecules, having the same geometry within the limits of accuracy. The structure of one of them is shown in Fig. 5. The mean Hg–N and Hg–C bond lengths are 2.12(3) and 1.98(4) Å.

The oxygen atom is distant 2.44 Å from the mercury atom, about 0.4 Å further than the length of the mercury–oxygen covalent bond and 0.4–0.6 Å closer than the sum of the van der Waals radii. In this case there is no doubt about the presence of coordination interaction. Here, as in the preceding structure, the bond angle opposite to the "additional" oxygen atom is diminished to 167°, the greater decrease being consistent with stronger intramolecular interaction between mercury and the heteroatom.

The presence of strong Hg...O coordination interaction implies that the quinonoid structure (II), whose predominance follows from the fact that mercury is covalently bound to the nitrogen atom, is accompanied by the benzenoid form (I).

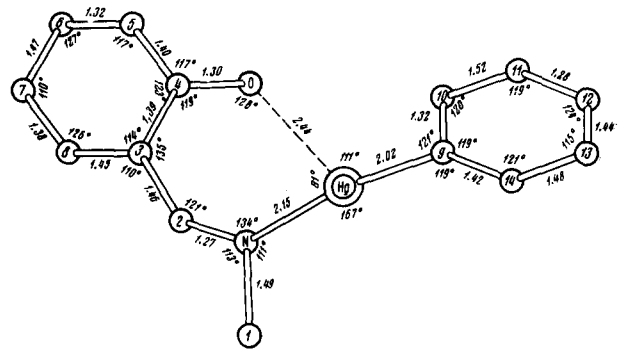


Figure 5.

A similar type of coordination of the mercury atom is found in 2-hydroxy-5-methylphenylmercury 4-methyl-2-nitrosophenoxide $C_7H_7OHg.C_7H_6ONO$ [42,43] (Fig. 6*a*). As in the preceding structure, the mercury atom is covalently bound through a carbon atom of the phenol ring and the nitrogen atom of the quinone monoxime. The unit cell contains two independent molecules, with mean Hg–N and Hg–C distances 2.14 and 2.04 Å. The C–N and N–O bonds (mean lengths 1.25 and 1.27 Å) are nearly double, since the molecular structure is best described by formula (II) (Fig. 6*b*).

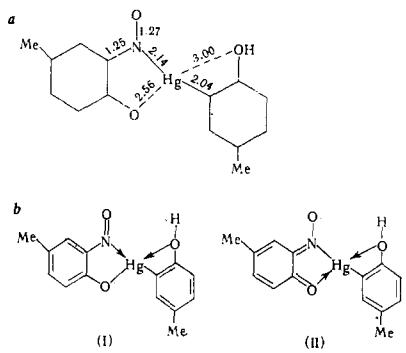

Figure 6.

The oxygen atom of the nitrosophenol is distant 2.56 Å from the mercury atom, which corresponds to coordination, but weaker than in phenylmercury *o*-methyliminomethylphenoxide. The probable reason for the weaker interaction is that a more symmetrical arrangement of the coordinated oxygen atom relative to the C–Hg–N fragment is

prevented by the geometrical rigidity of the five-membered "metal ring". The $O_{(1)}HgN$ and $O_{(1)}HgC$ angles are 71° and 115°, whereas in the salicylic derivative they are 81° and 111° respectively. The $N_{(1)}HgC$ angle away from the $O_{(1)}$ atom has also diminished to 174°. It is remarkable that a five-membered metal ring is formed in this structure, although the ligand is isoelectronic with salicylicidenimine, and on coordination of the mercury, not with the nitrogen but with the oxygen of the nitroso-group, would have formed a six-membered chelate metal ring analogous to that found in the above phenylmercury derivative of salicylicidenimine.

In all the above structures a shortening of the distance between the "additionally" coordinated heteroatom and mercury is sufficient to indicate interaction between these atoms without further corroboration. However, this is by no means always possible, and additional geometrical criteria of coordination must be used for such cases. They may be the deviation from the ideal XHgX angle opposite the "extra" atom, the symmetry of the position of the latter relative to the X–Hg–X fragment, and also the occurrence in the molecule of a conformation favourable to such interaction[44].

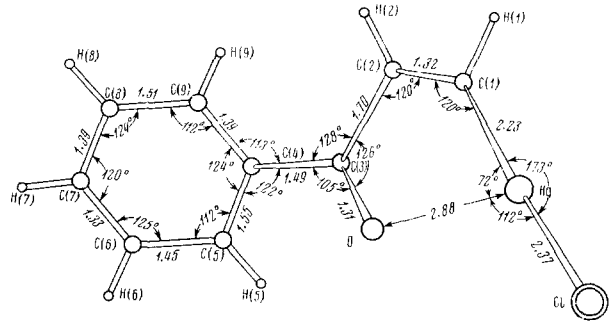

Figure 7.

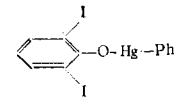
An example is 2-benzoylvinylmercury chloride, whose *cis*-isomer was more stable than the *trans*-isomer, which was attributed[45] to intramolecular Hg...O coordination. X-Ray structure determination established a cisoid conformation[46] (Fig. 7), in which the oxygen atom lay in the direction of the mercury atom. The Hg...O distance of 2.88(10) Å agreed within the limits of accuracy with the sum of the van der Waals radii (2.9–3.1 Å). However, the molecular conformation and the diminution to 173(2)° in the ClHgC angle opposite the oxygen atom are evidence of the above coordination.

Examination of *cis*-2-chlorovinylmercury chloride by gas-phase electron diffraction[47] gave Hg–C and Hg–Cl bond lengths (2.14(1) and 2.27(1) Å) that can be regarded as normal. The non-bonded intramolecular Hg...Cl distance is 3.27 Å, and the sum of the van der Waals radii 3.3–3.5 Å. This distance was regarded as corresponding to intramolecular coordination. However, it is determined in considerable measure by the geometrical rigidity of the molecule, and cannot be used as an unequivocal criterion of coordination. Such interaction might be indicated by a decrease in the CHgCl angle away from the "extra" chlorine atom. Linearity of the C–Hg–Cl fragment is in fact disturbed (the angle is 168.5(1.5)°), but the side to which the Hg–Cl bond is deflected is not stated. The presence of coordination in this molecule is supported also by results obtained by other methods (dipole moments, anomalies of chemical behaviour, nuclear quadrupole resonance spectra)[48–50].

Only the coordinates of the mercury and halogen atoms have objectively been established in the crystal structure of trichloromethylmercury bromide CCl_3HgBr.[51] The Hg...Cl distances were not equivalent: two were 3.21 Å, and one 3.15 Å, the decrease being attributed to coordination. However, the poor accuracy does not allow this conclusion to be accepted as entirely reliable. Nevertheless, the presence of interaction is indicated by the nuclear quadrupole resonance spectra of trichloromethylmercury bromide and chloride and of bistrichloromethylmercury.

The Hg...I distance in the crystal structure of phenylmercury 2,6-di-iodo-4-methylphenoxide



was determined[52,53] as 3.14 Å, which corresponds to strong intramolecular coordination.

4. Crystal Structures of Organomercury Compounds with Intermolecular Coordination of the Mercury Atom

Coordinative saturation of mercury can be attained not only by the intramolecular interaction with the heteroatom discussed in the preceding subsection but also by interaction with donor atoms of a neighbouring molecule in the crystal.

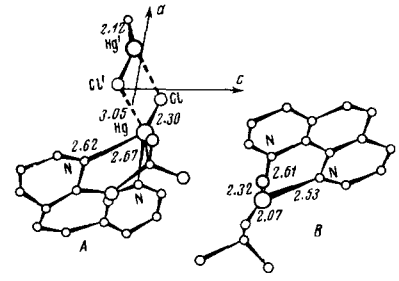


Figure 8.

X-Ray structure determination on the adduct of trichloromethylmercury chloride and 1,10-phenanthroline[54] indicated strong interaction between the mercury atom and the nitrogen atoms of the phenanthroline, with substantial disturbance of the linearity of the C–Hg–Cl fragment. The crystal structure contains two independent molecules A and B differing in geometry (Fig. 8), with CHgCl angles of 155° and 145° respectively. With such considerable disruption of the linear geometry of the mercury atom the Hg–C and Hg–Cl bond lengths—2.12 and 2.30 Å in A, and 2.07 and 2.32 Å in B—are almost the same as in linear

molecules. The Hg...N distances are 2.62 and 2.67 Å in A, and 2.53 and 2.61 Å in B. Coordination of the mercury atom in molecule B in the crystal conforms to a distorted tetrahedron; in A the additional effect of the close intermolecular Hg...Cl contact of 3.05 Å brings the coordination to distorted trigonal-bipyramidal.

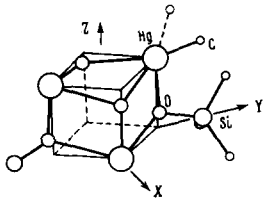

Figure 9.

Strong distortion of the linear geometry of the mercury atom has been found in methylmercury trimethylsiloxide[55]. The molecules are associated into tetramers (Fig. 9) having a cubane-like structure intermediate between the ideal cubane structure in the corresponding zinc and cadmium compounds (see below) and a structure with isolated molecules. Within the limits of accuracy the Hg–C and Hg–O distances of 2.09(40) and 2.11(20) Å correspond to normal covalent bonds in linear mercury molecules; the OHgC angle is 112(8)°. Thus even in this compound disturbance of the linear geometry of mercury is not accompanied by increase in Hg–O and Hg–C bond lengths. The coordination of mercury in the tetramer is supplemented by weak Hg...O interactions at distances of 2.75(20) Å to give a distorted tetrahedron. The arrangement of the methyl group attached to the mercury atom is random.

Several crystal structures have been described in which Hg...X coordination is achieved with considerably less distortion of the linear bond configuration of the mercury atom.

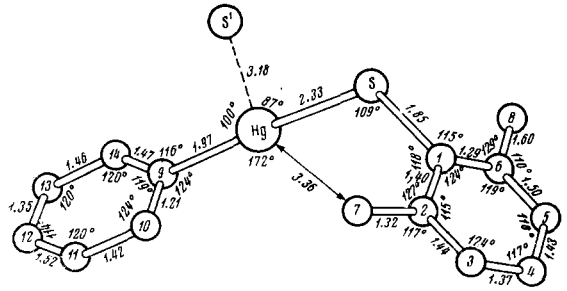

Figure 10.

An X-ray examination of phenylmercury 2,6-dimethylphenyl sulphide[44] had the aim of refining the van der Waals radius of the mercury atom, since intramolecular contact between the mercury atom and an electrically neutral methyl group should be present in this compound (Fig. 10). The Hg–C and Hg–X bond lengths are respectively 1.97 and 2.33 Å, and the SHgC angle is 172°. The angle between the HgSC(ω) plane and the plane of the thiophenol ring is 52.3°, with the mercury atom approaching a methyl group to 3.36 Å. On the assumption that contact occurs between the mercury atom and the carbon atom of the methyl group, whose hydrogen atoms do not prevent such contact, the van der Waals radius of the mercury atom is found to be ~ 1.6 Å, which lies between the two values suggested earlier[2]. The crystal structure involves intermolecular Hg...S′ coordination at 3.18 Å, which is 0.1–0.3 Å closer than the sum of the van der Waals radii. Such coordination is evidence also that the CHgS angle away from the S′ atom has decreased to 172° and that this atom is in a symmetrical position with respect to the C–Hg–S fragment. Furthermore, the angle at the sulphur atom (109°) is larger than the corresponding angle (100°) in the crystal structure of triphenyltin 2,4,6-trimethylphenyl sulphide[56], which may be due to a redistribution of electron density on the sulphur atom when it interacts with the mercury atom.

A similar increase in the angle at the sulphur atom (to 111°) was found in the crystal structure of mercury dimethanethiolate $(CH_3S)_2Hg$,[57,58] where intermolecular Hg...S interaction occurs at 3.25 Å, whereas in the structure of mercury diethanethiolate $(C_2H_5S)_2Hg$,[59] where such interaction is evidently absent (Hg...S = 3.56 Å), the HgSC angle is smaller (106°). The presence of coordination in the methyl derivative is confirmed by its higher melting point than those of the ethyl and propyl sulphides (175° compared with 76° and 71°C).

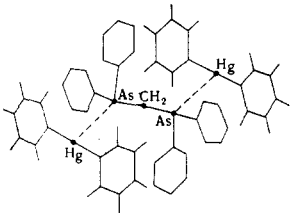

Figure 11.

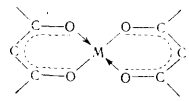
The presence of Hg...As coordination has been established in the crystal structure of the 2 : 1 adduct of bispentafluorophenylmercury and bisdiphenylarsinomethane[60,61] (Fig. 11). The arsenic atoms are situated symmetrically with respect to the bispentafluorophenylmercury molecules: the AsHgC angles are 90(3)° and 96(3)°. The Hg...As distance of 3.40 Å is 0.1–0.3 Å less than the sum of the van der Waals radii, and the CHgC angle away from the arsenic atom has closed to 173(4)°. Further evidence of Hg...As interaction is that the angle between the planes of the pentafluorophenyl rings is 7°, whereas it is 59.4° in the crystal structure of bispentafluorophenylmercury (see subsection II, 2). Such a tendency of the latter molecule to achieve planarity in the adduct facilitates approach of the arsenic to the mercury atom.

X-Ray examination of bisdipivaloylmethylmercury has established[62,63] that the mercury atom, in contrast to the atoms of transition metals, which form chelate complexes



with dipivaloylmethane, is attached to the two central carbon atoms of the ligands (Fig. 12). Only one moiety of the molecule is involved in additional Hg...O coordination (in conformity with which the thermal vibrations are smaller in this half). Such interactions lead to a decrease (to 170°) in the angle away from the two interacting oxygen atoms, to a lengthening to 2,18(3) Å of the Hg–C bond in the moiety involved in interaction (the length of the second Hg–C bond is 2.13(3) Å), and also to an increase to 120° of the angle at the central carbon atom in this moiety, which indicates a contribution by the sp^2 state of this atom.

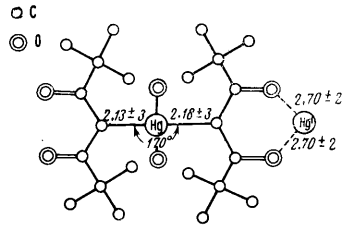


Figure 12.

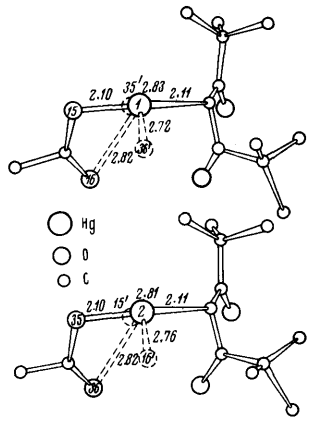

Figure 13.

In the crystal structure of dipivaloylmethylmercury acetate[64] the mercury atoms of two crystallographically independent molecules are involved in intermolecular coordination with oxygen atoms of acetate groups (Fig. 13): the oxygen atoms of the dipivaloylmethyl groups play no part in these interactions. The intramolecular Hg...O distances vary between 2.72 and 2.83 Å. The intramolecular Hg...O distance to the second oxygen atom of the acetate group (2.82 Å) is determined by the geometrical rigidity of the HgOCO fragment, so that we do not know whether it corresponds to interaction. Fig. 14 shows the coordination polyhedron of the mercury atom. As in certain other cases in which mercury is coordinated with more than two atoms corresponding to a more complicated polyhedron, the criterion of a decrease in bond angle at the mercury atom is ineffective or completely unsuitable.

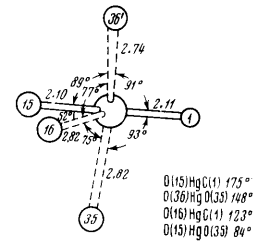

Figure 14.

A similar situation is found in the crystal structure of phenylmercury acetate[65] (Fig. 15). The Hg–$O_{(1)}$ and Hg–$C_{(1)}$ bond lengths are respectively 2.11 and 1.92 Å, and the OHgC angle is 170°. The distance to the second atom of the acetate group $O_{(2)}$ is 2.85 Å, but here, too, the question of intramolecular interaction is evidently unsettled. In the crystal the mercury atom is surrounded by oxygen atoms of neighbouring molecules at distances of 2.94, 2.95, and 3.11 Å. Although these distances coincide with the sum of the van der Waals radii (2.9–3.1 Å), the fairly symmetrical arrangement particularly of oxygen atoms about mercury in a plane approximately perpendicular to O–Hg–C suggests that they are responsible for coordination interactions. The original authors regard them as van der Waals contacts.

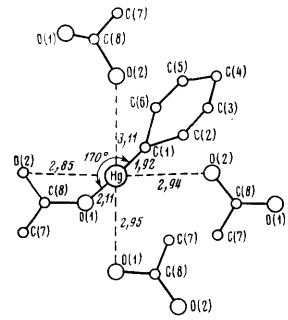

Figure 15.

An X-ray structure determination on 2-diethylaminoethylmercury chloride $(C_2H_5)_2N.CH_2.CH_2.HgCl$ was undertaken[66] to establish intermolecular Hg...N coordination in compounds of this type. The Hg–C and Hg–Cl bond lengths are 2.12 and 2.36 Å respectively. Coordination of the

mercury atom in the crystal is trebled by interaction with a nitrogen atom of a neighbouring molecule at 2.77(2) Å, with a decrease in the CHgCl angle to 173°.

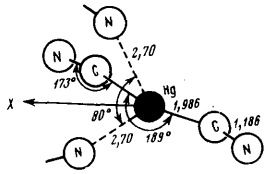

Figure 16.

X-Ray structure determination[67] and neutron diffraction[68] have given a closely similar intermolecular Hg...N distance in the mercury(II) cyanide crystal (2.70 and 2.74 Å). The former method shows that the CHgC angle away from the two coordinating nitrogen atoms (Fig. 16) has decreased to 171(2)°, and the Hg–C bond length is 1.986(16) Å. Neutron diffraction indicates that this angle is 175.0(2)°, and the bond length 2.015(3) Å. It is interesting to compare these results with those for methylmercury cyanide[13,14]. This molecule is linear, and the Hg...N distances (3.14 and 3.26 Å) are not shortened in the crystal. This is probably because replacing the cyanide group by methyl diminishes the positive charge on the mercury atom and weakens its ability to coordinate.

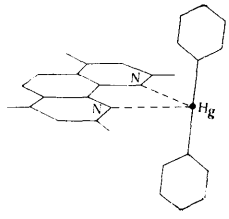

Figure 17.

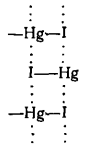
The crystal structure of the adducts of diphenylmercury with 2,9-di- and 2,4,7,9-tetra-methyl-1,10-phenanthroline[69] (Fig. 17) also show diminished coordinating power of mercury in the absence of electronegative substituents. One phenanthroline molecule is located near each diphenylmercury molecule in a plane approximately perpendicular to the C–Hg–C fragment and passing through the mercury atom (a second substituted phenanthroline molecule, not involved in contacts with the mercury atom, is also present). The Hg...N distances of 2.8–3.0 Å are greater in the two preceding structures, and close to the sum 2.8–3.0 Å of the van der Waals radii. Therefore coordination cannot be assumed on this basis alone, but its presence is suggested by such a specific relative arrangement of diphenylmercury and phenanthroline molecules.

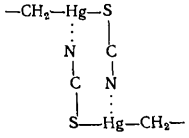
X-Ray structure determinations on several barenyl derivatives of mercury halides[70] established the presence of strong intermolecular Hg...I interaction in phenylbarenylmercury iodide

corresponding to 3.29 Å, which is 0.4–0.6 Å smaller than the sum of the van der Waals radii. Such interaction explains the spontaneous symmetrisation that occurs when the crystals are stored. Only the coordinates of the mercury and bromine atoms were determined in phenyl- and in methyl-barenylmercury bromide, and the Hg...Br distances shown to be respectively 3.42 and 3.56 Å, with the sum of the van der Waals radii 3.45–3.7 Å. However, the antiparallel arrangement of the Hg–Br fragments in the structure indicates weak intermolecular Hg...Br interaction.

Several crystal structures have been described in which the arrangement of heteroatoms in neighbouring molecules suggests the presence of coordination, although the atoms are no closer than the sum of the van der Waals radii. X-Ray examination of the compounds $CH_3O.C(CH_3)_2.C(CH_3)_2.CH_2.HgX$ showed[71] that, when X = I, the Hg–I bond length is 2.60 Å, and the intermolecular Hg...I distance 3.81 Å. Owing to weak intermolecular Hg...I interactions, infinite chains of antiparallel Hg–I fragments



appear in the crystal structure of this compound. In such compounds with X = SCN geometrical analysis of the coordinates of mercury and sulphur atoms reveals the formation of dimers



through the terminal nitrogen atoms of the thiocyanato-groups. The molecular configuration in the dimer corresponds to the isomer with closest approach of mercury and nitrogen atoms, probably as a consequence of coordination between them. Unfortunately, the Hg...N distances were not determined.

Intermolecular Hg..Cl interaction was established[72] in the crystal structure of 2-chlorovinylmercury chloride ClCH:CH.HgCl. The mercury atoms in three crystallographically independent molecules are coordinated by the chlorine atoms of neighbouring molecules; the Hg...Cl distances vary within the range 2.89–3.49 Å. The mean Hg–C and Hg–Cl bond lengths are respectively 2.10 and 2.30 Å. Unfortunately, no analysis of the coordinative environment of the mercury atoms is given in the paper.

X-Ray examination of phenylmercury halides established[73] that the Hg–Br bonds in the bromide have an antiparallel arrangement, with the mercury atom coordinated by four bromine atoms of neighbouring molecules (Hg...Br = 3.45 Å) in an octahedral environment. The Hg–C and Hg–Br bond lengths are 2.06 and 2.43 Å, and the CHgBr angle is 180°. The chloride and the iodide are isostructural with the bromide.

The crystal structures of *para*-derivatives of phenylmercury halides were also studied[74]. The coordinates of the mercury and chlorine atoms in *p*-tolylmercury chloride showed that the mercury atom is surrounded by three chlorine atoms of neighbouring molecules at 3.35, 3.35, and 2.99 Å. The packing of *p*-chlorophenylmercury chloride molecules in the crystal is closely similar to that of phenylmercury chloride, with a nearly antiparallel arrangement of Hg–Cl bonds. The tendency of the molecules to such an arrangement is so great that it is realised, although geometrical analysis shows that such packing will probably lead to the presence of closer intermolecular contacts.

An antiparallel arrangement of Hg–Br bonds was found also in *p*-tolylmercury bromide, in contrast to the corresponding chloride, and also leads to the presence of closer intermolecular contacts. This probably indicates that Hg...Br interaction is stronger than Hg...Cl interaction.

An antiparallel arrangement of Hg–Br bonds is impossible in the crystal structure of *p*-ethoxycarbonylphenylmercury bromide, containing a bulky *para*-substituent. The mercury atom in this crystal is surrounded by three bromine atoms of neighbouring molecules at distances 3.43, 3.43, and 3.55 Å (Hg–Br bond length 2.42 Å). *p*-Methoxyphenylmercury chloride, despite its large *para*-substituent, has the phenylmercury chloride type of crystal structure. This was explained by the "flexibility" of the methoxy-group, making it convenient for packing in the crystal.

III. ORGANOZINC AND ORGANOCADMIUM COMPOUNDS

The structures of the corresponding zinc and cadmium compounds have been studied considerably less than those of organomercury compounds. The reason is the great reactivity of the former, making their examination by X-ray or electron diffraction difficult.

The structures of dimethylzinc and dimethylcadmium, among organometallic compounds of type R_2M, have been studied by means of their Raman spectra[6]. Both molecules are linear. The Zn–C and Cd–C bond lengths are 1.929(4) and 2.112(4) Å, the latter thus being rather longer than Hg–C in dimethylmercury (2.094(5) Å). Thus the M–C bond length does not vary in parallel with the atomic number of the metal in the series zinc, cadmium, and mercury. A similar relation of bond lengths has been found for the dihydrides, in which the H–M distances in this series are 1.595, 1.762, and 1.740 Å. X-Ray examination of dimethylzinc[75] gave Zn–C = 1.96 Å, and a methyl group of a neighbouring molecule situated opposite the vacant *p*-orbitals of the zinc atom. This does not exclude weak interaction between them, like that observed in trimethylindium[75,76] and in trimethylaluminium[75,77].

Organozinc and organocadmium compounds in which the metal atom has a tetrahedral configuration are rather more stable, and have therefore been studied more thoroughly.

The crystal structure and the molecular structure of lithium tetramethylzincate were determined[78] by the powder method. The second of the two space groups $I\bar{4}2m$ and $I\bar{4}$, which differ in the orientation of the methyl groups, was chosen on the basis of crystallographic considerations. The zinc atom (Fig. 18) is located at a singular point on an inversion axis, and has distorted tetrahedral coordination. The Zn–C bond lengths of 2.07(15) Å were regarded as greater than the value of 1.929 Å in the linear molecule of dimethylzinc. However, the poor accuracy of this value does not permit the significance of such an increase to be assessed.

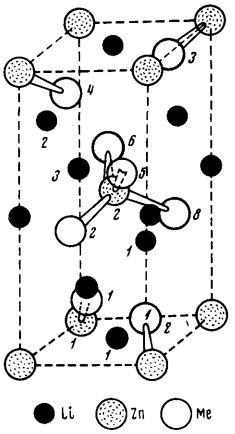


Figure 18.

Crystals of the isostructural potassium tetraethynylzincate and tetraethynylcadmate $K_2[Zn(C_2H)_4]$ and $K_2[Cd(C_2H)_4]$ have also been investigated by the powder method[79] (Fig. 19). In both compounds the metal atom has tetrahedral coordination. The $Zn–C_{(1)}$ distance of 2.0(1) Å was regarded as shortened by d_π–p_π interaction, although the poor accuracy evidently gives no grounds for such conclusions. The Cd–C distance is 2.5(1) Å.

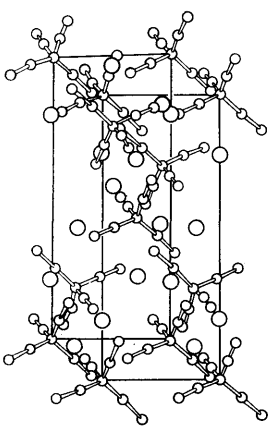

Figure 19.

The formation of tetra-, penta-, octa-, and poly-mers is very characteristic of organozinc and organocadmium compounds in the crystalline state. X-Ray examination of methylzinc methoxide[80,81] established the existence of a tetramer having a cubane structure (Fig. 20). Zinc and oxygen atoms occupy alternate corners of a distorted cube.

The Zn–C and Zn–O distances are 1.94 and 2.09 Å; the mean angles at the zinc and oxygen atoms are 83° and 96°.

On the basis of chemical and physicochemical investigations an analogous cubane structure was suggested[82-84] for the structurally unstudied compounds $[CH_3MOSi(CH_3)_3]_4$ (M = Zn, Cd) (Fig. 21) and $[CH_3ZnNP(CH_3)_3]_4$ (Fig. 22).

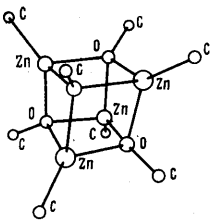

Figure 20.

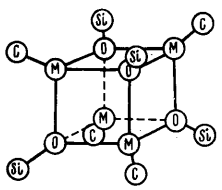

Figure 21.

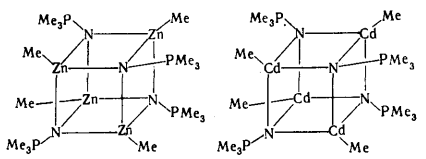

Figure 22.

X-Ray examination of the compound $Zn_7O_8(CH_3)_{14}$ shows[85] that it has a dicubane structure (Fig. 23) in which two kinds of zinc atoms differ in their coordination. The central zinc atom, located at a centre of symmetry, is octahedrally surrounded by methoxyl oxygen atoms at distances of 2.068–2.170 Å. The remaining zinc atoms have tetrahedral coordination with mean Zn–C distances of 1.953 Å, while the Zn–O distance varies between 2.026 and 2.147 Å.

The sulphur analogues—methylzinc isopropyl[86] and isobutyl[81] sulphides—have an interesting structure. The former is octameric (Fig. 24), but unfortunately the X-ray examination did not reveal the carbon atoms. The Zn–S distance varied in the range 2.161–2.489 Å. The zinc atoms in the latter compound (Fig. 25) are located at the vertices of a distorted square pyramid, and the sulphur atoms over the faces of this pyramid; bond lengths were not given.

Crystalline ethylzinc iodide does not have a tetrameric structure but is a coordination polymer[87,88] (Fig. 26), owing to the bulkiness of the iodine atom, which does not permit formation of a four-membered ring. This explains the difference in chemical behaviour (solubility in hydrocarbons) between this compound and the bromide and chloride, which have a tetrameric cubane structure in solution[89]. Nevertheless, the arrangement of zinc and iodine atoms is close to a cubane structure, which can be obtained (Fig. 27) simply by shifting two iodine atoms (as indicated by the arrows) in the four-membered fragment of the polymer. The zinc atom has a distorted tetrahedral coordination; the CZnI angle is 144.4(1.7)°, the Zn–C and Zn–I bond lengths are 1.95 and 2.64 Å, and the other two Zn–I distances to the iodine atoms of neighbouring fragments (C_2H_5ZnI) of the polymer are 2.91(6) Å.

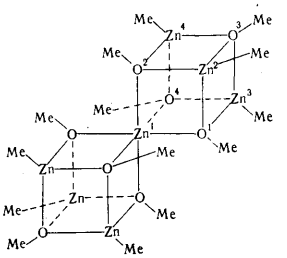

Figure 23.

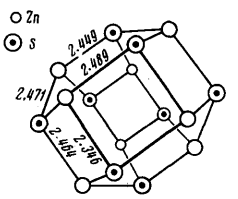

Figure 24.

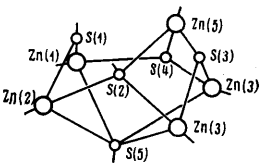

Figure 25.

The zinc atom in the crystal structure of the ionic methyldineopentylsulphonium tri-iododineopentylthiomethylzincate $[(C_5H_{11})_2SCH_3]^+[(C_5H_{11})_2SCH_2ZnI_3]^-$ is subject to distorted tetrahedral coordination[90] (Fig. 28) by three iodine atoms and one carbon atom. However, the Zn–I bonds have undergone more equalisation than in ethylzinc iodide (2.62, 2.63, and 2.68 Å), while the CZnI angle of 120°

shows maximum departure from the tetrahedral value; the Zn–C bond length is 2.14(3) Å.

---o0o---

This Review shows that hardly any structural studies have been made on organic derivatives of zinc and especially of cadmium, mainly owing to the high reactivity of these compounds.

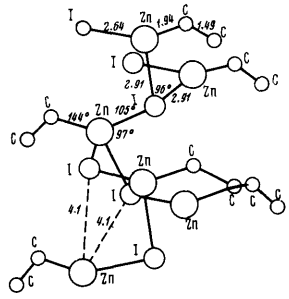

Figure 26.

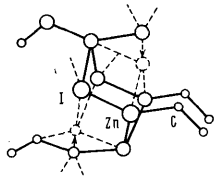

Figure 27.

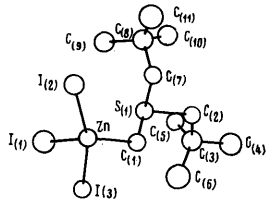

Figure 28.

The investigation of organomercury compounds, as already remarked, presents considerable difficulties owing to the great difference in atomic number between mercury and carbon. Only during recent years have papers appeared in which all the light atoms have been objectively revealed: in the vast majority of studies during the 1940s and 1950s either the coordinates of light atoms were not found at all or the accuracy of their determination was poor (~ 0.1 Å).

This aspect is especially significant in view of the fact that, in the investigation of organomercury compounds, interest lies not in establishing the structural formula, which usually requires no great accuracy, but in revealing weak intramolecular and intermolecular coordination interactions, whose analysis rests on fine changes in geometrical parameters (interatomic distances, bond angles). These interactions usually operate at large distances (~ 3 Å), close to the sums of the van der Waals radii. It is noteworthy, however, that the very concept of van der Waals radius was originally applied mainly to organogen elements, i.e. to non-metals and certain closely related classically non-transition elements (germanium, tin). However, the use of van der Waals radii of post-transition metals in which a *d*-shell has only just been filled, such as mercury, copper, etc., must evidently be approached with great caution.

The nature of the "additional" interactions discussed in the Review is not entirely clear. Electrostatic forces undoubtedly play an important part in many cases. However, it is difficult to explain the structure of many crystals, e.g. the adduct of diphenylmercury with phenanthroline, solely on the basis of electrostatic interactions. Not only further structural investigations but also appropriate quantum-chemical calculations are required to settle this question.

Gel Chromatography of Condensed Phosphates

V.V.Pechkovskii, G.Kh.Cherches, and M.I.Kuz'menkov

The principles of the application of gel chromatography are discussed, together with its potentialities in the investigation of inorganic polymers of phosphorus with the aim of determining molecular dimensions, fractionating a mixture, obtaining individual phosphates, and also analysing their molecular-weight composition. The development and the achievements of the gel chromatography of condensed phosphates are surveyed. The phenomena occurring in a gel during the elution of inorganic compounds are described for several salts. A list of 91 references is included.

III. Application of gel chromatography to the investigation of phosphates 91

I. INTRODUCTION

Molecular weight and degree of polydispersity are among the main characteristics of macromolecular compounds. Research has shown [1-6] that many properties of inorganic phosphate polymers depend directly on the size of the molecules. It is therefore very important to develop methods for investigating the molecular-weight composition of such polymers.

Almost all the methods known in the chemistry of macromolecular compounds—light scattering [1], ultracentrifuging [7,8], viscometry [1,9], chemical (end-group analysis) [10-12], and cryoscopic [13-15]—have been used to determine the mean molecular weight of condensed phosphates. Chromatographic methods of analysis (paper [16-18], ion-exchange [19-21], thin-layer [22-24], and electro-chromatography [25-27]) can be used to establish the molecular-weight distribution of polymers containing up to 10–14 phosphorus atoms in the chain. Precipitation [28-30] by means of various organic and inorganic reagents is, perhaps, the only method employed for the fractionation of macromolecular phosphates.

Promising new methods for isolating and separating condensed phosphates would contribute to further knowledge of their properties and structure. The production of porous gels varying in their permeability to molecules of different sizes was responsible for the rapid and widespread development of gel chromatography, a method of separation according to molecular weight†: since gel chromatography was first studied in 1959 on Sephadexes [31], more than 2000 publications have appeared on the application of the method.

Examples of hydrophilic gels used in gel chromatography are [32] dextrans—Sephadex (Sweden) and Molselekt (Hungary)—polyacrylamides—Bio-Gel P (USA) and Acrylex P (Hungary)—and agaroses—Sepharose (Sweden) and Bio-Gel A (USA). Organophilic examples include Sephadex derivatives and acrylic and polystyrene gels. Furthermore, dextran (ED, DED) and polyacrylamide (AM) hydrophilic gels and styrene—divinylbenzene (SDV) hydrophobic gels, similar in properties to the foreign products, have been manufactured in the USSR. [33] All the gels are produced as spherical granules of various sizes, and are divided into several types according to their porosity.

Gel chromatography was developed and used mainly for separating, isolating, purifying, and concentrating organic compounds, as well as for their molecular-weight analysis. A considerable number of reviews have been published on the theoretical basis of the method and its practical application in organic and biological chemistry [34-40].

The achievements and possibilities of gel chromatography have recently attracted the attention of inorganic chemists. The behaviour of halides, nitrates, sulphates, and perchlorates of alkali, alkaline-earth, and other uni- and bi-valent metals on Sephadexes and Bio-Gels has been investigated as a function of concentration, gel porosity, column height, eluent type, concentration, and pH, rate of elution, and temperature [41-52]. Gel chromatography has been used to study inorganic polymers such as phosphates [53-67], silicates [68], basic iron nitrates [69,70], and molybdates [71]. It has been employed to investigate complex formation with Trilon B [72,73] and other reagents [74,75]. Its application to the separation and investigation of various ions, complex compounds, and inorganic polymers has been reviewed [76,77].

These researches were decisive in establishing the processes occurring in a gel during the elution of electrolyte solutions. This knowledge served in turn as foundation for the practical application of gel chromatography to the determination of the sizes of ions, the separation and purification of inorganic substances, and the determination of the molecular-weight composition of inorganic polymers.

II. GEL CHROMATOGRAPHY OF INORGANIC COMPOUNDS

1. Processes occurring in the Gel during Elution

The solvent in a layer of a swollen gel can be regarded [34] as forming two phases—within and between the granules—so that the total volume of the layer can be expressed

(1)

where V_0 is the volume of solvent between the granules (external or free volume), V_i the volume of solvent inside the granules (internal volume), and V_m the volume of the

† The term *gel chromatography* is used in this Review as the most common in the chromatography of inorganic substances on gels.

gel matrix. Various phenomena may occur on the elution of dissolved molecules in such a system. Which phenomenon predominates is determined by the interaction of gel, solute, and solvent.

Numerous experimental results show that dissolved molecules are eluted from a gel chromatographic column in the order of their diminishing size or molecular weight. Such an inverse molecular-sieve effect is due to the fact that dissolved molecules of different sizes penetrate the swollen granules to different extents, which may be connected both with steric factors and with diffusion. The elution volume V_e of any solute is therefore intermediate between that of a substance which is completely excluded from the gel granules (equal to the free volume V_0) and the elution volume of a substance which is uniformly distributed between the two phases (equal to the total volume of solvent $V_0 + V_i$):

$$V_e = V_0 + K_d V_i, \qquad (2)$$

where K_d is the distribution ratio of the solute between the two solvent phases ($0 \leq K_d \leq 1$ in magnitude), which characterises the degree of penetration of solute inside the gel.

The above molecular-sieve mechanism is apparent in most cases of the gel chromatography of organic and inorganic substances; it is supported also by the consistency of experimental results with relations between elution parameters and molecular weights or sizes calculated on the basis of various models of gel structure [78-80]. However, several examples are known, especially in the elution of aromatic and heterocyclic compounds [81], their derivatives containing ionisable groups, and many inorganic salts [41], where the behaviour on gel chromatography cannot be satisfactorily explained solely by the molecular-sieve effect.

Secondary effects (secondary with respect to separation according to molecular weight, but in some cases decisive) are apparent in disturbances of the sequence of elution with diminishing molecular weight or size, in significantly overestimated ($V_e > V_0 + V_i$) or underestimated (in comparison with expectation from molecular size) elution volumes, in asymmetry of the chromatographic peaks, and in a dependence of the elution parameters on the concentration of the solute and on the nature and concentration of the eluent. These phenomena may result from specific interaction of the gel with certain substances and ions both in the separable mixture and in the eluent, as well as with their mutual complexes.

Abnormally high partition coefficients (or elution volumes) are a consequence of the retention of a substance in the column, owing to ion exchange or physical and chemical adsorption by the gel. The substance is then eluted by a volume of solvent exceeding $V_0 + V_i$, and the partition coefficient $K_d > 1$.

In several cases, on the other hand, substances are eluted from the column earlier than would be expected from their molecular size. This phenomenon, termed *ionic exclusion*, is attributed to the presence of a small quantity of negatively charged carboxylate groups in Sephadex, which repel solute anions, which are thus excluded from the gel granules and are eluted earlier.

Adsorption and ionic exclusion effects can be observed in the elution of sodium sulphate, chloride, nitrate, and perchlorate on Sephadex G-15 with 0.1 M sodium chloride solution [42]. The elution volumes of these salts increase in the sequence

$$Na_2SO_4 < NaCl < NaNO_3 < NaClO_4.$$

Sodium nitrate is eluted by a volume of solvent exceeding the total volume; the perchlorate is eluted still more slowly; and the partition coefficient of sodium sulphate (~0.1) is considerably smaller than the value to be expected from the radius of the hydrated sulphate ion [82]. Furthermore, experimental results on the elution of the chlorides of several metals with solutions of 0.1 M KCl + 0.01 M HCl, 0.1 M Na_2SO_4 + 0.005 M H_2SO_4, 0.1 M $NaNO_3$ + 0.01 M HNO_3, and 0.1 M $NaClO_4$ + 0.01 M $HClO_4$ on Sephadex G-25 showed that the partition coefficients of the metal ions in the nitrate and perchlorate systems were respectively 1.0–1.5 and 1.8–2.7, but those for the sulphate system were closely similar and small (up to 0.4). [43,44] These data indicate specific interaction between the gel and these ions, i.e. adsorption of nitrate and perchlorate ions and considerable exclusion of the sulphate ion.

Adsorption can be observed also in the elution of substances by eluents which by themselves are inert towards the gel. An example is the elution of zinc and cadmium chlorides on Sephadex G-10, which depends on the concentration of the eluting sodium chloride solution [45]: with increase in the eluent concentration chloride complexes are formed, whose adsorption on the gel produces values of $K_d > 1$.

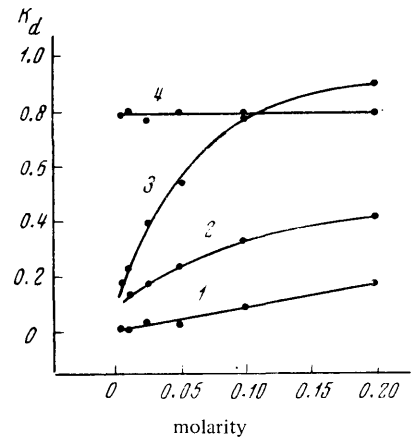

Figure 1. Effect of concentration of test material (in 50 ml of solution eluted with water on Sephadex G-10 at 35 ml h^{-1}) on its partition coefficient calculated from V_e, V_0, and V_i for [46]: 1) $Na_5P_3O_{10}$; 2) Na_2HPO_4; 3) NaCl; 4) glucose.

The ionic exclusion effect can be diminished by using a suitable eluent containing a supporting electrolyte to neutralise the action of the gel. Secondary effects are strengthened when water without a supporting electrolyte is used as eluent. In the elution of solutions of certain electrolytes with water, for example, their partition coefficients are relatively small and increase with the concentration of the solutions [46,47]. Use of an electrolyte as eluent increases the partition coefficients. The elution curves of non-electrolytes, e.g. glucose, do not depend on these factors (Fig. 1). To explain the processes occurring in a gel during the elution of electrolyte solutions the penetration of the supporting electrolyte into the interior of the gel phase was assumed to be incomplete owing to

steric and electrostatic factors[42,48]. Indications that part of the water involved in the swelling of a gel hydrates the polysaccharide chains of dextran[81] confirm the existence in the gel of a region which is inaccessible to dissolved molecules.

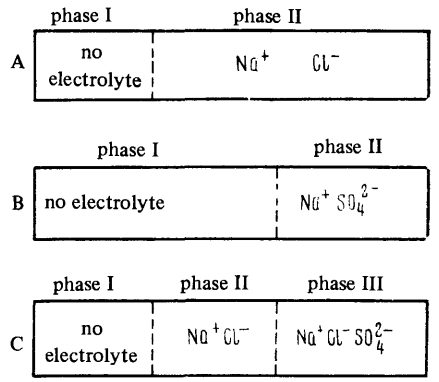

Figure 2. Diagram of distribution of ions in gel granules[42].

Thes properties of a gel are shown diagrammatically in Fig. 2. Their effect has been discussed in relation to the behaviour of magnesium ions in the $MgCl_2$–NaCl and $MgSO_4$–Na_2SO_4 systems[42]. If the supporting electrolyte, i.e. sodium chloride, penetrates inside the granules to only a limited extent, the interior of the gel is divided into two phases, as it were, distinguished by the presence or the absence of the given electrolyte (Fig. 2*A*). The degree of penetration by the electrolyte, i.e. the extent of phase (II), is determined mainly by the size of the larger ion. Since the effective ionic size increases from chloride through sodium to the sulphate ion, this phase will be smaller in the sulphate than in the chloride system (Fig. 2*B*). In a homogeneous sample–eluent system the efficiency of elution of magnesium ions will depend on the degree of penetration of the gegenion into phase (II), since the magnesium ion should be near its anion to preserve the electrical neutrality of the solution. In the chloride system the magnesium ions penetrate the gel to an extent determined by their size, since the chloride ion is smaller than the magnesium ion. In the sulphate system the penetration of magnesium ions is governed by the size of the sulphate ion, which is larger than magnesium. Thus the volume accessible to magnesium ions is smaller in the sulphate than in the chloride system. When a mixed solution of sodium chloride and sodium sulphate is used as eluent, the internal liquid phase is regarded as consisting of three regions (Fig. 2*C*), the additional phase (III) containing sodium, chloride, and sulphate ions. Since magnesium and sulphate ions interact to form complexes, penetration of the former into the gel will be determined by the relative sizes of phases (II) and (III). This may explain results obtained for the elution of magnesium chloride with solutions containing different ratios of sodium chloride and sulphate (Fig. 3).

It has already been stated that secondary effects are apparent also in the dependenee of the position and the shape of the elution curves on the concentration of the substance. The degree of asymmetry of the elution peak can be assessed by the ratio F/B,[46] where F and B are the distances from the ordinate for the peak to the ascending and descending portions of the curve measured at mid-height. For example, the effect of concentration on the elution volume and the symmetry of the peak has been investigated in the sample–eluent systems

$MgSO_4$–Na_2SO_4, $Mg(ClO_4)_2$–$NaClO_4$, $Mg(NO_3)_2$–$NaNO_3$[42], $MgCl_2$–NaCl, $SrCl_2$–NaCl, $BaCl_2$–NaCl[44].

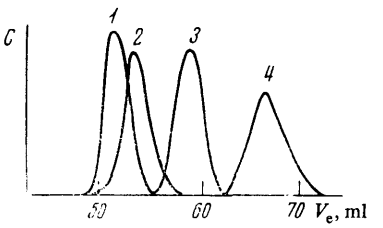

Figure 3. Variation of elution volume of Mg^{2+} ions from 0.01 M $MgCl_2$ (1 ml on Sephadez G-15 column 1.5 × 60 cm at 20–30 ml h^{-1}) with composition of eluent[42]: 1) 0.1 M Na_2SO_4; 2) 0.075 M Na_2SO_4 + 0.025 M NaCl; 3) 0.05 M Na_2SO_4 + 0.05 M NaCl; 4) 0.1 M NaCl; Here and on the other diagrams showing elution curves C denotes the relative concentration of the substance in the eluate.

Analysis of these results (Fig. 4) reveals three types of dependence of elution volume on concentration of the sample solution[44] according as $dV_e/d\lg[M]$ (i) vanishes (curves *1* and *2* at concentrations <0.1 M), (ii) <0 (curves *3*–*5* at <0.1 M and curve *6* at all concentrations investigated), and (iii) >0 (curves *1*–*5* at >0.1 M). In most cases the corresponding values of the ratio F/B were unity, <1, and >1.

These results reflect the processes occurring in the system. If a molecular-sieve mechanism alone operates, the elution curves are symmetrical, the partition coefficients are independent of concentration, and the relation $0 \leq Kd \leq 1$ is satisfied. With substances exhibiting symmetrical peaks at low concentrations and satisfying the above relation, the change in elution volume and in the shape of the peak with increase in concentration is attributed to diminished hydration of the ion and of the gel matrix with increase in the ionic strength of the solution, with a consequent increase in partition coefficient. Furthermore, the change in the degree of hydration may lead to the presence of hydrated ions of various sizes in the solution, whose elution curve will be non-Gaussian. A molecular-sieve mechanism then predominates. Asymmetry of the peaks and partition coefficients exceeding unity at low concentrations are a consequence of secondary processes.

2. Processing of Experimental Data and the Results of Gel Chromatography

Although the above secondary effects, representing an affinity for the gel phase, can sometimes be used for separation[34], the principal merit and the main use of gel chromatography consist in the relation between molecular

weight or size and the elution volume, which is possible when separation is due solely to a molecular-sieve mechanism. Various equations expressing the dependence of elution volume on molecular weight [34], "effective chain length" [83], Stokes radius [84], hydrodynamic volume [85], and molar volume [86] have been found for various substances. These equations contain parameters connected with the elution volume V_e/V_t and V_e/V_0, as well as partition coefficients, whose introduction permits comparison of results obtained with different columns and gels.

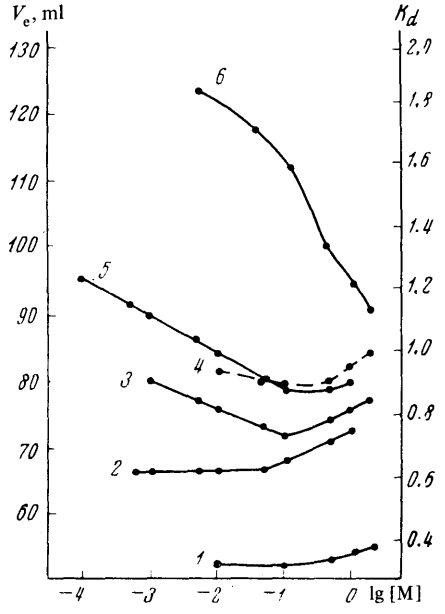

Figure 4. Dependence of elution volume and partition coefficient on sample concentration [M] (1 ml eluted at 20–30 ml h^{-1} on Sephadez G-15 column 1.5 × 60 cm with 0.1 M eluent) for the sample–eluent systems [42,44]: 1) $MgSO_4$–Na_2SO_4; 2) $MgCl_2$–NaCl; 3) $SrCl_2$–NaCl; 4) $Mg(NO_3)_2$–$NaNO_3$; 5) $BaCl_2$–NaCl; 6) $Mg(ClO_4)_2$–$NaClO_4$.

The partition coefficient characterises the behaviour of a substance in a gel, and a difference in its values for different substances may indicate differences in the mechanism of separation. From Eqn.(2) we have

$$K_d = \frac{V_e - V_0}{V_i} \qquad (3)$$

i.e. the free and internal volumes of the gel must be known in order to determine the partition coefficient. The former volume is determined by means of substances which are completely excluded from the gel and whose elution volume is $V_e = V_0$, while $K_d = 0$. A higher polysaccharide (dextran blue) and for inorganic systems a higher phosphate (e.g. Kurrol salt [53]) are most often used for this purpose.

The internal volume can be determined on the assumption that such compounds as hydrogen and sodium chlorides are uniformly distributed between the two phases, so that their elution volume $V_e = V_0 + V_i$ and $K_d = 1$. [46] The same hypothesis can be used to determine the internal volume for tritiated water THO. [53] However, comparison of the elution volumes of THO and $H_2^{18}O$ shows [87] that, owing to isotope exchange, the former has the rather larger elution volume. With the partition coefficient of the latter regarded as unity, those of tritiated water for Sephadexes G-10, G-15, and G-200 were determined as respectively 1.09, 1.06, and <1.02. [87]

In several cases the internal volume is determined by means of Eqn.(1), which gives

$$V_i = V_t - V_0 - V_m \ . \qquad (4)$$

The matrix volume of the gel is found from the specific volume of the latter (0.61). [88] The internal volume has been determined also [41] from the difference between the weights of the column containing the gel w, the empty column w_t, and the gel a transferred quantitatively from the column, washed with ethanol, and dried in a vacuum at 80°C for 6 h:

$$V_i = (w - w_t - a - \rho V_0)/\rho \qquad (5)$$

where ρ is the density of water.

In view of the presence in the gel of a region inaccessible to dissolved molecules, other workers [89] introduced the concept of an effective internal volume $(V_i)_{eff} = 0.8V_i$. It is advisable to use chloride and bromide ions—but not fluoride, iodide, sulphate, thiocyanate, copper(II), or iron(III)—for its determination.

Because of the uncertainty and difficulty of finding the internal volume, it is convenient to use the partition coefficient

$$K_{av} = \frac{V_e - V_0}{V_t - V_0} \qquad (6)$$

whose calculation depends on readily determinable quantities [80]. The relation between K_{av} and K_d is

$$K_{av} = K_d \frac{V_i}{V_i + V_m} \ . \qquad (7)$$

The difference in value between the two partition coefficients diminishes with increase in the porosity of the gel.

Partition coefficients are determined not only by the column method—i.e. under elution conditions—but also under static conditions [45,53,54]. The method is based on the postulate that the concentration of substances in the gel phase is the same as in the external liquid phase. Definite quantities of gel and solution of concentration C_1 of the substance in the eluent are stirred until equilibrium is established. After being allowed to settle, the concentration C_2 in the solution over the swollen gel is determined. We then have

$$K_d = 1 - \frac{V_0' + V_i'}{V_i'} \cdot \frac{C_2 - C_1}{C_2} \qquad (8)$$

where V_0' and V_i' are the free and internal volumes of the solvent. The sum $V_0' + V_i'$ is assumed to equal the volume of solution taken, and V_i' is determined by means of substances having $K_d = 0$.

Comparison of partition coefficients found by elution and under static conditions is used to estimate the contribution made by diffusion of the solutes to the separation [53,54]. Furthermore, the quantity $D = 100(C_1 - C_2)/C_1$ represents the contribution of adsorption, as a consequence of which $C_1 > C_2$ and $D > 0$. [45]

It was suggested[41] that the contributions of cation and anion to the partition coefficient of an ionic compound were additive:

$$K_d = \frac{s\Phi_c + t\Phi_a}{s+t} \qquad (9)$$

where t and s are the cationic and anionic charges, and Φ_c and Φ_a are the individual contributions of cation and anion to the partition coefficient. On the assumption that $\Phi_{Na} = 1$, the relative values of Φ_c and Φ_a were determined by a method similar to that used to find radii in a crystal. Good agreement was obtained with experimental partition coefficients for several salts on Bio-Gel P-2.

The use of gel chromatography to determine molecular weights, polydispersity, and molecular dimensions involves relating these characteristics with the elution parameters and employing the resulting mathematical and graphical formulae as calibration. In practice the elution volume is in most cases a linear function of the logarithm of the molecular weight. The best method for plotting a calibration straight line is to use monodisperse fractions of the test polymer, since the relation between molecular weight and molecular size may differ substantially for each type of compound. In several cases, however, calibration lines are obtained by means of standard specimens, e.g. narrow fractions of polystyrene or proteins[34].

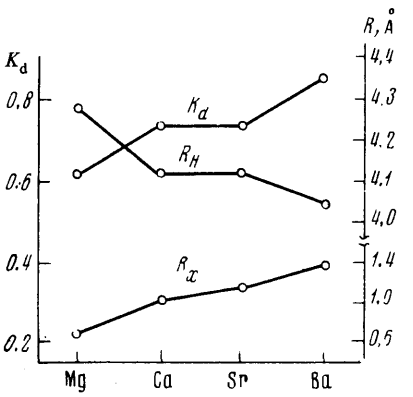

Figure 5. Comparison of partition coefficients and ionic dimensions of alkaline-earth metals[48] for 1 ml of 0.01 M solution eluted on Sephadex G-15 with 0.1 M NaCl + 0.01 M HCl at 20–30 ml h^{-1}: R_X = radius of ion in crystal; R_H = radius of hydrated ion.

The elution curve for the fractionation of a polydisperse polymer on an already calibrated column may be used to characterise its molecular-weight distribution. Analysis of the molecular weight and the quantity of each fraction obtained by preparative gel chromatography will also yield distribution curves.

Consideration of the various processes occurring during elution in a gel indicates that calibrations can be used to find ionic sizes or molecular weights when separation is due solely to a molecular-sieve mechanism. It is assumed that interactions among gel, substance, and eluent, apparent as adsorption, ionic exclusion, ion exchange, or complex formation, are absent.

The behaviour of inorganic salts in gel chromatography is in many cases consistent with a molecular-sieve mechanism. Comparison of the partition coefficients of alkaline-earth metal chlorides with the ionic radii, for example, shows (Fig. 5) that these salts are eluted in the sequence of diminishing size of the hydrated cations[48].

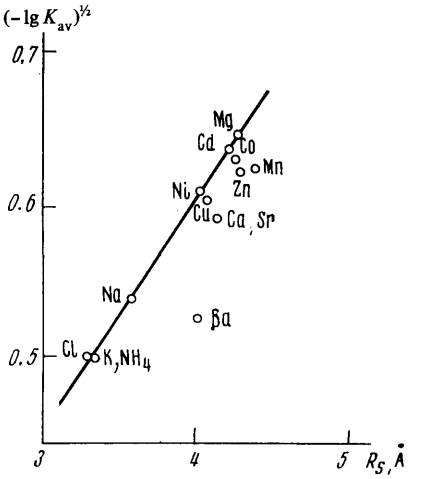

Figure 6. Relation between $(-\lg K_{av})^{1/2}$ and R_S for certain ions[43].

The model of a gel as a network of straight, rigid filaments, of infinite length and distributed at random in the gel[81], yields the relation

$$(-\lg K_{av})^{1/2} = A \cdot R_s + B \qquad (10)$$

between the partition coefficients and the radii R_S of dissolved molecules, where A and B are constants for a given gel. Fig. 6 illustrates the dependence of $(-\lg K_{av})^{1/2}$ on R_S for several ions eluted by 0.1 M potassium chloride solution on Sephadex G-15.[43] Results for ions which do not form chloride complexes and are not adsorbed on the gel lie on a straight line, which can be used as calibration for estimating the sizes of the ions.

The results given here illustrate the application of gel chromatography to the investigation of inorganic substances. It has been used to determine the sizes of various ions[43,48,72], as well as for the separation of ions[50–52] and the investigation of inorganic polymers. Information has been obtained on the properties of polysilicic acid[68], the existence of various types of polymeric molybdates[71], and the composition of $Fe(OH)_x(NO_3)_{3-x}$ polymers[69,70].

The rapid development of the application of gel chromatography to the investigation of inorganic polymers of phosphorus enables existing data to be generalised and further possibilities for the use of this method to be defined.

III. APPLICATION OF GEL CHROMATOGRAPHY TO THE INVESTIGATION OF PHOSPHATES

In order to establish rules for the gel-chromatographic behaviour of phosphates and to develop a technique, investigations were made on various individual phosphates [53–59], both linear and cyclic, and with different degrees of oxidation of the phosphorus, as well as specimens of polyphosphoric acids [58,60,61] and polyphosphates [62–67] having different molecular-weight distributions. Studies have been made of the effects of various factors on the behaviour of phosphates during chromatography—sample and eluent concentrations [55], pH, [54,55] rate of elution, temperature [57], gel porosity [55,57] and particle size [57], and the column parameters [57,58].

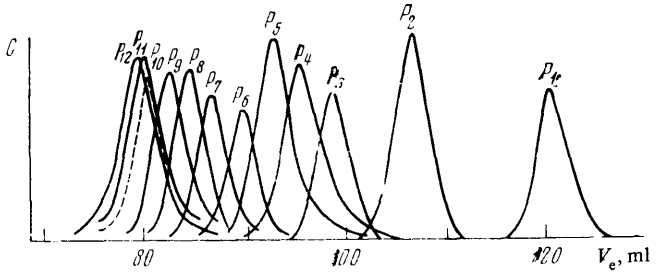

Figure 7. Elution curves for P_1-P_{12} linear polyphosphates [54] (1 ml containing 0.003–0.005 g-atom P litre^{-1} eluted on Sephadez G-25 column 1.5 × 90 cm with 0.1 M KCl of pH 7.0 at 20–30 ml h^{-1}).

Table 1. Partition coefficients of linear phosphates $Na_{n+2}P_nO_{3n+1}$ (0.003–0.005 g-atom P litre^{-1} eluted with 0.1 M KCl on Sephadex G-25).

P_n	K_d*	P_n	K_d	P_n	K_d	P_n	K_d

P_4	0.46			P_{11}	0.23		

*Values of K_d for P_4-P_{13} phosphates calculated from those of K_{av}^{54}.

The concentration of phosphate in the eluate fractions was determined colorimetrically (Refs. 53–55 describe chemical analysis for phosphorus) and refractometrically with appropriate instruments, e.g. an interferometer [58] or a flow-type differential refractometer [57]. In the investigation of polyphosphoric acids, the pH of the eluate was measured by means of a pH-meter having a specially designed flow-type microcell [60,61]. The degree of polymerisation of phosphates in the eluate fractions was monitored by potentiometric titration [66,67] and by paper chromatography [58,60,65].

Many authors mention that phosphates are eluted from a gel column in the sequence of decreasing molecular weight. This relation has been found for linear phosphates containing 1–12 phosphorus atoms in the chain, eluted with 0.1 M potassium chloride solution on Sephadex G-25 [54] (Fig. 7), and for sodium ortho-, pyro-, and tripoly-phosphates on Sephadexes G-10, G-15, G-25, and G-50 [55] (Fig. 8). The partition coefficients of linear phosphates (Table 1) and of compounds containing up to four phosphorus atoms in different states of oxidation (Table 2) lie in the range $0 \leq K_d \leq 1$.

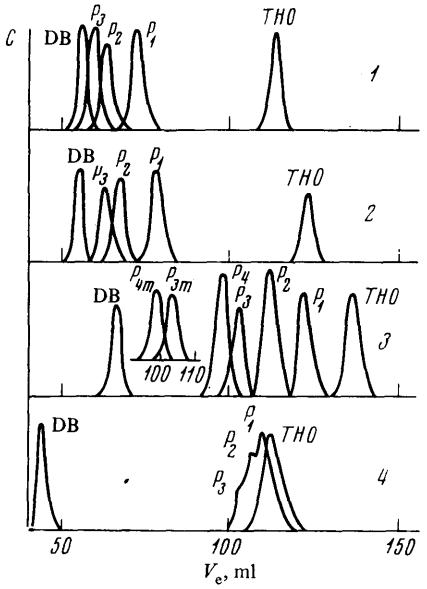

Figure 8. Elution curves of certain phosphates (1 ml of solution containing 0.002–0.005 g-atom P litre^{-1} eluted with 0.1 M KCl at 20–30 ml h^{-1}) on different Sephadexes [55]: 1) G-10 (column 1.5 × 90 cm); 2) G-15 (1.5 × 90); 3) G-25 (1.5 × 90); 4) G-50 (1.2 × 130). The peaks correspond to: P_1-P_4) polyphosphates containing a chain of 1–4 phosphorus atoms; P_{3m}) Na trimetaphosphate; P_{4m}) Na tetrametaphosphate; DB) dextran blue; THO) tritiated water.

Table 2. Effect of eluent concentration on partition coefficient K_d of phosphates [55]. (0.002–0.005 g-atom P litre^{-1} on Sephadex G-25).

*The superscript indicates the state of oxidation of the phosphorus, and the subscript the degree of polymerisation of the polyphosphate or metaphosphate (n_i).

The above results—the elution sequence, partition coefficients, and the symmetry of the peaks—are consistent with ideas on the sizes of polyphosphate anions and indicate that the mechanism of separation is based solely on a molecular-sieve effect.

Cyclic tri- and tetra-metaphosphates are eluted on Sephadex G-25 together with linear phosphates[55] (Fig. 8) according to their size.

Investigation of the dependence of the gel-chromatographic behaviour of polymeric phosphates on various factors has enabled important problems of technique to be solved and the most suitable parameters to be selected, whose use ensures the necessary conditions for a molecular-sieve mechanism to operate and for condensed phosphates to be analysed by means of calibration curves.

The availability of gels differing in porosity makes possible the analysis of polymers over a wide range of molecular weights. In the case of organic compounds limits have been found to the molecular weights, which are characteristic of each type of gel[34]. These limits may be different for inorganic substances, since other factors may then become more significant—ionic exclusion and hydration, and with phosphates the properties resulting from their polyelectrolyte nature.

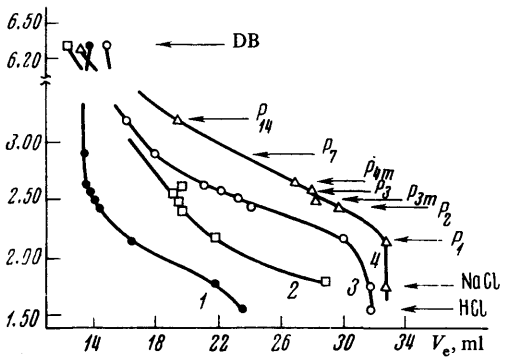

Figure 9. Dependence of relation between logarithm of molecular weight M [of phosphate] (eluted with 0.01 M NaCl) on gel porosity for columns 0.61–0.62 cm in diameter and 120–126 cm in height[57] of: 1) Sephadex G-10; 2) Bio-Gel P-2; 3) Sephadex G-25 (eluent 0.025 M Na_2HPO_4); 4) Sephadex G-50.

When an inhomogeneous sample of sodium polyphosphate of mean degree of polymerisation $\bar{n} = 14$ was eluted on Sephadexes G-25 and G-50, the partition coefficients of the component polyphosphates were closely similar and approached zero on Sephadex G-25, but distribution occurred throughout the accessible volume on G-50.[57] However, other factors—nature and concentration of eluent, quantity of sample solution—were not constant in this comparison. The shift in elution volumes and the difference in quality of separation characteristic of gels of different porosities are well illustrated by Figs. 8 and 9,[55,57] which show that the most satisfactory separation of oligophosphates is attained on Sephadex G-25.

The eluent may have a significant effect on the distribution of inorganic substances during elution. The influence of the supporting electrolyte on the separation of phosphates has also been studied. The partition coefficients of ortho-, pyro-, and tripoly-phosphates eluted with water on Sephadex G-25 are extremely low compared with the values obtained when potassium chloride solutions are used as eluent[55] (Table 2). The low values were explained by ionic exclusion, which is eliminated by the addition of potassium chloride to the eluent, for which purpose an electrolyte concentration <0.01 M was sufficient. The partition coefficients for anions with different states of oxidation of phosphorus increased slightly with the potassium chloride concentration (Table 2). Several explanations are possible for this effect: since polyphosphates possess the properties of polyelectrolytes, the size of their polyanions should diminish with increase in the ionic strength of the solution; another possible cause would be a decrease in the degree of hydration of the anions; furthermore, preliminary experiments showed[55] that the internal volume of Sephadex G-10 increased with the potassium chloride concentration of the eluent.

Examination of the behaviour of alkaline-earth metal chlorides in 0.1 M NaCl and 0.1 M NaCl + 0.01 M HCl showed[48] that the acid eluent gave the best separation. Such an eluent is undesirable with phosphates, owing to the increased probability of hydrolysis. The effect of the pH of the eluent on the partition coefficients was therefore examined. With linear phosphates[54] no appreciable changes in partition coefficients were observed with eluents having pH 2.0, 4.6, 7.0, and 9.2, obtained by adding respectively aqueous hydrochloric acid and phthalate, tris, and ammoniacal buffers to 0.1 M potassium chloride solution. Similar results were obtained in the separation of anions in which phosphorus was present in different states of oxidation[55]. Only on the addition of borate buffers of pH 7.0 and 9.2 were the partition coefficients lower, owing to electrostatic repulsion of phosphate ions and borate ions retained by the gel, which were able to interact with dextran depending on the pH.[90] The results confirmed yet again the need for careful choice of eluent if molecules are to be separated by a molecular-sieve effect.

Table 3. Dependence of partition coefficients K_d on concentration of sample[55] (on Sephadex G-25 eluted with 0.1 M KCl).

Phosphate*	Concentration, g-atom P litre^{-1}						
	0,001	0,005	0,01	0,05	0,1	0,5	1,0
P^3	0.78	0.78	0.78	—	0.79	—	0.80
P_1	0.78	0.79	0.79	—	0.80	—	0.80
P^4—P^4	0.66	0.66	0.66	0.69	0.71	—	—
P_2	0.62	0.63	0.63	—	0.69	—	—
P_3	0.52	0.50	0.51	0.55	0.57	0.66	0.70
P_{3m}	0.52	0.52	0.52	—	0.58	—	0.69

(—P^4—P^4—O—)$_2$	0.48	0.48	0.47	—	—	—	—
P_{4m}	0.46	0.46	0.45	—	0.50	—	0.63

* Notation as in Table 2.

In order to confirm the molecular-sieve mechanism it is necessary to determine the effect of the concentration of the test substances on their partition coefficients and the symmetry of the peaks. Table 3 lists values of K_d for certain phosphorus-containing compounds as a function of their concentration.

Fig. 10 illustrates the concentration dependence of the position and form of the elution peaks for sodium tripolyphosphate. With a sample concentration below 0.01 g-atom P litre^{-1} the elution curves are symmetrical, and the position of the peak remains unchanged. At higher concentrations the curves are displaced towards large volumes, and the peaks become unsymmetrical with $F/B > 1$. This was attributed to the presence of phosphate ions having different degrees of hydration. Furthermore, increase in the concentration of the polyphosphate is accompanied by a decrease in its dissociation[91], which with polyelectrolytes leads to a decrease in size of the polyanions. Similar results were obtained[57] for the effect of concentration on the elution parameters of sodium ortho-, pyro-, and tripoly-phosphates.

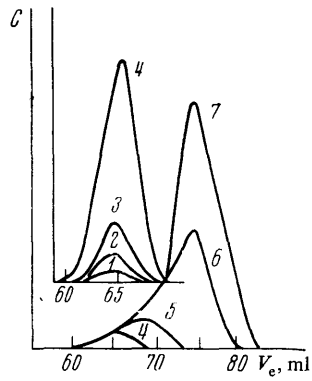

Figure 10. Dependence of elution curves for 1 ml of $Na_5P_3O_{10}$ (1.5 × 60 cm column of Sephadex G-25 eluted with 0.1 M KCl at 20–30 ml h^{-1}) on initial concentration[55] (g-atom P litre^{-1}): 1) 0.001; 2) 0.005; 3) 0.01; 4) 0.05; 5) 0.1; 6) 0.5; 7) 1.0.

Many authors state that the process becomes more efficient the longer the column, and this holds also for phosphates. The use of longer columns leads to a larger difference between the elution volumes of neighbouring polymer homologues and to better resolution of the peaks[58], but is accompanied by broadening of the curves, which has an adverse effect. Columns of height 60 and 500 cm give the same partition coefficients in the chromatography of a mixture of sodium ortho-, pyro-, and tripoly-phosphates on Sephadex G-25 with 0.01 M sodium chloride solution. The dependence of the elution of phosphates on the column parameters is obviously general in character.

In order to find the best conditions for the separation of substances a study was made[57] of the effect of various parameters on the resolution R of the peaks, defined by the equation

$$R = \frac{2(V_{e_2} - V_{e_1})}{w_{b_1} - w_{b_2}} \qquad (11)$$

in which the V_e are the elution volumes of adjacent peaks, and the w_b are their widths at the base. The resolution of sodium orthophosphate and tripolyphosphate is somewhat improved (Table 4) on decreasing the rate of elution, as a consequence of the diminished spreading of the bands. Raising the temperature has the opposite effect.

Completing our review of the different factors influencing the gel chromatography of phosphates and the techniques used, we can conclude that, within the limits investigated and allowing for actual applications, all the experimental conditions can be used for the gel chromatography of phosphates for analytical and preparative purposes.

Table 4. Effect of various factors on resolution R of $Na_5P_3O_{10}$ and Na_2HPO_4 peaks[57].

Experimental conditions		R
constant	variable	
Column dimensions, cm	Gel type	
diameter 0.61–0.62	Sephadex G-10	1.09
height 123.0–125.0	Sephadex G-25	1.47
	Sephadex G-50	1.35
	Bis-Gel P-2	0.87
Sephadex G-10 column, cm	Gel particle diameter, μm	
diameter 0.61	53–74	1.09
height 124.0–126.0	88–105	0.84
Sephadex G-25 (53–64 μm) (0.61 × 63.0 cm)	Rate of elution, ml min^{-1}	
temperature 22.0°C	0.16	1.69
	0.58	1.26
rate of elution 0.58 ml min^{-1}	22.0°C	1.26
	50.0°C	1.17

As mentioned earlier, various processes occurring in a gel as a result of interactions among the gel, test substance, and eluent affect the elution volumes (or partition coefficients), the elution sequence, the shape of the peak, and the dependence of these factors on the concentration of the substance. Investigations on phosphate polymers have shown that phosphates are eluted in the sequence of diminishing molecular weight, and that their partition coefficients in various gels lie in the range 0–1 and are constant with symmetrical curves over a certain concentration range. These results indicate the absence of interaction between phosphates and dextran. Furthermore, the identity of partition coefficients found under elution conditions and under static conditions indicates the absence of a diffusion contribution[53,54].

All the above facts indicate that, under certain conditions, the behaviour of phosphates on dextran gels is consistent with a molecular-sieve mechanism. It is therefore possible to use the method to separate and examine condensed phosphates, and important results in this field have already been obtained.

Firstly, it is now possible to obtain individual phosphates. When a solution of sodium polyphosphates having $\bar{n} = 3$, was fractionated on Sephadex G-15, components of a mixture with $n = 2-5$ were obtained in fairly pure form, isolated from the solution, and identified by paper chromatography and infrared spectroscopy.

Another important achievement of the application of gel chromatography to the investigation of phosphorus polymers is determination of the effective radii of many phosphate anions[54,55]. The radii were determined by means of a calibration line plotted from values of K_{av} and K_s for several ions, analogous to that shown in Fig. 6. The partition coefficients of the phosphorus-containing anions were calculated by means of Eqns. (6) and (7) with $V_i/(V_i + V_m) = 0.862$ for Sephadex G-25. The results show (Table 5) that these anions are considerably hydrated in aqueous solution, and that their size increases with the degree of polymerisation.

Finally, gel chromatography has been successfully used to determine the molecular-weight composition of a mixture of polyphosphates. A sample of sodium polyphosphates having $\bar{n} = 36$ was fractionated on Molselekt G-25,[66] the molecular weight of the polyphosphates in the eluate was determined by potentiometric end-group titration[11], and molecular-weight distribution curves were plotted from the fractionation results (Fig. 11). The reliability of the fractionation results is confirmed by the equality of the mean degree of polymerisation of the initial specimen and the sum of the products of the mole fraction x_i and the degree of polymerisation n_i of the ith fraction:

$$\bar{n} = \Sigma x_i n_i \quad . \qquad (12)$$

Table 5. Anionic radii R_S of phosphates[54,55] obtained from $(-\lg K_{av})^{1/3} = A \cdot R_s + B$

Phosphate*	R_s, Å	Phosphate	R_s, Å	Phosphate	R_s, Å
P^1	4.3	$P^4—P^3—P^4$	5.7	P_5	7.2
P^3	4.4	$P^3—O—P^4—P^4$	6.6	P_6	7.6
P_1	4.4	$P^5—O—P^4—P^4$	6.4	P_7	8.0
$P^3—P^4$	5.5	P_3	6.4	P_8	8.3
$P^4—P^4$	5.5	P_{3m}	6.4	P_9	8.6
$P^3—O—P^3$	5.8	$P^4—P^4—O—P^4—P^4$	6.8	P_{10}	9.0
$P^5—O—P^3$	5.7	$(—P^4—P^4—O—)_2$	6.8	P_{11}	9.2
P_2	5.7	P_4	6.9	P_{12}	9.3
		P_{4m}	6.9	P_{13}	9.8

*For notation see Tables 1 and 2.

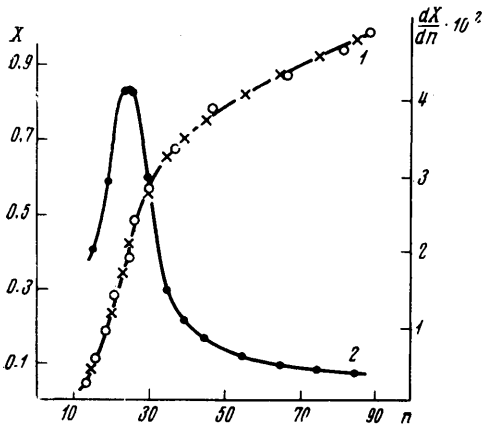

Figure 11. Numerical distribution curves for sodium polyphosphate with $\bar{n} = 36$ (0.5 g in 5 ml eluted on Molselekt G-25 column 1.3 × 80 cm with water at 26 ml h^{-1}):[66] 1) integral; 2) differential; ×) points chosen for graphical differentiation.

For the same purpose gel chromatography has been used to analyse a mixture of polyphosphates on Sephadex G-100.[67] Such investigations require a considerable quantity of the specimen, exceeding that at which the partition coefficient is still independent of concentration. Although a linear relation $V_e = k \lg M$ was obtained in these investigations, it can hardly be regarded as a calibration.

The calibration line (Fig. 12) for phosphates containing up to thirteen phosphorus atoms in the chain, determined by the use of individual phosphates obtained by ion-exchange chromatography[21], merits close attention in connection with the application of calibrated columns. Its possibility for calibration purposes was verified[54] by first determining by potentiometric titration the mean degree of polymerisation of a few polyphosphate specimens, and then chromatographing them on Sephadex G-25 with 0.1 M potassium chloride solution of pH 7.0. The concentration of the polyphosphates in each fraction was determined and also, from the calibration line, the degree of polymerisation, from which $\bar{n}$ in the initial specimen was calculated by a slightly modified form of Eqn. (12)

$$\bar{n} = \frac{\Sigma w_i}{\Sigma (w_i/n_i)} \qquad (13)$$

where w_i is the number of phosphorus atoms in the ith fraction. The good agreement between results obtained by the two methods showed the possibility of using this calibration (Table 6).

---o0o---

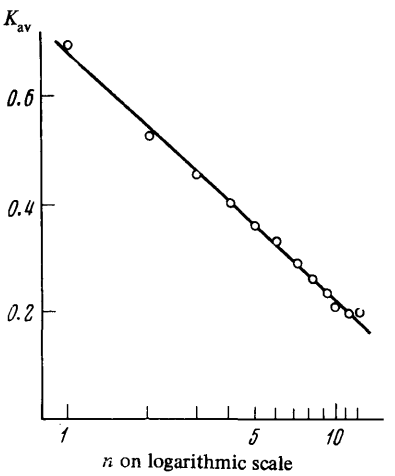

Figure 12. Relation between K_{av} and $\lg n$ for elution on Sephadex G-25 with 0.1 M KCl (pH 7.0) at 20–30 ml h^{-1}.[54]

Table 6. Comparison of mean degrees of polymerisation $\bar{n}$ of sodium polyphosphates obtained by gel chromatography and by potentiometric titration[54].

Method	$\bar{n}$					
Gel chromatography	3.2	8.4	9.3	9.5	12.0	14.0
Potentiometric titration	3.0	8.2	9.1	10.1	11.0	13.1

Gel chromatography has opened up new possibilities for the study of condensed phosphates. The achievements of the method, which was developed mainly for organic

chemistry, biochemistry, and clinical medicine, have proved useful for investigating inorganic phosphate polymers. The gel chromatography of phosphates has in turn confirmed several aspects of the method and has helped to expand its field of application.

Sulphur Hexafluoride

A.A.Opalovskii and E.U.Lobkov

An attempt is made in the present review to arrange systematically the available data for the physicochemical and, primarily, chemical properties of sulphur hexafluoride. The inertness usually attributed to sulphur hexafluoride on the basis of early data obtained by Moissan hindered the investigation of its chemical properties. This gap is now being successfully filled. Data are presented showing that sulphur hexafluoride can serve as an effective fluorinating agent whose advantages are due to its high fluorine content, its non-toxicity, and the ease with which it can be handled. It is shown that further advances in the development of the chemistry of sulphur hexafluoride and of its practical applications depend significantly on the rate of development of research in this field.

I. INTRODUCTION

Metal and non-metal hexafluorides constitute a large and interesting group of fluorine-containing compounds, a distinctive feature of which is a strikingly wide variety of chemical properties, ranging from an extremely high reactivity to the inertness characteristic of noble gases[1-11]. Despite the fact that more than half of the members of this group of compounds were discovered as early as the beginning of the present century[12-19], their active study began only from the 1940's in connection with the preparation and employment of the hexafluorides of a number of elements in certain stages of the manufacture of nuclear fuel[20-24]. The eighteen hexafluorides known at present can be divided into two groups on the basis of their chemical behaviour: non-metal hexafluorides (SF_6, SeF_6, TeF_6, PoF_6 and XeF_6) and metal hexafluorides (CrF_6, MoF_6, TcF_6, RuF_6, RhF_6, WF_6, ReF_6, OsF_6, IrF_6, PtF_6, UF_6, NpF_6, and PuF_6). Whereas the former (with the exception of XeF_6 and PoF_6) are regarded as the most inert compounds, the latter exhibit a high activity, for example in fluorination or hydrolytic reactions.

Naturally this classification is extremely arbitrary and qualitative. Thus the reactivities of xenon and polonium hexafluorides resemble those of the most reactive metal hexafluorides. There is no doubt that the hexafluorides of iodine, astatine, and radon, which are so far unknown but are possible in principle, will not be chemically inert either.

Excluding XeF_6 and PoF_6, we may note that the chemical reactivities of the known non-metal fluorides increase in the sequence $SF_6 < SeF_6 < TeF_6$. For example, sulphur hexafluoride is inert with respect to hydrolysis by water vapour up to 500°C, while TeF_6 is fully hydrolysed by water in 24 h.

A similar situation obtains also for the lower chalcogen fluorides (tetrafluorides). Indeed the vigorously fuming liquid SeF_4 corrodes glass rapidly even at room temperature, solid TeF_4 readily reacts with quartz, while gases SF_4 is completely inert with respect to the latter. The chemical reactivities of the lower chalcogen fluorides served as a basis for their use as promising fluorinating and complex-forming agents.

On passing from the highest to the lowest fluoride of the same chalcogen, the chemical reactivity increases,

which is shown particularly clearly by sulphur compounds, for which the greatest number of lower fluorides is known [25-29].

Thus the sulphur pentafluoride dimer S_2F_{10} is more reactive than SF_6. On heating, it reacts with copper, mercury, and platinum and its reaction with iron takes place at room temperature. However, hydrolysis by water or concentrated alkalis is extremely slow. Sulphur tetrafluoride is very rapidly hydrolysed by water and sulphur fluoride (thiothionyl fluoride) S_2F_2 is hydrolysed even by atmospheric moisture.

Thus the above comparison shows that, among the nonmetal fluorides, sulphur hexafluoride is chemically the most inert. On the other hand, its high fluorine content (78%)—one of the most important parameters determining the effectiveness of any fluorinating agent—cannot fail to draw attention as regards the possible use of this compound in fluorination and oxidation processes, as pointed out at one time by Simons in his well known monograph [29]. The chemical inertness of SF_6 is an extremely arbitrary concept like the term "inert substance" in general.

The recent growth of interest in sulphur hexafluoride is due to its exceptional dielectric properties [30,31]. As data (mainly physical) accumulate, the range of practical applications of SF_6 is being extended, involving fields such as astronautics [32,33], electronics [34,35], refrigeration technology [36-39], meteorology [40-43], metallurgy [44,45], machine engineering [46], laser engineering [47,48], and medicine [49].

The available information about the chemical properties of sulphur hexafluoride has not changed significantly since the synthesis of this compound. A number of reviews [30,31,50], the latest of which is ten years old, contribute nothing new to the chemistry of sulphur hexafluoride compared with the information which was already available to Moissan. The gas which he isolated was very inert. Its hydrolysis by water vapour was not observed up to 500°C and it did not react with refractory glass up to the softening temperature of the latter. The gas did not react with halogens, phosphorus, arsenic, carbon, silicon, boron, copper, and silver at red heat. No reaction was observed between SF_6 and HCl or NH_3.

Sulphur hexafluoride is not acted upon by hot CuO and $PbCrO_4$ and by fused KOH. Only boiling sodium reacts rapidly and quantitatively with SF_6, which was used as a basis for the determination of the composition of this compound. A fairly large number of substances (large under the conditions prevailing at the time) had been tried in the reaction with SF_6, which enabled Moissan to characterise the hexafluoride as a chemically inert gas and to regard it as comparable to nitrogen in this sense. Thus there arose a seemingly well justified barrier, which determined the subsequent course of studies on the chemistry of this compound. Only in recent years new experimental data suggested ways of overcoming this largely psychological barrier in connection with certain advances in the chemistry of sulphur hexafluoride. A number of interesting reports dealing with the possibility of using SF_6 as a potential fluorinating and oxidising agent were published [51-59]. A number of studies by the authors of the review were directed to the same end [60-67]. It appears that further expansion of practical applications of sulphur hexafluoride will depend significantly on the rate of development of such investigations and therefore a survey of the accumulated data is an essential step in the development. This is why the authors of the review considered in greatest detail the advances in the investigation of the physicochemical and chemical properties of SF_6.

II. THE SYNTHESIS OF SULPHUR HEXAFLUORIDE

Sulphur hexafluoride is usually synthesised by the reaction of sulphur with gaseous fluorine [68-75]:

$$S + 3F_2 = SF_6 + Q \quad .$$

Depending on the apparatus employed and the purity of the starting materials, the product contains up to 5% of impurities in the form of lower sulphur fluorides (S_2F_2, SF_2, SF_4, and S_2F_{10}), oxide fluorides (SOF_2, SOF_4, and SO_2F_2), and dioxide (SO_2) as well as impurities introduced with the fluorine (HF, OF_2, CF_4, C_2F_6, N_2, and O_2). The gas obtained after purification is 99.8% pure and contains 8×10^{-6}% of $SF_4 + S_2F_2$ and 15×10^{-6}% of H_2O, S_2F_{10}, HF, and the inert gases being absent [31]. It is noteworthy that this gas is physiologically completely harmless [76].

Attempts were made recently to synthesise SF_6 without using elemental fluorine. This was done primarily by the electrolysis of sulphur or sulphur-containing compounds (H_2S, SCl_2, S_2Cl_2, and CS_2) in anhydrous hydrogen fluoride [77-80]. The processes [81,82]

$$6MF + S + 3Cl_2 = 6MCl + SF_6$$

or

$$3MF_2 + S + 3Cl_2 = 3MCl_2 + SF_6 \quad ,$$

where M is a Group I–IV metal, and the pyrolysis of lower sulphur fluorides [83] were considered as the basis for the possible methods of synthesis. However, both of the above reactions lead to the formation of a gas with a low sulphur hexafluoride content requiring careful purification.

Thus the method of synthesising sulphur hexafluoride based on the interaction of the elements still remains the one well tested and technologically and economically viable procedure. Nevertheless the synthesis of SF_6 on an industrial scale without the use of elemental fluorine appears to be very promising, since the available data suggest that this procedure is quite realistic.

Although the analytical chemistry of sulphur hexafluoride has not developed adequately [83-87], we may note that gas and gas–liquid chromatography appear to be the most useful in this field. The determination of impurities by this procedure has been sufficiently well developed [88-90]. The solid carriers employed are usually silica gel, Chromosorb W, or the "Kel-F" polymer with added fluorinated liquid hydrocarbons, among which poly(chlorotrifluoroethylene) is most frequently used.

III. PHYSICAL PROPERTIES

The Structure and Spectra

The first convincing evidence in support of the octahedral structure of SF_6 was obtained in electron diffraction experiments [91,92]. Six normal vibrations may be expected for a molecule with O_h symmetry, of which three [$\nu_1(A_{1g})$, $\nu_2(Eg)$, and $\nu_5(F_{2g})$] are active in the Raman spectrum and two [$\nu_3(F_{1u})$ and $\nu_4(F_{1u})$] are active in the infrared spectrum. There is also an inactive vibration in both spectra (ν_6), which may be observed as a combination band. All five absorption bands of gaseous and liquid sulphur hexafluoride were discovered as early as 1934, but the refinement of their positions by using better apparatus and purer specimens is still being continued (Table 1) [93-105].

The Raman spectra of solid and gaseous sulphur hexafluoride are very similar [94], which was in fact to be expected in view of the high symmetry of the molecule.

Table 1. The fundamental vibrational wavenumbers of SF_6 (cm^{-1}).

State of aggregation	$\nu_1(A_{1g})$ stretching vibration	$\nu_2(E_g)$ stretching vibration	$\nu_3(F_{1u})$ deformation vibration	$\nu_4(F_{1u})$ stretching vibration	$\nu_5(F_{2g})$ deformation vibration	$\nu_6(F_{2u})$
Gaseous	772.4 775 769.4 773.5	639.5 641.7	940 947 932 939 947 947.9	615 613 614 615	522 525	363 344 345 347

However, with the exception of the ν_1 line, other lines in the spectrum of solid SF_6 are weak and their assignment is extremely indefinite.

The absorption spectrum of SF_6 in the region of ultrasoft X-rays differs strongly from the usual X-ray spectra [106,107] and has a pronounced non-hydrogen-like character.

The electronic structure of the sulphur atom has been specified as $3s^{1.64}3p^{3.50}3d^{0.19}$, which leads to an effective charge of the sulphur atom of +0.67. [108] The experimental effective charge of the sulphur atom obtained by Coulson's method [109] proved to be 2.50. [110] The latter value is more accurate, since it was determined from the $K\alpha$ emission line, which corresponds to a more realistic redistribution of the electron density of sulphur. We may note that the involvement of d electrons in the formation of a chemical bond has been established also in a theoretical study of the electronic structure of SF_6 by the LCAO-MO SCF method [111]. A direct experimental confirmation of this finding was obtained by La Villa [112], who measured directly the probability of the $3d-2p$ transitions.

The photoelectronic spectrum of sulphur hexafluoride, obtained on excitation with 584 Å monochromatic radiation [113], shows four thresholds of increasing ionisation current (15.35, 16.71, 18.11, and 19.50 eV), three of which correspond to the formation of SF_5^+, probably via the reactions [114]

$$SF_6 + h\nu \rightarrow SF_6^+ + e \ ,$$
$$SF_6^+ \rightarrow SF_5^+ + F \ .$$

The mass spectrum of sulphur hexafluoride was investigated in fair detail [116-128], since studies of this kind make it possible to account for the characteristics of the behaviour of SF_6 as a dielectric. The ability of sulphur hexafluoride to form negative ions on irradiation with low-energy electrons [116] is of great practical interest in connection with its characteristic large electron capture cross-section [32,33,115].

The mechanism of the interaction of sulphur hexafluoride with low-energy electrons (0–2 eV) can be represented schematically by the resonance absorption (capture) of an electron with formation of a metastable ion:

$$SF_6 + e \rightleftarrows (SF_6^-)^* \ , \qquad (1)$$

the ion either dissociates (dissociative capture):

$$(SF_6^-)^* \rightarrow SF_5^- + F \ , \qquad (2)$$
$$SF_5 + F^-$$

or is stabilised by collision with an extraneous molecule:

$$(SF_6^-)^* + A \rightarrow SF_6 + A \ . \qquad (3)$$

There are also data obtained in studies on sulphur hexafluoride by NMR; ^{19}F NMR spectra have been recorded for both gaseous SF_6 and the hexafluoride fixed in the form of clathrate compounds [129-135].

IV. PHYSICOCHEMICAL PROPERTIES

The main physical properties of sulphur hexafluoride are listed in Table 2. Under normal conditions, SF_6 is a colourless gas with a nearly theoretical density. On cooling to −63 °C, it condenses to a colourless solid, which may be fused under pressure. The triple point parameters are $t = -50.8$ °C and $P = 2.3$ atm. [156] The vapour pressure changes from 3.4 to 26.4 atm in the range from −40° to +30 °C. [157] At 94.30 K there is an endothermic transformation of solid SF_6.

The critical parameters of sulphur hexafluoride are as follows: $P_{cr} = 38.328 \pm 0.05$ kgf cm^{-2}, $t_{cr} = 45.560 \pm 0.05$ °C, and $v_{cr} = 198.0 \pm 0.4$ cm^3 $mole^{-1}$ (Makarevich and Sokolova [158]) and agree well with earlier data [36,139].

The temperature variation of the vapour pressure of SF_6 in the range from −30 °C to t_{cr}, derived by Elema [37] from experimental data [36,139,156,159], is

$$\lg P(\text{bars}) = 4.40538 - 8.47739/\theta - 3.72000/\theta^2 + 5.33334/\theta^3,$$

where $\theta = T/100$.

At the same time Mears et al. [160] obtained the following relation between the vapour pressure and temperature in the range 25–130 °C (the temperature in both equations are expressed on the Kelvin scale) using their own data and results quoted in the literature [137,139]:

$$\lg P(\text{bars}) = 4.41780 - 889.185/T - 0.56334 \times 10^{-3}T + 0.120040 \times 10^{-5}T^2.$$

The temperature variation of the density of liquid sulphur hexafluoride can be represented by a five-term equation [160]:

$$d(\text{g cm}^{-3}) = A_0 + \sum_{n=1}^{n=4} A_n(1 - T/318.80)^{n/3},$$

where $A_0 = 0.725$, $A_1 = 1.4721$, $A_2 = -0.282881$, $A_3 = 1.302590$, and $A_4 = -0.628493$. The absolute error in the determination of the density in the range from −41 ° to +42 °C does not exceed 0.1%.

The sublimation pressure of solid SF_6 is described by the equation

$$\lg P(\text{mmHg}) = A - B/T,$$

which is probably valid in the temperature range from 102 to 222 K (Table 3).

Solubility of Sulphur Hexafluoride

The behaviour of SF_6 in polar and non-polar solvents (Table 4) is of undoubted practical[164-167] and theoretical[168-170] interest. The solubility of sulphur hexafluoride in water (5.5×10^{-3} cm^3/cm^3 H_2O), determined for the first time by Friedman[171], is much lower than the solubilities of gases as helium (9×10^{-3}), molecular nitrogen (16×10^{-3}), xenon (118×10^{-3}), or argon (34×10^{-3}). The experimental entropy of solution (−50 e.u.) proved to be higher by more than 10 e.u. than the values calculated empirically[177-179]. The enthalpy of solution is also more negative than the enthalpy of condensation of SF_6, which is −4 kcal $mole^{-1}$.

*Recalculated from data of Ashton et al.[172]
**Recalculated from data of Gillespie and Humphreys[173].

It is noteworthy that the estimates of the thermodynamic properties of solution when the solubility of the gas is so low may not be adequately reliable. The use of better apparatus (accuracy to within a mole fraction of 10^{-6}) made it possible to obtain an expression for the temperature variation of the solubility of SF_6 in water, in the range 0–50°C:[172]

$$\lg X_2 = 6648.32/T + 45.2067 \lg T - 139.5793,$$

where X_2 is the mole fraction of SF_6 in water and T the temperature in K.

The heat and entropy of solution of sulphur hexafluoride can be determined from the relations.

$$\Delta H_2^\circ/R = \partial \ln X_2/\partial(1/T) = -2.303 \times 6648.32 + 45.2067\,T,$$

where the entropy of solution refers to the transfer of 1 mole of gas to a hypothetical solution of unit mole fraction. The enthalpy and entropy of solution of SF_6 in water calculated by this formula are respectively −4.9 kcal $mole^{-1}$ and −41 cal $mole^{-1}$ deg^{-1} [at 25°C].

The Formation of Clathrate Compounds

It is interesting to note that, despite the low solubility of sulphur hexafluoride in water and other solvents, the existence of two clathrate compounds of SF_6 has been established: the gas hydrate $SF_6.17H_2O$ and the clathrate derivative formed by Dianin's compound with sulphur hexafluoride ($6C_8H_{20}O_2.2SF_6$).[180-184]

The gas hydrate can be obtained by slowly forcing SF_6 into water until the gas pressure reaches 5–6 atm. White crystals resembling snow are formed at 0°C. It was established on the basis of the P–T phase diagram in the temperature range between −9° and 15°C that the gas hydrate of sulphur hexafluoride contains 17.02 moles of water per mole of sulphur hexafluoride at 0°C.[181] The vapour pressure at this temperature is 0.8 atm. The heats of formation of the hydrate from liquid water and ice are respectively −29.57 and 5.140 kcal $mole^{-1}$. The temperature and pressure corresponding to the coexistence of four phases (the SF_6 hydrate–liquid enriched in water–liquid enriched in SF_6–vapour) are 14°C and 20 atm.

The clathrate derivative formed by Dianin's compound[182,183] with sulphur hexafluoride can be obtained by keeping the ethanol modification of this compound, dissolved in decanol, at a 20–25 atm pressure of gaseous SF_6 and 130–140°C for 4–5 days. This results in the formation of a solid clathrate derivative whose composition is close to $6C_{18}H_{20}O_2.1.79SF_6$.[184] The product contains up to 13% SF_6, i.e. a little less than 2 moles (14.7%), probably owing to the limited solubility of sulphur hexafluoride in decanol. The melting point of the clathrate compound $6C_{18}H_{20}O_2.1.79SF_6$ is 163–165°C and its density is 1.3 g cm^{-3}.

It is quite evident that the capacity for the formation of clathrate compounds is not unusual for sulphur hexafluoride and the small number of examples known at present is due merely to the current state of research in this field. There is no doubt about the great promise and theoretical and practical value of the latter.

Thermochemical Properties

The heat of formation of sulphur hexafluoride under standard conditions was determined from calorimetric measurements of the heat of combustion of sulphur in fluorine. Such measurements were made for the first time by Yost and Claassen[141], who found ΔH_{298}° = −262 kcal $mole^{-1}$. A later study of a similar kind by Gross[185] yielded −288.5 ± 0.7 kcal $mole^{-1}$ as the heat of formation of SF_6 under standard conditions and, finally, according to O'Hare et al.[186], ΔH_{298}° = −291.7 ± 0.2 kcal $mole^{-1}$. The last value is probably the most accurate, which was confirmed by redeterminations using fluorine with a lower oxygen content[185].

The heat capacity of sulphur hexafluoride was determined experimentally by Eucken and Schröder[140] up to 13 K. These results were used by Kelley and King[187] to calculate the standard entropy of formation of SF_6, which proved to be 70.3 ± 0.7 cal $mole^{-1}$ deg^{-1}, in agreement with statistical calculations of this quantity: 69.5 to 70.7 cal $mole^{-1}$ deg^{-1}.[186,188-191]. The small differences between the entropies calculated by the statistical method are largely due to the differences between the molecular constants and particularly the S–F bond lengths employed.

Thermal Stability

The thermal dissociation of sulphur hexafluoride results in a gaseous mixture containing mainly the following components: S, F, e, SF_6, SF_4, SF_3, SF_2, SF, S_2, F_2, S^{2+}, F^+, F^-, and S^-.[192-195] Calculation of the mixture composition in the temperature range 1000–20 000 K at pressures of 1–20 atm in the dissociation range showed that

at 1000 K the mole fraction of atomic fluorine and sulphur tetrafluoride is 6×10^{-6} and that of molecular fluorine is 1×10^{-6}. Up to 1400 K ($P = 1-10$ atm), the mole fraction of SF_6 is still close to unity (0.992). Rapid dissociation begins at 2000 K with the appearance of new species: S, SF_2, SF, and S_2. At 3000 K SF_6 no longer exists and the decomposition products begin to be enriched in the ions S^+, F^+, F^-, and S^-. SF_4 disappears at 5000 K and the remaining molecules vanish at 7500 K, the plasma consisting of electrons, sulphur, and fluorine in atomic and ionised states [195].

V. CHEMICAL PROPERTIES

The chemical activity (reactivity of a particular compound is determined by the rate of reaction between the latter and another substance, provided of course that the process itself is thermodynamically feasible. In order to compare the reactivities of various compounds in relation to the same substance, the reaction rates compared must refer to the same stage, common to the processes under consideration occurring under comparable conditions. The isolation of the rate determining stage of the reaction and observation of the latter involve considerable difficulties, which increase on passing from homogeneous to heterogeneous systems. Therefore in practise one usually employs a systematic empirical procedure frequently based on qualitative observations. Naturally, such a procedure may be unreliable. Thus, recent studies of the chemical properties of molybdenum and tungsten hexafluorides [10,11] showed that both compounds are appreciably inert, in contrast to earlier investigations in which MoF_6 and WF_6 were regarded as vigorous fluorinating agents[29,196]. The difficulties of the empirical approach faced investigators with the necessity to establish some, at least qualitative, criteria for the prediction of the potentially possible changes in the chemical systems of the hexafluorides of several elements, since such systems are of some practical interest. One of these criteria is the thermal stability of the hexafluorides.

A comparative estimate of the thermal stabilities was made most completely and in greatest detail, using various physicochemical characteristics (the force constants of EF_6, the E–F bond energies, and the equilibrium constants for the dissociation reactions), by Galkin and Tumanov[2]. Table 5 presents the thermal stability series of the hexafluorides established by the authors on the assumption that the thermal stability is related to various physicochemical characteristics of the SF_6 molecule.

Analysis of the results led the authors to the conclusion[2] that the most objective criterion of the thermal stability of hexafluorides as a characteristic of their reactivity is apparently the thermodynamic stability constant (the reciprocal of the equilibrium constant for the dissociation reaction), characterising the partial dissociation of the hexafluorides to the corresponding tetrafluorides. The thermal stability estimated from the average E–F bond energy in EF_6 agrees fully with the thermodynamic estimate with the exception of ReF_6. The valence force constants and the interatomic distances are of the doubtful value, according to the authors, as characteristics of the chemical properties of hexafluorides.

† It was assumed that an increase in the thermal stability of the molecule entails a decrease of its reactivity [197].

Returning now to sulphur hexafluoride, it can be shown by estimating its reactivity from the thermodynamic stability constant that it is a fairly reactive substance capable of converting into the highest fluorides at any rate compounds of metals such as molybdenum, tungsten, or uranium. Indeed the conversion of UO_2 into UF_6 with the aid of sulphur hexafluoride was achieved recently [52].

On the other hand, the list of substances in relation to which sulphur hexafluoride is fairly reactive can be greatly extended if one assumes the possibility of another reaction pathway, based, for example, on the high electron affinity of SF_6. We may recall that sodium dissolved in the dimethyl ether of diphenylethylene glycol reduces sulphur hexafluoride even at room temperature and the reaction is apparently based on electron transfer from a diphenyl radical-ion to the SF_6 molecule with formation of the unstable radical-anion SF_6^-. [84]

Table 5. Variation of the thermal stabilities of hexafluorides with certain physicochemical characteristics of the molecules.

Physicochemical characteristic of the molecule	Variation of thermal stabilities with increase of the physicochemical characteristic of the molecule
Bond energy D_0^0	$UF_6>WF_6>NpF_6>MoF_6>PuF_6>ReF_6>TcF_6>OsF_6>>TeF_6>SF_6>SeF_6>IrF_6$
Thermodynamic stability constant: $MF_6 \rightarrow M(gas) + 6F(gas)$	$UF_6>WF_6>NpF_6>MoF_6>PuF_6>TcF_6>ReF_6>OsF_6>>TeF_6>SF_6>SeF_6>IrF_6$
Thermodynamic stability constant: $MF_6 \rightarrow MF_4(gas) + 2F(gas)$	$WF_6>MoF_6>UF_6>SF_6>NpF_6>PuF_6$

The above considerations should be used as the starting point in the search for ways of increasing the reactivity of sulphur hexafluoride in order to use it as a fluorinating agent. This is quite feasible, since the inertness of sulphur hexafluoride can be successfully overcome by various process activation procedures, including ordinary heating.

Reactions in an Electric Discharge

The lower sulphur fluorides (SF_2 and S_2F_2), whose reactivity is much higher than that of the initial sulphur hexafluoride, are formed under the conditions of an electric discharge [198-201].

The effect of a high-frequency electric discharge was used for preparative purposes in reactions of sulphur hexafluoride with chlorine and oxygen [202]. In the first case the process is accompanied by the formation of SF_5Cl, probably in accordance with the overall equation

$$SF_6 + Cl_2 \rightarrow SF_5Cl + ClF \quad .$$

The yield of SF_5Cl is 1.97×10^{-3} mole h^{-1}. Chlorine monofluoride (ClF) was not identified, evidently owing to its reaction with glass.

The reaction between SF_6 and O_2 (in proportions of 1.32 : 1) leads to the formation of SOF_4, the approximate yield of which is 0.11×10^{-2} mole h^{-1} (degree of conversion 18%) at a gas flow rate of 0.61×10^{-2} mole h^{-1}. The mechanisms of the two reactions could not be determined owing to the abundance of the SF_6 dissociation and ionisation products formed under the influence of the electric discharge.

Reaction Accompanying the Explosion of Metallic Wires in an Atmosphere of SF_6

Studies on the pyrolysis of hydrocarbons under the conditions of exploding wires using sulphur hexafluoride as the inert diluent established that the latter reacts with the exploding metals even at relatively low levels of the supplied energy [56,203,204]. This results in the formation of either the corresponding metal fluoride and sulphur tetrafluoride:

$$2/n\,M + SF_6 = 2/n\,MF_n + SF_4 \qquad (4)$$

or of the metal fluoride and elemental sulphur:

$$6/n\,M + SF_6 = 6/n\,MF_n + S \ , \qquad (5)$$

where n is an index corresponding to the highest degree of oxidation of the metal.

The particular reaction pathway depends on the molar ratio SF_6 : M. For example, the reaction with tungsten for the ratio SF_6 : W = 3.0 takes place in accordance with Eqn. (4). The fraction of WF_6 obtained by reaction (5) increases to 42% when the molar ratio of the components is 1.8. The yield of MoF_6 in reaction (5) involving molybdenum varies from 12 to 52% when the molar ratio SF_6 : Mo is reduced from 2.0 to 1.6 respectively.

The explosion of rhenium in an atmosphere of SF_6 leads to the formation of the volatile rhenium hexafluoride and heptafluoride. By selecting appropriate conditions, it is possible to obtain rhenium heptafluoride in which the ReF_6 content is minimal. Moreover the hitherto unknown involatile rhenium fluoride ReF_3, which cannot be obtained by direct synthesis from the elements, was formed in this reaction.

Thus sulphur hexafluoride becomes a very effective fluorinating agent under the conditions where a metal is exploded electrically. The processes investigated lead to the possibility of new syntheses of both SF_4 and specific metal fluorides without the use of elemental fluorine. It is interesting to note that the yield of reaction products is independent of the stoichiometry of the initial components, while the composition does depend on the latter. This makes it possible to regulate the purification of the volatile fluorides formed and it can serve as a basis for the synthesis of hitherto unknown inorganic fluorides.

The explosion of extremely small amounts of platinum or copper can initiate the above reaction between SF_6 and O_2, but the yield is lower [205,206].

The high kinetic barrier to the reaction between SF_6 and O_2 is probably due to the ability of fluorine to repel the electronegative oxygen [206]. In fact the rate of reaction can be increased appreciably in the presence of various gaseous additives (promoting agents), for example H_2, Cl_2, Br_2, and CH_4, the effectiveness of the promoting agent being inversely proportional to its electronegativity:

$$CH_4 > H_2 > Br_2 > Cl_2 \ .$$

Ion–Molecule Reactions

The SF_6 molecule belongs to the class of halogen-containing molecules, which are of considerable theoretical interest in connection with their characteristic large electron capture cross-sections. The radical-anion SF_6^- (or SF_5^-) formed on interaction with electrons is very reactive with respect to a series of fluorine-containing molecules: PF_3 and PF_5, [207] SiF_4 and BF_3, [208] and POF_3 and PSF_3. [209] Thus, when a mixture of two fluorides (SF_6 and AF_n) is introduced into an ionisation chamber and bombarded with thermal electrons (0–0.2 eV), the formation of AF_{n+1}^- anions may be observed in the mass spectrum:

$$AF_n + SF_6^- (SF_5^-) \rightarrow AF_{n+1}^- + SF_5 (SF_4) \ .$$

These cannot be formed independently under the given conditions (BF_4^- and SiF_5^- are observed in the mass spectrum only for energies in excess of 10 eV). [210,211]

Reactions on γ-Radiolysis

The high electron affinity of sulphur hexafluoride made it possible to use the latter as a specific electron acceptor in γ-radiolysis of substances [212–217], influencing in some way the composition of the final reaction products. The γ-radiolysis of water in the presence of SF_6, which was investigated recently, is accompanied by a high yield of F^-, which is formed only by the reaction between SF_6 and $\bar{e}$.aq. The reaction mechanism quoted above is consistent with the experimental data [212]:

$$SF_6 + \bar{e}aq \rightarrow (SF_6^{\cdot})^- \rightarrow SF_5^{\cdot} + F^- \ , \qquad (6)$$

$$SF_5^{\cdot} + 2H_2O \rightarrow OH^{\cdot} + H_3O + SF_4 + F^- \ , \qquad (7)$$

$$SF_4 + 9H_2O \rightarrow SO_3^{2-} + 6H_3O + 4F^- \ , \qquad (8)$$

$$SO_3^{2-} + OH;\ SF_6;\ H_2O_2 \rightarrow SO_4^{2-} \ . \qquad (9)$$

The Photochemical Effect of Infrared Radiation

Basov et al. [218], who studied the effect of infrared radiation from a CO_2 laser ($\lambda = 10.6\ \mu m$) on reactive gaseous systems, established that at certain intensities the vibrationally excited molecules react chemically. Thus irradiation of the N_2F_4–NO–$C_2F_4(C_2F_6)$ system results in a bright greenish-yellow flash, accompanying the process, and the starting materials react completely. It is noteworthy that, on normal heating of the system, the process is possible only at temperatures above 1500 K.

Irradiation of the SF_6–NO mixture also leads to an instantaneous reaction accompanied by a flash. SOF_2 is formed as one of the products. According to the authors, the mixture temperature does not then exceed 700°C, while the thermally activated mixture remains unreactive up to 1000°C. However, one should note that the conversion of SF_6 and NO is not complete. Pankratov [219] noted that this is due to the fact that the appearance of chemical reactivity may be caused by the excitation of stretching vibrations alone, while the radiation generated by the laser corresponds to the range of SF_6 deformation vibrations.

The results demonstrate the possibility of specific reactions, since the reaction of mixtures of starting materials under the influence of infrared radiation can be different from that at elevated temperatures when heated in the usual way. This factor is extremely important, since it leads to a method of synthesising new compounds involving extensive application of lasers in chemistry.

The Reaction on Heating

It is noteworthy that the simple and generally adopted method of accelerating reactions such as ordinary heating has for a long time been ignored by investigators, evidently in view of the negative results of the early studies mentioned above.

Despite Moissan's view that sodium is not acted upon by sulphur hexafluoride up to the boiling point of the metal (880°C), it was established in 1953 [220] that the reaction occurs even at 247°C ($K = 2.23 \times 10^{13}$ cm^3 mole^{-1} s^{-1}). At 500°C the reaction is accompanied by chemiluminescence, the most likely explanation of which is that one of the five stages is exothermic with liberation of sufficient energy to excite the sodium D line:

$$SF_6 + n\,Na \rightarrow SF_{6-n} + n\,NaF \quad .$$

At relatively low temperatures (180–200°C) sulphur hexafluoride fluorinates aluminium trichloride with an AlF_3 yield of the order of 15% and at 250°C it reacts with SO_3, forming sulphuryl fluoride in approximately 20% yield [221]:

$$2SO_3 + SF_6 = 3SO_2F_2 \quad .$$

Technological reports dealing with the regeneration of waste from nuclear fuel by its fluorination with sulphur hexafluoride were published recently [52,53]. For example, the fluorination of UO_2 in corundum reactors at 750 to 900°C with an $SF_6 : O_2 = 1 : 1$ mixture is accompanied by the formation of UF_6. The authors believe that the process proceeds in accordance with the following general reaction mechanism [52]:

$$UO_2 + SF_6 = UF_6 + SO_2 \quad .$$

The use of high temperatures (1000°C) made it possible to obtain under laboratory conditions comparatively pure protactinium pentafluoride by fluorinating protactinium pentoxide with sulphur hexafluoride [53]:

$$3Pa_2O_5 + 5SF_6 = 6PaF_5 + 5SO_2 + 2.5O_2 \quad .$$

Moreover, the same authors' thermodynamic calculation has shown that the high-temperature fluorination of PuO_2 can yield PuF_4 via the reaction

$$PuO_2 + SF_6 = PuF_4 + SO_2F_2$$

or

$$^3/_2PuO_2 + SF_6 = ^3/_2PuF_4 + SO_2 + ^1/_2O_2 \quad .$$

However, these calculations have not so far been confirmed experimentally.

Naturally the problem of the reactivity or inertness of sulphur hexafluoride can be solved in the light of the above facts only by a comprehensive investigation of its reactivity in relation to a number of elements and their compounds. Such a study was undertaken by the authors of the present review [60–67] and showed that the widely held view that SF_6 is chemically inert is extremely arbitrary and that the example quoted constitute exceptions rather than the rule.

It was established by differential thermal analysis (DTA) that the vast majority of the metals investigated (Table 6) react at a high rate in the range 500–600°C. [61]

The reactions with titanium and the lanthanides proceed particularly vigorously with inflamation. The rate of reaction with boron and silicon is not so high as with titanium or lanthanum, apparently because of the kinetic characteristics of the process, since, on raising the SF_6 flow rate, the reaction is so vigorous in this case too that the mixture becomes incandescent. In many instances the occurrence of the reaction can be detected from the change in the weight of the reaction product relative to that of the starting material.

Our thermodynamic assessment of the most probable processes occurring in the SF_6–M systems led to the following findings:

$$(1/n)M(solid) + \tfrac{1}{2}SF_6(gas) = (1/n)MF_n(solid) + \tfrac{1}{2}SF_4(gas), \qquad (I)$$

$$\Delta G_I^\circ = \Delta H^\circ_{MF_n} - T(S^\circ_{MF_n} - S^\circ_M) + 52250 \text{ cal equiv.}^{-1};$$

$$\tfrac{4}{3}nM(solid) + \tfrac{1}{6}SF_6(gas) = (1/n)MF_n(solid) + \tfrac{1}{6}nM_2S_n(gas), \qquad (II)$$

$$\Delta G_{II}^\circ = \Delta H^\circ_{MF_n} + \tfrac{1}{3}\Delta H^\circ_{M_2S_n} + \tfrac{1}{3}(4S^\circ_M - 3S^\circ_{MF_n} - S^\circ_{M_2S_n} + 34.9) + 48100 \text{ cal equiv.}^{-1};$$

$$(1/n)M(solid) + \tfrac{1}{6}SF_6(gas) = (1/n)MF_n(solid) + \tfrac{1}{12}S_2(gas), \qquad (III)$$

where $\Delta H^\circ_{MF_n}$ and $\Delta H^\circ_{M_2Sn}$ are the standard enthalpies of formation of the fluoride and sulphide respectively (in cal equiv.$^{-1}$), $S^\circ_{MF_n}$ and $S^\circ_{M_2S_n}$ are the standard entropies of formation of the fluoride and sulphide respectively (in cal equiv.$^{-1}$ deg^{-1}), and S°_M is the standard entropy of the metal (in cal equiv.$^{-1}$ deg^{-1}).

Table 6. Conditions in the reaction of sulphur hexafluoride with metals and oxides.

Note. 1) "none" implies that a thermal effect was not recorded on the thermograms; 2) ΔP is the relative change in weight (wt.%); 3) implies that an increase in weight was not determined.

It can be easily shown that under standard conditions $\Delta G^\circ_{II} < \Delta G^\circ_I < \Delta G^\circ_{III}$, but at high temperatures this relation can change. By solving the inequality $\Delta G^\circ_I - \Delta G^\circ_{II} < 0$ for T, we find that $\Delta G^\circ_I < \Delta G^\circ_{II} < \Delta G^\circ_{III}$ when $T \geq (12450 - \Delta H_{M_2S_n})/S^\circ_M - S^\circ_{M_2S_n} + 34.9)$, i.e. reaction (II), accompanied by the formation of the metal sulphide and fluoride, is thermodynamically most favoured when $T' < T$ and reaction (I), involving the formation of the metal fluoride only, is most likely at $T'' > T$.

A test of the thermodynamic calculations for the metal–SF_6 systems led to their confirmation in a detailed experimental study of the conditions and the nature of the interaction of sulphur hexafluoride with zinc and cadmium [62].

Both metals react with SF_6 after their fusion. X-Ray diffraction established that the reactions of zinc and cadmium with SF_6 involve the formation of the metal fluorides and sulphides.

The products of the reaction between cadmium and SF_6 were separated in water using the different solubilities of CdS and CdF_2. Chemical analysis established that the solute is CdF_2 and that the solid in equilibrium with the solution is CdS. The molar ratio of the two phases is close to $CdF_2 : CdS = 3 : 1$, which makes it possible to formulate the process as follows:

$$4Cd + SF_6 = 3CdF_2 + CdS \quad .$$

As for cadmium, the reaction between zinc and SF_6 is also accompanied by the formation of zinc fluoride and sulphide in the molar proportions $ZnF_2 : ZnS = 3 : 1$. As mentioned above, when the temperature is raised, reaction (I) with the metal becomes thermodynamically favoured. Using inequality (10), it can be shown that the required temperature is above 650°C for cadmium and above 750°C for zinc. Indeed the fluorination of cadmium at this temperature leads to the formation of CdF_2 alone; the reaction with zinc is also accompanied by an increase in the mole fraction of the fluoride up to the formation of pure ZnF_2.

Thus our experimental data in no way confirm a marked chemical inertness of sulphur hexafluoride, showing in fact that, even on moderate heating, SF_6 becomes an active fluorinating agent capable of "supplying" its fluorine to reactions involving the fluorination of both elements and compounds. However, the reaction with oxides takes place at higher temperatures (Table 6). The only solid product is the difluoride of the corresponding metal.

Thermodynamic analysis (under standard conditions) of the reactions between sulphur hexafluoride and metals of one of the types

$$^1/_2n\,M_2O_n + {}^1/_4SF_6 = 1/n\,MF_n + {}^1/_4SO_2F_2 \quad , \qquad (10)$$

$$^1/_2n\,M_2O_n + {}^1/_6SF_6 = 1/n\,MF_n + {}^1/_6SO_3 \quad , \qquad (11)$$

$$^1/_2n\,M_2O_n + {}^1/_4SF_6 = 1/n\,MF_n + {}^1/_4SOF_2 + {}^1/_8O_2 \quad , \qquad (12)$$

$$^1/_2n\,M_2O_n + {}^1/_6SF_6 = 1/n\,MF_n + {}^1/_6SO_2 + {}^1/_{12}O_2 \quad , \qquad (13)$$

$$^1/_2n\,M_2O_n + {}^1/_2SF_6 = 1/n\,MF_n + {}^1/_2SOF_4 \quad . \qquad (14)$$

shows that at 550°C all the reactions [except reaction (14)] are already thermodynamically feasible. A mass-spectrometric study of the composition of the gas phase showed[63] that the reaction products are sulphur dioxide and sulphuryl fluoride. The absence of sulphur trioxide can be readily accounted for, on the one hand, by its dissociation at the given temperatures and, on the other, by the possibility of its interaction with SF_6. Nor can one rule out the possibility that the sulphur oxide fluorides formed can themselves behave as fluorinating agents. The latter is of fundamental importance from the standpoint of the maximum utilisation of the fluorine contained in the initial sulphur hexafluoride. One may also note that the thermodynamic calculations are fully consistent with the experimental data, which showed the absence of sulphur oxide tetrafluoride from the gaseous reaction products, since ΔG°_{290} for reaction (14) is positive over the entire temperature range.

A number of investigators[222-225] have recently attempted to establish a quantitative relation between thermodynamic and kinetic process characteristics for reactions of the same type. Thus a study of reactions between the oxide of a Group IVA element and chlorine demonstrated the existence of an approximately linear relation between the free energy of reaction ΔG° and the temperature of the onset of reaction T_i, determined by the DTA method. If it is assumed that such correlations for reactions of the same type [reactions (10)–(13)] do occur, then T_i for any of the above reactions will be determined mainly by the difference $\Delta H^\circ_{MF_n} - \Delta H^\circ_{M_2O_n}$ kcal equiv.$^{-1}$, decreasing as the difference diminishes. It is noteworthy that T_i for reactions of the same type, whose rates do not differ appreciably, can serve as a qualitative measure of the reactivity of a particular component.

On the basis of the above hypothesis, T_i presumably decreases (and the reactivity of SF_6 increases) in the vertical series of the oxides of Group IA elements: $Li_2O > Na_2O > Cs_2O > K_2O = Rb_2O$, since $\Delta H^\circ_{MF_n} - \Delta H^\circ_{M_2O_n}$ varies in the sequence $Rb_2O = K_2O > Cs_2O > Na_2O > Li_2O$; for the oxides of Group IIA elements, we have $BeO > MgO > CaO > SrO > BaO$, since $\Delta H^\circ_{MF_n} - \Delta H^\circ_{M_2O_n}$ varies in the sequence $BaO > SrO > CaO > MgO > BeO$; finally for the oxides of Group IIIA elements we have $Al_2O_3 > In_2O_3 > Ga_2O_3 > Tl_2O_3$, since $\Delta H^\circ_{MF_n} - \Delta H^\circ_{M_2O_n}$ varies in the sequence $Tl_2O_3 > Ga_2O_3 > In_2O_3 > Al_2O_3$.

Table 6 shows that a similar correspondence is in fact observed for the oxides of Group IIA elements (MgO, CaO, SrO, and BaO) and Group IIIA elements (Al_2O_3, Ga_2O_3, and In_2O_3), despite the fact that T_i for In_2O_3 (610°C) and Ga_2O_3 (680°C) were determined by differential thermogravimetric analysis. All the lanthanide oxides react in the temperature range 450–700°C like the oxides of alkaline earth metals but even more vigorously (Table 6). Consideration of data for the oxides La_2O_3, Nd_2O_3, and Pr_6O_{11} shows that, according to the results of chemical and X-ray diffraction analyses, they react with sulphur hexafluoride, forming the corresponding metal trifluorides.

It is noteworthy that SF_6 is an extremely vigorous fluorinating agent on heating in the synthesis of not only binary fluorides but also complex fluorides. We showed this in a study of the reaction of sulphur hexafluoride with alkaline earth metal oxides in the presence of an alkali metal fluoride[64]. Alkaline earth metal complexes of the type M^IMF_3 synthesised in the solid phase are formed only at fairly high temperatures above 1000°C,[226,227] which naturally gives rise to certain difficulties both in the synthesis and in the subsequent purification of the products. On the other hand, in the fluorination of a mixture of an alkaline earth metal oxide and an alkali metal fluoride in specific stoichiometric proportions the corresponding complexes are formed at lower temperatures. For example, $KMgF_3$ was obtained under these conditions at 660°C, while the solid-phase synthesis requires the use of temperatures above 1000°C. The syntheses of the corresponding fluoro-complexes of alkaline earth metals were achieved under similar conditions: K_2MgF_4, $CsMgF_3$, $CsGaF_3$, $CsSrF_3$, and $BaLiF_3$. It was established by the DTA method that the temperature of the onset of reaction between SF_6, MO, and MF does not exceed 500°C in all cases. Under these conditions and up to 900°C, the MF_2–MF mixture does not undergo any changes associated with the formation of complex fluorides. The latter can be obtained in the MF_2–MF system only at temperatures not less than 1100–1200°C.[226,227]

Thus the above results show that sulphur hexafluoride is an extremely active fluorinating agent and can be used successfully in the synthesis of anhydrous binary and complex fluorides.

---o0o---

Presumably further advances in the application of sulphur hexafluoride (one of the most widely used hexafluorides) will be achieved primarily in connection with studies on its chemical properties, since the level of present research on the physical and physicochemical properties meets practical requirements adequately.

In this respect the most interesting and in practise most important results may be expected in studies on reactions where SF_6 behaves as a fluorinating agent. The practical interest in reactions of this kind is due to the high fluorine content in sulphur hexafluoride (78%), its inertness and non-toxicity under the usual conditions, and also the possibility of its activation by various procedures, ranging from the effect of electromagnetic radiation to ordinary heating. The data obtained by the present authors for the synthesis of both simple and complex inorganic fluorides involving sulphur hexafluoride suggest that SF_6 can be regarded as a new and very promising fluorinating agent, the possibilities of which have been by no means fully explored. It is quite evident that the requirements of both scientific research and industry involve extensive employment of increasing numbers of new fluorinating agents. Traditional fluorine, fluorine halides, and hydrogen fluorides can be in many cases replaced successfully by noble gas fluorides[228,229], alkali metal fluoride halides[230] and hydrogen fluorides[230-233], nitrogen[234] and phosphorus[235] fluorides, and the highest fluorides of certain metals[236]. There is no doubt that one is fully justified in including sulphur hexafluoride in the above by no means exhaustive list of the possible and promising fluorinating agents, this being confirmed by the advances in the chemistry of this compound.

The reactions of SF_6 with various gaseous compounds initiated by laser radiation are extremely interesting from the standpoint of the synthesis of new fluorine-containing compounds.

The study of the solubility of sulphur hexafluoride in water and other solvents is extremely fruitful in relation to further investigations of the nature of non-electrolytes and is of interest in connection with the possible synthesis of various derivatives of sulphur hexafluoride in non-aqueous media.

It is noteworthy that, although the method of synthesis of sulphur hexafluoride from the elements is fairly simple, it requires the use of expensive fluorine and of expensive apparatus in view of the corrosive nature of fluorine. The advances in recent years nevertheless give rise to the hope that it will be possible to introduce methods for the synthesis of sulphur hexafluoride without the direct use of fluorine, for example by the electrolysis of sulphur-containing compounds in liquid hydrogen fluoride.

The development of studies on the chemistry of this compound will undoubtedly entail the necessity for the development of the analytical chemistry of SF_6 and it appears likely that gas or gas–liquid chromatography will prove to be most useful in this field too.

Activation of Molecular Oxygen on Interaction with Transition Metal Complexes

A.V.Savitskii and V.I.Nelyubin

The present state of research and ideas in the field of the activation of molecular oxygen by transition metal complexes and matrix systems is described.
The bibliography includes 124 references.

I. INTRODUCTION

One way of increasing the reactivity of oxygen is its "chemical" activation, in particular its fixation on transition metal complexes. It is suggested that, owing to the many possible valences in the complexes, the activated molecule can not only react under mild conditions but also exhibits a definite selectivity in relation to the substrate.

The formation of complexes by molecular oxygen can occur in many heterogeneous catalytic oxidation processes[1], in the autoxidation of complexes[2], and also in biochemical processes. The mechanism of action and the functions of oxygen carriers in such processes are usually elucidated with the aid of homogeneous models[3-5]. Transition metal complexes, which are capable of binding molecular oxygen, are normally employed as model systems.

Two approaches to the study of the mechanism of the activation of oxygen via its coordination have been devised.

In the first, analytical approach the aim is to select a theoretical quantum-chemical model which can describe satisfactorily the binding of molecular oxygen and can predict the possible reactivity of coordinated oxygen. This approach presupposes the existence of a definite relation between the geometry of the dioxygen complex, the nature of the binding of oxygen, and a definite type of reactivity of the coordinated oxygen molecule.

The second approach involves the creation of synthetic models of heterogeneous and biochemical systems in which molecular oxygen is fixed. The approach is based on matrix effects, i.e. the aim is to simulate the conditions for the fixation of oxygen in systems with polymeric structural elements.

A combination of these two approaches in the study of the mechanism of the activation of molecular oxygen is probably the most fruitful.

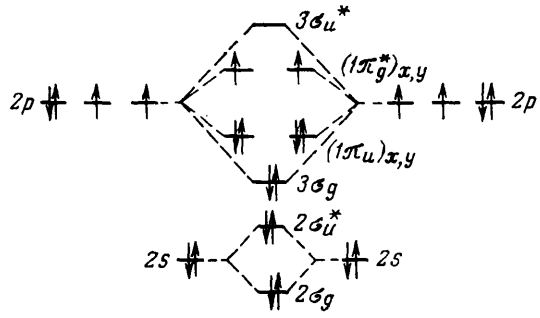
A number of reviews on this problem have been published in which the structure, binding, and reactivity of dioxygen complexes are discussed fairly extensively[6-11] and the general characteristics of the binding of oxygen are analysed[12,13].

Analogous processes have been dealt with in Soviet scientific literature: the activation of small molecules and new trends in the development of the chemistry of coordination compounds[14] and homogeneous catalytic oxidation of hydrocarbons[15]. However, one should note that the problem of activated binding and also the matrix principle of the fixation and activation of the oxygen molecule have not so far been adequately described.

In the present review an attempt is made to survey the latest results of studies of this kind.

II. THE STRUCTURE OF THE OXYGEN MOLECULE AND ITS ACTIVE FORMS

The structure of the oxygen molecule can be conveniently treated within the framework of molecular orbital method[16]. The two least strongly bound electrons are placed in doubly degenerate antibonding π orbitals and, according to the Hund rule, have parallel spins, i.e. the molecule has a triplet ground state $^3\Sigma_g$ (Fig. 1).



The bond between the atoms is due to the interaction of $2p$ electrons and consists of one two-electron σ bond $(3\sigma_g)^2$ and two three-electron π bonds $(1\pi_u)^2(1\pi_g^*)^1$. Each three-electron bond constitutes a combination of a pair of

bonding electrons and one antibonding electron in the same interaction plane. The bond order, defined as half the difference between the numbers of bonding and antibonding electrons, is two.

In chemical reactions of oxygen it is necessary to take into account the first excited state of the molecule $^1\Delta$(singlet) in which both π_g^* electrons occupy the same orbital and have antiparallel spins. The formal bond order is the same as in the ground state but the electron density is distributed less uniformly, since one π-interaction plane contains two electrons and the other contains four electrons. Therefore here one expects the appearance of an additional electrostatic repulsion, whose energy may contribute significantly to the energy of the $^3\Sigma \rightarrow {}^1\Delta$ excitation, which is 23 kcal mole^{-1}.[17]

The addition of electrons to the oxygen molecule leads to the population of antibonding orbitals, which entails a decrease of the O–O bond order. The observed changes in bond length and vibrational frequency confirm the existence of this tendency (Table 1).

Table 1. Characteristics of the O–O bond strengths.

Species	Calc. bond order	Bond length, Å	Stretching vibration frequency, cm^{-1}	References
O_2	2	1.21	1555	18,19
O_2^-	1.5	1.28 (KO_2)	1089	20,21
O_2^{2-}	1	1.49 (BaO_2)	880 (H_2O_2)	20,19

According to the results of *ab initio* MO SCF calculations, the $2\sigma_g$, $2\sigma_u^*$, and $3\sigma_g$ orbitals in different dioxygen species are mixed[22]. The directional character of hybrid orbitals in space is known[23] to be more marked compared with that of non-hybrid orbitals, which ensures a higher degree of overlapping on formation of σ bonds, in particular when the orbitals of both interacting species are hybridised. Furthermore, hybridisation leads to a decrease of the repulsion of the lone electron pairs. Therefore the ethylene-like reactive forms $O_2(^1\Delta)$, O_2^-, and O_2^{2-} with sp^2 hybridisation of the orbitals can play a definite role in complex formation.

III. THE NATURE OF ACTIVATING BINDING

The principle of the conservation of spin can impose limitations on the nature of the elementary processes in chemical reactions[8]. By virtue of spin conservation the interaction of the oxygen molecule in the triplet state with a molecule in the singlet state cannot lead to the formation of molecules in singlet states only. From this it follows that oxygen in the ground state is not a heterolytic (two- or four-electron) oxidant and reacts preferentially as a homolytic (one-electron) oxidant.

The main types of homolytic oxidation reactions occurring with conservation of spin are as follows:

(a) reaction with a molecule:

$$\overset{\uparrow\downarrow}{R}H + \overset{\uparrow\uparrow}{O_2} = \overset{\uparrow}{R} + \overset{\uparrow\downarrow\uparrow}{HO_2} \quad ;$$

(b) reaction with a radical

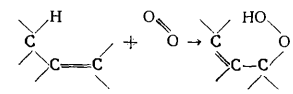
$$\overset{\downarrow}{R} + \overset{\uparrow\uparrow}{O_2} = \overset{\downarrow\uparrow\uparrow}{RO_2} \quad .$$

As a result of a termolecular homolytic reaction in which the oxygen molecule abstracts one hydrogen atom from each of two substrate molecules, the spin is also conserved[24,25]:

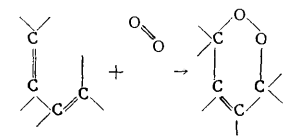
$$\overset{\uparrow\downarrow}{R}H + \overset{\uparrow\uparrow}{O_2} + \overset{\uparrow\downarrow}{R}H = \overset{\uparrow}{R} + \overset{\downarrow\uparrow\downarrow\uparrow}{HOOH} + \overset{\uparrow}{R} \quad .$$

The above homolytic reactions are difficult because they all occur with participation of free radicals, whose equilibrium concentration is as a rule very low under normal conditions.

In order to achieve the reaction without the involvement of free radicals, it is necessary to excite the oxygen molecule to the singlet state, for which, from the standpoint of spin conservation, it can react as a two-electron non-homolytic oxidant:



or



The formation of complexes by the oxygen molecule with transition metal compounds leads to a change in its spin state and in the nature of its reactivity. The activating effect of transition metal complexes is associated with the presence of closely spaced *d* levels of the metal ions, which are responsible for the ready formation of activated forms of different multiplicity.

When the oxygen molecule reacts with a doublet centre, a radical complex, capable of vigorous interaction not only with radicals but also with singlet molecules, can be formed:

$$\overset{\downarrow}{M} + \overset{\uparrow\uparrow}{O_2} = \overset{\downarrow}{M} \cdot \overset{\uparrow\uparrow}{O_2} \quad .$$

The interaction with a triplet centre can lead to the formation of a complex of singlet oxygen. It is assumed that a complex of triplet oxygen is formed in the first stage of the process. As a result of the change in molecular symmetry on complex formation, the energy degeneracy of the π_d^* orbitals is lifted, which facilitates the transition of the molecule to the singlet state:

$$\overset{\downarrow\downarrow}{M} + \overset{\uparrow\uparrow}{O_2} = \overset{\downarrow\downarrow}{M} \cdot \overset{\uparrow\uparrow}{O_2} = \overset{\downarrow\uparrow}{M} \cdot \overset{\downarrow\uparrow}{O_2} \quad .$$

The role of the triplet states of transition metal complexes in such processes is indicated by studies on the sensitised photoexcitation by molecular oxygen[26].

Coordination interaction alters the electronic structure of the molecule owing to the change in the population and disposition of its orbitals. The transition metal can withdraw electron density from certain bonding orbitals and shift it to certain antibonding orbitals, which is analogous to the electronic excitation of the free molecule. In terms of interatomic distances and valence angles, the coordinated molecule can resemble various activated forms of the free molecule[27]. A characteristic feature of this type of excitation is that it occurs solely due to the

coordination interaction with the metal atom without the external supply of energy. The heats of such complex formation processes are as a rule low, but the processes lead to considerable chemical changes in the coordinated ligand.

It is believed that the most significant factor in the activating complex formation between transition metal compounds and the oxygen molecule is its interaction with the metal atom, since in this case the specific role of the latter, associated with the presence of *d* valence states of different symmetry and spatial orientation, has the greatest effect. However, the nature of the ligand environment, whose influence extends via the metal atom to the coordinated molecule, is very important. Nor can one rule out the possibility of the activation of the oxygen molecule by its outer-sphere coordination[28].

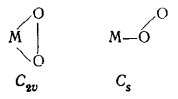
Evidently, apart from the electronic factor, the geometrical factor has an effect in the interaction between the dioxygen molecule and the activator, because definite steric hindrance to the binding of the oxygen molecule can probably lead to a definite strain in the bonds of the molecule and hence to a definite type of reactivity[29].

IV. THE STRUCTURE OF DIOXYGEN COMPLEXES

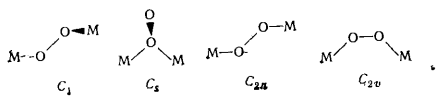
In the reaction with transition metal complexes the oxygen molecule behaves mainly as an electron acceptor, as shown by the results of studies using different methods (X-ray photoelectron spectroscopic[30,31], thermodynamic[32], and electrochemical[33]). The electron-donating capacity of the metal (the energy of the occupied *d* orbitals) can play a significant role in the binding of oxygen. Complexes with oxygen are usually formed by compounds of transition metals in the lowest oxidation state, which exhibit a sufficient electron-donating capacity to ensure charge transfer but not high enough to cause the dissociation of the O–O bond.

The nature of the binding of oxygen in the complex and the reactivity of the coordinated molecule are usually considered on the basis of the geometry of the oxygen adduct, since evidently the latter determines the state of oxygen in the complex and hence possibly also the type of reactivity of the bound oxygen.

Mononuclear complexes with different symmetries of the metal–dioxygen fragment—the closed (C_{2v}) and open (C_s) types—are known:



Furthermore, there are dinuclear complexes which can be regarded as structural derivatives of mononuclear complexes of the open type:



In mononuclear complexes of the open type and in the corresponding dinuclear derivatives the MOO valence angles are close to 120°, i.e. these configurations are apparently based on the state of the oxygen atom with sp^2-hybridised orbitals.

No dioxygen complexes known to have a linear configuration of the metal–dioxygen fragment have yet been obtained; this distinguishes them from the complexes of molecular nitrogen in which linear coordination is most typical. Probably in this case the different populations of the antibonding orbitals and hence the different molecular symmetries have an effect. In the nitrogen molecule there are two vacant π orbitals, which accept two pairs of *d* electrons from the metal and this favours the formation of a linear structure[34]. In the oxygen molecule there can be only one vacant π orbital (in the $^1\Delta$ state) which can accept only one pair of *d* electrons and this rules out a linear coordination in this case.

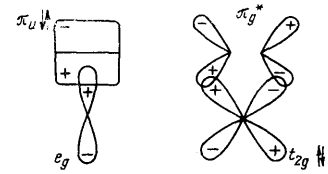


Figure 2. Griffith's model of a π-complex.

The formation of a dioxygen complex of the closed type may resemble the binding in olefin complexes[35], as pointed out by Griffith[36]. It is suggested that a σ bond is formed via an occupied π-bonding molecular orbital of oxygen and a vacant *d* orbital of the metal. Furthermore, there is a possibility of forming a π bond from the lone pair of *d* electrons of the metal atom and an antibonding orbital of the oxygen molecule (Fig. 2). Thus the energy splitting of the degenerate oxygen π^* orbitals in the ligand field of the complex is postulated.

Presumably when the degree of charge transfer from the metal to oxygen is fairly pronounced, the structure of the complex is best described by the model of a doubly coordinated σ complex, which may be important in the determination of the reaction mechanisms. The structural characteristics of a number of mononuclear complexes are presented in Table 2.

Table 2. Structural data for dioxygen complexes of the closed type (diamagnetic).

The influence of the metal can be estimated from experimental data for the structures of the cationic complexes of cobalt, rhodium, and iridium with bis(diphenylphosphinoethane) and bis(diphenylphosphinoethylene) ligands. The iridium atom is capable of forming a

stronger M–O bond than the rhodium atom and also of loosening the O–O bond (Table 2). This is attributed to the fact that the π-donor metal orbitals in the iridium complex must lie above those in the rhodium complex[38-44]. Neglecting the effect of the change of ligand, we may note that the observed sequence of changes in the $M-O_2$ bond lengths is consistent with the sequence of changes in the kinetic and activation parameters of the binding of oxygen by the bis(diphenylphosphinoethylene) complexes[44]. The difference between the energies of the *d* orbitals of the corresponding metal complexes probably plays a role here. The specificity of the bis(diphenylphosphinoethylene) ligand may be reflected in this series by the absence of a correlation between the M–O bond lengths on the one hand and the O–O bond lengths on the other.

It is noteworthy that the O–O bond length is very sensitive to changes in the ligand environment of the metal. As the auxiliary ligands become less electronegative (Cl > Br > I; PPh_3 > PPh_2Et), the O–O distance increases. A correlation is also observed between the O–O bond length and the degree of reversibility of the binding of oxygen. This can be explained by the fact that, with increase of the energy of *d* orbitals, the effect of the donation of π electrons to the antibonding molecular orbital is enhanced.

The O–O stretching vibration frequency in the spectra of complexes of the given type is greatly reduced compared with that for the free molecule, to a value of the order of 800–900 cm^{-1}.[45,46] The M–O stretching vibration frequency is in the range 450–600 cm^{-1}. A satisfactory correlation between these frequencies and the changes in the structural parameters of the compounds has not so far been obtained.

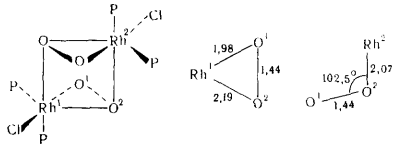

Figure 3. The structure of $[Rh(Ph_3P)_2ClO_2]_2$ (the bond lengths are given in Å).

The dinuclear diamagnetic complex $[Rh(PPh_3)_2ClO_2]_2$, in which two oxygen molecules are combined reversibly[47], is unusual (Fig. 3). Its unusual feature is that each oxygen molecule, which behaves as a bridging ligand, forms a coordinate bond of the closed type with one metal atom, behaving as an equatorial ligand, while the coordinate bond formed with the other metal atom is of the open type and oxygen behaves as an axial ligand. Each coordinated oxygen molecule forms two σ bonds: one via the occupied π_u orbital of oxygen and the vacant equatorial dsp^3 orbital of one metal atom and the other via the occupied nonbonding hybrid orbital of oxygen (*p* orbital with some *s* character) and the vacant axial dsp^3 orbital of the other metal atom. Furthermore, many-centre π bonding is postulated. This complex can be regarded as an intermediate structural type in relation to complexes of the open and closed types.

It is interesting that the coordinated oxygen molecule acquires the ability to form hydrogen bonds[43]. In the complex $Pt(PPh_3)_2O_2.2CHCl_3$ the hydrogen atoms of the solvate molecules are in the same plane as the Pt and O atoms, so that the PtOH angle is 180° and the O–H distance is 2.04 Å (Fig. 4). Compared with the benzene solvate, which shows no signs of the formation of hydrogen bonds, the O–O bond length is appreciably increased, while the M–O bond hardly changes (Table 2). It is so far not clear how the bond with the solvent species is formed: as a result of the excitation of the oxygen molecule or as a result of the excess negative charge on oxygen. The location of the hydrogen atoms in the same plane as the metal–dioxygen fragment suggests that the oxygen orbitals which form the $Pt-O_2$ bond are involved in hydrogen bonding, but the slight change in the Pt–O bond is not entirely consistent with this hypothesis.

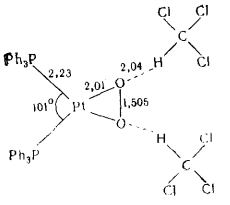

Figure 4. The formation of a hydrogen bond (the bond lengths are given in Å).

The complex $IrCl(PPh_3)_2(C_2H_4)O_2$, in which the simultaneous coordination of oxygen and ethylene has been demonstrated by infrared spectroscopy and NMR[48] (Fig. 5), can serve as a model of homogeneous catalytic oxidation.

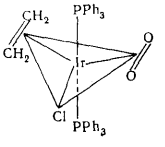

Figure 5. The proposed structure for $IrCl(PPh_3)_2(C_2H_4)O_2$.

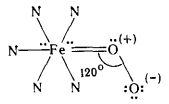
The paramagnetic complex $Ru(AsPh_3)_2Cl_2O_2$ should probably be assigned to the same structural type in view of the appearance of the 880 cm^{-1} band in the infrared spectrum[49]. Another paramagnetic complex, $Cr[N(i\text{-}Pr)_2.]_3O_2$, has an effective magnetic moment of 2.03 Bohr magnetons (B.M.) and a vibrational frequency of 980 cm^{-1},[50] which indicates the possible characteristics of its structure.

Aleksandrov et al. recently demonstrated the possibility of the formation of oxygen complexes with organic derivatives of post-transition metals[51]: the "reversible" adduct $Et_2Cd.2O_2$, with an intense 790 cm^{-1} band in its infrared spectrum, was obtained. The transfer of the π_g electron pair of oxygen to the vacant 5*s* or 5*p* orbital of the metal and also the interaction via the occupied 4*d* orbitals of the metal and the vacant π_g orbital of oxygen can make a definite contribution to bond formation on complex formation.

The iron complex with porphyrin and histidine, having the configuration of a tetragonal pyramid, is the active centre for the binding of oxygen in haemoglobin and myoglobin[52]. The planar porphyrin ligand is located at the base of the pyramid, the bivalent iron ion coordinated to four nitrogen atoms being in the centre. The apex of the pyramid is occupied by the tertiary nitrogen atom of histidine and the oxygen molecule adds to the base of the pyramid. The orientation of the dioxygen group relative to the iron atom has not so far been determined experimentally. According to Pauling[53], the structure of the coordination centre of oxyhaemoglobin can be represented as follows:



It is believed that the tervalent oxonium ion with sp^2-hybridised orbital is involved in the formation of a bond. From the standpoint of the molecular orbital method, this structure can be regarded as a π-bonded complex of the open type.

According to Griffith, the oxygen in oxyhaemoglobin is coordinated as in a complex of the open type[36]. Since in this case the iron ion must have a coordination number of seven, one may expect the occurrence of steric hindrance[54]. So far no model compound with a similar configuration has been obtained.

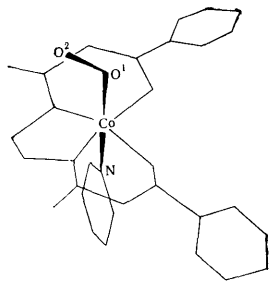


Figure 6. The structure of Co(bzacen)(pyridine)O_2.

The orientation of the coordinated molecule relative to the metal atom proposed by Pauling has been demonstrated for the tetraphenylporphyrin complex of cobalt with NO,[55] which is isoelectronic with the porphyrin complex of iron with oxygen. A similar orientation of the dioxygen group was established for Co(bzacen)(pyridine)O_2,[56] where bzacen is *NN'*-ethylenebis(benzoylacetoniminide) (Fig. 6). One should note that in these molecular structures the projection of the coordinated molecule onto the plane of the equatorial ligand lies between the adjacent bonds of the metal in the equatorial plane. The staggered conformation probably corresponds to minimum repulsion of the non-bonded atoms. However, this disposition of the dioxygen group should decrease the effectiveness of π-bonding since the maximum overlap of the oxygen p orbital with one of the metal t_{2g} orbitals may be expected for the eclipsed conformation[12,57]. The unusual conformation of oxygen can be one of the factors determining the possibility of the reversible binding of oxygen to haemoglobin.

Three types of dioxygen compounds of cobalt, in which the coordinated oxygen molecule forms an obtuse CoOO angle, are distinguished: mononuclear paramagnetic, dinuclear diamagnetic, and dinuclear paramagnetic (Table 3).

Mononuclear complexes are formed on direct interaction between certain bivalent cobalt compounds and oxygen. Their magnetic moments are 1.85 ± 0.35 B.M., which is evidence for the presence of one unpaired electron in the complex[65,66]. According to ESR studies[67-71], the unpaired electron is located in an orbital having 10–20% of metallic character, i.e. is localised preferentially at the dioxygen group. X-Ray photoelectron spectroscopic[31] and thermodynamic studies[32] suggest that the charge state of the metal corresponds more closely to cobalt(III) than to cobalt(II). The bond with the oxygen molecule can arise as a result of spin pairing and electron transfer from the metal atom to oxygen. The coordinated molecule has the character of the molecular ion O_2^-, forming a donor–acceptor bond with the tervalent cobalt atom via the sp^2-hybridised lone electron pair with some delocalisation of the unpaired electron over the metal[65,66,72]. In mononuclear complexes of this type the O–O interatomic distance (1.26 Å)[56] and the O–O stretching vibration frequency (1120–1140 cm^{-1})[66] correspond to the structural parameters of the O_2^- ion (Table 1).

The presence of an additional electron in the mononuclear cobalt analogues of oxyhaemoglobin can be responsible for some of its structural characteristics. Since the iron atom in oxyhaemoglobin has a stable 18-electron inert gas shell, the additional electron must be located in an oxygen orbital. Owing to the high energy of the vacant $3\sigma_g$ orbital, the electron interacts with the π_g orbital, displacing the electron pair involved in the dative π interaction on the metal side. Thus a considerable weakening of the π-bonding component may be expected in cobalt analogues of oxyhaemoglobin as compared with oxyhaemoglobin itself.

Apart from the mononuclear complexes, fairly numerous dinuclear oxygen complexes of cobalt are known. Assuming the formation of covalent bonds between cobalt ions and the oxygen molecule, it is believed that the latter undergoes a two-electron reduction[13]. The resulting dinuclear complex can be regarded as a coordination compound of the peroxide type: $Co^{III} \leftarrow O_2^{2-} \rightarrow Co^{III}$.

The dinuclear coordination of the peroxide anion can be achieved in two ways: by the addition to each oxygen atom of one metal atom (C_1) or by the addition of both metal atoms to one oxygen atom (C_S).

The one-electron oxidation of the diamagnetic complexes leads to the corresponding paramagnetic compounds. As for the mononuclear complexes, there is a tendency towards the retention by the metal of the stable 18-electron shell, i.e. an electron must be removed from the dioxygen group:

$$Co^{II} \leftarrow O_2^{2-} \rightarrow Co^{III}—\bar{e}=Co^{III} \leftarrow \dot{O}_2^- \rightarrow Co^{III} \quad .$$

ESR spectra confirm the preferential location of the unpaired electron in the dioxygen group[73]. In contrast to the diamagnetic complexes, the metal–dioxygen fragment in the dinuclear paramagnetic complexes has a planar structure (C_{2h}), in accordance with its superoxide character.

The data presented in Table 3 show that, as the π-bonding electron pair is transferred towards the dioxygen group, the strength of the M–O bond increases and that of the O–O bond falls. The changes in the valence angles

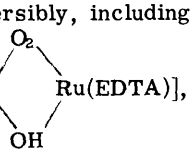
of the $Co-O_2-Co$ groups can be accounted for by a change in the character of the orbitals involved in the binding of the oxygen molecule.

X-Ray diffraction studies have established that the orientation of the dioxygen group relative to the equatorial ligand is the same as for the mononuclear complexes.

Dinuclear compounds of other transition metals are known, in which the oxygen is bound reversibly, including



the diamagnetic complex $K_2Na[(EDTA)Ru(O_2)Ru(EDTA)(OH)]$, obtained by Ezerskaya and Solovykh[74,75], where EDTA is the tetrabasic residue of ethylenediaminetetra-acetic acid, and the paramagnetic complex $[Mn(Salen\dagger)]_2O_2$, whose effective magnetic moment is 2.79 B.M.[76]

The role of the specific ligand environment of the metal in biological oxygen carriers is manifested by a change in the thermodynamic parameters of the oxygenation process[77-85].

The differences between the stabilities of the oxygen complexes of cobalt with different equatorial ligands (for example TMPP and Salen, Table 4) are probably due to the differences between the π-acceptor capacities of these equatorial ligands. π-Conjugated macrocyclic systems do not as a rule promote strong binding of oxygen. For certain complexes with the same type of ligand environment, ΔG° may be correlated with pK_a for the axial ligand. A decrease in the stability of the mononuclear oxygen complex with sterically hindered axial ligands (2,6-lutidine, 2,4,6-collidine, and quinoline) has been noted. The sterically hindered groups in the ligand prevent its effective approach to the metal, weakening the stabilising *trans*-influence on the metal–oxygen bond. As a result of the distortion of the configuration, the stability of the dinuclear compound may be reduced[84]. For a rigidly bound equatorial ligand of the type of porphyrin, the importance of steric hindrance of the coordination of the axial ligand increases[81].

V. MATRIX FIXATION OF OXYGEN

The stabilisation of the oxygen-fixing centre of haemoglobin is probably promoted by the matrix effect. The basic unit of haemoglobin is the planar tetracoordinate complex of iron(II) and protoporphin. The haemoglobin

molecule contains four haem groups, which are linked by peptide chains via histidine to the protein moiety. Each of the four protein chains forms a fairly complex three-dimensional structure around the haem in such a way that the latter is located in a fold of the protein chain (matrix) within which oxygen may be bound.

In accordance with Pauling's hypothesis[53], it is believed that the terminal atom of the coordinated oxygen molecule, which carried an excess negative charge, is oriented towards the NH group of distal histidine, forming a hydrogen bond. Thus a two-point fixation of the molecule is achieved by a cooperative interaction with the metal complex and with the histidine group of the protein (Fig. 7).

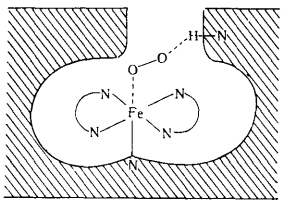

Figure 7. A model of the matrix fixation of oxygen by haemoglobin.

Presumably the matrix effect plays a dual role: firstly it prevents the irreversible interaction of molecular oxygen with the active component of haemoglobin and secondly it rules out the possible oxidation of labile substrates.

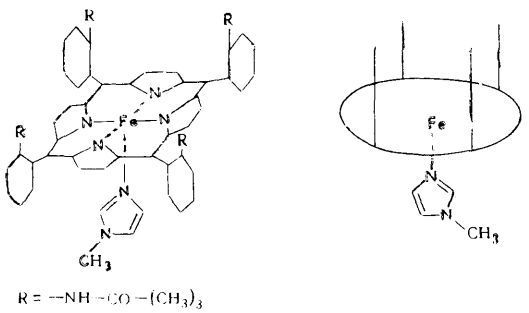

Figure 8. The unit of a matrix with artificial steric hindrance and a schematic representation of the element.

Definite information about the occurrence of the matrix principle in the fixation of molecular oxygen can be provided by a study of the binding of oxygen in synthetic models. A number of approaches to the creation of models based on the matrix principle may be noted. In the first case the model is formed by the incorporation of an analogue of the active centre in the polymer being formed. A cavity should be created over the active centre. The cavity is usually produced by incorporating in the polymer a model compound in which a small molecule, particularly CO, is reversibly combined. After the formation of the polymer, the small molecule is removed (by flushing with an inert gas).[29,86]

The second approach involves the creation of artificial steric hindrance around the active centre[87] (Fig. 8).

Apart from the creation of artificial steric hindrance, the elements of matrix systems can be formed by employing the conformations of the ligand environment[88] (Fig. 9). According to certain observations[88], the steric hindrance influences the stability of the adduct of molecular oxygen with the metal complex.

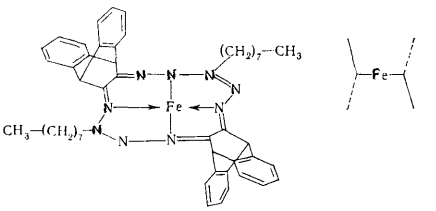

Figure 9. A model of the matrix formed as a result of the conformation of the ligand environment and a schematic representation of the model.

However, the matrix effect can be shown under certain conditions even in the absence of steric hindrance, when one employs a model in which there is an appreciable cooperative interaction with the ligand environment[89,90] (Fig. 10). The cooperative interaction in matrix systems has a definite advantage over simple complexes which are haemoglobin analogues. According to the results of Cheng and Traylor[86], there is a very significant difference between the degrees of binding of molecular oxygen to the iron(II) complex in which the *trans*-ligand (pyridine) is coordinated to the iron ion only and the analogous complex in which pyridine is additionally linked to the equatorial ligand (Fig. 10).

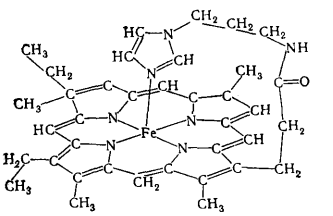

Figure 10. A model of the matrix with an independent linkage between the axial and equatorial ligands.

Together with a change in reactivity, one can also expect a change in selectivity when the *trans*-ligand is replaced; this has been confirmed by studies on the binding of carbon monoxide and molecular oxygen. In particular, these results show that, when imidazole in the *trans*-position is replaced by pyridine, the system loses its ability to bind oxygen[86].

Furthermore, the results of studies involving similar systems lead to the conclusion that the coordinated oxygen molecule is additionally stabilised when there is a possibility of the formation of a hydrogen bond with fragments of the system (two-point fixation)[86].

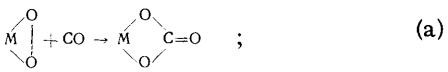
Coboglobins apparently occupy a special place among matrix systems[91,92], since the protein moiety is fully retained in their structure. Consequently the study of the binding of oxygen by coboglobins can elucidate the role of the protein moiety in this process.

Furthermore, the employment of such systems as haemoglobin analogues makes it possible to elucidate certain characteristics of the influence of the metal on the effects accompanying the addition of the oxygen molecule (the phosphate effect, the Bohr effect, and *gem–gem* interaction). In particular, a definite difference has been observed[92] between the *gem–gem* interactions in coboglobin and haemoglobin during the binding of oxygen.

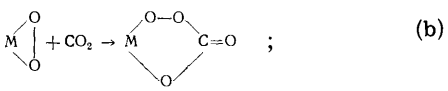
VI. REACTIVITY OF THE COORDINATED MOLECULE

Two main types of reactions of the complexes are distinguished: the inner-sphere interactions with preliminary coordination of the substrate in the inner sphere and the outer-sphere interactions where there is no inner-sphere coordination of the substrate. Evidently in the first case both oxygen and the substrate are activated, while in the second case only oxygen is activated.

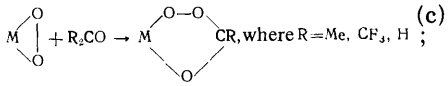
The reactions can be stoichiometric or catalytic. The addition of small molecules to the dioxygen complexes of Group VIII metals must be classified as stoichiometric oxidation reactions[93–99]:



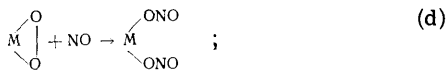
(a)



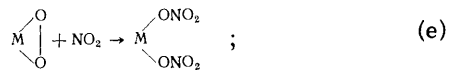
(b)



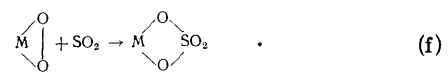
(c)



(d)

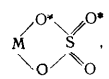


(e)

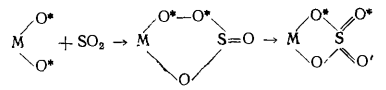


(f)

All the reactions with coordination-unsaturated platinum complexes take place readily and probably involve an inner-sphere mechanism[100]. The coordination-saturated rhodium and iridium compounds react only with NO_2 and SO_2, i.e. molecules in which the aprotic acid properties are most pronounced. In these cases one might postulate a mechanism involving a simple outer-sphere addition. However, studies with isotopically labelled oxygen in the complex have shown that the label is distributed in the product in the following manner:



i.e. the dissociation of the O–O bond is accompanied by the dissociation of the M–O bond[101]. The electrophilic attack by SO_2 is probably directed to the negatively charged oxygen atom, facilitating the heterolytic dissociation of the M–O bond with subsequent insertion of the SO_2 molecule in this bond and a further rearrangement of the resulting peroxide complex:

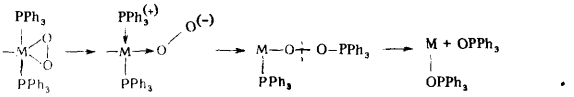


Oxygen π complexes of the closed type catalyse the oxidation of tertiary phosphines to the corresponding oxides[91,102–104] and also of isocyanides to isocyanates[45]. Since the substrates undergoing oxidation can function as specific π-acceptor ligands, presumably the reactions have an inner-sphere mechanism. According to the results of kinetic studies, all the intermediate complexes contain substrate molecules and have an 18-electron coordination sphere (Table 5), which is specific to inner-sphere catalysis according to Halpern's hypothesis[105].

Table 5. Characteristics of the intermediate complexes.

Composition	No. of coordinated ligands	No. of electrons in valence shell of metal	References
$Ru(O_2)(SCN)(NO)(PPh_3)_3$	6	18	104
$Ir(O_2)(I)(CO)(PPh_3)_2$	5	18	38
$Pt(O_2)(PPh_3)_3$	4	18	95

A remarkable reaction is catalysed by a ruthenium complex. According to infrared spectroscopic data[104], the coordination of the oxygen molecule in the initial 16-electron compound $Ru(O_2)(SCN)(NO)(PPh_3)_3$ is of the closed π-complex type, i.e. the coordination number is probably six. The addition of the PPh_3 molecule leads to the formation of a sterically strained configuration with a coordination number of seven, which can promote the inner-sphere *cis*-migration of the ligand with a change in the orientation of the dioxygen group relative to the metal atom:



In the general case there is also a possibility of an inner-sphere mechanism with a simultaneous transfer of two ligands.

The electronic factor can determine the possibility of the inner-sphere oxidation reaction for a specific geometry of the complex. The latter should probably also ensure both definite relative positions of the oxygen and reacting ligand molecules and a definite stoichiometry (in particular for concerted reactions).

The lack of data precludes an adequately detailed discussion of the interesting reaction involving the catalytic hydrogenolysis of molecular oxygen in the presence of a number of complexes[106]. However, it is known that oxygen-fixing complexes can accelerate the autoxidation of

hydrocarbons[107-111]. Reactions of this type can proceed via an outer-sphere mechanism, since they have certain features of radical-chain processes, in particular they are retarded in the presence of specific inhibitors. It is also possible that in some cases the initiating effect of the metal complexes is not associated with the activation of molecular oxygen but with the acceleration of the decomposition of the hydroperoxides arising in the oxidation of the substrate[71-111]. However, the sensitisation of molecular oxygen by the complex appears to be more probable in many cases[109]. It has been noted[110] that complexes in which oxygen is least strongly bound exhibit the highest activity in the autoxidation of styrene. It is suggested that the sensitising species in such reactions may be a mononuclear complex of the superoxide type[11]:

$$M^{n+} + O_2 \rightarrow M^{(n+1)} + \dot{O}_2^- \xrightarrow{RH} M^{(n+1)} + OOH^- + R\cdot \ ;$$

$$M^{(n+1)} + OOH^- \rightarrow M^{n+} + HOO.$$

Mononuclear cobalt complexes of the superoxide type have been used as model compounds for the investigation of the mechanism of outer-sphere oxidation reactions. The ESR signal of the oxygen complex of corrinoid [Co^{II}(vitamin B_{12})] in the presence of small amounts of one-electron reducing agents (hydroquinone, *p*-phenylenediamine, ascorbic acid, and thiols) is replaced by the signal of the radical of the oxidised substrate, i.e. a one-electron oxidation–reduction reaction takes place between the oxygen complex and the substrate[71]. In the presence of excess reducing agent cobalt(II) is regenerated and the corresponding catalytic reaction occurs.

Table 6. Polarographic reduction of oxygen complexes[33].

Compound	Half-wave potential, V	Medium, reference electrode
(DMF) (*o*-Phenylenesalen)Co(O_2)	-0.300	DMF, Ag|AgCl, KCl
(DMF) (3-CH_3O-Salen)Co(O_2)	-0.324	Ditto
(DMF) (Salen)Co(O_2)	-0.420	"
(DMF) (acacen)Co(O_2)	-0.520	"
(Pyridine) (*o*-Phenylenesalen)Co(O_2)	-0.656	Pyridine, sat. cal.e-de
(Pyridine) (3-CH_3O-Salen)Co(O_2)	-0.660	Ditto
(Pyridine) (Salen)Co(O_2)	-0.660	"
O_2	-0.810	DMF, Ag|AgCl, KCl
O_2	-0.836	Pyridine, sat. cal.e-de

* *o*-Phenylenesalen = *o*-phenylenebis-salicylidene-ethylenediamine (Ed. of Translation).
** Salen = bis-salicylidene-ethylenediamine (Ed. of Translation).
*** acacen = *NN'*-ethylenebis(acetylacetoniminide) (Ed. of Translation).

It follows from the results of polarographic studies[33] that paramagnetic cobalt complexes of oxygen are more powerful one-electron oxidants than free oxygen or the initial non-oxygenated cobalt(II) species. The half-wave potential corresponding to the reversible one-electron reduction of the oxygen complex decreases as the electron-donating effect of the ligand environment of this metal becomes enhanced. Both the equatorial and the axial ligand then have an effect. For a more basic *trans*-ligand (pyridine), the electron-donating effect of the equatorial ligand is not differentiated (Table 6).

It follows from the data in Table 6 that the transfer of the negative charge from the metal atom to oxygen decreases the oxidising capacity of the oxygen complex, which can be readily understood within the framework of a simplified model postulating the location of the unpaired electron at the dioxygen group. Since the metal atom has a filled 18-electron shell and the oxygen has an accessible half-filled orbital, the reducing electron must occupy the latter. Evidently the energy of this orbital depends on the effective charge of the dioxygen group. Therefore the addition of the electron will be hindered by energy factors when the dioxygen group has an excess negative charge. In this case the most labile oxygen complexes, in which the M–O_2 bond is largely covalent, should exhibit the greatest oxidising capacity.

The results show that the labile mononuclear complex (PPh_3)(Salen)Co(O_2) can give rise to non-chain catalytic oxidation of aliphatic alcohols under mild conditions[112].

Thus two extreme types of active structures are characteristic of mononuclear oxygen complexes. They differ in the nature of the relative orientation of the oxygen molecule and the metal atom, in the degree of π-bonding, and in the spin state: they are diamagnetic π-complexes of the closed type and paramagnetic σ-complexes of the open type. The coordinated oxygen molecule in the diamagnetic complex bears some similarity to the oxygen molecule in the singlet state, which can account for its involvement in inner-sphere reactions of the non-radical type. In the paramagnetic complex the coordinated molecule resembles the active superoxide radical, and this is the reason for the occurrence of outer-sphere reactions of the radical type. Apart from these extreme structures, definite information about the nature of the activation of the molecule can be provided by structures of intermediate type.

It has been shown[49] that the high-spin complex $Ru(AsPh_3)_2Cl_2O_2$ readily combines with an SO_2 molecule, forming the corresponding sulphate, like a low-spin π-complex. The unpaired electrons are in this case probably located at the metal and the coordinated dioxygen group is spin-paired, i.e. the reactivity of the complex is determined by the state of the coordinated molecule and not of the metal atom.

There is so far no information about the nature of the reactivity of diamagnetic complexes of the open type. Presumably the coordinated oxygen molecule can exhibit a hydride acceptor activity.

It is known that dinuclear cobalt complexes are capable of oxidative combination with SO_2 and NO_2 molecules[113,114], but the mechanisms of these interesting reactions have not been elucidated.

The problem of creating an artificial matrix catalyst, an analogue of an oxidase-type enzyme, is extremely urgent. It was established recently[115] that the polymeric ligand poly-4-vinylpyridine causes a sharp increase of the catalytic activity of copper ions in the autoxidation of ascorbic acid. Although the interpretation of this effect is at present difficult, studies of this kind appear promising. The problem of the synthesis of the catalytic matrix can be solved on the basis of the specific sorption effect by obtaining "imprints" of the surface of the solid with the given orientation of the substrate molecule relative to the active centre[116].

---o0o---

Studies on the activation of molecular oxygen have been recently carried out mainly using biological models for the fixation of molecular oxygen. They have yielded many

new data. Calculation by the Hückel molecular orbital method[117] on the fragment M–O_2–M, where M is an element of the first transition series ranging from titanium to nickel (there is an analogy with dinuclear dioxygen complexes), yielded some information about the specific role of the metal and also about the nature of the binding of the dioxygen group. The calculation demonstrated that the population of the M–O_2 bond is a maximum in the middle of the series of 3*d* complexes. This variation is determined by the fact that the overlap integrals of the d_{yz} and p_y orbitals decrease on passing from titanium to nickel and the coefficient defining the contribution of the d_{yz} orbital to the bonding molecular orbital increases in the same direction.

It has been suggested on the basis of calculations that σ-bonding, responsible for the strengthening of the M–O_2 bond, is more important in non-dissociable compounds, while the population of the O–O bond in such compounds is smaller than in dissociable compounds, which is consistent with the concept of a greater weakening of the O–O bond in non-dissociable compounds.

The results of ultraviolet spectroscopic studies on the interaction of catalytically active 'onium compounds of the type M_nAX, where A = S, P, Se, or Te and X = Cl, Br, I, BF_4, or ClO_4, with molecular oxygen were used to carry out a semiquantitative calculation by the SCF method[118], from which it follows that (1) not only fully populated *d* orbitals but also only partly populated orbitals can be involved in the activation of molecular oxygen, (2) the electron density of *d* orbitals can serve as a measure of the activation of molecular oxygen, and (3) the *d* orbitals of the catalytic centre can interact with the molecular orbitals located above the $1\pi_g$ orbital.

An X-ray diffraction analysis of an iron complex which is a matrix model of myoglobin has been carried out for the first time[119] (Fig. 8). It showed that the Fe–O–O plane is bisected by the angle between the two adjacent Fe–N bonds in the equatorial plane, which is probably a common feature of both iron and cobalt complexes (Fig. 6).

Resolution of the structure of the Fe–O–O fragment demonstrates the possibility of two statistically equally probable positions of the dioxygen group in mutually perpendicular planes.

Depending on the position of the Fe–O–O plane, the *trans*-ligand plane can be either parallel to the former or at right angles to it. The authors note that a difference between the two extreme positions of the *trans*-ligand plane is possible in principle, but the effect caused by this difference has not so far been discovered. A calculation yielded the following results: d_{O-O} = 1.23 ± 0.08 and 1.26 ± 0.08 Å, the angle Fe–O–O = 135° ± 4° and 137° ± 4°, and d_{Fe-O} = 1.75 ± 0.02 Å. The reduced Fe–O bond length is comparable with the Co–O bond length, which is usually in the range of 1.90 Å.

Among the new dioxygen complexes (matrix models of myoglobin), mention should be made of the paramagnetic complex Fe(αααα-TpivPP)$(THF)_2O_2$ (μ = 2.4 B.M.)[120] where αααα-H_2TpivPP = *meso*-tetra-(αααα-*o*-pivalamidophenyl)porphyrin and THF = tetrahydrofuran. This complex is capable of many repetitions of the deoxygenation–oxygenation cycle in the solid state with concomitant changes in magnetic susceptibility.

The structure of the mononuclear complex $(Et_4N)_3[Co(CN)_5O_2].5H_2O$,[121] in which the Co–O–O angle is 175° ± 2° according to structural studies, i.e. the Co–O–O fragment is nearly linear, is of considerable interest. Unfortunately the authors note that the accuracy of the observed Fe–O–O angles and O–O bond lengths is greatly influenced by the thermal motion of the O_2 group.

The high-spin complex[122] $[Bu_4N][Co(PFP)(HPFP)O_2]$, where Bu_4N is tetrabutylammonium and PFP and HPFP are the dibasic and monobasic residues of perfluoropinacol $[(CF_3)_2C(OH)C(OH)(CF_3)_2]$ occupies a special place. Its magnetic moment is 3.64 ± 0.04 B.M. Studies of its electronic spectra led to the hypothesis that a Co–O_2 bond is formed in this complex without charge transfer.

A copper complex of a polymeric ligand[123], capable of reversible interaction with molecular oxygen and carbon monoxide, was obtained for the first time quite recently[123]. A polyoxime, obtained from an alternant copolymer of ethylene and carbon monoxide, was used as a ligand. Its

unit is described by the formula $\{[CH_2-CH_2]_{1.2}[C]\}$ and its molecular weight is 4000. It is believed that copper is in the monovalent state.

The latest electrochemical studies on dioxygen complexes of cobalt[124] showed that the redox potential of the Co^{II}/Co^{III} system reflects the overall effect of the σ- and π-interactions and steric factors, in conformity with the specific ligand environment.

Thermodynamics of the Interaction of the Lanthanides with Other Elements

A.P.Bayanov

The thermodynamic characteristics (Gibbs free energies, enthalpies, and entropies) of the interaction of the lanthanides with various elements to form binary compounds and solid or liquid alloys are described. The dissociation energies of gaseous compounds are briefly analysed and experimental and calculated data are compared. The variation of the thermodynamic characteristics of the compounds in the lanthanum-lutetium series is considered from the standpoint of the electronic structures of the components. The thermodynamic behaviour of europium and yttrium in relation to the other lanthanides is discussed.
The bibliography includes 360 references.

I. INTRODUCTION

The bulk of the thermodynamic data for the lanthanides was obtained in the last two—three decades. The thermodynamic properties of numerous simple and complex lanthanide compounds both in the solid state and in solution were investigated during this period[1-4]. Towards the end of the 1960s refractory lanthanide compounds and alloys began to be studied. The experimental technique of the investigation of such systems is fairly complex and the number of the relevant experimental studies increased slowly. For this reason, the thermodynamic characteristics of many such compounds have been calculated.

The early investigations of the thermodynamic properties of lanthanide compounds are described in Serebrennikov's[5] and Gschneidner's[6] monographs and in Montgomery's review[7]. We shall consider some of these early studies because the data obtained in them have been transferred without due critical analysis from handbook to handbook, owing to the lack of other results, and have served in many publications as "reference" experimental data. During the last 5—7 years, reviews have been published on the thermodynamics of lanthanide halides[8,9] and oxides[10-14], certain refractory compounds of lanthanides with *p* elements[11,15,16], and alloys[17]. Krestov's monograph[3] deals with the thermodynamic characteristics of the lanthanide ions in the gaseous state and in solution, the temperature variation of the properties of certain lanthanide compounds, and the changes which they undergo in ionisation, hydration, dissolution, formation and ionic sublimation reaction.

The aim of the present review was to give a systematic account and to carry out a critical analysis of the experimental data for the thermodynamics of the interaction of the lanthanides with other elements and to compare them with calculated values. Particular attention was devoted to the relation between the thermodynamic characteristics and the electronic structures of the system components.

II. HALIDES

The trichlorides have been most thoroughly investigated among lanthanide halides. Systematic calorimetric studies on crystalline lanthanide trichlorides were carried out by Bommer and Hohmann[18-20]. Their results agree with those of Matignon[21,22], but in both sets of investigations insufficiently pure lanthanides were used. In later studies by Spedding and coworkers[23-25], Montgomery[26,27], Stuve[28-31], and Polyachenok[32] purer lanthanides were employed. Comparison of the enthalpies of formation of lanthanide trichlorides (Table 1) shows that the corresponding values for $EuCl_3$ and $YbCl_3$ are more positive than the enthalpies of formation of the adjacent lanthanide trichlorides. This apparent anomaly has been accounted for theoretically[35,36].

Table 1. Enthalpies of formation of lanthanide trichlorides.

Lanthanide trichloride	$-\Delta H^\circ_{298}$, mole^{-1}	Refs.	Lanthanide trichloride	$-\Delta H^\circ_{298}$, kcal mole^{-1}	Lanthanide trichloride
$LaCl_3$	255.91±0.20	25	$GdCl_3$	240.09±0.30	25
	255.9	33		239.6	33
	256.18±0.28	26	$TbCl_3$	238.33±1.50	30
$CeCl_3$	252.84±0.02	23, 24		238.4	33
	251.5	33	$DyCl_3$	236.6	33
$PrCl_3$	252.09±0.02	25		235	34
	252.0	33	$HoCl_3$	240.29±1.70	30
$NdCl_3$	245.62±0.02	23, 24		237.8	33
	248.97±0.26	28	$ErCl_3$	239.07±0.20	25
	247.4	33		238.0	33
	246.5	32	$TmCl_3$	235.82±0.40	31
$SmCl_3$	244.18±0.41	27		236.3	33
	244.1	33	$YbCl_3$	229.37±0.72	31
$EuCl_3$	218.74±0.65	29		229.4	33
	219.5	33	$LuCl_3$	234.5	33

While the majority of lanthanides in the solid state under standard external conditions have three valence electrons, europium and ytterbium have only two valence electrons under the same conditions[5]. In the trichlorides all the lanthanides are tervalent. The interaction with chlorine entails a change in the number of valence electrons of europium and ytterbium from two to three and the associated rearrangement of the electronic structure:

$$\mathrm{Eu\,[II,\ 4}f^{7}5d^{0}6s^{2}\mathrm{]} \rightarrow \mathrm{Eu\,[III,\ 4}f^{6}5d^{1}6s^{2}\mathrm{]},$$

$$\mathrm{Yb\,[II,\ 4}f^{14}5d^{0}6s^{2}\mathrm{]} \rightarrow \mathrm{Yb\,[III,\ 4}f^{13}5d^{1}6s^{2}\mathrm{]}.$$

It has been established[35,36] that the energy required for the completion of the above processes is 22 kcal mole^{-1} for europium and 9 kcal mole^{-1} for ytterbium. Other lanthanides are not involved in processes of this kind. As a result the Gibb's free energies and enthalpies of formation of $EuCl_3$ and $YbCl_3$ are more positive than the corresponding values for the trichlorides of the adjacent lanthanides.

Latimer[37] calculated the entropy of formation of lanthanide trichlorides by combining their absolute entropies and the entropies of the initial elements. His entropy data[37] and the experimental enthalpies of formation served as a basis for the calculation of the Gibbs free energies of formation of lanthanide trichlorides[7,37]. The Gibbs free energies for the lanthanide trichlorides were also determined by Karapet'yants[38] by the method of comparative calculation. The thermodynamic characteristics of the formation of individual lanthanide trichlorides have also been investigated[39-47].

Some authors[43-46] calculated the thermodynamic functions of formation of liquid lanthanide dichlorides. The enthalpies of formation of crystalline samarium, ytterbium[48,49], europium[50], and neodymium[32] dichlorides have been determined calorimetrically at 298 K as -195.6 ± 1.0, -184.5 ± 1.7, -197.0 ± 1.3, and -163.2 kcal mole^{-1} respectively. These results are consistent with the values calculated for praseodymium, neodymium, samarium, europium, erbium, and ytterbium dichlorides from the fusion diagrams and vapour pressures in systems of the type $Ln-LnCl_3$.[51-56] According to Turnbull and Watts[57] and Valentine et al.[58] the Gibbs free energy of the formation of $PrCl_2$ is -156 kcal mole^{-1} and its enthalpy of formation is -158 kcal mole^{-1} [57] or -167 kcal mole^{-1}.[58] The enthalpies of formation of all the lanthanide dichlorides have been calculated from the Born–Haber cycle[51,59,60]. The enthalpies of formation of the crystalline dichlorides exhibit double periodicity in the series of lanthanides—there are extrema corresponding to $EuCl_2$ and $YbCl_2$ (Fig. 1). The difluorides exhibit a similar relation[59]. The standard enthalpy of formation of EuF_2 evaluated from tensimetric data[61] is -284 ± 17 kcal mole^{-1}.

Experimental enthalpies of formation of lanthanide trifluorides were obtained by Polyachenok[62,63]: -405, -401, -395, -389, and -378 kcal mole^{-1} for LaF_3, PrF_3, NdF_3, GdF_3, and ErF_3 respectively. Their accuracy is to within 5–7 kcal mole^{-1}. The data for the above five trifluorides were also used to estimate by interpolation the enthalpies of formation of the trifluorides of other lanthanides[63]. The enthalpies of formation of trifluorides at 298 K have been determined in a calorimetric study of the precipitation of lanthanide trifluorides from aqueous solutions[64,65] and the following values were obtained (in kcal mole^{-1}): -403.7 ± 1.5 for LaF_3, -402.0 ± 1.5 for CeF_3, -401.5 ± 1.5 for PrF_3, -398.5 ± 0.5 for NdF_3, -398.6 ± 4.0 for SmF_3, -373.8 ± 4.0 for EuF_3, -397.5 ± 0.5 for GdF_3, -388.6 ± 2.0 for ErF_3, and -382.1 ± 2.0 for YbF_3.

The following expressions for the Gibbs free energies of formation of lanthanide trifluorides have been obtained by an e.m.f. method using a solid electrolyte (anionic conductor):

$\Delta G = -(411.38 \pm 0.81) + (57.46 \pm 0.9) \cdot 10^{-3}T \pm 1.4$ kcal/mole LaF_3, (Refs.66,67),

$\Delta G = -405 + 52.71 \cdot 10^{-3}T$ kcal/mole NdF_3, (Ref.68),

$\Delta G = -402 + 50.77 \cdot 10^{-3}T$ kcal/mole GdF_3, (Ref.68),

$\Delta G = -400.5 + 48.42 \cdot 10^{-3}T$ kcal/mole DyF_3, (Ref.68),

$\Delta G = -397.5 + 45.66 \cdot 10^{-3}T$ kcal/mole ErF_3, (Ref.68),

$\Delta G = -394.5 + 44.89 \cdot 10^{-3}T$ kcal/mole β-LuF_3, (Ref.68).

$\Delta G = -387 + 37.08 \cdot 10^{-3}T$ kcal/mole α-LuF_3, (Ref.68).

The enthalpies of formation of lanthanide trifluorides calculated[59] from the Born–Haber cycle are higher by 30–50 kcal mole^{-1} than the experimental values. The data of Brewer et al.[69], which have been used in a number of texts[3,8,70,71], are also higher than the experimental results. On the other hand, the data in the handbook of Wicks and Block[72] are lower than the experimental enthalpies of formation of the trifluorides[62-68,73]. The thermodynamic functions of formation of certain lanthanide fluorides were studied in other investigations also[74-81]. Certain data[4,65,72] reflect the energy of the change in the number of valence electrons of europium[36]. In others this factor[3,34,63,78] is disregarded.

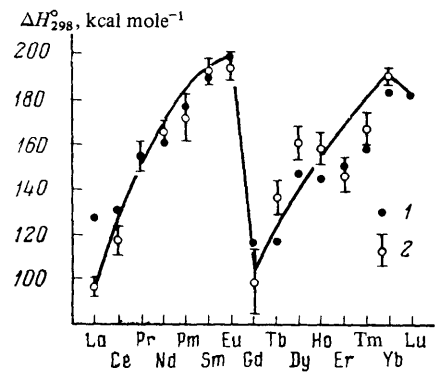

Figure 1. The standard enthalpies of formation of solid lanthanide dichlorides: 1) Novikov and Polyachenok's data[59]; 2) Johnson's data[60].

Estimates of the enthalpies of formation of crystalline lanthanide tribromides have been published[8,47,69,72,79,80]. The data quoted by Wicks and Block[72] are appreciably lower in absolute magnitude than those in other publications. The effect of the change in the number of valence electrons of europium and ytterbium from two to three has been reflected in the enthalpies quoted by Thoma[8], but has been disregarded by other authors[34,78,79]. The thermodynamic functions of europium tribromide[82] and dibromide[83] have been determined experimentally. The enthalpy and Gibbs free energy of formation of $EuBr_3$ at 293.15 K are respectively -186 ± 3.0 and -179.3 ± 3.0 kcal mole^{-1}. For solid $EuBr_2$, $\Delta H^{\circ}_{298} = -178.0 \pm 3.0$ kcal mole^{-1}, $\Delta S^{\circ}_{298} = -16.2 \pm 3.0$ e.u., and $\Delta G^{\circ}_{298} = -173.2 \pm 3.0$ kcal mole^{-1}. Estimates are available for samarium, europium, and ytterbium dibromides[69].

The experimental determinations of the enthalpies of formation of lanthanide tri-iodides[8,20] are inconsistent. The Gibbs free energies have been calculated[37,38]. The data in handbooks[71,72] for the tri-iodides have only been estimated, as in other publications[69,78,84]. The formation of solid EuI_2 at 298.15 K is accompanied by the evolution of -138.0 ± 5 kcal mole^{-1} of heat[85].

The enthalpies of formation and dissociation energies of gaseous lanthanide monohalides, dihalides, and trihalides have been studied[86-97]. According to tensimetric data, the dissociation energies of EuI_2,[95] $EuCl_2$,[95] and $YbCl_2$,[96] are respectively 156.0 ± 5.0, 212.0 ± 2.3, and 193.5 ± 3.2 kcal mole^{-1}. Certain problems of the energetics and stability of gaseous lanthanide halides have been solved by Polyachenok[94] by estimating the thermodynamic quantities using methods of comparative calculation. The atomisation energies of various groups of lanthanide halides in the lanthanum–lutetium series exhibit a double periodicity with minima corresponding to europium and ytterbium. The standard enthalpies of formation of lanthanide monohalides and dihalides show that their stability increases from lanthanum to europium and from gadolinium to ytterbium. The enthalpies of formation of lanthanide trihalides vary monotonically in the series La–Lu with extrema at Eu and Yb. The accuracy of the estimates[94] obtained by methods of comparative calculation is to within ≈10–15 kcal mole^{-1}.

III. CHALCOGENIDES

The principal data for the enthalpies of formation of the oxides were obtained calorimetrically by the combustion of lanthanum[21,98-102], cerium[99,100,103-105] Ce_2O_3,[106,107] neodymium[99,105,108], samarium[105,106,109,110], europium[111,112], gadolinium[113], dysprosium[114,115], holmium[116], erbium[105,117], thulium[118], ytterbium[114], and lutetium[119] in oxygen and by low-temperature calorimetric measurements for the dissolution of the lanthanides and the oxides La_2O_3,[21,26,120,121] Pr_2O_3 (hexagonal)[122,123], Pr_2O_3 (cubic)[123,124], $PrO_{1.833}$,[122,123] PrO_2,[124] $PrO_{1.717}$,[122] $PrO_{1.804}$,[122] Nd_2O_2 (hexagonal)[14], Sm_2O_3,[110] Eu_2O_3,[29,112] $TbO_{1.500}$,[125,126] $TbO_{1.710}$,[125] $TbO_{1.805}$,[125] $TbO_{1.510}$,[126] $TbO_{1.709}$,[126] $TbO_{1.817}$,[126] $TbO_{1.975}$,[126] $TbO_{2.000}$,[126] and Dy_2O_3.[115] The available entropies of the lanthanide oxides have been recently analysed[10,14] by a method for the calculation of entropy based on Latimer's scheme for the resolution of the entropy of a compound into those of its atomic components. The entropies of formation of the latter were calculated by combining the entropies of the lanthanides and their oxides[14]. The enthalpies, Gibbs free energies, and entropies of formation of various lanthanide oxides are compiled in Tables 2 and 3.

Having analysed various high-temperature data for the oxides, Holley et al.[14] tabulated the enthalpies ΔH°_T, entropies ΔS°_T, and Gibbs free energies ΔG°_T of formation of the lanthanide oxides in the temperature range 100–2000 K.

The oxides with a cubic structure have more negative enthalpies of formation than those of the oxides with monoclinic or hexagonal structures. The Gibbs free energies and entropies of formation of europium and ytterbium sesquioxides are lower than the values for the corresponding oxides of the adjacent lanthanides.

The thermodynamic functions of the oxides in the composition range CeO_2–Ce_2O_3 have been investigated[128-131] by an electromotive force method in cells with a solid oxide electrolyte (an anionic conductor). The equilibrium oxygen pressures over cerium oxides were measured in the same composition range[128,132,133] at temperatures from 600° to 1170°C by a dynamic method in an H_2O–H_2 or CO_2–CO gas stream. The thermodynamic properties of the oxides $PrO_{1.5}$–$PrO_{1.714}$ were also studied electrochemically[134]. Data obtained by various experimental methods for solid lanthanide oxides agree satisfactorily with one another.

Table 2. Thermodynamic characteristics of the formation of lanthanide oxides[14,110,112].

Oxide	$-\Delta H^\circ_{298.15}$, kcal mole^{-1}	$-\Delta S^\circ_{298.15}$, e.u.	$-\Delta G^\circ_{298.15}$ kcal mole^{-1}

The enthalpy of formation of crystalline $EuO_{1.02}$ was determined calorimetrically[135] at 298 K as -145.2 ± 2.8 kcal mole^{-1}. The Gibbs free energies of formation of EuO, YbO, and SmO are respectively −10, 7, and 13 kcal mole^{-1}.[136]

Although rough estimates of the dissociation energies D°_0 of gaseous lanthanide monoxides had been obtained in earlier studies[137-139], the first accurate values of D°_0 were apparently obtained for LaO,[140-143] NdO,[141-143] SmO,[141-143] GdO,[142,143] TbO,[143] and LuO[142,143] by the mass-spectrometric method in combination with Knudsen's method. These characteristics were investigated in greatest detail by Ames[144,145]. Subsequent studies[146-150] yielded similar results. The dissociation energy of LaO was found to be 192.5,[140] 187.0 ± 4.6,[141] 186.4 ± 4.6,[142] 190.5 ± 4.6,[143] 193.5,[145] 192.5,[146] 189.5,[148] 190.3 ± 1.0,[147]

and 189.9 ± 1.0 [148] kcal mole^{-1}. The following dissociation energies have been obtained for other lanthanide monoxides (in kcal mole^{-1}): 190.5,[143] 193.5,[145] 185.2,[151] and 188.6 [152] for CeO, 175.8,[143] 182,[145] and 171.0 ± 6.9 [151] for PrO, 171.0 ± 4.6,[141] 163.4 ± 4.9,[142] 168.1 (169),[143] 172.1 (174.5),[145] 163.0,[151] and 170.3 [16] for NdO, 142.7 [143] and 142.4 ± 4 [145] for SmO, 133.3,[143] 134.7 ± 1.3,[145] and 133.9 [153] for EuO, 162.0 ± 6.9 [143] and 173 ± 3 [145] for GdO, 170.3 [143] and 173.8 [145] for TbO, 150.4 ± 0.6 for DyO,[145] 152.7 ± 2.0 for HoO,[145] 151.6 ± 0.8 for ErO,[145] 139.2 ± 0.7 for TmO,[145] 88.4 ± 0.8 for YbO,[145] and 159.5 ± 6.9 [143] and 167 ± 3 [145] for LuO. The corresponding enthalpies of formation of the gaseous monoxides are also quoted in the above studies. Gordienko et al.[16] recommend the following values of ΔH_0° (kcal mole^{-1}):

LaO	CeO	PrO	NdO	SmO	EuO	GdO	TbO	DyO	HoO
31.3	22.3	33.3	36.2	34.5	32.7	17.8	20.0	20.1	23.8
ErO	TmO	YbO	LuO						
17.1	20.8	—7.2	5.5

The thermodynamic characteristics of lanthanide sulphides were apparently obtained for the first time by Matignon[22] and Biltz[102]. Subsequently these investigations were assessed critically[154–156] using for the calculation of the enthalpies of formation of the solid sulphides the heats of solution of the lanthanides quoted in other reports[23–25]. After recalculation, the relevant values were found to be close to the enthalpies of formation of the sulphides based on data derived from systematic calorimetric studies[156–158]. The enthalpies of formation of the sulphides and the dissociation energies of the gaseous lanthanide monosulphides are quoted in Table 4. The studies were carried out mass-spectrometrically[159–166]. The enthalpies of formation of solid sulphides of different compositions are compiled in Table 5. The entropies and Gibbs free energies of formation of lanthanide sulphides have been estimated[7,37,76,167] and the high-temperature thermodynamic characteristics of solid lanthanide monosulphides have been tabulated[16,163,164,168,169].

The dissociation energies of the gaseous sulphides were determined mass-spectrometrically[170–175]. The variation of the dissociation energies of the gaseous monosulphides, monoxides, monoselenides[176,177], and monotellurides[176] in the La–Lu series is illustrated in Fig. 2. The dissociation energies[161,178] of PrSe, NdSe, and SmSe are much higher[176]. The standard enthalpies of formation of LaSe, PrSe, NdSe, SmSe, and EuSe calculated from mass-spectrometric data are −82, −123.5, −151.5, −147.0, and −107.5 kcal mole^{-1} respectively. The considerable difference between the enthalpies of formation of SmSe and EuSe is unexpected, because samarium and europium in the monoselenides are both bivalent[179].

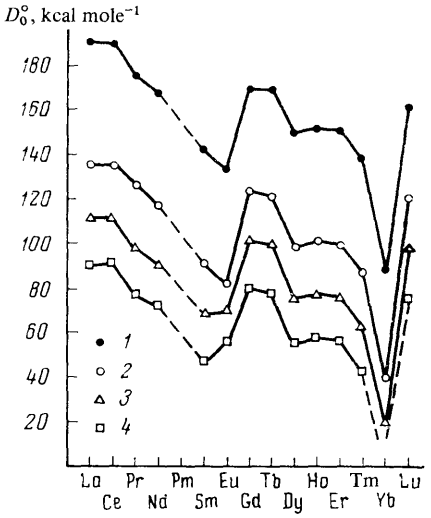

Figure 2. Variation of the dissociation energies of the monochalcogenides in the series of lanthanides: 1) monoxides; 2) monosulphides; 3) monoselenides; 4) monotellurides[176].

The enthalpies of formation of Gd_2Se_3 (−255.3 ± 8.1 kcal mole^{-1}),[180] Gd_2Te_3 (−221.4 ± 5.3 kcal mole^{-1}),[180] and La_2Te_3 (−187.5 ± 6.1 kcal mole^{-1})[181] were determined calorimetrically. The Gibbs free energies, enthalpies, and

entropies of formation of the higher lanthanum tellurides were calculated from e.m.f. data[182]:

	$-\Delta G_{880°K}$, kcal g-atom^{-1}	$-\Delta H$, kcal g-atom^{-1}	$-\Delta S$, e.u.
$La_{0,25}Te_{0,75}$	27.30±0.01	28.26 ± 0.16	1.42 ± 0.22
$La_{0,286}Te_{0,714}$	31.30±0.01	32.30±0.15	1.62±0.20

IV. PNICTIDES

The enthalpy of formation of LaN is lower[183-186] than that of CeN (Table 6) in which cerium is partly present in the quadrivalent state[6]. In the series of lanthanide arsenides[187] the enthalpy of formation of YbAs has the highest (least negative) value in consequence of the expenditure of energy in the change of the number of valence electrons of ytterbium from two to three[36]. The enthalpies of formation of the monoarsenides have been determined by differential calorimetry within wide confidence limits. The intermediate compounds in the lanthanum–antimony system and gadolinium antimonide have high enthalpies of formation and negative entropies of formation in the temperature range 653–803 K investigated by an e.m.f. method[188-191] (Table 7). The heats of atomisation of praseodymium monopnictides decrease from arsenic to bismuth[192].

Table 6. Enthalpies of formation of lanthanide mononitrides[183-186] and monoarsenides[187].

Compound	$-\Delta H°$, kcal mole^{-1}	Compound	$-\Delta H°$, kcal mole^{-1}

V. CARBIDES, SILICIDES, AND BORIDES

The main studies on the thermodynamics of the formation of lanthanide dicarbides have been carried out mass-spectrometrically in combination with Knudsen's tensimetric method[193-223]. The dissociation energies of the gaseous dicarbides and the heats of evaporation, atomisation, and formation of solid dicarbides were calculated in these investigations using the Second and Third Laws of thermodynamics. The thermodynamic characteristics of formation of a number of dicarbides and sesquicarbides have been studied by an e.m.f. method[224,225] and calorimetrically[105]. The enthalpies of formation of the lanthanide dicarbides calculated from the results of different investigations agree provided that the Third Law was used in the calculations. The standard enthalpies of formation of lanthanide dicarbides calculated from e.m.f. data using the Second Law differ appreciably from tensimetric data[225].

Table 8. Standard enthalpies of formation of lanthanide dicarbides.

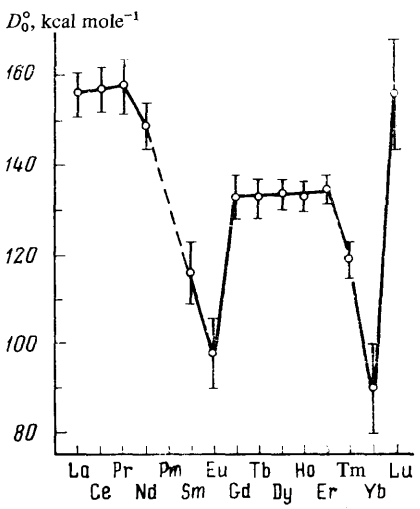

Figure 3. Variation of the Ln–C_2 bond energy in the series of lanthanides[218-220].

The enthalpies of formation of various lanthanide dicarbides are compiled in Table 8. They vary about 20 kcal mole^{-1}. The variation of the Ln–C_2 bond energy in the series of gaseous lanthanide dicarbides exhibits double periodicity (Fig. 3).

The Gibbs free energies of formation of lanthanum, cerium, praseodymium, and neodymium sesquicarbides from the liquid lanthanides and solid graphite, determined by an e.m.f. method[224], are higher than the values calculated for Ce_2C_3 from the phase diagram[227]. The enthalpy of formation of $CeC_{1.5}$ was found to be -21.1 ± 0.7 kcal mole^{-1} at 298.15 K by combustion in a bomb calorimeter[105]. The standard enthalpy and entropy of formation of Ho_2C_3 are -11.1 kcal mole^{-1} and 5.1 e.u. respectively according to tensimetric data[226].

The thermodynamic studies on the silicides are apparently limited to LaSi, β-$LaSi_2$, and β-$CeSi_2$, whose enthalpies of formation are respectively -30.0,[228] -44.4,[228] and -50 [229] or -45 [230] kcal mole^{-1}.

The first enthalpies of formation of lanthanum, cerium, and yttrium borides were obtained in Refs. 231–237. They were used to calculate by the thermochemical logarithmic rule the enthalpies of formation of the hexaborides of the entire series of lanthanides[234,235]. However, the monotonic increase of the modulus of this quantity in the series from lanthanum to lutetium is unlikely.

The heats of dissociation of the gaseous hexaborides and the enthalpies of formation of the solid compounds have been determined from mass-spectrometric measurements[236-242] by the method of Langmuir and Knudsen. The heats of dissociation decrease steadily from LaB_6 to SmB_6 (Table 9). A similar variation has been observed also for lanthanide diborides[243].

Table 9. Enthalpies of dissociation and formation of lanthanide hexaborides[241,242].

Lanthanide hexaboride	Temp. range, K	Enthalpy of dissociation, kcal mole^{-1}	Enthalpy of formation, kcal mole^{-1}

GdB_6	2170–2500	127.0±2.8	−31±4
TbB_6	1980–2350	128.7±3.4	−34±5

VI. HYDRIDES

The thermodynamic characteristics of the formation of the dihydrides of the majority of lanthanides and also of some of their dideuterides have been calculated from the temperature variation of the pressure of hydrogen formed on dissociation of these compounds (Table 10).[244-256] On passing from the hydrides to the deuterides, the thermodynamic functions of formation diminish. Gschneidner reported[257] that the enthalpies of formation of terbium, dysprosium, thulium, and lutetium dihydrides are close to the enthalpies of formation of the dihydrides of the adjacent lanthanides. The equilibrium pressure and partial thermodynamic characteristics of hydrogen were also studied for lanthanum[258,259] and gadoliunium[260] dihydrides. The enthalpies of dissociation of the higher non-stoichiometric lanthanide hydrides to the dihydrides have been calculated[261-263] as 10–20 kcal/mole H_2. There has been only one calorimetric study[264] on $LaH_{2.8}$, $CeH_{2.7}$, and $PrH_{2.7}$.

VII. METALLIC ALLOYS WITH *p* ELEMENTS

The first studies[265-267] carried out by an e.m.f. method using a liquid electrolyte (a cationic conductor) already demonstrated a marked interaction of the lanthanides with bismuth and lead. The results of studies up to 1969 on the thermodynamics of lanthanide alloys have already been reviewed[17]. The intermediate phases in the cerium–lead, praseodymium–lead, and neodymium–lead systems were investigated[268] by a modified Knudsen method.

Table 10. Enthalpies and entropies of formation of lanthanide dihydrides.

E.m.f. studies on the cerium–lead system[269] yielded appreciably different thermodynamic characteristics of formation of $CePb_3$, particularly as regards the Gibbs free energy. The ytterbium–aluminium system was studied tensimetrically over a wide range of compositions and the equation $\Delta G^\circ_T = -17\,473.16 + 9.405\,T$ (cal mole^{-1}) was fitted to the Gibbs free energies of formation of $YbAl_2$ in the range 773–873 K.[270] The alloys of lanthanides with aluminium gallium, indium, thallium, tin, lead, and bismuth were studied mainly in the range of compositions with a high content of the non-lanthanide metal. The thermodynamic characteristics of formation of compounds of the lanthanides with the above *p* elements found by an e.m.f. method and the equations for the temperature variation of the activity coefficients of the lanthanides in the liquid alloys are presented in Table 11. When a galvanic cell of the amalgam type is used in the study of the thermodynamic properties of lanthanide–aluminium alloys, it is necessary to take into account the displacement of the lanthanide ion from the electrolyte by aluminium. This factor was neglected in a number of the investigations[271,272,297,298], which probably accounts for certain discrepancies between the data of Kober et al.[272] and Degtyar' et al.[299], the latter having been obtained by a method based on the distribution in the system aluminium–lanthanum–bismuth. Calorimetric studies on the enthalpies of mixing of the lanthanides with aluminium were begun recently[297,298,300]. Palenzona and Cirafici[301] determined the enthalpies of formation of thirteen compounds of lanthanides and lead of the type $LnPb_3$ by dynamic differential calorimetry. Ferris et al.[302] calculated with a low accuracy the activity coefficients of lanthanum, cerium, neodymium, gadolinium, and dysprosium in liquid, bismuth-based alloys. Smith[303] estimated the heat of solution of samarium in lead as 15 kcal g-atom^{-1}.

The enthalpies of formation of $LaSn_3$ found by an e.m.f. method[288], high-temperature calorimetry of the dissolution process[304,305], and dynamic differential calorimetry[306] agree with one another. The enthalpies of formation of lanthanide–tin compounds of the type $LnSn_3$ and the relative partial molar enthalpies of solution of the lanthanides in tin are compiled in Table 12.

*** $\Delta\bar{H}_{Ln}$.

It has been established on the basis of the magnetic properties of $EuSn_3$, $YbSn_3$, $EuPb_3$ and $YbPb_3$ that europium and ytterbium in these compounds are bivalent[316,317]. The enthalpies of formation of $EuSn_3$ and $YbSn_3$ (Table 12) are close to the values which can be obtained by interpolation from the enthalpies of formation of compounds of the type $LnSn_3$ of the adjacent tervalent lanthanides. The lanthanide–lead compounds of the type $LnPb_3$ exhibit a similar behaviour[301].

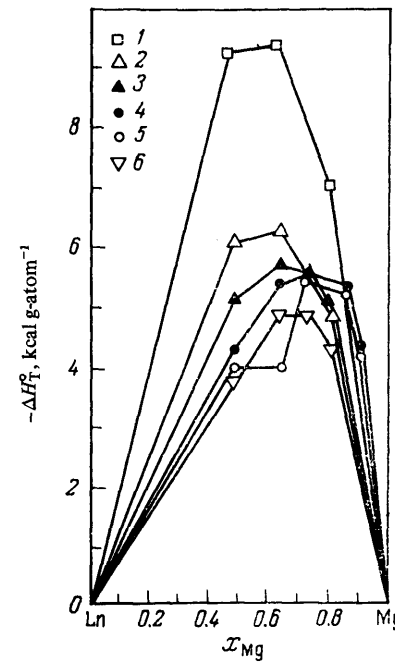

Figure 4. Enthalpies of formation of the intermediate compounds in different systems[318]: 1) Lu–Mg; 2) Er–Mg; 3) Gd–Mg; 4) Nd–Mg; 5) Ce–Mg; 6) Dy–Mg.

VIII. ALLOYS OF LANTHANIDES WITH *s* AND *d* ELEMENTS

The magnesium alloys have been most thoroughly investigated in this group. The intermediate compounds in systems formed by magnesium with cerium, neodymium, gadolinium, dysprosium, erbium, and lutetium have been studied by Knudsen's method[318]. The maximum in the thermodynamic characteristics of formation shift from the composition $CeMg_3$ to $GdMg_2$ and then to LuMg (Figs. 4 and 5). In liquid lanthanum–magnesium melts[319] the maximum Gibbs free energy of mixing of the components is also displaced towards $LaMg_3$. The Gibbs free energies of formation of 12 compounds having the composition LnMg (except for europium and ytterbium) have been studied in the temperature range 700–800 K.[320] The results of two studies[318,320] for the heavy lanthanides differ appreciably. The partial thermodynamic characteristics of cerium in magnesium-based solutions have been calculated at 1083 K: $\Delta\bar{H}^\infty_{Ce} = -26.8$ kcal g-atom^{-1},[321] $\Delta\bar{S}^{exc\,\infty}_{Ce} = -9.8$ e.u.,[321] and $\Delta\bar{G}^{exc\,\infty}_{Ce} = -16.4$ [321] or -15.5 [322] kcal g-atom^{-1}. The partial thermodynamic characteristics

of magnesium have been determined for neodymium–magnesium and samarium–magnesium alloys[323]. The authors[324] explain the negative enthalpy of solution of cerium in sodium by the influence of impurities.

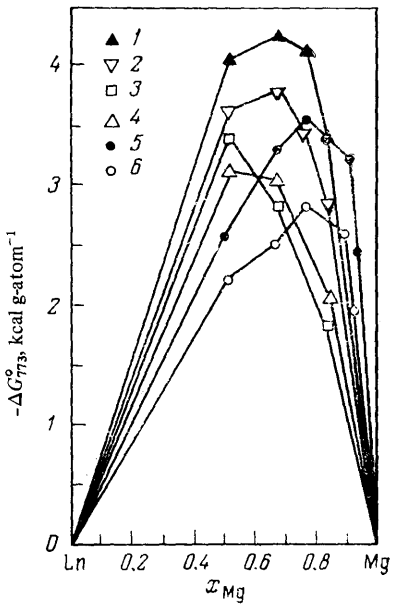

Figure 5. Gibbs free energies of formation of the intermediate compounds at 773 K in different systems[318]: 1) Gd–Mg; 2) Dy–Mg; 3) Lu–Mg; 4) Er–Mg; 5) Nd–Mg; 6) Ce–Mg.

The fairly high volatility of zinc and its remoteness in the electrochemical series from the lanthanides made it possible to investigate lanthanide–zinc alloys by Knudsen's tensimetric method[325-328] and by e.m.f. methods[329-333]. The solid intermediate compounds have been studied in the systems cerium–zinc[325], samarium–zinc[326], praseodymium–zinc[327], and neodymium–zinc[328] and in some of the investigations[325,327] the liquid alloys were also studied. Chiotti[334] showed, using a new method for the integration of the Gibbs–Duhem equation, that some of his earlier results[327] were incorrect. The thermodynamic characteristics obtained by Chiotti and Mason[325,326] were analysed by the present authors in an earlier publication[17].

Alloys of lanthanum, cerium, and praseodymium with zinc and cadmium (Table 13) have been studied by an e.m.f. method[329-333]. The behaviour of lanthanum, cerium, and praseodymium in liquid zinc- and cadmium-based alloys is consistent with Henry's Law. The enthalpies of formation of $NdZn_{11}$, $NdCd_{11}$, and $SmCd_{11}$ have also been estimated[333] by a method of comparative calculation as -86.16, -69.65, and -68.34 kcal mole^{-1} respectively. The Gibbs free energies of formation of compounds of the type LnCd vary about -7 kcal g-atom^{-1} as a function of the atomic number of the lanthanide[320]. The results of thermodynamic studies on the samarium–mercury system by tensimetric[335] and e.m.f. [336] methods do not agree, particularly as regards the enthalpies and entropies (these differ in sign). The interpretation of the e.m.f. of the cell

$$Sm\,|\,Sm(ClO_4)_3 + LiClO_4 + \text{dimethylformamide}\,|\,Sm(Hg)$$

requires further consideration.

The thermodynamic characteristics of $LaIr_2$ [337,338] and of the intermediate compounds in the cerium–iridium system[338,339] have been determined by an e.m.f. method using a solid electrolyte (an anionic conductor). The Gibbs free energies of formation (in kcal mole^{-1}) of $LaIr_2$ and $CeIr_2$ in the temperature range 950—1200 K are described by the equations

$$\Delta G^{\circ}_{LaIr_2}(\pm 0.45) = -(44.0 \pm 2) + (1.13 \pm 2)\cdot 10^{-3}T,$$

$$\Delta G^{\circ}_{CeIr_2}(\pm 4) = -(62.5 \pm 4) + (0.10 \pm 3.3)\cdot 10^{-3}T.$$

The thermodynamic characteristics of $CeIr_3$, $CeIr_5$, and Ce_2Ir_7 differ little from those of $CeIr_2$.

Gingerich and coworkers[340-342] demonstrated the high stability of the gaseous monaurides. Their dissociation energies are as follows (in kcal mole^{-1}): 79.5 ± 5.0 for LaAu, 75.5 ± 3.5 for CeAu, 73.0 ± 5.0 for PrAu, 69.5 ± 6.0 for NdAu, 66.8 for TbAu, 60 ± 3 for HoAu, and 78.5 for LuAu. The dissociation energy of HoAg (28.6 ± 4 kcal mole^{-1}) is lower than that of HoAu (59.7 ± 3 kcal mole^{-1})[341]. The atomisation energies of lutetium, holmium, and terbium diaurides have been calculated[342]. The calculation of the bond energies in lanthanide monaurides and diaurides using Pauling's model of a single polar bond yielded results in good agreement with experiment. The dissociation energies of EuAg have been determined experimentally (31.0 ± 3.0 kcal mole^{-1}) and calculated theoretically on the basis of Pauling's model (33.4 kcal mole^{-1})[343].

IX. GENERAL CHARACTERISTICS

The present author calculated the energies of mutual exchange between 14 lanthanides and various elements for 1078 systems from the properties of the initial components by the Hildebrand–Mott method[344]. The most positive energies were found for the mutual exchange between the majority of lanthanides (with the exception of europium and ytterbium) and s^1 elements. Negative values are characteristic of the energies of mutual exchange between

all the lanthanides and *p* elements. Compared with other lanthanides, the energies are higher for the mutual exchange between europium and ytterbium and d^5 elements and lower for the mutual exchange with *s* elements.

The Gibbs free energies and enthalpies of formation of europium and ytterbium compounds are consistent with the general variation of these characteristics for compounds of the type $LnSn_3$ (Table 12) and $LnPb_3$,[301] monosulphides (Table 4), and dicarbides (Table 8) in the series of lanthanides. The Gibbs free energies and enthalpies of formation of the sesquioxides (Table 2), monoarsenides (Table 6), trichlorides (Table 1), and trifluorides are more positive for the europium and ytterbium compounds than for the compounds of the adjoining lanthanides. According to the present author's data[345,346] the interaction of calcium and cadmium with europium and ytterbium is more favourable on energy grounds than the interaction with the adjacent lanthanides. These features of the thermodynamic characteristics of europium and ytterbium compounds, which distinguish them from those of the compounds of other lanthanides, are probably determined by the nature of the interaction of various elements with the 5*d* electrons of the lanthanides.

If the formation of the compound requires three valence electrons of the lanthanide, then in the case of europium and ytterbium, which have only two valence electrons in the metallic state under standard conditions[6], $4f-5d$ transitions, accompanied by an increase in the number of valence electrons to three and a corresponding energy expenditure (22 ± 2 kcal mole^{-1} for europium and 9 ± 2 kcal mole^{-1} for ytterbium), take place. The Gibbs free energies and enthalpies of formation of the europium and ytterbium compounds are then smaller than the corresponding quantities for the formation of similar compounds of the adjacent lanthanides.

When the enthalpies of formation of europium or ytterbium compounds fit the general variation of the enthalpies of formation of lanthanide compounds, it is postulated[315] that the third valence electron of the lanthanide (a 5*d* electron[6,347]) is not involved in the formation of the chemical bond (or its contribution to the bond energy is small), is delocalised, and is responsible for the metallic conduction. Europium and ytterbium compounds of this type (for example monochalcogenides[179]), in which there are only two valence electrons (i.e. in europium and ytterbium)[179], may prove to be semiconductors or insulators.

We shall consider the thermochemical behaviour of europium and ytterbium, involving a greater ease (on energy grounds) of the interaction of a non-lanthanide element with europium or ytterbium than with adjacent lanthanides, from the standpoint of the configurational model of matter developed by Samsonov and coworkers[348-350] using as an example lanthanide–calcium alloys. The valence electrons of calcium in the excited state do not include more than one *d* electron per atom and tend to assume the d^0 configuration. The valence electrons of the lanthanides (except for europium and ytterbium) include one–two *d* electrons per atom and also tend to assume the d^0 configuration. In the calcium–lanthanide system each component tends to give up its valence *d* electron to the other component. This leads to an antagonism between calcium and the lanthanide, the separation of the liquid alloys into two phases[6], and positive Gibbs free energies, enthalpies, and entropies of mixing of the components[346]. Europium and ytterbium do not have 5*d* electrons and their mixing with calcium involves a decrease in enthalpy[346].

In compounds of the type LnN and $LnIr_2$ lanthanum is tervalent and cerium is quadrivalent[6] (the "true" valence is determined by the number of electrons delocalised from the given atom[351]). The Gibbs free energies and enthalpies of formation of CeN and $CeIr_2$ are higher than those for LaN and $LaIr_2$ respectively. This combination of the thermodynamic characteristics of the lanthanum and cerium compounds shows that the contribution of the fourth valence electron of cerium to the energy of the chemical bond with nitrogen and iridium is fairly large, particularly since the increase of the number of valence electrons of cerium from three in the pure metal to four in the compound requires an energy of about 50 kcal g-atom^{-1}.[36] It has been established that the change in the number of valence electrons from three in metallic samarium to two in the compound involves a change in the Gibbs free energy and enthalpy of 6.2 ± 1.7 kcal g-atom^{-1} under standard external conditions[352].

The variation of the Gibbs free energies and enthalpies of formation of binary lanthanide compounds as a function of the atomic number of the element is complex. On passing from lanthanide trichlorides to oxides, the stability series is inverted. Whereas in the trichloride series the maximum enthalpy of formation corresponds to $LaCl_3$ (Table 1), in the series La_2O_3–Gd_2O_3–Lu_2O_3 the maximum corresponds to Lu_2O_3 (Table 2). The enthalpies of formation of lanthanide dicarbides (Table 8) and dihydrides (Table 10) remain virtually constant from lanthanum to lutetium. The variation of the enthalpies of formation of the solid lanthanide compounds has been considered on the basis of the concepts of the energy of stabilisation by the crystal field[1,3,34,353,354], the promotion energy, and bond multiplicity[355,356]. The observed relations are largely qualitative.

The dissociation energies of gaseous lanthanide compounds decrease in the series from lanthanum to europium and from gadolinium to ytterbium. Charkin[357] showed that the variation of the dissociation energies in the series of lanthanide compounds is determined by the variation of the excitation energies of the valence electron configurations of the lanthanides. It has also been shown[16,165] that the dissociation energies of the compounds vary with the degree of involvement of the lanthanide *d* electrons in the formation of chemical bonds. However, the nature of the relation between the dissociation energies of lanthanide monoxides or monosulphides and the same series of degrees of involvement of *d* electrons, calculated[358] from the properties of the lanthanides alone, remains obscure. Apparently the degrees of involvement of $4f$, $5d$, $6s$, and $6p$ valence electrons of the lanthanide in the formation of chemical bonds and hence the set of valence electron configurations can nevertheless change on passing from one class of lanthanide compounds to another (particularly in the solid state). This in fact leads to different changes in the thermodynamic characteristics in the series of solid lanthanide compounds. The proposed explanation of the variation of the Gibbs free energies or enthalpies of formation in the series of lanthanide compounds is consistent with Gschneidner's study[359], where four types of relations between the degree of involvement of $4f$ electrons in the chemical bond and the atomic number of the element were established on the basis of 33 series of lanthanide compounds.

In conclusion we may note that the thermodynamic characteristics of lanthanide compounds have been used[191,360] to determine the type of chemical bond. Comparison of the experimental and calculated enthalpies of formation of intermetallic lanthanide compounds showed[360]

that there is a predominantly metallic type of bond in the intermediate compounds of the lanthanide–magnesium systems; in lanthanide alloys with *p* elements there is a considerable contribution by ionic-covalent bonding. Thus the study of the thermodynamics of the interaction of the lanthanides with various elements permits certain conclusions concerning the nature of the valence electrons involved in the formation of the chemical bond and the type of bond in the compounds formed.

The Structure and Methods of Synthesis of Thiirans

A.V.Fokin and A.F.Kolomiets

The data presented in the review confirm the earlier results concerning a structural similarity between the two-carbon skeleton of the thiiran ring and the double bond of alkenes.
The available data on the syntheses and structures of thiirans and alkene episulphoxides and episulphones are treated systematically. The methods for the formation of the thiiran ring are classified and synthetic procedures based on homolytic, anionotropic, and cationotropic closure of thiiran rings and on thiiran reactions occurring without the opening of the ring are discussed.
The bibliography includes 236 references.

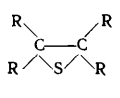
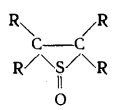
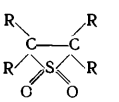
I. INTRODUCTION

Thiirans (alkylene sulphides or epithioalkanes) are saturated sulphur-containing three-membered heterocyclic compounds with structure (I). The thiiran 1-oxides (II) and 1,1-dioxides (III) can also be included in this group.



(I);


(II);


(III)

Until recently thiirans were believed to be of purely theoretical interest, their chemistry being investigated to elucidate the nature of three-membered heterocyclic compounds, but in the last few years the attitude towards these substances changed radically. The accumulated information about the properties and reactivities of thiirans made a significant contribution to theoretical organic chemistry and demonstrated the wide scope of their applications in syntheses of polymeric substances, physiologically active compounds, detergents, oil additives, etc.

More than 400 studies have now been made on the properties and methods of synthesis of thiirans. Almost half of these have been discussed in previous reviews[1-9]. The considerable advances achieved in the chemistry of thiirans during the last decade led us to undertake a new survey of the available information about this interesting branch of organic chemistry.

In contrast to previous reviews on thiirans, in the present article attention has been concentrated on a systematic arrangement of the data. The available information about the structures of thiirans is discussed critically, the known methods of thiiran synthesis are classified, and the mechanisms of the closure of thiiran rings are considered. In order to elucidate in greater detail certain problems, analogies have been drawn between thiirans and their heteroanalogues—oxirans and aziridines.

The limited size of the review precluded a detailed description of all the problems involved in the topic under consideration. The present state of thiiran chemistry is described on the basis of publications during the last two decades. Earlier communications are quoted only when necessary to illustrate certain postulates.

II. THE STRUCTURE OF THIIRANS

The problems concerning the structure of three-membered cyclic compounds have been the subject of a lively discussion begun by Walsh[10] in 1947, who considered Zimakov's concepts[11] in relation to the characteristics of the structure of oxiran. In the course of the discussion and subsequent studies, significant arguments were adduced, demonstrating the structural similarity between cyclopropane[12] and particularly its heteroanalogues on the one hand and ethylenic hydrocarbons on the other.

One of the first pieces of evidence confirming certain structural analogies between cyclopropane, oxiran, thiiran, and alkenes was obtained by Linnett[13]. The force constants of the C–H bonds in methylene groups, which he calculated from Raman and infrared spectra, proved to be 5 for cyclic compounds and 5.1 for ethylene. The closeness of these values and their considerable difference from the constants of the C–H bonds in the methylene groups of paraffins (4.6) indicate, according to the author, a greater similarity between the valence states of the carbon atoms in cyclopropane and its heteroanalogues to those in ethylenic compounds compared with the corresponding states in paraffins. This conclusion was confirmed by subsequent studies on the structures of cyclopropane heteroanalogues.

The results of electron diffraction studies on aziridine[14,15], oxiran, and thiiran[16] (Table 1) suggest that the transformation of an acyclic compound into a three-membered heterocycle is accompanied by a rearrangement of the hybrid states of the atoms forming the ring. The C–C bond lengths in all these compounds are similar and intermediate between the C–C bond length in diamond (1.544 Å) and the C=C bond length in ethylene (1.344 Å). It is interesting to note that the distance between the carbon atoms in cyclopropane heteroanalogues is close to the length of the central bond in butadiene (1.483 Å), which can be regarded, according to Dewar's ideas[17], as a simple sp^2–sp^2 σ bond. The C–H bond lengths in cyclopropane heteroanalogues are similar to the corresponding bond lengths in ethylene (1.086 Å), while the HCH angle exceeds by 6.5–6.9° the tetrahedral angle and approaches the HCH angle in ethylene. The lengths of the bonds

between the carbon atoms of the ring and the heteroatom are equal or slightly greater than the lengths of the corresponding bonds in acyclic amines, ethers, and sulphides.

The above data on the structures of cyclopropane heteroanalogues suggest that their molecules contain two types of *endo*-bonds. The two-carbon skeleton has an enhanced *s* character compared with the saturated C–C bond. According to its fundamental parameters, this bond approaches the σ bond in ethylene. The remaining two *endo*-bonds are formed from the *p* electrons of the heteroatom and the partly hybridised *p* electrons of the carbon atoms. This results in a type of overlapping of atomic orbitals which is intermediate between the lateral π-bonding and terminal σ-bonding overlapping.

The principal parameters of the molecules  .

Parameter	X		
	NH	O	S
Bond length, Å			
C—C	1.480	1.467	1.492
C—H	1.083	1.082	1.078
C—X	1.488	1.436	1.819
HCH angle	116°41′	116°41′	116°00′
CXC angle	—	61°24′	65°48′

The electronic state of the heteroatoms in aziridine, oxiran, and thiiran can be inferred only from certain indirect data. The studies of the ability of three-, four-, and five-membered heterocycles to form a hydrogen bond with phenol[18], of their capacity for complex formation with iodine[19], and of their heats of solution in chloroform[20] indicate an enhanced *s* character of the free electrons of the heteroatom in three-membered heterocycles compared with four- and five-membered heterocyclic compounds and acyclic amines, ethers, and sulphides. This is also indicated by the chemical shifts of the α- and β-CH_2 groups in the NMR spectra of cyclopropane heteroanalogues[21,22]. Thus the formation of a three-membered heterocycle entails a change in the electronic states not only of carbon atoms but also of the heteroatom in the ring.

The enhanced *s* character of the lone electron pairs of the heteroatoms is evidence for the presence of an unusual conjugated system in molecules of cyclopropane heteroanalogues. It is quite likely that the sharp differences between the ring strain energies of cyclopropane on the one hand (25 kcal $mole^{-1}$ [23]) and aziridine, oxiran, and thiiran (14, 13, and 9 kcal $mole^{-1}$ respectively) on the other are due to the stabilisation of the cyclic state in heterocyclic compounds by the π-electrons of the heteroatoms.

The above features of the structures of cyclopropane heteroanalogues are shown most clearly in the series of thiiran compounds owing to the greater covalent radius of the sulphur atom compared with those of the nitrogen and oxygen atoms and the high lability of its 3*p* electrons. The enhanced sp^2–sp^2 character of the C–C bond in thiirans has been confirmed, apart from the data quoted above, by a study of the structure of propylene sulphide [2-methylthiiran][24]. The CH_3–CH bond length (1.513 Å) is smaller than the C–C bond length in diamond by an amount equal to the difference between the effective covalent radii of the carbon atom in the sp^3- and sp^2-hybrid states, which suggests that the bond is of the sp^3–sp^2 type. The existence of 2-thiiranone[25] and 3-hexafluoroisopropylidene-2,2-bistrifluoromethylthiiran[26],

may be regarded as one of the pieces of evidence confirming the sp^2 hybrid state of the carbon atoms in the thiiran ring.

The enhanced *s* character of the C–C bond in thiirans is due to the pronounced *p* character of the C–S bond. In the ethylene sulphide [thiiran]–ethylene sulphoxide–ethylene sulphone series the inclusion of the sulphur *p* electrons in additional valence bonds lowers the stability of the thiiran ring and alters the nature of the C–C bonds. The C–C bond length calculated from microwave spectra of ethylene sulphone[27] proved to be 1.586 ± 0.01 Å. This suggests that the carbon atoms of the thiiran ring in ethylene sulphone are in the sp^3 hybrid state.

The pronounced *p* character of the C–S bond is responsible for the pseudo-unsaturated character and the electrophilic properties of thiirans, which has been confirmed by spectroscopic studies on phenylthiirans substituted in the *para*-position[28]. It is quite likely that vacant 3*d* orbitals of the sulphur atom contribute to the π-electron density of the thiiran ring, because a satisfactory agreement has been achieved between experimental and calculated spectroscopic characteristics when account was taken of not only 3*s* and 3*p* but also 3*d* levels of this element[29].

The enhanced pseudo-unsaturated character of the thiiran ring is responsible for its greater stability compared with the oxiran ring, which has been confirmed by a comparative study of the behaviour of *p*-methoxyphenyloxiran and *p*-methoxyphenylthiiran under solvolysis conditions[30]. The greater stability of the thiiran ring compared with the oxiran ring is also indicated by lower strain energy of the thiiran ring (relative to the oxiran ring), determined from the difference between the heat of formation and the sum of the individual bond energies[32], and by the lower strain entropy and enthalpy of thiiran compared with oxiran[30] (59.19 e.u. and 38.44 kcal $mole^{-1}$ for oxiran and 21.47 e.u. and 17.62 kcal $mole^{-1}$ for thiiran).

The thiiran molecule can be represented, like those of aziridine and oxiran, by an asymmetric rotator with the symmetry plane perpendicular to the plane of the C–C ring. For this reasons, its 2,3-disubstituted derivatives exist as two geometrical isomers (*cis*- and *trans*-). The internally compensated *cis*-isomers of the symmetrical 2,3-disubstituted thiirans are optically inactive. Monosubstituted thiirans, the *trans*-isomers, and the *cis*-isomers of 2,3-disubstituted thiirans can be obtained in an optically pure state[31–35].

III. METHODS FOR THE SYNTHESIS OF THIIRAN COMPOUNDS

The reactions of acyclic or certain cyclic compounds leading to the formation of three-membered sulphur-containing rings are most frequently used to synthesise thiirans. However, methods based on reactions of thiirane derivatives without ring opening have also been used successfully in many instances.

1. METHODS BASED ON THE HOMOLYTIC CLOSURE OF THIIRAN RINGS

a. Addition of Sulphur to Alkenes

The early attempts to add atomic sulphur formed in the pyrolysis of diethyl tetrasulphide to ethylene, propene, and cyclohexene were relatively ineffective [36]. The yield of thiiran derivatives did not exceed several per cent in view of the low yield of atomic sulphur in the reaction

$$R{-}CH{=}CH_2 + C_2H_5(S)_4C_2H_5 \xrightarrow{150^\circ} R{-}\underset{\diagdown S \diagup}{CH{-}CH_2} .$$

Best results were obtained using carbon oxide sulphide as a source of atomic sulphur [37-39]. Irradiation of a mixture of carbon oxide sulphide in ethylene or propene with ultraviolet light (255–229 nm) at 25°C leads to the formation of the corresponding thiirans in a yield of 60–100% relative to the olefin which has reacted. However, the degree of conversion of alkenes in such reactions is very low. 1,2-Epithiobutene [2-ethylthiiran], *cis*- and *trans*-butylene sulphides, and isobutylene sulphide [2,2-dimethylthiiran] were obtained in low yields under the same conditions. Only butadiene reacts anomalously under the conditions of photolytic sulphur addition, giving rise to vinyldithiacyclobutane and thiophen [40].

Under photolysis conditions, hexafluorocyclobutene is readily acted upon by atomic sulphur [41]. The resulting perfluorocyclobutylene sulphide is unstable and has a half-life of about 1 min at 20°C. Tetrafluoroethylene reacts at 445° with elemental sulphur to form a mixture of tetra-, tri-, and mono-sulphides [42,43]. Tetrafluorothiiran was obtained under these conditions in a yield of 2%.

The formation of thiirans on reaction with sulphur under photolysis conditions is a typical free-radical process. The sulphur atom in both the singlet and triplet states enters readily into this reaction [38], which proceeds with a low activation energy [39]. Under the reaction conditions, the formation of the thiiran is accompanied by its photolytic decomposition, which is the reason for the low degree of conversion of alkenes in this reaction.

$$R{-}CH{=}CH_2 + S^* \rightarrow R{-}\underset{\diagdown S \diagup}{CH{-}CH_2} \xrightarrow{S} R{-}CH{=}CH_2 + S_2 .$$

A careful study [43] has shown that the high-temperature reaction of tetrafluoroethylene with sulphur proceeds via a stage involving the formation of difluorocarbene:

$$CF_2{=}CF_2 \xrightarrow{>400^\circ} :CF_2 \xrightarrow{S} CF_2{=}S \xrightarrow{CF_2:} \underset{\diagdown S \diagup}{CF_2{-}CF_2} .$$

b. Condensation of Sulphur and Its Compounds with Diazoalkanes

This reaction was historically the first process whereby it was possible to obtain thiirans as individual compounds. Before its discovery, the formation of thiirans in reactions was inferred only from the evolved polyalkylene sulphide [44,45] and it was believed that these substances do not exist in a monomeric state [45].

In 1916–1920 Staudinger and coworkers [46-48] reported the formation of thiirans in the reaction between diazoalkanes and aromatic thioketones, thiophosgene, and thiobenzoyl chloride:

$$RR'CN_2 + R''R'''C{=}S \rightarrow \underset{\diagdown S \diagup}{RR'C{-}CR''R'''} .$$

The reactions proceed smoothly at room temperature and the final products are isolated in high yields after the evolution of nitrogen ceases.

The scope of Staudinger's method for the synthesis of thiirans and also some of the limitations in their applications have been determined in studies by Schonberg and coworkers [49-56]. According to their data, thiobenzophenones, thioxanthene, and other aromatic cyclic thioketones react unambiguously only with diaryldiazomethanes. The reactions with diazomethane, diazoethane, and ethoxycarbonyldiazomethane result in the formation of 1,3-dithiolans:

$$Ar_2C{=}S + R{-}CHN_2 \rightarrow \begin{array}{c} Ar_2C{-}CAr_2 \\ | \quad\quad | \\ S \quad\quad S \\ \diagdown CH \diagup \\ | \\ R \end{array} .$$

Thiirans have also been obtained by the reaction of diaryldiazoalkanes with other thiono-compounds, including diphenyl trithiocarbonate, the chlorides of phenyldithiocarbonic and phenylthiocarbonic acids, and xanthogen sulphide:

$$Ar_2CN_2 + S{=}\overset{X}{\underset{Y}{C}} \rightarrow Ar_2C\overset{X}{\underset{S \quad Y}{\diagup \quad \diagdown}}C .$$

(X=SC_6H_5; Cl; SC(S)OR; OC_6H_5; Y=SC_6H_5; OC_6H_5; OR)

The reaction of diazoethane with thiocarbonic acid derivatives is similar to that of diaryldiazomethanes [52]. However, in this case too diazomethane reacts anomalously with formation of 1,3-dithiolan derivatives.

Aliphatic thioketones have recently been successfully introduced into the reaction with diazoalkanes [57]. In this case the reaction involving diazomethane yielded the normal condensation products—2,2-disubstituted thiirans:

$$RR'C{=}S + CH_2N_2 \rightarrow \underset{\diagdown S \diagup}{RRC{-}CH_2} .$$

Cycloalkenethiones react with diazoalkanes to form a complex mixture of products from which thiirans, dithiolans, and alkenes were isolated [58]. The reactions of diazomethane [59], diazoethane, and dimethyldiazomethane [60] with thioketones and thio- and dithio-carboxylates led to the isolation, together with thiirans, of olefins and 1,2,3- and 1,3,4-thiadiazolins. In certain cases, for example in the reaction between fluorenethione and diphenyldiazomethane [64], the only products were alkenes.

In contrast to aromatic thioketones [65], hexafluorothioacetone readily forms 2,2-bis(trifluoromethyl)thiirans not only on reaction with diphenyldiazomethane but also with ethoxycarbonyldiazomethane [61]. The fluoride of perfluorothiopropionic acid also reacts with diazoalkanes, but the resulting thiirans readily undergo spontaneous sulphur elimination and the final outcome of such reactions is the formation of alkenes [62]:

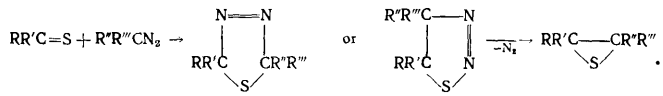
$$CF_3CF_2C(S)F + (C_6H_5)_2CN_2 \rightarrow \underset{\diagdown S \diagup}{CF_3CF_2CF{-}C(C_6H_5)_2} \xrightarrow{-S} CF_3CF_2CF{=}C(C_6H_5)_2 .$$

Thiocarbonyl fluoride enters into exchange reactions with diphenyldiazomethane [43,63], which leads to the formation of tetraphenylthiiran:

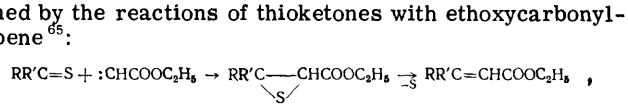
$$2(C_6H_5)_2CN_2 + CF_2{=}S \rightarrow \underset{\diagdown S \diagup}{(C_6H_5)_2C{-}C(C_6H_5)_2} .$$

The mechanism of the complex reactions in thiono-compound–diazoalkane systems has not been investigated thoroughly. The hypothesis that the diazoalkane initially

undergoes the Pechmann condensation with the thiono-compound to form 1,2,3- or 1,3,4-thiadiazolin, whose decomposition with liberation of nitrogen is accompanied by a free-radical closure of the thiiran ring at the C–C or C–S bond, is quite likely:

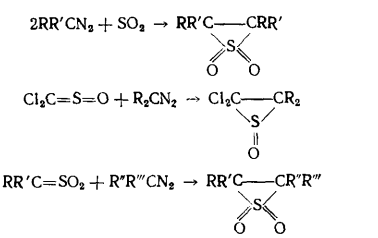


All the reactions in such systems can also be accounted for on the hypothesis of the initial formation of carbenes in the reaction mixture. The addition of the latter to the C=S bond can lead to the formation of both a thiiran and a 1,3-dithiolan. The latter mechanism of the formation of thiirans from thiono-compounds and diazoalkanes is confirmed by the reactions of thioketones with ethoxycarbonylcarbene [65]:

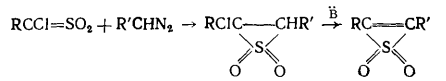


and also by the reactions of diazoalkanes with sulphur [64,66], which take place readily under the usual conditions of the above syntheses, where the formation of a carbene is the most likely process:

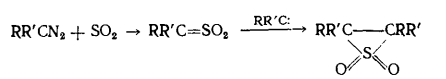
The ability to condense with coordination-unsaturated sulphur compounds is a common property of diazoalkanes. Apart from thiono-compounds and sulphur, sulphur dioxide [67–76] and sulphenes [77–80] react smoothly with diazoalkanes:



These reactions do not always proceed unambiguously. In certain cases alkenes [71] or derivatives of 1,3,4-thiodiazines are the side products of these processes [70,79]. 3-Alkyl-2-halogenothiiran 1,1-dioxides are converted under the reaction conditions into thiiren 1,1-dioxides:

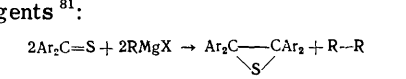


The mechanism involving the preliminary formation of carbenes is regarded as the most likely pathway to the formation of the thiiran 1,1-dioxide ring [76]:

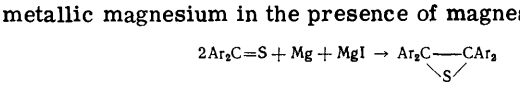


c. Condensation of Thiones with Carbenes

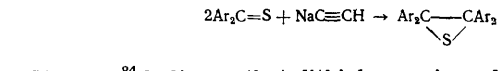
In 1927 Schonberg et al. reported the formation of tetra-arylthiirans in reactions of thiobenzophenones with Grignard reagents [81]:



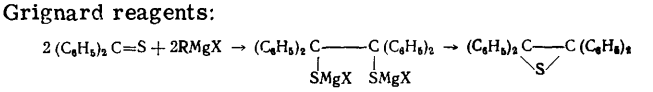
The results of this reaction is independent of the nature of the organomagnesium compound: thioketones react readily with alkyl- or aryl-magnesium bromides or iodides and are converted into thiirans in high yields. Similar results were obtained on treating thioketones with metallic magnesium in the presence of magnesium iodide [82]:



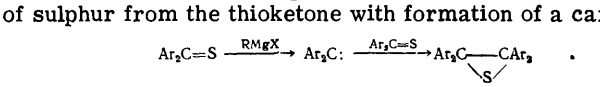
Later the formation of thiirans was observed on treating thioketones with sodium acetylide [83]:



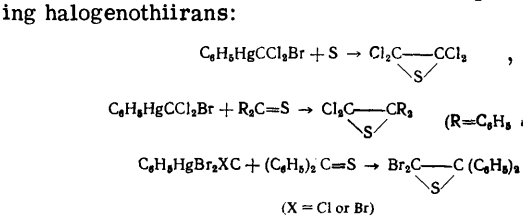
Moreau [84] believes that dithiobenzopinacol is an intermediate in the reaction between thiobenzophenone and Grignard reagents:



However, a recent investigation of these reactions [85] led to the conclusion that the primary step is the elimination of sulphur from the thioketone with formation of a carbene:

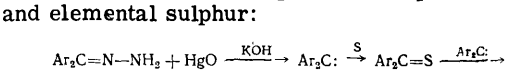


The condensation of carbenes with sulphur and thiones have been widely investigated by Seyferth et al. [86], who used various phenyl(trihalogenomethyl)mercury compounds as a source of carbenes. The bromodichloro-, dibromochloro-, and tribromo-methyl derivatives react smoothly with sulphur, thiophosgene, and thiobenzophenone, forming halogenothiirans:



Only phenyl(trifluoromethyl)mercury fails to form a thiiran in the reaction with thiobenzophenone [87].

The marked ability of carbenes to react with elemental sulphur and thiones has been used to develop a simple preparative method for the synthesis of tetra-arylthiirans [88,89]. It consists in treating ketone hydrazones with mercury(II) oxide in the presence of potassium hydroxide and elemental sulphur:



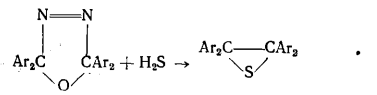
The conversion of phenylmethanesulphonyl chloride into 2,3-diphenylthiiran on heating with triethylamine in methylene chloride or ether probably also involves the formation of a carbene [90].

The possibility of synthesising polyfluorothiirans by pyrolytic reactions of fluoro-compounds with formation of difluorocarbene in the presence of sulphur and its compounds has been demonstrated in a number of studies. These syntheses include the high-temperature combination of tetrafluoroethylene with sulphur [43] and the reactions of 2,2,3-trifluoro-2-trifluoromethyloxiran with thiocarbonyl fluoride, thiocarbonyl chloride fluoride, and perfluorothioacyl fluorides also belong to syntheses of this type [49,91–94]:

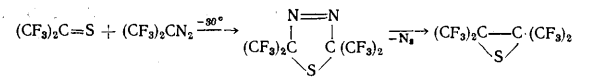
The yield of polyfluorothiirans under these conditions is usually low owing to the occurrence of side reactions involving the final products, in which they undergo sulphur elimination and isomerisation.

d. Syntheses of Thiirans by the Pyrolysis of Heterocyclic Compounds

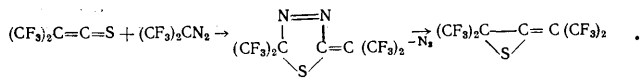
There are at present few examples of these reactions. In 1939 Schonberg and Barakat [95] showed that thiirans are formed in high yields on heating oxadiazines in an atmosphere of hydrogen sulphide:



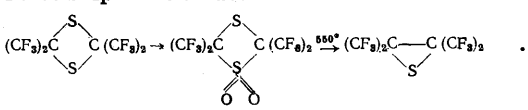
Middleton [26] obtained from perfluorothioacetone and bis(trifluoromethyl)diazomethane under mild conditions 2,2,5,5-tetra(trifluoromethyl)-1,3,4-thiadiazine, which he converted into tetra(trifluoromethyl)thiiran by pyrolysis:



Bis(trifluoromethyl)thioketen reacts similarly to hexafluorothioacetone. The first example of thiirans whose ring is linked to the substituent by a C=C bond was obtained in this way:



Middleton also developed a method for the preparation of perfluoro-derivatives of tetra-alkylthiirans from thioketone dimers [96]. By oxidising the latter with chromium trioxide in nitric acid, he obtained sulphones which he converted into thiirans by pyrolysis over platinum in an atmosphere of sulphur dioxide:



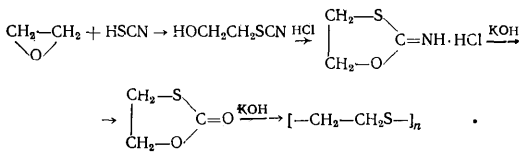
Tetrafluorothi-iran was obtained together with other products also in the pyrolysis of tetrafluorodithiacyclobutane [94]:

There is no doubt that the above syntheses of thiirans have a free-radical mechanism. In many of these, except the last, a homolytic closure of the thiiran ring with formation of a C–C bond takes place.

2. REACTIONS INVOLVING THE ANIONOTROPIC SUBSTITUTION OF THE OXYGEN ATOM IN OXIRANS BY A SULPHUR ATOM

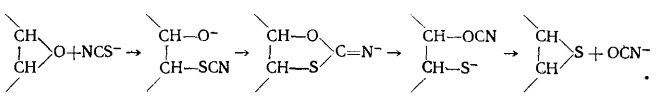
The syntheses of thiirans by the reaction of their oxygen analogues with alkali metal thiocyanates and thiourea have now become classical and are recommended for use on a preparative scale as the most convenient procedures of this kind [97].

The history of the devlopment of this method has been described in very great detail in Weissberger's review [7] and one need only note that all the stages of the conversion of oxiran into thiiran in the reaction of the former with thiocyanates were first described in 1937 by Sergeev and Kolychev [98]. Having obtained 2-thiocyanatoethanol by the reaction of oxiran with thiocyanic acid, the authors converted it almost quantitatively into the hydrochloride of ethylene monothiocarbonate imine [the hydrochloride of 2-imino-1,3-oxathiolan]. The latter was converted on treatment with an equivalent amount of alkali into ethylene monothiocarbonate [2-oxo-1,3-oxathiolan] and with an excess of alkali into poly(ethylene sulphide).



On the basis of the results of Sergeev and Kolychev [98], Ettlinger [99] proposed a mechanism for the reaction of oxirans with alkali metal thiocyanates whose validity was proved rigorously by van Tamelen [100] and independently by Price and Kirk [31].

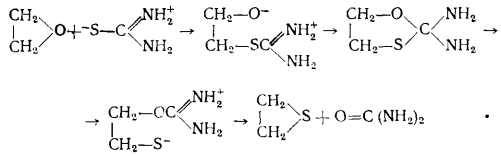
Ettlinger believes that the formation of thiirans in these reactions involves the nucleophilic opening of the oxiran ring by the thiocyanate anion, the isomerisation of the resulting alkoxide anion via an intermediate cyclic state into a thiolate anion, and the conversion of the latter into the thiiran with elimination of the cyanate anion:



According to this mechanism, the conversion of the oxiran ring into a thiiran ring should involve two Walden inversions in the *trans*-opening and *trans*-closure of the ring. Only oxirans derived from acyclic and unstrained cycloalkenes can be expected to give rise to thiirans. Those derived from strained cycloalkenes should not react, because the formation of an intermediate bicyclic ion with two strained rings by *trans*-closure is impossible.

Van Tamelen showed that cyclohexenylene oxide {cyclohexeno[*b*]oxiran} reacts with potassium thiocyanate, 2-thiocyanatocyclohexanol, and the hydrochloride of cyclohexenylene monothiocarbonate imine {the hydrochloride of 2-iminocyclohexeno[*d*]1,3-oxathiolan} and is smoothly converted into cyclohexenylene sulphide {cyclohexeno[*b*]thiiran} in the presence of bases. Cyclopentenylene sulphide {cyclopenteno[*b*]thiiran} is not formed from the corresponding oxiran and potassium thiocyanate. Price and Kirk showed that an intermediate iminoether is formed in the reaction between 2-methyloxiran and potassium thiocyanate, having isolated it in the form of the 4-nitrobenzoate. Moreover they obtained L(–)-2,3-dimethylthiiran by the reaction of D(+)-2,3-dimethyloxiran with potassium thiocyanate. All these findings are consistent with Ettlinger's ideas concerning the mechanism of the conversion of oxirans into thiirans.

A similar mechanism for the formation of thiirans in the reaction of oxirans with thiourea was proposed by Culvenor et al.[101]:



Bordwel and Andersen[102] believe that the transition state in this process is formed from a neutral molecule of *S*-(2-hydroxyalkyl)isothiourea and not from the 2-alkoxyisothiuronium ion. They base this view on the observation that high yields of thiirans are obtained only in media with a pH close to 7.

The mechanisms proposed by Ettlinger and Culvenor for the conversion of oxirans into thiirans were confirmed further by recent studies on the reactions of potassium thiocyanate and thiourea with optically active 2-phenyloxiran, 2-methyl-3-phenyloxiran, and 2,3-diphenyloxiran[35]. It was shown that the conversion of the above compounds into thiirans entails the inversion of the configuration of the initial molecule at both carbon atoms of the ring, which can only be understood when account is taken of the formation of cyclic transition states in the reaction.

The scope of the synthesis of thiirans from oxirans by reaction of the latter with alkali metal thiocyanates or thiourea is very great. Thiiran and 2-methylthiiran[103-105], the *cis*- and *trans*-isomers of 2,3-dimethylthiiran[31,34], 2,3-dimethylthiiran[103], 2-hexylthiiran[106], 2-diethoxymethylthiiran[107], 2-vinylthiiran[108], cyclohexeno[*b*]thiiran and its derivatives[103,108], 2-chloromethylthiiran[103], alkoxy- and aryloxy-methylthiirans[109-113], alkylthiomethyl- and dialkylaminomethyl-thiirans[100,113], 2-phenylthiiran and its ring-substituted derivatives[28,35,114,115], esters of epithiodienecarboxylic acids [thiiranylalkenecarboxylic acids][116], 4-piperidinylthiirans[33], and other compounds have been obtained by this method.

The extensive studies on these reactions by Culvenor et al.[108] showed that only thiirans with electronegative groups attached to the thiiran ring cannot be obtained by this method because of the ease of elimination of sulphur in the course of their formation. However, later investigations established that under certain conditions of synthesis even thiirans which readily lose sulphur can be obtained from oxirans. For example, *cis*- and *trans*-2,3-diphenylthiirans were obtained in yields up to 90%[117] under the conditions of the Bordwel synthesis by the initial condensation of the corresponding oxirans with thiourea sulphate and subsequent cautious alkaline treatment of the resulting isothiuronium salts.

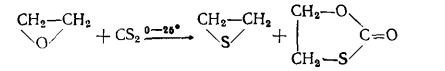
The yields of thiirans in the reactions of oxirans with alkali metal thiocyanate of thiourea are 30–80% and depend significantly on the process conditions. The reactions are usually carried out at 0–20°C under homogeneous conditions, using water, lower alcohols[101-103,108], and mixtures of alcohol and acetic acid[118] as solvents. According to patent data[119], a higher yield of thiirans is achieved when anhydrous polar solvents are used.

Ammonium thiocyanate, aryl- and diaryl-thioureas, thiocarboxylic acid amides, and certain thiocarboxylic acids have been used instead of alkali metal thiocyanates and thiourea[24,103]. The reactions with these substances take place under the conditions of the synthesis of thiirans from oxirans by reaction with thiourea or alkali metal thiocyanates.

Industrial methods for the synthesis of thiirans from their oxygen analogues and readily available sulphur-containing compounds, such as carbon oxide sulphide and carbon disulphide, are now being developed. Durden et al.[120] showed that at 150°C oxiran forms a copolymer with carbon oxide sulphide in the presence of bases. However, when these substances are brought into contact over a basic catalyst under more severe conditions (at about 200°C), thiiran is formed. The best catalyst for these reactions proved to be trilithium phosphate:

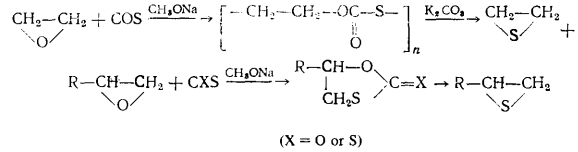
According to patent data, the formation of thiirans from oxirans and carbon oxide sulphide or carbon disulphide in the vapour phase is catalysed by sodium fluoride, its mixtures with other sodium halides, the halides of other alkali and alkaline earth metals, alkaline earth metal oxides, and alkali metal sulphides[121-123]. The yield of low-boiling thiirans reaches 90% in relation to the oxiran which has reacted.

Thiiran can be obtained in yields up to 80% from oxiran and carbon disulphide in the presence of a mixed catalyst consisting of partly hydrated lithium chloride and triethylsulphonium iodide[124,125]. Ethylene monothiocarbonate-[2-oxo-1,3-oxathiolan] is a side product:



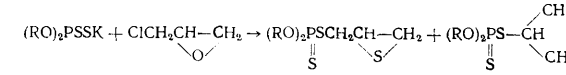
Somewhat less satisfactory results were obtained when the reaction was catalysed by lithium chloride in the presence of hydrogen sulphide[126]. The main products in the presence of these catalysts are ethylene mono- and dithiocarbonates [2-oxo-1,3-oxathiolan and 2-oxo-1,3-dithiolan] and thiiran is formed in yields up to 20%.

When the catalyst is sodium methoxide, the above reactions give rise to polymeric substances[127] or alkylene mono- and di-thiocarbonates [alkyl derivatives of 2-oxo-1,3-oxathiolan or 2-oxo-1,3-dithiolan][128,129], which can be converted into thiirans on heating with alkaline agents:



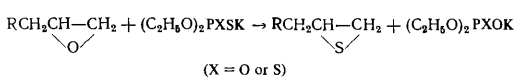
(X = O or S)

Interesting reactions involving the conversion of 2-chloromethyloxiran into derivatives of 2-methylthiiran have been described by Schroder[130]. According to his data, the reactions of 2-chloromethyloxiran with an excess of salts of *OO*-dialkylphosphorodithioic acid in water lead to *OO*-dialkyl *S*-thi-iranylmethyl phosphorodithioates. These data were confirmed by Nuretdinova[131], who also showed that small amounts of thietan derivatives are formed in the reactions together with thiirans:



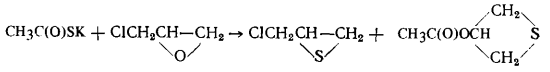
Arbuzov and Nuretdinova[132,133] studied the reactions of 2-chloromethyloxiran, 2-methyloxiran, glycidyl phenyl ether [2-phenoxymethyloxiran], and *OO*-diethylphosphonomethyloxiran with thiolic acid salts. Potassium salts of

phosphorothioic and phosphorodithioic acids react smoothly with oxirans and the corresponding thiirans were isolated in yields of 40–55%:

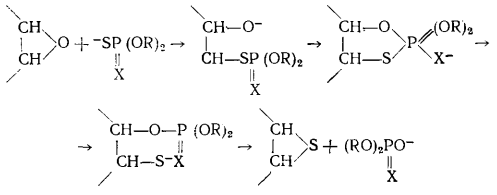


(X = O or S)

On reaction with the triethylammonium salt of *OO*-diethylphosphorodithioic acid, 2-chloromethyloxiran is also converted into 2-chloromethylthiiran. However, the reaction with thioacetic acid salts gives rise to a mixture of 2-chloromethylthiiran and 3-acetoxythietan:



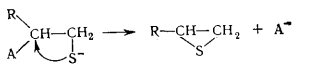
The mechanism of the conversion of oxirans into thiirans by the reactions with thiolic acid salts is satisfactorily consistent with the scheme devised by Ettlinger and Culvenor:



The validity of this scheme is also confirmed by the susceptibility of *S*-(2-hydroxyethyl) esters of thiocarboxylic and phosphorothioic acids [134] to cleavage by bases with formation of thiirans or their polymers. The formation of thiirans in the acid-catalysed reaction of oxirans with phosphine sulphides [135] also proceeds in accordance with Culvenor's mechanism

The marked influence of the polarity of the solvent must be regarded as a characteristic feature of the above methods of synthesis of thiirans from oxirans. In an aqueous homogeneous medium the process is usually exothermic. Heat is required for the reaction in less polar solvents. This is due primarily to the specific features of the anionotropic reactions in ionic alkoxide–thiolate rearrangements and in the closure of the thiiran ring. The driving force in the first process is provided by the high energy of the thioacyl linkage. The favourable effect of the polar solvent is in this case evident, as in other instances of the nucleophilic substitution at coordination-unsaturated carbon and phosphorus atoms.

The completion of the stage involving the formation of thiiran rings from oxiran rings is very similar in all the cases considered. The conversion of the thiolate anion into thiiran can be regarded as anionotropic ring closure with elimination of the weaker nucleophile (the alkoxide anion):



The anionotropic closure of the thiiran ring is promoted by the comparatively low enthalpy associated with the thiiran ring strain, the low capacity for solvation and hence the high reactivity of the thiolate anion, and the marked influence of the solvolysis of the eliminated alkoxide anions.

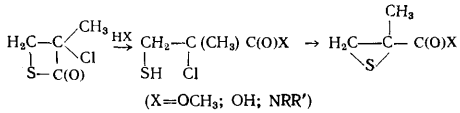
3. THE ANIONOTROPIC FORMATION OF THIIRANS FROM 2-SUBSTITUTED ALKANETHIOLS AND THEIR DERIVATIVES

Historically the first example of these reactions is the syntheses of thiirans by Delepine's method [136–140], which were described soon after Staudinger's reports of the syntheses of tetra-arylthiirans. Delepine's method made it possible to obtain for the first time the lowest thiirans. The syntheses are based on the reaction of vicinal dithiocyanato- and halogenothiocyanato-alkanes with sodium sulphide:

Thiiran and 2-methylthiiran [136–141], tetramethylthiiran [142], thi-iranylalkanecarboxylic acids [143], and cyclohexeno[*b*]thiiran and its derivatives [144] were obtained by this method. The reactions are usually carried out in lower alcohols, aqueous alcohol, or water. The usual alkaline agents can be used instead of sodium sulphide [143,145]. Thi-iranylalkanecarboxylic acids are synthesised by treating the corresponding vicinal dithiocyanato-derivatives with sodium hydroxide [143]. The yield of the lowest thiirans in syntheses by Delepine's method is usually low owing to their polymerisation in the course of their formation. However, substances which are relatively stable under the conditions of the syntheses were obtained in virtually quantitative yields [142]. Delepine's method can be of practical interest for the conversion of higher olefins into thiirans in view of the availability of effective methods for the formation of vicinal chlorothiocyanato-alkenes.

The syntheses of thiirans from 2-halogenoalkanethiols, analogous to the halogenohydrin syntheses, were published for the first time in 1939. [146–148] A high yield of thiiran (up to 98%) was obtained under relatively mild conditions by adding alkali to chloroethanethiol, keeping the pH of the medium at about 7.5–9.5. Cyclohexeno[*b*]thiiran and cyclopenteno[*b*]thiiran (yield up to 80%), [100] as well as 2-mercaptomethylthiiran and 2-mercaptomethyl-2-methylthiiran [149] were obtained by this method under similar conditions.

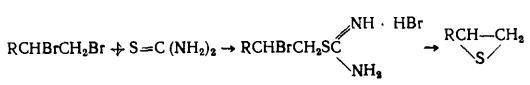
The reaction has been widely used by Knunyants and coworkers [150–156] in the syntheses of thioglycidic acids and their esters and amides. Numerous attempts to obtain these compounds by the reaction of glycidic acid derivatives with potassium thiocyanate or thiourea [104,157], by treating vicinal dithiolacetates with bases [158,159], and by the reaction of thioketones with chloroacetates [160] proved to be unsuccessful. The simplest examples of compounds of this series were obtained for the first time in good yields by treating the thiolactone of α-chloroisobutyric acid with ammonia and amines [150], with a mixture of alcohol and triethylamine [151], or with a dilute solution of alkali [152]. The reactions involves the preliminary opening of the thiolactone ring:



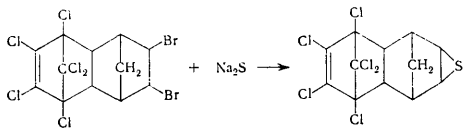
(X=OCH$_3$; OH; NRR')

Similar compounds have also been synthesised in yields up to 90% by mild alkaline treatment of derivatives of α-chloro-β-mercaptocarboxylic acids [153–156] obtained by the hydrolysis of the corresponding acyl derivatives.

2-Halogenoalkylisothiuronium salts, formed by the reaction of vicinal dihalogenoalkanes with thiourea, react similarly to 2-halogenoalkanethiols [161]:

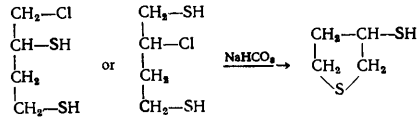


The conversion of vicinal dihalogenoalkanes into thiirans by reaction with sodium sulphide probably involves the formation of 2-halogenoalkanethiols [162]:



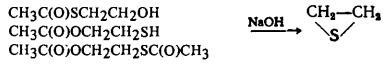
The mild conditions in the formation of the thiiran ring in the alkaline treatment of 2-halogenoalkanethiols make it possible to obtain thiirans containing highly reactive groups, for example 2-chloromethylthiiran [163]:

The reactions of 2-halogenoalkanethiols usually proceed unambiguously and the yield of products exceeds 70%. An anomalous reaction was observed only in the cyclisation of 3-chloro-1,4-dimercaptobutane and 4-chloro-1,3-dimercaptobutane [149], where 3-mercaptothiolan was isolated instead of the expected 2-(2-mercaptoethyl)thiiran:

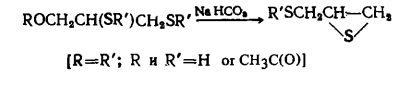


Thus the scope of the synthesis of thiirans from 2-halogenoalkanethiols is very great. The method makes it possible to obtain thiirans derived from strained cycloalkenes and thioglycidic acids, which are not formed in other synthesis.

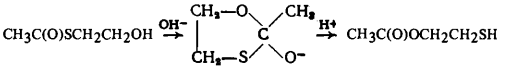
The first reports of the syntheses of thiirans from *O*-acetyl, *S*-acetyl, and *OS*-diacetyl derivatives of 2-mercaptoalkanols were published in 1949: [164-166]



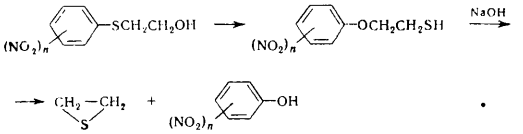
Partly or fully acylated 2,3-dimercaptopropanol was converted by this method into 2-mercaptomethylthiiran or into 2-acetylthiothiiran:



After analysing the above studies [164-166], Culvenor et al. [101] concluded that the formation of thiirans in these and similar instances known at the time is a consequence of the high capacity of 2-substituted thiols for isomerisation. They believe that the conversion of acylthioalkanols into thiirans is due to their marked ability to undergo anionotropic reactions:



Hence it followed that a wide variety of mercaptoalkanol derivatives of the type $RSCH_2CH_2OH$, in which R is an electronegative group with a coordination-unsaturated central atom, can be converted into thiirans. This was in fact confirmed by Culvenor et al. [101] for the reaction of 2-hydroxyethyl nitrophenyl sulphides with bases:



Culvenor's ideas stimulated extensive studies on the above reactions and were confirmed subsequently. Ethylene monothiocarbonates were decomposed by alkali [167], and thiiran could be synthesised in 70–80% yield by treating them with sodium methoxide. Cyclopenteno- and cyclohexeno-[*b*]thiirans were obtained in high yields from *trans*-2-acetylthiocyclopentyl acetate and *trans*-2-acetylthiocyclohexanol [168]. The same compounds were obtained [169] by the alkaline decomposition of *trans*-2-acetylthiocycloalkyl toluene-*p*-sulphonates. Doyle et al. [149] investigated the syntheses of thiirans from the triacetates of the dimercapto-derivatives of isobutyl, pentyl, hexyl, and decyl alcohols. Fully acylated 6-mercaptoglucose was converted into thiiran by treatment with sodium methoxide [170]. Similar compounds were also obtained by the alkaline decomposition of *S*-acyl-*O*-tosyl derivatives of carbohydrates [172-174]. The synthesis of thiirans from *O*-(2-mercaptoalkyl) esters of *O*-alkyl- and *O*-arylcarbonic and arylcarbamic acids and from *S*-(2-hydroxyalkyl)esters of *O*-alkylthiocarbonic and arylthiocarbamic acids has been patented [171]. The best yields of thiiran (67–80%) was obtained from the 2-mercaptoalkyl esters by treating the latter with sodium methoxide. When aqueous alkalis are used, the yield depends on the nature of the thiirans formed and varies from 25 to 85%.

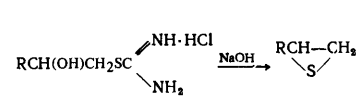
A catalytic method for the conversion of 2-mercaptoalkyl acetates into thiirans was developed recently [175]:

The esters are supplied to the reaction zone in a mixture with xylene in an atmosphere of nitrogen. The catalyst is based on aluminium with added sodium, iron, and silicon oxides. The degree of conversion of 2-mercaptoethyl acetate is 85% and the yield of thiiran reaches 70.5%.

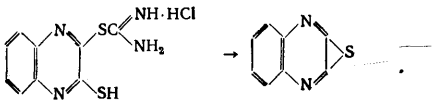
According to Harding et al. [165], 2-methylthiiran is obtained in low yield when 1,2-dimercaptopropane is treated with alkali. However, under the usual conditions 2-mercaptoalkanols are not converted into thiirans. A high-temperature alkaline cyclisation of monothioethylene glycol probably occurs when thiiran is obtained from ethylene, hydrogen sulphide, and oxygen [176]:

Like *S*-acyl derivatives of mercaptoalkanols, 2-thiocyanatoethanol [98] and 2-thiocyanatocyclohexanol [100] can be converted into thiirans. Decyl thiocyanate reacts similarly in the presence of sodium hydride [177] and a 2-hydroxylalkylisothiuronium salt:

or on treatment with alkali [178,179]:



The hydrochloride of 3-isothiuronium-2-mercaptoquinoxaline is converted into thiiran even on crystallisation from dimethylformamide [180]:



In the presence of bases thiirans are formed readily not only from thiocyanatoalkanols but also from their acyl derivatives [181].

The derivatives of thiocyanatoalkanols, formed when cyclic alkylene carbonates are cleaved by alkali metal thiocyanates, undergo a spontaneous transformation into thiirans [182-184]. The mechanism of these reactions is analogous to that of the formation of thiirans from oxirans. The yield of thiirans reaches 65%. Cyclic alkylene monothiocarbonates [alkyl derivatives of 2-oxo-1,3-oxathiolan] are converted into thiirans in the presence of bases at 200°C. [185,186] Treatment of *NN*-dialkylaminomethyl derivatives of cyclic ethylene monothiocarbonates [2-oxo-1,3-oxathiolans] with alkali leads to the formation of 2-hydroxymethylthiiran [187]:

The last groups of reactions to be considered comprises those of 2-substituted polythio-compounds. The reduction of di-(2-hydroxyethyl) disulphide with di-isobutylphosphine results in the formation of thiiran together with ethylene monothioglycol [188]:

Substituted thiirans have been obtained by the reduction of di-(2-chloroalkyl) disulphides with a mixture of sodium sulphide and sulphite [189]:

The yield of 2-methylthiiran in this reaction reaches 77%.

A method has been patented for the synthesis of 2-methylthiiran from propene and sulphur monochloride [190]. Di-(2-chloropropyl) disulphide is first obtained in the presence of Friedel–Crafts catalysts and is then cyclised at 80–90°C over a mixture of sodium sulphide and carbonate:

A similar method was used to synthesise bisepithioalkanes from diene hydrocarbons [191]. The reduction of polymeric disulphides to thiirans was achieved in this case with the aid of aluminium in water.

Stereospecific syntheses of thiirans from alkenes have been achieved by the initial condensation of the latter with arenesulphenyl chlorides and the subsequent decomposition of the resulting aryl 2-chloroalkyl disulphides with sodamide or sodium sulphide [192,193]:

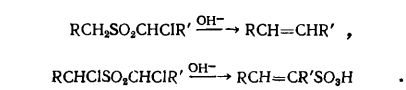
Cyclohexeno[*b*]thiiran, *cis*- and *trans*-2,3-dimethylthiiran [192], and thiirans derived from norbornenes [193] were obtained in this way in yields up to 70%.

Thiiran was also obtained in the decomposition of 2-chloroethyl 2-nitroethyl disulphide in the presence of potassium benzoate [194]:

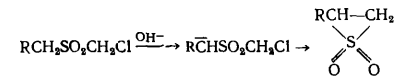
The above transformations of vicinal dithiocyanato- and halogenothiocyanato-alkanes, 2-halogenoalkanethiols, acyl derivatives of 2-mercaptoalkanols, 2-substituted dialkyl disulphides, and 1,2-dimercaptoalkanes into thiirans take place under conditions promoting the formation of 2-substituted thiolate anions. The anionotropic cyclisation of the latter takes place under mild or severe conditions depending on the nature of the substituent in the anion. The anionotropic formation of the thiiran ring takes place most readily in reactions of 2-halogenoalkanethiols.

4. ANIONOTROPIC REACTIONS OF DERIVATIVES OF α-HALOGENOSULPHIDES

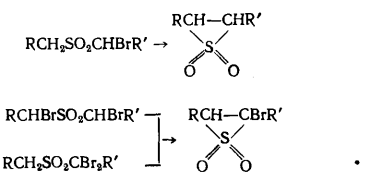
In 1940 Ramberg and Backlung [195] described a rearrangement of α-halogenosulphones accompanied by the elimination of sulphur dioxide and the formation of alkenes. αα-Dihalogenosulphones are converted into alkenyl sulphonates in these reactions:



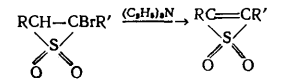
Somewhat later it was suggested on the basis of kinetic studies of these reactions [196] that the primary step in them is the elimination of a proton and cyclisation of the resulting anion with formation of a thiiran 1,1-dioxide:



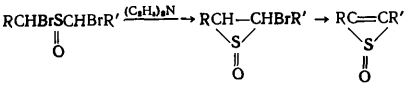
An experimental confirmation of the mechanism of the Ramberg–Backlung rearrangement was obtained by Neureiter and Bordwell [73,75], Paquette and coworkers [197-203], and Carpino and coworkers [204-206], who showed that, when a mixture of α-halogeno-, αα-dihalogeno-, and αα′-dihalogeno-sulphones is heated with triethylamine under mild conditions, the hydrogen halide is split off and thiiran 1,1-dioxides are formed:



Halogenothiiran 1,1-dioxides undergo further reactions under the above process conditions with formation of thiiren 1,1-dioxides:



α-Halogenosulphoxides undergo cyclisation reactions similar to those of α-halogenosulphones [206]:



Syntheses of thiirans from non-oxidised α-halogenosulphides under the conditions of anionotropic reactions have not been described.

5. THE FORMATION OF THIIRANS AS A RESULT OF CATIONOTROPIC REACTIONS OF ACYCLIC COMPOUNDS

Reactions involving cationotropic closure of thiiran rings have been little investigated. However, the data already available on these problems show that the practical applications of such syntheses are promising.

A method for the pyrolytic decomposition of 2,3-dimercaptopropanol to 2-mercaptomethylthiiran, which is of merely historical interest as the first attempt at the synthesis of thiirans by cationotropic reactions, was patented in 1948: [207]

$$HOCH_2CH(SH)CH_2SH \xrightarrow[-H_2O]{} HSCH_2CH\!-\!CH_2 \quad (S)$$

Better results were obtained in the pyrolysis of mercaptoalkanols in the presence of acids. Ethylene monothioglycol is converted into thiiran over potassium hydrogen sulphate at a temperature as low as 120°C. [208] The pyrolytic decomposition of ethylene monothioglycol in the monobutyl ether of triethylene glycol in the presence of t-dodecyl mercaptan [7,7-dimethyloctanethiol] and sulphuric acid leads to the formation of thiiran in 92.3% yield [209]. The initial cleavage of the C–OH bond with formation of the carbonium ion, which cyclises with elimination of a proton, is most likely in these reactions:

$$HOCH_2CH_2SH \xrightarrow[-HO^-]{} \overset{+}{C}H_2\!-\!CH_2SH \xrightarrow[-H^+]{} CH_2\!-\!CH_2 \quad (S)$$

This mechanism of the closure of the three-membered ring, involving the elimination of a cation, may be called cationotropic.

A few other reactions involving the formation of thiiran rings, which can be classified as cationotropic, are also known. Petrov and Sokol'skii [210] described the formation of 2-methylthiiran from chloromethyl ethyl sulphide in anhydrous hydrofluoric acid. Bearing in mind the ease of the heterolytic dissociation of the C–Cl bond in chloromethyl sulphides, the initial compound presumably dissociates with formation of a carbonium ion. The latter undergoes cationotropic cyclisation, facilitated by the $+I$ effect of the methyl group:

$$CH_3\!-\!CH_2\!-\!S\!-\!CH_2Cl \xrightarrow[-Cl^-]{} CH_3\!-\!\overset{H}{\underset{}{CH}}\!-\!\overset{+}{S}\!-\!CH_2 \xrightarrow[-H^+]{} CH_3\!-\!CH\!<\!\begin{matrix}CH_2\\S\end{matrix}$$

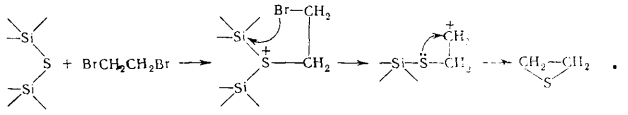
In this case cationotropic reactions do not involve the sulphur atom and the thiiran ring is formed from the carbon skeleton. There are similar reactions between $\alpha\alpha'$-dibromosulphoxides and phosphorus tris(dimethylamide) [211], which most probably involve the preliminary formation of an adduct of the quasiphosphonium type:

$$RCHBrSCHBrR' \;(\overset{\|}{O}) + [(CH_3)_2N]_3P \rightarrow RCH\!-\!CHR' \;(S,\overset{\|}{O}) + [(CH_3)_2N]_3PBr_2$$

The unusual reactions of compounds containing both sulphur and silicon with alkyl halides can be regarded as another example of processes of this kind [212]. On heating with dibromoethane, hexamethylcyclotrisilthiane decomposes by the reaction

$$[(CH_3)_2Si]_3S_3 + BrCH_2CH_2Br \rightarrow \begin{matrix}CH_2\!-\!CH_2\\ \diagdown S \diagup\end{matrix} + (CH_3)_2SiBr_2$$

The reactions in this system involving a preliminary alkylation of the sulphur atom can be attributed to the low strength of the Si–S bond and the high affinity between silicon and halogen atoms. The cationotropic transformations in this reaction involve the sulphur atom:



Reactions involving the cationotropic formation of episulphonium salts are of the same type. In a study by Gladshtein and Soborovskii [213] the methiodide of thiiran was obtained by treating the 2-thiocyanatoethyl ester of dimethylcarbamic acid with methyl iodide. The sulphonium salt formed initially in this reaction decomposes on heating to 100°C with decarboxylation and in the presence of methyl iodide undergoes further reactions:

$$(CH_3)_2NC(O)OCH_2CH_2SCN + CH_3I \rightarrow (CH_3)_2NC(O)OCH_2CH_2S\!-\!\underset{I}{\overset{CH_3}{CN}} \xrightarrow[-CO_2]{100^\circ}$$

$$\rightarrow (CH_3)_2NCH_2CH_2S\!-\!\underset{I}{\overset{CH_3}{CN}} \rightarrow CH_2\!-\!CH_2 \;(S^+\!-\!CH_3)\; I^- + (CH_3)_2NCN$$

Judging from the properties quoted by Gladshtein and Soborovskii [213], the structure $(CH_3)_2NCH_2CH_2SCH_3.ICN$ may be attributed to the decarboxylation product. Its conversion into the episulphonium salt is due to the cleavage of the C–N bond by iodine cyanide:

$$(CH_3)_2NCH_2CH_2SCH_3 + ICN \rightarrow \overset{+}{C}H_2\!-\!CH_2\!-\!\overset{+}{S}(CH_3) \rightarrow CH_2\!-\!CH_2\;(S^+\!-\!CH_3)$$

Knunyants and coworkers [214] described an elegant method for the preparation of episulphonium salts by the reaction of the amides of β-chloro-α-methylthioalkanecarboxylic acids with silver toluene-p-sulphonate. The reactions take place readily in solution in acetonitrile:

$$ClCRR'CR''C(O)NHR''' \rightarrow RR'C\!-\!CR''C(O)NHR'''\;(S^+\!-\!CH_3)$$
$$\quad\quad SCH_3$$

They proceed via a stage involving the formation of a carbonium ion, which rearranges to the sulphonium ion.

The above examples demonstrate the ready formation of thiiran rings by cationotropic reactions of 2-substituted thiol derivatives. The cationotropic closure of the thiiran ring can be achieved by the formation of the two-carbon skeleton or the C–S bond of the ring.

6. THE REACTIONS OF THIIRANS WITH RETENTION OF THE THIIRAN RING

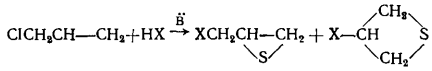
There have been only a few syntheses of thiirans by this procedure. It has been shown in a patent [215] and in another report [113] that 2-acylthiomethylthiirans can be obtained by the selective acylation of 2-mercaptomethylthiiran:

$$HSCH_2CH\!-\!CH_2\;(S) \xrightarrow{(CH_3CO)_2O} CH_3C(O)SCH_2CH\!-\!CH_2\;(S)$$

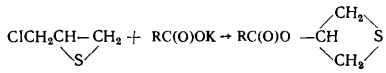
The electrophilic opening of the thiiran ring by acid anhydrides and chlorides takes place under more severe conditions, which makes it possible to obtain high yields of products formed by the acylation of the mercapto-group.

A wide variety of 2-methylthiiran derivatives have also been obtained by the nucleophilic substitution of the halogen atom in 2-halogenomethylthiirans. Unambiguous reactions occur only when 2-chloromethylthiiran reacts with thiophenols [216-219] and aliphatic thiols [220-223]. 2-Alkyl(aryl)methylthiirans are usually synthesised in aqueous media, using sodium and potassium hydroxides as the condensing agents:

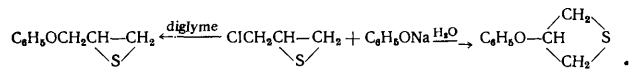
The reactions of 2-halogenomethylthiirans with phenols, alcohols, carboxylic acids, thiolocarboxylic acids, and *OO*-dialkylphosphorodithiolic acids are accompanied by side reactions as a result of the thiiran–thietan rearrangement:



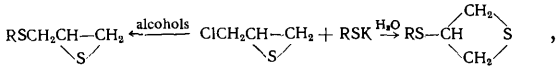
Under certain conditions, the side reaction can predominate and may even be the only one occurring. For example, the reaction of 2-chloromethylthiiran with potassium acetate in acetic acid results in the formation of 3-acetoxythietan and not a thiiran derivative [109]. 3-Acyloxythietans have also been obtained in a similar reaction of 2-chloromethylthiiran with sodium or potassium methacrylate, carbonate, chloroacetate, and benzoate in aqueous solutions [224,225]:



The mode of these reactions depends in many cases on the nature of the solvent employed. According to Sander [226], sodium phenoxides react with 2-chloromethylthiiran in diglyme to form 2-phenoxymethylthiirans, while in an aqueous medium the products are 3-aryloxythietans:



A similar behaviour was demonstrated by Arbuzov and coworkers [225,227-234] in reactions of *OO*-dialkylphosphorodithioate and thioacetate salts with 2-chloromethylthiiran. In aqueous solutions they observed the isomerisation of the thiiran ring to the thietan ring, while in anhydrous alcohols the main products were 2-acylthiomethylthiirans:

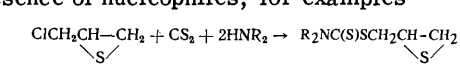


where R = CH_3CO or $(C_6H_5O)_2P(S)$. Similar results are presented in a patent [232].

The course of the thiiran–thietan rearrangement depends to some extent also on the nature of the reactants employed. In the reaction between 2-chloromethylthiiran and thioacetates the thietan derivative is formed in a greater amount than in the reaction with *OO*-diethylphosphorodithioate [225]. As the electrophilic properties of the initial thiiran are enhanced, its tendency to isomerise in the reaction increases [228]. 2-Bromomethylthiiran is readily converted into a thietan derivative even under anhydrous conditions, while 2-acetoxymethylthiiran forms thiiran derivatives on reactions with salts of thiolic acids even in aqueous media.

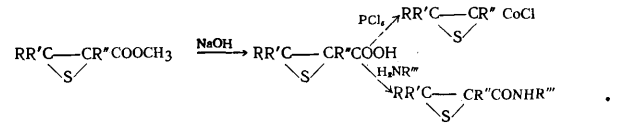
The available information suggests that the thiiran–thietan rearrangement proceeds at the stage involving the formation of an ion pair. Unambiguous transformations with retention of the thiiran ring presuppose the creation of conditions for the formation of an ion pair, the recombination of which to an uncharged molecule takes place before the isomerisation of the cation. The loosening of the ion pair by the solvation shell promotes the isomerisation of the thiiran ring to the thietan ring.

The three-membered ring of 2-chloromethylthiiran constitutes a weaker electrophilic centre than the carbon atom of the 2-methyl group. As a result, it is possible to obtain a wide variety of 2-methylthiiran derivatives from 2-chloromethylthiiran in complex systems and in the presence of nucleophiles, for examples [233,234]:

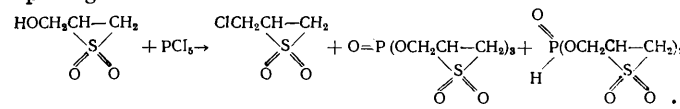


In the presence of aqueous alkali 2-chloromethylthiiran reacts with alcohols to form 2-alkoxymethylthiirans in yields up to 40% : [235]

Despite the relatively high susceptibility of the thiiran ring to cleavage, thiirans could not be made to undergo a wide variety of reactions. Knunyants and coworkers [152,153] described reactions of thioglycidic acids and their derivatives which do not involve ring opening. They showed that methyl esters of epithioglycidic acids are hydrolysed under mild conditions by dilute alkalis. The thioglycidic acids obtained in this way could be converted under mild conditions into acid chlorides and amides:

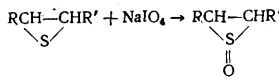


The reactions of 2-hydroxymethylthiiran 1,1-dioxide with phosphorus pentachloride also proceed without ring opening [187]:



The reactions of thiirans involving a change in the valence state of the sulphur atom constitute a special group. Mild oxidation of thiiran with hydrogen peroxide or perbenzoic acid leads to the formation of polyethylenesulphone [poly(thiiran 1,1-dioxide)] [71]. However, 2,3-diphenylthiiran is converted smoothly into thiiran 1-oxide or 1,1-dioxide in the presence of hydrogen peroxide or 3-chlorobenzoic acid [177,211]:

Thiiran 1-oxides and their homologues are obtained in high yields only on mild oxidation with sodium periodate in methanol [236]:



Thus the possibility in principle of the synthesis of thiiran compounds by reactions involving the substituents at the carbon atoms of the thiiran ring and the oxidation of the sulphur atom has now been established.

---o0o---

The available data on the chemistry of thiirans are much less extensive than those for their nitrogen- and oxygen-containing heteroanalogues. However, the number of reactions leading to the closure of thiiran rings which have now been investigated is not less then the number of tested methods for the synthesis of oxiran, aziridine, and their homologues.

The available information about the syntheses of thiirans embraces virtually all possible types of methods for the homolytic and heterolytic formation of ring *endo*-bonds. Syntheses of thiirans involving the formation of their two-carbon skeleton via a homolytic mechanism and also via anionotropic and cationotropic cyclisation have been described. Methods based on the homolytic, anionotropic, and cationotropic closure of thiiran rings at the C–S bond have been widely investigated.

Numerous procedures for the preparation of thiirans are formally similar to the syntheses of aziridines and oxirans. For example reactions involving the anionotropic closure of thiiran rings at the C–S bond resemble the Gabriel–Wenker syntheses of aziridines and the chlorohydrin syntheses of oxiran and its homologues. Also similar are the methods for the synthesis of *N*-, *O*-, and *S*-heteroanalogues of cyclopropane based on the condensation of imines, carbonyl compounds, and thiocarbonyl compounds with carbenes, the pyrolysis of nitrogen-containing heterocyclic compounds, and cationotropic transformations of acyclic compounds. Thiirans are formed more readily in such reactions than oxirans and aziridines and the reactions themselves are more general. This is undoubtedly because of the smaller strain in thiiran rings and the characteristics of the electronic structure and behaviour of the sulphur atom.

The greater ease of formation of thiiran rings on energy grounds compared with oxirans is clearly shown in the reactions of derivatives of 2-mercaptoalkanols. The formation of three-membered heterocycles from ethylene carbonate and monothiocarbonate [2-oxo-1,3-dioxolan and 2-oxo-1,3-oxathiolan] takes place under virtually identical conditions (200°C). In the latter case the only product is thiiran. Thiiran and not oxiran is also formed from 2-mercaptoethanol and its acyl derivatives under the conditions of the anionotropic and cationotropic ring closure.

The methods for the synthesis of thiirans discussed in the review suggest a great scope for the synthesis of these compounds from simple readily available substances. From this point of view, there is no doubt that further development of thiiran chemistry can serve as one of the rational ways of solving problems which are at present important, namely that of the utilisation of sulphur and its simple compounds. On the other hand, the great synthetic possibilities in the series of thiiran compounds lead to good prospects for theoretical research. It is sufficient to mention that the discovery of the formation of thiiran compounds containing a ring formed at the double bonds of alkenes or in a chain of conjugated double bonds [26,180] is of general theoretical interest. The chemistry of thiirans with a halogen attached to the ring suggests ways for the investigation of the simplest heteroaromatic compounds with three-membered rings [206]. The syntheses and reactions of thiiran derivatives are of interest for modern stereochemistry.

Functionally Substituted Cyclopropanes

L.A.Yanovskaya and V.A.Dombrovskii

Progress in the synthesis of functionally substituted cyclopropanes is surveyed together with certain of their properties as well as aspects of their structure and the transmission of electronic effects through the cyclopropane ring. A list of 225 references is included.

CONTENTS

I. Introduction 154
II. Synthesis of functionally substituted cyclopropanes 154
III. Some reactions of functionally substituted cyclopropanes 161
IV. Structure and transmission of electronic effects through the cyclopropane ring 162

I. INTRODUCTION

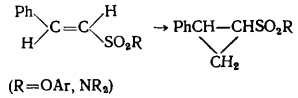
Functionally substituted cyclopropanes are of considerable interest. Firstly, they are fairly widely distributed in Nature. Examples are well known insecticides present in pyrethrum (*Chrysanthemum cinerariaefolium* Vis.), which are chrysanthemic esters and pyrethrolone or cinerolone ethers; and *cis*- and *trans*-isomers of 2-chloro-3-non-7'-ene-1', 3', 5'-triynylcyclopropylmethyl acetate have recently been detected[1] in *Centaurea ruthenica* Lam. The attractant of the American cockroach *Periplaneta americana* is also a cyclopropane derivative, for which the structure 2-isopropylidene-3,3-dimethylcyclopropyl propionate was suggested[2]. Furthermore, several cyclopropane derivatives, e.g. 2-(2,6,10,14-tetramethylpentadeca-1,5,9,13-tetraenyl)-3-(4,8,12-trimethyltrideca-3,7,11-trienyl)cyclopropylmethyl pyrophosphate (prephytoene pyrophosphate), are intermediates in the biosynthesis of steroids and carotenoids[3]. Several cyclopropane derivatives possess interesting physiological properties, like the above-mentioned derivatives of chrysanthemic acid, which have hitherto attracted the attention of chemists seeking new insecticides[4,5]. They exhibit not only insecticidal but also other types of activity. Thus several ketones have shown high anti-inflammatory activity[6].

The use of functionally substituted cyclopropanes as a convenient model for studying the ability of the cyclopropane ring to conjugate with the π-electrons of multiple bonds and examining the transmission of electronic effects through the ring has enabled a considerable approach to be made during recent years to solving this most complicated problem. Finally, several behavioural peculiarities of functional groups attached to a cyclopropane ring have been discovered recently.

The growing interest in functionally substituted cyclopropanes has led to the appearance of many publications on their synthesis, structure, and properties, but no systematic review of these results. The last survey of cyclopropane chemistry appeared in 1962 [7] and, of course, does not represent the present-day situation. The well known Houben—Weil work of reference[8] (1971) deals with methods for synthesising a cyclopropane ring irrespective of their possible use to obtain particular functional derivatives. We have therefore considered it useful to examine the most important papers on the synthesis, properties, and theoretical aspects of the chemistry of functionally substituted cyclopropanes which appeared between 1962 and 1973, referring to earlier work only in cases of extreme necessity.

II. SYNTHESIS OF FUNCTIONALLY SUBSTITUTED CYCLOPROPANES

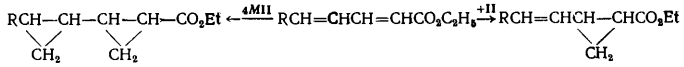
A most important advance in the synthesis of functionally substituted cyclopropanes during this period has been the practical introduction of the readily available sulphur ylides, which are able to transfer a methylene group to the polar double bonds of many unsaturated compounds to form cyclopropane derivatives. Examples are dimethylsulphonium methylide $(CH_3)_2\overset{+}{S}-\overline{C}H_2$ (I),[9-12] dimethylsulphoxonium methylide $(CH_3)_2\overset{+}{S}(O)-\overline{C}H_2$ (II),[13,14] aryldimethylaminosulphoxonium methylides $ArN(CH_3)_2.\overset{+}{S}(O)-\overline{C}H_2$ (III),[15,16] methyldialkylamino-oxosulphonium methylides $(CH_3).NAlk_2\overset{+}{S}(O)-\overline{C}H_2$ (IV),[17] etc. Among the suggested ylides, (II) and the highly reactive (IV) have been most widely used. Cyclopropanes can be synthesised also by means of functionally substituted sulphylides, such as dimethylsulphonium phenacylide $(CH_3)_2\overset{+}{S}-\overline{C}H.CO.C_6H_5$ (V),[18-20] methylphenylsulphonium phenacylide (VI),[21,22] dimethylsulphonium alkoxycarbonylmethylides $(CH_3)_2\overset{+}{S}-\overline{C}H.COOR$ (VII),[23-26] etc. Thus both mono- and poly-functional cyclopropanes can be synthesised by the use of sulphylides. Of course, not all the proposed sulphylides are synthetically equivalent. For example, the sphere of action of the methylide (I) is restricted to esters and amides of $\alpha\beta$-unsaturated carboxylic and sulphonic acids[27]. Thus ethyl cinnamate reacts with the ylide (I) to form ethyl *trans*-2-phenylcyclopropane carboxylate in 54% yield. Similarly, *trans*-2-phenylethylenesulphonic esters and amides are converted into those of *trans*-2-phenylcyclopropanesulphonic acid[27]:



(R=OAr, NR_2)

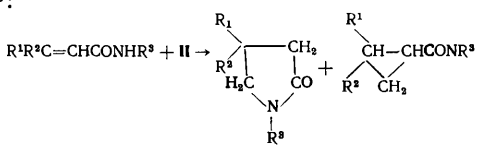
$\alpha\beta$-Unsaturated aldehydes and ketones react with (I) to form oxirans[11,12,14].

The methylide (II) is able to react also with esters of $\alpha\beta$-unsaturated mono- and di-carboxylic acids[10,28-31] to form high yields of esters of cyclopropane-mono- and -di-carboxylic acids. It is interesting that esters of diene acids react preferentially at the $\alpha\beta$-position. When a large excess of the methylide (II) is used, however, the diadduct can also be obtained[32]:



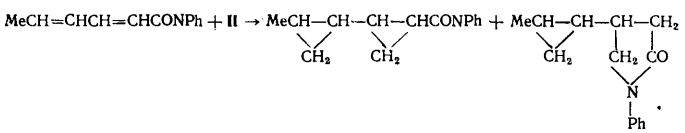
It must be emphasised that optically active 3-arylpropene-2-carboxylic esters yield optically active 2-arylcyclopropanecarboxylic esters on reaction with (II).[33] For example, (−)-menthyl and (+)-bornyl esters of cinnamic, *o*- and *p*-methoxycinnamic, and other acids react in this way.

Nitriles and amides of $\alpha\beta$-unsaturated acids also react with the methylide (II).[28,30,31,34] The former give nitriles of cyclopropanecarboxylic acids. Thus a 52% yield of 2-phenylcyclopropyl cyanide has been obtained from cinnamonitrile. Depending on their structure, amides will form amides of cyclopropanecarboxylic acids[35], pyrrolidones[30,34], or mixtures of an amide and a pyrrolidone[30,35]:

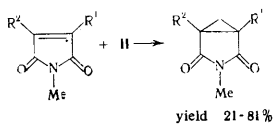


R^1	R^2	R^3	(VIII) Yield, %	(IX) Yield, %
H	H	H	50	0
Ph	H	H	0	40
Me	H	Ph	80	11

Sorbanilide forms a mixture[30,35]:

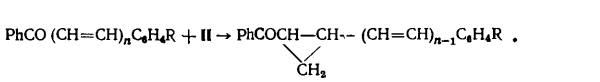


Reaction takes place between α-aryl-*N*-methylmaleimides and (II) without complications[34]:



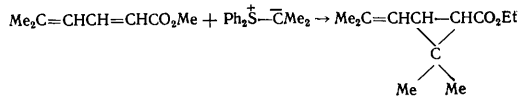
yield 21-81%

The reaction of conjugated ketones with the ylide (II), in contrast to that with (I), usually gives cyclopropyl ketones (aldehydes also form oxirans). Thus 5-methylhex-3-en-2-one and 3,6-dimethylhept-3-en-2-one are converted into the corresponding cyclopropyl ketones in 35–80% yields[30,31]. Alkyl aryl ketones—1-phenylbut-2-en-1-one[36] and chalcones[14,37]—react similarly, to give good yields of *trans*-aryl-2-benzoylcyclopropanes. In the case of vinylogues of chalcones reaction occurs at the double bond adjacent to the carbonyl group[37]:



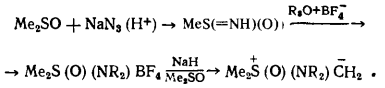
Use of the dideuterated methylide (II) enables aryl-2-benzoyl-3,3-dideuterocyclopropanes to be obtained[38,39].

The very reactive diphenylsulphonium isopropylide can be used for the synthesis of *gem*-dimethylcyclopropane systems having carbonyl functions[40]. A good yield of methyl (±)-*trans*-chrysanthemate has been obtained in this way[40]:



Methyl 2,2-dimethylcyclopropanecarboxylate (yield 71%) has been obtained similarly from methyl acrylate, dimethyl *cis*- and *trans*-3,3-dimethylcyclopropane-1,2-dicarboxylates (yields 75% and 82%) have been obtained from dimethyl maleate and fumarate respectively, etc.

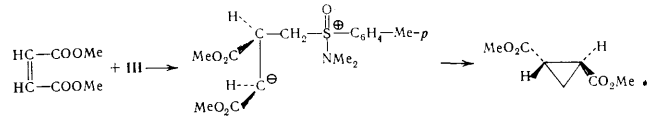
Use of the ylides (III) (Ar = C_6H_5) [15,16] and especially (VI) [17,41] has been recommended during recent years for the synthesis of functionally substituted cyclopropanes. These are readily accessible reagents, formed from dimethyl sulphoxide:



Cyclopropanes are easily formed by means of (III) and (IV) from cinnamic esters, mesityl oxide, benzylidenacetophenone, cyclohexenone, cinnamonitrile, phenyl styryl sulphone, etc. in yields of 50–98%. However, the main reaction product obtained from acrylo-*p*-toluidide is *N*-*p*-tolylpyrrolid-2-one.[30]

Use of the optically active (*R*)(−)-dimethylamino-oxo-*p*-tolylsulphonium methylide enables optically active cyclopropanes to be obtained in a quite high degree of optical purity. Thus the reaction of this ylide with methyl cinnamate gives methyl *trans*-(1*S*, 2*S*)-(+)-2-phenylcyclopropanecarboxylate in 76% yield with 30.4% optical purity[42].

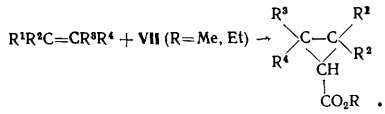
The reaction with sulphylides involves the intermediate formation of a betaine, which is confirmed by the formation of a single product—dimethyl *trans*-(1*S*, 2*S*)-cyclopropane-1,2-dicarboxylate (yield 50%, optical purity 17.8%)—on addition of the optically active ylide (III) (R = *p*-$CH_3C_6H_4$) to dimethyl maleate:



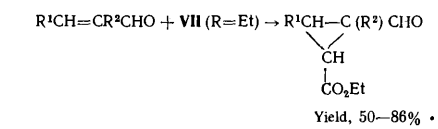
Formation of a *trans*-isomer from an initial *cis*-compound might have been explained by rotation about the single bond in the intermediate betaine, provided that formation of the latter was reversible. However, the above ylide (III) is able to isomerise dimethyl maleate into dimethyl fumarate[42].

Among the functionally substituted ylides (V)–(VII) the ethoxycarbonylide (VII) has found most extensive application during recent years, and provides an easy route to polyfunctionally substituted cyclopropanes. The ylide (VII) (R = C_2H_5) reacts readily with $\alpha\beta$-unsaturated esters (acrylic, methacrylic, crotonic, etc.), $\alpha\beta$-unsaturated ketones (methyl vinyl ketone, mesityl oxide), and nitriles (acrylonitrile) to form 45–90% yields of the corresponding

cyclopropanes when the reaction is conducted in an aprotic solvent (acetone, benzene, dichloromethane) at 45—80°C:[23-25,43]



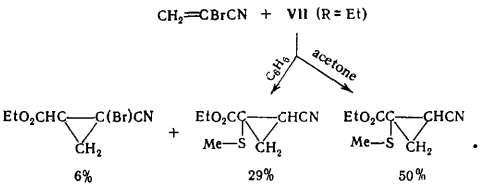
A most interesting feature of this ylide (VII) is that it reacts with $\alpha\beta$-unsaturated aldehydes, not at the carbonyl group like all other sulphylides, but at the double bond to form aldehyde derivatives of cyclopropane:



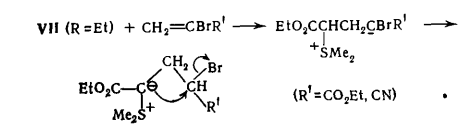
Yield, 50—86%.

Only acylic derivatives are obtained when the reaction is conducted in alcohol[44].

It is interesting that reaction of the ethoxycarbonylide (VII) with 2-bromoethyl acrylate in benzene forms a mixture of diethyl 1-bromocyclopropane-1,2-dicarboxylate and 1-methylthiocyclopropane-1,2-dicarboxylate (yields 36% and 25%), whereas in acetone only the latter product is formed in 52% yield. Reaction with α-bromoacrylonitrile occurs similarly:

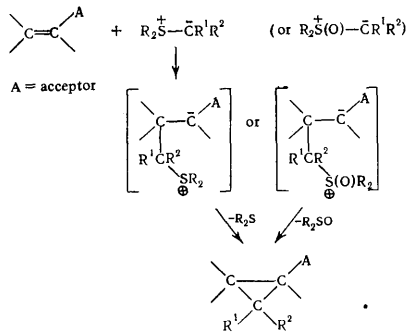


This can be explained by nucleophilic displacement in the intermediate betaine in polar solvents[24]:



The ylide (VI) reacts similarly to **VII** with $\alpha\beta$-unsaturated esters and ketones[21,22]. 1,2-Dibenzoyl-3-phenylcyclopropane (yield 77%) and 1,2,3-tribenzoylcyclopropane have been obtained by its use[20].

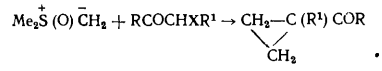
Methylene transfer is usually regarded as nucleophilic addition of the sulphylide at the polar double bond followed by elimination of a sulphide or a sulphoxide:



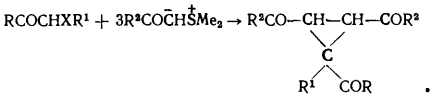
Transfer involving formation of a carbene is possible in certain special cases, e.g. in the decomposition of benzyldiphenylsulphonium tetrafluoroborate by the action of n-butyl-lithium in the presence of acenaphthylene in oxolan at −40°C with the formation of an isomer of 2-phenylphenalene[45], in the thermal decomposition of phenacyldimethylsulphonium bromide in the presence of cyclohexene with the formation of 7-benzoylbicyclo[4,1,0]heptane[18], and in the thermal decomposition of dimethylsulphonium aroylylides to 1,2,3-triaroylcyclopropanes[46].

In most cases transfer of the methylene group of sulphylides occurs stereospecifically with exclusive formation of *trans*-isomers[28,32,36-39,47]. Sometimes, however, e.g. in the reaction of the ylides (IV) with cinnamonitrile, a mixture of *cis*- and *trans*-isomers is formed (21% + 79%).[17] Similarly, the action of the ylide (VII: R = C_2H_5) on methacrylaldehyde give a mixture of *cis*- and *trans*-isomers in the proportions 68:2, with acrylaldehyde and crotonaldehyde the mixture contained 17—18% of the *cis*-isomer, with methyl vinyl ketone 2%, ethyl acrylate 3%, and methyl acrylate 9%. Chalcone, however, gave a mixture of roughly equal quantities of *cis*- and *trans*-isomers[43].

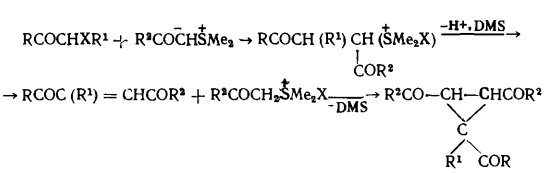
The use of sulphylides in the synthesis of cyclopropanes is not confined to reaction with activated double bonds. It was observed[22] in 1966 that the ylide (VI) reacts with bromoacetic ester in chloroform to give ethyl 2,3-dibenzoylcyclopropanecarboxylate, though in only 4,1% yield. It has since been suggested[48,49] that cyclopropyl ketones and cyclopropanecarboxylic esters can be synthesised by the action of the ylide (II) on α-halogenoketones (1-bromo-3,3-dimethylbutan-2-one, 2-chlorocyclohexanone, ω-bromoacetophenone, 2α-chlorotestosterone acetate, etc.) and on esters of α-halogenated acids (ethyl α-bromobutyrate, methyl α-bromo-α-phenylacetate):



The reaction is conducted with excess of the ylide in oxolan at −20° to −30°C, and the yields vary from 13% to 40%. The use of ylides of type (VI) enables trisubstituted cyclopropanes to be synthesised[50]:



Yields are 65—87% with bromo-ketones and phenacylides, and vary from 50% to 90% with alkoxycarbonylides. The probable reaction scheme



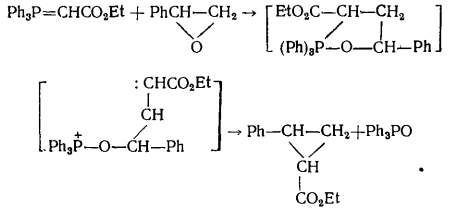
was suggested[50].

A further route for synthesising polyfunctional cyclopropanes by means of sulphylides is the reaction between mono- or di-substituted vinyldimethylsulphonium methyl sulphates $R^1.CH:CR.S(CH_3)_2CH_3SO_4$ and sodium derivatives of acids in alcoholic solution at 0°C:[51-53]

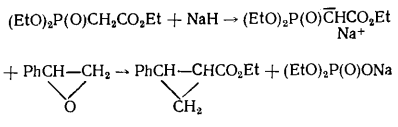
This method has been used to obtain 1,1-dicyano-2-phenylcyclopropane (yield 30%) from malononitrile, ethyl 1-cyano-2-phenylcyclopropanecarboxylate (60%) from

cyanoacetic ester, diethyl 2-phenylcyclopropane-1,1-dicarboxylate (60%) from malonic ester, etc. In every case only the *trans*-derivative was formed[53].

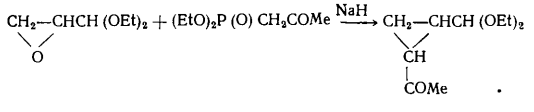
Phosphonium ylides also can be used for synthesising functionally substituted cyclopropanes, but to a limited extent. The most interesting method is the reaction of stable phosphonylides with epoxides[54-56], first described in 1962.[54] Thus ethyl triphenylphosphoranylidenacetate reacts with the α-oxides of oct-1-ene, cyclohexene, and styrene to form the corresponding cyclopropanecarboxylic esters and triphenylphosphine oxide. When styrene *l*-(−)-α-oxide is used, the optically active *trans*-cyclopropane is formed, though in low optical yield:



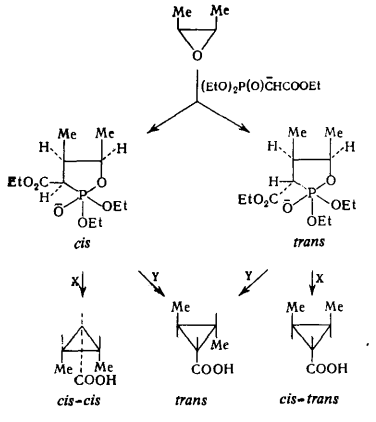
Phosphonate carbanions react similarly to phosphoranes with α-oxides of alkenes[57-61]. Thus ethyl diethoxyphosphinylacetate reacts with phenyloxiran in the presence of sodium hydride in diglyme at 85°C to form ethyl 2-phenylcyclopropanecarboxylate (yield 42%):[57]



A most interesting example is the synthesis of the acetal of 1-acetyl-2-formylcyclopropane in 60% yield[62] by the reaction of diethyl acetonylphosphonate with 2-diethoxymethyloxiran in the presence of sodium hydride in diglyme at 100—110°C:

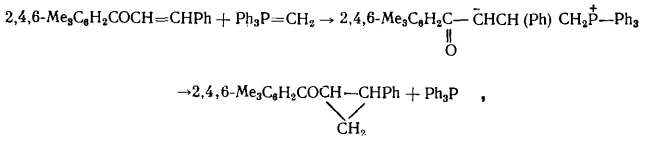


Fairly detailed investigations[54,58,63,64] led to the following mechanism for the reaction of phosphonates with oxides:



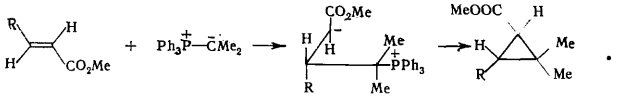
Such a scheme is supported by a study of the reaction of optically pure *trans*-(+)(2*R*, 3*R*)-2,3-dimethyloxiran and of the corresponding *cis*-isomer with ethyl diethoxyphosphinylacetate[64], to give after hydrolysis of the optically active *trans*-isomer a mixture of 90% of *trans*-(+)(2*S*, 3*S*)-2,3-dimethylcyclopropanecarboxylic acid, 6% of *cis*-2,*cis*-3-dimethylcyclopropanecarboxylic acid, and 1% of *cis*-2,*trans*-3-dimethylcyclopropanecarboxylic acid; the *cis*-isomer gave a mixture of 4% of racemic *trans*-2,3-dimethylcyclopropanecarboxylic acid, 6% of the *cis*,*cis*-isomer, and 90% of the *cis*,*trans*-isomer. Such proportions are explained by the relative quantities of intermediate cyclic products and(or) the relative possibility of X processes (direct decomposition of the intermediate ring by a synchronous mechanism or via a zwitterion) and Y processes (ring opening followed by attack from the rear); in the opening of the *cis*-oxide they undoubtedly represent steric control of the reaction after opening of the phosphonate ring.

Phosphylides can in some cases react also with $\alpha\beta$-unsaturated aldehydes and ketones to form cyclopropanes, not alkenes. Thus methylenetriphenylphosphorane reacts with mesityl α-styryl ketone[65] to form mesitoyl-2-phenylcyclopropane and triphenylphosphine:



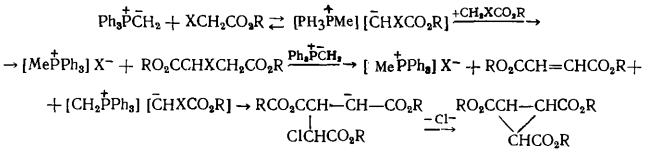
Steric hindrance by the mesityl group probably prevents reactions at the carbonyl group.

A convenient synthesis of *trans*-2,2-dimethylcyclopropanecarboxylic esters is based on the 1,4-addition of triphenylphosphonium isopropylide to *trans*-$\alpha\beta$-unsaturated esters followed by cyclisation of the intermediate with elimination of triphenylphosphine[66]:



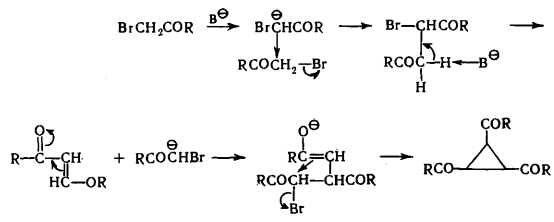
Stable arsenic ylides react[67] with fumaric ester and *trans*-dibenzoylethylene to give good yields of the difficultly accessible 1,2,3-trisubstituted cyclopropanes in which all three substituents are electron-accepting:

Certain phosphylides react with esters of α-halogenated acids to form trialkyl cyclopropane-1,2,3-tricarboxylates[68,69], for which the scheme

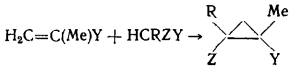


was suggested. The phosphylide thus acts as a base analogous to potassium t-butoxide, whose action on α-chloroacetamide gives *trans*-cyclopropanetricarboxamide[70]. Similar changes are produced also by the action

of lithium in liquid ammonia on ethyl bromoacetate[71] or of sodium hydride in Hexametapol on benzyl bromides or halogeno-acetic esters[72,73]:

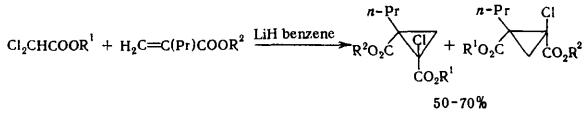


The formation of unsaturated compounds during the reaction is confirmed by the fact that ethyl bromoacetate reacts with ethyl acrylate or diethyl fumarate under the same conditions to form respectively diethyl cyclopropane-*trans*-1,2-dicarboxylate (yield 32%) and triethyl cyclopropane-*trans*-1,2,3-tricarboxylate (64%).[73] Thus the above reactions represent a particular case of the synthesis of cyclopropanes by the interaction of unsaturated compounds, activated by electron-accepting substituents (alkoxycarbonyl, cyano), with α-halogenated acids, ketones, or nitriles in the presence of hydrides or alkali-metal alkoxides[74-79]:



The isomer in which the electron-accepting groups activating the initial molecules are arranged in mutually *cis*-positions is often the principal or even the only product in this reaction. Thus methyl methacrylate reacts with methyl chloroacetate to give a 69—71% yield of a mixture of 93% of *cis*- and 7% of *trans*-dimethyl 1,2-dimethylcyclopropane-1,2-dicarboxylates; with methyl dichloroacetate only dimethyl *cis*-1-chloro-2-methylcyclopropane-1,2-dicarboxylate is obtained, in 74% yield. However, the reaction of methyl methacrylate with ethyl iodoacetate gives a 21% yield of a mixture of equal quantities of *cis*- and *trans*-isomers[74].

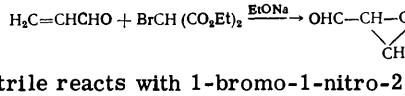
This method has recently undergone further development. Esters formed with different alcohols can be used, e.g. ethyl dichloroacetate and methyl α-propylacrylate, to give cyclopropanedicarboxylic esters with different alkyls[80]:



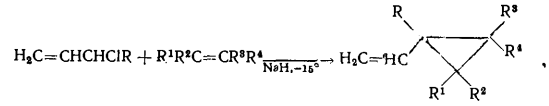
50-70%

The reaction is especially selective when an alcohol corresponding to the dichloroacetate is used to decompose the reaction mixture.

α-Unsaturated aldehydes also undergo this reaction. Thus acrylaldehyde and ethyl bromomalonate in the presence of sodium ethoxide give a 50% yield of diethyl 2-formylcyclopropane-1,1-dicarboxylate[81]:



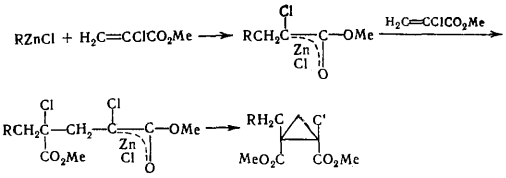
Malononitrile reacts with 1-bromo-1-nitro-2-R-ethylenes (R = C_2H_5, C_6H_5, p-$NO_2C_6H_4$) to form 1,1-dicyano-2-nitro-3-R-cyclopropanes[82]. Substituted vinylcyclopropanes can be obtained by applying the reaction to derivatives of 2-chlorobut-3-enoic acid[83]:



(R=CO_2Me, CN; R^4=COOMe, CN)

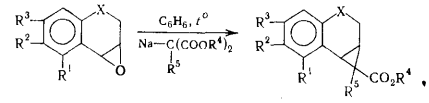
The stereochemistry of this reaction is controlled by the solvent: the formation of *cis*-isomers is favoured by solvents of low dielectric constant, and that of *trans*-isomers by solvents of high dielectric constant. In the reaction of 2-chlorobut-3-enonitrile with methyl acrylate in toluene, for example, methyl 2-cyano-2-vinylcyclopropanecarboxylate is formed with a total yield of 33%, comprising a 73 : 27 mixture of *cis*- and *trans*-isomers; when the reaction is conducted in Hexametapol the same cyclopropane is formed in 41% yield, comprising a 13 : 87 mixture.

A method proposed recently for synthesising cyclopropanedicarboxylic acids is based on the reaction of 2 moles of an α-chloroacrylate with 1 mole of an alkylzinc halide[84-87], and also enables *cis*-isomers to be obtained:



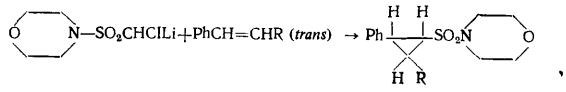
Partial asymmetric synthesis can be effected by the use of an optically active alkylzinc methoxide or a mixture of diethylzinc and an optically active alcohol (*l*-menthol).

Another new reaction for the formation of a cyclopropane ring consists in the nucleophilic opening of an oxide in the presence of a sodiomalonic ester in a non-polar medium[88,89]:



(X = CH_2, O) yield 37-64%

Addition of α-chloromorpholinosulphonylmethyl-lithium to an activated double bond to yield a cyclopropane[90] may be of interest:



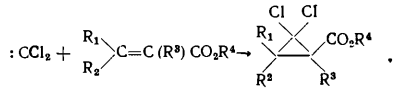
(R=SO_2Ph, CN, NO_2) yield 21-73%

Such are the new synthetic methods which are of interest for the preparation of functionally substituted cyclopropanes. In addition, traditional methods have undergone further development, Firstly, unsaturated compounds have been treated with carbenes, which behave as electrophilic reagents[91]. Synthesis is based mainly on the addition of carbenes to functionally substituted alkenes. Functionally substituted carbenes—phenoxycarbene[92-96], alkoxycarbenes[97-100], selenocarbenes[10] sulphocarbenes[102,103], dicyanocarbenes[104-107], and several others—are seldom used in cyclopropane formation, with the exception of ethyl carbenecarboxylate[108-113].

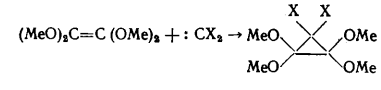
As in previous years the main sources of carbenes have been diazo-compounds and polyhalogenated derivatives, with published methods of cyclopropane synthesis differing

mainly in the mode of generation of the carbenes. It has been suggested that catalysts—copper powder[2,114,115], palladium acetate[116]—should be added to the diazo-compounds, in addition to the usual processes. Thus 2,4-dimethylpent-2-ene reacts with diazoacetic ester in the presence of copper powder to give ethyl 2-isopropyl-3,3-dimethylcyclopropanecarboxylate in 54% yield[2]. Similar methods of preparation have been used for *cis,cis*- and *trans,trans*-2-aryl-3-methylcyclopropanecarboxylic acids and esters[114], as well as for ethyl 2-methyl-3-propenylcyclopropanecarboxylates[115]. The corresponding cyclopropanes are formed by the action of diazoacetic ester on alkenes in the presence of palladium acetate in hexane[116]:

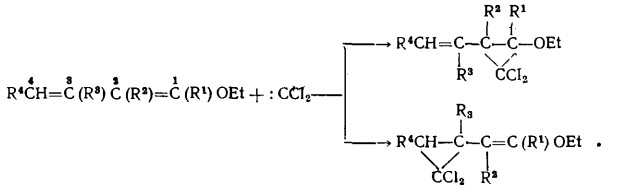
Dihalogenocarbenes have recently found fairly wide application for the synthesis of functionally substituted cyclopropanes. Besides traditional methods of generation (action of aqueous alkalis or alkoxides on polyhalogeno-derivatives) it has now been suggested that they should be generated by the action of aqueous caustic soda on polyhalogeno-derivatives in the presence of benzyltriethylammonium chloride as catalyst. The dichlorocarbene produced in this way adds e.g. at the double bond in $\alpha\beta$-unsaturated acids to form dichlorocyclopropanecarboxylic esters[117]:



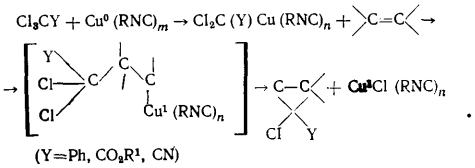
Interesting new examples have also been reported of the synthesis of functionally substituted cyclopropanes by means of dihalogenocarbenes. Thus dichlorocarbene adds at the double bond in acrylaldehyde diethyl acetal to form 1,1-dichloro-2-diethoxymethylcyclopropane in 33% yield[118]. An analogous reaction takes place with tetramethoxyethylene to give good yields of 1,1-dihalogeno-2,2,3,3-tetramethoxycyclopropanes[119]:



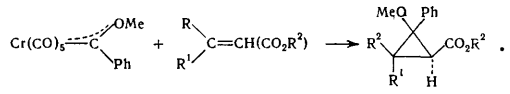
1-Ethoxybuta-1,3-dienes are also able to add dichlorocarbene. The reaction occurs non-stereospecifically, predominantly (67—100%) at the 3,4-double bond to give a mixture of substituted 1,1-dichloro-2-ethoxycyclopropanes (*trans*-1,2,*trans*-3,4 and *trans*-1,2,*cis*-3,4) in 20—40% yield[120]:



Polyhalogeno-derivatives can be used in other ways for the synthesis of cyclopropanes. Thus it has recently been suggested that alkenes having an electron-deficient double bond should be treated with copper carbenoid derivatives obtained by the reaction of trichloromethyl derivatives with copper and isocyanides[121,122]:



Functionally substituted cyclopropanes can be synthesised by the reaction of $\alpha\beta$-unsaturated esters with carbene complexes of transition-metal carbonyls. [123] For example, the complex of methoxy-phenylcarbene with chromium pentacarbonyl reacts stereospecifically when heated with *trans*-cinnamic, fumaric, and maleic esters to give 2-methoxy-2-phenylcyclopropane-mono- and -di-carboxylic esters:

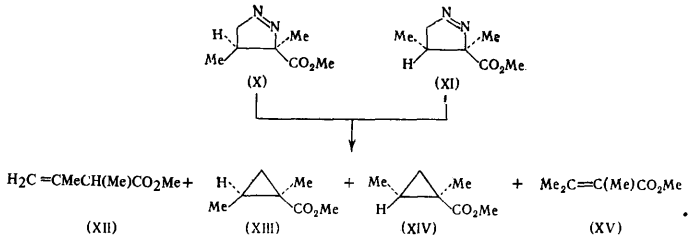


Several improvements have been introduced also into one of the oldest syntheses of cyclopropanes—the Simmons—Smith reaction. Thus an improved modification has recently been suggested in which the zinc—copper couple has been replaced by a zinc—silver couple, which enables functionally substituted cyclopropanes to be obtained in higher yields than by the original method. For example[124]

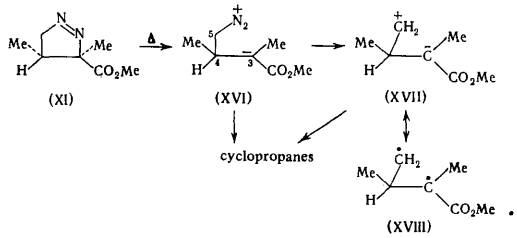
The Simmons—Smith reagent can be used[125] for the partial asymmetric synthesis of cyclopropanes from (−)-menthyl esters of $\alpha\beta$- and $\beta\gamma$-unsaturated carboxylic acids. Optically active *trans*-2-methylcyclopropanecarboxylic acid (yield 20—35%), *trans*-2′-methylcyclopropylacetic acid (54.5%), methyl *trans*-2-phenylcyclopropanecarboxylate (7—33%), and other derivatives have been obtained by this method[125].

The pyrolysis of pyrazolines is widely used to obtain cyclopropanes, and has been discussed in detail in several reviews[8,126,127]. We shall consider below only the most interesting new examples of the preparation of functionally substituted cyclopropanes by this method. Firstly, a detailed study by gas—liquid chromatography of the pyrolysis of methyl *cis*- and *trans*-3,4-dimethyl-Δ^1-pyrazoline-3-carboxylates showed[128] that, contrary to the widely held view, the configuration of the original molecule is in several cases not preserved in the thermal cleavage of Δ^1-pyrazolines, and the process is more complicated. For example, the pyrolysis of both *trans*- and *cis*-isomers (X) and (XI) gives a mixture of methyl 2,3-dimethylbut-3-enoate (XII), methyl *trans*-1,2-dimethylcyclopropanecarboxylate (XIII), methyl *cis*-1,2-dimethylcyclopropanecarboxylate (XIV), and methyl 2,3-dimethylbut-2-enoate

(XV), in the respective proportions 0.15 : 1.22 : 1.00 : 1.16 (X) and 0.24 : 0.70 : 1.00 : 3.73 (XI):



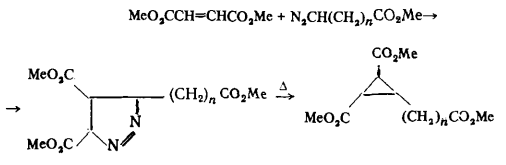
Since both mechanisms (ionic and biradical) suggested earlier for the thermal cleavage of Δ^1-pyrazolines involve preservation of the initial configuration, the non-stereospecificity observed in the above example was explained[128] on the assumption that the intermediate (XVI) is first formed, and is then converted with the loss of nitrogen into the intermediate (XVII), whose cyclisation yields the cyclopropanes:



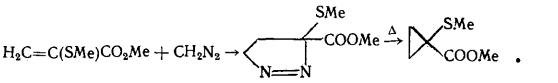
Loss of stereospecificity may result from free rotation about the $C_{(3)}-C_{(4)}$ bond, most probably in (XVI), since (XVII), which may resonate with the biradical (XVIII), would cyclise extremely rapidly.

Several new examples of the preparation primarily of cyclopropanemonocarboxylic acids and their derivatives by the pyrolysis of Δ^1-pyrazolines have been described during recent years[129-132]. Thus methyl 1-methylcyclopropanecarboxylate (yield 63%) has been prepared from methyl methacrylate via the corresponding Δ^1-pyrazoline; and a mixture of ethyl *cis*- and *trans*-2-phenylcyclopropanecarboxylates[133] from substituted styrenes and diazoacetic ester.

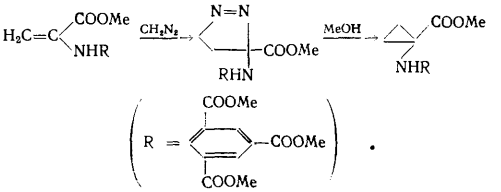
Furthermore, various cyclopropanes containing two carboxy-groups—in the ring or in the ring and in the side-chain—have been obtained by the thermal decomposition of Δ^1-pyrazolines from esters of unsaturated dicarboxylic acids[134-137]. The addition of ω-diazoalkanoic esters $N_2CH[CH_2]_nCOOCH_3$ ($n = 1-4$) to esters of unsaturated dicarboxylic acids is especially interesting, and leads to the formation of Δ^1-pyrazolinetricarboxylic acids, whose thermal decomposition gives cyclopropanetricarboxylic esters[138,139]:



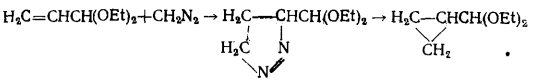
A few examples have also been reported of the preparation of cyclopropanecarboxylic acids containing other functional groups. Thus the Δ^1-pyrazoline obtained from methyl α-methylthio-acrylate and diazomethane is converted when heated (50°C) into methyl 1-methylthiocyclopropanecarboxylate[140]:



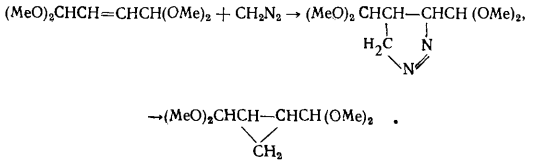
Similarly, boiling in methanol the Δ^1-pyrazoline from the tetramethyl ester of α-2, 4, 6-tricarboxyanilinoacrylic acid and diazomethane gives the tetramethyl ester of *N*-1′-carboxycyclopropylaniline-2, 4, 6-tricarboxylic acid[141,142]:



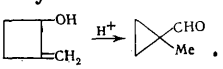
The Δ^1-pyrazoline from acrylaldehyde acetal and diazomethane is converted by pyrolysis at 400—450°C and 1 mm pressure into the acetal of cyclopropanaldehyde[143]:



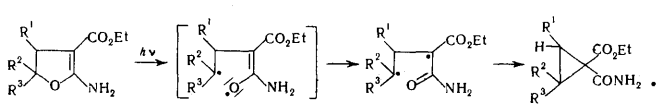
A method has been worked out[144] also for preparing 1, 2-bisdimethoxymethylcyclopropane[144] by the decomposition under similar conditions of 3, 4-bisdimethoxymethyl-Δ^1-pyrazoline, obtained from the easily accessible diacetal of fumaraldehyde and diazomethane, the yield reaching 93%:



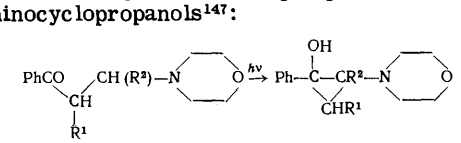
A few cases have been reported in which functionally substituted cyclopropanes have been formed in other ways. Thus heating 2-alkylidenecyclobutanols in a sealed tube or with 5% sulphuric acid converts them quantitatively into 1-alkylcyclopropanaldehydes[145]:



Irradiation of ethyl 2-amino-4, 5-dihydro-3-furoates in dioxan or oxolan in the presence of triphenylene or 2-naphthyl phenyl ketone as sensitiser yields a mixture of isomeric ethyl 1-carbamoylcyclopropanecarboxylates[146]:



Finally, the irradiation of certain 3-amino-ketones in dioxan in an atmosphere of nitrogen gives 80—95% yields of 2-aminocyclopropanols[147]:



Thus almost any functional cyclopropane can be prepared by variations on the different methods available.

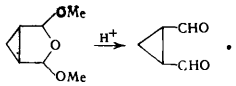
A fundamentally different method of obtaining functionally substituted cyclopropanes is to introduce functions into or to modify existing functional substituents in the cyclopropane ring, which presupposes a knowledge of the behaviour of various functional groups in the ring. Many data have been published on the reactions of cyclopropane rings involving rupture or change in the ring[7]. Considerably fewer publications have appeared on the reactions of functional groups attached directly to the cyclopropane ring. The following Section will be devoted to the most interesting new examples of such reactions.

III. SOME REACTIONS OF FUNCTIONALLY SUBSTITUTED CYCLOPROPANES

In most cases the behaviour of functional groups attached to a cyclopropane ring is almost identical with their behaviour in other classes of compounds. It has been shown during recent years, for example, that cyclopropylmethanol is oxidised to the aldehyde by hydrogen peroxide in the presence of iron(II) salts[148], aluminium isopropoxide[149], and also 1*N* aqueous ammonium cerium nitrate[150] (in the last case the yield of the aldehyde reaches 64%):

The acid hydrolysis of acetals of cyclopropane aldehydes goes in the usual way. Thus the diethyl acetal of cyclopropanaldehyde gives a 50% yield of the aldehyde when heated with 1*N* trichloroacetic acid[143]. The diethyl acetal of 2,2-dichlorocyclopropanaldehyde is hydrolysed, when heated with 12% sulphuric acid, to give a 50% yield of the corresponding aldehyde[118]. Finally, the hydrolysis of 1,2-bisdimethoxymethylcyclopropane gives, on heating with 6% phosphoric acid and removal of the resulting methanol by distillation, a 60% yield of cyclopropane-*trans*-1,2-dialdehyde[144] (the use of other acids or other conditions led to resinification and decomposition of the final hydrolysis product):

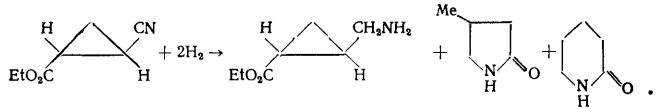
Hydrolysis of 2,4-dimethoxy-3-oxabicyclo[3,1,0]hexane even yielded the very unstable cyclopropane-*cis*-1,2-dialdehyde[151,152]:



Cyclopropyl cyanide undergoes fairly smooth reduction to cyclopropanaldehyde by the action of lithium hydrotriethoxyaluminate[153] or lithium hydrotri-n-butoxyaluminate[153]; and amides of cyclopropanecarboxylic acids, e.g. the ethylenamide[154] and the dimethylamide[155], are reduced quite smoothly by lithium tetrahydroaluminate, dihydrodiethoxyaluminate, or hydrotriethoxyaluminate. Yields of the aldehyde reach 20–60%, but, since it reacts under alkaline conditions, it can generally be isolated only as the 2,4-dinitrophenylhydrazine.

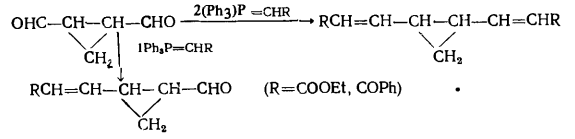
Cyclopropanecarbonyl chloride is reduced by lithium dihydrodi-t-butoxyaluminate to the aldehyde[154] (isolated only as the 2,4-dinitrophenylhydrazone). Similarly, Rosenmund reduction of cyclopropane-1,2-dicarbonyl dichloride gave cyclopropane-1,2-dialdehyde[156] (which also could be isolated only as the 2,4-dinitrophenylhydrazone).

The cyclopropane ring is preserved when ethyl *trans*-2-cyanocyclopropanecarboxylate undergoes catalytic reduction over Raney nickel under 50 atm at 35–37°C to ethyl 2-aminomethylcyclopropanecarboxylate[157]:



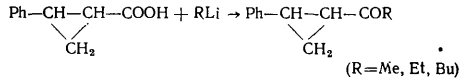
Boron hydride complexes reduce *N*-alkylidenecyclopropylamines only at the alkylidene group to the corresponding *N*-substituted cyclopropylamines in 70–90% yields[158].

Condensation of *trans*- and *cis*-2-phenylcyclopropanaldehydes goes normally with the sodium derivatives of phosphonacetic ester or benzylphosphonate to form ethyl *trans*- and *cis*-β-2-phenylcyclopropyl-α-R-acrylates (yield 50–60%).[159] Similarly, the condensation of dimethyl 2-formylcyclopropane-1,1-dicarboxylate with dimethyl 2-oxoheptylphosphonate gives a 70% yield of the αβ-unsaturated ketone[160]. Cyclopropane-1,2-dialdehyde also reacts with phosphonacetic ester, giving a 50% yield of diethyl cyclopropane-1,2-bis-α-R-β-acrylate[144]. Phosphonacetophenone and phosphonacetonitrile do not react with cyclopropane-1,2-dialdehyde under these conditions. The dialdehyde reacts normally under the conditions of the Wittig reaction, being converted by ethyl triphenylphosphoranylidenacetate and by phenyl triphenylphosphoranylidenemethyl ketone into products in which one or both aldehyde groups have reacted depending on the proportions of the reactants (yields 33–45%).[144]

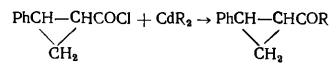


It is interesting that the condensation of phosphonacetic ester with dibenzoylcyclopropane in the presence of sodium hydride involves only one of the carbonyl groups even in the presence of excess of the reagent, and gives ethyl β-2-benzoylcyclopropylcinnamate[156].

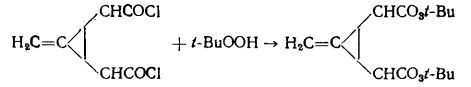
Treatment of the stereoisomeric 2-phenylcyclopropanecarboxylic acids with an alkyl-lithium under ordinary conditions gave the cyclopropyl ketones[161]:



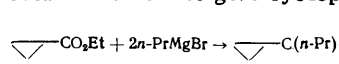
A dialkylcadmium converts cyclopropanecarbonyl chlorides also into ketones[161]:



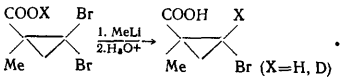
It is interesting that the action of t-butyl hydroperoxide on 3-methylenecyclopropane-1,2-dicarbonyl dichloride in pyridine gives a 70% yield of the di-t-butyl bisperoxycarboxylate[162]:



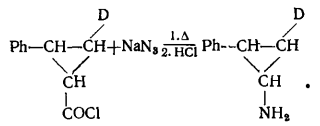
Ethyl cyclopropanecarboxylate reacts normally with *n*-propylmagnesium bromide to give cyclopropyldipropylmethanol[163]:



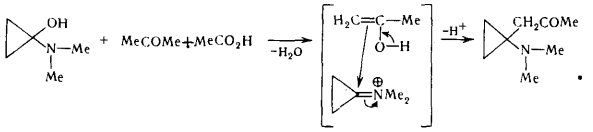
It is interesting that methyl-lithium causes stereoselective reduction of the bromine atom in the *cis*-position relative to the carboxyl in 2,2-dibromo-1-methylcyclopropanecarboxylic acid[164]:



Azides of stereoisomeric 2-deutero-3-phenylcyclopropanecarboxylic acids undergo the usual rearrangement to amines when heated[165]:

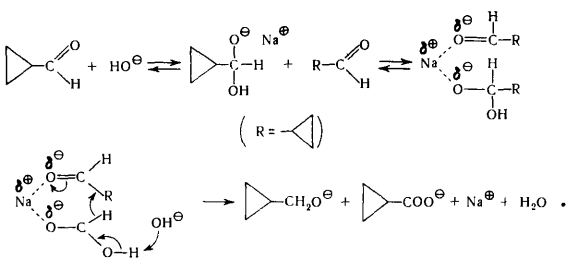


A Mannich base is obtained when 1-dimethylaminocyclopropanol is heated with acetone and acetic acid (at 65°C for 20 h):[166]



Acid hydrolysis of α-cyclopropyl-β-methoxystyrene goes normally to α-cyclopropylphenylacetaldehyde, which condenses in the usual way with but-3-en-2-one to give 4-cyclopropyl-4-phenylcyclohex-2-enone[167].

It has recently been shown that cyclopropanaldehyde, which contains an α-hydrogen atom, undergoes not an aldol condensation but the Cannizzaro reaction on treatment with aqueous alkali, with the formation of cyclopropylmethanol and cyclopropanecarboxylic acid. This is a second-order reaction with respect to aldehyde and alkali, and exhibits a small positive salt effect. Together with the absence of a deuterated cyclopropylmethanol when the reaction is conducted in heavy water, this suggests the reaction mechanism[168]



It is interesting that cyclobutanaldehyde forms aldol condensation products when treated with aqueous alkali[169].

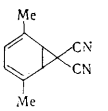
Thus functionally substituted cyclopropanes exhibit not only trivial behaviour but also unusual reactions, perhaps a consequence of structural peculiarities of the cyclopropane ring. The next Section will deal with current views on the structure of this ring system.

IV. STRUCTURE AND TRANSMISSION OF ELECTRONIC EFFECTS THROUGH THE CYCLOPROPANE RING

Cyclopropane is formally a saturated compound, in which the carbon atoms would have been in a state of sp^3 hybridisation. However, the angles between the carbon atoms in the cyclopropane ring differ markedly from those in saturated compounds. Two principal theories of the electronic structure of cyclopropane have been advanced, and examined in detail in a review[7]. According to Walsh[170] a carbon atom in cyclopropane is in a state of sp^2 hybridisation. Two sp^2 orbitals of each carbon atom form bonds with s orbitals of hydrogen. The remaining six electrons (two from each carbon atom) are involved in bond formation between the carbon atoms, of which four electrons belong to bonds formed by the overlapping of $2p$ orbitals, while the remaining two electrons form a three-centre orbital. This model explains the enhanced reactivity of the carbon–carbon bonds in cyclopropanes, evident in the easy rupture of the ring. The intensified p-character of the bonds in cyclopropane is confirmed by dipole moments and quadrupole magnetic resonance data obtained in a study of cyclopropyl chloride[171,172]. This model will also explain the ability of the cyclopropyl group to "conjugate" with π-electron systems, where "conjugation" implies the possibility of overlap of the three-centre orbital with π- and p-orbitals of a substituent (a vinyl group, a lone pair of electrons of an oxygen or a nitrogen atom, etc.)[173–175].

In the Coulson–Moffitt model[176] the carbon atoms are situated at the corners of an equilateral triangle, and hybridisation is such that two orbitals of any carbon form an angle of 104° in the plane of the ring. The carbon–carbon bonds are then curved (banana-shaped), the carbon atoms are in a state of $sp^{4,12}$ hybridisation, and the orbitals of the carbon–hydrogen bonds are in a state of $sp^{2,28}$ hybridisation[177]. The angle between the axes of the $sp^{4,12}$-hybridised orbitals is 104°.

The presence of curved bonds in cyclopropane is supported experimentally by the distribution of electron density in 7,7-dicyano-2,5-dimethylnorcaradiene



found by X-ray diffraction. The bending of the carbon–carbon bonds in the cyclopropane ring was shown to be ~20° (theoretically 22°). These results indicated also that the cyclopropane ring forms an angle of 73° with the cyclohexadiene plane[178].

Although the two models of cyclopropane are mathematically equivalent[179], the Coulson–Moffitt model permits certain predictions which cannot be made by means of the Walsh model. Furthermore, a model with curved bonds can be used to depict orbitals in those cyclopropane molecules which cannot be represented solely in terms of sp, sp^2, and sp^3 hybridisation.

Various methods of quantum-chemical calculations have lately been used to study the electronic structure of cyclopropane[180–182]. Non-empirical calculations by the LCAO-MO self-consistent field method have established[183] that overlapping of the d-orbitals of the carbon atoms in the carbon–carbon bonds is possible, as well as the above two types, and should be taken into account in discussion of the hybridisation of the carbon atoms in the cyclopropane ring.

Calculations have shown that, in the ground state of cyclopropane, the highest electron density is concentrated on the carbon atoms, diminishes in the region between the hydrogen atoms attached to carbon, but is quite high between the carbon atoms along the carbon–carbon axis, and some charge is also concentrated at the centre of the ring. Thus the bonds retain a considerable p-character in the proposed model, which will explain the ability of the

cyclopropane ring to "conjugate" with π-electron systems.

Optimum conditions for interaction between the cyclopropane ring and the p-orbitals of an adjacent carbon atom in the side-chain are satisfied if the plane of the ring and the axes of the p-orbitals are parallel[177,184-189].

The possibility of electronic interactions between the cyclopropane ring and unsaturated groups and the transmission of the effect of substituents through the ring have been studied by many chemists[170,186-192]. An induction mechanism of transmission is evidently fully applicable to the cyclopropane ring. Hitherto, however, there has been no generally accepted view on the possibility of a mesomeric mechanism of transmission of electronic effects through the ring, i.e. on the possibility of conjugation between the cyclopropane ring and multiple bonds, and this problem remains a matter of controversy.

—CH_2CH—	1685	—	1685	—	—	1687	—

Infrared spectroscopy, Raman spectra, nuclear magnetic resonance spectra, dipole moments, and pK_a values of acids have been used to study the interaction of a three-membered ring with adjacent unsaturated groups in the ground state. The effect of substitution on the infrared frequency of the functional group has been studied in greatest detail on 1,2-diphenylcyclopropyl cyanides, when the cyanide frequencies correlate with the α-constants of the substituents. However, the slope of the correlation graph is considerably smaller than for the corresponding series of cyanostilbenes. Furthermore, the CN frequencies in cyclopropanes are appreciably lower than that in benzyl cyanide (2256 cm^{-1}—Table 1).

Comparison of the carbonyl frequencies of 1-aryl-2-benzoylcyclopropanes and of substituted chalcones, benzophenones, and 1-aryl-2-benzoylethanes[37] (Table 2) shows that replacement of an ethylene unit by a cyclopropane ring or a vinylene fragment produces a large shift (~20 cm^{-1}) in the carbonyl frequencies, which confirms the ability of the cyclopropane ring to conjugate with the carbonyl group. However, the introduction of various *para*-substituents into the phenyl ring in 1-benzoyl-2-phenylcyclopropanes has little effect on the carbonyl frequency.

Table 3. Integral intensities of bands due to cyclopropanes and to unsaturated compounds.

Compound	Integral intensities of bands		
	C_6H_5, 1660 cm^{-1}	C=C, 1640 cm^{-1}	C=O, 1700 cm^{-1}
trans-1-Phenyl-2-vinylcyclopropane	1320	1250	–
1-Phenylbuta-1,3-diene	19600	48000	–
4-Phenylbut-1-ene	480	400	–
Ethyl *trans*-β-2-phenylcyclopropylacrylate	2900	9500	2700
Ethyl *cis*-β-2-phenylcyclopropylacrylate	1200	4500	1350
Ethyl 5-phenylpenta-2,4-dienoate	50500	16500	12000
Ethyl 3-methyl-5-phenylpent-2-enoate	590	2000	580

Raman spectroscopy was used to make very detailed studies[194,195] of the interaction of a cyclopropyl group with unsaturated side-chains. The ability of the ring to transmit the conjugation of attached groups was determined by examining the Raman spectra[196] of a series of 1-phenyl-2-R-vinylcyclopropanes and corresponding unsaturated or saturated compounds. Comparison of the integral intensities (Table 3) indicates that a three-carbon ring is able to conjugate with attached unsaturated groups and to transmit their influence provided that conformations most favourable for such conjugation are established, so that the π-orbitals of the substituent are able to overlap the Walsh three-centre orbital of the cyclopropane ring.

The proton magnetic resonance spectra of 1,2-diphenylcyclopropyl cyanides reveal[193] a correlation between the chemical shifts of the 2- and 3-hydrogen atoms and the constants of the substituents:

$$\nu(\text{Hz}) = K(0{,}4\sigma_I + 0{,}7\sigma_M) .$$

A correlation analysis established that the substituents affect the chemical shifts of the protons mainly by a mesomeric mechanism.

A comparative study of the proton magnetic resonance spectra of *trans*-1-benzoyl-2,2-dideutero-3-R-phenylcyclopropanes, *trans*-2-benzoyl-3-R-phenyloxirans, and *cis*- and *trans*-2-benzoyl-1-cyclohexyl-3-R-phenylaziridines in deuterochloroform and in benzene showed that the differences between the chemical shifts in these two solvents correlated with the σ, σ^0, and σ^+ constants of the substituents. However, the best correlation is obtained by using the Swain F and R constants (the field-effect and resonance constants respectively). Values of 25.7, 23.3, and 13.4 were found for the reaction constants ρ of the cyclopropane, oxide, and ethylenimine rings

respectively. These results agree well with a study of the ^{19}F nuclear magnetic resonance spectra of series of compounds p-F.C_6H_4.X.C_6H_4.Y, which gave the values of ρ (the slope in ppm) −2.20, 0.84, −1.21, and −1.20 according as X was CH : CH, $CH_2.CH_2$, a cyclopropane ring, or an oxide ring. However, the substituent constants σ_1 and σ^0_R found for the cyclopropyl group in a ^{19}F-n.m.r. study of m- and p-fluorophenylcyclopropanes[200] were closely similar to those for alkyl substituents. Hence it was concluded that, in the ground state of the fluorocyclopropane molecule, the phenyl and cyclopropyl groups do not interact by a mesomeric mechanism.

Table 4. Dipole moments of ketones R.C_6H_4.X.CO.C_6H_5 (in benzene at 25°C).

R	No bridge	—CH=CH—	—CH—CH— (CH$_2$)		
	μexp	μexp	μexp	μcalc	μinter
H	2.99	3.07	2.45	2.90	−0.45
Cl	2.95	2.57	1.82	1.91	−0.01
Br	2.96	2.91	1.89	1.90	−0.01
NO_2	4.23	4.16	3.68	4.10	−0.42
m-NO_2	—		3.61	4.10	−0.49
MeO	—	3.60	2.97	2.80	0.17

The very small interaction moments $\mu_{inter} = \mu_{exp} - \mu_{calc}$ indicate (Table 4) absence of appreciable conjugation between the π-electron system of the p-R.C_6H_4 group and benzoyl in *trans*-1-benzoyl-2-p-R-phenylcyclopropanes. Comparison of the dipole moments of these cyclopropanes with those of corresponding benzophenones and chalcones (Table 4) shows that introduction of the cyclopropane ring lowers the dipole moments in comparison with benzophenones, and does not increase them, as with chalcones: i.e. cyclopropyl ketones are less polar than are benzophenones[201].

Finally, pK_a values were determined for a series of *para*-substituted *trans*-2-phenylcyclopropanecarboxylic, cinnamic, and β-phenylpropionic acids in dilute aqueous solution[202] and later in 50% ethanol[203] in order to assess the ability of the cyclopropane ring to transmit electronic effects, and a correlation analysis of the data was made. The results were contradictory. In aqueous solution the series of phenylcyclopropanecarboxylic acids and the series of phenylpropionic acids had closely similar reaction constants ρ (0.182 and 0.212 respectively; for the series of cinnamic acids ρ = 0.466), which indicates absence of interaction between the phenyl group and carboxyl through the cyclopropane ring. In alcoholic solution, however, an appreciable difference was observed between the reaction constants of the two series (0.473 and 0.344 respectively for the cyclopropane and phenylpropionic series): i.e. under these conditions the cyclopropane ring transmits electronic effects appreciably better than does an ethylene bridge. This discrepancy may be due to variation in the conformation of the compounds with the solvent. Indeed, it has been known for some time[204] that the degree of ionisation of stereoisomeric cyclopropanecarboxylic acids containing one, two, or three substituents in the ring depends to a greater extent on their spatial configuration than on the polar nature of the substituents.

It is clear from the above discussion that any conclusion on the ability of the cyclopropane ring to conjugate or to transmit effects in the ground state cannot be examined without qualification to all cyclopropane systems. Nevertheless, an inductive effect—not a mesomeric effect—predominates in the ground state in the majority of examples.

An analogy between the cyclopropane ring and the double bond can very often be traced in the excited state. The problem of the conjugation of substituents and of the transmission of their electronic effects through the cyclopropane ring in the excited state was studied quite widely by means of ultraviolet spectroscopy[200-214]. The main criterion of the possibility of conjugation between the cyclopropane ring and a substituent is a bathochromic shift and intensified absorption in comparison with model compounds not containing a cyclopropane ring.

Table 5. Wavelengths λ_{max} (nm in alcohol) in the compounds $C_2H_5O.CO.CH : CH.X.CH : CH.COOC_2H_5$ in comparison with $CH_3.CH : CH.COOC_2H_5$.

X	λ_{max}	ε
No bridge	264	30300
—CH=CH—	304	46800
C_6H_4	323	46200
—CH—CH— (CH$_2$)	252	22800
MeCH=CHCO$_2$Et	206	15520

Thus the sharp bathochromic shift (4—10 nm) in the electronic spectra of 1-aryl-2-benzoylcyclopropanes in comparison with 1-benzyol-2-phenylethane indicates interaction between the benzoyl chromophore and the cyclopropane ring. However, the nature of a substituent in the benzene ring has hardly any effect on the position of the maximum of the benzoyl chromophore[37]. The presence of a bathochromic shift in the electronic spectra of compounds of general type $C_2H_5O.CO.CH : CH.X.CH : CH.COOC_2H_5$ (Table 5) indicates quite definite interaction between chromophores separated by a cyclopropane ring[144]. Bathochromic shifts (5—29 nm) [211,212] have been observed also in the electronic absorption spectra of cyclopropylacrylic esters and corresponding models containing no cyclopropane ring. The introduction of substituents capable of conjugation into a benzene ring attached to a cyclopropane ring causes bathochromic shifts and some strengthening of absorption bands[193].

Variation from 0 to 90° in the orientation of the cyclopropane ring relative to the bisecting plane in a series on conformationally rigid p-nitrophenylcyclopropanes has little effect on the electronic interaction between the cyclopropyl group and the nitrophenyl or phenyl chromophore, according to a study of the electronic spectra of such compounds. This indicates that inductive effects play the main part in these series[215]. In an interesting example of the steric suppression of conjugation of the cyclopropane ring with double bonds[216] disturbance of the arrangement of the ring in the plane of the double bonds optimum for conjugation, on the introduction of methyl groups into the ring or into a side-chain, causes hypsochromic shifts in the electronic spectra of cyclopropylacrylic esters.

Comparison of the electronic spectra of stereoisomeric 1-phenyl-2-R-cyclopropanes (R = COOH, COR', $CONH_2$, NR'_2, CH : CH.COOH, or CH : $CH.COOC_2H_5$) with the spectra of monosubstituted cyclopropanes (phenylcyclopropane and β-cyclopropylcrotonic ester) indicates that the cyclopropane ring is able to transmit the effect of attached groups, but to a less extent than can be vinylene bridge. Differences in the spectra of ethyl *cis*- and *trans*-β-2-phenylcyclopropylacrylates can be explained by steric effects on the formation of a single conjugated system and linked with the relative orientation and the degree of overlap of the orbitals of the three-membered ring with the π-orbitals of neighbouring unsaturated groups. Such overlapping is evidently weaker in the *cis*-isomers, which is probably responsible for the hypsochromic displacement of the longer-wavelength absorption band and its diminished intensity in comparison with the *trans*-isomers[217].

In contrast to earlier results[218] indicating absence of appreciable conjugation between a cyclopropyl ring and substituents (study of the electronic and circular dichroism spectra of *trans*-2-phenylcyclopropanecarboxylic acid), a subsequent careful investigation[219] of the ultraviolet and circular dichroism spectra of the same acid has revealed the presence of some electronic interaction between phenyl and carboxyl chromophores and the transmission of electronic effects through the cyclopropane ring.

Steric conditions necessary for maximum delocalisation of electrons in a system comprising cyclopropyl and an unsaturated group in an excited state were postulated by several workers[170,184,185,207,213,220]: (i) the π-bonds of the unsaturated group and the cyclopropane ring should be coplanar; and (ii) the plane containing the atoms of the unsaturated group should cut the three-membered ring along a bisecting line. However, study of conjugation effects in phenylcyclopropane derivatives with a fixed spatial arrangement of the phenyl group and the cyclopropane ring led to the conclusion that no preferred geometry exists for conjugation between them[209]. Examination of the electronic spectra of many cyclopropyl ketones indicated also considerable conjugation interaction between the three-membered ring and the unsaturated centre even when only one cyclic carbon–carbon bond was involved in conjugation[205]. Thus conjugation and the transmission of electronic effects through a cyclopropane ring in the excited state constitute an extremely complicated problem.

Table 6. Reaction constants ρ for $R.C_6H_4.X.COOC_2H_5$ (correlation analysis of alkaline hydrolysis constants).

X	ρ	X	ρ
$-CH_2-CH_2-$	0.591		0.812
trans-CH=CH-	1.314		
cis-CH=CH-	1.122		1.02

Relatively little study has been made of the transmission of the effect of substituents through the cyclopropane ring in a reactive state. Thus correlation analysis of the alkaline hydrolysis constants of ethyl *meta*- and *para*-substituted *trans*- and *cis*-2-phenylcyclopropanecarboxylates in 87.8% ethanol at 37°C enabled reaction constants to be determined for these series (Table 6) and the ability to transmit electronic effects in comparison with *cis*- and *trans*-cinnamic, β-phenylpropionic, and phenylpropiolic esters to be assessed as lying in the sequence[221]

$$CH_2.CH_2 < \textit{trans}\text{-}\Delta < \textit{cis}\text{-}\Delta < \textit{cis}\text{-}CH:CH < \textit{trans}\text{-}CH:CH < C:C.$$

Measurements of ionisation constants were used to assess the effect of two phenyl groups separated by a three-membered ring in 2,3-diphenylcyclopropanecarboxylic acids[222].

Correlation analysis of a kinetic study of the reaction of diphenyldiazomethane with *trans*-2-arylcyclopropanecarboxylic acids in toluene at 35–65°C established that use of the σ-constants of substituents in the aromatic ring gives the best correlation of the esterification rate constants. The transmission factor π' for the three-carbon ring was also calculated[223]. The result (0.40) was close to the value π' = 0.33 calculated from the p*K* of cyclopropanecarboxylic acids[224]. The data indicate that the effect of the aryl group is transmitted to the carboxyl mainly by an inductive mechanism.

Correlation analysis of the half-wave reduction potentials of compounds $R.C_6H_4.X.CO.C_6H_5$ (where X represents vinylene, cyclopropylene, or a single bond) in acid medium (pH 2.4 in 50% dimethylformamide) revealed that the best results are obtained by using the Hammett σ-constants and the Taft σ^0-constants. Values of ρ (in mV) corresponding to the above bridges X were −130 (σ), −272 (σ and σ^0), and −339 (σ).[225] Since benzophenones (standard series) and cyclopropyl ketones had different mechanisms of reduction, however, the transmission factor π' unfortunately could not be calculated. The observed correlation of half-wave potentials with the σ^0-constants indicates the important part played by inductive effects in the series of cyclopropyl ketones studied.

Effect of Conditions of Synthesis on the Structure of Polyphenylsilsesquioxane Macromolecules

I.I.Tverdokhlebova and T.A.Larina

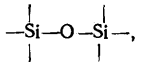
All data published up to 1973 on the hydrodynamic properties and molecular-weight parameters of organosilicon ladder polymers are surveyed. The reasons for the formation of polyphenylsilsesquioxane macromolecules of various structures are assessed. A list of 63 references is included.

Several investigations during recent years have shown that the polymerisation of compounds whose functionality exceeds two produces not three-dimensional cross-linked polymers but polymers having a two-strand linear structure[1-10]. Such systems have been termed *ladder polymers*.

The possibility of a ladder structure for several polymers was predicted by Berlin[11]. Carbon-chain ladder polymers can be obtained by the cyclisation of linear polymers, as well as by the polymerisation of polyfunctional monomers[12-14]. Among known ladder polymers are cyclopentadiene[15,16] and cyclobutadiene[17]. Aromatic ladder polymers can be obtained by the photopolymerisation of acetylenes[18]. The synthesis of ladder polyquinoxalines has been reported[19]. Ladder polymers are known comprising oxygen- and nitrogen-containing heterocycles[20,21], as well as inorganic ladder compounds[22-24]. This is by no means a complete list of work on ladder polymers belonging to various classes of compounds. Broad surveys of this topic have appeared[25,26].

Ladder polymers are of considerable interest in connection with their valuable properties due to their structural peculiarities, notably the two-strand structure of the macromolecules. Such polymers possess solubility, enhanced thermal stability, strength, and inertness towards corrosive media.

Organosilicon polymers, polyphenylsilsesquioxanes, also form ladder polymers[27-30]. Silsesquioxanes are compounds in which every silicon atom is attached to three oxygen atoms and an organic substituent: $[RSiO_{1.5}]_n$. The polycondensation of trifunctional compounds in which the functional groups are equally reactive should produce a disordered, random network[31]. However, because the functional groups differ in reactivity or the latter may vary during the reaction, and also owing to steric factors, ordered structures may be formed. The tendency of the monomer to form rings may also produce a certain ordering. Siloxanes possess the unique ability of varying the bond angle



so that the chain is very flexible, and rings varying in structure and size may be formed. The disordered, irregular structures appearing in the early stages of the reaction are able to rearrange into regular structures only when condensation occurs in the presence of a catalyst which will rupture

bonds. In the hydrolysis and subsequent condensation of phenyltrichlorosilane and other organotrichlorosilanes in the presence of alkali, for example, cagelike silsesquioxanes were isolated, as well as polymers to which a two-strand ladder structure was ascribed[28-30,32]. The main factor governing the formation of silsesquioxanes having a particular structure is the nature of the substituent attached to the silicon atom, as well as the conditions of synthesis.

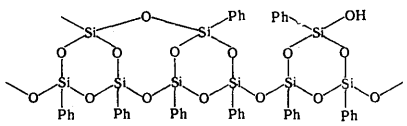


Figure 1. Structure of polyphenylsiloxane macromolecules suggested by Andrianov[2].

The first publication in which condensation of the hydrolysis products of phenyltrichlorosilane was assumed to involve the formation of internal rings, was due to Andrianov[2]. In his suggested structure (Fig. 1) every silicon atom is attached to three oxygen atoms and an organic substituent. Every unit corresponds to the formula $RSiO_{1.5}$.

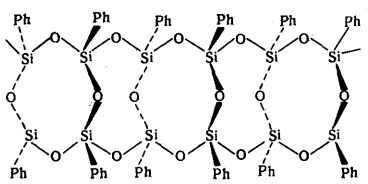

Figure 2. Structure of polyphenylsiloxane macromolecules suggested by Brown[6].

A polymer of general formula $(RSiO_{1.5})_x$ was first obtained by Brown[6] by the equilibrium condensation of hydrolysis products of phenyltrichlorosilane, and was assigned the structure shown in Fig. 2. Brown established that the main conditions governing the formation of a cyclolinear polymer during anionic polymerisation are temperature and solute concentration. Condensation of

the hydrolysis products in dilute solution (up to 5%) yields mainly oligomers of low molecular weight having a cagelike structure[28,29]. Those illustrated in Fig. 3 were isolated as pure crystals[30]. However, the cagelike compounds may also have an incompletely cyclised, defect structure (Fig. 3*b*). In the concentration range 5–7% polymers of low molecular weight (prepolymers) are formed at equilibrium. When equilibrium is established in concentrated (85–95%) solutions at 250°C, a soluble cyclolinear (ladder) polymer of molecular weight exceeding 4×10^6 is formed, to which Brown assigns a *cis*-syndiotactic structure[30]. At 100% concentration a gel is formed. With variation in solution concentration ladder polymers pass into cagelike polymers and conversely (Fig. 4).

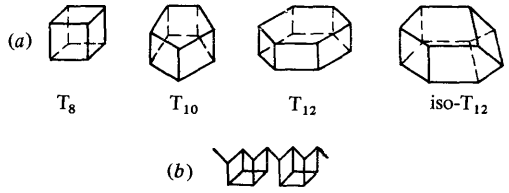

Figure 3. Cagelike compounds[28,29].

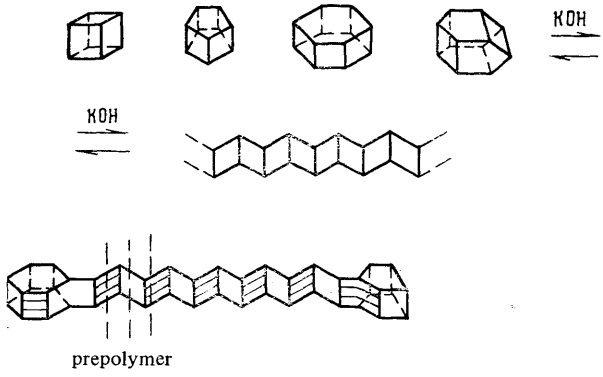

Figure 4. Conversion of cagelike compounds into a ladder polymer (and conversely).

Such ability to pass from cagelike compounds into ladder polymers was responsible for their technical application[31,33,34]. Raising the temperature of the solution converts a lower polyphenylsiloxane coating into a polymer of high molecular weight. The work of Andrianov and his colleagues supports Brown's hypothesis that cagelike compounds may pass into a ladder polymer[35,36] (Fig. 5).

The preparation of a polyphenylsiloxane of high molecular weight by condensing the hydrolysis products of phenyltrichlorosilane in the presence of caustic potash at 250°C was described[27], and the influence of the medium on the mechanical properties, molecular weight, and structure of the polymer macromolecules was studied. The higher the boiling point of the solvent, the larger the molecular weight attained by the polymer. The nature of the solvent had no significant effect on the structure of the polymer macromolecules. A mechanism of formation of a cyclolinear polymer by internal cyclisation at hydroxy-groups was suggested[37].

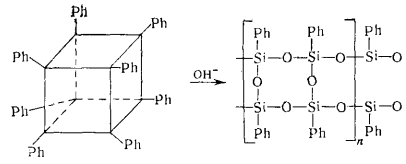

Figure 5. Transition of cagelike compounds into a ladder polymer[35,36].

Brown's conclusion that polyphenylsiloxanes obtained from hydrolysis products of phenyltrichlorosilane had a *cis*-syndiotactic structure was based on a study of the properties of solutions, X-ray examination, infrared and ultraviolet spectra, and calculation of bond angles[30]. The infrared spectra of a cyclolinear polyphenylsiloxane give a well resolved doublet in the region of 1045 and 1155 cm^{-1}. Ultraviolet spectra agree well with the suggested cyclolinear structure[29], and X-ray structural analysis shows that a chain segment comprises four units[7,30]. However, only strictly determined conditions of synthesis can yield a regular polyphenylsiloxane with a two-strand ladder structure.

The use of Stuart–Briegleb models to examine the possible formation of cyclolinear polyphenylsiloxanes suggested[32] that a regular structure could result only from the reaction of rings whose silicon atoms lay in the same plane, with either *cis*- or *trans*-hydroxyls. Analysis showed that only a *cis*-structure in the boat form, when the 1,2-hydroxyls of one monomer condense with the 3,4-hydroxyls of another monomer, can lead to the formation of a *cis*-isotactic polyphenylsiloxane having a double-chain structure. The silicon atoms then lie in one plane, with bridging oxygen atoms on one side, and chain oxygen atoms on the other side of the plane (Fig. 6).

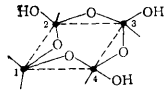

Figure 6. *cis*-Structure of T_4 in the chair form[32].

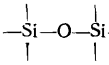
With bulky substituents (e.g. phenyl), however, the



angles are distorted. It has therefore been assumed[32] that an isotactic structure with phenyl substituents attached to the silicon atom will be formed if it is postulated that the chain can be screwed along its axis.

The hypothetical condensation of *trans*-T_4† in the chair form by condensation of the 1,2-hydroxyls of one ring with the 4,3-hydroxyls of another ring should produce a *cis*-syndiotactic ladder structure (Fig. 7). Condensation in other possible ways should produce non-cyclolinear structures, e.g. branched and network. Among such types of ring condensation are those of *cis*-T_4 in the chair form, of *trans*-T_4 in the chair form (1,2-hydroxyls of one ring with the 3,4-hydroxyls of another ring), and *trans*-T_4 in the boat form[32].

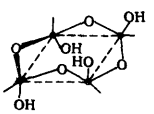


Figure 7. *trans*-Structure of T_4 in the chair form[32].

Thus all the above discussion shows that formation of a cyclolinear structure (Fig. 2) is possible but requires the observance of definite reaction conditions. In cases in which existence of *trans*-T_4 in the boat form is not energetically more favourable than other conformations, the formation of non-cyclolinear structures is possible.

The mechanism of the formation of ladder polymers is complicated and dependent on the conditions of synthesis. Formation of a double-chain structure can probably involve either condensation at free hydroxy-groups of a lower prepolymer[37] or a stage of rearrangement of cagelike compounds[38]. Frey[39] put forward the hypothesis that the resulting polyphenylsiloxane is highly ordered only in individual polycyclic segments distributed at random along the chain.

Table 1. Optical anisotropy and rigidity of various polyphenylsiloxanes (PPS).

Polymer	$10^{-5}M$	$10^{25}(\alpha_1-\alpha_2)$, cm^3	A, Å	S
PPS-1	1.0	—1230	136	54
PPS-2	0.65	—1060	84	34
PPS-3	3.7	—1800	178	71

A double-chain structure should lead to enhanced rigidity of the polymer macromolecules. This is confirmed by several studies both of the properties of polyphenylsiloxane solutions[32,37-47] and of the physicochemical properties of such polymers in the condensed state[7,38,48-52]. High chain rigidity of polyphenylsiloxane obtained by treating hydrolysis products of phenyltrichlorosilane with potassium hydroxide in various solvents was shown by an investigation of its behaviour in solution. The calculated anisotropy of polarisability of a segment $\alpha_1 - \alpha_2$ was compared with experimental values[37,40]. It was shown[53] that $\alpha_1 - \alpha_2 = +4.8 \times 10^{-25}$ cm^3 for linear polydimethylsiloxane (a single-chain polymer). The introduction of 10% of phenyl groups into the flexible polydimethylsiloxane macromolecule diminished the flexibility only slightly, although the sign changed from positive to negative: -2.4×10^{-25} cm^3. Double-chain polyphenylsiloxane was found[40] to have $\alpha_1 - \alpha_2 = -1740 \times 10^{-25}$ cm^3.

Tsvetkov et al. have shown[46] that polyphenylsiloxanes obtained by different workers possess different rigidity parameters (Table 1). According to the results of various workers[7,35,42,44,46,54] the parameter a in the Mark–Kuhn–Houwink (MKH) equation $[\eta] = KM^a$, which is connected with the flexibility of the polymer chain, varied from 0.70 to 1.50 depending on the number of fractions into which the polymer had been separated (Table 2).

Table 2. Parameters a and K in the MKH equation for polyphenylsiloxanes.

Equation	Solvent	T, °C	No. of fractions	Ref.
$[\eta] = 1.305 \cdot 10^{-7} \cdot M^{1.29}$				
$[\eta] = 1.93 \cdot 10^{-4} \cdot M^{0.63}$	benzene	20	6—10	37
$[\eta] = 1.47 \cdot 10^{-5} \cdot M^{0.916}$	benzene	25	18	
$[\eta] = 1.33 \cdot 10^{-5} \cdot M^{0.92}$	chloroform	25		
$[\eta] = 1.77 \cdot 10^{-5} \cdot M^{0.895}$	toluene	37		42
$[\eta] = 0.58 \cdot 10^{-5} \cdot M^{0.978}$	*o*-xylene	65		
$[\eta] = 1.568 \cdot 10^{-5} \cdot M^{0.897}$	θ-solvent (ethylene dichloride)	50.5		
	benzene		13	
$[\eta] = 2.38 \cdot 10^{-3} \cdot M^{0.9}$	bromoform			41
	benzene + butyl acetate (6:4)	21		
$[\eta] = 7.7 \cdot 10^{-4} \cdot M^{0.9}$	benzene		13	41
$[\eta] = 7.6 \cdot 10^{-3} \cdot M^{0.7}$	benzene			
$[\eta] = 1.3 \cdot 10^{-4} \cdot M^{1.09}$	benzene			
$[\eta] = 2.1 \cdot 10^{-5} \cdot M^{0.88}$	benzene		10	
$[\eta] = 4.898 \cdot 10^{-4} \cdot M^{0.94}$	benzene		13	44
$[\eta] = 4.624 \cdot 10^{-3} \cdot M^{0.74}$	bromoform			
$[\eta] = 1.09 \cdot 10^{-8} \cdot M^{1.48}$				
$[\eta] = 2.74 \cdot 10^{-7} \cdot M^{1.16}$	benzene	20	26	55, 56
$[\eta] = 1.25 \cdot 10^{-8} \cdot M^{1.47}$	benzene	40		
$[\eta] = 1.54 \cdot 10^{-6} \cdot M^{1.12}$	benzene	20	25	
$[\eta] = 2.66 \cdot 10^{-7} \cdot M^{1.24}$				55, 56
$[\eta] = 6.95 \cdot 10^{-7} \cdot M^{1.17}$	benzene	40		
$[\eta] = 5.41 \cdot 10^{-4} \cdot M^{0.72}$	benzene	20	25	
$[\eta] = 5.03 \cdot 10^{-4} \cdot M^{1.32}$				
$[\eta] = 8.72 \cdot 10^{-4} \cdot M^{0.68}$	benzene	25		55, 56
$[\eta] = 5.60 \cdot 10^{-8} \cdot M^{1.31}$				
$[\eta] = 5.06 \cdot 10^{-8} \cdot M^{1.32}$	benzene	40		

It must be borne in mind that, if the macromolecules possess enhanced rigidity, the intrinsic viscosity is almost independent of the solvent used for its determination and of the temperature of measurement. Its value remains almost unchanged throughout the range of molecular-weight determination in benzene, bromoform, and the θ-solvent[42,46,55]. Similar constancy of intrinsic viscosity has been observed with variation in the temperature of a polyphenylsiloxane solution. This indicated that volume (long-range) effects had no appreciable influence on the dimensions of macromolecules in solution and that the high value of the exponent a in the MKH equation was due, not to volume effects, but to the enhanced skeletal rigidity of the macromolecules[57,58].

Differences in the parameter a are therefore probably due to the presence in the polyphenylsiloxane of macromolecules not having a ladder structure. As shown above, a possible cause of the simultaneous formation of different polymer structures might be the appearance of various

† [For the "T" nomenclature cf. Ref. 29 (Ed. of Translation)].

types of polycyclic prepolymers in the initial stage of condensation[28,29,32]. Another possible reason might be increased probability of detachment of phenyl groups when reaction has proceeded for a long time, with the formation of more complicated structures, in particular strongly branched macromolecules of higher molecular weight (microgels). Guyot et al.[59] have shown that the degradation of polyphenylsiloxane consists not in depolymerisation with rupture of the two-strand siloxane bond but in the detachment of phenyl groups with the formation of benzene. This explains the improved thermal stability of the polyphenylsiloxane, since removal of a chain fragment from a ladder macromolecule—in contrast to a single-chain macromolecule—requires several simultaneous ruptures. In addition, the parameter a may vary with the proportion of defects in the macromolecules, which may be due to the presence of residual, unchanged hydroxy-groups. However, the number of such groups in polyphenylsiloxane macromolecules is so small that no method of physicochemical analysis has yet been able to accomplish their quantitative determination.

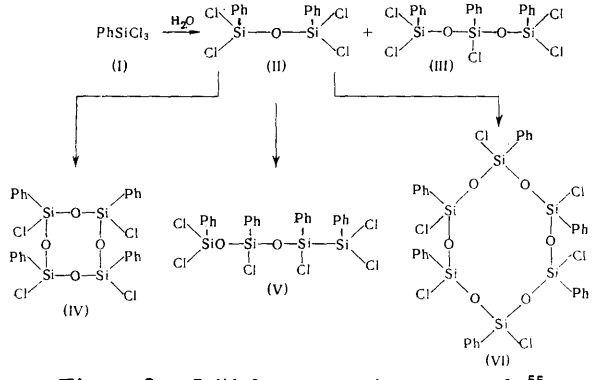

Figure 8. Initial monomeric compounds[55].

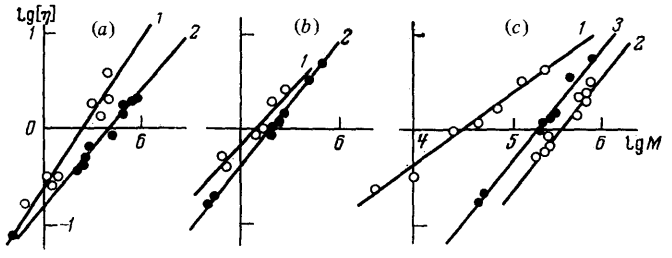

Figure 9. Dependence of $\lg[\eta]$ on $\lg M$ for polyphenylsiloxanes obtained from different monomers[55].

To examine the role of the initial monomeric compounds in forming polyphenylsiloxanes having a ladder structure, the compounds (I)–(IV) (Fig. 8)‡ were each subjected to hydrolysis under the same conditions with subsequent polycondensation and polymerisation in the presence of potassium hydroxide. All the polyphenylsiloxane fractions were found to be identical in elementary composition, which corresponded to the chain unit $(C_6H_5SiO_{1.5})_4$, but they differed considerably in hydrodynamic properties. Fig. 9 shows that the polymers consisted of two types of macromolecules differing in structure or in proportion of structural defects. All the polyphenylsiloxanes synthesised gave two straight lines when $\lg[\eta]$ was plotted against $\lg M$, with different values of the parameter a in the MKH equation: i.e. the precipitant–solvent system chosen[55] enabled for the first time the separation of polyphenylsiloxanes both according to molecular weight and according to structure (Table 2). Intrinsic viscosities obtained for the polymers $PPS(III,_3)$ and $PPS(IV,_3)$ (polyphenylsiloxanes produced by polymerising the monomers (III) and (IV) (Fig. 8) for 3 h), as well as the parameters a, were closely similar to the characteristic viscosities and the value $a = 1.29$ found[37] for polyphenylsiloxanes resulting from compound (I).

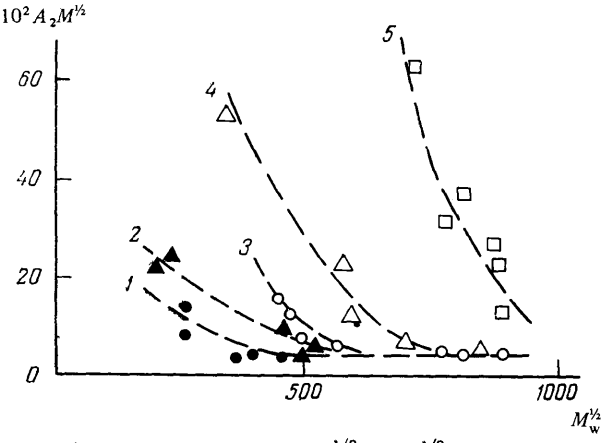

Figure 10. Dependence of $A_2M^{1/2}$ on $M^{1/2}$ for polyphenylsiloxanes with various values of a in the MKH equation: 1) 1.12; 2) 1.24; 3) 1.32; 4) 1.48; 5) 1.49.

Fig. 10 shows that polyphenylsiloxanes obtained from products of the partial hydrolysis of phenyltrichlorosilane and having different values of a in the MKH equation correspond to different variations of $A_2M^{1/2}$ with $M^{1/2}$ (where A_2 is the second virial coefficient)[56,60]. This dependence is non-linear even at quite high molecular weights, which suggests that the macromolecular chains are of finite length in this region and hence are rigid. The graph of $A_2M^{1/2}$ against $M^{1/2}$ moves to the right with increase in a. Calculations of the dimensions of the macromolecules based on several theories showed[61–63] that the rigidity parameter $[\overline{h_0^2}/M]^{1/2}$ increases with a (where $[\overline{h_0^2}]^{1/2}$ is the mean square distance between the ends of a macromolecular chain, and M is the molecular weight).

Thus a polyphenylsiloxane comprising both macromolecules having a two-strand ladder structure and a different, defective structure can be obtained depending on the nature of the initial monomer and the conditions of synthesis.

‡ [Compounds (V) and (VI) are not mentioned in the Russian text (Ed. of Translation)].

The structural defectiveness may be due to the detachment of phenyl groups when reaction continues for a long time. Cleavage of the silicon–oxygen bond under these conditions is less probable. Unchanged hydroxy-groups may also disturb the regularity of the ladder structure.

Chromatography in a Stream of Water Vapour

M.S.Vigdergauz and Sh.M.Rakhmankulov

Methods of gas chromatography using water vapour as carrier gas, various ways of generating water vapour and its mixtures with other gases, and also the usefulness of various detecting systems are surveyed. The effect of water vapour on the retention and on the form of the chromatographic zones is analysed in detail. Use of a vapour eluent shows promise in preparative gas chromatography. The bibliography contains 64 references.

I. INTRODUCTION

One of the principal directions in the development of gas chromatography is the improvement of methods for controlling the sorption properties of columns, by (i) modifying solid supports in order to eliminate the effect of adsorption on the form of the elution zones of (especially strongly polar) sorbates, (ii) modifying adsorbents to change the form (usually to straighten) the sorption isotherms of separable compounds, and also to decrease the sorption coefficients of substances having high boiling points, (iii) increasing the solubility of sorbates in the gas phase, and hence diminishing their partition coefficients between stationary and mobile phases, and (iv) using mixed stationary liquids in order to regulate the degree of separation of components of complicated mixtures.

The use of water vapour as mobile phase is an extremely effective procedure for controlling sorption characteristics in the above ways. In gas–liquid chromatography, water vapour interacts with active centres in the solid support, and may also form binary systems with stationary liquids whose composition is regulated by the use of mixed eluents. In gas-adsorption chromatography the blocking of adsorption centres by water molecules ensures more symmetrical sorbate peaks, together with substantial acceleration of the analysis. Conditions can also be chosen under which an aqueous layer, which acts as sorbent in the chromatographic process, is formed on the adsorbent (or inert support). Finally, the solubility of sorbates in the mobile vapour phase can be increased to a certain extent by raising the pressure in the column.

Use of a vapour eluent also has other advantages—(*a*) the possibility of working both with some detection systems for gas chromatography (catharometer, flame-ionisation detector, etc.) and with systems which detect in the liquid phase, (*b*) cheapness, enabling this eluent to be used in high-output preparative apparatus and works chromatographic equipment, and (*c*) the possibility of complete condensation of the eluate without the use of low temperatures, which almost completely eliminates loss of material in the traps of chromatographic equipment.

The impossibility of analysing readily hydrolysable substances, of course, imposes a significant limitation on the use of water vapour. Furthermore, the danger of condensation imposes a temperature restriction.

The advantages of water vapour as a mobile phase, resulting from the possibility of modifying the solid support, were realised in 1958 by Knight[1], who, on saturating helium as carrier gas with water vapour, observed an increase in symmetry of the chromatographic zones of alcohols, amines, and water. Similarly, in 1964 Kolesnikova et al.[2] worked with moistened helium and obtained symmetrical water peaks. It was noted in particular that moistening the helium changes the sequence of elution of water and butanol. Still earlier, in 1957, Turkel'taub et al.[3] saturated the air carrier gas with water vapour in order to study the effect of the moisture content of silica gel on the chromatographic separation of gases. Water vapour was first used directly as eluent in 1960[4] (this was a continuation of earlier work[5] in which the eluent was alcohol vapour). Photocolorimetric detection was used. At the same time (1960) a Japanese patent was issued[6] on the use of water vapour as mobile phase, and a similar method was described later[7].

In 1964 Davis et al.[8], using a mixture of helium and water vapour as mobile phase, achieved a sensitivity of $2 \times 10^{-6}\%$ of ethanediol with the use of a flame-ionisation detector. Similarly, a mixture of nitrogen and water vapour was used to analyse aqueous solutions of organic acids[9]. Lowering the column temperature with a mixture of water vapour and helium results in a layer of water forming on the solid support; this serves as stationary phase for separating both polar and non-polar substances[10-12]. Beginning in 1967 Nonaka published a series of investigations on chromatography in water vapour using a flame-ionisation detector[13-22]. Mixtures of n-alkanes, aromatic hydrocarbons, alcohols, amines, aldehydes, acids, etc. were analysed, including aqueous emulsions and suspensions of concentration $10^{-2}-10^{-4}\%$. Fig. 1 shows some of the chromatograms obtained in these researches. Similar materials were analysed by Rudenko and his coworkers[23,24].

In a later paper Nonaka [21] added formic acid and hydrazine hydrate to the water vapour in order to block adsorption centres on the solid support more completely when analysing aliphatic acids and alkylamines (by analogy with a principle suggested by Knight [1]). Zhukhovitskii and his coworkers [25-27] have shown the suitability of water vapour for determining impurities in water and in salt solutions. They developed a two-stage method involving the use of a column on which water vapour is sorbed better, and a second column in which it is sorbed worse, than the impurities to be determined. Use of a flame-ionisation detector enables a sensitivity of 5×10^{-7}% to be achieved. The present Reviewers have investigated [28] the chromatographic separation of substances under steam pressures of 1–8 atm in the column. Raising the pressure tended both to shorten the analysis and to give more symmetrical peaks of polar sorbates (Fig. 2).

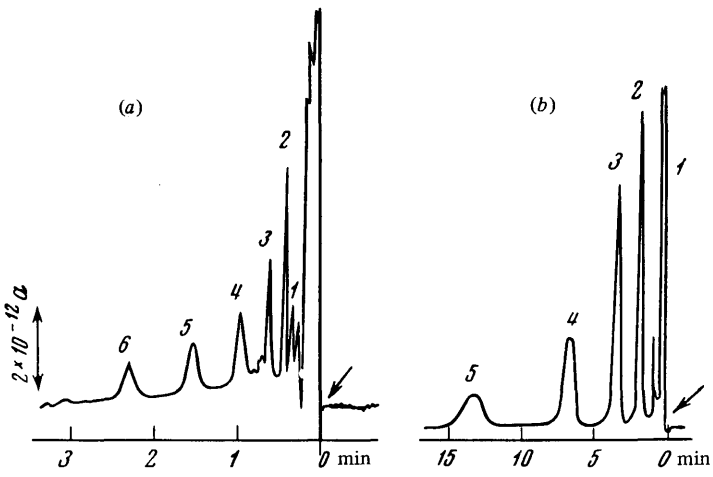

Figure 1. Chromatograms of solutions of polar compounds obtained in a flow of water vapour [20].
(*a*) Glass column of length 2.6 m and internal diameter 2.2 mm filled with firebrick (LBK-28) modified with hydrogen fluoride, with a stream flow of 71 ml min^{-1} at 130°C: 1) methanol; 2) ethanol; 3) propan-1-ol; 4) n-butanol; 5) n-pentanol; 6) hexanol.
(*b*) Glass column of length 2.6 m and internal diameter 1.8 mm filled with Chromosorb PAW with 3% of ortho-phosphoric acid and a steam flow of 42 ml min^{-1} at 170°C: 1) solvent (carbon tetrachloride); 2) lauric acid; 3) myristic acid; 4) palmitic acid; 5) stearic acid.

In 1973 Mar'yakhin and one of the present Reviewers [29], Rudenko et al. [30,31], and also Klesment [32] used water vapour as eluent in preparative gas chromatography.

Conditions for the separation of substances in a stream of water vapour or its mixtures are given in the Table.

II. PREPARATION OF MOBILE PHASE

A mixed eluent can be generated by saturating a gas with water vapour by passing the former either through a moistened granular layer [1] or over the surface of water [9]. A mixed eluent can be obtained also by bubbling through a thermostatted water layer [10]. Helium was passed [1] through a tube 0.6 m in length and 6 mm in diameter immersed in a water bath; the tube was filled with moistened C-22 support, and the relative humidity of the gas at the outlet from the column was ~50% at room temperature. A current of nitrogen entered [10] the lower part of a thermostatted steel vessel, in which it bubbled through a layer of water; the temperature of the vessel was 70 to 95 ± 0.1°C, and that of the tube connecting it with the chromatograph injector was 100°C.

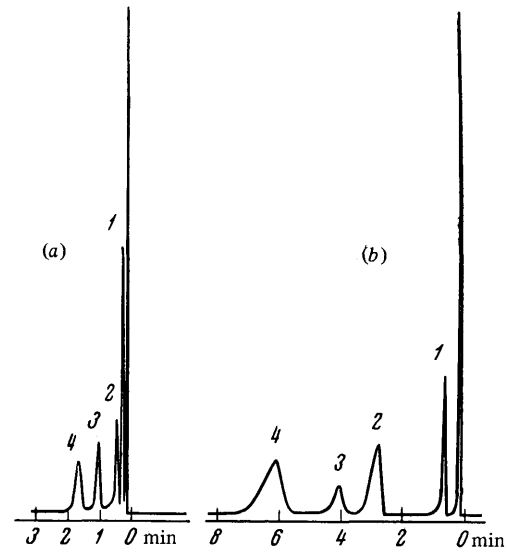

Figure 2. (*a*) Chromatogram of a mixture of normal alcohols and aniline obtained at 125°C on a column of length 0.7 m and internal diameter 2.9 mm filled with high-vacuum silicone grease applied to Chromosorb W: 1) hexanol; 2) aniline; 3) nonanol; 4) decanol.
(*b*) Chromatogram of a mixture of dialkyl phthalates obtained at 170°C on column (*a*): 1) dimethyl; 2) di-isobutyl; 3) dibutyl; 4) di-isopentyl.

Fig. 3*a* represents the system for obtaining a mixed eluent used by Mori and Arimoto [9]. The steam generator was a horizontal thermostatted cylinder half filled with water. Nitrogen passed over the water and entrained the vapour above its surface.

Fig. 3*b* illustrates equipment for generating pure water vapour [4]. Water from the reservoir *1* was transferred at 0.075–0.05 ml min^{-1} by the pump *2* through a microheater *3* comprising a stainless-steel U-tube of length 30 cm and diameter 4 mm placed in a metal cylinder. The column was covered throughout its length with asbestos string, on which was wound nichrome wire. From the microheater the vapour entered a glass chromatographic column, at the outlet from which it condensed and was guided to the detector.

Conditions of separation in a stream of water vapour or its mixtures.

Aqueous (0.01%) alcohols, aldehydes, ketones, esters	steam	HF-modified firebrick; Isolite (50% SiO_2)	110–210	fi	13
Polyalcohols, organic acids, phenols, amines	steam	KF- or H_3PO_4-modified brick; Chromosorb P with 3% H_3PO_4; MgO	100–270	fi	14
Aliphatic acids (C_2–C_{18}); dil. aq. benzoic, salicylic, lactic acids	steam	Chromosorb P with 3% H_3PO_4	135–230	fi	15
Phenol, cresols, 2,4-dimethylphenol, *p*-ethylphenol, *p*-t-butylphenol (dil. aq. solns.)	steam	Chromosorb PAW with 3% H_3PO_4	135–205	fi	16,20
Pentane solns. of C_{10}–C_{14} *n*-alkanes	He sat. with H_2O at 20°C	46% H_2O on Chromosorb P	20	fi	11
n-Alkanes (C_{10}–C_{18}, C_{24}), octane isomers	He sat. with H_2O at column temp.	4–46% H_2O on Chromosorb P; 10% H_2O on Porasil C treated with HNO_3 + H_2SO_4 and washed to neutrality	20–85	fi	12
n-Alkanes (C_1–C_6), benzene, toluene ($\geqslant 5 \times 10^{-7}$% in H_2O and salt solns.)	steam	hydrophobic silica gel; activated carbon BAU; Apiezon L on Celite 545	110–180 (programmed)	fi	25,26, 27
Aqueous (0.5–0.02%) acids—aliphatic C_6–C_{18} and dicarboxylic, iso- and tere-phthalic, citric	N_2 + H_2O	diatomitic solid support (Shimalite AW) treated with 1.5% H_3PO_4	230–290	fi	9
n-Alkanes (C_5–C_9), benzene, toluene, isomeric xylenes, ligroin (as 0.1–10^{-4}% aq. emulsion)	steam	alumina	110–260	fi	17,19, 20
Naphthalene, 1- and 2-methylnaphthalenes, anthracene, chrysene, terphenyl, triphenylene, biphenyl, quaterphenyl (as 0.01–10^{-4}% aq. emulsion or suspension)	steam	Chromosorb PAW	130–260	fi	18,20
N-Alcohols (C_1–C_6), aldehydes, ketones, ethers, alkylamines, pyridine, aniline, toluidine, glycols, C_2–C_{18} aliphatic acids and esters, dicarboxylic acids	steam	diatomitic brick modified with HF, KF, or KHF_2; diatomitic brick ignited after addition of H_3PO_4; ignited MgO	110–260	fi	20
Aliphatic acids (C_2–C_{18}), alkylamines (C_3–C_{18}), ethylenediamine, aminoethanol	steam + 10% formic acid; steam + 20% hydrazine hydrate	Corning GLC-100 porous glass beads, Chromosorb GAW	125–200	fi	21
n-Alcohols (C_6–C_{10}), di-isoalkylamines, aniline, benzylamine, dimethylaniline, ethylaniline, diethylaniline, aliphatic acids (C_2–C_6) (including 0.05% aq. solns.)	steam	10% polyethylene glycol 4000 on Chromaton; 10% polydimethylsiloxane SKTV-1 on Chromaton	150	fi	24
n-Alkanes (C_{10}–C_{15}), di-isoalkylamines, benzylamine, mono- and di-methyl- and -ethyl-benzylamines (preparative isolation)	steam	SKTV-1 polydimethylsiloxane on Chromaton; polyethylene glycol adipate on Chromosorb A	130–210	fi	30,31
Alkanes, alkylbenzenes (preparative isolation)	steam; N_2 + H_2O	25% polyethylene glycol adipate on Spherochrome-1	120–140	fi	29
Coal tars (preparative separation)	steam	21% Apiezon L on Rysorb C (flow from fractionating column)	programmed at 20–55 deg h^{-1}		32

*Detectors: ca = catharometer; ph = photocolorimeter; fi = flame-ionisation detector.

In the apparatus used by Nonaka [13–21] (Fig. 3*c*) one stage in the preparation of the eluent was purification of the stream over copper oxide at 500–600°C.

The Reviewers used the arrangement in Fig. 3*d* to examine the chromatographic behaviour of substances under high pressures of water vapour. Nitrogen from a cylinder entered the upper part of a vessel half filled with distilled water. From here the nitrogen pressure transferred water to a tube located in the thermostat and filled with metal turnings to increase the evaporating surface. The resulting water vapour passed through a buffer vessel to diminish fluctuations in the flow rate, and entered the chromatographic column, in which the required pressure was established by means of a capillary at the outlet. Most of the water vapour then escaped into the atmosphere, and only a small quantity entered the flame-ionisation detector. The flow of water vapour through the column could be regulated by varying the pressure of the nitrogen entering the vessel *7*.

In 1962 standard equipment was advertised for generating steam for use in gas chromatography [34]. The device comprised a steel boiler containing an electric heater and fitted with a safety valve. Steam production reached 1 litre min^{-1} at pressures up to 3 kg cm^{-2}. Mixtures of water vapour with nitrogen of controllable composition could also be obtained.

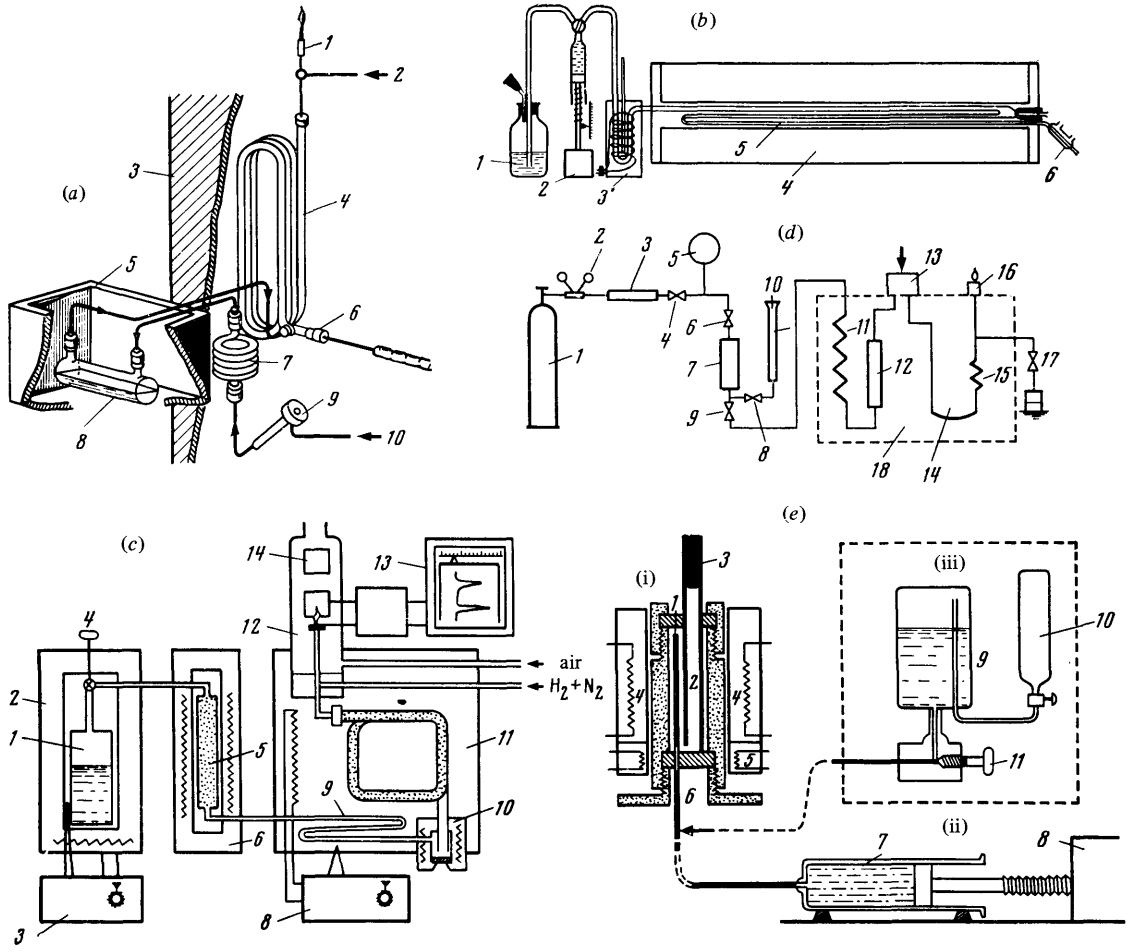

Figure 3. Diagrams of types of chromatographic apparatus. (*a*) Apparatus for operations with mixed eluent [9]: 1) flame-ionisation detector; 2) hydrogen; 3) thermostat for columns; 4) glass column; 5) thermostat for steam generator; 6) sample introduction; 7) helical tube; 8) steam generator; 9) unit for admission of carrier gas; 10) carrier gas. (*b*) Apparatus for chromatography in a flow of water vapour [4]; 1) water reservoir; 2) pump; 3) steam microgenerator; 4) thermostat; 5) glass column; 6) condenser. (*c*) [Alternative] apparatus for chromatography in flow of water vapour [13-20]: 1) steam generator; 2) electrical heater for generator; 3) thermoregulator for generator; 4) needle valve; 5) column containing CuO; 6) CuO column heater; 7) air thermostat; 8) thermostat controller; 9) buffer for water vapour; 10) introduction of sample; 11) analytical column; 12) flame-ionisation detector; 13) recording system; 14) hygrometer. (*d*) Apparatus used by Reviewers: 1) nitrogen cylinder; 2) high-pressure regulator; 3, 4, 6, 8, 9, 17) needle valves; 5) standard manometer; 7) vessel containing distilled water; 10) funnel for filling (7); 11) preliminary column filled with metal turnings; 12) buffer vessel; 13) introduction of sample; 14) chromatographic column; 15) capillary; 16) flame-ionisation detector; 18) thermostat. (*e*) Apparatus for generating mixtures of water vapour with formic acid and with hydrazine hydrate [21]: i) evaporator; ii) liquid pump; iii) alternative solution feed system; 1) eluent evaporator; 2) point of introduction of sample; 3) analytical column; 4) electrical heaters; 5) electrical heater for membrane; 6) capillary for feeding eluent; 7) glass syringe; 8) driving mechanism; 9) vessel containing water or solution; 10) gas cylinder; 11) needle valve.

Nonaka [21] used a modified chromatograph evaporator (Fig. 3*e*) to evaporate mixtures of water with formic acid and hydrazine hydrate. The Reviewers varied the pH of water vapour by placing aqueous formic acid and ammonia of various concentrations in vessel 7 in Fig. 3*d*.

The flow of the vapour eluent in the column was not measured directly in several investigations, owing to the difficulties encountered. Nonaka [20] used a specially designed hygrometer to determine the flow of water vapour. The weight of water G (in g min^{-1}) condensed at the outlet from the column has been measured [29], and hence the flow of vapour calculated by means of the equation

$$V_a = \frac{G \cdot P \cdot v}{P_0} \qquad (1)$$

where v is the specific volume of the vapour at pressure P in the column and the temperature of the column, and P_0 is the atmospheric pressure.

The Reviewers made preliminary use of an ordinary carrier gas to measure

$$C = \frac{V_\alpha j t_{0i}}{g} \quad (2)$$

where V_α is the speed of the gas leaving the column at the temperature of the latter, t_{0i} the retention time of the unsorbed substance, g (g) the weight of the stationary liquid or the adsorbent, and j the pressure gradient factor. The specific retention volume with the vapour eluent was then calculated by means of the formula

$$V_g^T = \left(\frac{t_R}{t_0} - 1\right) \cdot C \quad (3)$$

where the retention times of sorbate and unsorbed substance t_R and t_0 were measured in a stream of water vapour. In both cases methane was used as unsorbed substance.

III. DETECTION

Several of the usual chromatographic detectors are entirely suitable for working with water vapour. Knight [1] used a catharometer to detect substances in a flow of helium saturated with water. Comparison of the thermal conductivity of water vapour with those of other substances indicates that a catharometer can be used with chromatography in water vapour provided that the flow is sufficiently accurately stabilised to avoid fluctuations. Apparently a density balance can also be used in work with water vapour. The temperature of the detectors should, of course, be such as to exclude the possibility of condensation of the vapour.

An argon detector is obviously unsuitable for work with water vapour [35,36]. It was shown [37] that a tenfold increase in the concentration of water in argon (from 10^{-5} to 10^{-4} vol.%) diminishes the sensitivity of the detector by 75%. The permissible concentration of moisture in the gas for a helium detector is 10^{-4}%. [38] The range of linearity of the detector readings becomes shorter with increase in the concentration of water.

A flame-ionisation detector is most suitable with chromatography in water vapour, since it is only slightly sensitive to water. This detector has almost invariably been used with this eluent. Although the signal of a flame-ionisation detector for water is very small, it is considered to exist [39]. Water present in a sample influences the sensitivity of a flame-ionisation detector to substances eluted with it [40]. However, Amirov et al. have found [41] that the sensitivity of such a detector to water is 0.01–0.001% of its sensitivity to benzene, a conclusion confirmed by another worker [42]. The background current of a flame-ionisation detector doubles with increase in the concentration of water in argon from 10^{-4} to 1%. [43] Nevertheless, increasing the concentration of water in argon by a factor of 10^4 (from 10^{-6} to 10^{-2} vol.%) diminishes the sensitivity of the detector to ether by only 29%. When the oxygen supplied to the detector burner was saturated with water at various temperatures [44], saturation up to 12.2 mole % lowered the sensitivity of the detector by 18.7%. Water can be determined by using carbon monoxide instead of hydrogen in the flame-ionisation detector, whose sensitivity is improved by adding small quantities of water or hydrogen to the carbon monoxide. Thus the above results justify the use of a flame-ionisation detector in chromatography using water vapour as eluent. The decrease in sensitivity in the presence of water vapour is so small that very dilute ($5-10 \times 10^{-7}$%) solutions of organic substances can be analysed [20,26]. Nonaka [20] used additional preheating of the detector to avoid condensation of water vapour in the burner. A flame-ionisation detector made of glass [46] has been used [24]. Furthermore, detectors based on automatic titration of the eluate may be suitable for work with a vapour eluent [47].

IV. EFFECT OF WATER VAPOUR ON THE RETENTION AND ON THE ZONE PROFILES OF THE CHROMATOGRAPHED COMPOUNDS

No exhaustive theory has been published to describe the effect of water vapour on the retention and the spreading of chromatographic zones. However, existing results show that water vapour can successfully be used as mobile phase both in gas-adsorption and in gas–liquid chromatography. In the former the water blocks certain active centres of the adsorbent, tending to straighten the sorption isotherms of the test substances. If the stationary liquid in gas–liquid chromatography does not dissolve water, the effect of water vapour is to modify the solid support. In these cases competitive adsorption occurs between water vapour and the test sorbates, the former usually being the more strongly adsorbed, so that elution is accompanied by a displacement effect. Fig. 4 shows as example chromatograms obtained [34] for a mixture of alcohols, with water vapour and nitrogen as eluent. This phenomenon is not observed, of course, if the support or the adsorbent is hydrophobic. The dissolution of water in the stationary liquid produces a binary stationary phase, whose ability to sorb the test substances can be controlled by varying the water content (by varying the temperature, the water vapour content of the mixed eluent, or the pressure).

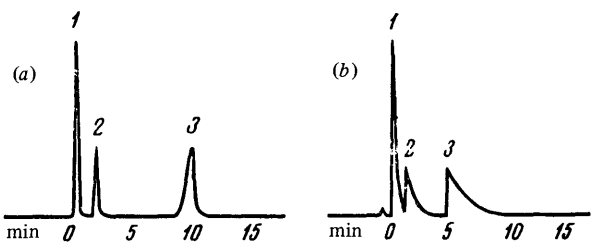

Figure 4. Chromatograms obtained [34] on column containing 5% Silicone SE-30 on diatomite at 200°C with different carrier gases (pressure at inlet 1.4 kg cm^{-2}): *a*) stream; *b*) nitrogen for n-alcohols: 1) dodecyl; 2) tetradecyl; 3) hexadecyl.

Measurements have been made in the Reviewers' laboratory [29] of the linear retention index of aromatic hydrocarbons on a column containing 25% of polyethylene glycol adipate on Spherochrome-1 with nitrogen and steam eluents at various temperatures. The change to water vapour produced a significant increase in the retention indices, especially at lower temperatures: at 130°C the indices of the aromatic hydrocarbons in water vapour exceed those in nitrogen by 1–1.5, which corresponds to 100–150 on Kováts logarithmic scale. This increase is due to the shortened retention times of the n-alkanes used as standards. A similar increase

in the logarithmic retention indices of polar compounds has been observed [24] in water vapour at 150°C, the shift amounting to 50–80 for organic acids. The composition dependence of linear retention indices for a mixed eluent (nitrogen plus water vapour) was almost linear [29].

The replacement of nitrogen by water vapour and dissolution of the latter in the stationary phase leads to a change in form of the sorption isotherms [29]. Whereas with nitrogen the peaks for aromatic hydrocarbons were usually blurred mainly at the tail (provided that samples were sufficiently large), predominant spreading of the front was observed in water vapour. The peaks of n-alkanes, characterised by spreading of the front, became still more unsymmetrical on passing to water vapour. Thus the form of the chromatographic peaks can be controlled by varying the composition of the eluent. With small samples the efficiency of a column operating with steam is quite high. According to Nonaka [20] the height equivalent to a theoretical plate may be 1–2 mm, the optimum speeds of the mobile phase being almost the same as with the usual eluents.

When the column is filled with a solid support at a temperature below the dew-point, a layer of water is formed on the support, and serves as mobile "stationary" phase for separating mixtures. Volatile solvents were first used as "stationary" phases in 1958. [48] Porter and Johnson [49] studied the behaviour of volatile solvents as mobile and liquid phases under conditions of circulatory chromatography. In a detailed study of the behaviour of mobile organic liquid phases in gas chromatography [50,51] heptane, benzene, ethanol, and other compounds served as both gas and liquid phases. These compounds have recently been used as mobile phases [52,53]. Water has served simultaneously as vapour and liquid phases [10-12,54]. Phifer and Plummer [10] analysed polar compounds with good solubility in water, which ensured considerable retention of them in the column.

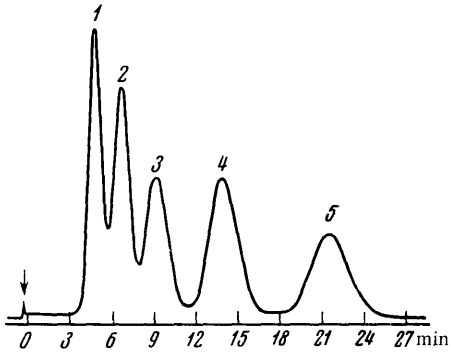

Figure 5. Separation of C_1–C_5 n-alcohols in a flow of a mixture of nitrogen and water vapour [10] at 70°C: 1) pentanol; 2) butanol; 3) propanol; 4) ethanol; 5) methanol:

It is interesting that, since water interacts by means of hydrogen bonds with alcohols undergoing analysis, the elution sequence observed is opposite to the usual order (Fig. 5). Karger et al. [11,12] investigated the behaviour of non-polar sorbates, which, being almost insoluble in water, were eluted very rapidly from the column. The relative rate of elution of alkanes on a column with water exceeded those on columns with Apiezon and with polyethylene glycol by factors of 30 000 and 67 respectively. On a column with water n-tetracosane is eluted even at 85°C, which is 306 deg below its boiling point (the vapour pressure of n-tetracosane at 85°C is 2×10^{-4} mmHg). In the separation of n-alkanes the ratio of the degree of separation to the duration of analysis on a column with water at 20°C exceeded that on a column with squalane by a factor of 12. This confirms the conclusion [55,56] that the rapidity of analysis of non-polar compounds is increased on passing to polar stationary phases. Karger et al. showed that the activity coefficients of n-alkanes in water are of the order of 10^6. According to Pecsap and Martin [54] these quantities for C_5–C_7 n-alkanes are $(1-8) \times 10^3$ at 20°C. These workers studied also the thermodynamics of the dissolution in water of various other organic compounds, including alcohols, aldehydes, and chlorinated methanes.

Water was used as stationary liquid in earlier work [57,58] to separate chlorinated methanes at 20°C. Here, however, a dry carrier gas was used initially. Varying the percentage impregnation of kieselguhr with water led to a change in the elution sequence of the sorbates.

Giddings et al. [59,60] studied the effect of surface-active additives on the efficiency of a column with water deposited on glass beads. The carrier gas was moistened helium. Experiments at 2°C showed that a small addition to water of a surface-active agent, in particular hexadecanol, led to marked broadening of the sorbate peak owing to the additional resistance to mass transfer at the surface.

V. PREPARATIVE GAS CHROMATOGRAPHY

The use of water vapour and its mixtures in preparative gas chromatography is extremely promising, since it will lower the economic cost, enable the selectivity of the column to be controlled, and also ensure complete recovery of the separated substances. In particular, water vapour and its mixtures with organic vapours will ensure complete condensation of the eluate after passing through the column even at ordinary temperatures by the use of running water as coolant [29]. Such a procedure enables losses of separable substances to be almost eliminated, and of course is preferable to published methods [61-63] of the low-temperature condensation of argon and carbon dioxide emerging from the column.

It is interesting that, if the eluent is a mixture of water vapour and the vapour of a water-insoluble organic compound, condensation of the eluent in the trap is followed by extraction of the separable substance, which condenses in one of the phases (aqueous or organic). Thus the proportions of the components of the mobile phase (water vapour and organic eluent) should be chosen, depending on the nature of the separable substances, to ensure that the latter is concentrated sufficiently.

Preparative isolation of individual aromatic hydrocarbons has been accomplished [29] on a column of internal diameter 20 mm and length 3.2 m containing 25% of polyethylene glycol adipate on Spherochrome with water vapour and its mixtures as carrier gas. Hydrocarbons and polar compounds have been isolated [30,31] in a flow of water vapour on columns of a silicone and of polyethylene glycol acetate. It has also been reported that water vapour may be used in projected industrial chromatographic equipment, which would eliminate the eluent recirculation and fine purification system [64].

An original method for the preparative separation of complicated mixtures by combining fractional distillation with chromatography in a stream of water vapour has been suggested by Klesment [32]. The separable mixture (coal or shale tar) was run into the still of a fractionating column and steam-distilled, with the flow from the upper part of the column (of height 40 cm and efficiency 7–10 theoretical plates) continuously entering a chromatographic column of length 2.8 m and internal diameter 12 mm containing 21% of Apiezon L on Rysorb C operating with temperature programming. Narrow fractions (0.2–1 ml) were collected in vacuum receivers (residual pressure 50 mmHg) at equal time intervals. Fractions boiling up to 400°C were isolated by the above method.

Thus the use of water vapour as mobile phase represents a definite stage in the development of gas chromatography.

Compatibility of the Methods of Calculation and Semiempirical Parameters in the Theory of Molecules with Conjugated Bonds

I.A.Misurkin and A.A.Ovchinnikov

Various methods for the selection of the parameters of the model π-electron Hamiltonian are discussed, certain aspects of the interaction of π electrons with the σ skeleton are considered, and the scope of various methods for the calculation of the electronic structures of molecules and radicals wtih conjugated bonds are analysed.
The bibliography includes 90 references.

1. INTRODUCTION

The modern theory of the electronic structures of compounds with conjugated bonds employs the π-electron approximation, which has been analysed in detail in a previous review by the present authors[1]. According to this approximation, it is possible to obtain all the observed characteristics of conjugated many-electron systems if only the π electrons are considered explicity in the quantum-chemical calculation. The properties of π electrons are specified by an effective model Hamiltonian[4]:

$$H = \sum_{p,q,\eta} h_{pq} c^{+}_{p\eta} c_{q\eta} + \sum_{p,q,\eta,\rho} \gamma_{pq} c^{+}_{p\eta} c_{p\eta} c^{+}_{q\rho} c_{q\rho}, \qquad (1)$$

where $c^{+}_{p\eta}$ and $c_{p\eta}$ are the operators of the creation and annihilation of an electron with a spin η in the state with the function $\varphi_p(\mathbf{r})$ localised at an atom p, h_{pq} is the one-electron parameter for the kinetic energy and the energy of attraction of the σ skeleton, and γ_{pq} is the parameter for the Coulomb repulsion of the π-electrons at the atoms p and q.

A minimal representation of second quantisation is employed in the review: in formulating the Hamiltonian and other operators and in considering the derivation of important results obtained by Linderberg (in Section 2, a).

In the present review attention is concentrated on the problem of the consistency between the method of calculation and the calculated molecular characteristics and also the problem of consistency between the semiempirical parameters (h_{pq}, γ_{pq}, etc.) and the method of calculation. Certain problems of the interaction of π-electrons with the σ skeleton, where the question of the π-electron approximation and its possibilities becomes most acute, are likewise examined.

2. VARIOUS METHODS FOR THE DETERMINATION OF THE PARAMETERS OF THE MODEL π-ELECTRON HAMILTONIAN

We shall consider certain methods or schemes for the parametrisation of the effective model Hamiltonian which differ from the two general parametrisation schemes (Scheme 1 and Scheme 2) examined in the previous review[1]. All these schemes normally give good agreement with experiment and similar effective Hamiltonian parameters. Such are the parametrisation schemes for conjugated systems with N and O heteroatoms[2] and with amino-groups[3], and for conjugated hydrocarbons[4]. In these studies the authors altered somewhat the generally accepted values of the parameters in order to achieve a better description of the experimental data for molecules of the specified type. Calculations have been made[5] on heterocyclic conjugated molecules with N, O, and S atoms and in a subsequent study[6] fairly combersome formulae were proposed whereby all the empirical parameters of the earlier investigation[5] were reproduced with satisfactory accuracy (using Slater's $2p_z$ functions). These formulae were obtained from model physical ideas concerning the π-electron system and the σ skeleton.

This parametrisation procedure is convenient in computer calculations and is formally (but not in reality) less empirical than Scheme 1. Empirical information is contained, as in Scheme 2, in the effective charges of Slater's functions and in the special form of the formulae for the parameters[1,6].

The simple parametrisation schemes of the Pariser–Parr–Pople (PPP) method (neglect of the parameters of the Coulomb interaction between electrons in non-adjacent atoms, neglect of the relation between $\beta_{\mu\nu}$ and $R_{\mu\nu}$, etc.) have been used in calculations on polysubstituted benzenes and five-membered heterocycles with N, O, and S atoms[7], azabenzenes and azanaphthalenes[8], and substituted benzenes, pyridines, and pyrimidinones[9]. It is interesting to note that the optimal values of the same parameters of the model Hamiltonian for molecules of different homologous series differ somewhat as a rule. This is typical for a semiempirical theory.

In one of the parametrisation schemes for hydrocarbons[10,11] the benzene excitation energies (as in the old Pariser–Parr method[12]) and the benzene ionisation potential are used to determine $\gamma_{\mu\nu}$ and βCC. If the excitation energies (in terms of the ZDO approximation) depend on the differences between the $\gamma_{\mu\nu}$, then the $\gamma_{\mu\nu}$ themselves enter into the expression for the ionisation potential obtained using Koopman's theorem. As a result, somewhat unusual values of the parameters were obtained for benzene: βCC = −2.4 eV and γ_{11} = 9.4 eV[10] or βCC = −2.5 eV and γ_{11} = 8.2 eV.[11] The remaining $\gamma_{\mu\nu}$ were estimated from formulae of the Mataga–Nishimoto type[12].

We believe that it is more natural to employ a corrected Koopman's relation [see the previous review[1], formula (32)] or to compensate the inaccuracies in the Koopman's relation by introducing a special parameter ΔW_0 [see the previous review[1], Eqns. (15)–(17)], as was done in Scheme 1, particularly since the improvements introduced by the new parameters are insignificant. For example the energy of the $S \rightarrow T$ transition in anthracene is ΔE = 1.84 eV (experimental value), ΔE = 1.79 eV (value obtained with the new parameters[10]), and ΔE = 1.66 eV (value calculated by the PPP scheme taking into account excited configurations made up from Hückel molecular orbitals[13]).

a. The Linderberg Method for the Calculation of Resonance Integrals

The new possibilities for the creation of a unified parametrisation scheme for the effective Hamiltonian arose after the publication of Linderberg's study[14]. In order to calculate the resonance integral $\beta_{\mu\nu}$ or the parameter $h_{\mu\nu}$ in the PPP(1) Hamiltonian, Linderberg employed a familiar quantum-mechanical relation for the momentum $\mathbf{p}$ in terms of the commutation relation

$$[\mathbf{r}, H] \equiv \mathbf{r}H - H\mathbf{r},$$

the coordinates $\mathbf{r}$, and the Hamiltonian H:

$$i\hbar \frac{d\mathbf{r}}{dt} = [\mathbf{r}, H] = i\hbar \frac{\mathbf{p}}{m}, \qquad (2)$$

where H is the PPP(1) Hamiltonian, $\hbar$ the Planck constant, and m the mass of the electron. In the second quantisation representation the operators $\mathbf{r}$ and $\mathbf{p}$ can be expressed as follows in terms of the electron creation and annihilation operators:

$$\mathbf{r} = \sum_{q,\eta} \mathbf{R}_q c^+_{q\eta} c_{q\eta}, \qquad \mathbf{p} = \sum_{\nu \neq s, \eta} \mathbf{p}_{\nu s} c^+_{\nu\eta} c_{s\eta}, \qquad (3)$$

where $\mathbf{R}_q$ is the coordinate of the atom q with which the basis function $\varphi_q(\mathbf{r})$ is associated. The matrix element $\mathbf{p}_{\nu s}$ has the following form (ν and s are neighbouring atoms):

$$\mathbf{p}_{\nu s} = \int \varphi_\nu(\mathbf{r})(-i\hbar\nabla)\varphi_s(\mathbf{r})\,d\mathbf{r} = \int \varphi(\mathbf{r}-\mathbf{R})(-i\hbar\nabla)\varphi(\mathbf{r})\,d\mathbf{r} = -i\hbar\nabla_R \int \varphi(\mathbf{r}-\mathbf{R})\varphi(\mathbf{r})\,d\mathbf{r} = -i\hbar\nabla_R S(R). \qquad (4)$$

where $\mathbf{R} = \mathbf{R}_S - \mathbf{R}_V$ and $S(R)$ is the overlap integral between $\varphi_s(\mathbf{r})$ and $\varphi_\nu(\mathbf{r})$.

Using Eqns. (1), (3), and (4), we obtain from Eqn. (2) the relation between the parameter $h_{\nu s}$ of the Hamiltonian and the matrix element $\mathbf{p}_{\nu s}$ of the momentum:

$$i\hbar\,\mathbf{p}_{\nu s} = h_{\nu s}(\mathbf{R}_\nu - \mathbf{R}_s),$$

or, finally, we obtain the following formula for the resonance integral:

$$h_{\nu s} \equiv \beta_{\nu s}(R) = \frac{\hbar^2}{m}\frac{1}{R}\frac{dS}{dR}, \quad R = |\mathbf{R}_\nu - \mathbf{R}_s|. \qquad (5)$$

The Slater functions with Z_{eff} = 3.18 for carbon and Z_{eff} = 3.8 for nitrogen as well as the Hartree–Fock functions for these atoms were used as the atomic $2p_z$ functions from which the $\varphi_s(\mathbf{r})$ functions were constructed with the aid of Lowdin's orthogonalisation procedure[15]. The results of the calculation (together with certain refinements[16]) for the benzene and ethylene bonds and the aniline CN bond are presented in Table 1. It was found that the observed βCN and βCC are close to the empirical values determined from the absorption spectra.

Linderberg's scheme for the calculation of resonance integrals has been used in calculations on a number of molecules with heteroatoms[17,18]. It was found that the results of the calculation agree well with experiment and are close to the results obtained in calculations employing the usual parametrisation schemes[19].

We believe that the derivation of relations between theoretical parameters, such as the Linderberg relation (5), constitutes a fruitful procedure for the development of the theory and for the achievement of its internal self-consistency.

We may note certain inaccuracies in the derivation of Eqn. (5), which was taken from Linderberg's paper[14]. According to this derivation, the overlap integral S is

calculated with the orthogonal functions $\varphi_p(\mathbf{r})$. Therefore the overlap integral $S = 0$ for $\varphi_s(\mathbf{r})$ and $\varphi_p(\mathbf{r})$ ($s \neq p$), which does not prevent the derivative dS/dR from being non-zero. However, the functions $\varphi_p(\mathbf{r})$ are made up by the superposition of non-orthogonal atomic functions $\chi_i(\mathbf{r})$ of the $2p_z$ type localised at atoms i (see the previous review[1] for more detail):

$$\varphi_p(r) = \sum_i \chi_i(r)\, c_{ip}\,.$$

Table 1. The resonance integrals calculated by Linderberg's method[14] [the upper figures represent the value calculated using Slater's functions and the lower figures the values obtained with the Hartree–Fock functions for the C and N atoms. The last columns list the resonance integrals ($-\beta$) for benzene obtained by an improved calculation using Slater's functions with different Z (Jug[16])].

Molecule	Designation of resonance integral	C-C bond			
		R, Å	$-\beta$ (R), eV	$Z = 3.18$	$Z = 2.58$
Ethylene	β_{12}	1.34	2.685 2.588		
Benzene	β_{12}	1.4	2.42 2.38	2.27	2.47
	β_{13}	2.42	0 0	—0.05	—0.02
	β_{14}	2.8	0.14 0.19	0.08	0.13
		CN bond			
Aniline	β CN	1.47	1.75 1.77		

Therefore in Eqns. (3) and in subsequent treatment $\mathbf{R_q}$ is not a coordinate of the atom q. Formally $\mathbf{R_q}$ is a diagonal matrix element, expressed as a function of $\mathbf{r}$, calculated using the functions $\varphi_q(\mathbf{r})$:

$$\mathbf{R}_q = \int \varphi_q(\mathbf{r})\, \mathbf{r}\, \varphi_q(\mathbf{r})\, d\mathbf{r}\,.$$

On the other hand, the true coordinate of the atom q, which will now be designated by $\mathbf{R}^0_q$, is equal to the diagonal matrix element expressed as a function of $\mathbf{r}$, using the functions $\chi_q(\mathbf{r})$:

$$\mathbf{R}^0_q = \int \chi_q(\mathbf{r})\, \mathbf{r}\, \chi_q(\mathbf{r})\, d\mathbf{r},$$

and it is readily seen that $\mathbf{R_q} \neq \mathbf{R}^0_q$. Furthermore, Eqn. (3) for the operator $\mathbf{r}$ is inaccurate also because non-zero matrix elements with the off-diagonal indices p and q, expressed in terms of the functions $\varphi_p(\mathbf{r})$, were neglected in its formulation. The exact formula for the operator $\mathbf{r}$ is

$$\mathbf{r} = \sum_{pq,\eta} \mathbf{R}_{pq} c^+_{p\eta} c_{q\eta}, \quad \mathbf{R}_{pq} = \int \varphi_p(\mathbf{r})\, \mathbf{r}\, \varphi_q(\mathbf{r})\, d\mathbf{r}.$$

These inaccuracies were corrected in subsequent studies†, but we shall not consider this problem in greater detail‡ in view of the fairly cumbersome nature of the expressions.

†In Linderberg's[20] and Jug's[21] studies.

‡Various aspects of the employment and interpretation of Eqn. (5) are discussed in a recent study[22].

Linderberg's idea, employing the fundamental relation between the coordinate and the momentum, appears to us more attractive and fruitful than direct calculation of $\beta_{\mu\nu}$ with specified functions and potentials of the Goeppert–Mayer and Sklar type (see, for example, Yoshida and Kobayashi[6] whose calculated $\beta_{\mu\nu}$ are very close to the semiempirical values). At the same time, we believe that in the future it will be necessary to compare carefully these two methods for the calculation of $\beta_{\mu\nu}$.

3. PROBLEMS OF THE INTERACTION OF π ELECTRONS WITH THE σ SKELETON

The problem of the interaction of π and σ electrons have always been of interest for the semiempirical theory of conjugated systems, since the limits of the applicability of the π-electron theory are then elucidated and the significance of the semiempirical formulae employed is discovered.

a. The Mixing of One-Electron σ and π Energy Levels in Conjugated Molecules

Studies have been published recently indicating the mixing of one-electron σ and π energy levels in conjugated systems, which seemingly constitutes evidence against the π-electron approximation. Thus analysis of experiments on the photoionisation of benzene[23,24] showed that a filled σ energy level is located in benzene between filled π levels. A similar pattern with mixing of σ and π energy levels follows also from numerous calculations on various molecules in terms of the SCF approximation, which have given rise to a lively discussion[25].

Many investigators found the reports of such mixing of σ and π levels very unexpected, because all the properties of conjugated systems, including absorption spectra, had been satisfactorily explained hitherto with the aid $\pi \rightarrow \pi^*$ transitions alone. All previous experience in the quantum chemistry of conjugated system could be reconciled with the mixing of σ and π energy levels only by postulating a weak interaction between the σ- and π-electron systems. This was in fact found to be the case.

A study of transition probabilities by the Hückel method for all the valence electrons of naphthalene and anthracene[25] showed that the transition probabilities (oscillator strengths) for the $\sigma \rightarrow \pi^*$ transitions are smaller by 3–4 orders of magnitude than for the $\pi \rightarrow \pi^*$ transitions. In $\sigma \rightarrow \pi^*$ transitions the emission is polarised perpendicular to the plane of the conjugated molecules, because only matrix elements of the type[25]

$$I = \langle \varphi_{s_i} | z | \varphi_{z_i} \rangle\,,$$

where φ_{s_i} and φ_{z_i} are $2s$ and $2p_z$ functions of the atom i, contribute to the transition moment (in terms of the one-centre approximation). The quantity $I \leqslant a_0$ (a_0 is the Bohr radius) is in fact independent of the molecular size and the number of atom i.

In $\pi \rightarrow \pi^*$ transitions the emission is polarised in the molecular plane and matrix elements of the type

$$X_i = \langle \varphi_{z_i} | x | \varphi_{z_i} \rangle, \quad Y_i = \langle \varphi_{z_i} | y | \varphi_{z_i} \rangle$$

contribute to the transition amplitude. X_i and Y_i are essentially coordinates of the atoms i, so that they are comparable to the dimensions of the conjugated molecule, exceeding appreciably the value of a_0.

There is yet another cause of the decrease of the probability of the $\sigma \rightarrow \pi^*$ transitions. When the two molecular orbitals involved in the $\sigma \rightarrow \pi^*$ transition are formulated:

$$\psi^\sigma = \sum_i c_i^\sigma \varphi_{s_i} + \text{члены с } \varphi_{x_i}, \varphi_{y_i}$$

$$\psi^\pi = \sum_i c_i^\pi \varphi_{z_i},$$

the $\sigma \rightarrow \pi^*$ transition amplitude becomes

$$\langle \psi^\sigma | z | \psi^\pi \rangle = \langle \varphi_{s_i} | z | \varphi_{z_i} \rangle \sum_i c_i^\sigma c_i^\pi = I \sum_i c_i^\sigma c_i^\pi. \quad (6)$$

It was discovered that this amplitude is small also because the coefficients c_i^σ are as a rule small for the highest occupied σ orbitals.

This analysis shows that the lines of the $\sigma \rightarrow \pi^*$ transitions must be much weaker than those of the $\pi-\pi^*$ transitions, which predominate in the experimental spectrum. The different polarisations of emission in $\pi \rightarrow \pi^*$ and $\sigma \rightarrow \pi^*$ transitions may assist the observation of weak $\sigma \rightarrow \pi^*$ transitions. Furthermore, it is quite likely that ionisation from filled σ orbitals was indeed observed in the photoionisation of benzene and other molecules[23,24,26].

We may note that, for small conjugated molecules such as ethylene and formaldehyde, $\sigma \rightarrow \pi^*$ transitions (and $\pi-\sigma^*$ transitions) are just as intense as the $\pi \rightarrow \pi^*$ transitions. This also follows from Eqn. (6), since in ethylene, for example, the coefficients c_i^σ are relatively large[25].

b. Calculations on Non-planar Conjugated Systems

The interaction of σ and π electrons becomes significant when non-planar conjugated systems are considered. So far very few studies have been devoted to calculations on the electronic structures of such systems. For example, stilbene and diphenylbutadiene molecules, in which the coplanarity breaks down as a result of rotation about the central C–C bond of one part of the molecule relative to the other by an angle α, have been considered[27,28]. In the calculation by the PPP method the usual parameters were used and only the resonance integral of the central bond was multiplied by $\cos\alpha$. A good agreement has been obtained[28] with the experimental position of the first singlet energy level, while in another study[27] not even a qualitative explanation of the energy level shifts on passing to a non-planar system was obtained.

We believe that the problem of the parameters for non-planar conjugated systems cannot be solved by a simple alteration of the resonance integral for one bond. The interactions between non-bonded atoms in the molecule become significant in non-planar systems[28] and it is necessary to take into account more accurately the repulsion of the positively charged σ skeleton[29]. In non-planar systems the π-electron orbitals are no longer orthogonal with respect to the orbitals of the electrons in the σ skeleton. Therefore, in order to consider π electrons separately, as before, i.e. in order to retain the π-electron approximation, it is necessary to carry out the orthogonalisation (for example, by Löwdin's method[15]) of the π-electron orbitals in the non-planar configuration with respect to the orbitals of the new σ skeleton. Only then is it possible to understand how the effective parameters of the model π-electron Hamiltonian are changed relative to the planar case.

c. The Hyperfine Structure of the ESR Spectra and the McConnell Formula

The interaction of σ and π electrons can be readily observed by ESR (and NMR) methods, when a spin density ρ^π appears in the π-electron system. The spin density ρ^π in π-electron radicals, radical-ions, or triplet states of conjugated molecules polarises the electrons of the σ skeleton and leads to the appearance of a spin density ρ^σ in the σ-electron system. As a result of the contact interaction of ρ^σ with the magnetic moments of the nuclei in the conjugated system (when these nuclei have magnetic moments), a hyperfine structure (HFS) appears in the ESR method[30], the additional (hyperfine) splitting of the ESR Zeeman line by each magnetic nucleus is specified by the hyperfine splitting constant. In the case of hydrocarbons the HFS of the ESR spectra depends on the proton splittings a_{H_i} in the Ci–Hi bonds.

According to the theory of McConnell and Chesnut[31], the splitting a_{H_i} is proportional to the exchange integral calculated using the $2p_z$ functions (φ_{z_i}) of the atoms Ci and the functions of the ground (Φ_σ) and excited (Φ_{σ^*}) states of the electrons in the Ci–Hi bond:

$$a_{H_i} = \text{const} \cdot \langle \Phi_\sigma \varphi_{z_i} | \Phi_{\sigma^*} \varphi_{z_i} \rangle. \quad (7)$$

Making certain assumptions, the relation known as the McConnell formula was obtained from Eqn. (7):[31]

$$a_{H_i} = Q \rho_i^\pi, \quad (8)$$

where ρ_i^π is the π-electron spin density at the atom C_i linked to Hi and Q is a constant. Eqn. (8) made it possible to employ the results of the calculation of ρ_i^π in the interpretation of ESR spectra. As a result, ESR became one of the procedures for the investigation of the electronic structures of conjugated systems.

Subsequently analysis of the systematic deviations from McConnell's formula [Eqn. (8)] for hydrocarbon radical-cations and radical-anions led to a refinement of this formula[32] by the introduction of a relation between a_{H_i} and the π-electronic charge q_i of the atom Ci:

$$a_{H_i} = (Q' + Kq_i)\rho_i^\pi. \quad (9)$$

This relation, known as the Colpa–Bolton formula, was obtained from Eqn. (7) on the assumption that the charge q_i influences the σ orbital of the C–H bond[32].

Detailed analysis of the approximations leading to the McConnell formula [Eqn. (8)] showed[33] that the formula is correct only in the zeroth approximation. A more accurate formula for a_{H_i} includes both the diagonal elements of the spin density matrix $Q_{ii} = \rho_{ii}^\pi$ and the off-diagonal elements Q_{ij} ($Q_{ij} = c_i^0 c_j^{0*}$, where c_j^0 is a coefficient of the jth atomic orbital for the unpaired electron molecular orbital). This more general formula is[33]

$$a_{H_i} = -26{,}07 Q_{ii} - 10.40 \sum_{k\ (i\ \text{neighbours})} Q_{ik}\ (\text{gauss}). \quad (10)$$

A similar formula was proposed for a_{H_i} even earlier[34].

The results of the calculation of a_{H_i} by Eqn. (10) are presented in Table 2, which shows that Eqn. (10) represents satisfactorily the changes in a_{H_i} on passing from a cation to an anion and therefore constitutes a generalisation of both the McConnell [Eqn. (8)] and Colpa–Bolton [Eqn. (9)] formulae.

Nevertheless, the McConnell and Colpa–Bolton formulae are widely used in semiempirical calculations, because

they make it possible to determine with satisfactory accuracy (to within about 10–15%) both the relative and absolute HFC constants not only for protons but also for other nuclei (^{13}C, ^{14}N, etc.)[35]. Eqns. (8) and (9) are usually treated as empirical relations with the constants Q, Q', and K.

Table 2. The hyperfine splittings a_{H_i} for the positive and negative ions of naphthalene and anthracene[33].

Molecule	Sign of ion	No. of atom	a_{H_i}, G expt.	a_{H_i}, G Eqn.(10)
	−	1	−4.90	−5.11
		2	−1.83	−1.78
	+	1	−5.54	−5.64
		2	−2.06	−1.89
	−	1	−2.74	−2.74
		2	−1.51	−1.35
		9	−5.56	−5.45
	+	1	−3.11	−2.80
		2	−1.40	−1.24
		9	−6.56	−6.68

Relations between the experimental constants $a_{H_i}^{exp}$ and $a_{H_i}^{calc}$ calculated by Eqns. (8) and (9) for a large number of π-electron radicals have been analysed[36]. The ρ_i^π were calculated by ten different methods, optimum values of the constants Q, Q', and K being selected for each method. It was found that all the methods for the calculation of ρ_i^π yield a good agreement between $a_{H_i}^{exp}$ and $a_{H_i}^{calc}$. The average discrepancies are $\leqslant 1$ G, although in a few instances they may reach 2–3 G. However, the optimum constants Q, Q', and K depend markedly on the method of calculation (Table 3).

Table 3. The optimum constants Q' and K (gauss) in the Colpa–Bolton formula [Eqn. (9)] for different methods of calculating spin densities[36].

Method of calculation of spin density	Q'	K
Hückel	35.62	16.78
Hückel + CI (Ref.37)	31.50	16.86
McLachlan	25.05	18.37
UHF	20.43	10.60
UHF with annihilation of the quartet	28.50	12.66

It was also noted[36] that the optimum constants depend on the number of neighbours of the carbon atom and on the sign of its spin density. These fine features are not taken into account in the McConnell formula [Eqn. (8)]. A characteristic example is the benzyl radical, where the ratio $a_{H_2}/a_{H_4} < 1$ (in contrast to the McConnell formula), while according to all the methods of calculation employed, the ratio of the spin densities of the carbon atoms $\rho_2^\pi/\rho_4^\pi \geqslant 1$ (Table 4).

A non-empirical calculation of the electronic structure of the benzyl radical in terms of the SCF approximation taking into account all the electrons (σ and π), carried out by Kruglyak et al.[44], yielded directly the spin densities of the *ortho*- and *para*-protons. The ratio of these densities $\rho_{H_2}^\sigma/\rho_{H_4}^\sigma < 1$, in agreement with experiment, while the ratio of the spin densities in the π-electron system was still incorrect: $\rho_2^\pi/\rho_4^\pi \gtrsim 1$. The calculation showed that the $\sigma \rightarrow \pi$ interaction had an insignificant influence on the π orbitals and on the distribution of spin density in the π-electron system. It was therefore concluded that the McConnell formula is inadequate for the calculation of a_{H_i} for the benzyl radical[44].

Table 4. Spin densities calculated by different methods[38].

Radical	No. of atom	Method of calculation: SCF	SCF + singly excited configurations	full CI[c]	UHF	UHF with annihilation	Hückel	McLachlan	$\lvert a_{H_i}\rvert$ (expt.) G

4. THE DISTRIBUTION OF SPIN DENSITY IN RADICALS

a. The Hückel Method

The application of the Hückel method makes it possible to obtain a qualitatively correct distribution of spin density in the radical[45–48]. In combination with the McConnell formula, the Hückel method permits the interpretation of fairly complex ESR spectra, which may have an unresolved HFS for a solid phase. In the interpretation of such spectra of the radicals of certain acetylene derivatives the necessity to take into account the real bond lengths in the radicals in order to obtain a correct spin density distribution was demonstrated for the first time[48]. The "bond length–bond order" formula and the linear relation between the resonance integral β and the bond length, $\beta = \beta_0 + \delta(R - R_0)$, were used for this purpose in the

Hückel approximation. It was found that the exponential relation [49]

$$\beta = \beta_0 \exp[a(R_0 - R)] \qquad (11)$$

frequently leads to an incorrect spin density distribution in radicals with long and short bonds (from 1.45 to 1.20 Å). For example in the radical $C_{(1)}H_2-C_{(2)}\equiv C_{(3)}H$ the ratio of the spin densities at the $C_{(1)}$ and $C_{(3)}$ atoms is

$$\rho_1^\pi/\rho_3^\pi = (\beta_{23}/\beta_{12})^2$$

and Eqn. (11) leads to a very high value of this ratio, in conflict with experiment [48]. The region of applicability of Eqn. (11) is limited to small changes in bond lengths, were the exponential relation barely differs from a linear relation.

For aromatic radicals, where all the $R \simeq R_0 = 1.4$ Å, the influence of differing bond lengths on the spin density distribution was not studied systematically. Nevertheless allowance for the real geometry of the radicals can alter the calculated ρ_i^π by 5–10%. This remark applies not only to the Hückel method but also to other methods in which the interaction between electrons is taken into account.

The Hückel method yields satisfactory relative values of not unduly small spin densities ρ_i^π, but fails to predict small (positive and negative) values of ρ_i^π. A negative spin density appears as a result of the repulsion of π electrons with opposed spin projections, which can accumulate at different atoms and lead to a pattern of alternating signs of the spin density at neighbouring atoms. Therfore, in order to describe such spin density distributions, it is necessary to take into account explicitly the interaction of π electrons. The changes in spin density $\Delta\rho_i^\pi$ due to inclusion of the π-electron interaction are as a rule small ($|\Delta\rho_i^\pi| < 0.1$), which accounts for the relative success of the Hückel method.

b. Methods with Different Molecular Orbitals for Different Spins. Projection of the Wave Functions on to States with a Correct Total Spin

In order to take into account the electron interactions, it is reasonable to employ the SCF method with different molecular orbitals for electrons having different spins [50–55]. In this method two electrons with opposite spins do not occupy the same molecular orbital (as in the simple SCF method) but two different molecular orbitals. As a result, an electron having one spin is largely located at one set of atoms in the molecule, while an electron having another spin is located at another set of atoms. Owing to the decrease of the Coulomb interaction energy of these electrons, the total energy of the molecule is lower than in the simple molecular orbital method [50,51]. The method using different molecular orbitals for different spins is equivalent to the method of interacting configurations and is used to calculate the electronic structures of conjugated molecules [56]. Its application to conjugated radicals provides a natural explanation of the appearance of negative spin densities in the system.

One of the variants of this method is called the unrestricted Hartree–Fock method (UHF). The wave function of the radical in the UHF method (one Slater determinant of molecular spin orbitals) consists of a superposition of functions for different spins and can be represented as follows:

$$\Phi = \sum_{S=1/2}^{N/2} a_S \Phi_{1/2}^S , \qquad (12)$$

where $\Phi_{1/2}^S$ are orthonormalised functions which are the eigenfunctions of the operator of the square of the total spin $\hat{S}^2$ with eigenvalues $S(S+1)$ and the operator of the projection of the total spin $\hat{S}_z$ with $S_z = 1/2$. In order to separate the components having the spin $S = 1/2$ (the radicals have a doublet ground state) from Eqn. (12), a fairly cumbersome spin projection operation is necessary. The application of the operator [57]

$$O_{1/2} = \prod_{k\,(\neq 1/2)}^{N/2} [k(k+1) - \hat{S}^2]$$

to function (12) eliminates all terms except $a_{1/2}\Phi_{1/2}^{1/2}$. The operator $\hat{S}^2$ for a system of N electrons is

$$\hat{S}^2 = -\frac{1}{4}N(N-4) + \sum_{i<j}^{N} P_{ij}^\eta,$$

where P_{ij}^η interchanges the spin coordinates of the electrons i and j.

In view of the complexity of the projection operation, it has been suggested [58,59] that one excludes from function (12) only the quartet component ($S = 3/2$), which apparently makes the next highest contribution to the function Φ after the component with $S = 1/2$. The quartet is annihilated by the operator

$$\hat{A} = \hat{S}^2 - 15/4.$$

The closeness of the average value of $\langle\Phi|S^2|\Phi\rangle$ to $3/4 = S(S+1)$ for $S = 1/2$ can serve as a criterion of the closeness of the function Φ to the doublet state. Usually $\langle\Phi|S^2|\Phi\rangle > 3/4$ and the annihilation of the quartet reduces the average value of $\hat{S}^2$. However, it has been shown [60] that in certain cases the mean $\hat{S}^2$ increases after the annihilation of the quartet. The observed ineffectiveness of the annihilation of the quartet depends on the choice of the parameters of the PPP Hamiltonian [60].

The UHF method and the UHF method with partial annihilation are fairly complex and the results obtained for the distribution of spin density are so far only qualitatively consistent with one another and with the results of calculations with complete allowance for the interaction of π electrons (Table 4).

In certain cases, particularly in analytical calculations for large molecules with a regular structure, another technique of projecting the wave function on to a state with a correct total spin is more convenient [61–63]. This technique employs the operator of a finite rotation in spin space by the Eulerian angles $\tilde{\alpha}$, $\tilde{\beta}$, and $\tilde{\gamma}$:

$$\hat{R} = \exp(-i\hat{S}_z\tilde{\alpha}) \cdot \exp(-i\hat{S}_y\tilde{\beta}) \cdot \exp(-i\hat{S}_z\tilde{\gamma}).$$

The action of the operator $\hat{R}$ on the function Φ_m^S, the eigenfunction $\hat{S}^2$, and $\hat{S}_z$ (with a spin S and its projection $S_z = m$) is defined by the formula

$$\hat{R}\Phi_m^S = \sum_{n=-S}^{S} D_{nm}^{(S)}(\tilde{\alpha}\tilde{\beta}\gamma)\,\Phi_n^S, \qquad (13)$$

where $D_{nm}^{(S)}(\tilde{\alpha}\tilde{\beta}\tilde{\gamma})$ is the Wigner D-function [64]. D-Functions possess the property of orthogonality, which is important for our problem:

$$\int_0^{2\pi} d\tilde{\alpha} \int_0^{\pi} d\tilde{\beta}\sin\tilde{\beta} \int_0^{2\pi} d\tilde{\gamma}\, D_{nm}^{(S)}(\tilde{\alpha}\tilde{\beta}\tilde{\gamma})\, D_{n'm'}^{(S')*}(\tilde{\alpha}\tilde{\beta}\tilde{\gamma}) = \frac{8\pi^2}{2S+1}\delta_{SS'}\delta_{nn'}\delta_{mm'}. \qquad (14)$$

We allow the operator $\hat{R}$ to act on the function Φ [Eqn. (12)]. Using Eqn. (13), we obtain

$$\hat{R}\Phi = \sum_{S_1=1/2}^{N/2} a_{S_1} \sum_{n=-S_1}^{S_1} D_{n1}^{(S_1)}(\tilde{\alpha}\tilde{\beta}\tilde{\gamma})\,\Phi_n^{S_1} . \qquad (15)$$

We multiply both sides of Eqn. (15) by $D^{(S)}_{S_{Z1/2}}(\tilde{\alpha}\tilde{\beta}\tilde{\gamma})$ and integrate with respect to all the angles, as in Eqn. (14); then, using Eqn. (14), we obtain

$$a_S \Phi^S_{S_z} = \frac{2S+1}{8\pi^2} \int_0^{2\pi} d\tilde{\alpha} \int_0^{\pi} d\tilde{\beta} \sin\tilde{\beta} \int_0^{2\pi} d\tilde{\gamma} D^{(S)*}_{S_z 1/2}(\tilde{\alpha}\tilde{\beta}\tilde{\gamma}) \hat{R}\Phi \ . \qquad (16)$$

In order to isolate the doublet component, it is necessary to put $S = S_Z = 1/2$. In principle, Eqns. (16) can be used also in calculations on molecules employing different variants of the method with different molecular orbitals for different spins (see, for example, Refs. 61–64).

c. McLachlan's Method

Since the changes in the spin densities $\Delta\rho_i^{\pi}$ due to the inclusion of the interelectron interaction in polyatomic radicals are small compared with unity, one can employ perturbation theory in order to take into account the effect of electron interactions on the distribution of spin density. Instead of a complete solution of the SCF equations in the UHF method, McLachlan [65] employed the perturbation theory and obtained an approximate formula for the spin density. The spin density of the π electrons in the atom i is given by the formula [65]:

$$\rho_i = \rho_i^{\circ} - \lambda \sum_k \pi_{ik} \rho_k^{\circ}, \qquad (17)$$

where π_{ik} is the coefficient of the mutual polarisability of the atoms i and k, $\rho_i^{\circ} = |c_i^{\circ}|^2$ is the spin density calculated by the Hückel method (c_i° is the coefficient of the molecular orbital of the unpaired electron of the atom i in the Hückel method), and $\lambda \simeq \gamma_{11}/2|\beta| \simeq 1.2$ is an empirical constant.

There are several modern schemes based on the McLachlan method for hydrocarbons [43] which lead to a satisfactory agreement with experiment when McConnell's formula is used to calculate the hyperfine splittings.

McLachlan's method has been used successfully to calculate the proton, ^{13}C, and ^{14}N splittings in compounds with heteroatoms, In order to calculate the ^{13}C and ^{14}N splittings, McConnell's formula [Eqn. (8)] was modified by adding contributions proportional to the spin densities at the neighbouring atoms [45–47]. For example the formula

$$a_N = 23.1\rho_N - 6.3\rho_C \qquad (18)$$

is used to calculate the hyperfine splitting constant for nitrogen in the cyano-group C≡N. Similar formulae are used also for other hyperfine splittings [66]. Empirical formulae of type (18) are very similar to Eqn. (10), which constitutes a generalisation of the McConnell and Colpa–Bolton formulae for hydrocarbons: the mutual influence of atoms is taken into account in these formulae.

A paradoxical situation existed for some time: calculations of hyperfine splittings for compounds with heteroatoms by McLachlan's method [45–47] agreed better with experiment than calculations by the UHF method or the SCF method in the multi-configuration approximation [39], despite the fact that McLachlan's method is an approximation to the UHF method.

The situation became clarified after the calculation by the UHF method (with annihilation of the quartet) using the parameters of the PPP Hamiltonian which reproduced satisfactorily the excitation and ionisation energies of the corresponding molecules [66]. It was found that in this case the agreement with experiment is better than in McLachlan's method: the average deviation from the experimental values of the hyperfine splitting proved to be ±0.59 G, while in McLachlan's method the average deviation was ±0.86 G. [46,47] In this calculation [66] new values of the parameters in the formulae for the splittings were selected. The high effectiveness of the annihilation of the quartets was noted, probably by virtue of a successful choice of the PPP Hamiltonian parameters: the mean values of $\hat{S}^2$ after annihilation differed from the exact value for the doublet (0.75) only in the third decimal place [66]. This example yet again demonstrates the necessity for employing sets of parameters adjusted for consistency in semiempirical calculations.

d. Calculations with Partial and Full Configuration Interaction

Kuprievich et al. [40] calculated the spin structure of the benzyl radical by the SCF method with subsequent inclusion of singly excited, doubly excited, ect. configurations until all the configurations (404) for the ground state were included, i.e. complete account was taken of the interaction of π electrons. The results of the calculation are presented in Table 5, which shows that the spin densities calculated taking into account all possible configurations are reproduced with satisfactory accuracy (to within ≤ 10%) when account was taken of singly excited configurations only. In this connection we may note the satisfactory qualitative and quantitative agreement with experiment obtained in SCF calculation of the spin structure of radicals which include the configurations of the ground state and all singly excited configurations [37,39]. We may note that in the above studies use was made of both molecular orbitals adjusted for consistency and of Hückel molecular orbitals, which are fairly close to one another and which led to similar spin densities.

Table 5. The spin structure of the benzyl radical in terms of the configuration interaction method [40].

No. of atom	Spin densities			
	ground state (GS) and single excitations (15 configurations)	GS and single and double excitations (89 configurations)	GS and single, double, and triple excitations (239 configurations)	full configuration interaction (404 configurations)
7	0.706	0.741	0.722	0.724
1	−0.095	−0.100	−0.110	−0.112
2	0.174	0.165	0.183	0.183
3	−0.058	−0.058	−0.069	−0.070
4	0.156	0.146	0.161	0.161

Calculations taking into account all possible excited configurations (full configuration interaction) have been carried out also in other studies [41]. The spin densities calculated for certain radicals by different methods are compared in Table 4 with the values calculated allowing for the full configuration interaction.

5. CERTAIN RECENT METHODS FOR THE CALCULATION OF THE ELECTRONIC STRUCTURES OF MOLECULES OTHER THAN THE PARISER–PARR–POPLE METHOD

a. The Method of "Molecules in Molecules"

In calculations on large conjugated molecules consisting of several fragments linked by one or two bonds the method of "molecules in molecules" (MIM) has been used successfully. As a rule, the absorption spectra of such a molecule contain lines and bands characteristic of the isolated fragments. This serves as a "criterion" for the application of the MIM method.

In the MIM method one calculates initially (the electronic structures of the individual fragments (for example by the PPP method). The wave function of the entire molecule is constructed as a superposition of the product of the wave functions of the fragments, the ground and several excited states of each fragment and the state with charge transfer from one fragment to another being considered. The total number of configurations of this kind involved in the construction of the wave function is much smaller than in calculations on the molecule by the PPP method. The results of the calculation agree with experiment just as well as the complete calculation by the PPP method. This was demonstrated, for example, in the calculation on decacyclene (36 atoms), which consists of three fragments—acenaphthylene molecules (12 atoms)[67]. The general postulates of the theory of the MIM method have been described together with a brief survey of the literature by von Niessen[68].

The MIM method has been used[69] for calculations on the $S-T$ and $T-T$ transitions in aromatic molecules. In these calculations the experimental energies were used for the fragments (for the corresponding matrix elements of the Hamiltonian) instead of the energies calculated by the PPP method, as in the study of Brugmann et al.[67] This led to a satisfactory agreement with experiment. Thus use was made of the old idea put forward by Moffitt[70,71] (on which the method of "atoms of molecules" is based), who employed the experimental energies for the atoms (O, N, etc.) in calculations on the molecules (O_2, N_2, etc.).

b. The Random Phase Approximation and the Multi-configuration Interaction Method

Mestechkin[72–74] used successfully the approximation of random phases (in the semiempirical version for conjugated systems using the technique of density matrices) to calculate the electronic structures of condensed aromatic molecules[72–74]. A special parametrisation scheme was used which, as we have seen, is reasonable for various methods in the semiempirical theory. As a result, it was possible to calculate the positions of the triplet levels to within about 0.1 eV (for the lowest levels) and with a somewhat poorer accuracy for the highest levels.

In the random phase approximation configurations are taken into account in a compact form and the configurations themselves do not arise explicitly. If the same configurations were considered explicitly, then in principle the calculation would be more accurate, although it would be much more laborious and time consuming.

The condition for the applicability of the random phase approximation is the smallness of the relative changes in the π-electron density at the atom on excitation of the molecule, namely[75]

$$\Delta q_l/q_l \ll 1 \quad \text{or} \quad \Delta q_l \ll 1\,, \tag{19}$$

since the π-electron densities at atoms in conjugated molecules are $q_l \simeq 1$. The greater the charge redistribution in the molecule, i.e. the greater the Δq_l, the higher the excitation energy. Therefore the accuracy of the random phase approximation falls for high excitation energies. A similar criterion of the applicability of the random phase approximation (spin densities much less than unity) exists also for triplet excitations[75].

The random phase approximation has so far been rarely used to investigate conjugated systems[72–80]. Therefore the scope of the method has still not been fully explored.

The same remark holds also for the multi-configuration interaction method (MCI). In the MCI method the wave function of the system Φ is constructed as a superposition of several (n) configurations Φ_i (each configuration consists of a Slater determinant comprising molecular spin orbitals):

$$\Phi = \sum_{i=1}^{n} c_i \Phi_i.$$

The coefficients c_i and the coefficients of the linear combinations of molecular orbitals used to construct the Φ_i are found by a special procedure. This yields both the function of the ground state (with the coefficients c_i^0) and the functions of the n-1 excited states (with the coefficients c_i^k, $k = 1, 2, \ldots, n-1$).

The MCI method is used to calculate various molecular characteristics, including the distributions of spin densities in radicals[38]. Different versions of the MCI method have been developed by Japanese[81] and Soviet[82] investigators.

The MCI method resembles somewhat the MIM method and the random phase approximation. As in the random phase approximation, account is taken in the MCI method of the interaction of π electrons and of excited configurations, but the contributions of these configurations are calculated exactly and the number of configurations is small; as in the MIM method, the configurations are selected on the basis of simple considerations (for example, on the basis of their energies, on symmetry grounds, etc.).

c. The Method of Full Configuration Interaction

Calculations with full allowance for the interaction of π electrons, with full configuration interaction, occupy a special place in the theory of conjugated systems. If we are interested in all the energy levels and all the properties of the system, the method of full configuration interaction is equivalent to the problem of the determination of these properties. Then, using the same effective parameters of the model π-electron Hamiltonian to describe all the properties of the molecule, we can detect the inaccuracies of the π-electron approximation itself. Calculations with full configuration interaction are interesting not only as a method for the complete investigation of the system properties but mainly because such calculations reveal the scope of various approximate methods.

The method of calculation with full configuration interaction proposed by the present authors[75,83,84] is very convenient for the ZDO approximation when the PPP

Hamiltonian is used. In this method [84] the wave function Φ for the system of N electrons is expressed in the form

$$\Phi = \sum_{i=1}^{l_S^N} \psi_i(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N)\theta_i(\eta_1\eta_2 \ldots \eta_N),$$

where the spin functions θ_i are defined by the spin state of the system and the coordinate functions ψ_i are expressed as an expansion in products of the atomic orbitals $\varphi_n(\mathbf{r})$:

$$\psi_i = \sum_{n_1=1}^{K}\sum_{n_2=1}^{K} \ldots \sum_{n_N=1}^{K} c_i(n_1 n_2 \ldots n_N)\varphi_{n_1}(\mathbf{r}_1)\varphi_{n_2}(\mathbf{r}_2) \ldots \varphi_{n_N}(\mathbf{r}_N),$$

where K is the number of different atomic orbitals [the dimension of the basis set $\varphi_n(\mathbf{r})$]:

$$l_S^N = \frac{(2S+1)\cdot N!}{(N/2+S+1)!\,(N/2-S)!},$$

where S are the spin states.

The requirement that Φ be antisymmetric with respect to interchange of the particles (the Pauli principle) and allowance for molecular and spin symmetry decrease the number of unknown coefficients $c_i(n_1 n_2 \ldots n_N)$ and establish simple linear relations between the latter. These relations reduce the large number of coefficients $c_i(n_1 n_2 \ldots n_N)$ to a comparatively small number M of unknown coefficients which can be found from the Schrödinger equation $H\Phi = E\Phi$ or $H\psi_i = E\psi_i$, where H is the Hamiltonian of the system and E the total energy.

The required matrix $H_{\mu\nu}$ for the secular equation can be found in the simplest possible way by a sequence of simple operations [84]. The degree of this secular equation, obtained as a result of the variation of the average total energy with respect to M unknown coefficients, is equal to the number of all the configurations μ, ν, ..., possible for the given state. A characteristic feature of this method of allowance for all configurations [84] is that, owing to the ZDO approximation, the PPP Hamiltonian has the following features: (1) the off-diagonal elements $H_{\mu\nu}$ consist of simple linear combinations of resonance integrals β_{mn} or are zero; (2) the number of zero elements $H_{\mu\nu}$ is several times greater than that of the non-zero elements; (3) the diagonal elements $H_{\mu\mu}$ consist only of linear combinations of the parameters α_m and γ_{mn} and such combinations can be calculated very simply.

These characteristics of the matrix $H_{\mu\nu}$ make it possible to reduce the problem of full configuration interaction for a system of N electrons (with $N > K$) to the simpler problem of total configurational interaction for a system of $2K-N$ particles (holes). In this change from electrons to holes the off-diagonal $H_{\mu\nu}$ are not altered and the new $H_{\mu\mu}$ are calculated according to the same simple rules. For example, the full configuration interaction for thiourea $CS(NH_2)_2$ constitutes a two-electron problem involving a basis set of four molecular orbitals, while the PPP method constitutes a six-electron problem with the same basis set (two π electrons are contributed by each N atom and the C and S atoms each contribute one π electron).

The results of calculations on ethylene, the allyl radical and radical-ions, butadiene, and benzene with full configuration interaction have been compared with the experimental values and the results of calculations by the PPP method [84]. It was found that (1) the correlation energy E_{corr} (i.e. the difference between the energy of the ground state found with full configuration interaction and the energy of the ground state found by the PPP method) is given approximately by the relation

$$E_{corr.} \approx -(0.11 \div 0.13)\cdot N(\text{eV})$$

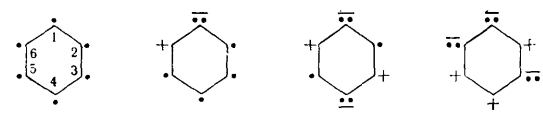
(this relation holds also for the benzyl radical [40]); (2) the optimum values of the parameters of the model Hamiltonian in the PPP method and in the method with full configuration interaction differ appreciably (Table 6). This confirms the view that the disadvantages of the approximate method are transferred to the effective parameters and the latter are therefore different for different methods.

Table 6. The excitation energies of benzene (PPP and full configuration interaction methods) [84] (eV).

Parameters	Method	Designation of energy state				
		$^1A_{1g}$	$^3B_{1u}$	$^1B_{2u}$	$^1B_{1u}$	$^1E_{1u}$
I	PPP	0 (−12.85)	3.7	4.8	5.9	6.75
	full CI	0 (−13.64)	3.35	4.1	6.2	5.07
II	PPP	0 (−15.5)	4.36	5.43	5.57	6.87
	full CI	0 (−16.17)	4.1	4.83	5.8	6.7
Experiment		—	3.7	4.8	5.9	6.76

I $\beta = -2.4$ $\gamma_{11} = 6.1$ $\gamma_{12} = 2.1$ $\gamma_{13} = 0.7$ $\gamma_{14} = 0$
II $\beta = -2.6$ $\gamma_{11} = 4.64$ $\gamma_{12} = 1.39$ $\gamma_{13} = \gamma_{14} = 0$

The covalent-ionic structure of the wave functions of benzene has also been studied [75,83,84]. Components with the coefficients $c_i(n_1 n_2 \ldots n_6)$, in which all the indices n_m are different, correspond to covalent structures in the function Φ; for unipolar structures, the coefficients have a single pair of identical indices (for example, $n_1 = n_2$); for dipolar structures, there are two pairs of indices ($n_2 = n_5$, $n_3 = n_6$), etc. Benzene structures with different polarities (with an indication of the atomic charges) are quoted below as an example:



The dots in the formulae denote π electrons. Non-zero coefficients of the type $c(123\,456)$, $c(112\,345)$, $c(124\,541)$, and $c(131\,366)$ correspond to these structures.

Table 7. Relative contributions (%) of covalent and polar (ionic) structures to the wave functions of certain benzene energy states [75,84].

Energy state, method of calculation		Type of structure			
		covalent	unipolar	dipolar	tripolar
$^1A_{1g}$	full CI	14.7	48.6	32.6	4.1
$^1A_{1g}$	Hückel method	7.9	42.7	42.4	7
$^3B_{1u}$	full CI	31.6	51.7	16.7	—

It was found that the polar structures make the main contribution to the ground state of benzene (see Table 7).

The contribution of each part of the function to the energy is approximately the same. Indeed calculation of

the energy of the ground state of benzene without vibrational structures (with polar structures alone!) increased the energy of the ground state (bond energy −16.17 eV) by only 2.3 eV. It is interesting to note that the contribution of covalent structures to certain excited states can increase [$^3B_{1u}$, the lowest benzene triplet (Table 7)] or can be rigorously equal to zero (for the $^1B_{1u}$ and $^1E_{1u}$ energy states of benzene).

Thus we conclude that structures of different polarity play different roles in the formation of different energy states. If we begin with the approximation in which structures of some kind are neglected, we shall be making different errors for different energy states. The non-uniformity of the contributions of different types of structures to different energy states and different properties can be used in calculations to reject insignificant structures.

These conclusions concerning the structure of the wave function demonstrate the lack of validity of the valence bond methods in which the role of covalent structures is overestimated.

The large contribution of polar (ionic) structures to wave functions is a consequence of the relative weakness of the Coulomb repulsion of π electrons in conjugated systems. In this connection it is interesting to note that, in the calculation on the ground state of benzene by the Hückel method (all the $\gamma_{mn} = 0$), the covalent-ionic structure of the wave function is reproduced correctly (Table 7). This is also a consequence of the relative weakness of the Coulomb interaction of π electrons and at the same time throws light on the relative success of the Hückel method in the calculation of certain properties of conjugated molecules and radicals.

d. The Hückel Method

Despite the development of various methods for calculations on conjugated systems, the simple Hückel molecular orbital method still retains its value and is frequently used. The Hückel method yields results which agree adequately with experimental data. This applies both to the properties of the ground state (bond lengths, charge densities, and spin densities) and to singlet excitation energies[9,85], ionisation potentials and electron affinities[86], and other properties of conjugated molecules[87]. The results of calculations on a large number of conjugated hydrocarbons by the Hückel method (molecular orbital coefficients and energies, bond orders, polarisabilities, etc.) have been tabulated[88,89]. Using these data for hydrocarbons the special perturbation theory of Coulson and Longuet-Higgins[88,89] greatly simplifies calculations, on the analogous molecules with heteroatoms.

Various versions of the Hückel method have been examined and analysed by Peacock[87]. Among other problems, he considered certain possibilities of improving the Hückel method based on known relations between Coulomb (α_n) and resonance (β_{mn}) integrals of the Hückel method on the one hand and the parameters of the effective PPP Hamiltonian on the other. The Hückel and PPP methods were compared in relation to a number of examples with analysis of the differences between the predictions of various molecular properties[86,87,90]. In particular, the inductive effect of π electrons can also be incorporated in the Hückel method using the so called ω technique (see, for example, Ehrenson[86]). This technique is analogous to the method whereby the inductive effect of electrons is taken into account in Scheme 2 of the PPP method (see the previous review[1]).

The Hückel method is also used to simplify calculations by the PPP method. One then employs the fact that self-consistent molecular orbitals are close to the molecular orbitals of the Hückel method. This makes it possible to use the Hückel molecular orbital method with the formal procedures of the PPP method to construct the excited configurations with subsequent determination of the excitation energies, etc. by the PPP method. Such a computational method has been used both for hydrocarbons[13] and for heterocycles[90].

---o0o---

In conclusion we must mention that by no means all problems of the theory of conjugated systems have been considered here and in the previous review[1]. We may mention, for example, the theory of large conjugated systems, the theory of the reactivities of conjugated systems, and other problems which are important for the interpretation of experiments.

Examination of the vast quantum-chemical field which constitutes the semiempirical theory of conjugated systems is very difficult if only because the relevant research itself has not been completed. Therefore, in writing this review the authors frequently wished to postpone it and to undertake the development or simply the confirmation of certain aspects of the theory. If similar thoughts have also occurred to the reader, we can regard our task as fulfilled.

Conformational Analysis of Bicyclo[3,3,1]nonanes

N.S.Zefirov

The development of the principle of conformational analysis is associated mainly with the employment of cyclohexane and its heteroanalogues as model compounds. The present review surveys data on the conformational analysis of another system containing six-membered rings—bicyclo[3,3,1] nonane. A set of conformational problems, which have been successfully solved using the above bicyclic system, are discussed, the fundamental principles are formulated, and the great scope of the applications of this model in conformational research is demonstrated.
The bibliography includes 213 references.

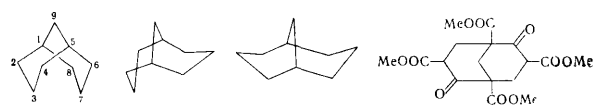
I. INTRODUCTION

The concepts of conformational analysis constitute an extremely effective tool in the hands of the chemist whereby it is possible to understand more deeply the mechanisms of a wide variety of processes. Hence there is clearly an urgent need for a deeper understanding of the concepts and theories of dynamic stereochemistry. The general postulates of conformational analysis are based to a large extent on data for cyclohexane derivatives, its polycyclic derivatives, and its heteroanalogues such as, for example, monosaccharide derivatives, six-membered heterocycles, etc. Nevertheless the employment of cyclohexane derivatives is not always most useful. For example, one of the fundamental problems involves the study of factors which determine the possibility of the existence and the energy of flexible forms (boat, "twist-form"); problems of the reactivity of the functional groups in these conformations are also fundamental. However, there are no convenient model compounds of the cyclohexane series with the boat conformation and with a sufficiently large set of functional groups suitable for the investigation of problems of this kind. Indeed the majority of compounds of this type assume the form of a somewhat deformed (usually flattened[1]) chair and the difference between the free energies of the boat and chair forms is fairly large (5—7 kcal mole^{-1}).[2,3] Therefore many approaches to this problem are associated with the synthesis of cyclic structures (frequently containing heteroatoms), which might exist in a flexible conformation or contain individual fragments which might simulate the geometrical relations in the flexible conformation of cyclohexane (see, for example, Whitlock[4] and Adachi et al.[5]).

The study of derivatives of bicyclo[3,3,1]nonane is of great interest in this connection. We emphasise that at the beginning of the present century Rabe et al.[6] already used the bicyclo[3,3,1]nonane system for the solution of certain problems in theoretical chemistry.

Three conformations free from angular strain can be postulated for bicyclo[3,3,1]nonane itself: dichair (I), chair-boat (II), and diboat (III). In 1922 Meerwein and Schürmann[7] proposed on the basis of intuitive considerations the double chair conformation for the so called "Meerwein's ester" (IV).



(I) (II) (III) (IV)

However, systematic studies on this conformational problem began little more than ten years ago and significant progress was achieved literally in the last few years. The bibliography on this question has been steadily expanding and considerable advances have now been achieved in the understanding of the general problems of the conformational analysis of bicyclononanes. In the present review an attempt is made to examine the present state of the subject, to formulate the fundamental conformational problems which might be solved by resorting to model bicyclononane systems, and to assess the prospects of research in this field. The data are treated on a logical and not a historical basis. Apart from a greater theoretical rigour, this is justified by the considerable development of this field in recent times, which makes it difficult and sometimes simply impossible to follow the historical genesis of the ideas and the questions of priority.

II. GENERAL PROBLEMS OF THE CONFORMATIONAL ANALYSIS OF BICYCLO]3,3,1]NONANES

Although conformations (I)—(III) are free from angular strain, nevertheless none is free from a strong destabilising interaction between the non-bonded atoms. The destabilisation of the boat conformations (II) and (III) is due to the same factors which operate in the case of the boat conformation of cyclohexane, namely the presence of eclipsed ethane conformations and the flagpole—flagpole repulsion between the hydrogen atoms[2]. In the chair-boat

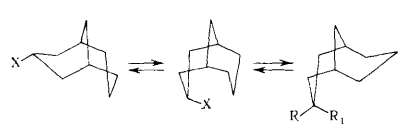
structure (II) the ring in the boat form cannot be appreciably deformed to give the twist-form owing to the rigidity of its junction with the second ring. One can probably imagine only a moderate twisting. However, since for each chair-chair conformation (I) one obtains in the inversion process two chair-boat conformations (II), the latter conformation is twice as likely to be produced. In other words the formation of form (II) is preferred on entropy grounds to the extent of $R \ln 2$. On the other hand, the diboat conformation (III) should correspond to the maximum on the energy curve. A twisted conformation, which can be called the ditwist-form, corresponds to the minimum. In this conformation the flagpole and eclipsed interactions, which are characteristic of the undistorted form (III), are appreciably diminished. This conformation is the only flexible form and is therefore more favourable from the standpoint of the entropy factor.

The chair conformation is usually greatly stabilised by the enthalpy factor (see, for example, Zefirov and Kazimirchik[8]). However there is a specific destabilising factor for the dichair conformation (I), namely the extremely powerful attraction of the *endo*-hydrogen atoms in the 3- and 7-positions. Simple calculations using the normal angles and bond lengths show that the difference between the 3-*endo*- and 7-*endo*-hydrogen atoms should be only 0.81 Å![3] We may recall that the van der Waals radius of hydrogen is 1.2 Å.[9] Therefore in the initial studies the authors gave preference to the chair-boat conformation (II) (for example in the investigations of de la Mare et al.[10] and Leonard and Morrow[11]; however, see Hall[12]) and this view has been reflected in textbooks[13].

However, one must emphasise that the above structures are limiting and one can imagine that in specific instances these ideal forms will suffer greater or smaller distortions, which will lead to a decrease of strain. For example, the flattening of the six-membered rings in conformation (I) and the bending of the C—H bonds in the 3- and 7-positions (i.e. the decrease of the $H-C_{(3)}-H$ or $H-C_{(7)}-H$ angle) can reduce the internal energy. Below it will be shown that such changes in geometry do indeed occur, as a result of which the double chair conformation is usually the most stable.

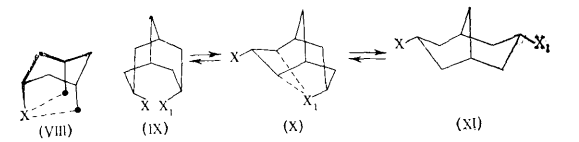
Furthermore, one can determine fairly reliably certain conformational trends arising on passing to functional derivatives and associated with the introduction of substituents, heteroatoms, etc.

Firstly, it is quite evident that the introduction of a 3-*endo*- or 7-*endo*-substituent more bulky than the hydrogen atom will cause a sharp increase of the steric repulsion in the dichair conformation (V) and its sharp destabilisation. Of the two alternative chair-boat conformations, (VI) and (VII), conformation (VI), which has a substituent in the bowsprit position [which is approximately equivalent to the position of the substituent in the equatorial conformation (VIIa)], should be more stable.



(VI) (V) (VII, R = H, R_1 = X; VIIa, R = X, R_1 = H)

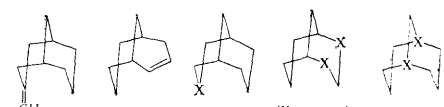
Secondly, the 3-*endo*- and 7-*endo*-positions in conformation (I) are equivalent to the axial position for cyclohexane derivatives of type (VIII). Therefore a functional derivative of type (V) or (VII) is subjected to two additional 1,3-axial interactions, analogous to those in (VIII).



(VIII) (IX) (X) (XI)

Although the extent of such interaction should be different from that observed in cyclohexane by virtue of the differences in geometry, nevertheless one can imagine that in the presence of a very bulky group X in compound (V) such interaction should lead to the destabilisation of the dichair form. For a monofunctional derivative of type (V), this factor is indistinguishable from the previous factor associated with the 3—7 repulsion factor [it will evidently effect the relative stabilities of forms (VI) and (VII), hindering strongly conformation (VI)]. However, in 3—7 disubstituted derivatives (IX) this factor can stabilise the diboat conformation (XI), but not the chair-boat conformation (X).

Thirdly, it is possible to trace certain tendencies associated with the introduction of trigonal carbon atoms into the bicyclononane skeleton. Thus it is evident that the introduction of a trigonal atom in the 9-position should lead to some stabilisation of the boat conformations (II) and (III) owing to the elimination of the flagpole—flagpole interaction, although it is difficult to predict *a priori* the extent of such stabilisation. Furthermore, the introduction of a trigonal atom in the 3-position, for example in compound (XII), leads to a decrease of the 3—7 repulsion and hence to the stabilisation of the dichair form. The introduction of a double bond in the 2,3-positions, as in compound (XIII), should also result in a marked flattening of the cyclohexene ring and a sharp diminution of the 3—7 repulsion.



(XII) (XIII) (XIV) (XV, X = O; XVII, X = S) (XVI)

In conclusion of this section one should note particularly that many problems in the conformational analysis of bicyclo[3,3,1]nonanes have been studied in relation to heteroanalogues of this system. In broad outline, the geometry of bicyclic molecules containing the "usual" heteroatoms (oxygen, nitrogen, and even sulphur) simulates fairly satisfactorily the geometry of the carbon analogue. For example, it is not fortuitous that the conformational analysis of six-membered heterocycles reveals in broad outline the same fundamental conformational characteristics as were discovered for cyclohexane derivatives[8,14,15]. Therefore in this case one can preduct beforehand certain conformational features. Thus the introduction of a heteroatom in the 3-position, as in compound (XIV), should lead to the stabilisation of the dichair conformation by virtue of the decrease of the 3—7 repulsion. Furthermore, the introduction of heteroatoms into the bicyclononane skeleton leads to changes in the geometry which largely depend on the relative lengths of the C—C and C—heteroatom bonds. If the latter is appreciably shorter, the introduction of heteroatoms in the 2- and 4-positions, as in compound (XV), or in the 1- and 5-positions, as in compound (XVI), should lead to an enhancement of the 3—7 repulsion. The converse should also

probably be true, namely a decrease of the 3—7 repulsion with increase in the length of the C—heteroatom bond, as in compound (XVII).

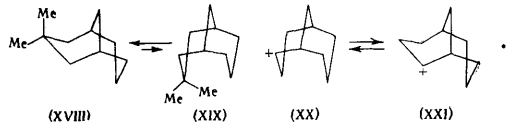
However, many "anomalies", "effects" specific to heterocyclic compounds, due to the electrostatic interactions of the heteroatoms, the interactions of the lone electron pairs, etc. are now known[8,9,16-27]. Therefore it is necessary to examine critically data on the heteroanalogues, bearing in mind the specific features of the model compounds investigated. On the other hand, the use of heteroanalogues significantly extends the range of problems which can be solved with the aid of the bicyclic model.

III. CALCULATIONS OF THE GEOMETRY AND ENERGY

To calculate the geometry and relative energy of molecules, either semiempirical quantum-chemical methods or Westheimer's classical approach are used nowadays[28,29]. The latter is widely employed in its current modifications for the calculation of the geometries of fairly complex compounds[3,30-36]. The first calculation on the bicyclo[3,3,1]nonane molecule by this method was carried out by Gleicher and von R. Schleyer[37], who calculated the geometry for the dichair conformation only. The $C_{(3)}\ldots C_{(7)}$ distance was estimated as 2.96 Å (cf. 2.56 Å for the ideal form[3,38]) and the $C_{(1)}C_{(2)}C_{(3)}$ angle was estimated as 113°. These data indicate a considerable flattening of the "wings" of the molecule. A more rigorous calculation was performed by Allinger and coworkers[3,38]. In this case too the dichair conformation differed fairly appreciably from the ideal conformation. In the first place the $C_{(3)}\ldots C_{(7)}$ distance increased to 3.18 Å and the $H_{(3)}C_{(3)}H_{(3)}$ and $H_{(7)}C_{(7)}H_{(7)}$ angles decreased to 95.2°. This resulted in an increase of the *endo*-$H_{(3)}\ldots$*endo*-$H_{(7)}$ distance from 0.81 Å for the ideal structure to 2.25 Å. Nevertheless, despite the considerable distortion of the structure and the strong non-bonding interaction, the dichair conformation (I) is more stable than the chair-boat conformation (II). Calculation of the enthalpy difference yielded 2.73 kcal mole^{-1} in favour of conformation (I).[3,38] Another calculation gave 3.7 kcal mole^{-1} for this difference[39]. However, the authors point out that this value may be too high.

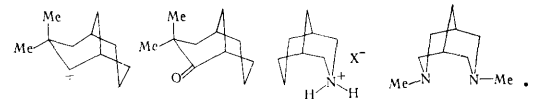
In another instance the calculated ΔH was appreciably less than 5.9 kcal mole^{-1} adopted for the enthalpy difference between the flexible and chair forms of cyclohexane[2,8,40]. Evidently this difference is caused by the appreciable relative destabilisation of the dichair.

The situation for 3,3-dimethylbicyclo[3,3,1]nonane differs significantly. A calculation has shown[39] that conformation (XVIII) is more stable to the extent of 3.9 kcal mole^{-1} than (XIX):



(XVIII) (XIX) (XX) (XXI)

The geometries of certain carbenium ions, incorporated in the bicyclo[3,3,1]nonane skeleton, have also been calculated by this method[37,39]. Thus it has been found that the dichair conformation (XX) of the 2-bicyclo[3,3,1]nonyl cation is more stable than conformation (XXI) to the extent of 2.7 kcal mole^{-1}.[39] The chair-boat conformation of the cation (XXII) is more stable than the dichair conformation, the difference between the energies being 4.4 kcal mole^{-1}.[39] Data for the carbonium ions are not only of intrinsic interest but also as model data for compounds with a trigonal carbon atom; for example, the above calculation confirms the greater stability of the chair-boat conformation of the ketone (XXIII):[39]

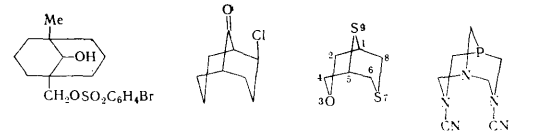


(XXII) (XXIII) [XXIV, (a) X = Br; (b) X = Cl] (XXV)

Semi-empirical quantum-chemical methods—the extended Hückel and CNDO/2 methods—have been used in calculations on the conformations of the aza-analogues of bicyclo[3,3,1]nonane[41]. Thus the hydrobromide (XXIVa) has an energy minimum in the dichair conformation with a $C_{(7)}\ldots N_{(3)}$ distance of 2.9 Å. Dimethylbispidine (XXV) also has a minimum for the dichair conformation, but the $N_{(3)}\ldots N_{(7)}$ distance is 2.5 Å, which is close to the corresponding distance in the ideal conformation. Evidently the main difference is associated with the presence of the 3- and 7-*endo*-hydrogen atoms in compound (XXIV). We may also note that the problem of the conformations of the 3,7-diheteroanalogues is of special interest in connection with the problem of the dipole—dipole or orbital interaction between the heteroatoms (see Section VI, 5).

IV. EXPERIMENTAL DATA ON THE GEOMETRY OF BICYCLO[3,3,1]NONANE DERIVATIVES

The first X-ray diffraction studies showed that the double chair conformation is characteristic of the majority of carbocyclic and heterocyclic bicyclo[3,3,1]nonane derivatives. Dobler and Dunitz[42] were the first to show that the hydrobromide (XXIVa) of 3-azabicyclononane has a flattened dichair conformation. The $N_{(3)}\ldots C_{(7)}$ distance is increased to 3.02 Å owing to the flattening (see the calculation of Chakrabarty et al.[41]). The $H_{(3)}\ldots H_{(7)}$ distance between the *endo*-hydrogen atoms can be estimated as 1.8 Å.[43,44] The molecular structure of a carbocyclic compound—the *p*-bromobenzenesulphonate (XXVI)—has been determined[43,44]. Both rings in (XXVI) have a distinct chair conformation, but the structure deviates appreciably from ideality and the two rings are appreciably flattened.



(XXVI) (XXVII) (XXVIII) (XXIX)

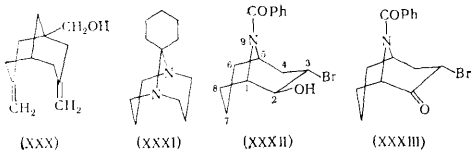
The $C_{(2)}C_{(3)}C_{(4)}$ and $C_{(6)}C_{(7)}C_{(8)}$ angles are on average 114° and the $C_{(3)}\ldots C_{(7)}$ distance is 3.05 Å. The structure of the chloroketone (XXVII) has been determined[45]. The steric repulsion of the methylene groups also leads to the flattening of the molecule and the $C_{(3)}\ldots C_{(7)}$ distance is 3.11 Å, which is much more than 2.1 Å expected for the ideal bicyclononon-9-one. We must emphasise that neither the presence of a trigonal atom in the 9-position nor the presence of the 2-*exo*-substitute in the ketone (XXVII) leads to the destabilisation of the dichair conformation. We may also recall the data concerning

the structure of the 3,7-diheteroanalogues of bicyclononane. It has been found[46,47] that 3-oxa-7,9-dithiabicyclo[3,3,1]nonane (XXVIII) exists in the dichair conformation. It is interesting that the plane passing through the $C_{(1)}$, $S_{(9)}$, and $C_{(5)}$ atoms intersects the $C_{(2)}O_{(3)}C_{(4)}$ plane at an angle of 2° and the $C_{(6)}S_{(7)}C_{(8)}$ plane at an angle of 32°45′. The appreciable flattening of the dithiane ring is evidently associated with the smaller barrier to rotation about the C—S bond compared with the C—O bond (see the relevant discussion in the author's earlier review[8]). A dichair conformation was also found for compound (XXIX), the angles $N_{(1)}C_{(2)}N_{(3)}$ and $N_{(1)}C_{(8)}N_{(7)}$ being 133—136°.[48]

There are literature data for the geometry of bicyclo[3,3,1]nonane itself[49]. It too has the dichair conformation, since it forms mixed crystals with adamantane in which this "conformation" is rigidly fixed. The lattice parameters led to the conclusion that the molecule is flattened; unfortunately the parameters of the molecular structure were not determined (for other X-ray diffraction data, see Sections VI, 5 and VI, 6).

Thus X-ray diffraction results have shown that in the crystal the dichair conformation is preferred, with an appreciable flattening of the wings of the molecule, which leads to an increase of the valence angles in the 2-, 3-, 4-, 6-, 7-, and 8-positions by 4° relative to the normal value.

There are certain data on the geometry of compounds of the above type in solution. Thus the identity of the infrared spectra in solution and in the solid phase for compounds (XXVI) and (XXVII) [43,44,50] makes it possible to extend the X-ray diffraction data also to the geometry of the molecule in solution. The development of studies on molecular geometry in solution is associated mainly with two modifications of the NMR method. Firstly, this involves the use of shift reagents[51,52]. Thus a study has been made[53] on the chemical shifts induced in the presence of Eu(DPM)$_3$ † for 1-hydroxymethyl-3,7-dimethylenebicyclo[3,3,1]nonane (XXX).



(XXX) (XXXI) (XXXII) (XXXIII)

The $C_{(3)}\cdots C_{(7)}$ distance was estimated as 3.1 Å, in agreement with the dichair structure (for the limitations of the method, see Section VI, 6).

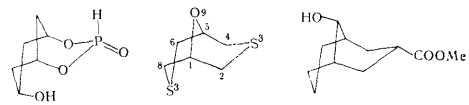
Secondly, a convenient means of investigating the geometry of six-membered systems is provided by the so called NMR "*R*-method".[54-57] In particular, this method has been used to investigate 1,5-diazabicyclo[3,3,1]nonane (XVI, X = N) and its pentamethylene derivative (XXXI).[53] The spin—spin coupling constants for the fragment $-CH_2-CH_2-$ in these compounds indicate an appreciable flattening, which leads to a decrease of the $N_{(1)}C_{(2)}C_{(3)}C_{(4)}$ dihedral angle to 48° and 45° respectively (cf. the 54.5° angle for cyclohexane[1]). This is satisfactorily correlated with the X-ray diffraction studies: the analogous dihedral angles of compounds (XXVI) are in the range 43.6—45.2°;[44-58] in compound (XXIVa) the dihedral angles are 43.0° in the cyclohexane ring and 50.2° in the piperidine ring[42,58].

†DPM = dipivaloylmethane.

As shown in Section II, the appearance of the boat conformations (II) and (III) may be expected when there is a sharp enhancement of the non-bonding interactions, which usually takes place after the introduction of bulky substituents in the 3-*endo*-position. The first compound investigated in this series was 9-benzoyl-3-*endo*-bromo-2-*exo*-hydroxy-9-azabicyclo[3,3,1]nonane (XXXII).[59,60]

As was to be expected, the substituted ring assumes the boat form. The amide nitrogen atom $N_{(9)}$ is planar, so that the geometry of the molecule of (XXXII) resembles that of bicyclo[3,3,1]nonan-9-one [for example, compound (XXVII)]. The $C_{(3)}\cdots N_{(9)}$ distance is 2.56 Å. The displacements of the $C_{(3)}$ and $C_{(7)}$ atoms from the $C_{(1)}C_{(2)}C_{(4)}C_{(5)}$ and $C_{(5)}C_{(6)}C_{(8)}C_{(1)}$ planes are respectively 0.64 and −0.63 Å, which is more than in the dichair conformation [0.51 Å for the ketone (XXVII) [45]], but less than for the ideal cyclohexane conformation (0.73 Å). Thus the ring having the chair form in the chair-boat conformation is distorted much less than in the dichair conformation. These data were confirmed by a study of the structure of the ketone (XXXIII).[61] The molecule of (XXXIII) also assumes the chair-boat conformation with a $C_{(3)}\cdots N_{(9)}$ distance of 2.61 Å and with displacements of the $C_{(3)}$ and $C_{(7)}$ atoms from the $C_{(1)}C_{(2)}C_{(4)}C_{(5)}$ and $C_{(5)}C_{(6)}C_{(8)}C_{(1)}$ planes of 0.64 and −0.65 Å.

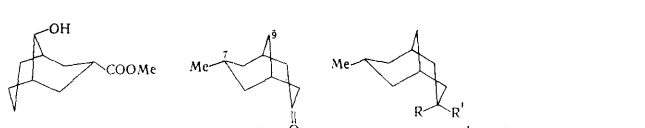
There are literature data for the boat conformations of the heteroanalogues of bicyclo[3,3,1]nonane. Thus it has been found[62,63] that one of the isomeric alcohols (XXXIV), obtained in the acid cleavage of phosphatrioxa-adamantane derivatives has the chair-boat conformation, the heterocyclic ring being in the boat form (see Section VI, 3).



(XXXIV) (XXXV) (XXXVI)

It has been shown[46,47] that 9-oxa-3,7-dithiabicyclo[3,3,1]nonane (XXXV) has the chair-boat configuration; the $C_{(2)}S_{(3)}C_{(4)}$ and $C_{(6)}S_{(7)}C_{(8)}$ planes intersect the $C_{(1)}C_{(5)}O_{(9)}$ plane at angles of 76°9′ and 11°45′ respectively. The $S_{(3)}\cdots O_{(9)}$ distance is 2.84 Å (for the relevant discussion and other data, see Section VI, 5).

Only isolated data are available for the geometry of conformation (II). The chair-boat conformation has been demonstrated[64] by the shift reagent method for the epimeric hydroxyesters (XXXVI) and (XXXVII), but the geometrical parameters were not determined (see also Vegar and Wells[65]).



(XXXVII) (XXXVIII) (XXXIX, R = OH, R′ = Me)

[XL, (a) R = OH, R′ = H; (b) R = H, R′ = OH]

A study of the induced chemical shifts established that compounds (XXXVIII), (XXXIX), and (XLa) have the chair-boat conformation with $C_{(7)}-C_{(9)}$ distances of 2.8, 2.65, and 2.65 Å respectively[66] (cf. Kimoto et al.[52]).

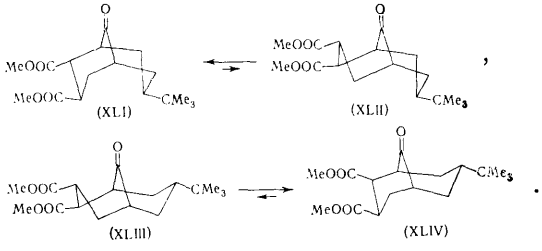
Thus X-ray diffraction data confirm the conclusion reached in Section II that the introduction of a 3-*endo*-substituent stabilises the chair-boat conformation. Despite the small number of experimental results, one may conclude that the geometry of the ring in the chair

form in this conformation is closer to that of the usual cyclohexane derivatives. The smallest intramolecular contact in conformation (II) obtains for the $C_{(3)}...C_{(9)}$ distance (or $C_{(7)}...C_{(9)}$ depending on the numbering system).

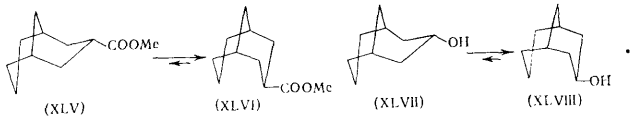
There are no literature data for conformation (III).

V. EXPERIMENTAL VALUES OF THE THERMODYNAMIC PARAMETERS OF THE CONFORMATIONAL EQUILIBRIA IN THE SYSTEM

As already mentioned in Sections II and III, one of the main problems in the conformational analysis of bicyclononanes is the determination of the relative stabilities of different conformations and the derivation of energy relations between them. Qualitative data can be obtained from results on the epimerisation of the corresponding functional derivatives. For example, the overall isomerisation of the methoxycarbonyl derivatives takes place on a preparative scale in the direction (XLII) → (XLI) and also (XLIII) → (XLIV).[67]‡ Bearing in mind the configurations of the compounds (see Sections VI, 3 and VI, 4) and hence the fact that epimerisation in controlled by the change in the conformation of the skeleton, these data make it possible to establish a qualitative sequence corresponding to the decrease of the energies of the conformations: diboat > chair-boat > dichair[67].



The first quantitative data were probably obtained in a study of the epimerisation of the esters (XLV) and (XLVI).[68] The equilibrium position was achieved starting from both isomers and the observed equilibrium constant corresponds to $\Delta G_{20^\circ} = -2.7$ kcal mole^{-1}. On the basis of the foregoing (see Sections II and IV), this value was assumed to be the difference between the free energies of conformations (I) and (II).

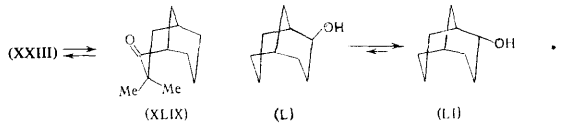


The analogous epimerisation of the isomeric alcohols (XLVII) and (XLVIII) gives rise to an equilibrium mixture containing 96.4% of the *exo*-isomer (XLVIII). Hence $\Delta G_{94^\circ} = -2.51$ kcal mole^{-1}.[69] This value is satisfactorily correlated with that observed by Appleton et al.[68] Since ΔG is independent of the nature of the substituent, this shows clearly that the difference between the free energies can be attributed solely to the different conformations of the skeleton.

‡ The paper of McEuen et al.[67] should also be referred to for the definitions of the terms adopted in the present review to designate different positions (bowsprit, gunnel, etc.).

If it is assumed that the entropies of the two conformers are the same§, then ΔH is 2.5–2.7 kcal mole^{-1} and can be compared with the energy difference calculated theoretically (see Section III). It is readily seen that the agreement between the experimental and calculated values is fairly satisfactory.

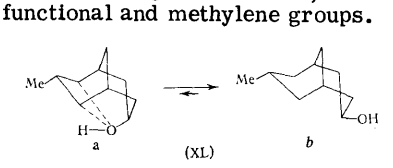
It has been found[39] that the ^{1}H NMR spectrum of the ketone (XLIX) depends on temperature. If it is assumed that this is related to the conformational equilibrium, ΔH can be estimated as 1 kcal mole^{-1}. The authors believe that this is also associated with an equilibrium of the type (I) ⇌ (II) and postulate a greater stability of conformation (XXIII) (see Section VI, 2).



There are no quantitative data on the conformational equilibrium (II) ⇌ (III).

There are also isolated literature values of ΔG_R for the substituents in the bicyclononane fragment. Thus epimerisation of bicyclo[3,3,1]nonan-2-ols (L) and (LI) yields values of ΔG_{OH} equal to −0.56 kcal mole^{-1} [69] and −0.559 kcal mole^{-1} [70] in isopropyl alcohol and −0.25 kcal mole^{-1} [69] in cyclohexane. It is interesting to compare these values with those found for cyclohexanol: 0.52 kcal mole^{-1} in aprotic media and 0.87 kcal mole^{-1} in protic solvents[71]. The equilibrium epimerisation of 2-methylbicyclo[3,3,1]nonanes at 230°C leads similarly to a mixture containing 72% of the equatorial isomer[72]. Hence it is possible to estimate $\Delta G^{230^\circ C}_{Me}$ as approximately 1 kcal mole^{-1}. This value is also much lower than that observed for methylcyclohexane (1.70 kcal mole^{-1}).[71] The decrease of ΔG_R for the 2-position in the bicyclo[3,3,1]nonane system can be attributed to the occurrence of the equatorial *endo*-$R_2...$*endo*-$H_{(8)}$ interaction[39,69].

Interesting data on the epimerisation of the alcohols (XL, a and b) have been obtained[52]. The authors found that the free energy difference $\Delta G_{OH} = -2.18$ kcal mole^{-1} when equilibrium is established in isopropyl alcohol at 110°C. Evidently this difference cannot be attributed to an equilibrium of the type (I) ⇌ (II), but in fact represents the conformational energy of the substituent (cf. Hirsch[71]). The difference between the conformational energies must therefore be due to the occurrence of two unfavourable 1,3-axial–axial $CH_2...OH$ interactions in conformation (XLa) compared with the analogous $CH_2...H$ interactions in conformation (XLb). Assuming that the energy of the first is 1.9 kcal mole^{-1} [2] and that of the second −0.85 kcal mole^{-1},[2,71] it is possible to estimate the difference between the conformational energies as 2.1 kcal mole^{-1}. This agrees very well with the experimental value. It is also evident that the bicyclo[3,3,1]nonane system may be convenient for the investigation of the 1,3-interaction between the functional and methylene groups.

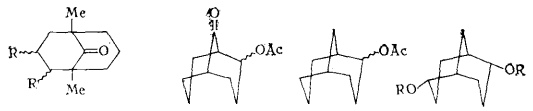


§ This hypothesis implies the neglect of the contribution of the alternative chair-boat conformation and hence of the entropy of mixing $R(x_1 \ln x_1 + x_2 \ln x_2)$.

VI. CONFORMATIONS OF FUNCTIONAL DERIVATIVES AND HETEROANALOGUES OF BICYCLO[3,3,1]NONANE

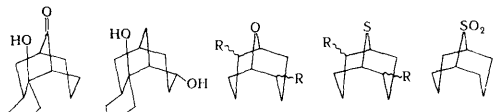
1. Determination of the Conformations of Bicyclo-[3,3,1]nonanes by Infrared Spectroscopy and ^{1}H NMR

The characteristic features of the application of infrared spectroscopy for a qualitative assignment of the conformations in the bicyclo[3,3,1]nonane series are based on the following factor. The spectra of polycyclic and skeletal compounds, in which two or more methylene groups are sterically in very close proximity, are known to contain anomalous infrared absorption bands due to C—H bonds in the region of 1490 and 2990 cm^{-1}. The infrared spectra of many bicyclo[3,3,1]nonane derivatives also contain these bands, which has been attributed to the $C_{(3)}H_2 \ldots C_{(7)}H_2$ interaction in the double chair conformation[43,44,73,74]. The proof is based on the following data[43,73]. Compound (LIIa) has an absorption band at 1490 cm^{-1}, whence it follows that the possible $C_{(3)}—C_{(9)}$ or $C_{(7)}—C_{(9)}$ interactions are not the cause of this anomaly. The intensity of this band in the infrared spectrum of the deuteriated compound (LIIb) is approximately halved. We may note that in the adamantane infrared spectrum there is no absorption in this region[75].



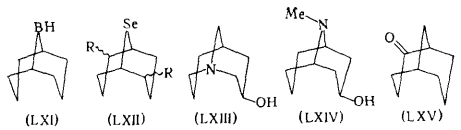
[LII, (a) R = H; (b) R = D] (LIII) (LIV) (LV, R = MeCO; LVa, R = H)

The high-frequency stretching vibration band at 2990 cm^{-1} and the deformation vibration band at 1490 cm^{-1} indicate the existence of the dichair conformation. The conformations of the ketone (XXVII) and its equatorial epimer[50], of the acetates (LIII),[76] (LIV),[77] and (LV),[78] of the alcohol (XLVIII)[69] and its 1,5-dimethyl analogue[79], of the condensed systems (LVI) and (LVII),[80] etc. were elucidated in this way. We emphasise that the dichair conformation of many 9-heteroanalogues of the bicyclo-[3,3,1]nonane system, for example of compounds (LVIII),[81-83] (LIX),[84,85] (LX),[85] (LXI),[86] and (LXII),[87] was in fact demonstrated by infrared spectroscopy.



(LVI) (LVII) R = Br, I, OAc, HgX (LVIII) R = H, Cl (LIX) (LX)

Infrared spectroscopy makes it possible to distinguish reliably bicyclo[3,3,1]nonane derivatives from the isomeric bicyclo[4,2,1]nonane derivatives[77,82,83,85,87], which are frequently obtained as a mixture in syntheses bases on cyclo-octadiene[88].

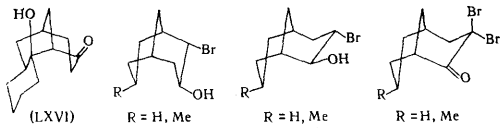


(LXI) (LXII) (LXIII) (LXIV) (LXV)

However, in many cases it was noted that the above absorption bands are not shown in the infrared spectrum even if the compound is known to exist in the double chair conformation. As an example, we may mention the aminoalcohols (LXIII) and (LXIV).[89] These bands are absent from the infrared spectra of the ketones (LXV)[77] and (LXVI).[80] In the latter case the presence of the trigonal carbon atom is responsible for the more planar ring conformation and hence for the significant separation of the transannular methylene groups (see Section VI, 2).

The application of ^{1}H NMR in this series of compounds is based on the familiar characteristics of the changes in the chemical shifts of the *a*- and *e*-protons and, what is more important, on the relation between the constant $^3J_{HH}$ and the dihedral angle (the Karplus equation). In conformation (I), the vicinal constants for the $H_{(1)}H_{(2)}$ and $H_{(2e)}H_{(3)}$ protons correspond to the *ae*- or *ee*-constant (2—4 Hz) and the constants of the $H_{(2a)}H_{(3a)}$ protons correspond to the *aa*-constant (9—12 Hz) for cyclohexane derivatives. Two larger $H_{(1)}H_{(2e)}$ (approximately 10 Hz) and $H_{(2a)}H_{(3)}$ (approximately 10—12 Hz) proton coupling constants should be observed for the boat conformation. The greatest difficulty is associated with the following factor: in conformational analysis there exist two alternative chair-boat conformations, as a result of which there is no sharp change in the hyperfine coupling constants. Furthermore, the flattening of the wings of the molecule in conformation (I) also increases the constant $J_{H_{(1)}H_{(2a)}}$ (for a detailed discussion of this problem, see Zefirov and Rogovina[90]). For the monosubstituted derivatives of type (VI), (V), (L), (LI), (LIV), (LV), (LVIII), etc., a clear-cut assignment can be achieved when a large (in excess of 9 Hz) vicinal hyperfine coupling constant is observed. All these features have been widely used to elucidate the configurations of the substituents and also for conformational assignments[52,77,91-100].

In particular, the conformation of the alcohol (XLVIII)[69,99] and its 1,5-dimethyl analogue[79], of the epimeric alcohols (XL, a and b),[52,53] of the epimeric chloroketones of the type (XXVII),[50] of the isomeric bromohydrins (LXVII) and (LXVIII),[68] and of the dibromoketone (LXIX)[68] were demonstrated by ^{1}H NMR.

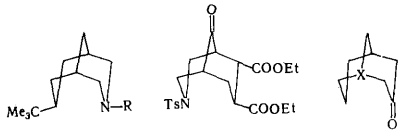


(LXVI) R = H, Me (LXVII) R = H, Me (LXVIII) R = H, Me (LXIX)

2. Conformations of Carbonyl Derivatives of Bicyclo-[3,3,1]nonane and its Monoheteroanalogues

In the first place it is necessary to consider the conformational analysis of monoheterobicyclo[3,3,1]nonanes. From the foregoing data, it is already clear that a wide variety of 2-*endo*-, 2-*exo*-, and 3-*endo*-monosubstituted derivatives of bicyclo[3,3,1]nonane and also 9-heterobicyclo[3,3,1]nonanes exist preferentially in the double chair conformation. The introduction of heteroatoms in the 1-, 2-, and 3-positions also should not apparently alter qualitatively the relative stabilities of the conformations. Although there are no data for 1-azabicyclo-[3,3,1]nonane, the existence of the 1,5-diaza-derivatives (XVI, X = N) and (XXXI) in the dichair conformation[58] confirms this view. There are literature data showing that 3-azabicyclononanes also exist in the dichair conformation for a wide variety of substituents at the nitrogen

atom. The amine (LXX),[93] *N*-benzoyl-3-azabicyclo-[3,3,1]nonane (XIV, X = $NCOC_6H_5$),[92] the toluene-*p*-sulphonate (LXXI),[101] and the hydriodide of *N*-methyl-3-azabicyclo[3,3,1]nonane[91] may be quoted as examples. It has been found by ^1H NMR that derivatives of 3-oxabicyclo-[3,3,1]nonane (XIV, X = 0) [102,103] and even of 3-thiabicyclo-[3,3,1]nonane (XIV, X = S) [90] exist in the dichair conformation. The latter example shows that even the introduction of a bulky hexoatom such as sulphur does not lead to qualitative changes in the relative energetic stabilities of conformations (I) and (II).

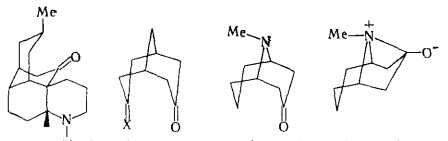


(LXX) (LXXI) (LXXII, X = CH) (LXXIII, X = N)

We shall now consider the problem of the conformational analysis of carbonyl compounds. The introduction of a carbonyl group in the six-membered ring is known to decrease appreciably the difference between the enthalpies of the boat and chair conformations; for example, the enthalpy of the boat–chair conformational transition of cyclohexanone is only 3.9 kcal $mole^{-1}$.[36,39,68] Therefore the introduction of the carbonyl group should decrease the difference between the energies of conformations (II) and (I). On the other hand, the introduction of a trigonal atom should cause some flattening and hence some stabilisation of form (I) as a result of the diminution of the 3–7 repulsion. When the C=O group is introduced into the 3-position, the repulsion of hydrogen atoms is altogether eliminated and only the *endo*-$H_{(7)} \ldots C_{(3)}$=O interaction remains. It is difficult to predict the balance of these factors, particularly for 2-oxo-derivatives[39,68].

The experimental data for 9-oxo-derivatives show that these compounds exist in the dichair conformation [compounds (XXVII),[45,50] (LII),[43,73] (LIII),[76] and (LVI) [80]]. This was to be expected, since the fragment with the carbonyl group is part of the rigid bridge system and a decrease in the barrier to rotation about the CO–C bond cannot affect the conformational energy. However, the data for 3-oxo-derivatives are contradictory. The conformation of bicyclo[3,3,1]nonan-3-one (LXXII) itself was investigated by ^1H NMR using a shift reagent[65]. It follows from the variation of the proton chemical shift with the concentration of the shift reagent that the carbonyl-containing ring must be planar. This was interpreted as indicating a conformational equilibrium between the dichair and chair-boat forms with a 1 : 1 conformer ratio. However, ultraviolet spectroscopic and ^1H NMR data for the 1-aza-analogue (LXXIII) indicate a pronounced flattening in the dichair conformation[104]. Detailed study of the conformation of the parent ketone (LXXII) should probably be continued.

We may note that X-ray diffraction analysis led to the determination of the geometry of the product obtained by the cleavage of the methiodide of lycopodine (LXXIV).[105] The bicyclononanone fragment is forced to adopt the dichair conformation, because the cyclohexane ring forms part of the rigid polycyclic system and the methyl group fixes the conformation of the second ring.

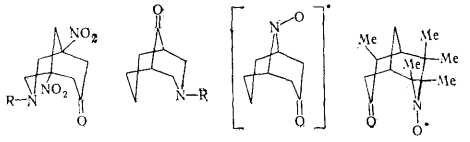


(LXXIV) [LXXV (a) X = CH_2; (b) X = O] (LXXVI) (LXXVII)

There are no data for the conformation of 3-methylenebicyclo[3,1,1]nonane (XII). Bearing in mind that 3,7-dimethylenebicyclononanes of type (XXX) exist in the dichair conformation[53], presumably the same conformation will be preferred also for ketones of type (LXXV).

In analysing the conformational equilibria of aminoketones, it is necessary to take into account an additional factor, namely the interaction of these groups in the direction $R_3\overset{+}{N} + C{=}O \rightarrow R_3\overset{+}{N}{-}C{-}O^-$. Transannular interactions of this type have been studied fairly thoroughly[106–109]. In the bicyclononane series this problem was encountered in a study of pseudopelletierine (LXXVI). The infrared spectrum of this compound indicates the absence of a transannular interaction between the amino- and carbonyl fragments of type (LXXVII), which supports the dichair conformation[108]. This was also confirmed by dipole moment data[108] and measurements of the Kerr constants[110]. The ^1H NMR spectra led to the conclusion that pseudopelletierine is in the conformation (LXXVI) with pronounced distortion of the piperidinone ring[98]. Possibly the marked flattening prevents the transannular interaction between the amino- and carbonyl groups in compounds of type (LXXVIII).[107] Similarly the aminoketone (LXXIX) also exists in the dichair conformation. The absence of an interaction between amino- and carbonyl fragments in the chair-boat conformation follows from dipole moment data and infrared spectra[111]. The infrared spectra do not contain bands in the range 2600–2800 cm^{-1}.[112,113]

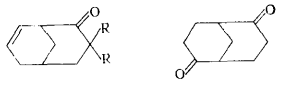
X-Ray diffraction analysis of the free radical (LXXX), which exists in a dimeric form, showed that it has the dichair conformation[114]. However, it is possible that the assumption of a tetracoordinate configuration by nitrogen on formation of the dimer is responsible for the destabilisation of the chair-boat conformation. Judging from the ESR spectrum and the dipole moment, another nitroxyradical (LXXXI) also exists in the dichair conformation[115].



(LXXVIII) (LXXIX) (LXXX) (LXXXI)

Only isolated data are available for 2-oxo-derivatives. There are no experimental results for the ketone (LXV), although (see Section III) a number of investigators tend to give preference to the chair-boat conformation on the basis of indirect evidence[39,68]. The equilibrium (XXIII) ⇌ (XLIX) has been observed for the 3,3-dimethyl-2-oxo-derivative (see Section V). However, the conformation of the more stable isomer has not been demonstrated experimentally[39]. As stated in Section II (see also Section VI, 7), the introduction of a double bond leads to a flattening of the ring, which tends to reduce the strain in conformation (I). Therefore the chair-half-chair conformation has been postulated for the ketone (LXXXIIa)[39].

The authors assume the same conformation also for the dimethyl derivative (LXXXIIb) on the basis of the similarity of its ultraviolet spectrum to that of the unsubstituted ketone, which naturally cannot be regarded as very reliable evidence.



[LXXXII, (a) R = H; (b) R = Me] (LXXXIII)

The dichair conformation has been assumed for the diketone (LXXXIII) on the basis of circular dichroic data[116]. In a number of studies[117,118] the dichair conformation was assumed for carbonyl derivatives of bicyclo[3,3,1]nonane without proof. There is no doubt that the problem of the conformations of 2-oxo-derivatives requires additional research. It is desirable to use for this purpose simple models, such as the ketone (LXV).

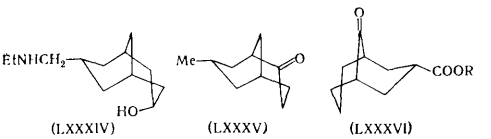
3. The Chair-Boat Conformation

We shall now consider the equilibrium (V) $\rightleftharpoons$ (VI) $\rightleftharpoons$ (VII) involving monosubstituted bicyclononanes (Section II). As stated in Section II, the introduction of a 3- (or 7-) *endo*-substituent destabilises conformation (V) and stabilises boat conformations. The problem arises of the ratio of conformations (VI) and (VII). The equilibrium position between them should be determined by two strongly destabilising 1,3-*aa*-interaction of type X... CH_2 in conformation (VII). On the other hand, in conformation (VI) the substituent occupies the bowsprit position and therefore the difference between energies of conformations (VI) and (VII) is associated with the energy of the X-*endo* $\rightleftharpoons$ X-bowsprit transition. Since the bowsprit position in conformation (VI) can be regarded as approximately equivalent to the equatorial position in conformation (VIIa), the energy difference for the (VII) $\rightleftharpoons$ (VI) transition can be estimated approximately from the energy of the (VIIa) $\rightleftharpoons$ (VI) transition. Data on the epimerisation of alcohols (XL) ($\Delta G_{OH} \simeq 2.18$ kcal mole^{-1})[52] were presented above. Thus conformer (VI) will predominate to a large extent in the conformational equilibrium; according to the data presented in Section V, the energy difference can be estimated from the energy of the X... CH_2 interaction for 1,3-disubstituted cyclohexanes.

The foregoing considerations are also valid when a choice is to be made between alternative conformations of type (X). The bowsprit position will be occupied by a substituent with more pronounced X... CH_2 repulsion. The preferred conformations of alcohols (XL)[52] and (LXXXIV)[119] confirm this postulate.

However, the above conclusion is valid only for equivalent rings in the bicyclo[3,3,1]nonane fragment. In principle, the introduction of heteroatoms can alter appreciably the energy difference between the boat and chair forms and hence disturb the above ratio of conformations (VI) and (VII). For simple mono- and di-heteroanalogues of cyclohexane, very sharp differences in this ratio are not usually observed[8,40], but in more complex cases this factor has to be taken into account.

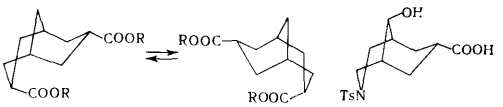
We shall consider next the influence of the nature of the 3-*endo*-substituent on the existence of this conformation. Evidently a bulky substituent such as the t-butyl group should appreciably destabilise conformation (I) and should exhibit a pronounced tendency to occupy the bowsprit position in the chair-boat conformation (II). As an example, one may compare the diester (XLIV)[67] with the epimeric ester (XLI). The 3-*endo*-methyl group also stabilises the chair-boat conformation [see compounds (XXXVIII),[66] (XXXIX),[66] and (XL).[52,66]]. It is interesting that ^{1}H NMR data for the ketone (LXXXV) indicate the existence of the normal form of the carbonyl-containing ring[68]. Furthermore, the introduction of the 3-*endo*-carboxy- or 3-*endo*-alkoxycarbonyl group also leads to conformation (II) [see compounds (XXXVI) and (XXXVII),[64] (XLII),[67] (XLV),[68] and (LXXXVI)[67]].



(LXXXIV) (LXXXV) (LXXXVI)

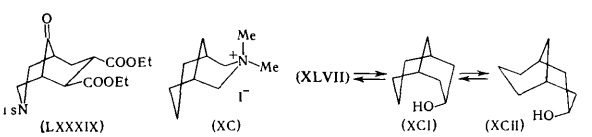
A more complex situation is observed for the dibasic acid (LXXXVIIa) and its diester (LXXXVIIb). The significant broadening of the ^{1}H NMR line at −90°C indicates the occurrence of a conformational equilibrium. However, the presence of two averaged hyperfine coupling constants J_{2a3} and J_{2e3}, both equal to 7.1 Hz, shows that the contribution of the chair-boat conformation predominates[120]. This is probably true also of other *cis*-3,7-disubstituted bicyclononanes of type (X). It has been shown for compounds (XXXII),[59,60] (XXXIII),[61] (LXVIII), and (LXIX)[68] that the introduction of a bromine atom also stabilises the chair-boat form. In the cyclohexane series the bromine atom is not regarded as a "large" substituent ($\Delta G_{Br} \simeq$ 0.38 kcal mole^{-1}),[71] since the effects of the bulk of bromine and of the length of its bond cancel out. However, in the series of bicyclo[3,3,1]nonane the bromine atom does behave as a "large" substituent.

This is true of simple heteroanalogues (see Section VI, 2). For example, the chair-boat conformation has been found for the azabicyclononanes (XXXII),[59,60] (XXXIII),[61] (LXXXVIII),[121] and (XXXIX).[101] Although the hydriodide of 3-methyl-3-azabicyclo[3,3,1]nonane[91] and the hydrochloride[91] and hydrobromide[42] of compound (XXIV) have the dichair conformation, the methiodide (XC) exists in the chair-boat conformation[91].



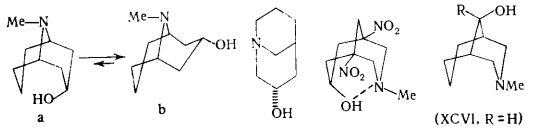
[LXXXVII, (a) R = H; (b) R = Me] (LXXXVIII)

The problem of the influence of the 3-*endo*-hydroxy-group on the preferred conformation is interesting. Firstly, this is a moderately large substituent and, secondly, the hydroxy-group can form hydrogen bonds, which can influence appreciably the position of the conformational equilibrium (see, for example, Baggett et al.[122] and Barker et al.[123]). It has been shown by ^{1}H NMR that the chair-boat conformers of 3-*endo*-bicyclo-[3,3,1]-nonanol (XLVII)[65,69,99] and of its 1,5-dimethyl derivative[79] predominate greatly. However, a study of the temperature variation of the hyperfine coupling constants and the application of shift reagents indicate the occurrence of an equilibrium[65,79,99]. However, it is not clear which form, (XCI) or (XCII), is in equilibrium with the main conformer (see also Section VII).



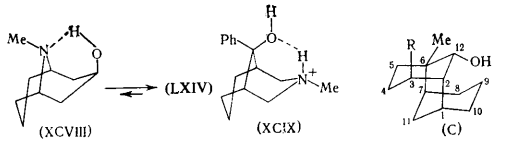
(LXXXIX) (XC) (XLVII) $\rightleftharpoons$ (XCI) $\rightleftharpoons$ (XCII)

The same problem was investigated in detail for 3α-granatanol (XCIII). Aaron et al.[89] used the method of conformational assignment based on the study of the shape of the fundamental OH stretching vibration bands in the infrared spectra. They concluded that the amines (XCIII) and (XCIV) exist in the dichair conformation. However, a detailed study of this problem showed that 3α-granatanol exists mainly in the chair-boat conformation (XCIIIb).[97-99] This is probably also true of the amine (XCIV). We may note that analysis of the band shapes in the infrared spectrum should be used with caution (see the discussion in the paper of Joris et al.[124]).



(XCIII) (XCIV) (XCV) (XCVI, R = H) (XCVII, R = Ph)

Interesting data were obtained in a study of the aminoalcohol (XCV). The infrared spectrum indicates the presence of an intramolecular hydrogen bond in this compound; thus the stabilisation of the double chair conformation by the hydrogen bond predominates over the steric repulsion due to the *endo*-functional group. This result is probably general (see Section VI, 6). It is appropriate to consider here data on the conformational equilibrium of 3β-granatanol (LXIV) and the aminoalcohol (XCVI). The infrared spectrum of the aminoalcohol (XCVI) fails to show the presence of an intramolecular hydrogen bond, which rules out the alternative chair-boat conformation[93,125]. According to ^{1}H NMR data, 3β-granatanol has the preferred dichair conformation (LXIV). However, the infrared spectrum demonstrates the presence of an intramolecular hydrogen bond, which indicates the presence of a small amount (about 11 %) of the conformation (XCVIII).[89,91] It is noteworthy that a change in conformation can occur when bicyclic amines and their derivatives are protonated (see also Section VI, 6). For example, the conformation (XCIX) has been adopted for the protonated form of the amine (XCVII), which exists in the dichair conformation[126].



(XCVIII) (LXIV) (XCIX) (C)

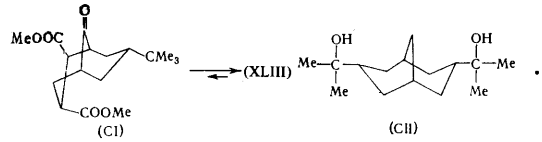
In complex polycyclic compounds the 3-*endo*-group can be constrained to form part of a dichair conformation. For example, X-ray diffraction analysis of a tricyclo-[5,3,1,1^{2,6}]dodecane (C) derivative showed that the hydroxy-group is in the *endo*-position[127]. The $C_{(9)}\ldots O$ and $C_{(4)}\ldots C_{(11)}$ distances are 2.90 and 3.09 Å respectively. Comparison of the angles shows that the hydroxy-group at $C_{(12)}$ actually causes a smaller flattening of the $C_{(8)}C_{(9)}C_{(10)}$ fragment than the $C_{(11)}$ methylene group of the $C_{(3)}C_{(4)}C_{(5)}$ fragment.

As shown in Section IV, the phosphorus-containing alcohol (XXXIV) assumes the chair-boat conformation. This conformation is determined by the strong repulsion of the two 3,7-*endo*-substituents in the dichair conformation. It is interesting that the dioxaphosphorinane ring assumes the boat form[62], probably owing to the general tendency by the P=O group to occupy the equatorial position[63].

In conclusion we may note that the problem of the conformations of bicyclo[3,3,1]nonane derivatives with a small substituent in the 3-*endo*-position is of great interest and merits a detailed study.

4. The Diboat Conformation

According to the discussion in Section II, the diboat conformation is to be expected for 3,7-disubstituted derivatives of type (IX). For a fairly bulky substituent X, the diboat conformation (XI) should be preferred rather than the chair-boat conformation (X). The ratios of forms (X) and (XI) depends on the ratio of the 1,3-*aa*-repulsion energy in the X... CH_2 fragment and the energy difference for the chair-boat conformations, which should be of the same order of magnitude in the (X) → (XI) transition as for unsubstituted cyclohexane. It has been shown for compounds (XLa),[52] (LXXXIV),[119] and (LXXXVII)[120] that the hydroxy-, carboxy-, and methoxycarbonyl groups cannot destabilise the conformation (X). However, the presence of two axial methoxycarbonyl groups in the 2- and 3-positions in the ester (CI) leads to appreciable destabilisation of the chair-boat conformation[67]. Therefore the diboat conformation (XLIII) is preferred and the methoxycarbonyl groups occupy the bowsprit and gunnel positions. It is noteworthy that the presence of the trigonal atom in the 9-position should tend to decrease the strain in the boat conformation.

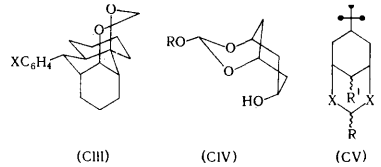


(CI) (XLIII) (CII)

^{1}H NMR showed that the diol (CII) exists in the diboat conformation[120], which is undoubtedly related to the great bulk of the substituents.

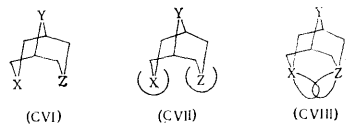
5. The Conformations of Di- and Poly-heteroanalogues of Bicyclo[3,3,1]nonane. The Problem of the Steric and Orbital Interactions of the Heteroatoms

As mentioned above (Section II), the introduction of heteroatoms into compounds of type (XV) or (XVI) can intensify the non-bonding interactions by virtue of the shortening of the C–heteroatom bond. Measurements of the dipole moments of a series of compounds of type (CIII) showed that the 1,3-dioxan ring is in the chair-boat conformation[128]. An analogous conformation was attributed to compound (CIV),[129] probably owing to the presence of the *endo*-substituent [see also compound (XXXIV)[62,63]]. The diamines (XVI, X = nitrogen) and (XXXI)[58] have the conformation of a strongly flattened dichair. Thus the problem under consideration is far from having been solved and its investigation will have to be continued in relation to simpler examples of type (CV).



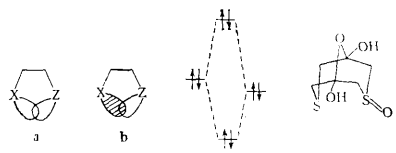
(CIII) (CIV) (CV)

An extremely interesting conformational problem arises for 3,7-diheterobicyclo[3,3,1]nonanes of type (CVI). There is no steric repulsion of the hydrogen atoms in these compounds (X and Z are nitrogen, oxygen, or sulphur).



(CVI) (CVII) (CVIII)

However, three other types of interaction can be envisaged here. Firstly a dipole–dipole (or a charge–charge) interaction. For the usual heteroatoms, this factor should lead to repulsion and its extent should diminish down the Group of elements in the Periodic System. Secondly, we have purely steric repulsion, which at short distances is associated with the repulsion of the filled electron shells as in formula (CVII). This interaction is usually described satisfactorily by Hill's formula[130,131] or by another similar expression for the interaction potential[30,132]. An interaction of this kind presupposes a spherical symmetry of the electron shells of the type present in compound (CVII) [3] (for a discussion of the "bulkiness" of the electron pair, see Robb et al.[133]). Thirdly, we have the orbital interaction called the "hockey stick effect"[16,22,134,135], illustrated in formula (CVIII). We shall consider the last problem in greater detail. For the eclipsed (or *gauche*) conformation of a disubstituted ethane fragment of type (CIX), the overlapping of orbitals leads to the formation of the bonding (CIXa) and antibonding (CIXb) combinations and the consequent splitting of the levels [formula (CX)]. Such interaction of the orbitals "through space"[22,134,136-141] leads to the destabilisation of conformation (CIX) (antibonding predominates over bonding[137,142]). An alternative conformation (for example *trans*) should arise, provided that it is allowed by structural factors. The alternative conformation for the situation illustrated in formula (CVIII) is of the chair-boat type. The degree of repulsion should be proportional to the overlapping and should increase down the Group in the Periodic System[22].



(CIX) (CX) (CXI)

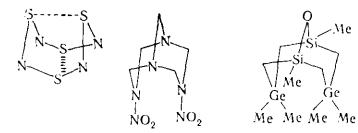
However, as shown for the first time by Hoffmann[136, 137,139], the groups X and Z can interact not only "through space" but also "through the bond", which can alter sharply the relative stabilities of the conformations[143,144]. Model compounds of the bicyclononane series can be used conveniently to isolate the orbital repulsion effect, since we can neglect the interaction between the heteratoms via four bonds.

We shall now consider experimental data on the conformations of compounds of type (CVI). Derivatives of 3,7-diazabicyclo[3,3,1]nonane (bispidine) have been studied most (see Section VI, 6). The calculated[41] and experimental[145] data for 3,7-dimethylbispidine (XXV) show that the dichair conformation predominates.

A large series of compounds of type (CVI) has been investigated[46,47,90]. In all cases where two oxygen atoms or an oxygen and a sulphur atom are present in the 3- and 7-positions [compounds (XXVIII) and (CVI) with X = Y = Z = O or X = S and Y = Z = O] the dichair conformation is preferred [for the geometry of (XXVIII), see Section IV]. However, the situation changes sharply when there are two sulphur atoms (or sulphur and selenium atoms[90]) in the 3- and 7-positions. Compound (XXXV) and compounds of type (CVI, X = Z = S, Y = CH_2; X = S, Y = O, Z = Se) exist in the chair-boat conformation[46,47,90].

It is interesting to consider the problem of the causes of such destabilisation of conformation (I). The $S_{(3)}...S_{(7)}$ distance for the hypothetical dichair conformation of (XXXV) can be calculated from the geometry of compound (XXVIII) and is found to be approximately 4.6 Å. This distance is much greater than the sums of the van der Waals radii of two sulphur atoms (3.6–3.8 Å).[146]. The experimental S...S distances are in the range 3.6–4.0 Å.[147-150] Thus the study of the geometry of molecules of type (XXVIII) and (XXXV) makes it possible to attribute the destabilisation of the dichair form to orbital repulsion.

In this connection the data of Abrahamsson and Rehnberg[147] require consideration. They found that the sulphoxide (CXI) has the dichair conformation with an extremely short $S_{(3)}...S_{(7)}$ distance of 3.17 Å. Attraction forces apparently operate between the sulphur atoms, possibly due to the positive charge on the sulphoxide sulphur atom. Examples of the stabilisation of sulphoxides and sulphones by dipole–charge attraction have been described in the literature[30,135]. We may also note that in the S_4N_4 molecule (CXII), which consists of an eight-membered ring simulating the geometry of the perimeter of the bicyclo[3,3,1]nonane molecule, there is strong attraction between two sulphur atoms, as a result of which the distance between them is 2.69 Å.[151,152]



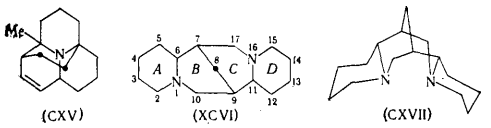
(CXII) (CXIII) (CXIV)

In conclusion of this section we may mention the conformations of polyheteroanalogues of bicyclo[3,3,1]nonane, for which only isolated and non-systematic data are available. Thus it is known that derivatives of triazaphosphabicyclononane (XXIX) [48] and tetraazabicyclononane (CXIII) [153] exist in the dichair conformation. The authors observed in the ^1H NMR spectrum of compound (CXIV) the signal of the *AB* system of the methylene protons and two signals of the methyl groups at the germanium atoms, which was used as evidence in support of the absence of an asymmetric conformation of type (II).[154] However, this reasoning is controversial and the solution of the problem requires ^1H NMR measurements at low temperatures.

6. Conformations of Alkaloids Containing the Azabicyclo[3,3,1]nonane Fragment

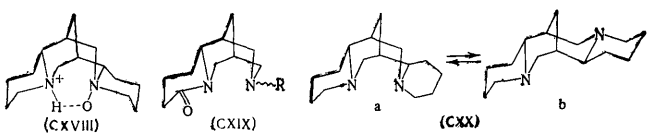
The azabicyclo[3,3,1]nonane skeleton is a component of the structures of many alkaloids. Thus the 3-azabicyclononane fragment is part of the compositions of certain diterpene alkaloids[155]; many alkaloids are also based on 9-azabicyclononane derivatives[117,156,157]. As an example, one may quote porantherine (CXV); X-ray diffraction analysis of its hydrobromide shows the presence of the 9-azabicyclononane fragment in the dichair conformation[157].

However, alkaloids of the Lupin family probably constitute the most important class. In the present section we shall consider the problem of their structures, but only in so far as this concerns the subject of the present review as a whole. Alkaloids of this group have the structure (CXVI) and as regards conformations can be divided into three groups depending on the configurations of the $C_{(11)}$ and $C_{(6)}$ centres. The dichair conformation (CXVII) should be the most stable for α-isosparteine, which has *endo*-substituents at these centres. X-Ray diffraction analysis of α-isosparteine hydrate shows that this compound does indeed have the conformation (CXVII) with an $N_{(1)} \ldots N_{(16)}$ distance of 3 Å.[158]



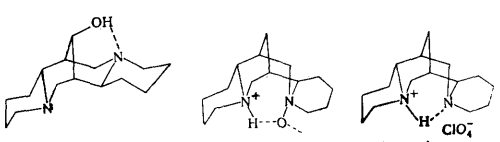
(CXV) (XCVI) (CXVII)

Next it was found that this conformation should be attributed to the cation of isosparteine *N*-oxide (CXVIII).[159,160] Despite the presence of the *endo*-substitute in (CXVIII), the dichair configuration is stabilised by the intramolecular hydrogen bond (see Section VI, 3). This is responsible for the enhanced basicity of the *N*-oxide itself, for which the dichair conformation has also been adopted[159,160]. We may also note that the dichair conformation has been attributed to various lactam structures with related configurations[156,159-163]. As an example, one may quote the tricyclic lactam (CXIX).[163] The study of the influence of the anisotropy of the nitrogen atom on the chemical shifts of the methylene protons enabled the authors to reach a conclusion about the conformation of the substituent at the nitrogen atom. The hydrogen atom occupies the axial position (CXIX, R = H), while the ethyl group occupies the equatorial position. It is not clear whether the stabilisation of the axial position of the hydrogen atom is a consequence of its small bulk or of the presence of the intramolecular hydrogen bond.



(CXVIII) (CXIX) a (CXX) b

We shall now formulate the conformational problem which arises for alkaloids of the sparteine series (we believe that in a number of studies it was artificially made more complicated[164,165]). On the basis of the foregoing considerations, two conformations (CXX, a and b) can be postulated for sparteine (CXX). One of them includes a bicyclononane fragment in the dichair conformation but has an axial substituent at $C_{(11)}$ and therefore a *cis*-junction of the *C* and *D* rings of the quinolizidine fragment. *A priori* estimates of the stabilities of these conformations are difficult owing to the lack of data on conformational equilibria in model quinolizidine systems. It is known only that *trans*-quinolizidine is more stable than the *cis*-isomer, but the available quantitative data are subject to a scatter of 2.1—4.6 kcal mole^{-1}.[166-169]



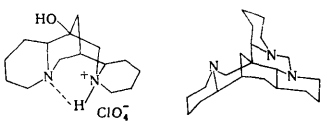
(CXXI) (CXXII) (CXXIII)

Infrared spectroscopic and ^{1}H NMR studies on compounds with the sparteine skeleton[161,162,164,170,171] showed that the *C* ring has the preferred boat conformation (CXXb). This is shown particularly clearly by the hyperfine coupling constant $J_{H_{(7)}H_{(17)}} = 10$ Hz.[164] The chair-boat conformation has also been demonstrated for 8-hydroxysparteine (CXXI)[170] by the presence of the intramolecular hydrogen bond.

However, the difference between the free energies of conformations (CXXa) and (CXXb) is probably relatively small. At any rate the formation of complexes via the two nitrogen atoms, which is possible only in the dichair conformation, may alter appreciably the position of the conformational equilibrium. Such coordination takes place, for example, when sparteine reacts as a bidentate ligand with organolithium[172] or organoaluminium compounds[173], which permits asymmetric syntheses. Incidentally, this indicates the necessity for caution in the employment of shift reagents in ^{1}H NMR conformational studies on compounds of this series.

The hydrogen bond has a similar effect. Thus the sesquiperchlorate of sparteine *N*-oxide (CXXII) exists, like compound (CXVIII), in the dichair conformation owing to the presence of the intramolecular hydrogen bond[174,175]. Borovyak et al.[176] obtained an extremely interesting result. They showed by X-ray diffraction of sparteine monoperchlorate (CXXIII) that this salt assumes the dichair conformation with a distance between the nitrogen atoms of only 2.79 Å. The sharp difference between the conformations of sparteine (in solution) and of its salt (in the crystalline state) can be attributed either to the difference between the states of aggregation or to the stabilisation of the dichair conformation by the intramolecular hydrogen bond on protonation of one nitrogen atom. It would be useful to undertake a study of the conformations of sparteine salts in solution.

There are few data on the conformations of β-isosparteine. The dichair conformation has been adopted for this compound[170]. The same conformation has been found for the monoperchlorate of the 7-hydroxy-derivative of (CXXIV) in the crystalline state[177]. However, it is possible that the presence of the hydrogen bond alters in this case too the conformational pattern characteristic of the free base.



(CXXIV) (CXXV)

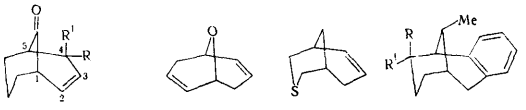
The chair-boat conformation has been found for the azabicyclononane fragment of compound (CXXV).[178] These data were obtained for the free bases and all complicating factors (for example, hydrogen bonds) are absent. Therefore the *trans*-junction of the quinolizidine fragment is probably a more important factor for conformational specificity than the dichair conformation.

7. Conformations of Unsaturated Derivatives of Bicyclo-[3,3,1]nonane and Its Heteroanalogues

The introduction of a double bond into the bicyclo[3,3,1]-nonane skeleton leads to a fairly marked distortion of the geometry. The presence of the 2,3-double bond [compound (XIII)] leads to a sharp decrease of the 3—7 repulsion owing to the flattening of the cyclohexene ring.

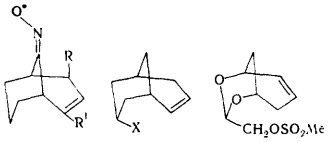
Evidently the saturated ring will have the chair conformation. By virtue of the rigid junction between the rings and the requirement that the $C_{(1)}C_{(2)}C_{(3)}C_{(4)}$ fragment must be planar, the cyclohexene ring in compound (XIII) should be rigid and incapable of inversion.

Experimental data confirmed this hypothesis. A marked flattening of the unsaturated ring in the epimeric ketones (CXXVI) and (CXXVII) has been indicated by J_{45}(CXXVI) = 6.4 Hz and J_{45}(CXXVII) = 0 [179] (cf. Zefirov and Rogovina[90], Section VI, 1).



(CXXVI, R = Ph, R' = H) (CXXVII, R = H, R' = Ph) (CXXVIII) (CXXIX) (CXXX)

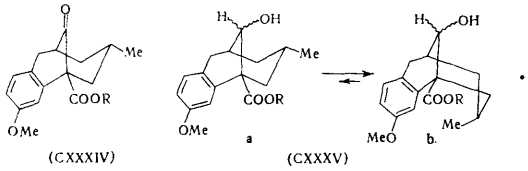
A similar flattening has been observed also in the diene (CXXVIII).[90] A conformation of type (XIII) has also been found for heteroanalogues [the sulphide (CXXIX) [90]], benzo-derivatives [compounds of type (CXXX) [180]], and stable free radicals of type (CXXXI) [181] [cf. compounds (LXXX) and (LXXXI), Section VI, 2].



(CXXXI) (CXXXII) (CXXXIII)

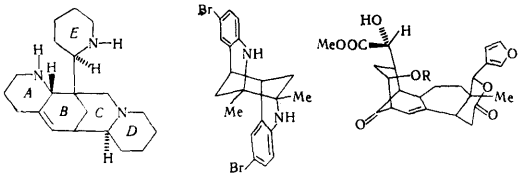
However, the conformational problem specific to the unsaturated compounds of the series under consideration is of greatest interest. It can be formulated as follows: since the unsaturated ring is appreciably flattened, it is interesting to discover whether the chair conformation of the saturated ring is retained in the presence of a 7-*endo*-substituent in compounds of type (CXXXII).

There are few available literature data but they nevertheless lead to the definite conclusion that there is a sharp decrease of 3—7 repulsion in systems of type (CXXXII). For example, the chair conformation has been attributed to the methanesulphonate (CXXXIII).[129] Interesting data have been obtained by Colvin et al.[182] The methyl group in compounds (CXXXIV) and (CXXXV) gives rise to a doublet in the ^{1}H NMR spectrum with δ = 0.8 and 0.4 p.p.m. respectively. The difference of 0.4 p.p.m. can be accounted for as follows. The methyl group in compounds (CXXXIV) is remote from the benzene ring, because the saturated ring assumes the boat conformation. Reduction of the carbonyl group leads to the appearance of flagpole—flagpole repulsion in the boat conformation, which results in an equilibrium between (CXXXVa) and (CXXXVb) and a shift of the methyl group signal owing to the steric proximity of the benzene ring. This is confirmed by the chemical shift of the compounds epimeric with respect to the methyl group, which evidently have the chair conformation in both cases[182].



(CXXXIV) (CXXXV)

The chair conformation has been found for the nitrogen-containing ring in the azabicyclononane fragment in podopetaline hydrobromide (CXXXVI).[183] The *A*, *D*, and *E* rings also have the chair form, but the *B* ring assumes the "sofa" conformation[183-186]. Thus there is a *cis*-junction between the *C* and *D* rings of the quinolizidine fragment of this compound, while in the saturated alkaloid (CXXV) there is a *trans*-junction[178] (see Section VI, 6). This example clearly demonstrates a decrease of the 3—7 repulsion for unsaturated systems of the type under consideration. There are data for the geometries of other complex compounds, for example the diamine (CXXXVII) [187] or the *p*-iodobenzoate of destigloylswietenine (CXXXVIII).[188,189] We may note that compounds of type (CXXXII) have recently become relatively readily available[190,191], so that it would be desirable to investigate the problem under consideration quantitatively on simple models.



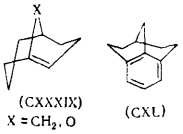
(CXXXVI) (CXXXVII) (CXXXVIII)

The syntheses of compounds of type (CXXXIX) containing a double bond at the bridgehead were described recently[192-196] and the limitations of Bredt's rule were thus demonstrated. The unsaturated ring in these structures should be a rigid half-boat in which the requirement of minimum twisting of the double bond is met. The saturated ring should have the chair form. We may note an interesting aromatic hydrocarbon (CXL).[197] Although the authors postulate the existence of several possible conformers, this does not appear to be a realistic assumption, because (CXL) should have a unique rigidly fixed structure.

VII. CONFORMATIONS AND REACTIVITIES OF BICYCLO-[3,3,1]NONANE DERIVATIVES

In this section we shall consider briefly the possibility of applying chemical methods of bicyclo[3,3,1]nonanes and their reactions will be discussed.

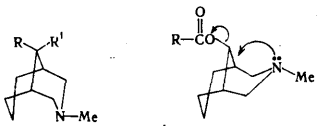
Information about the preferred conformations can be obtained from kinetic and stereochemical data. For example, the similarity of the relative rates of solvolysis of the epimeric *p*-nitrobenzoates (CXLI) and (CXLII) confirms that the dichair conformation is preferred, because in the chair-boat conformation one might expect a synartetic acceleration of solvolysis for the *anti*-epimer (CXLIII).[125,126,198]



(CXXXIX) X = CH_2, O (CXL)

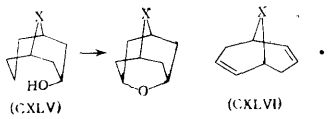
A similar addition of organomagnesium compounds to the ketone (LXXIX) leads to almost equal fractions of the

epimeric alcohols (CXLIV), a and b, which is also logical for the dichair conformation[126].



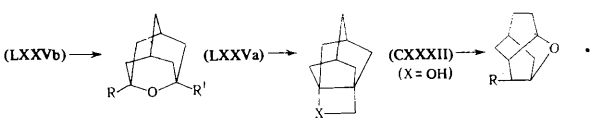
(CXLI, R = *p*-$NO_2C_6H_4COO$; R^1 = H)
(CXLII, R = H; R^1 = *p*-$NO_2C_6H_4COO$)
(CXLIII)
[CXLIV, (a) R' = OH; (b) R = OH]

Bearing in mind the non-bonding $H_{(3)} \ldots H_{(7)}$ interaction, compounds of the bicyclo[3,3,1]nonane series will presumably be converted into derivatives with adamantane-like structures. Evidently such conversion takes place in the dichair conformation. For example, the oxidation of alcohols of type (CXLV) by lead tetra-acetate is accompanied by cyclisation to oxa-adamantane derivatives[99,199].

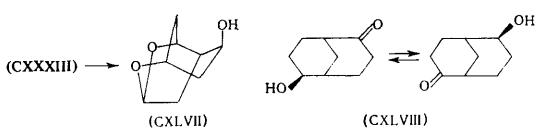


(CXLV) (CXLVI)

A wide variety of numerous transformations of 3,7-functional derivatives of bicyclo[3,3,1]nonanes into derivatives with an adamantane structure are known[200-207]. We may quote, for example, the cyclisation of dienes of type (CXLVI) and the diketone (LXXVb) to oxa-adamantane derivatives, of the methylene derivative (LXXVa) to noradamantane derivatives, and of the enol (CXXXII, X = OH) to isoadamantane derivatives[201-207].

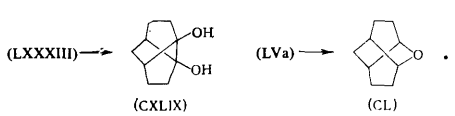


We may also note that the cyclisation of the methanesulphonate (CXXXIII) to the tricyclic compound (CXLVII) is one of the stages in the total synthesis of prostaglandin $F_{2\alpha}$.[129]



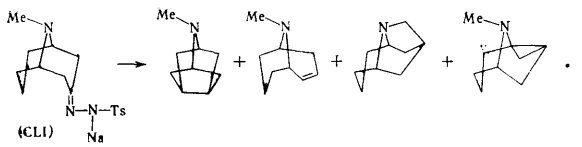
(CXLVII) (CXLVIII)

The steric proximity of the 3,7-positions makes hydride transfer possible[191,207,208]. Deuterium exchange involving the ketol (CXLVIII) indicates the occurrence of an intramolecular stereospecific 2—6 hydride shift[210]. The transition state in this reaction should include the diboat twist-conformation. We may also note the cyclisation of the diketone (LXXXIII) to a pinacol[7], which has the nortwistane skeleton, and also the cyclisation of the diol (LVa) to oxatwistane (CL).[211] These are not exhaustive examples, showing merely how the bicyclo[3,3,1]nonane fragment can react.



(CXLIX) (CL)

Naturally, conformational assignments on the basis of the structure of the products obtained must be made with caution, because the energies of conformational transitions are usually small compared with activation energies. We may point out, for example, that the decomposition of the tosylhydrazone (CLI) leads to a complex mixture of products, including some with a fixed chair-boat conformation[212,213].



(CLI)

---o0o---

It follows from the foregoing data that the bicyclo-[3,3,1]nonane system is a convenient model for the solution of a large set of problems in conformational analysis. In particular, the possibilities provided by this model for the investigation of the reactivities of functional groups in the boat conformation or of problems concerning the transannular interactions of heteroatoms and functional groups are frequently completely unique. There is no doubt that the great possibilities of this system in relation to problems of conformational analysis will be ultilised in the future.

New Ideas on the Mechanism of Direct Syntheses of Alkyl(aryl)chlorosilanes

R.A.Turetskaya, K.A.Andrianov, I.V.Trofimova, and E.A.Chernyshev

Studies on the direct syntheses of alkyl(aryl)chlorosilanes, which have served as a basis for the development of new ideas on the reaction mechanism formulated mainly in the last 2-3 years, are reviewed. The direct syntheses are used in the industrial manufacture of the most important organosilicon monomers. The new ideas on the mechanism proved to be extremely useful in determining the rules for the control of technological processes. The ideas concerning the specific role of chlorine transfer processes and the chain mechanism of the formation of alkyl(aryl)chlorosilanes which are discussed here were not dealt with in the previous reviews.
The bibliography includes 204 references.

III. The mechanism of chlorine transfer from the organic chloride to silicon 214

I. INTRODUCTION

Data on the reaction kinetics and the adsorption of gaseous reactants are examined in detail in the published reviews on the mechanisms of the direct syntheses of alkyl(aryl)-chlorosilanes[1-5], but other extremely important aspects of the reaction mechanism are discussed inadequately, since they began to be considered in the literature only in the last few years. These aspects are the decisive role and mechanism of chlorine transfer from the organic chloride to silicon and also the composition and importance of the surface intermediates.

The ideas developed in the above investigations explained the observed findings and in many cases made it possible to formulate the research needed to intensify and improve the direct syntheses, which constitute the foundation of the industrial manufacture of the principal organosilicon products[6,7].

The direct synthesis of alkyl(aryl)chlorosilanes is an extremely complex and specific heterophase catalytic process in which a multicomponent mixture of compounds is formed and the properties of the solid reactant change significantly in the course of the reaction. For this reason, chemical methods were resorted to (and proved to be fruitful) together with physical and physicochemical procedures. The extensive experimental data accumulated in the development of technological processes also proved to be very useful.

The results of the main studies devoted to the mechanism of the direct syntheses of alkyl(aryl)chlorosilanes are surveyed in the present review in the light of new ideas.

II. SURFACE INTERMEDIATES—PRODUCTS OF THE PARTIAL CHLORINATION OF SILICON

The bonds linking silicon atoms in the crystal lattice are extremely strong (the heat of sublimation of silicon is 110 kcal mole^{-1})[8] and are broken only under the influence of powerful reagents, for example halogens, hydrogen halides, or alkalis. The breakdown of the silicon crystal lattice, which is necessary for the reaction with organic chlorides, also begins in all probability with attack on its surface atoms (primarily those with unsaturated valences, of which there are about 10% according to Haneman[9]) by chlorine. The affinity of silicon for chlorine is illustrated, in particular, by the high strength of the Si–Cl bond (85 kcal mole^{-1} compared with 58 kcal mole^{-1} for the Si–C bond[10]).

In the absence of a catalyst, direct syntheses of alkyl-(aryl)chlorosilanes begin only when chlorine or hydrogen chloride is introduced or at the decomposition temperature of the organic chloride, especially with evolution of hydrogen chloride[11-17]. Therefore a decrease of the decomposition (dehydrochlorination)[18] temperature in the series of alkyl chlorides with increase in the size of the alkyl group is correlated with the decrease of the temperature of the direct synthesis of the corresponding alkylchlorosilanes (the yields of $RSiHCl_2$, $RSiCl_3$, and $HSiCl_3$ are then higher and those of R_2SiCl_2 are lower than in the synthesis of the lowest alkylchlorosilanes[19-22]). The introduction of hydrogen chloride[23-32] or its additional formation in the reaction zone[7,33-35] as a rule accelerates the processes sharply.

Therefore studies dealing with the induction period in the direct syntheses are of considerable interest[36-38]. Investigations by pulse chromatography showed that the induction period is due primarily to the decomposition reactions of the organic chloride; chlorine is then fully bound to the surface of the solid reactant. In the desorption from the solid surface at the end of the induction period at 450 to 600°C, a relatively large amount of trichlorosilane and silicon tetrachloride, which appear to be the main products of the secondary reaction[39], is removed and chlorine and hydrogen chloride are evolved in very small quantities. The formation of alkyl(aryl)chlorosilanes at an appreciable rate begins when a definite amount of bound chlorine is present on the solid surface[38]. Therefore preliminary treatment of the solid reactant by chlorinating agents leads to a decrease of the temperature of the start of the formation of alkyl(aryl)chlorosilanes in the subsequent reaction between the solid and the organic chloride. The removal of chlorination products leads to the deactivation of the solid reactant, while its repeated treatment by chlorine or hydrogen chloride restores its reactivity[37,40].

In a number of studies[11,12,41-51], starting with those of the discoverer of the direct synthesis (Rochow)[11], the involvement of intermediates—products of the partial chlorination of silicon of the type of $SiCl_n$ (where $n < 4$) and HSiCl, was postulated.

Assuming the involvement of organic radicals in the formation of alkyl(aryl)chlorosilanes, Rochow showed that methyl radicals obtained from tetramethyl-lead add to chlorinated silicon only (chloromethylsilanes, which are formed as long as chlorine is present on the surface, were subsequently also detected[52] at 500°C in the reaction of dimethyl ether with a silicon–copper alloy subjected to preliminary treatment with hydrogen chloride). However, this reaction does not occur with $SiCl_4$. On this basis, Rochow proposed a mechanism for the formation of alkyl(aryl)chlorosilanes with participation of partial silicon chlorination products. Similar views on the mechanism of the direct synthesis were expressed by other investigators[45–47]. Czech investigators used the concept of the involvement of the surface compound $SiCl_2$ in devising mechanisms for the formation of $HSiCl_3$ (Joklik and Bažant[43]) and CH_3SiCl_3 (Joklik and Bažant[44]).

The experimental data for the direct syntheses, on which a mechanism of the formation of chloromethylsilanes, chloroethylsilanes, and trichlorosilane with participation of the compounds $SiCl_n$ and HSiCl can be based[12,42,53], were subsequently confirmed by kinetic studies[48–50,54].

There are literature data for the formation of the partial silicon chlorination product $SiCl_2$ by the reaction of silicon tetrachloride with silicon above 1000°C[55–66] and also by the pyrolysis of trichlorosilane, hexachlorodisilane, or perchloropolysilanes[67–69]. The results of kinetic[56], spectroscopic[60], and mass-spectrometric[61] studies on this compound have been published. It has been established that dichlorosilylene can be readily inserted in an M–Cl bond (M = B, P, or C)[70]; when it reacted with methyl chloride in the presence of copper at 350°C, it was possible to obtain chloromethylsilanes[71]. Interesting synthetic possibilities involving the use of dichlorosilylene for the preparation of organosilicon heterocyclic compounds[67,69] and other substances[72] have been demonstrated. The preparation and properties of the chloropolysilanes $(SiCl)_x$,[73] $(SiCl_2)_x$,[71,74], etc.[75–78] have been studied.

In an investigation[79] of the mechanism of the chlorination of metals it was claimed that the addition of chlorine takes place in the gas phase as a result of the reaction with the metal vapour which is always present at the surface. On the other hand, other workers[80] believe that the chlorination of silicon takes place on the surface with participation of atoms linked to one another. It has been stated[41] that the first chlorine atom adds to silicon in the solid phase and the remaining silicon valencies are saturated in the gas phase.

Mass-spectrometric studies on the products of the reaction of silicon with chlorine[81], hydrogen chloride[82], and copper(I) chloride[83] demonstrated the formation on the surface of SiCl, $SiCl_2$, and $SiCl_3$, which can escape into the gas phase under certain conditions[82–84]. The possibility of the existence of gaseous SiCl, $SiCl_2$, and $HSiCl_2$ was confirmed by thermodynamic calculation and the existence of $SiCl_2$ was confirmed by ultraviolet spectroscopic data[85].

The products obtained by the partial chlorination of silicon can react with methyl chloride after being desorbed into the gas phase[42]. However, the gas-phase reactions are apparently unimportant for the direct synthesis: studies on the kinetics and mechanisms of the reactions lead to the conclusion that the formation of hydrogen-containing and alkyl(aryl)chlorosilanes is a purely heterogeneous process[21,86–94]. The application of the method involving separate calorimetric measurements[95–98] showed that all the exothermic stages of the processes take place on the surface. Consequently the main bulk of the products of the partial chlorination of silicon react in the direct synthesis as surface compounds. Recent studies yielded experimental data on their properties, compositions, and role in the overall processes involved in the direct synthesis.

It has been shown that products obtained by the chlorination of the silicon surface are comparatively stable both at room temperature and at the temperatures of the syntheses. It has been established mass-spectrometrically that, even several hours after formation, they can be desorbed from the surface by hydrogen chloride in the form of trichlorosilane close to room temperature[82] or by evacuation at an increased temperature[39]; they can be fully desorbed only after heating the specimens at 600°C for many hours[37] (the claim that the desorption ceases after the specimens of chlorinated silicon have been heated at 310°C[82] is inconsistent with the results of experiments in which the chlorination products were involved in the reactions at temperatures of about 500°C[37,52]).

To determine the nature and compositions of these compounds, formed directly in the reaction zone under the conditions of direct synthesis, the silicon surface containing the partial chlorination products was methylated by methylmagnesium chloride and was rechlorinated after the removal of magnesium chloride; a mixture containing CH_3SiCl_3, $(CH_3)_2SiCl_2$, and $(CH_3)_3SiCl$ was formed[99]. The interaction of chlorinated silicon with the Grignard reagent to form an $Si-CH_3$ group is possible only in the presence of a covalent bond between chlorine and silicon. On this basis, the authors concluded that the chlorination of silicon, which is responsible for the sharp increase of its reactivity in the subsequent reaction with an organic chloride, leads to the formation of the surface intermediates SiCl, $SiCl_2$ and $SiCl_3$ [corresponding to the formation of CH_3SiCl_3, $(CH_3)_2SiCl_2$, and $(CH_3)_2SiCl$].

The presence of the surface compounds $SiCl_n$ alters significantly the state of the surface and its adsorption properties. Adsorption studies by the contact potential difference (CPD) method showed that the chemisorption of the organic chloride from the solid reactant surface in the positively charged β-form is the initial stage of the direct synthesis responsible for the weakening of the bond between silicon (acceptor) and the crystal lattice[100–103]. After treating a silicon–copper alloy (2.4% Cu) with hydrogen chloride at 150°C, the nature of the subsequent chemisorption of hydrogen chloride on the alloy changes appreciably, in particular the positively charged form of the adsorbate becomes more stable[104]. The strengthening of the adsorption linkage between HCl and the silicon–copper alloy (8.63%) after its exposure to an atmosphere of HCl is also indicated by chromatographic data[105].

The presence of Si–Cl bonds on the silicon surface promotes more active chemisorption of methyl chloride on the latter. The desorption of the chlorination product as a result of the heat treatment of the specimen *in vacuo* lowers its adsorption capacity, which is reduced to a minimum after heating at 1150°C; the synthesis of chloromethylsilanes directly afterwards promotes the restoration of the adsorption capacity of the specimen[46]. To a first approximation, the adsorption of methyl chloride on the chlorinated specimen in the β-form active in the direct synthesis corresponds to a change in the surface potential, which is approximately twice as large as in adsorption on the nonchlorinated specimen[106].

Some authors[106–108] believe that the compounds $SiCl_n$ are responsible for the formation of active centres on which the reacting organic chloride molecule is adsorbed: its interaction with silicon is facilitated by the presence of an electronegative substituent at the silicon atom in the crystal lattice. It has been shown[107] that, when silicon is treated with hydrogen fluoride rather than hydrogen chloride, the

temperature of the start of its reactions with methyl chloride is reduced even more: the higher electronegativity of fluorine present as a substituent at the silicon atom facilitates to a greater extent the interaction of the halogenated silicon with methyl chloride. One of the causes of this is the stronger bond between the chlorine atoms of the adsorbed organic chloride molecules and the halogenated silicon atoms on the surface compared with the non-halogenated atoms. Bonds involving *d* orbitals (in particular chemisorption bonds) are known to be strengthened when electronegative substituents are attached to silicon[109] (in our case chlorine). The strengthening of the adsorption linkage between the organic chloride and silicon weakens the bonds between the silicon atom and the crystal lattice and is a necessary condition for the rupture of these bonds[106].

In the latest systematic studies on the kinetics and mechanisms of the reactions of HX[4,5,48,104,110–112] and CH_3X[4,5,111] (X = Cl or Br) with silicon and germanium the idea that the M–M bond strength (where M = Si or Ge) determines the rate of the direct synthesis of hydrogen-containing silanes and germanes, halogenomethylsilanes, and halogenomethylgermanes has been developed. In support of these views, the authors quote in the first place the following evidence: (1) the decrease of the reaction temperature and activation energy with increase in the amount of impurities in silicon facilitating the dissociation of the Si–Si bonds in the transition state[48,104,113]; (2) the increase of the plasticity of the surface layers of single-crystal silicon due to the decrease of the specific surface energy of the crystal and hence of the Si–Si bond strength as a result of the introduction of microamounts of copper (0.0013–0.3%), which tend to increase the reactivity of silicon in the synthesis of trichlorosilane and dichloromethylsilane[111]; (3) the similarity of the kinetic characteristics of the reactions of silicon or germanium with HX or CH_3X regardless of the nature of the halogen (chlorine or bromine)[4,5,110]; (4) the correlation between the Si–Si and Ge–Ge bond strength on the one hand and the activation energy of the chlorination of hydrobromination of silicon and germanium on the other [112]; (5) the parallel variation of the activation energies for the synthesis of trichlorosilane or trichlorogermane with M–M bond strengths following the introduction of germanium into silicon or conversely[5]. All these findings are satisfactorily consistant with the postulated involvement of surface compounds containing Si–Cl bonds, which weaken the bonds between silicon atoms and the crystal lattice, in the formation of active centres.

These ideas are also confirmed by results[100,103] obtained in studies of the chemisorption of various chloro-derivatives on solid reactants treated with hydrogen chloride at 450°C, i.e. containing the surface products of the partial chlorination and hydrochlorination of silicon, although the authors assume without experimental evidence that the chemisorption takes place at silicon atoms.

Surface compounds of the type SiX_n are directly involved in the formation of the final products of the direct synthesis. This has been confirmed experimentally[99,107]. In the reaction of methyl chloride with the surface of silicon treated with hydrogen fluoride, the products are fluoromethylsilanes and chlorofluromethylsilanes[99]. An increase in the degree of preliminary chlorination of silicon leads to an increase of the amount of chloromethylsilanes obtained in the reaction between silicon and methyl chloride injected in a single pulse under conditions which virtually rule out the supplementary formation of the compounds $SiCl_n$.[107]

The products of the partial chlorination of silicon on the surface also serve as active centres for the decomposition of the organic chloride. For example, in the interaction of methyl chloride with chlorinated silicon, even under the conditions of a very low degree of chlorination where chloromethylsilanes still cannot be detected, the amount of hydrocarbons is significantly greater than in the reaction with non-chlorinated silicon[107].

Ideas concerning the composition of the products of the partial chlorination of silicon and the mechanism of their involvement in the formation of alkyl(aryl)chlorosilanes (with and without catalysts), which follow from experimental results, were first put forward in a study of the synthesis of chlorophenylsilanes (for R_2SiCl_2 and $RSiCl_3$)[108,114] and chloroethylsilanes (for $RSiHCl_2$ and partly $RSiCl_3$)[12].

Subsequently the identification of fluoromethylsilanes and chlorofluoromethylsilanes, obtained in the reaction of methyl chloride with solid reactant surfaces subjected to a preliminary treatment with hydrogen fluoride, confirmed the above hypothesis[99]. The possibility of the involvement of SiX, SiX_2, and SiX_3 in the formation of $RSiX_3$ and of SiX in the formation of R_2SiX_2 was demonstrated; the formation of $RSiHX_2$ with participation of HSiX cannot be ruled out. CH_3SiFCl_2, CH_3SiF_2Cl, CH_3SiF_3, and $(CH_3)_2SiFCl$ were clearly identified and $CH_3SiHFCl$ and $(CH_3)_3SiF_2$ were tentatively identified in the reaction of methyl chloride with surface compounds of the type SiF_n. Additional data for the compositions of the intermediates in the direct synthesis were obtained in a study of the interaction between dimethyl ether and the surfaces of solid reactants treated with Cl_2 or HCl.[115] The compound $HSiCl_2$ (corresponding to CH_3SiHCl_2 detected in the products), which is probably involved in the formation of $RSiHCl_2$, can exist on the surface together with SiCl, $SiCl_2$, $SiCl_3$, and HSiCl. In another investigation the silicon surface was treated with hydrogen chloride or chlorine under the conditions of the preferential formation of products of the partial chlorination of silicon on the surface: SiCl or $SiCl_2$ and $SiCl_3$. $(CH_3)_2SiCl_2$ or CH_3SiCl_3 respectively predominated in the products of the reaction of methyl chloride with the surface of the chlorinated silicon specimens[107].

Since different final products can be formed (depending on the properties of the solid reactant and the reaction conditions) in reactions involving the same surface compound (see p.15), a clear correlation between the composition of the compounds $SiCl_n$ and the final reaction products is on the whole impossible. Thus, under the conditions of rapid decomposition of organic chlorides, the compounds SiCl are gradually converted into $SiCl_3$, participating ultimately in the formation of $RSiCl_3$. The same applies to the compounds $SiCl_2$. If the rate of decomposition is low and the reactivity of the solid with respect to the formation of the Si–C bond is adequate (mainly in the presence of a catalyst), the compounds SiCl are probably involved mainly in the formation of R_2SiCl_2 and the compounds $SiCl_2$ are involved in the formation of alkyl(aryl)trichlorosilanes[99,108].

III. THE MECHANISM OF CHLORINE TRANSFER FROM THE ORGANIC CHLORIDE TO SILICON

1. The Transfer of Chlorine in the Formation of Individual Alkyl(aryl)chlorosilanes.

A seemingly paradoxical increase not only of the overall reactivity but also of the selective reactivity of the solid reactants in the formation of dialkyl(aryl)chlorosilanes (compounds with a relatively low chlorine content) after the introduction into the reaction of small amounts of chlorine or chlorine donors (HCl, CuCl, $HSiCl_3$, etc.) has been observed

in studies on the synthesis of chloromethylsilanes[7], chloroethylsilanes[53], and chlorophenylsilanes[106,114,116,117]. For example, the addition of 0.5–1.5% CuCl increases the yield of dichlorodiethylsilane by 25–30%[53,85] and the addition of water, which leads to the formation of hydrogen chloride in the reaction zone, increases the yield by a factor of 1.5.[53] Fig. 1 illustrates the influence of added hydrogen chloride on the reaction of chlorobenzene with a solid reactant consisting of a mixture of silicon and copper powders (40%)[108]. With increase of hydrogen chloride concentration in the reaction mixture to 12%, the rate of formation of dichlorodiphenylsilane increases approximately by a factor of five, despite the fact that hydrogen chloride is not involved in the overall reaction whereby it is synthesised.

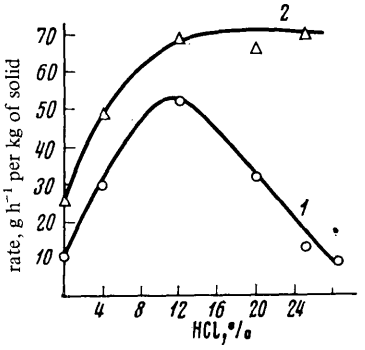

Figure 1. Variation of the rates of formation of dichlorophenylsilane (curve *1*) and trichlorophenylsilane (curve *2*) as a result of the introduction of hydrogen chloride in the synthesis of the chlorophenylsilanes on a mixture of silicon and copper powders.

In the direct synthesis of trichlorophenylsilane without a catalyst (at about 600°C with the ratio HCl : C_6H_5Cl = 1 or 4–1.8)[7,15], hydrogen chloride is again not involved in the overall reaction scheme, in contrast to other processes for the synthesis of alkyl(aryl)trichlorosilanes[37,118]: the yield of trichlorophenylsilane is about one mole for three moles of the chlorobenzene which has reacted and the overall amount of silicon tetrachloride and trichlorosilane corresponds to the amount of hydrogen chloride which has reacted. In the absence of hydrogen chloride, the reaction barely proceeds (the degree of conversion of chlorobenzene does not exceed 5%).

Such experimental results suggested that chlorine or chlorine donors, in particular CuCl and HCl which react with silicon to form the surface compounds $SiCl_n$, initiate the process, the compounds $SiCl_n$, which serve as the active centres for the reaction, being regenerated[106,108]. Similar ideas about the mechanism of the formation of dialkyldichlorosilanes were put forward in early investigations[53,85], where it was found that the amount of chlorine in dichlorodiethylsilane, formed when ethyl chloride interacts with chlorinated silicon in the absence of a catalyst, greatly exceeds the amount of chlorine combined in the preliminary chlorination of silicon.

The employment of pulse chromatography yielded an experimental confirmation of these ideas about the direct syntheses[99,107].

Silicon tetrachloride and chloromethylsilanes were detected together with chlorofluoromethylsilanes when silicon treated with hydrogen fluoride was allowed to react with methyl chloride at 350–450°C. The interaction of methyl chloride with non-halogenated silicon atoms is virtually ruled out under these conditions. Therefore the formation of halogeno-derivatives of silicon without fluorine might have been a consequence only of the addition of chlorine to silicon atoms adjoining the SiF_n surface species, i.e. a consequence of the regeneration of the surface compound — a product of the partial chlorination of the adjoining silicon atom after the completion of the cycle involving the formation of alkyl(aryl)chlorosilanes[99].

The deactivation of the solid reactants after the desorption of $SiCl_n$ and the restoration of their reactivity on chlorination show that constant regeneration of these compounds during synthesis is a necessary condition for the retention of the reactivity of the solid reactant in the course of the entire process[106].

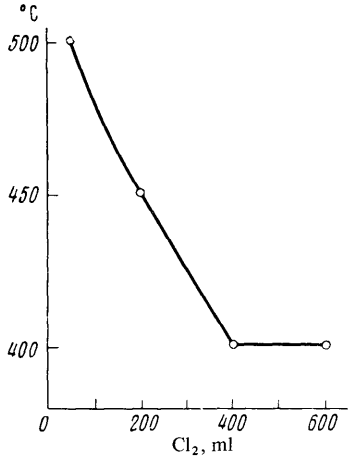

Figure 2. Effect of the degree of chlorination of silicon on the measured temperature of its steady reaction with methyl chloride.

It is very significant that preliminary chlorination of silicon lowers not only the temperature of the beginning of its reaction with methyl chloride but also the temperature of the development of the process in which the rate of the reaction already begun does not decrease during subsequent injections of methyl chloride. An increase in the degree of chlorination lowers the observed temperature of the steady reaction involving the formation of chloromethylsilanes (Fig. 2)†. Since a steady reaction requires that the products of the partial chlorination of silicon be replenished and

† The gradual inhibition of the formation of trichloromethylsilane and $SiCl_4$ as $SiCl_n$ is removed, observed[37] in the reaction of methyl chloride with the surface of chlorinated silicon at 350–500°C, is associated with the fact that the chlorination was carried out with 200 ml of chlorine at 350°C; Fig. 2 presents the results of experiments with specimens chlorinated at 400°C.[107]

at the temperatures considered (below 600°C) the decomposition of methyl chloride on silicon with formation of $SiCl_n$ is negligible, evidently $SiCl_n$ is renewed in the course of the reaction itself[107]. Only the decomposition of RCl [without the formation of alkyl(aryl)chlorosilanes] on the active centres leads to the ultimate formation of chlorosilanes alone and is not accompanied by the generation of new active centres.

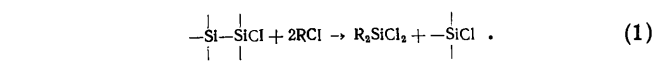
Semenov, Voevodskii, and Vol'kenshtein[119–121], Roginskii[122], and others[123] developed hypotheses concerning heterogeneous-catalytic processes with surface or fixed chains, occurring on repetition of reaction cycles at the active centres formed previously on the catalyst surface. Such views are close to those concerning the catalytic process involving a non-stoichiometric initiator, for example carbon monoxide, in the hydropolymerisation of olefins on a cobalt catalyst[124–126]. Polymerisation, initiated hydropolymerisation, and the synthesis of hydrocarbons from CO and H_2 are nowadays classified as catalytic processes involving the formation of surface chains[127].

The study of the mechanism of the direct synthesis of alkyl(aryl)chlorosilanes suggests that many reactions involved in this process, which are of greatest practical importance, can be classified as catalytic heterophase reactions with surface chains proceeding with participation of an initiator[99,106–108,114]. The initiators can be chlorine or chlorine donors (CuCl and HCl). They form surface compounds of the type $SiCl_n$ (by partial chlorination of silicon), which are involved in the formation of active centres for the reaction. The chemisorption and subsequent reaction of the organic chloride at the active centres lead to the formation of the final reaction products with regeneration of the active centre at an adjoining silicon atom. The cycle is completed by the desorption of the final product into space and the regeneration of $SiCl_n$ is accompanied by the liberation of other silicon atoms, whose valencies probably remain free and which are thus available for the surface reaction. The characteristic features of the direct synthesis are the formation of initiators (chlorine compounds) in the reaction zone on decomposition of the organic chloride and also the possibility of the occurrence of reactions with participation of initiators introduced from outside.

The data concerning the chain mechanism of the direct synthesis are consistant with the theoretical postulates concerning the chain mechanisms of reactions on the surface of solids. However, an unambiguous confirmation of this requires certain additional quantitative studies, which are of fundamental interest for the solution of general problems of the theory of heterophase reactions of this kind.

Experimental studies on adsorption in direct syntheses of chlorosilanes and alkyl(aryl)chlorosilanes proved the validity of the mechanism involving the chemisorption of the organic chloride without dissociation of a single-atom active centre[103,128]; it has been shown[128] that the hypothesis of the dissociative adsorption of methyl chloride at two centres in the formation of dichlorodimethylsilane[1,21,86–88,93,129] is invalid. In the light of the foregoing one must assume that the active centre on the surface of the solid reactant in the direct synthesis includes silicon atoms, one (for R_2SiCl_2) or more (for $RSiCl_3$) valencies of which are bound to chlorine.

In all probability the reactions in the formation of dialkyl(aryl)chlorosilanes are accompanied by a rearrangement of the coordination sphere with transition of the reacting silicon atom to a state with an increased valence[106,130]. However, we believe that the available data are inadequate to infer unambiguously the composition of the intermediate complexes in the direct synthesis of alkyl(aryl)chlorosilanes. The mechanism of the formation of dialkyl(aryl)chlorosilanes, supported by experimental evidence, can be represented schematically as follows[99,106–108,114]:



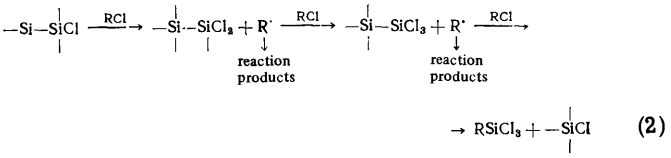
$$-\overset{|}{\underset{|}{Si}}-\overset{|}{\underset{|}{SiCl}} + 2RCl \rightarrow R_2SiCl_2 + -\overset{|}{Si}Cl \quad (1)$$

A similar mechanism was put forward in another study[130], where an attempt was made to elaborate it in greater detail in conjunction with the consideration of tentative intermediate stages, in particular the formation of the surface compounds $RSiCl_2$, etc. The approximate calculations carried out in that investigation confirmed that the formation of the dialkyl(aryl)chlorosilane molecule can be accompanied by the regeneration of the surface compound — the product of the partial chlorination of the silicon atom at the centre of a neighbouring tetrahedron.

The proposed mechanism reflects satisfactorily the experimental findings. The increased yields of dialkyl(aryl)chlorosilanes after the introduction into the reaction of optimum amounts of chlorine donors (HCl and CuCl), the acceleration of the formation of dialkyl(aryl)chlorosilanes in the initial stage of the reaction[131] after the generation of sufficient active centres, and the selective formation of R_2SiCl_2 under conditions where the decomposition processes take place at the minimum rate[7] (the increase of the degree of chlorination of silicon and chain termination in the formation of R_2SiCl_2 are relatively inhibited) can be understood.

The formation of R_2SiCl_2 at advanced stages in the reaction involving silicon (i.e. as the solid reactant is deactivated) is known to be promoted by a gradual increase of temperature in the reaction zone[132]. The decomposition of the organic chloride is then accelerated. Under certain conditions, this leads to the formation of new active centres, the generation of new chains, and the restoration of the rate of formation of the dialkyl(aryl)chlorosilane.

It has been suggested[107,108] that the formation of alkyl(aryl)trichlorosilanes proceeds in all probability with chain propagation (in the absence of a catalyst):



$$\rightarrow RSiCl_3 + -\overset{|}{Si}Cl \quad (2)$$

or with chain termination (in a catalytic process).

$$\overset{|}{SiCl_3} + RCl \rightarrow RSiCl_3 . \quad (3)$$

Podgornyi et al.[133] adopted these mechanisms with an additional consideration of possible intermediate stages.

CH_3SiFCl_2, CH_3SiF_2Cl, and CH_3SiF_3 were evidently detected owing to these factors in the formation of trihalogenomethylsilanes by the reaction of methyl chloride with the surface of silicon treated with hydrogen fluoride[99]. Therefore in the synthesis of trichlorophenylsilane in the absence of a catalyst the introduction of hydrogen chloride (the reaction initiator) makes it possible to increase very sharply (by a factor greater than 10) the rate of formation of the required product[108]. The reaction begins with the interaction of hydrogen chloride involving the formation of $SiCl_n$ active centres. The latter can react with hydrogen chloride, forming trichlorosilane and silicon tetrachloride (their content in the mixture of products is usually about 35%) or the compounds $SiCl_n$ can enter into the composition of the active centres on which chlorobenzene decomposes with formation of more highly chlorinated products and adds

on with regeneration of the products of the partial chlorination of silicon. Thus the amount of consumed HCl corresponds to the amount of trichlorosilane and silicon tetrachloride formed.

In the presence of a catalyst the temperature of the synthesis of chlorophenylsilanes can be reduced by approximately 150 deg C. Then in the absence of hydrogen chloride the formation of the primary active centres involving the surface compounds $SiCl_n$ proceeds mainly in the catalytic decomposition of chlorobenzene and chlorination of silicon by the CuCl formed, which plays the role of an initiator. The additional introduction of relatively small amounts of hydrogen chloride results in this case too in an increase of the rate of the process and (to the greatest extent) of the rate of synthesis of dichlorodiphenylsilane (Fig. 1). With increase of the concentration of hydrogen chloride, the rate of formation and content of dichlorodiphenylsilane in the mixture of reaction products through a maximum. Under the conditions adopted, hydrogen chloride not only initiates the process but also behaves as a reactant in the formation of trichlorophenylsilane, which is illustrated by the sharp decrease of the fraction of products derived from phenyl radicals per mole of trichlorophenylsilane with increase of the amount of added hydrogen chloride[108]. The involvement of hydrogen chloride leads to an increase of the degree of chlorination of the surface compounds and evidently to chain termination. As a result, the overall rate of formation of chlorophenylsilanes falls (with increase of the fraction of trichlorophenylsilane in the reaction products).

When the reaction is carried out in the presence of solid reactants with a high catalytic activity, the overall rate of formation of chlorophenylsilanes in specific syntheses of dichlorophenylsilane is always higher, owing to the chain mechanism of its formation, than in processes with preferential formation of trichlorophenylsilane[20,108,134].

Alkyl(aryl)dichlorosilanes are always formed with participation of hydrogen chloride and the surface intermediates $HSiCl$.[7,53,99,128,135]. The experimental evidence for the mechanism of the process

$$\begin{matrix} H \\ -Si- \\ Cl \end{matrix} \xrightarrow{RCl} RSiHCl_2 \qquad (4)$$

is quite reliable. However, we believe that there is no justification for the total exclusion of chain reactions from this process (for example, with participation of the surface compounds $HSiCl_2$)[115].

The formation of trialkyl(aryl)chlorosilanes R_3SiCl, the products of the disproportionation of alkylation of R_2SiCl_2,[136,137] also involves the chlorination of silicon, which is responsible for the primary formation of R_2SiCl_2.

It is noteworthy that the above mechanisms of the interaction between the organic chloride and the solid reactant is simplified (in particular the role of the copper catalyst in the mechanisms is not taken into account) and do not reflect fully the complex process in which the formation of particular products of the partial chlorination of silicon and the nature of their subsequent interaction with the organic chloride (the intermediates can also interact) are influenced by a multiplicity of different factors.

2. The Role of the Catalyst. The Involvement of Copper in the Transfer of Chlorine from the Organic Chloride to Silicon

With increase of the R–Cl bond strength[138] in the series $C_3H_7Cl < C_2H_5Cl < CH_3Cl < CH_2 = CHCl < C_6H_5Cl$, the temperature of the direct synthesis of the corresponding alkyl(aryl)chlorosilanes rises[7,21,22]. This suggests that the activation of the organic chloride[7,53,85,106] is an important condition for the successful occurrence of the process. Copper is known to catalyse the reactions with organic chlorides[139] and has been used widely[140] also in direct syntheses.

The vast majority of the relevant publications deal with the methods of preparation and properties of the copper catalyst. In considering the role of copper in the direct synthesis of alkyl(aryl)chlorosilanes attention has been concentrated on the activation of silicon.

The activation of pure silicon is possible as a result of the change in the electronic state of the surface atoms ("the collective electronic effect") and the decrease of the Si–Si bond strength when microamounts of copper (about 10^{17} atoms cm^{-3}) are dissolved in it[111,128]. (Shiihara and Iyoda[141] was the first to draw attention to the dependence of the increase of the activity of silicon on the decrease of the Si–Si bond strength when copper, iron, aluminium, or calcium are present in its silicon lattice). However, this effect is characteristic not only of copper but also of certain other elements present in silicon[128,142]. This conclusion is confirmed by the higher reactivity of technical silicon, which usually contains about 2% of impurities, compared with pure silicon in all the direct synthesis investigated[31,48,86,104,113,143]. Therefore the practical importance of this effect of copper in the employment of technical silicon is small and copper does not stabilise the reactivity of various technical silicon specimens differing in their collective electronic properties in the initial state[128].

The increase of the reactivity of surface silicon atoms is more significant when chlorine atoms combine with them[37,106,130]. Surface compounds of the type $SiCl_n$ also behave as centres for the activation of the organic chloride[107].

The involvement of copper in the transfer of chlorine from the organic chloride to silicon via the mechanism

$$RCl + Cu \rightarrow CuCl + R^{\cdot} \text{ or its reaction products,} \qquad (5)$$

$$CuCl + Si \rightarrow \begin{matrix} | \\ -SiCl \\ | \end{matrix} + Cu \qquad (6)$$

was suggested in the first study of the mechanism of the direct synthesis of alkyl(aryl)chlorosilanes[11]. Many investigators who studied the direct synthesis subsequently reached the same conclusion[7,41,45–47,53,141]. Furthermore, it has been shown for the reaction with methyl chloride that the ability of copper to form copper(I) chloride determines to a large extent its activity in the direct synthesis of chloromethylsilanes[144]. An attempt has actually been made[45] to relate the decrease of the induction period in this process to the catalytic influence of the aluminium present in silicon on the formation of CuCl.

Assuming that the stage involving the transfer of chlorine to silicon with participation of CuCl is the most important link in the entire process, Japanese[141,145–150] and German[45–47,151–153] investigators made a detailed study of the reaction between copper(I) chloride and silicon. The temperatures of the onset of reaction[146,151,152] and many other kinetic characteristics[145,147–149] were determined and the different stages of the interaction[148,149,152]; the composition of the compounds formed[152], and the effect of various factors on the reaction[45,141,148–150] were studied.

Interesting data on the involvement of copper in chlorine transfer to silicon with formation of the $SiCl_n$ intermediates were obtained recently in a study of the direct synthesis by pulse gas chromatography[99,107]. When silicon was treated with chlorine, the main product of its subsequent reaction with methyl chloride was trichloromethylsilane[107].

The presence of copper in the silicon alloy was responsible for the formation of dichlorodimethylsilane in similar experiments[99]. Dichlorodimethylsilane was found to predominate also in the reaction of methyl chloride with silicon (in the absence of copper) treated with hydrogen chloride.

Under the conditions adopted, chloromethylsilanes are obtained almost wholly with participation of the $SiCl_n$ surface compounds formed beforehand. When chlorine is replaced by hydrogen chloride in the preliminary treatment of silicon, the species SiCl,[107] whose involvement in the reaction with methyl chloride leads to the formation of dialkyl(aryl)chlorosilanes as the main product, predominates among the $SiCl_n$ surface species instead of $SiCl_2$ and $SiCl_3$. The formation of dichlorodimethylsilane in the reaction with the silicon–copper alloy suggests that in the presence of copper the chlorination of silicon also leads to the preferential formation of SiCl. Thus copper involved in the chlorine transfer processes apparently influences the composition of the compounds $SiCl_n$, promoting the formation of the partial silicon chlorination products which are responsible for the synthesis of dialkyl(aryl)dichlorosilanes.

Therefore the introduction of copper(I) chloride into the reaction zone can increase significantly the content of dialkyldichlorosilanes in the mixture of products. The removal of CuCl from the solid reactant in the direct synthesis (by reducing it with hydrogen) leads to the disappearance of the dialkyldichlorosilane $[(C_2H_5)_2SiCl_2]$ from the reaction products[53,85]. The involvement of the copper catalyst in the transfer of chlorine to silicon probably constitutes an extremely important function of the catalyst in direct syntheses whose temperature is much lower than the temperature of the reaction between copper(I) chloride and silicon.

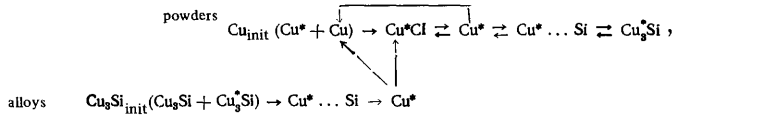
If the decomposition (dehydrochlorination) of the alkyl chloride proceeds at a temperature lower than that at which copper(I) chloride is reduced by silicon or the synthesis is carried out with introduction of hydrogen chloride from outside, the surface products of the partial chlorination of silicon are formed readily also without the involvement of copper (by the reaction between silicon and HCl) and the above function of the catalyst is not manifested. These data have been interpreted in some studies[21,104,111–113,128] as evidence for the rejection of the involvement of CuCl in all the processes of the direct synthesis.

Some investigators refer to the possibility of the synthesis, for example of chloroisopropylsilanes (in which the compounds $SiCl_n$ and HSiCl are formed by the reaction of silicon with hydrogen chloride, produced by the dehydrochlorination of isopropyl chloride) at 110–120°C, while CuCl is reduced by silicon under analogous conditions only at 260°C.[21] Others motivate their objections by the fact that the CuCl introduced from outside did not accelerate the reaction with hydrogen chloride in their experiments[104]. However, under these conditions an acceleration of the reaction was not in fact to be expected, since the synthesis occurred, according to the data of the above investigators themselves, at temperatures (230° and 220°C for the purified and technical silicon respectively[104]) lower than that of the reaction of CuCl with silicon (269° and 234°C for the same silicon specimens[113]). This applies also to the introduction of copper(I) bromide (the temperature of its reduction by silicon is 300°C[112]) in the reaction between hydrogen bromide and silicon (reaction temperature 220°C[110]).

When pure silicon (99.9999%) is used, the temperature of the synthesis of trichlorosilane and dichloromethylsilane (from methyl chloride and hydrogen chloride) increases to 320°C.[104,111]. Therefore it is quite understandable why in the presence of CuCl these products are formed at a temperature as low as 260–280°C,[111] which corresponds according to the author's data, to the temperature of the reduction of CuCl by pure silicon (279°C)[113].

In the synthesis of alkyl(aryl)chlorosilanes (R = CH_3, C_2H_5, or C_6H_5) the introduction of CuCl as a rule activates the reactions[7,53,116] and CuCl is directly involved in the formation of the required product[53,85]. However, the role of CuCl in the direct synthesis of alkyl(aryl)chlorosilanes is apparently not limited to the transfer of chlorine from the organic chloride to silicon. The prolonged activity of the copper catalyst observed in the processes can be accounted for by the high catalytic activity of the copper itself, which is continually formed as a result of the reduction of copper(I) chloride[116]. The activity of the copper catalyst obtained by the reduction of CuCl by silicon has been demonstrated in the synthesis of chloromethylsilanes[21,154]. In particular, at a temperature as low as 250–300°C this copper forms with silicon the intermetallic compound Cu_3Si, while in the presence of crystalline copper, which is relatively inactive in the synthesis, Cu_3Si is obtained only at temperatures above 1000°C.[144]

Generallising from the literature data, the involvement of copper in the synthesis can be represented by a series of complex reversible phase transformations which the most active fraction of the initial copper or Cu_3Si gives rise to CuCl, which is reduced by silicon with formation of unstable catalytically active copper, the intermediate Si–Cu compounds, and ultimately intermetallic phases, including Cu_3Si:[116,117,131]



where an asterisk denotes an active form of copper and Cu is crystalline copper with a low activity.

The activity and the necessary concentration of the initial copper in the reaction zone depend markedly on its properties (for example, the proportion of structural defects) and the conditions in the formation of CuCl [in particular the energetics of reaction (5)][117]. An increased proportion of structural defects can be achieved by mechanical treatment of the powders (copper flakes) or by rapid cooling of silicon–copper alloys[155]. Reaction (5) becomes more favourable on energy grounds, particularly after the addition of promoting additives–Group II elements (see subsection 3 of the present Section).

All this promotes a sharp increase of activity and at the same time a decrease of the optimum catalyst concentration[6]. Possibly not all the copper in the reaction zone catalyses the direct synthesis: the active form of copper is responsible for catalysis. If the entire copper introduced were involved in the process, then in the course of the phase transformation the reactivity of the solid reactants having the same chemical composition would ultimately reach the same level, which is inconsistent with experimental data. Experiment shows that, in order to attain satisfactory rates the selectivities in the synthesis of alkyl(aryl)chlorosilanes in the presence of highly active copper, a very low content of the latter in the solid reactant is sufficient[53,156]. However, under inductrial conditions it is as a rule necessary to employ higher copper concentrations, since during the process part of the copper may be deactivated by harmful impurities in the reactants and by side products and can also undergo recrystallisation[53,157,158]. Therefore, in order to utilise the silicon as fully as possible, it is frequently desirable to introduce the required amount of catalyst gradually in the course of the synthesis and not all at once. This makes it possible to reduce the rates of the

undesirable decomposition reactions of the organic chloride under the influence of the organic chloride under the influence of the excess amounts of copper.

The weakening and dissociation of the C–Cl bond and the formation of CuCl apparently constitute a slower stage than the transfer of chlorine from copper to silicon[116]. Therefore in the direct synthesis of alkylchlorosilanes (280 to 370°C) the steady-state concentrations of copper(I) chloride determined in the solid reactant under experimental conditions are much higher (up to 8%)[85] than in the synthesis of chlorophenylsilanes (at most about 1%)[131], where the formation of CuCl is hindered by the increased strength of the bond between chlorine and the phenyl group[138], the interaction of chlorine with silicon being accelerated at a high temperature in the reaction zone (450°C)[159,160].

Possibly the intermediate CuCl determined in the solid reactants removed from the reactor during the direct synthesis does not constitute an independent phase, but is bound chemically to the solid reactant in the form of a surface compound[21,46]. It is also likely that the product of the reaction of the organic chloride with copper in the solid reactant is more reactive than ordinary CuCl and reacts with silicon at a lower temperature, particularly since ordinary CuCl exists in a polymeric form[161–163].

The composition of the admixtures in silicon greatly influences its reactivity (the temperature of the onset of reaction) in the interaction with CuCl[113,141] and the composition of the compounds formed from CuCl and silicon or from HCl and silicon in the presence of copper[141]. The influence of various elements in the solid reactants on the direct synthesis of chloromethylsilanes[164–169], chloroethylsilanes[143], and chlorophenylsilanes[170], which is known and has been frequently discussed, is in many respects determined by their influence on the formation of surface compounds of the type $SiCl_n$ (in particular from CuCl and silicon), which play a most important role throughout the process.

Intermetallic compounds of copper and silicon, including Cu_3Si (the so called η-phase) evidently serve as a source of the formation and renewal of the catalytically active copper, but it has been established[171] that Cu_3Si does not play the exceptional role which was attributed to it in some investigations[1,21,86,93,129,154,172]. (The activity of the intermetallic phases obtained in the reduction of CuCl by silicon is higher than that of the alloy phases[131,144]).

The intermediate surface compounds of silicon and copper, in the silicon atoms of which electronic changes associated with the local effect of copper (the "local electronic effect") take place, are apparently important for the catalysis of the synthesis of alkyl(aryl)chlorosilanes (without the involvement of hydrogen chloride), in particular of the selective formation of dialkyl(aryl)dichlorosilanes[128]. However, the author does not explain in what way the local effect of copper facilitates the formation of dialkyl(aryl)dichlorosilanes.

3. The Involvement of Promoting Agents in the Transfer of Chlorine from the Organic Chloride to Copper and Silicon.

Analysis of the literature shows that the introduction of promoting additives is the most effective means of increasing the overall activity and of controlling the selectivity of the solid reactants in the direct synthesis. Elements of all the Groups in the Periodic System (and combinations of compounds of these elements), other than those of Groups VI and VII, have been recommended in numerous publications[143,165,166,173–186].

The majority of promoting agents have been discovered empirically and they influence one of the parameters of one or two similar processes. Thus antimony and bismuth activate the synthesis of chloromethylsilanes[31,181] and chloroethylsilanes[53], but do not affect the formation of chlorophenylsilanes[170], while sodium compounds added in the preparation of chloromethylsilanes[179] deactivate the solid reactants in the synthesis of chlorophenylsilanes[170]. Calcium and its compounds promote the preferential formation of hydrogen-containing dichloroethylsilane[143], associated with the dehydrochlorination of ethyl chloride[135], while in the synthesis of chlorophenylsilanes they increase the yield of chlorotriphenylsilanes[170], which is formed without the involvement of hydrogen chloride.

The attempts to explain the mechanism of the effect of certain additives to silicon–copper alloys in the synthesis of chloromethylsilanes[169,187] were not continued, since the proposed explanations are difficult to reconcile with the hypotheses concerning the mechanism of the direct synthesis.

Some investigators[116,117,188] put forward the idea that very effective promoting agents for various direct syntheses, particularly those involving the selective formation of dialkyl(aryl)dichlorosilanes (zinc, cadmium, and their compounds), participate in the transfer of chlorine from the organic chloride to copper and silicon via reactions (5) and (6). The experimental data are in good agreement with this hypothesis.

In the synthesis of chlorophenylsilanes in the presence of the most active promoting agents (cadmium compounds) the solid reactants contain as a rule not less than 1% CuCl, the solid reactants with less active promoting agents (zinc compounds) contain about 0.5% CuCl, while in the absence of promoting agents the CuCl content does not exceed the error of its determination (± 0.05%)[131].

The involvement of CuCl in the phase transformations of the solid reactant is accompanied by the formation of Cu_3Si (Krylov et al.[144]) (see also the scheme on p. 218. Therefore the relative content of Cu_3Si in the solid reactant can serve by convention as a measure of the involvement of CuCl in the process. When a mixture of silicon and copper powders is heated in the presence of promoting agents ($ZnCl_2$, $CdCl_2$) in an atmosphere of nitrogen at 450°C, the intermetallic compound Cu_3Si is formed (up to 70% of the total amount of copper). In analogous experiments without promoting agents Cu_3Si is not formed[116,131].

We believe that the change in the reactivity of the solid reactants (with and without promoting agents) during the synthesis of chlorophenylsilanes and the correlation between the relative content of Cu_3Si in the solid reactants and their reactivity (Fig. 3) also indicate an effect by the promoting agents on the chlorine transfer processes, which determine the course of the synthesis[131]. This is apparently of greatest significance in the initial most important period in the formation of the active form of the catalyst with participation of CuCl. By being involved in the formation of CuCl, the promoting agents thereby influence the phase transformations as a whole. The latter has an appreciable effect on the synthesis.

The fact that the presence of promoting agents in the solid reactant affects significantly the influence of the active source of chlorine (hydrogen chloride) introduced into the reaction zone (Fig. 4) constitutes yet another confirmation of the hypothesis that promoting agents influence the chlorine transfer processes. Fig. 4 shows that in the synthesis using a solid reactant without promoting agents the introduction of HCl can accelerate the formation of chlorophenylsilanes by a factor of 3.5, in the presence of zinc

only by a factor of 2, and in the presence of cadmium or a cadmium-zinc mixture the rate remains constant or falls[116].

Evidently the promoting agents involved in chlorine transfer facilitate the latter. It has been shown[108] that the characteristics of the reactions occurring when both promoting agents and HCl are introduced agree well with the chain mechanism of the direct synthesis.

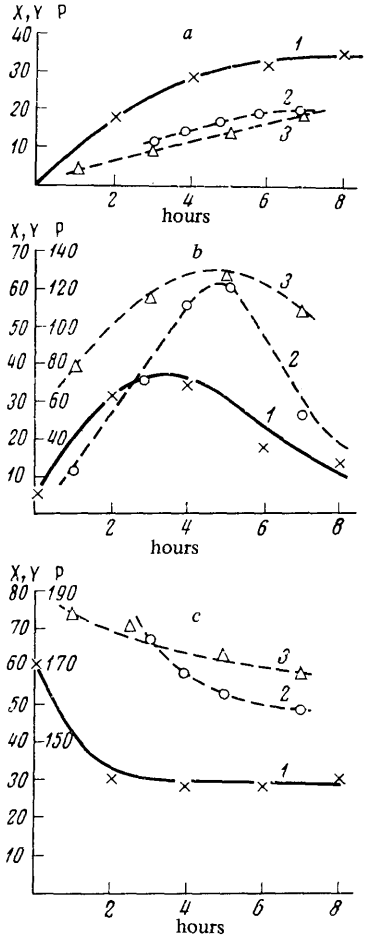


Figure 3. Phase composition of the solid reactants (curves *1*), their overall reactivity in the synthesis of chlorophenylsilanes (curves *2*), and their selectivity in the formation of dichlorodiphenylsilane (curves *3*): *a*) for a silicon–copper composition; *b*) for a silicon–copper–zinc oxide composition; *c*) for a silicon–copper–cadmium chloride composition; *X* = copper contained in Cu_3Si (per cent of total copper); *Y* = dichlorodiphenylsilane content in the mixture of reaction products (%); *P* = rate of formation of chlorophenylsilanes in the presence of 1 kg of solid reactant (g h^{-1}); the time from the start of synthesis is plotted as abscissa.

The involvement of promoting agents in chlorine transfer is also manifested in their influence on the synthesis of chlorophenylsilanes when another chlorine donor (trichlorosilane) is introduced[114]. The rate and selective reactivity in the direct synthesis of alkyl(aryl)chlorosilanes are to a large extent determined by the concentration and composition of the surface compounds $SiCl_n$. The effect of trichlorosilane reduces virtually to the involvement of the silyl radical $SiCl_3^{\cdot}$ in the process.

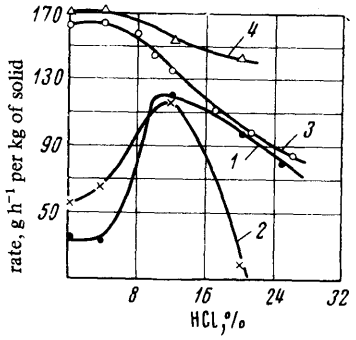

Figure 4. Effect of hydrogen chloride on the synthesis of chlorophenylsilanes in the presence of different solid reactants: *1*) without promoting agents; *2*) with zinc oxide; *3*) with cadmium chloride and zinc oxide; *4*) with cadmium chloride; the percentage of HCl in the mixture with chlorobenzene is plotted as abscissa.

In the absence of promoting agents, when the transfer of chlorine from chlorobenzene to silicon is relatively difficult, the introduction of trichlorosilane in all probability results in further formation of the compounds $SiCl_n$, corresponding to different degrees of chlorination, via the mechanism

$$-\overset{|}{\underset{|}{Si}}- \xrightarrow{SiCl_3^{\cdot}} -\overset{Cl}{\underset{|}{Si}}- + SiCl_{2\,ads} \cdot \qquad (7)$$

This results in an increase of the rate of formation of $C_6H_5SiCl_3$ and, what is most interesting, of $(C_6H_5)SiCl_2$ (Fig. 5). Fig. 5 shows that in the presence of $CdCl_2$ the rate of formation of $(C_6H_5)_2SiCl_2$ falls and the rate of formation of $C_6H_5Cl_3$ increases. This is consistent with the hypothesis that the presence of $CdCl_2$ has a favourable effect on the formation of the surface compounds SiCl via the mechanism

$$-\overset{|}{\underset{|}{Si}}- \xrightarrow[Cu,CdCl_2]{C_6H_5Cl} -\overset{Cl}{\underset{|}{Si}}- + \underset{\text{reaction products}}{C_6H_5^{\cdot}} \cdot \qquad (8)$$

In this case the involvement of the silyl radical apparently leads to an increase of the degree of chlorination via the mechanism

$$-\overset{Cl}{\underset{|}{Si}}- \xrightarrow{SiCl_3^{\cdot}} -\overset{Cl}{\underset{Cl}{Si}}- + SiCl_{2\,ads} \qquad (9)$$

and the formation of surface compounds which determine the synthesis of alkyl(aryl)trichlorosilanes. In conformity with these mechanisms, the formation of $C_6H_5SiCl_3$ with participation of trichlorosilane and in the absence of promoting agents is not accompanied by the liberation of the reaction products obtained from the phenyl radical:

$$SiCl_{2\,ads} + C_6H_5Cl \rightarrow C_6H_5SiCl_3 \cdot \qquad (10)$$

In the presence of $CdCl_2$ one mole of products from the phenyl radical is formed per mole of $C_6H_5SiCl_3$, which probably corresponds to the initial formation of SiCl with participation of chlorobenzene via mechanism (8).

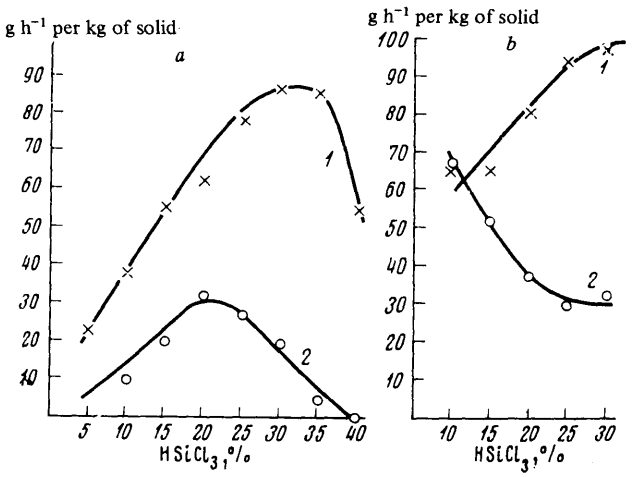

Figure 5. Rates of formation of trichlorophenylsilane (curves *1*) and dichlorodiphenylsilane (curves *2*) in synthesis in the presence of trichlorosilane; *a*) involving a silicon–copper reactant; *b*) involving a solid reactant with added cadmium chloride.

In their explanation of the mechanism of the action of promoting agents on chlorine transfer processes in the direct syntheses some investigators[116,117,188] began with the postulate that the transfer of chlorine to copper is appreciably hindered owing to the comparatively high strength of the bonds between the copper atoms in the crystal lattice, which can reach 81.1 kcal mole^{-1} (Skinner[8]) (in particular for powdered copper). It therefore appears useful to replace the single-stage formation of CuCl via reaction (5) by an energetically more favourable two-stage process, for example via the mechanism

$$RCl + M \rightarrow MCl + R^{\cdot}, \quad (11)$$
$$MCl + Cu \rightarrow CuCl + M. \quad (12)$$

Here the metal M must satisfy the following requirements: (a) it must be relatively readily atomised or must have a lower heat of sublimation than copper; (b) it must have a relatively high affinity for chlorine, which does not, however, exceed the chlorine–copper bond strength. These requirements are met, in particular, by Group II metals (zinc and cadmium), which, as already stated, are the most common and effective promoting agents in the direct synthesis[134,189–203]. Approximate calculations in the above studies showed that the formation of CuCl by reactions (11) and (12) with participation of promoting metals (including the processes where zinc or cadmium oxides or chlorides are introduced into the solid reactants) is preferred on energy grounds.

In the synthesis or chloromethylsilanes the use of the above promoting agents in combination with other procedures made it possible to achieve a virtually selective synthesis of the most valuable monomer, $(CH_3)_2SiCl_2$, the values of other reaction parameters being high. In the synthesis of chloroethylsilanes the content of $(C_2H_5)_2SiCl_2$ reaches 70 to 80% of the weight of the compounds formed[6].

Compared with the synthesis of chloromethylsilanes and chloroethylsilanes, the synthesis of chlorophenylsilanes at a high rate with the selective formation of $(C_6H_5)_2SiCl_2$ is most difficult, because the transfer of chlorine to copper and silicon is additionally hindered by the greater strength of the C–Cl bond in chlorobenzene[138] and the solid reactants consist of powdered mixtures instead of alloys[131]. For this reason the effect of the above Group II elements is particularly marked in this process[6,204] (see Table).

Effect of zinc, cadmium, and their compounds on the synthesis of chlorophenylsilanes.

Promoting agent	Rate of formation of mixture of chlorophenylsilanes, g h^{-1} per kg of solid reactant	Contents in mixture of reaction products, %			
		C_6H_5	$C_6H_5SiCl_3$	$(C_6H_5)_2$	$(C_6H_5)_2SiCl_2$
None	30–35	13–30	32–43	12–23	16–20
Zn or its compounds	50–80	14–17	26–32	2–3	45–50
Cd or its compounds	120–170	4–7	26–32	7–11	47–60
Mixture of Zn and Cd or their compounds*	150–200	2–7	4–15	0.3–1.0	70–80

* When combined promoting agents are used, the content of $(C_6H_5)_3SiCl$ in the reaction products reaches 5–9%.

The use of zinc and cadmium compounds as promoting agents made it possible for the first time to achieve more complex direct syntheses of organosilicon derivatives of heterocyclic compounds[202] and also of alkyl(aryl)chlorosilanes containing Si–C–Si linkages[203] with quite satisfactory results.

The regulation of the chlorine transfer processes and of the formation of the $SiCl_n$ surface intermediates by the introduction of promoting agents into the solid reactant and of chlorine donors into the gas phase made it possible to devise different versions of specific industrial synthesis[6].

The involvement of promoting agents in the chlorine transfer processes does not rule out the possibility of their influence on other stages of the process, in particular on the formation of the catalyst Si–C bond[116]. However, their effect on the chlorine transfer stage evidently plays a major role, because this state to a large extent determines the course of the entire direct synthesis.

Many important practical problems have been solved successfully on the basis of the ideas discussed above, whose development involved a major contribution by S. A. Golubtsov. This can serve as one of the criteria for the assessment of their validity and importance.

Advances in the Chemistry or Organosilicon Polymers

V.V.Korshak and A.A.Zhdanov

The great synthetic possibilities in the chemistry of organosilicon systems and the wide variety of their properties are discussed. The high reactivity of cyclic organosilicon systems with respect to various rearrangements and polymerisation, which gives rise to unlimited possibilities for the synthesis of macromolecular organic derivatives of the elements, is specially considered. The bibliography includes 222 references.

I. INTRODUCTION

In view of the successful development of the chemistry of organic polymers, chemists during the first half of the 20th century had great expectations, and not without justification, from silicon as the closest analogue of carbon. However, a more detailed investigation of the chemistry of organosilicon compounds showed that silicon is incapable of forming very long polymeric chains made up of carbon atoms (analogous to polymeric carbon chains). The idea of the formation of a polymeric chain from alternating silicon and oxygen atoms led to the discovery of a new class of high-molecular-weight compounds—polymers with inorganic principal molecular chains.

K.A.Andrianov played a leading role in formulating and developing this new field of polymer chemistry. This branch of chemistry reached the greatest development in his studies and those of his numerous students.

The development of the chemistry of organosilicon polymers began in 1937 in a study by Andrianov[1] where the possibility of the formation of polymer chains from alternating silicon and oxygen atoms was demonstrated[1,2].

The research by Andrianov's school is distinguished by an exceptionally wide range of studies and by the practical applications of most of them. The investigations by Andrianov and his students laid the foundations of the chemistry of polymeric organic derivatives of the elements, which led to the discovery of the class of thermostable polymers.

Polyorganosiloxanes were the first polymers meeting the more rigorous requirements of many branches of modern engineering. These polymers have a high thermal stability and a high resistance to moisture, are chemically inert, and resist the action of sunlight, oxygen, and ozone. The chemical compositions and structures of compounds of this class are responsible for their valuable technical properties.

In terms of structure, polyorganosiloxanes occupy an intermediate position between organic polymers and silicate structures. This class of polymers has no analogues in nature as regards composition and constitutes a truly synthetic class.

Andrianov's research in the field of polyorganosiloxanes enabled him to formulate and apply in subsequent investigations the principle of combining in the polymer chain elements with appreciably different electronegativities. This idea has been reflected in a number of Andrianov's studies in the field of polyorganosiloxanes derivatives of the elements.

During the last 15 years Andrianov carried out fundamental research in the field of non-traditional and specific structures of polymeric molecules (cyclonetwork, cyclolinear, ladder, spirocyclic, etc.) in addition to studies on the classical structures of organosilicon polymers (linear and branched). The fundamental principles of the formation of the siloxane chain as well as the chemical and physical properties of polymers of the polyorganosiloxane series have been described in a number of monographs[3-6] embracing the literature data up to 1964. The main practical applications of substances of this class have been described in other monographs[7-16]. The aim of the present review was to examine studies carried out in recent years by the Soviet School of Chemists working in the field of organic silicon chemistry and headed by Andrianov.

II. LINEAR AND BRANCHED POLYORGANOSILOXANES

The polymerisation reactions of cyclic organosilicon compounds have now acquired great theoretical and practical interest, since they provide one of the most important ways of synthesising oligomers and high-molecular-weight compounds with inorganic and organic-inorganic molecular chains[4,5]. The vast majority of initiators employed consist of compounds whose molecules contain one nucleophilic centre (for example, OH^-, $\rangle NH_2^-$, or R_3SiO^-).

Andrianov and coworkers developed methods for synthesising many-centre initiators[17]. Three-centre initiators were obtained via the scheme

$$RSiCl_3 + 3NaOSi(CH_3)_2OSi(CH_3)_2ONa \rightarrow RSi[OSi(CH_3)_2OSi(CH_3)_2ONa]_3,$$

where R = CH_3, C_2H_5, or C_6H_5. Four-centre initiators were prepared by a similar reaction:

$$SiCl_4 + 4\,NaOSi(CH_3)_2OSi(CH_3)_2ONa \rightarrow Si[OSi(CH_3)_2OSi(CH_3)_2ONa]_4 .$$

Polymerisation in the presence of many-centre initiators made it possible [17-19] to obtain high-molecular-weight polymers having a branched star-shaped molecular structure:

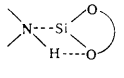
$$Si[OSi(CH_3)_2OSi(CH_3)_2ONa]_4 + n/4\,[(CH_3)_2SiO]_4 \rightarrow$$
$$\rightarrow Na[OSi(CH_3)_2]_lOSi(CH_3)_2OSi(CH_3)_2O\diagdown\!\diagup Si \diagup\!\diagdown OSi(CH_3)_2OSi(CH_3)_2O[Si(CH_3)_2O]_lONa \rightarrow$$
$$\rightarrow Na[OSi(CH_3)_2]_kOSi(CH_3)_2OSi(CH_3)_2O \diagup \quad \diagdown OSi(CH_3)_2OSi(CH_3)_2O[Si(CH_3)_2O]_mONa ,$$
$$l + k + l + m = n .$$

It was established that the order of the polymerisation reaction remains constant (it is first order with respect to the monomer) with increase of the number of functional groups in the initiators from 1 to 4. When two-centre initiators are employed, there is no interaction between the terminal functional groups and polymerisation proceeds independently via both reaction centres. With increase of the number of functional groups in the catalysts, there is a gradual decrease of the rate of polymerisation owing to the resulting steric hindrance due to adjacent side chains. The determination of the average number of branching centres by Kirby's method (from viscometric and light scattering data) showed that the branching of the molecules corresponds to the structure of the initial initiator [20,21]. The polydispersity coefficient of the polymers obtained amounts to 1.89–2.90, which indicates the occurrence of interchain exchange and chain transfer reactions at high conversions of the initial cyclic monomer [21].

It is interesting that the polymerisation of trimethyltriphenylcyclotrisiloxane in the presence of branched initiators does not lead to the formation of polymers with a star-like structure [22].

Studies on the type of change in the molecular weight distribution on polymerisation of various organocyclosiloxanes established that the polymerisation of octamethylcyclotetrasiloxane in the presence of NaOH involves chain transfer processes and the resulting polymer exhibits a high tendency towards depolymerisation. In the polymerisation of the same monomer in the presence of the initiator $(CH_3)_3SiON(CH_3)_4$ (with its subsequent elimination from the reaction sphere) a polymer is formed and secondary processes (chain transfer, branching) are not observed [23,24]. When the initiator is not removed, heating of the polymer *in vacuo* from 50° to 360°C leads in this case to depolymerisation with subsequent branching of the macromolecules.

The ideas on the mechanism of the anionic polymerisation of organosiloxane rings are based on the hypothesis of the formation of complexes between organocyclosiloxanes and nucleophilic agents [4]. A series of studies [25-30] undertaken to test this hypothesis established that molecular complexes are formed between amines and cyclosiloxanes [26-28]. The lifetimes of these complexes were established by NMR and it was found that the complexes are of a type different from that postulated previously. An experimental test of the possibility of the existence of complexes of the type NH...O$\begin{matrix}\diagup Si\\ \diagdown Si\end{matrix}$ showed [29] that the formation of a complex involving bonding of this kind is unlikely. The available data suggested a quasicyclic structure for the complexes with a non-linear hydrogen bond of the type



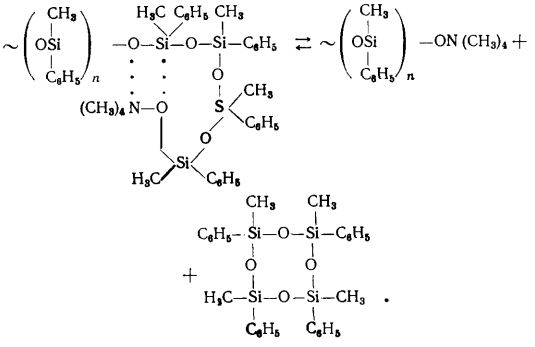
Furthermore, it was established that in the case of amines, in the absence of spectroscopically detectable admixtures of water, initiation begins with a direct attack on a ring silicon atom by the nitrogen atom [26,27].

A special series of studies in recent years was devoted to the investigation of polyorganosiloxanes containing phenyl groups at the silicon atom. Earlier investigations demonstrated an enhanced thermal stability of compounds of this class [31-33].

A study of the polymerisation of *cis*-trimethyltriphenylcyclotrisiloxane established that, owing to the high reactivity of the initial compound, the polymerisation reaction

$$[CH_3(C_6H_5)SiO]_3 + (CH_3)_4NO\left(\begin{matrix}CH_3\\|\\Si{-}O\\|\\C_6H_5\end{matrix}\right)_n{-}H \rightleftarrows (CH_3)_4NO\left(\begin{matrix}CH_3\\|\\SiO\\|\\C_6H_5\end{matrix}\right)_{n+3}{-}H \ldots$$

proceeds at a high rate. The depolymerisation reaction, leading to the formation of eight-membered and higher methylphenylcyclosiloxanes, proceeds at a relatively low rate and becomes appreciable only at high conversions [34-36]:

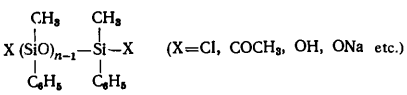


The polymerisation of *cis*-methylphenylcyclotrisiloxane in bulk, in the solid phase, and in solution leads to the formation of polymers whose actual molecular weight is appreciably lower than the molecular weight calculated from the ratio of the initiator and the cyclic compound. This can be accounted for by chain transfer reactions, traces of water and alcohols acting as chain-transfer agents. A preliminary removal from the reaction sphere of the possible chain-transfer agents leads to an increase of the rate of reaction almost by an order of magnitude and to a significant increase of the molecular weight of the resulting polymer [36].

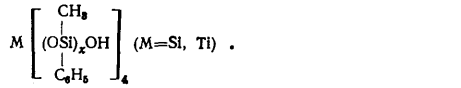
The highest yield of the polymer (95–98%) is achieved in the heterophase polymerisation of *cis*-trimethyltriphenylcyclotrisiloxane in hexane, which readily dissolves the initial cyclic compound but not the resulting polymer [37]. Side reactions, which usually lead to a broadening of the molecular weight distribution, are ruled out in this method and the polymer formed has an exceptionally low polydispersity coefficient ($M_w/M_n = 1.04$). Thermomechanical studies and studies on the hydrodynamic properties of polymethylphenylsiloxane showed that its chains are more rigid than those of polydimethylsiloxane [22].

One of the most promising procedures, which gives rise to great possibilities for controlling the composition and properties of polymers, involves the synthesis and study of linear and branched oligomers capable of conversion as a result of polymerisation and polycondensation into high-molecular-weight compounds with specified technical properties. A very important feature is that the polymerisation and polycondensation processes can be carried out directly in the finished articles.

The preparative methods devised hitherto make it possible to obtain oligomeric methylphenylsiloxanes having a wide range of terminal groups with different compositions [38,39].



The reactions of such oligomers with monomeric tetrafunctional compounds lead to the formation of oligomeric cross-like compounds with functional groups at the ends of the branches:

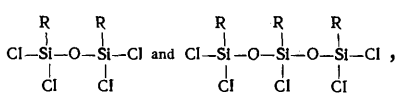


Both linear and cross-like oligomers, containing hydroxy-groups at the ends of the branches, are capable of further polycondensation. Polymers with $M = 10\,000$ and a glass point of 35°C can be obtained from linear oligomers [40]. The condensation of cross-like oligomers proceeds via both intermolecular and intramolecular mechanisms with formation of products having complex cyclic structures [41].

The glass points of linear oligomers decrease with increase of the molecular weight, while in the case of the cross-like oligomers they depend little on the lengths of the side chain but do vary significantly as a function of the nature of the terminal functional groups [42].

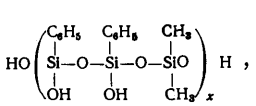
Cross oligomers with terminal hydroxyls exhibit the greatest resistance to thermo-oxidation, since on heating they form three-dimensional structures [43]. The replacement of the central silicon atom by titanium increases the thermal stability. Branched cross-like oligomers containing a certain amount of γ-trifluoropropyl groups show the greatest lubricating capacity [43].

Together with the methods of synthesis of siloxane oligomers described above, the hydrolytic condensation method merits a more detailed study, since the syntheses of the majority of organosilicon polymers are based on hydrolytic condensation processes and on the condensation of alkyl(aryl)chlorosilanes with different numbers of functional groups. The method of hydrolytic condensation in the vapour phase developed by Andrianov and coworkers [44,45] makes it possible to obtain organochloropolysiloxanes having the composition



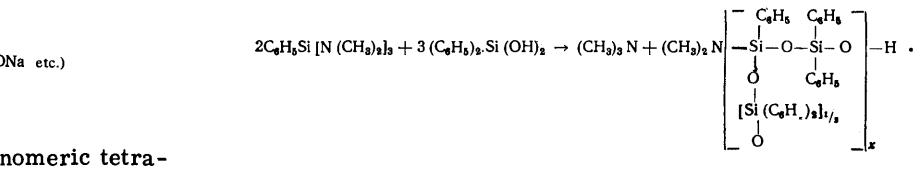
where R = C_6H_5 or C_2H_5.

The cohydrolysis of these compounds with dialkyl(aryl)-dichlorosilanes [44,46] yields oligomeric products having the composition

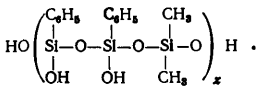


which were used to investigate the characteristics of three-dimensional polycondensation. It was established that the degree of reaction at the gel formation point and the critical branching coefficients exceed by a factor of 1.5–2 the values calculated by Flory's statistical theory. The explanation is that the condensation of the cohydrolysis products proceeds with a decrease of the number of functional groups owing to the formation of cyclic structures in the polymer units.

A similar feature was observed [44] in the condensation of aminosilanes and hydroxysilanes via the mechanism

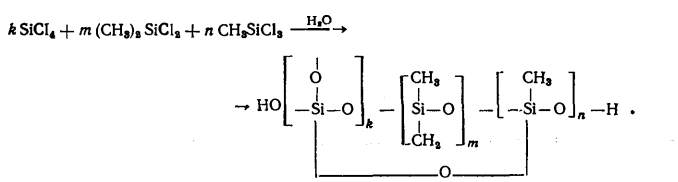


In this case the degree of reaction exceeds 90% but the resulting polymer is soluble and thermoplastic. Coatings with an appreciable resistance to petrol and oil were obtained [47] on the basis of the polyphenyldimethylphenylsiloxane oligomers investigated, which had the general formula



A study of polyfunctional systems, i.e. systems where the average number of functional groups in the initial monomers is greater than three, is of considerable interest. In such systems the C/Si ratio is appreciably reduced, which should lead to an enhancement of their thermal stability. Products of the cohydrolysis of silicon tetrachloride with dichlorodimethylsilane and chlorotrimethylsilane can serve as examples of such systems [48,49].

It was established that the yield of the gel fraction as a function of the number of functional groups in the initial system can be expressed by a polynomial equation [48], the yield of insoluble products depending also (separately) on the number of functional groups in the chlorosilanes employed. When appropriate hydrolysis conditions have been chosen, the above systems can give rise to soluble products despite the large number of functional groups in the system:



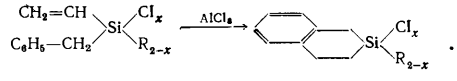
Oligomers with the above composition form protective coatings on metals, glass, and other materials. However, properties suitable for practical applications are achieved only when the average number of functional groups in the initial system is reduced to 2.6. [42]

The properties of polyorganosiloxane oligomers can be effectively modified by changing the nature of the organic group at the silicon atom as well as the number of functional groups in the initial monomers. The use of alkyl-(aryl)halogenosilanes containing 6–10 carbon atoms in the organic group attached to silicon in hydrolytic condensation reactions yielded compounds having the general formula $[RSiO(OH)]_n$, where $n = 6$ or 8 and R = i-C_5H_9, C_6H_{13}, C_8H_{17}, or C_9H_{19}. [50] These compounds condense in steps via an intramolecular mechanism. The cohydrolysis of higher alkyltrichlorosilanes with chloromethylsilanes and chlorophenylsilanes involves intramolecular condensation at a temperature not less than 60–65°C. [51] At lower temperatures each compound is hydrolysed separately.

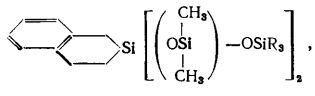
The cohydrolysis products are viscous transparent liquids, which polymerise in the presence of nucleophilic

agents. The methods devised for the synthesis of polyalkylsiloxanes served as the basis of a procedure whereby one can synthesise organosilicon liquids of new types with improved lubricating properties [52]. It was established that the introduction of units containing higher aliphatic groups at the silicon atom into polyorganosiloxane varnishes eliminates the formation of pores and bubbles when the varnishes dry out in thick layers [53].

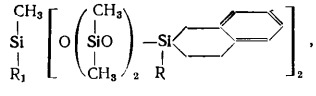
The modification of the properties of organosiloxane oligomers by altering the nature of the organic group at the silicon atom was continued in a series of studies by Andrianov on the synthesis and properties of compounds with arylalkyl groups at the silicon atom. The method of synthesis of compounds with arylalkyl groups at the silicon atom of the type $(C_6H_5CH_2CH_2)_xSiCl_{4-x}$ by the addition of chlorovinylsilanes to aromatic hydrocarbons, which was developed previously [54,55], served as the basis for the synthesis of bicyclic compounds via an intramolecular alkylation reaction [56-58]:



The introduction of silicon atoms with attached bicyclic fragments either into the siloxane chain or as blocking groups at the end of the chain yielded oligomeric products having the composition [59,60]

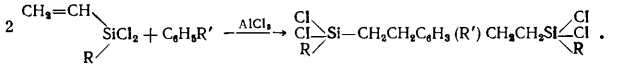


where R = CH_3, C_2H_5, or C_6H_5, or



where $R_1 = C_2H_4C_6H_4Cl$, which exhibit effective lubricating properties at high temperatures and retain them when used for a long time.

The viscosity of these compounds varies sharply with temperature and the activation energy for their viscous flow is high. Compounds suitable as high-temperature lubricants without these disadvantages were obtained by the above reaction [54,55], whereby one can also synthesise products of double intermolecular alkylation [60-62]:



Similar compounds were obtained also on the basis of compounds with two aromatic rings (diphenyl ether, diphenylmethane, biphenyl) [61]. In this case both silicon atoms add to the same aromatic ring via ethyl bridges:

$$[(CH_3)ClSiC_2H_4]_2C_6H_3—X—C_6H_5,$$

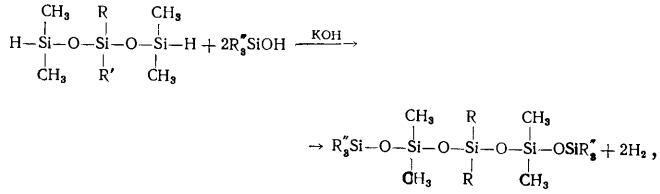
where X = CH_2 or O.

The replacement of chlorine atoms in the above compounds by trialkyl(aryl)siloxy-groups [60] yields the compounds

$$RC_6H_3\{C_2H_4SiR'_n[OSi(C_2H_5)_3]_{3-n}\}_2,$$

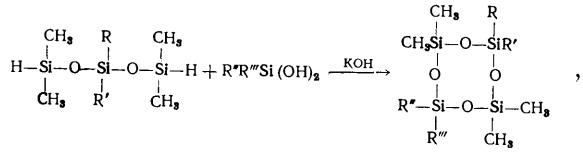
where R = H, CH_3, Cl, C_6H_5O, C_6H_5, or $C_6H_5CH_2$. They were used as the basis for high-temperature lubricants [63].

Together with hydrolytic condensation, the dehydrocondensation reaction is of interest for the synthesis of polyorganosiloxane oligomers [64-66]:



where R = CH_3 or C_2H_5, R′ = C_2H_5 or C_6H_5, and R″ = C_2H_5 or C_6H_5.

The method permits a specific heteromolecular condensation and homomolecular condensation can be prevented. This reaction can be included in the category of heterofunctional reactions, which were investigated in detail previously [3,4], but it has the advantage that it proceeds under milder conditions (40–80°C) at a high rate and with a high degree of conversion [66,67]. It also makes it possible to synthesise organocyclosiloxanes with known positions of the dialkyl(aryl)siloxane units in the ring [67]:



where R = CH_3 or C_2H_5, R′ = C_2H_5 or C_6H_5, R″ = C_2H_5 or C_6H_5, and R‴ = C_6H_5.

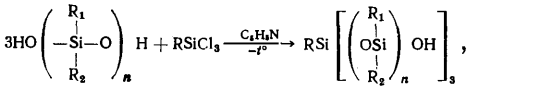
The X-ray diffraction studies, directed by Andrianov, on industrial and laboratory specimens of high-molecular-weight dialkyl(aryl)siloxane elastomers merit special consideration [68-73]. These investigations greatly amplified and extended the available data concerning the nature and physical properties of viscoelastic polydialkyl(aryl)siloxanes. The study of the effects of temperature, duration of exposure to a given temperature, deformation, the number and type of modifying groups, vulcanisation, and the amount and type of filler on the crystallisation processes of polydimethylsiloxanes (in the temperature range between −45° and −120°C) permitted a clear assessment of the influence of the above parameters on the process.

When modifying groups are introduced into the polymer, the rate and degree of crystallisation are described by relations with extrema [68,69]. The type of modifying groups does not have a significant influence on the crystallisation process. Vulcanisation [70] of polysiloxane elastomers affects the crystallisation processes like the introduction of modifying groups. The maximum rate of crystallisation is observed in the presence of an open vulcanisation network ($n \simeq 3000$). The introduction of a filler [71] accelerates the primary crystallisation process, because the filler orients on the surface the sections of the macromolecules which function as crystallisation nuclei. The rate of secondary crystallisation decreases with increase of the amount of filler and with increase of its activity. The crystallisation of deformed specimens proceeds via stages with an amorphous texture, the temperature of the onset of crystallisation being displaced towards higher values [72,73].

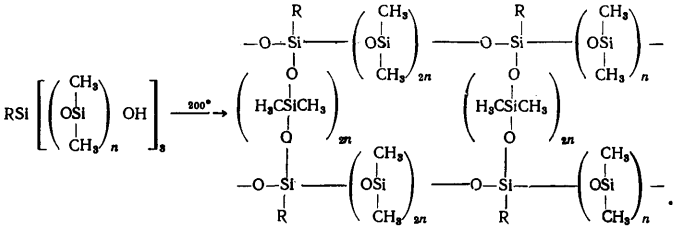
III. POLYMERS WITH CYCLONETWORK MOLECULAR STRUCTURES

The series of studies by Andrianov and coworkers described in this section was devoted to the investigation of a special class of polymeric compounds. This group of polymers is distinguished by a branched and partly cross-linked structure in which the siloxane bridges which behave as the cross-linking elements are polymeric. These compounds are obtained as a rule by polycondensation methods. Their synthesis makes it possible to regulate the distribution of the various groups or atoms in the polymer chain, which enables one to create polymers with a specified molecular structure and to regulate the properties of the polymers, whereas traditional hydrolytic polycondensation methods with subsequent catalytic polymerisation of the hydrolysis products as a rule lead to polymers with a non-order distribution of structural units.

The method of synthesising polyalkyl(aryl)siloxanes from polyfunctional oligomeric blocks is of interest for the preparation of polymers with an ordered structure [74-80]. Trifunctional alkyl(aryl)siloxane oligomers were synthesised in accordance with the scheme [81,82]

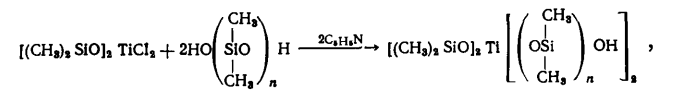


where R, R_1, and R_2 = CH_3 or C_6H_5 and n = 2, 6, 9, 14, or 32. The polycondensation of such oligomers leads to polymers with an ordered structure:

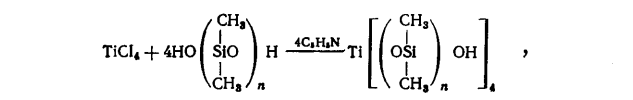


Polymers having this structure are thermoelastic and have satisfactory dielectric parameters [68]. The latter property is a consequence of the characteristic features of the method of synthesis of the polymers from oligomeric blocks. The polymers obtained by this procedure contain virtually no low-molecular-weight products and the polydispersity coefficient of the final product is low. The capacity of such polymers for crystallisation on cooling depends on the chain length between the cross-linking points. A polymer with a chain comprising 64 siloxane units crystallises in the temperature range between −67° and −72°C. When there are 18 siloxane units between the bridges, the polymer does not crystallise and passes to a vitreous state [68].

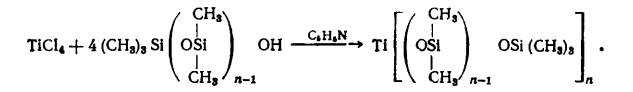
Compounds having a similar structure and containing polyfunctional metal atoms at the branching centres were obtained by heterofunctional condensation reactions. Titanodimethylsiloxane oligomers with linear and branched structures were obtained as follows [83-90]:



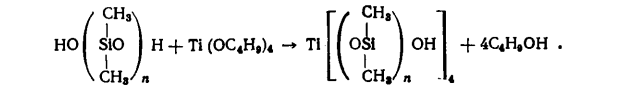
where n = 9, 22, 34, 42, and 52, and



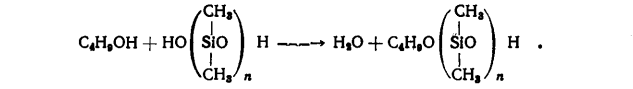
where n = 5, 13, 22, 25, 34, 42, 48, 52, 68, 80, or 104;



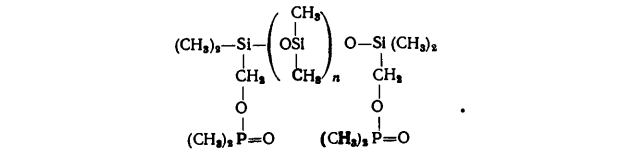
Compounds with this type of structure can also be obtained on the basis of tetrabutoxytitanium [90]:



The reaction proceeds in the above direction only when butanol is rapdily removed from the reaction sphere; otherwise the water formed in the reaction hydrolyses tetrabutoxytitanium to titanium dioxide:

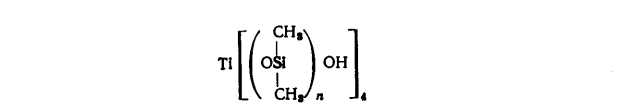


Oligomers having the above structure can react with the hydroxy-groups at the ends of the branches with formation of association complexes. As the concentration of hydroxy-groups increases (with decrease of the length from 34 dimethylsiloxane units to 13), they are gradually transformed from viscous liquids into gel-like substances. The above intermolecular interaction also leads to an increase of the packing density of the molecules. Similar features were likewise noted for polydimethylsiloxane oligomers with terminal dimethylphosphinate groups [85,86]:

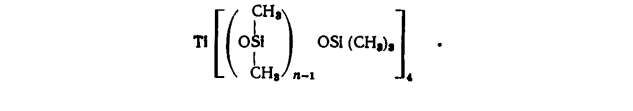


The activation energy for viscous flow, the density, and the refractive index increase with decrease of the distance between the terminal groups, which can be explained by the intensification of the interaction between the molecular chains with increase of the concentration of the polar groups per unit volume.

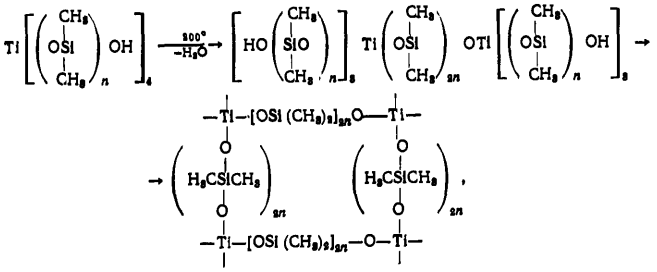
The variation of density with the length of the dimethylsiloxane chain for compounds of the type



is of a type opposite to that observed for the compounds [84]



The formation of polymers with a cyclonetwork structure [89] on condensation of branched oligomers proceeds in two stages via the formation of a soluble polymer:



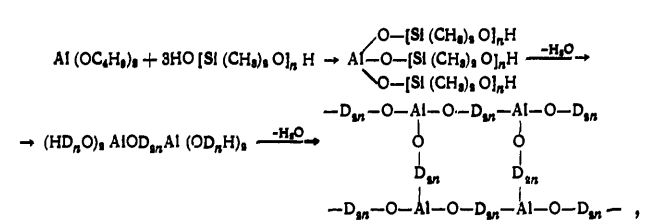
where n = 9, 18, 22, 25, 34, 42, 52, 62, 80. The structure formation reaction is first order and the structure formation rate constant decreases with increase of the average degree of polymerisation n in the initial oligomer. As the cyclonetwork structure develops in the polymer and solubility is lost, the polymer remains in the viscoelastic state up to 350°C.

X-Ray diffraction studies on these compounds showed [91] that they are amorphous at room temperature and their structure consists of packed bundles of dimethylsiloxane chains analogous to the packing of the molecular chains in polydimethylsiloxane. On cooling, the substances crystallise in the same temperature range as polydimethylsiloxane. It is interesting that, with increase of the hydroxy-group content in the compounds, the rigidity of the system rises, crystallisation is hindered, and the polarisability and dielectric losses increase [91].

A study of the thermal degradation of polytitanodimethylsiloxanes *in vacuo* showed [92] that degradation with rupture of the siloxane linkage and the formation of hexamethylcyclotrisiloxane is the rate-determining process. However, the introduction of a titanium atom into the siloxane chain appreciably reduces the rate of degradation. The rupture of the Si–O bond is accompanied by the homolytic rupture of the Si–C bond with liberation of hydrogen, methane, and ethane [93].

Compounds having a similar composition were obtained by the heterofunctional condensation of aluminium butoxide with difunctional oligomeric polyalkyl(aryl)siloxanes [94–97].

In this case the branching centre is the aluminium atom. The reaction proceeds in several stages:



where D designates the dimethylsiloxane unit $(CH_3)_2SiO$. A cross-linked polymer with a cyclonetwork structure is formed in the final stage of the process. The gel-formation rate constant depends little on the chain length of the initial oligomer, but amounts to 3.7×10^{-2}–1.4×10^{-2} h^{-1} when n for the oligomer ranges from 20 to 177 for a formally first order of the reaction with respect to the yield of the gel.

Thermal degradation of polymers of this type takes place in the temperature range 275–450°C. The main product is hexamethylcyclotrisiloxane and at 350°C methane and ethane are formed. The activation energy and the reaction order hardly depend on the distance between the nodes of the network. In this case the degradation process is a complex multistage reaction in which one can distinguish (a) thermal polycondensation in the initial stage, (b) random degradation of the polymer chain with formation of low-molecular-weight cyclic products, and (c) abstraction of organic groups from the silicon atom [92,93].

The polymers with a cyclonetwork structure examined in this section together with linear and branched polydimethylsiloxanes are convenient objects for the investigation of physicochemical properties.

A series of such studies greatly extended the existing knowledge of the nature of the siloxane chain in polymers having different structures [98–109]. An electron microscope study of polyalumino- and polytitano-dimethylsiloxanes showed that in both soluble and insoluble states these polymers have a two-stage globular supermolecular structure which is apparently of a type common to cross-linked viscoelastic polymers [98–101]. In the course of crystallisation the only structural form of polydimethylsiloxanes and polymetallodimethylsiloxanes comprises spherolytic formations. With increase of the distance between the metal atoms in the chain, the degree of crystallinity increases [102,103] together with the rate of crystallisation, which approaches the rate for high-molecular-weight polydimethylsiloxanes [100]. It is interesting that the above relation is much more pronounced for aluminium atoms at the nodes of the network than for titanium atoms.

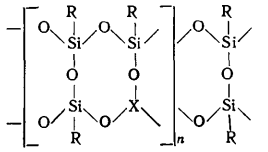
The somewhat specific character of the mechanical properties of the polymers (dependence of the modulus of elasticity, tensile strength, and deformation on n) is associated with the characteristics of the molecular and supermolecular structures [102,103]. The degree of structure formation in polyaluminodimethylsiloxanes can also be estimated by studying the relaxation properties. It was found that the increase of the equilibrium stress at the end of relaxation is faster for polymers with a low value of n. This conclusion agrees well with data obtained in a study of the kinetics of three-dimensional condensation and can be expressed by the relation $\lg \sigma_\infty = A - B \lg n$, where σ_∞ is the equilibrium stress at the end of relaxation, n the length of the siloxane chain between the nodal aluminium atoms, and A and B are constants characterising the given polymer.

The above relation makes it possible to investigate polymers in those cases where the lack of solubility precludes the investigation of the polymer structure by the usual methods [102,103].

IV. POLYMERS WITH CYCLOLINEAR LADDER MOLECULAR STRUCTURES

The possibility of the existence of polymeric molecules with a cyclolinear structure was first suggested by Andrianov together with one of the authors of the present review [104] and was subsequently confirmed by studies discussed in detail in a monograph [4]. Further investigations were directed towards finding new ways of synthesis and also to study the possibility of obtaining polymers having this structure, a high molecular weight, and different compositions of the elementary units. These compounds, which were subsequently called in the literature "ladder

polymers", have chain units with a silsesquioxane structure and can be represented by the general formula



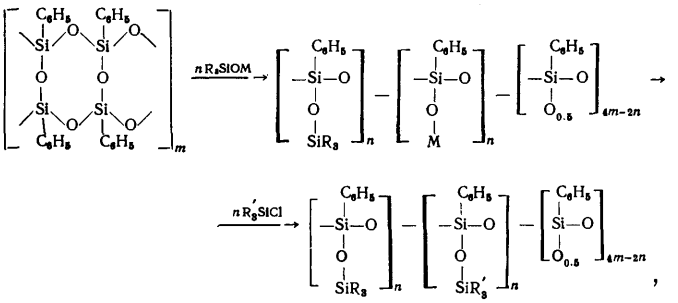
where X = Si, Al, Ti, Sn, etc.

A high-molecular-weight polyphenylsilsesquioxane, obtained initially by the high-temperature condensation of the hydrolysis product of trichlorophenylsilane [105], was subsequently obtained also by the polymerisation of a crystalline octamer [106] having the composition $(C_6H_5SiO_{4.5})_8$. In a series of tested polymerisation solvents (diphenyl ether, Dowtherm, nitrobenzene, anisole, and dimethylformamide) dimethylformamide proved to be best. In this case it is possible to obtain a polymer with a specific viscosity of 5.8. The polymer yields transparent films with a glass point above 400°C. The weight losses on heating to 500°C are 1.5–3.5% and not more than 15% at 600°C. The main polymer chain remains virtually unchanged up to 900°C. [107]

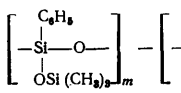
The specific structure of the molecule of the cyclolinear polyphenylsilsesquioxane in many respects determines its unusual physical properties. Thus the optical anisotropy of the molecules of this polymer exceeds by a factor of tens and hundreds the analogous parameters of the linear polymethylphenylsiloxane [108]. The number of monomer units per segment calculated from the experimental data is approximately 50, which exceeds by a factor of 10 the corresponding value for polymethylphenylsiloxane. This constitutes additional confirmation of the two-chain structure of the molecules of this ladder polymer. It is interesting that the high rigidity of the chain has little influence on the rotational mobility of the phenyl side groups [108]. It was noted that different specimens of the ladder polyphenylsiloxane have appreciably different molecular rigidities. This can be accounted for by the different proportions of structural defects in the molecules [109]. The nature of the flexibility of the ladder polymeric structure is different from that in linear polymers. It has a microdeformation mechanism (and not a rotational isomeric mechanism) involving microdistortions of the valence angles in the thermal vibrations of the atomic groups.

Appreciable differences between the structures of ladder polyphenylsiloxanes were also observed in a study of their hydrodynamic properties [110]. The values of the parameter a in Mark–Kuhn–Howink equation vary in the range 0.63–1.29.

The above investigations established that, regardless of the nature of the initial monomer, the synthesis of the polymers leads to two types of macromolecular structures. For each type of structure, there is a specific Mark–Kuhn–Howink equation. An electron microscope study on these two types of structures showed that they produce different supermolecular structures. Polymers with $a > 1$ give rise to structures of the fibrillar type and those with $a < 1$ give rise to globular structures. High values of the parameter a can be explained only by the high rigidity of the macromolecules, which causes appreciable deviations of the molecular coils from the Gaussian type even in the region of high molecular weights. The chemcal properties of the ladder polyphenylsilsesquioxane are determined by the high positive charge on the silicon atom and the negative inductive effect of the phenyl group, which increases the reactivity of the polymer in relation to nucleophilic agents. A polymer with a molecular weight of 30 000–40 000 was chosen for investigation. The reaction, carried out in accordance with the scheme

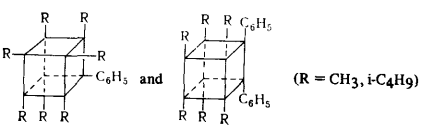


leads to oligomers with the above structure and a molecular weight of 1000–4000. [111,112] The ratio of units of different structure is statistical. Rearrangements of the siloxane skeletons with formation of six-membered structural fragments take place in the course of the above reaction together with the rupture of the silsesquioxane chain. The interaction of polyphenylsilsesquioxane with hexamethyldisiloxane at 250–260°C [113] leads to the formation of oligomers of the type



The analogous reaction with octamethylcyclotetrasiloxane [114] at 250°C leads to products with a viscosity smaller by a factor of 20 than that of the initial polyphenylsilsesquioxane.

A series of studies have been made on the synthetic possibilities and properties of ladder polymers containing, together with phenyl groups at the silicon atom, also groups with a different composition [115–129]. The synthesis and investigation of three-dimensional cyclic compounds of the type



(where each vertex contains a silicon atom and each edge represents a siloxane linkage) established that the introduction of electron-accepting phenyl substituents into the cage compounds is a necessary condition for their polymerisation, but is insufficient for their rearrangement to cyclolinear ladder polymers.

Cohydrolysis of a mixture of various alkyl(aryl)trichlorosilanes to compounds with a polycyclic structure and subsequent anionic polymerisation established a number of characteristics of the formation of the ladder structure [117,118]. An increase of the content of aliphatic substituents in the polycyclic systems decreases the rate of polymerisation. This effect is more pronounced the greater the length of the hydrocarbon chain of the alkyl substituents.

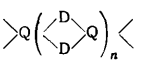
Compounds with alkyl substituents containing not more than three carbon atoms (regardless of the structure of the organic group) give rise to three-dimensional structures on polymerisation. The most favourable conditions for the formation of a ladder polymeric molecule arise when a double bond is introduced into the hydrocarbon chain of the substituent in the α-position relative to the silicon

atom. A similar effect is achieved when substituents are introduced into the phenyl group in the β-position relative to the silicon atom. The study of the hydrodynamic and dynamo-optical properties of the above polymers and of poly-3-methylbut-1-enylsilasesquioxane [123,124,129] made it possible to estimate the skeletal rigidity of the macromolecules. The thermomechanical and mechanical properties of these polymers [120,127] depend on the nature of the surrounding groups, the film-forming capacity being retained when the composition of the chain unit is altered. The thermal stability of ladder polymers greatly exceeds that of linear polyorganosiloxanes [121,126,127].

V. POLYMERS WITH SPIROCYCLIC AND SPIROLADDER MOLECULAR STRUCTURES

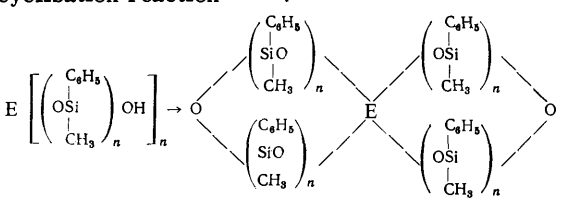
This class of polymers, which have an extremely unusual structure of the main molecular chains, opens a new chapter in the chemistry of organosilicon polymers, which has been developed very vigorously in recent years by Andrianov [128].

Polymers of this group contain cyclic fragments linked to the atom of an element forming part of two rings which constitute the molecular chain. The structure of a spirocyclic polymer can be represented schematically as follows:



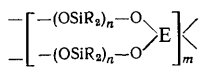
where D are bifunctional fragments and Q is the spirocyclic centre (a silicon or a polyvalent metal atom).

The possibility and ways of synthesising such polymers were predicted by earlier studies [137]. Thus it was noted that, when cross-like oligomers of type $E[(OSiR_2)nOH]_4$ are condensed, polymers with a molecular network structure are formed only when the distance between the central atom E and the functional group is large. The condensation of oligomers with small values of n leads to soluble polymers, which can be accounted for by an intramolecular cyclisation reaction [136,137]:



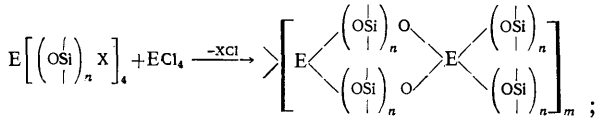
The compound with $n = 1$ is crystalline (E = Si), while those with $n = 3$ (E = Si or Ti) are amorphous under the usual conditions.

This reaction also involves the formation of a soluble polymer without hydroxy-groups. Thus the reaction proceeds simultaneously with intermolecular condensation and formation of polymers of the type

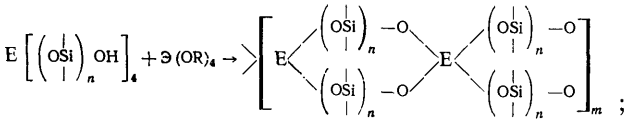


The following reactions have been used to synthesise spirocyclic polymers [128]:

(1) exchange reactions:

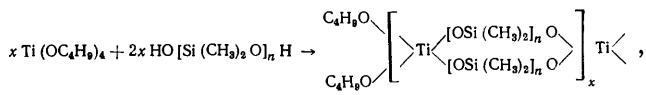


(2) polycondensation of tetrafunctional compounds:



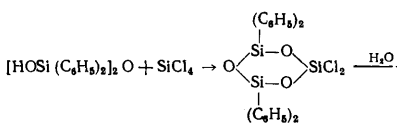
(3) condensation of bifunctional compounds with tetrafunctional compounds:

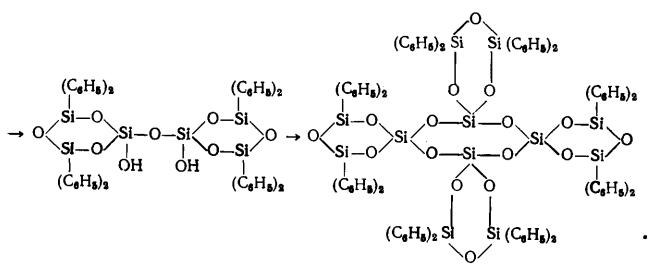
For example, polyspirotitanodimethylsiloxanes were obtained by the reaction [138]



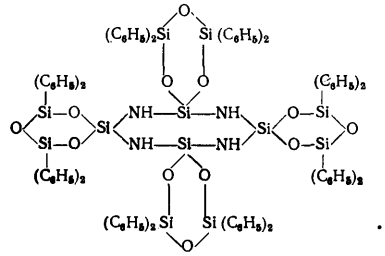
where $n = 2$, 3, or 4 and the molecular weight reaches 2000–3500. The low degree of polycondensation can be accounted for by the steric hindrance suffered by the reactant molecule on approaching the functional groups of the molecule of the polymer being formed. The spiro-structure of the resulting polymer is stable up to 300°C, [139] the spirocyclic fragments in the polymer molecules undergoing a rearrangement only at 400°C. Hydrodynamic and optical studies on these polymers [129] demonstrated the presence of a high degree of intramolecular order and a high equilibrium rigidity of the macromolecules.

One of the ways of obtaining polymers with a spirocyclic structure is catalytic polymerisation of organospirosiloxanes. The initial spiro-compounds were obtained by a multistage synthesis [130–133]:

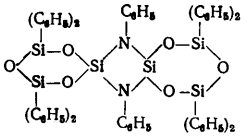




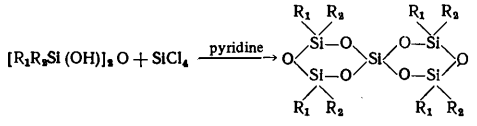
The last stage proceeds with difficulty and only at 280–300°C (owing to the screening effect of the diphenylcyclotrisiloxane fragments). The replacement of the second, hydrolytic stage in the above scheme by ammonolysis with ammonia makes it possible to obtain a silazane–siloxane spiro-compound:



On the other hand, when the ammonolysis is carried out with aniline, it is possible to obtain ultimately by the above scheme a spiro-compound with a four-membered silazane ring:

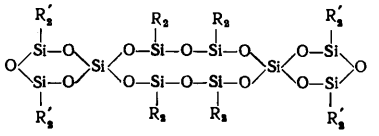


The above syntheses were achieved in the absence of a hydrogen chloride acceptor in the first stage. On the other hand, in the presence of pyridine, the spiro-compound is obtained in one stage:

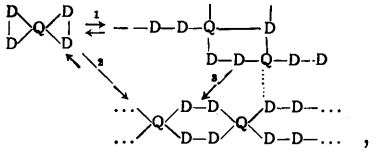


where R_1 and R_2 = CH_3 or C_6H_5.

In the course of high-temperature distillation these compounds partly rearrange to higher spirocyclic products:



It is interesting that the formation of cross-linked products is not observed. When organospirobicyclosiloxanes are subjected to anionic polymerisation in bulk [134,135], the growing polymer chain is involved in two competing reactions (intermolecular and intramolecular interactions). This can be represented by the scheme

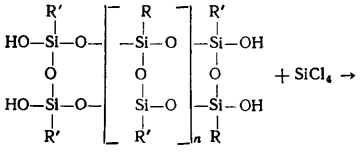


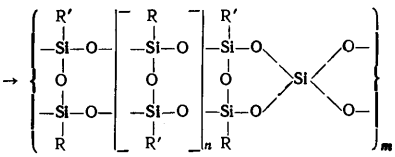
where D are bifunctional fragments and Q are tetrafunctional fragments.

The process proceeds both with formation of soluble (pathway 2) and cross-linked products (pathway 1). The content of the gel fraction falls as the surrounding methyl groups are replaced by phenyl groups. When the molecule of the initial compound contains exclusively phenyl groups, the gel is not formed.

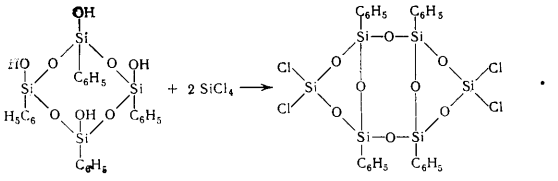
The polymerisation of the above compounds in dilute solutions [134] as a rule leads to the exhaustion of the initial cyclic fragments.

Compounds having polymer chains containing simultaneously fragments with spiro- and ladder structures constitute a special group of polymers. In their synthesis by heterofunctional condensation the most favourable conditions for the formation of the expected structure occur when the initial stage of the reaction proceeds at a low temperature in not too dilute solutions [140,141]:



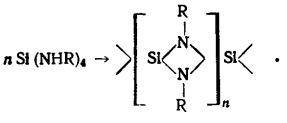


where R = C_6H_5, R′ = i-C_4H_9 or C_6H_5, and n = 0–2. The length of the cyclotetrasiloxane fragment (the value of n) affects the possibility of obtaining spiro-groups. For n = 2 and R = R′ = C_6H_5, it proved possible to obtain polymers with a characteristic viscosity of 0.12–0.22 dm g^{-1}, while for n = 0 the expected structures could not be produced. These results were explained by stepwise condensation:



The polycyclic compound formed has the *cis*-structure like the initial tetrol $[C_6H_5Si(OH)O]_4$. When the resulting polycyclic compound reacts with an equimolar amount of the tetrol, spiro-groups are not formed owing to the *cis*-conformation of the reactants.

The study of the hydrodynamic and optical properties of polyisobutylphenylsiloxane with a spiroladder structure [142] showed that the molecules have the properties of fairly flexible non-fluid coils, resembling Gaussian coils from the hydrodynamic standpoint. Such flexibility can be accounted for by structural defects. On the other hand, the behaviour of polymethylphenylspirosiloxane molecules (with 8 and 16 atoms in the ring) in solution differs from the usual behaviour of semirigid regular chains with both small and large segments, which can be explained from the standpoint of non-linear structures of the network type [141]. Spirocyclic polymers with a silazane structure [128] were synthesised by the reaction

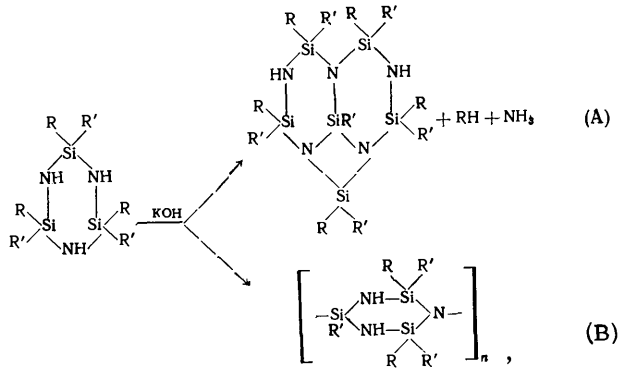


VI. POLYORGANOSILAZANES

Great hopes were associated with studies on polyorganosilazanes because there are many unsolved problems related to the synthesis, structures, and properties of organosilicon polymers, which could not be solved solely in relation to compounds of the siloxane series.

The reaction of organocyclosilaxanes with nucleophilic agents is the most promising from the standpoint of polymer chemistry. However, it differs appreciably from the analogous reaction of organocyclosiloxanes. In the first place, in contrast to organocyclosiloxanes, organocyclosilazanes exhibit a greater tendency to undergo substitution reactions than addition reactions. In this respect their properties resemble aromatic systems [142,143]. The reaction of dialkyl(aryl)cyclosilazanes with nucleophilic agents [144–154] is accompanied by the evolution of the hydrocarbon corresponding to the organic group attached to the silicon atom and the formation of cyclic polymers which soften at a high temperature. When the silicon

atom is surrounded by aliphatic groups, the reaction proceeds as follows:

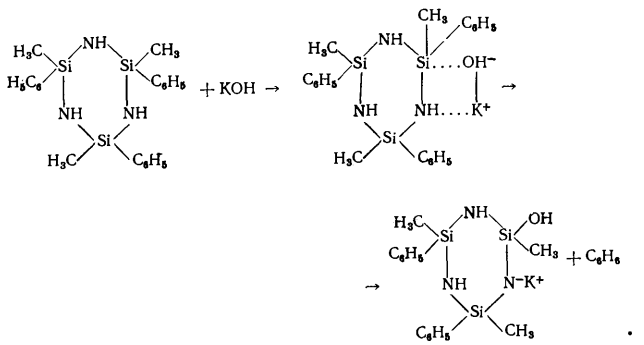


(A)

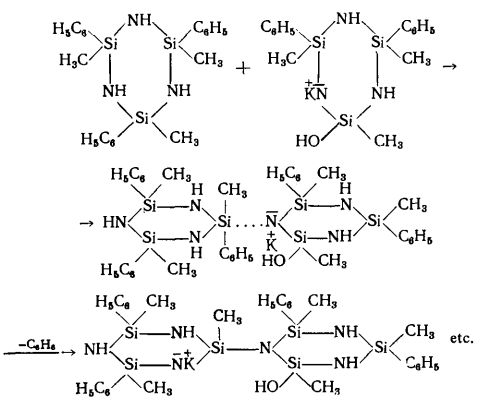
(B)

where R = CH_3 or C_2H_5 and R′ = C_2H_5, C_4H_9, or C_6H_{13}. It is interesting that compound (A) is chemically inert and remains unchanged when acted upon by catalytic amounts of alkali. The product (B) is formed via condensation without ring opening and not via compound (A).

The anionic polymerisation of methylphenylcyclosilazanes also does not proceed via ring opening, but involves the formation of a transition complex which weakens the Si–C bond and not the Si–N bond:



The subsequent reaction proceeds via the coordination of the molecules of the initial compound to the resulting anion, which contains the $\rangle N^-$ fragment:



The resulting polymers have a filamental or branched structure. An increase in the bulk of the organic group at the silicon atom stabilises the transition complex and hinders its conversion into the active state. As a result, the reaction rate falls sharply. The reaction involving trimethyltrinonylcyclotrisilazane does not begin up to 300°C. The influence of the groups surrounding the silicon atom is also associated with steric effects. Bulky groups (hexyl, octyl, and nonyl) hinder the polymerisation.

Studies on the possibility of synthesising polymers with silazoxane chains [155–159] revealed the fundamental pathways leading to the formation of polymers of this type. The synthesis of the polymers by the condensation method proved to be promising [157–159]:

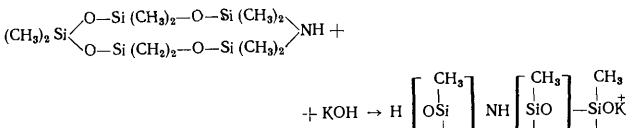
$$RN(H)[Si(CH_3)_2O]_n Si(CH_3)_2NHR \xrightarrow[-RNH_2]{t^\circ} \rightarrow R(H)N\{[Si(CH_3)_2O]_n Si(CH_3)_2NR\}_m H,$$

where R = H or C_2H_5 and $n = 4-10$, 11, or 40.

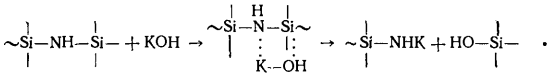
The polymers consist of swelling insoluble substances with a distinct region of a viscoelastic state. A study of the thermo-oxidative degradation of these polymers showed [160] that the introduction of a nitrogen atom into the siloxane chain stabilises it to some extent.

The anionic polymerisation of cyclosilazoxanes containing hydrogen at the nitrogen atom was unsuccessful.

The ring is opened initially at the siloxane linkages:

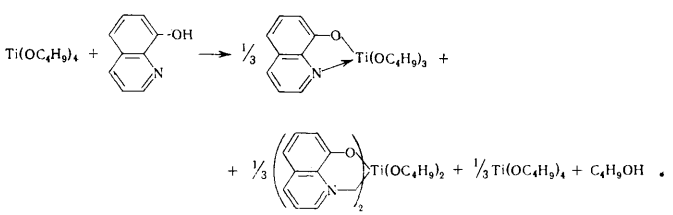


In the second reaction stage the polymeric chains are ruptured at the silazane linkages:

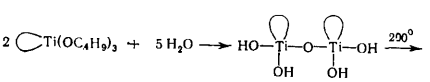


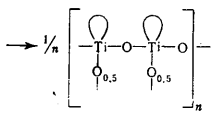
VII. POLYORGANOSILOXANE DERIVATIVES OF THE ELEMENTS

Polymers of this class were synthesised for the first time and investigated in detail by Andrianov's School. The main bulk of studies in this field have been described in a monograph [4]. Some of the investigations formally concerned with this field were examined in the preceding sections of the present review. This section deals with certain investigations published after the publication of Andrianov's monograph [4]. Numerous studies were devoted to polytitano-organosiloxanes. The replacement of one or two butoxy-groups in tetrabutoxytitanium by 8-hydroxyquinolinato-groups makes it possible to reduce the number of groups with which the titanium atom can interact to three and two respectively [161]:

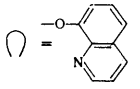


Hydrolysis of the tributoxy-compound with subsequent thermal condensation leads to polymers having a metalloxane structure [162]:

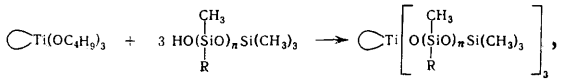




where



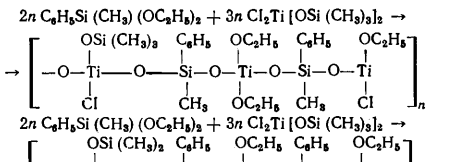
The reaction of the above trifunctional compound with hydroxylated polysiloxane oligomers leads to the formation of branched oligomers [163,164]:



where n = 15, 60, 98, 170, or 350 and R = CH_3 or C_6H_5.

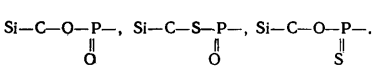
The resulting oligomers proved to be convenient model compounds for the study of the dependence of physicochemical properties on the siloxane chain length. It is interesting that the polydispersity coefficient of the oligomers does not differ significantly from that of the initial hydroxylated polyorganosiloxanes. The presence of 8-hydroxyquinolinatotitanoxane groups intensifies the intermolecular interaction and the packing density of the molecules, which affect the density, activation energy for viscous flow, and the free volume of the resulting oligomer [165]. An increase in the length of the siloxane chain in the branches has the opposite effect on the above parameters. The competing effects of various structural elements are observed particularly clearly in studies on the dynamic viscosity of oligomers. It has been established [164] that the introduction of 8-hydroxyquinolinatotitanoxane groups into polydimethylsiloxanes increases their thermal stability and the oligomers mentioned above are effective inhibitors of the thermo-oxidative degradation of liquid polydimethylsiloxanes.

Polymers with an unusual structure of the main chain, containing alternating titanium and silicon atoms, were obtained by heterofunctional condensation [166]:

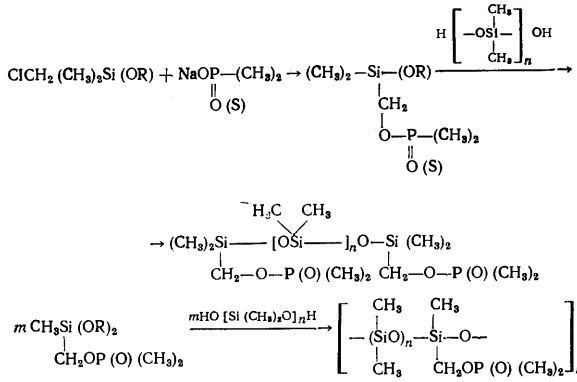


The resulting polymer is a viscoelastic product, which can be readily drawn into threads. Owing to the presence of hydrolysable groups the polymer is not resistant to moisture.

A number of studies have been made on the synthesis and properties of polyorganosiloxane polymers containing phosphorus atoms in the side chains [167-171]. In contrast to the majority of earlier studies on the nature of the Si–O–P linkage, the above series of investigations was devoted to compounds containing the groups

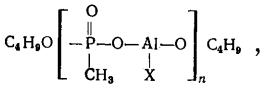


Such groups are much more resistant to hydrolysis than the Si–O–P group. Compounds of the siloxane series containing phosphinate groups or their thio-analogues in the methyl substituent at the silicon atom are synthesised by the reaction

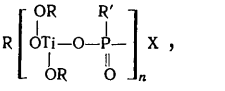


where n = 9, 13, 45, 75, or 130. By altering the proportions of the dimethylphosphinate and dimethylsiloxane groups, it is possible to vary the properties of the polymers within wide limits.

In this section of the review it is appropriate to mention studies dealing with methods for the synthesis of polymers with inorganic main molecular chains, without silicon atoms. These are primarily polyaluminomethylphosphonates [172-175]

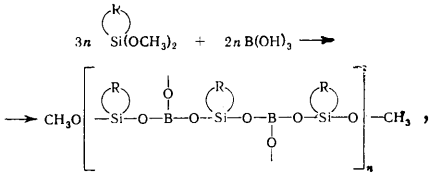


where X = Cl or C_4H_9, poly(dialkylphosphinyl)titanoxanes $\{[(CH_3)_2P(O)O_2TiO]\}_x$, [176,177] and polytitano-organophosphonates [178-180]

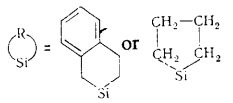


where R = C_4H_9, R′ = CH_3 or $CH_2{=}C(C_6H_5)$, and X = Cl, OH, or OC_2H_5. A detailed study of the properties of polytitano-organophosphinates established that their degradation at temperatures up to 400°C involves only the abstraction of the organic groups with retention of the Ti–O–P linkage [197,202]. It was established that these compounds can be used as thermostabilisers to improve the heat resistance of polyorganosiloxane varnishes and enamels [206]. The introduction of an organophosphinoxytitanoxane group into polyorganosiloxanes increases the resistance of the latter to thermo-oxidative degradation [202,203]. These results constituted the basis for the formation of siloxane resins with enhanced thermal stability [204,205].

Polyorganosiloxanes containing boron have been described [181-188]. Polymers with very variable compositions have been studied. Polyborosiloxanes containing silicon atoms in the main chain and at the same time silicon atoms behaving as the heteroelement in the heterocycle were obtained by the reaction

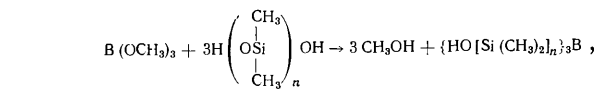


where

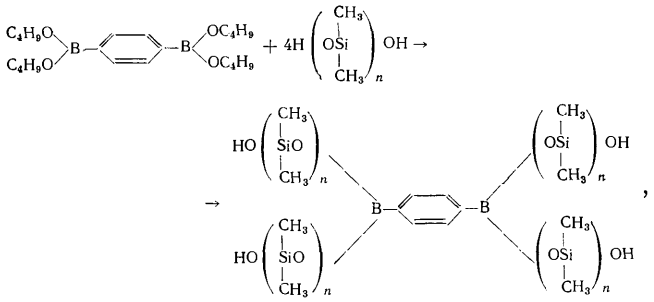


Polymers with this composition have a high resistance to thermo-oxidative degradation [186-188].

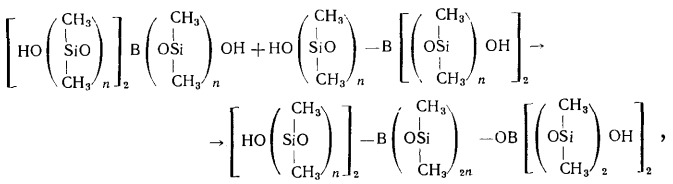
Branched polyborodimethylsiloxanes are synthesised by heterofunctional condensation [181-183]:



where n = 9, 13, 25, 45, 74, 135, or 220,

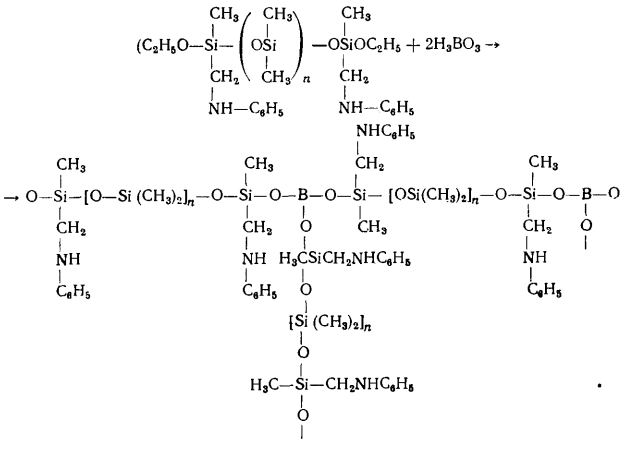


where n = 30, 46, 76, 95, or 235, and by homofunctional condensation [184,185]:



where n = 13, 25, 46, 74, or 200.

In the last of the polymers quoted the boron content is insignificant, and yet leads to an appreciable improvement of thermal stability compared with polydimethylsiloxanes [189]. The resistance of the SiOB linkage to hydrolysis was increased by the introduction of phenylaminomethyl groups among the organic substituents surrounding the silicon atom [183]:



The reason for the increased resistance to hydrolysis is in this case the formation of a coordinate bond between the nitrogen atom of the phenylaminomethyl group and the boron atom, which hinders the formation of a transition complex with water in the hydrolysis of these compounds.

A comparatively new development in the field of polymeric organosiloxane derivatives of the elements is the synthesis of polymetallo-organosiloxanes with reactive groups at the silicon atom, in particular vinyl groups [190-193]:

where M = Al or Ti. The resulting polymetallovinylsiloxanes can copolymerise with vinyl monomers (styrene and methyl methacrylate) and can undergo hydride addition reactions with compounds containing the SiH group. Both methods make it possible to vary widely the properties of the polymers both as a result of a change in the nature and amount of the metal introduced into the polymer and as a result of the selection of the appropriate vinyl monomer. The products of the addition of polytitanovinylsiloxanes to polyorganoaluminosiloxanes proved to be very effective components of heat-resistant adhesive compositions [193].

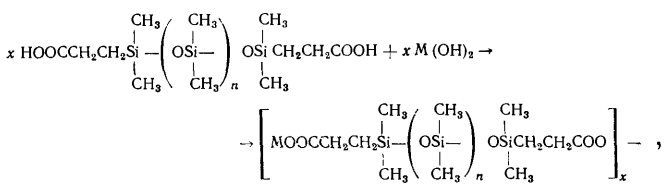
Polymeric organosiloxane derivatives of the elements constitutes a class of polymers differing from the majority of organic polymers, primarily by their high heat resistance. It is therefore quite natural that numerous studies have been devoted to the thermal and thermo-oxidative degradation of polymers of this class [189,194,201,207,208,209].

The above series of studies established the relation between the structure of the polymer unit, the nature of the heteroatom, the composition of the organic group at the silicon atom, and many other structural characteristics on the one hand and the thermal stability of the polymer on the other.

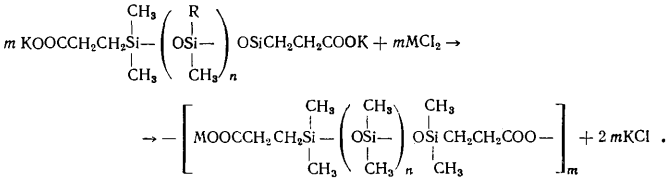
In conclusion of this section, we shall mention a number of studies on the synthesis and properties of polydimethylcarboxyatometalloxyloxanes containing metal atoms in the main chain linked to a silicon atom via a carboxylate group [212-222].

An attempt to introduce bivalent metal atoms into the siloxane chain was described in earlier investigations [210,211] and was found to involve many difficulties. A series of studies by Andrianov and coworkers [212,222] constitutes the most successful attempt at the introduction of bivalent metals into the siloxane chain, the carboxylate groups surrounding the metal atoms determining in many respects the unusual properties of these polymers.

The polymers were synthesised in two ways: (a) from the metal hydroxides:

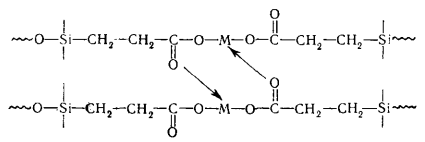


where M = Ca, Zn, Cd, Pb, or Co, and (b) from the metal chlorides:



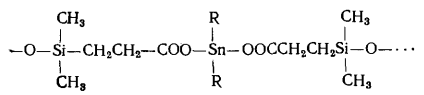
With increase of the distance between the metal atoms in the polymer chain, the viscosity of the polymer rises. Polymers with n = 20 are already rubber-like. Those with n = 50–70 are insoluble in the usual organic solvents

owing to the marked influence of interchain coordinate bonds of the type



The polymers become soluble when 2–3% of pyridine, which disturbs the above interactions, is introduced into the system. The presence of such linkages is also indicated by the high yield temperatures of the polymers and the high viscosities of the low-molecular-weight oligomer products of this type.

An additional confirmation of the presence of coordinate bonds in polymers of this kind has been provided by the study of a polymer based on quadrivalent tin, where such interactions are ruled out:



The properties of this polymer differ appreciably from those described above. Assuming the possibility of the formation of coordinate bonds between polymetallodimethylsiloxane macromolecules and their influence on the thermomechanical properties of the polymers, the metals investigated can be arranged in the following sequence in terms of decreasing intermolecular interaction forces due to these linkages [217,218]: Co > Zn > Pb,Ca > Cd.

This series agrees well with the order of decreasing coordination capacities of the metals. Studies on solutions of these polymers showed that, when the metal content is small (one atom for 30–100 silicon atoms), the conformation of the polymer molecule does not differ from that of the dimethylsiloxane polymers in solution [216]. It has also been established that the nature of the metal atom does not affect the rate of crystallisation of the polymers [218], but has an appreciable influence on the thermal degradation [222]. The thermal stability of the polymer increases with increasing basicity of the metal. These results together with those obtained by the chromatographic analysis of the thermal degradation products make it possible to elucidate the mechanism of the thermal decomposition of polymers of this type.

Problems of the Chemistry of Thermostable Organic Polymers

A.A.Berlin

The effect of π-electron delocalisation, due to polyconjugation in macromolecular structures, on the thermal and thermo-oxidative stability of polymers is surveyed, and data are given indicating that thermal oxidation is activated by the centres produced by the rupture of strained chemical bonds during thermolysis. Certain general problems and advantages in the synthesis of polyconjugated thermostable oligomers and high polymers are discussed. A list of 76 references is included.

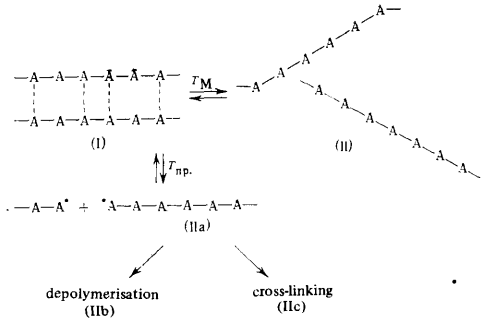
I. INTRODUCTION

The action of heat on a polymeric material may cause processes of two kinds, resulting in reversible and irreversible changes in its physicochemical properties. The first type involves phase transitions or variation in molecular mobility in amorphous regions of polymers. Such changes are taken to characterise the deformative thermal stability or thermophysical stability of polymers and polymeric materials. Irreversible change in the physicomechanical properties of polymers, in contrast, are mostly due to chemical changes in the polymer caused by the temperature and the environment. Such changes are related to the chemical thermal stability or thermochemical stability. In the absence of a reactive environment, e.g. oxygen, thermochemical degradation may be more or less reversible, although the attainment of complete reversibility is in practice difficult owing to the finite probability of anomalous recombination and cross-linking. The variation in the thermophysical stability of polymeric materials during processing and service is due in most cases to degradation and cross-linking: i.e. it is connected with their chemical thermal stability. Therefore the thermochemical stability may well be the main property from which the temperature range for practical application of the polymer can be assessed.

There are thus two states that are most dangerous in use—melting (or softening) and degradation of the polymer (beginning at a limiting temperature T_{lim})—a situation which is shown clearly by the scheme



The thermal conditions for the transition from (I) to (II) or to (IIa) are governed by the decrease in free energy $\Delta G = \Delta H - T\Delta S$, and are characterised at equilibrium by the phase transition or chemical conversion temperature $T_{tr} = \Delta H/\Delta S$. The temperature T_{tr} is obviously higher the smaller are H_{tr} and ΔS. Such conditions can be realised in polymer systems whose macrochains contain no weak chemical bonds and are characterised by strong intermolecular interaction (H_I small), as well as by a slightly larger S_{II} than S_I. This is possible in rigid systems, when the decrease in chain length on degradation produces a sharp drop in flexibility, and also during cross-linking processes.

Although the above considerations relate to thermal transformations in polymers, they have some significance for thermal oxidation processes initiated by the rupture of chemical bonds. The irreversible character of thermal oxidation and cross-linking complicate the thermodynamic treatment of the relation between the structure and the thermochemical stability of polymers, bringing a kinetic examination of the process to the forefront.

Since the thermochemical stability of polymers at high temperatures (at or above 300°C) depends primarily on the strength of the chemical and intermolecular bonds and on the molecular mobility of the structural units, we must consider the effect of electron delocalisation along the chains of the macromolecules on the thermal stability of polymeric materials. Further justification for such an approach to the problem of thermal stability is that the character of the electron delocalisation (conjugation) along large segments of polymer chains should influence not only the strength of the bonds linking them but also the molecular mobility and intermolecular interaction.

The Reviewer has repeatedly pointed out that enhancing the thermal stability (chemical and physical) of organic polymers requires the "designing" of macromolecules having a developed system of conjugation by π-electron delocalisation[1-3]. Electron delocalisation can be shown to determine the thermal stability not only of so called organic polymers but also of polymers with inorganic chains. Indeed, the data in Table 1, gathered from several sources[4,5], show that in all cases the strength of a bond is improved by its polarisation and many-centred character. From this it may be concluded that macromolecules of highly thermostable polymers can be constructed in three main ways.

1. Formation of a polyconjugated system of multiple bonds and aromatic and/or heterocyclic rings. The polymer chain then contains extended segments in which a

particular type of π-conjugation is established. Such systems possess considerable rigidity, and form stable supermolecular structures[6].

2. The building up of macromolecules by means of "quasi-cumulene"[7] dative bonds formed by the delocalisation of p-electrons of one heteroatom into d- or p-electron vacancies of another element attached to it, e.g.

Such compounds include polysiloxanes and other organometallic[8,9] and inorganic[10,11] polymers. With substances of this type (in any case those with p,d-conjugation) chain flexibility does not create conditions preventing delocalisation, since flexibility is realised not so much by rotation about valency bonds as by the deformation of bond angles[7]. Thus high elasticity can be combined here with thermochemical stability of the polymeric material.

Table 1. Effect of delocalisation of π- and p-electrons on bond energy.

Bond	Conjugation	Energy, kcal mole^{-1}	Bond	Conjugation	Energy, kcal mole^{-1}
$C_{aliph}-C_{aliph}$	—	83.0	$C_{aliph}-Si$	—	78.0
$C_{arom}-C_{arom}$	$\pi-\pi$	98.0 (105)	$Si-\ddot{O}$	$p-d_v$	106.0
$C_{aliph}-\ddot{N}H$	—	82.0	$B-N$	$p-p_v$	115.0
$C_{arom}-\ddot{N}H$	$p-\pi$	110.0	$B-\ddot{O}$	$p-p_v$	113.0
$C_{aliph}-\ddot{O}$	—	93.0			
$C_{arom}-\ddot{O}$	$p-\pi$	107.0			

Arrows: .....delocalisation of π-electrons;
----delocalisation with displacement of p-electron density;
d_v, p_v electron vacancies.

3. Formation of block-copolymer structures including fragments of π-electron conjugation[1] and organometallic or inorganic fragments with p,d-delocalisation of valency electrons. Such structures may be expected to exhibit an interesting combination of the physicomechanical properties characteristic of polyconjugated polymer systems and compounds with dative bonds[2].

In this Review we shall examine certain problems associated with the thermal stability of organic polymers containing more or less extended fragments of π-conjugation.

II. PECULIARITIES OF THE STRUCTURE AND THE THERMOCHEMICAL STABILITY OF POLYCONJUGATED SYSTEMS

It has now been shown that the high thermochemical stability of polyconjugated polymer systems is due to processes which, in the absence of oxygen, tend to extend the polyconjugated chain. The ultimate results of such changes is the formation of graphite, amorphous carbon, or products of similar electronic structure. Special allowance must be made for this fact in the study of degradative changes in polyheteroarylenes.

The conversion of "saturated"† into polyconjugated polymers and then into graphite or amorphous carbon is accompanied by a decrease in the free energy of the system. Thus calculations show[12] that, in the thermal degradation of polyethylene and several other high polymers, graphitisation is considerably more advantageous thermodynamically than are other chemical changes. This leads to the following consequences.

1. The use of polyconjugated systems to obtain thermostable materials becomes increasingly advisable the closer such polymers approach graphite in structure and thermodynamic characteristics.

2. The widely held view that the primary structure of a polymer gives adequate criteria for judging its thermal stability cannot be regarded as correct. In fact, the energetic advantage of conversion to more extensive conjugation indicates that assessment of the thermochemical stability of a polymer should be based not so much on the specified (initial) structure of a polymer as on allowing for the chemical changes and the nature of the final products formed by the action of heat and of the environment.

For example, such polymers as cellulose, poly(vinyl alcohol), poly(vinyl acetate), polyacrylonitrile, etc. are able to form highly thermostable films and fibres as a result of degradative processes yielding polyconjugated systems, and at 2000°C forming graphite structures[3,13]. This applies also to the almost colourless polytetraphenylphenylene[14], in which the arrangement of phenylene units is non-coplanar owing to the large number of substituents. When a film of this polymer is heated, it splits off benzene, and becomes coloured, less soluble, and paramagnetic. It is not surprising, therefore, that the weight losses rapidly approach a limit on heating (400–500°C) and that the material withstands prolonged heating, especially in the absence of oxygen.

3. Since growth of the polyconjugated chain during the thermolysis of polyconjugated systems entails considerable contractions and is accompanied by degradative processes, it is reasonable to pay special attention to the synthesis of polyconjugated polymers of ladder and block–ladder structure[15,16], as well as polymer chains with regularly alternating branches, including polyconjugated fragments. The increasing interest taken in the synthesis and investigation of such structures thus becomes understandable[17].

Polyconjugated systems are characterised by the formation of stable association complexes by intermolecular donor–acceptor interaction. Such aggregates probably constitute a microphase, impair the solubility of the polyconjugated system, and raise the softening or flow point above those of saturated analogues[6].

It has been shown experimentally that polyconjugated polymers belong structurally to microheterogeneous systems, since association complexes (d = 10–50 nm) pack into larger spherical supermolecular structures (d = 1–5 μm) (Fig. 1).[6] Although the question of special intermolecular forces in polyconjugated polymers and their decisive importance in the physics and chemistry of the systems was considered as long ago as 1958,[2] due attention was not paid to it by research workers until recently, when the problem was again raised in connection with the study of the formation of polyconjugated chains[7] and the structure of organic semiconductors[18–20].

† "Saturated" polymers are those not containing π-bonds conjugated through large fragments or throughout the macromolecule.

In order to elucidate this matter a calorimetric determination was made of the conjugation energy, and the contribution to it of intermolecular π-electron interaction in individual and polymeric hydrocarbons—oligoarylvinylenes and polyarylenes—was calculated[6]. The difference between the total conjugation energy and that in the benzene rings was adopted as the criterion for assessing the intermolecular exchange interaction of π-electrons of polyconjugated chains; it was termed the "structure stabilisation energy" ΔH_π.

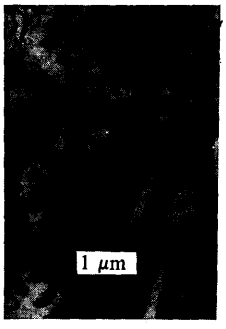


Figure 1. Electron micrograph of unshadowed platinum–carbon replica with amorphous benzene–naphthalene copolymer.

An additional contribution of 6.0–12.0 kcal mole^{-1}, appreciably exceeding known conjugation energies (2–4 kcal mole^{-1}) for buta-1,3-diene and its vinylogues, was found for individual polyene hydrocarbons containing terminal phenyl groups. It would have been wrong to attribute this difference to intramolecular delocalisation. It is more reasonable to suppose that the observed values are due mainly to intermolecular exchange interaction. On passing to polymers having a conjugated system the values of ΔH_π may exceed those found for the corresponding model systems, and may reach hundreds of kilocalories calculated for the average macromolecule. The above properties of polyconjugated systems indicate considerable intermolecular interaction and a tendency for their macromolecules to associate. The presence of strong intermolecular interactions in polyconjugated systems is largely responsible for their thermal stability, rigidity, and several other specific properties.

Existing data indicate the high radical reactivity of polyconjugated systems and its activation by paramagnetic centres present in them ("local activation effect")[6,21]. This is why self-inhibition is observed in the thermal (and at lower temperatures also in the thermo-oxidative) degradation of polyconjugated systems or "saturated" polymers capable of conversion into the former when heated[22,23]. Thus the polyconjugated polyphenylacetylene undergoes thermo-oxidative degradation considerably more slowly and to a considerably less extent than does its hydrogenated analogue, polystyrene (Fig. 2)[22,23]. With rise in temperature self-inhibition of the thermal degradation of polyconjugated systems is exhibited as far as extensive carbonisation of the polymer. The rate of the process is diminished by three-dimensional cross-linking of the polyconjugated system. The opposite results are observed with thermo-oxidative degradation: insoluble and infusible network polymers are less thermostable than their fusible and soluble analogues (Fig. 3).

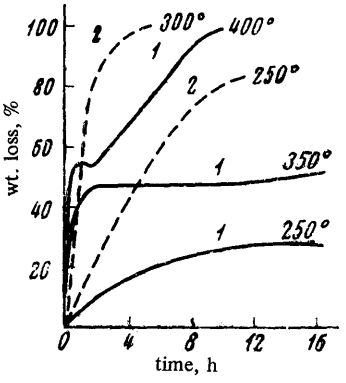

Figure 2. Thermo-oxidative degradation of: 1) polyphenylacetylene ($\overline{M}_n$ = 5000); 2) polystyrene (9000).

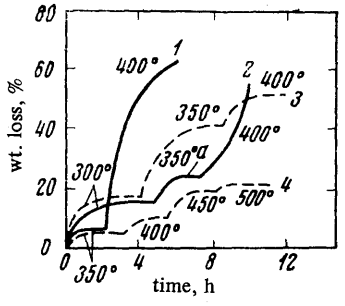

Figure 3. Weight-loss curves for: 1) three-dimensionally cross-linked insoluble block copolymer of poly-5-ethynyl-2-methylpyridine ($\overline{M}_n$ = 1700) with *p*-diethynylbenzene in air; 2) poly-5-ethynyl-2-methylpyridine (soluble fraction) in air (a = point corresponding to conversion into insoluble, infusible polymer); 3) as (2) in argon; 4) block copolymer in argon.

The probable explanation of such specific behaviour is that degradation of a polyconjugated system starts with the cleavage of weak bonds primarily in segments of disrupted conjugation. The resulting radicals can react to form a thermodynamically more stable polyconjugated structure. This process entails increased contractions and internal stresses which, at temperatures close to the carbonisation point, are able in turn to cause the local rupture of bonds. The macroradicals formed during degradation become stuck in the rigid polymer, with a greater loss of mobility the more rigid the polymer framework. The presence of radical centres having a relatively low ionisation potential catalyses the thermal oxidation. Oxygen may then be activated by the formation of charge-transfer complexes.

A different picture is observed in the thermal degradation of polyconjugated systems in the absence of oxygen, when the retained radicals probably act as traps binding active centres of the breakdown products responsible for the development of degradative processes. Convincing evidence of the creation of active centres during thermolysis is provided by our observation of reactivity in three-dimensionally cross-linked polymers (phenol–formaldehyde resites, polymers and copolymers of *p*-diethynylbenzene) thermolysed at 450–500°C. Such polymers exhibit semiconductor properties and are typical polyconjugated systems; they contain fused aromatic structures with paramagnetic centres at concentrations of $10^{19}-10^{20}$ spins g^{-1} and a narrow electron spin resonance signal (a singlet) of line width 3–4 Gauss [3,18]. Thermolysis products freshly prepared in a vacuum of $10^{-3}-10^{-5}$ mmHg possessed several specific properties: (i) their thermal oxidation passed at 300°C into combustion [24]; (ii) they were effective catalysts for the radical polymerisation of acrylates and several other electron-accepting monomers (Fig. 4) [25]; and (iii) keeping the thermolysates in oxygen, argon, or a vacuum, or the presence in the polymers of plasticisers capable of inactivating radicals (e.g. diphenylenemethanediols or phenolic alcohols in the case of phenol–formaldehyde oligomers), produces a decrease in the number of paramagnetic centres and sharp drops in the rate of oxidation of the thermolysates and in their catalytic activity towards radical polymerisation (Figs. 5 and 6).

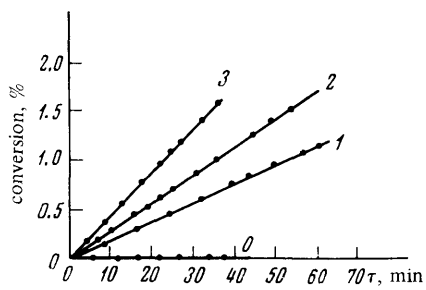

Figure 4. Variation of rate of polymerisation of methyl methacrylate catalysed by 2% of a dephenolated thermolysed phenol–formaldehyde resite with content of paramagnetic centres in the latter (spins g^{-1}): 0) no catalyst; 1) 2×10^{18}; 2) 1.7×10^{21}; 3) 5×10^{21}.

Similar regularities have been observed in the thermal and thermo-oxidative degradation of heterochain polyconjugated systems. An example is provided by results [3,26] obtained for polydiphenylamine, whose rate of degradation above 400°C is very low both in argon and in oxygen. Only on the initial portions of the rate curves are significant weight losses observed, as a consequence of the volatility of fractions of lower molecular weight and fragments of linear polymer molecules formed on degradation. The initial losses therefore increased as the molecular weight of the polymer fell from 2000 to 800. The process in argon slowed down as the polymer was "sewn up" and lost solubility during degradation (Fig. 7).

Degradation in oxygen exhibits more complicated kinetics. After formation of a three-dimensional structure and complete loss of solubility the process accelerates, owing to exothermic reactions involving oxygen and the contribution of the thermomechanical degradation of stressed structures. Polydiphenylamine remains completely soluble in polar solvents on the initial, non-stationary section, while its molecular weight increases to 6000–8000. After this, as the start of accelerated breakdown is approached, the solubility of the polymer diminishes rapidly.

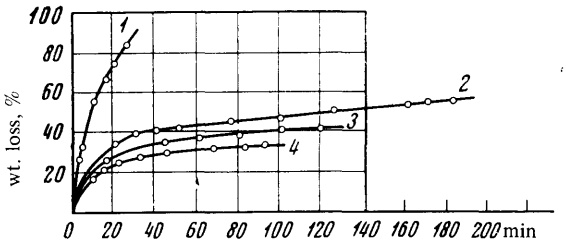

Figure 5. Thermo-oxidative degradation at 300°C and 1 atm of a thermolysed resite: 1) "freshly thermolysed" resite; 2) resite after 12 h in oxygen; 3) resite after 36 h in oxygen; 4) phenol containing the resite.

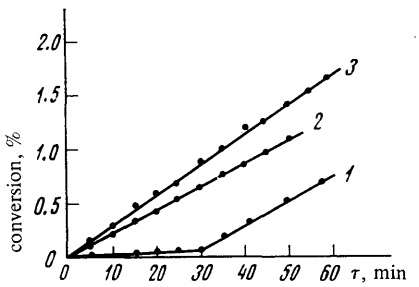

Figure 6. Catalytic activity, in the polymerisation of methyl methacrylate, of a thermolysed resite after exposure to air for (min): 1) 60; 2) 30; 3) 10.

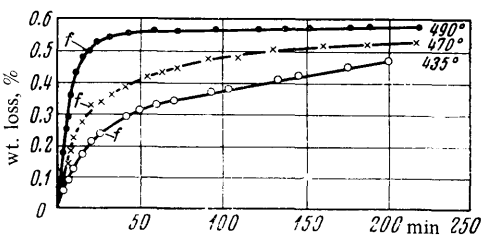

Figure 7. Weight losses in the thermal degradation of polydiphenylamine ($\overline{M}_n$ = 820) in argon.

Analysis showed that the main gaseous products of the degradation of polydiphenylamine in air were carbon and nitrogen dioxides. Degradation evidently begins with addition of an oxygen molecule at a double bond in the quinonimine structure and formation of a cyclic peroxide, which decomposes with the evolution of nitrogen dioxide.

Kinetic data indicate that the concentration of paramagnetic centres increases during the initial stages of degradation in air, then decreases, and again begins to rise almost simultaneously with the appreciable increase in rate of decomposition (Fig. 8). The variation in the concentration of paramagnetic centres in argon resembles the corresponding weight-loss curves [26].

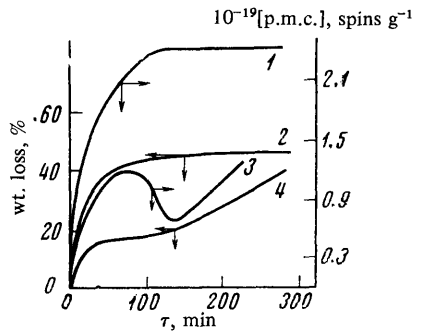

Figure 8. Variation in concentration of paramagnetic centres [p.m.c.] and weight losses in the thermolysis and thermal oxidation of polydiphenylamine: 1) [p.m.c.] in argon at 490°C; 2) loss in weight in argon at 490°C; 3) [p.m.c.] in air at 412°C (the polymer loses solubility and fusibility at the point of inflexion); 4) loss in weight in air at 412°C (as for curve *3*).

If a specimen is first heat-treated in argon until solubility is lost, and then placed in oxygen, the concentration of paramagnetic centres in the polymer falls rapidly, while its rate of decomposition increases autocatalytically. Preliminary thermal oxidation, on the other hand, improves the thermal stability of the polymer (Fig. 9).

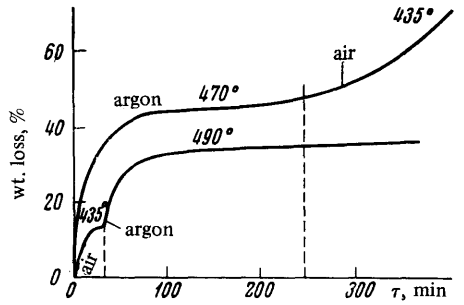

Figure 9. Rate of loss in weight when polydiphenylamine is heated in argon and in air.

This rule is probably explained by the increased concentration of active radicals trapped in the thermolysis of polydiphenylamine and their destruction ("burning out") in the preliminary thermal oxidation of the polymer. The broadening of the e.s.r. signal with the appearance of a fine structure indicates that the centres formed differ in nature from those in the original polymer associated with low-lying triplet levels. Condensation takes place more rapidly in oxygen, and the time for formation of a completely cross-linked structure is shortened. In the initial stages of formation of the network the paramagnetic centres are able to react with active radicals and be used up. As the structure becomes more rigid the rate of formation of new active radicals (by the rupture of stressed bonds) rises, and the concentration of paramagnetic centres reaches a limiting value.

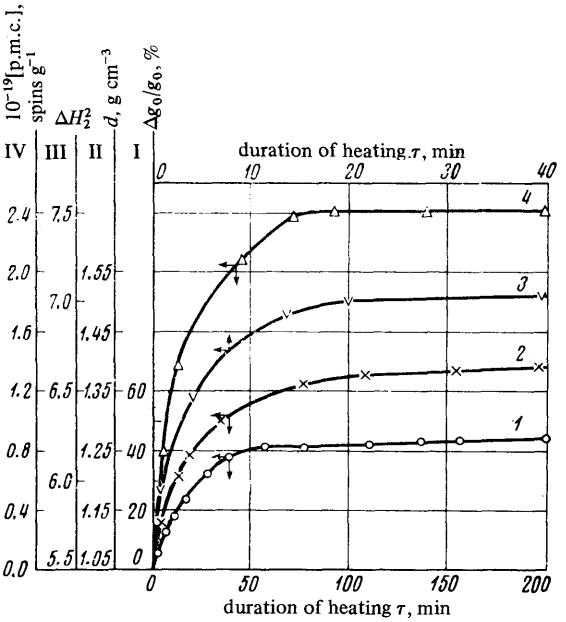

Figure 10. Rate of loss in weight and change in properties of thermolysate of polydiphenylamine ($\overline{M}_n$ = 2000) in argon at 470°C: 1) loss in weight; 2) density; 3) second magnetic moment of n.m.r. spectra; 4) concentration of paramagnetic centres from e.s.r. data.

The correctness of the above ideas can be confirmed by data indicating a correlation of the rate of thermal degradation of polydiphenylamine with the rate of increase in density, the increase in the concentration of paramagnetic centres, and the decrease in the molecular mobility of the polymer during its heat-treatment (Fig.10).

The limitation of the degradation curve of polydiphenylamine under isothermal conditions, which is general for polyconjugated systems [20,21], coincides with the completion (under the given conditions) of rearrangement of the polymer structure and formation of more thermostable fragments of fused aromatic rings. This process may be repeated with rise in temperature, which is responsible for the stepwise form of the weight-loss curves.

Thus the presence of oxygen should help to "burn-out" the most stressed portions with the formation of more

stable structures. Fig. 9 shows that preliminary treatment of polydiphenylamine in air at 435°C improves significantly its thermal stability in argon at 490°C, whereas heat-treatment of the polymer in argon diminishes its thermo-oxidative stability. In the latter case the structure formed on heat-treatment contains reaction centres, which in an oxygen atmosphere are able to react even during the formation of the network.

The whole of the above discussion indicates that the active centres produced in the thermolysis of cross-linked polymers act as initiators. Formation of the thermolysates probably involves relaxation processes leading to a decrease in the active surface area and partial destruction of paramagnetic centres. The presence in the polymer of substances of low molecular weight, capable of reacting with the radicals formed and exerting a plasticising action, enhances the probability of destruction of the radicals that have "stuck", and this improves the thermo-oxidative stability of the polyconjugated polymer [22-24].

Thus trivial considerations of the "cage" effect as a factor inhibiting a chain process cannot be used to describe the high-temperature degradation of rigid cross-linked and polyconjugated systems. The above results must be taken into account in developing methods for the synthesis and stabilisation of thermostable organic polymers.

III. SYNTHETIC PATHS TO THERMOSTABLE ORGANIC POLYMERS

When considering the formation of macromolecules of polyconjugated polymers, we must take into account the great tendency of these substances to form stable association complexes by intermolecular exchange interaction of unpaired electrons delocalised along the conjugated chain and π-electrons of multiple bonds [6]. In the absence of steric hindrance, therefore, chain growth in such macromolecules is accompanied by their aggregation and consequent impairment of the solubility of the resulting polymer. A direct consequence of this is diminished accessibility of reactive groups to the reagent and a change in their reactivity owing to resonance stabilisation caused by intra- and inter-molecular delocalisation of π-electrons [3,6]. The above specific features of the formation of polyconjugated macromolecules make it difficult to obtain polymers of high molecular weight and to process them into various goods and materials. This gives rise to difficulties in synthesising soluble or fusible conjugated oligomers and high polymers, capable of conversion into three-dimensionally cross-linked, parquet, and ladder polymers at the processing stage. These difficulties can be overcome by the use of reagents yielding polyconjugated macromolecules having side chains or groups that prevent dense packing of the chains. Methods based on the synthesis of polyconjugated systems containing polar and in particular ionogenic groups, responsible for specific solvation and solubility of the polymer in polar media, are also gaining importance.

Polyconjugated systems of high molecular weight (e.g. polyheteroarylenes) are often obtained also by a two-stage method involving the formation of soluble polymers, in which π-electron delocalisation is confined to small structural units, with subsequent conversion into polyconjugated systems by intramolecular reactions.

In view of the tendency of polyconjugated molecules to associate, which impedes or excludes their processing as solutions or melts, conversion of a high polymer into a polyconjugated system during synthesis may be advisable if the structure of the macromolecules of the resulting polyconjugated high polymer is unfavourable to their dense packing. Thus the problem of the controlled synthesis of highly thermostable organic polymers capable of being processed can be solved only if the specific structure and properties of polyconjugated polymers are taken into account. The considerable progress made in this field supports the principle that the study of polymers having a developed system of π-electron conjugation forms the scientific foundation for highly thermostable polymers.

The above specific aspects of the formation and structure of polyconjugated systems suggest the following main routes for the synthesis of oligomers and high polymers suitable for service at high temperatures and subject to radiation.

1. Synthesis of soluble and fusible oligomers with a polyconjugated system and the development of methods for their conversion into three-dimensional or planar network structures without significant disturbance of polyconjugation or the creation of molecular defects. Attainment of this aim requires the presence in the macromolecules of side-groups preventing dense packing but able under conditions of thermolysis (or radioysis) to bind macromolecules without any appreciable contribution of degradtive processes causing weight losses, increased contraction, and stresses.

2. Preparation of soluble compounds of high molecular weight with valency saturated chains and containing groups necessary for the formation of polyconjugated systems by intramolecular cyclisation and elimination, and in several cases structural units with π-electron conjugation. A polymer suitable for processing can be obtained at the synthesis stage only if the macromolecules contain either substituents that prevent dense packing or ionogenic groups.

3. Discovery of methods for synthesising block copolymers containing various polyconjugated fragments or connecting portions of "saturated" and of polyconjugated structure. Block copolymers containing organometallic blocks and fragments of π-electron (e.g. aromatic) polyconjugation may become especially important. In the last case not only plastics but also elastomers combining high thermal stability with strength may be obtained.

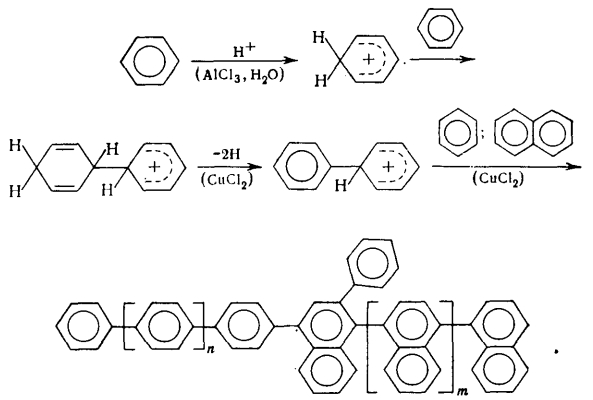
1. Polyconjugated Oligomers

Soluble oligomers suitable for the production of thermostable network polymers have been successfully synthesised in the cases of polyconjugated systems containing aromatic or heterocyclic rings joined either directly or through heteroatoms (polyheteroarylenes).

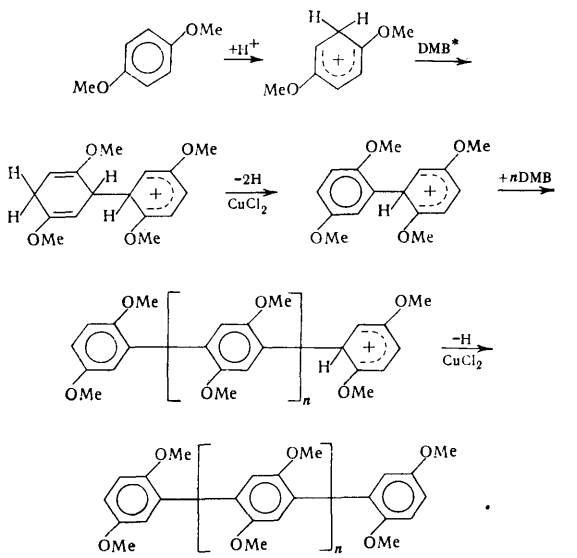
Among polyconjugated carbon-chain compounds, special interest attaches to branched oligoarylenes [27-29] and ladder oligomers of disubstituted buta-1,3-diyne [30-33]. Soluble and fusible (up to 250–400°C) oligoarylenes ($\overline{M}_n$ = 1000–3000) have been obtained by the cationic dehydrocopolycondensation of benzene with aromatic hydrocarbons in the presence of Lewis acids and dehydrogenating agents [copper(II) chloride, nitrobenzene, etc.].

The impossibility of synthesising high-molecular-weight polyarylenes in the melt and in solution is probably due to the above inactivation, characteristic of polyconjugated systems, of the reaction centre in donor–acceptor complexes formed by the growing polymer chains. Soluble and fusible polymers of naphthalene and anthracene, their

copolymers with benzene [27,28], and also polymers and copolymers of bi- and ter-phenyls [29], possess thermochemical stability in air up to 500 and in an inert gas up to 900°C. The probable mechanism of the oxidative polycondensation of aromatic hydrocarbons can be represented by a scheme analogous to that of Kovačic [34]:



Polycondensation in the presence of oxidants and Lewis acids has recently been extended to quinol and its derivatives, which has led to the synthesis of soluble oligoquinones and oligoalkoxyphenylenes having $\overline{M}_n$ = 1000 to 1500:



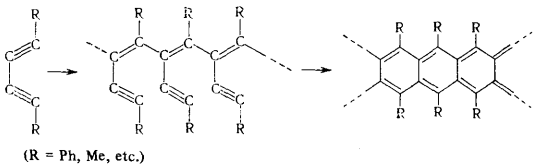
*p-dimethoxybenzene

Such polymers are stable in air up to 350°C, and are of considerable interest for the preparation of thermostable plastics and electron-exchange materials of high capacity (9–17 mg-equiv. g^{-1}). [35]

Various modifications of the Wurtz–Fittig, Ullmann, and several other reactions have been used to prepare soluble polyarylenes from aromatic monomers containing phenyl, methyl, and nitro-substituents [3,14].

A promising route to oligoarylenes suitable for processing is the high-temperature (340–450°C) dehydropolycondensation of acenes and their derivatives in the presence of conjugated paramagnetic polymers, which serve as activators. The soluble oligoanthracene obtained in this way is superior in thermal stability to the analogue synthesised by the use of Lewis acids [36,37].

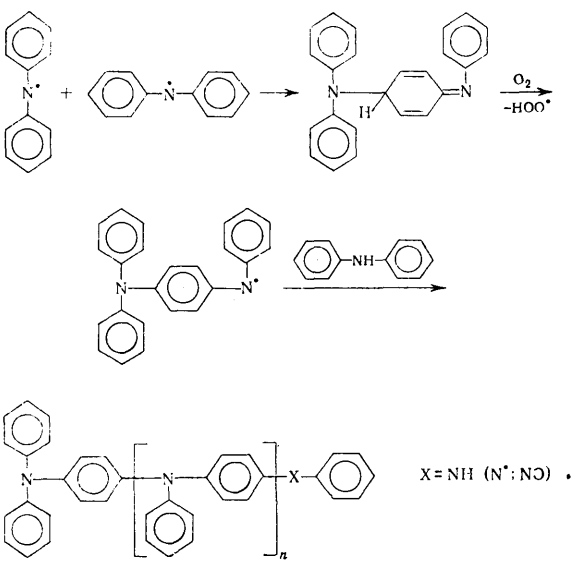
The synthesis of soluble polyconjuated oligomers having a ladder structure is of considerable interest. Such substances have been obtained by the thermal (195–400°C) and the catalytic [with $(C_4H_9)_3Al$ + $TiCl_3$ at 50–70°C] polymerisation of 1,4-diphenyl- and 1,4-dimethyl-buta-1,3-diynes [30–32]:



(R = Ph, Me, etc.)

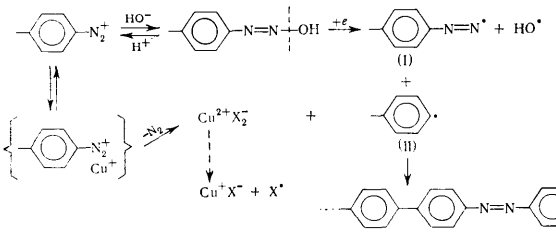
A ladder oligodiphenylbutadiyne having $\overline{M}_n$ = 3000–5000 dissolves readily in aromatic hydrocarbons, chloroform, dioxan, etc. Treatment of films of cyclised oligodiphenylbutadiyne at 1000–3000°C was accompanied by relatively small (15–35%) weight losses and yielded carbon having a graphitic structure. The electrical conductivity of the products at 300°C was 1.7–15 ohm^{-1} cm^{-1}, and the activation energy of conduction 0.04–0.06 eV. Products of the high-temperature treatment of oligodiphenylbutadiyne did not lose weight when heated in air to 700°C.

The oxidative polycondensation of secondary aromatic amines opens up interesting potentialities for the directed synthesis of polyconjugated systems [38–40]. It has been established experimentally that the oxidation of amines by oxygen in the melt at 200–250°C yields soluble, fusible oligomers of $\overline{M}_n$ = 1500–3000, possessing high thermochemical stability (temperature of progressive decomposition 450–500°C) and able to inhibit the thermo-oxidative and radiation degradation of carbocyclic and heterocyclic polymers. Available data suggest that polyarylenepolyamines are formed by the scheme

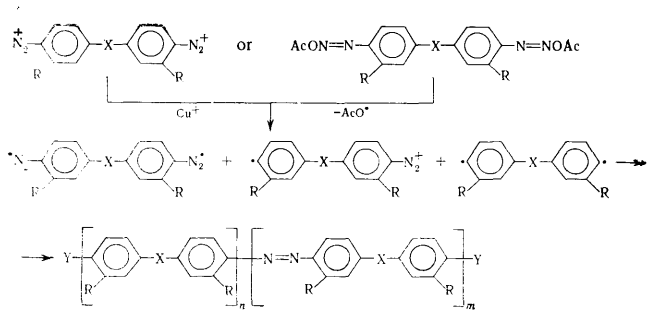


The polydeazotisation of aromatic bisdiazonium salts and bisnitrosoacylamines [41,42] shows great promise for the synthesis of soluble and fusible polyconjugated oligomers. This reaction is an example of non-equilibrium polycondensation by a radical mechanism. The deamination of

aromatic bisdiazonium salts in the presence of reductants probably has the mechanism [42,43]



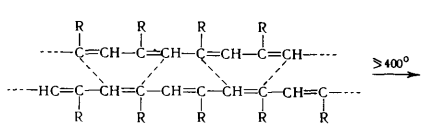
Interaction of radical centres of the growing chain with chloride ions in the redox reaction complex leads to chain termination. This liberates an electron, which is captured by the oxidised copper cation. Chain growth can cease only by conversion of the end of the growing polymer molecule into an inactive, stable radical having a considerable proportion of quinonoid structure. The content of combined nitrogen in the resulting oligomers varies with their structure from 1–2% to 7–8%. Bisdiazonium salts or bisnitrosoacylamines containing loosening phenyl, alkyl, or ionogenic groups in the aromatic ring must be used to obtain soluble oligoazoarylenes of $\bar{M}_n$ = 4000–8000:

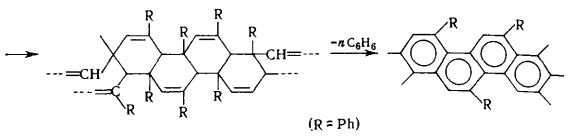


where X represents O, S, CH_2, or a single bond and R = H, Alk, Ar, COOH, OH, SO_3H, NO_2, or NHCOR.

Oligoazoarylenes are similar to oligophenylenes or the corresponding oligoarylenes in thermochemical stability [41,49]. Surprisingly, the elementary composition of oligoazoarylenes varies little when they are heated to 500–700°C, and azo-groups conjugated with benzene rings are preserved in the oligomer up to 700–1000°C. Polydeazotisation can be used to obtain oligoheteroarylenes containing metallocene groups [44]. Such polymers possess high thermochemical stability in an inert atmosphere (up to 700–800°C), but in the presence of oxygen they are degraded at 350°C.

The possibility of improving the thermal stability while maintaining solubility by appropriate heat-treatment of polyconjugated oligomers containing loosening fragments is based on controlling the fragments of a fused aromatic containing loosening groups [23,32,45]. Thus heating polyphenyl(phenoxy or pyridyl)acetylenes at 350–400°C for a short time ($1\frac{1}{2}$–2 h) converts them into soluble, dark-coloured oligomers containing fused aromatic structures [22,32]. This involves degradation with partial elimination of side radicals: e.g. in the thermolysis of polyphenylacetylene





the loss in weight at 400°C is 50% (H_2, C_6H_6, and $C_{12}H_{10}$ are eliminated), and the resulting black polymer retains solubility and possesses higher thermal stability (Fig. 11), electrical conductivity [2,45], and concentration of paramagnetic centres (the last by 10^3) than the initial polymer.

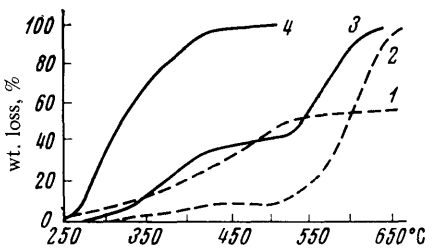


Figure 11. Thermal and thermo-oxidative degradation of soluble polyphenylacetylenes prepared in: 1) vacuum at 400°C; 2) presence of oxygen at 400°C; 3) presence of oxygen at 150°C; 4) vacuum at 150°C. At point *a* the polymer loses its fusibility and solubility [cf. Figs. 3 and 8].

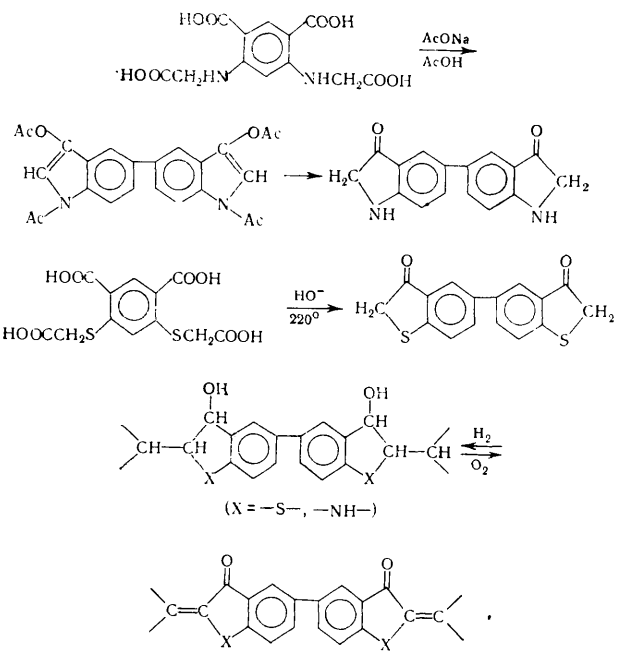
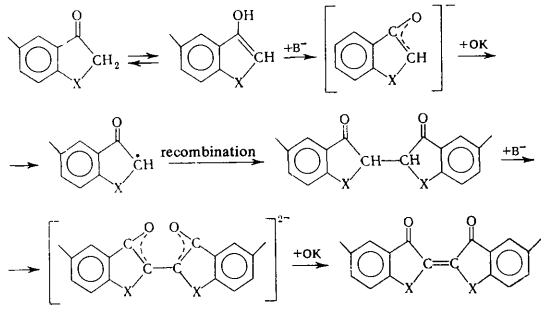
The recently developed principle of the reversible conversion of insoluble into soluble polymers by redox reactions in polyconjugated oligomers and polymers [46,47] is also acquiring great importance. This method is analogous to vat dyeing, and the first "vat polymers" have been polyindigoids. Polyindigo and polythioindigo have been synthesised by oxidative polycondensation [42,46,47]



Electron spin resonance spectra obtained during the process and investigation of the products formed by termination of the growing chains on a stable radical (1,1-diphenyl-2-picrylhydrazyl) suggest the mechanism



B = base; OK = oxidant (O_2; etc.)

for the oxidative polymerisation of indoxyl and its analogues [42].

Polyindigo and polythioindigo are oligomeric polyconjugated systems of $\overline{M}_n = 4000$ possessing the magnetic and semiconducting properties usual for substances of this type. Polymeric indigoids (especially polythioindigo) also exhibit high thermal stability (up to 400–500°C) and are easily reduced by dithionite to the leuco-form, which is soluble in alkaline aqueous solution. Oxidation of the leuco-form in air yields polyindigo again. These transitions are reversible [42]. Vat dyeing with polymeric indigoids improves the thermal stability and the strength of several synthetic fibres (Fig. 12). Polyindigoids are promising also for obtaining heat-resistant coatings and as resins possessing electron-exchange and catalytic properties.

In connection with the above it is becoming urgently necessary to seek new synthetic routes to soluble oligomeric homo- and hetero-arylenes, e.g. oligoarylenazomethines [45,48], oligoarylenacetylenes [50,51], and several other polyconjugated oligomers.

2. Conversion of Polyconjugated Oligomers into Network Polymers

The transition from polyconjugated oligomers to polymeric materials and articles requires the development of rational methods permitting the conversion, at the processing stage, of fusible compositions into thermostable products possessing a specified set of physicomechanical properties. We shall now consider processes that have been suggested for "hardening" polyconjugated systems.

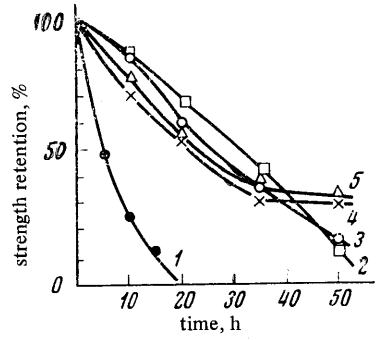


Figure 12. Strength of fibre based on a bicyclic lactam and caprolactam in air at 200°C after stabilisation with: 1) control; 2) thioindigo; 3) indigo; 4) polythioindigo; 5) polyindigo.

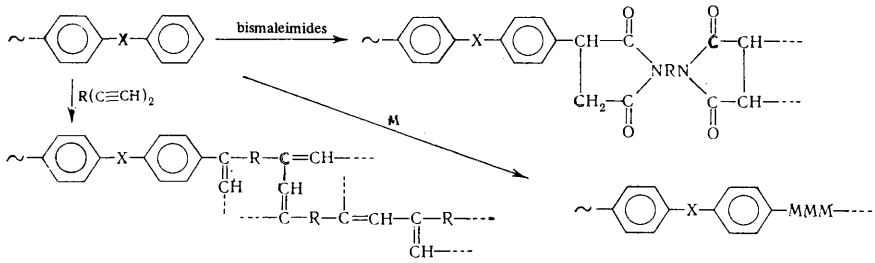
(*a*) Interaction of polyconjugated oligomers with compounds containing multiple bonds

Polyarylphenylenes, polyarylenes, and polyheteroarylenes containing paramagnetic centres have been shown in a series of studies [52–56] to be capable of spontaneous three-dimensional block copolymerisation at 150–200°C with *p*-diethynylbenzene and with bismaleimides of aromatic diamines or their analogues ("quasi-radical block polymerisation"). The polyconjugated oligomers containing paramagnetic centres initiate polymerisation of the electron-accepting monomers [25,54,56,57]:



X = $-C_6H_4-$, $-N{=}N-$, $>CO$, $>SO_2$, etc.; R = arylene; M = monomer

The discovery of this reaction, specific to polyconjugated systems, permitted the synthesis of thermostable soluble and three-dimensionally cross-linked block copolymers. The systems of compatible polyconjugated polymer and monomer (in several cases the latter was the solvent) were so chosen that compositions based on them possessed fluidity at the high temperature required to form the article. It is especially noteworthy that the "hardening" of a composition by quasi-radical block copolymerisation does not require the use of special

catalysts and is not accompanied by separation of products of low molecular weight, which might complicate the processing technology and impair the properties of the material.

The mechanism of quasi-radical block copolymerisation has been investigated on the systems formed by polyphenylacetylene with maleic anhydride and with methyl metacrylate[56-58]. Nuclear magnetic resonance shows that the first step is formation of a charge-transfer complex between the polyconjugated oligomer and the monomer:

$$P\uparrow\!---\!\downarrow P \overset{K_e}{\rightleftarrows} P\uparrow + M \overset{K_1}{\rightleftarrows} [P\uparrow\!---M]$$
(donor-acceptor complex)

where P↑---↓P represents associated polyphenylene macromolecules containing paramagnetic centres (the symbol ↑ denotes the presence of unpaired electrons), M a monomer molecule, and P the polyconjugated polymer. The complex [P↑---M] can be formed only if polyconjugated system and monomer are densely "packed" and if the electrophilic character of the latter is enhanced. Under otherwise similar conditions, therefore, the π-complex formation that limits polymerisation will depend on the structure and the configuration of the polyconjugated system and the monomer. The reaction is most probably initiated by thermal excitation of the reactants to a biradical state, followed by isomerisation to monoradicals, which carry on the chain polymerisation in contact with the surface of particles of the polyconjugated system. Formation of a block copolymer is evidently a consequence of termination or transfer of the growing chain. Such a mechanism can be represented to a first approximation by the scheme

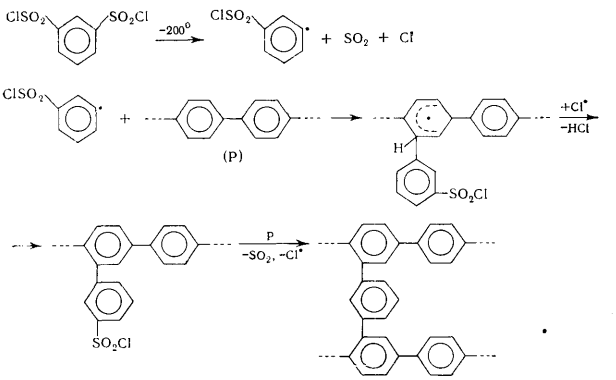
$$[P\uparrow\!---M] \overset{+M(k_i)}{\rightleftarrows} [P\uparrow\!---M\!---M] \xrightarrow{E(k_t)} [P\uparrow\!---M_1\!---M_2]$$
$$[P\uparrow\!---M_1] \xrightarrow{+M(k_p)} [P\uparrow\!---M_1MMM^{\cdot}] \xrightarrow{+M_nMMM^{\cdot}(k_t)} P\uparrow + [M]_n$$
$$P\uparrow + MMMM \overset{k't}{\rightarrow} P\uparrow - MMMM \ .$$

According to this scheme, raising the temperature and conducting the reaction in a homogeneous melt or solution should increase the yield of the block copolymer. When an insoluble polymeric polyconjugated system is used as catalyst, e.g. the pyrolysate of a phenol–formaldehyde resite[25,59], and the process is carried out at a moderate temperature ($\leq 100°C$), a stereoregular homopolymer is formed. It follows also from the scheme that the reaction velocity should be proportional to the concentration of the polyconjugated system raised to a degree $n < 1$ and to that of the monomer raised to a degree $n > 1$. All these suggestions showed good agreement with experiment[29].

The use of soluble and fusible compositions of polyarylenes with various cross-linking agents as binders for plastics reinforced with carbon or asbestos fibres will yield thermostable materials suitable for prolonged service at 300–350°C.[20] Such polymer systems are promising also for the production of thermostable coatings and adhesives.

(*b*) Formation of networks in polyconjugated oligomers by radical substitution

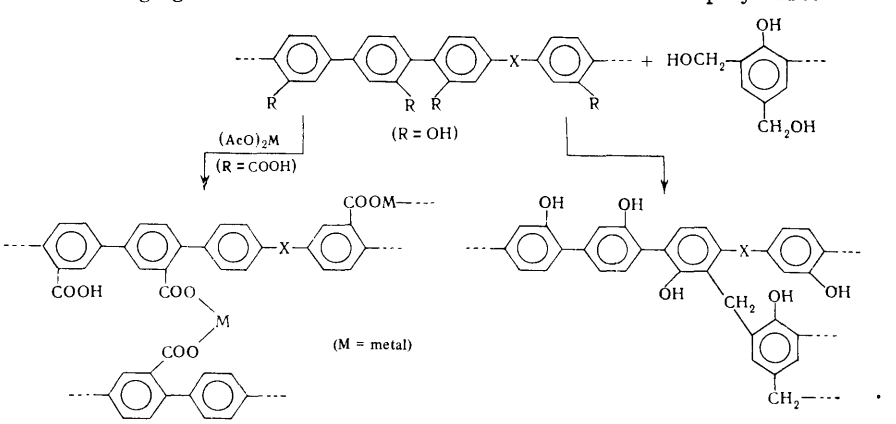
This method is based on the interaction of polyconjugated systems with aryl radicals formed by the high-temperature (150–200°C) degradation of aromatic disulphonyl dichlorides and certain other compounds:



Among the many possible cross-linking agents benzene-*m*- and *p*-disulphonyl dichlorides have acquired practical importance[60]. This reaction has recently been proposed for the synthesis of oligophenylene ($\overline{M}_n = 1775$), which can then be cross-linked or processed[61]. The reaction is accompanied by chlorination and the separation of by-products, which in several cases makes processing difficult and the method less promising than quasi-radical block copolymerisation. Nevertheless, high-strength asbestos and carbon plastics have been obtained by the use of benzenedisulphonyl dichlorides with additional heat-treatment[60,61].

(*c*) Conversion of polyconjugated oligomers into three-dimensionally cross-linked polymers by reactions of functional groups

Polyphenylenes and polyazophenylenes containing hydroxyl or carboxyl react with hydroxymethyl derivatives of phenols, phenol–formaldehyde resols, epoxide oligomers, metal salts, etc. to form infusible thermostable "cross-linked" polymers:



This method of "hardening" polyconjugated polymer systems has certain advantages over radical substitution (e.g. absence of chemically aggressive reaction products), but requires the presence of functional groups in the polyconjugated macromolecules. Known methods for the synthesis of carbon-chain oligomers depend on the use of aromatic or hydroaromatic hydrocarbons as starting material. Their conversion into polymers capable of being "hardened" by interaction with the above condensing agents requires the introduction of hydroxy-,[61] carboxy-,[2] or amino-groups into the aromatic rings.

In this connection considerable interest attaches to the polydeazotisation of aromatic bisdiazonium salts described earlier, which enables us to pass directly to oligoarylenes and oligoheteroarylenes containing almost any functional groups in the polyconjugated macromolecules, and to convert them into various types of network polymers[2,42].

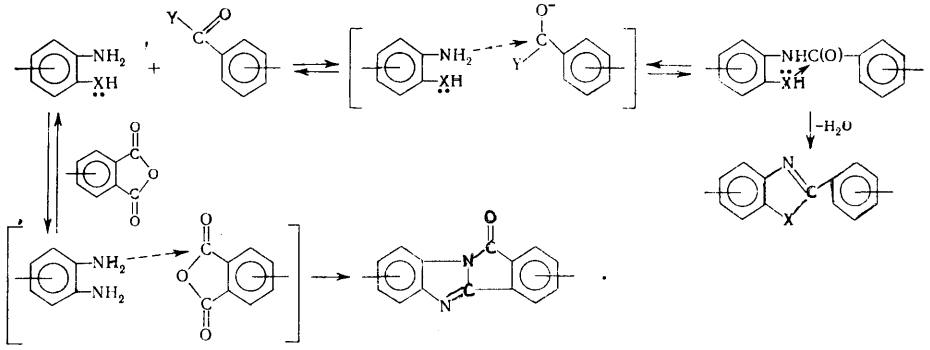
3. Synthesis of Polyconjugated Polymers of High Molecular Weight

The chemistry of polyconjugated polymers indicates that polyconjugated systems of high molecular weight can be produced only when difficulties in the growth of chains of continuous polyconjugation have been overcome. This can be achieved when there is maximum exclusion of π-electron delocalisation through large fragments of the macromolecules at the stage of chain growth, since only then are the possibilities of intermolecular aggregation and inactivation of the reaction centre diminished (see earlier). When the aim is to obtain a soluble high-molecular polyconjugated substance, it is also necessary to design the macromolecules to contain loosening groups or variegated fragments preventing dense packing of the chains.

These problems are solved most simple for "saturated" high polymers, capable of passing into polyconjugated systems by intramolecular detachment[2,18]. Examples of such processes are the thermo-oxidative dehydration of polysaccharides, dehydrocyclisation of polyacrylonitrile, dehydrochlorination of poly(vinyl chloride), and dehydration of poly(vinyl alcohol).

Considerably later (from 1960) an analogous method was applied to polycondensations yielding polypyromellitimide and several other polyheterocycloarylenes[63], and from 1966 to the synthesis of phenylated polyphenylenes[27,29]. Chain growth in the synthesis of polyheterocycloarylenes leads to the formation of compounds (e.g. polycarboxyamides, poly-*OO*-carboxyaminoamides) in which π-electron conjugation is confined to aromatic rings and groups attached directly to them. Polycondensation under mild conditions in a strongly polar medium at 20 to 70°C therefore yields initially chains of high molecular weight, which are then converted into polyconjugated high polymers by intramolecular cyclisation and detachment. Such conversion can be effected during synthesis or during subsequent processing of the prepolymer into articles.

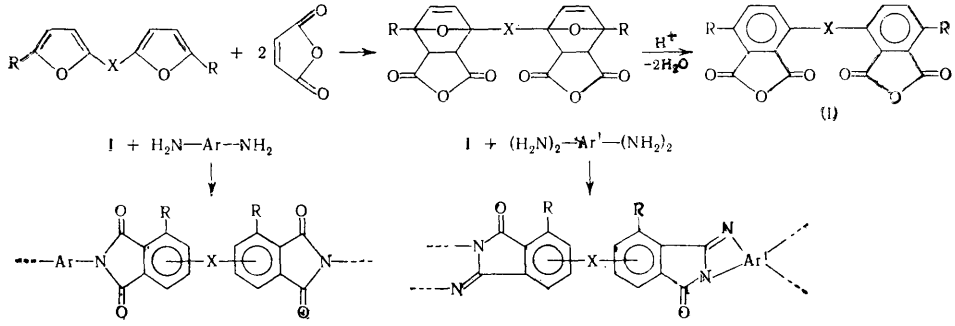
Loosening groups, e.g. phenyl, must be introduced into the chain in order to obtain soluble, almost completely cyclised polyheterocycloarylenes. Aromatic polyimides, polybenzimidazoles, polybenzoxazoles, polyimidazopyrrolones, polybenzimidazobenzophenanthrolines, polyquinoxalines, and many other polyheteroarylenes have been synthesised in this way[17,63]. The generality of the principle underlying the synthesis of high polymers having conjugated aromatic and heterocyclic ring systems is illustrated by the scheme



(X = NH, O, S, CONH, COO; Y = Cl, OR, CHO)

A promising line of advance in the field of polyheterocyclic polyconjugated systems is the synthesis of soluble polyimidazopyrrolones, polybenzimidazobenzophenanthrolines (pyrrones), and polyquinoxalines of semi-ladder, ladder, and block–ladder structure[1,17]. Solutions of pyrrones have been used to obtain strong and highly thermostable fibres, films, and foam plastics which are stable in an inert atmosphere up to 800°C and whose physicomechanical properties remain unchanged on irradiation with a dose of 10^4 Mrad.[16,17]

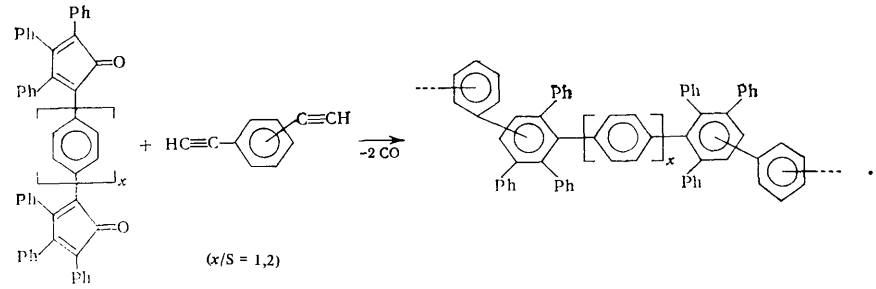
A recent advance of interest in developing the chemistry of polyheteroarylenes is the synthesis of polyimides and polyimidazopyrrolones from aromatised diadducts of maleic anhydride and various bisdienophilic compounds, e.g.[64]



(R = H, Ar; X = —CH=NArN=CH—; —Ar— —CH_2OOCArCOOCH_2—)

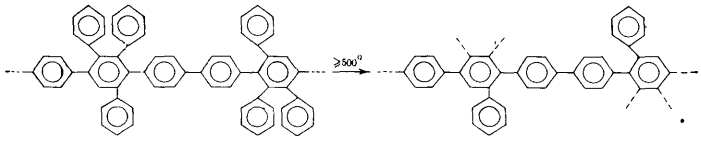
Investigation of the cyclopolycondensation of dianhydrides of tetracarboxylic acids with di- and tetra-amines has shown[64,65] that the most complete cyclisation is attained when the process is conducted as a single stage in polyphosphoric acid at 200–250°C. In the intramolecular cyclisation of the initially formed polyamino-acids and especially polyaminoamides the relative immobility of structural units in the chain evidently impedes the contact of reactant groups, which limits development of the conjugated chain and increases the proportion of weak bonds in the polymer. On the other hand, two-stage cyclopolycondensation is in practice unsuitable for obtaining thick articles, for cementing monolithic materials, or for producing reinforced plastics, since cyclisation occurs at a relatively high temperature and is accompanied by the evolution of volatile products. It is therefore very urgent to solve the problem of obtaining heterocyclochain polyconjugated systems that are soluble but yet of sufficiently high molecular weight. Polymers containing fragments that destroy the symmetry of the structure and diminish the density of packing of the macromolecules satisfy these conditions[6,63]. Interesting possibilities are opened up by the use of "reactant plasticisers" to facilitate the flow of pyrrones and their cross-linking during injection moulding and extrusion[66] and by the use of oligomeric analogues for the processing of pyrrones.

Aromatic carbocyclic–chain polyconjugated systems of high molecular weight have recently been acquiring increasing importance, as have the heterocyclic–chain type. Thus the polyaddition of diacetylenic aromatic hydrocarbons (e.g. *p*-diethynylbenzene) to bistetraphenylcyclopentadienones (tetracyclones) in toluene at 180–250°C gives a quantitative yield of a benzene-soluble, amorphous, weakly coloured polyphenylpolyphenylene[14]:



(x/S = 1,2)

The molecular weight of the phenylated polyphenylene is 20 000–100 000. In nitrogen at 575°C the polymer loses 30–35% of its weight, and passes into an insoluble brown product which in an inert environment is stable up to 800°C. This involves dephenylation and cross-linking[14]:



Paramagnetic centres appear in the polymer during heat-treatment and dephenylation, and its electrical conductivity increases.

The observed regularities are easily explained by the non-coplanarity of the aromatic rings in the polyphenylpolyphenylenes, which prevents conjugation from extending to more than two benzene rings. Favourable conditions are thereby created for the formation of a polymer of high molecular weight, which itself should not be regarded as thermostable. On thermolysis, however, the detachment of bulky groups changes the conformation of the chain with the appearance of a more coplanar polyconjugated polyphenylene; this is responsible for the thermal stability and other properties of the final material. Thus the example of phenylated polyphenylene bears an analogy to very many facts known for various polyheteroarylenes and heterocyclic–chain polymers.

Together with the data surveyed earlier, all this suggests that polyconjugation plays a decisive part in the formation of thermostable polymers and their subsequent transformations when subjected to powerful influences.

IV. ROLE OF POLYCONJUGATION IN THE THERMAL STABILITY OF POLYMERIC MATERIALS

We have come a long way and attained very considerable results during the fifteen years since the first publication establishing the concept of polyconjugation and its application to the synthesis of thermostable and semiconducting polymers [2]. The number of investigations inclined to accept these ideas and using them to develop rational methods for obtaining polymeric materials possessing high strength and thermal stability is now increasing [48,67,68].

However, several workers [69,70] approach the problem of the thermal stability of polymeric substances without taking into account intra- and inter-molecular π-electron delocalisation, i.e. in disregard of the main concepts of the chemistry and physics of polyconjugated systems. These investigators consider the difference in chemical nature between rings and other groups in the units, the configuration of the chains, and intermolecular interaction in the initial polymers. They completely ignore the role of π-electron delocalisation (conjugation) through fragments or through the chain of the macromolecules and its contribution to the intermolecular interaction and supermolecular structuring of polymeric substances. Further, they disregard the fact that the thermal stability of a material is determined in many cases not so much by the nature of the initial polymer as by the structure of the polymeric product formed by the action of thermal and other powerful factors. Yet, as shown above, it is electron delocalisation in the chains of the initial polymer and its thermal conversion products which determines the internal energy and the stability of the material under severe processing and service conditions.

It must be especially borne in mind that complicated chemical and structural changes take place in an organic polymer at high temperatures. These are responsible for (i) the growth of fragments of fused aromatic or heteroaromatic rings, with a consequent decrease in the internal energy and increase in the thermal stability of the system, and (ii) the associated increase in rigidity of the macromolecular chains and formation of three-dimensionally cross-linked polyconjugated structures. The latter processes (ii) are accompanied by increases in contraction and internal stresses, and they activate local thermal cracking of the most stressed bonds. Thus the chemical and structural changes observed in a polymer subjected to high temperatures are a prerequisite for the formation of reactive σ-radicals, as in mechanical degradation of macromolecular substances [71].

Further cross-linking with the accumulation of σ-radicals is probably the main reason for the poor stability of many cyclochain polymers under oxidising conditions at high temperatures. Thermal oxidation in such systems is initiated by reactions of σ-radicals, formed and "frozen" in the network, with oxygen at the surface of the specimen. The heat thus evolved activates neighbouring bonds and groups with the subsequent development of degradative processes. Owing to the restricted molecular mobility of the network, moreover, part of the heat evolved on interaction between oxygen and the radical cannot be dissipated in thermal lattice vibrations, and may be emitted as chemiluminescence [72], which also activates the development of thermal oxidation, as has recently been shown for the chemiluminescent initiation of polymerisation [73].

It is also possible that "hot" radicals [74] play a definite part in this process. The evolution of heat and the autocatalytic character of the high-temperature oxidation of rigid network polymers (polyconjugated systems) may be responsible for the observed thermal ignition of thermolysed resites [24]. This suggestion is supported by the above correlation of the increase in density and decrease in molecular mobility of the cross-linked thermolysate with increases in the degree of conversion and in the rate of thermal oxidation, and also by the catalysis of radical polymerisation by resite specimens that have been thermolysed at 450°C. The hypothesis is supported also by the loss of ignitability and catalytic activity which we have observed [24] after blocking of the active centres of these substances.

The views and experimental facts considered in this Review indicate that organic polymers with high resistance to thermal oxidation cannot be synthesised on the basis of rigid-chain, ladder, parquet, or network structures not containing fragments that increase the thermal mobility of the molecular framework. A directly opposite point of view is often adopted on this matter.

The concept of polyconjugation and the ideas underlying the chemistry and physics of polyconjugated systems are applicable also to aromatic carbon-chain and heterochain polymers. Such substances as phenol–formaldehyde resites, aromatic polyamides, polyimides, etc. are usually regarded as saturated polymers comprising aromatic rings separated by the particular groups. Such polymers surpass acyclic analogues in strength and thermal stability, and in several cases (polypyromellitimides) are closely similar to polyphenylenes and polycycloheteroarylenes containing large fragments of continuous conjugation. Hence it is deduced that the thermal stability of organic polymers is due to the presence of stable rings and the consequent rigidity of the macromolecular chains [14,69,70]. Such ideas hardly touch the essence of the phenomenon, although they reflect certain of its consequences.

Table 2. Polyconjugation in aromatic polyamides [75].

No.	Molecular structure	η_{sp}	Long-wavelength absorption λ_{max}, nm	10^{-15} [p.m.c.], spins g^{-1}
1	Benzanilide	—	276	**

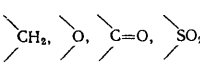
12*		1.27	330	24.6

*Specimens 11 and 12 were obtained by precipitating polymer 7 from dilute solution in sulphuric acid (with water and ethylene glycol respectively). This considerably diminished the crystallinity of the polymer.
**Not detected.

Recent quantum-chemical and spectral investigations have shown that aromatic polyamides, polyimides, and other types of polyheteroarylenes are polyconjugated polymers [75]. The presence of the bridging groups



does not exclude π-electron delocalisation through extended fragments of the macromolecule[75]. Such polymers showed high π-electron exchange interactions along the chain, bathochromic shifts in the ultraviolet absorption spectra with increase in length of the macromolecule, and also the narrow e.s.r. singlet, with the g-factor of a free electron and becoming more intense with increase in molecular weight, that is characteristic of polyconjugated systems (Tables 2 and 3). The same work has established that the presence of *meta*-substituted aromatic units (e.g. in polyisophthalamides), like the presence of electron-accepting bridging groups in the amine component, diminishes the polyconjugation effect by changing the electron configuration of the molecules. All this is consistent with existing views on polyconjugation and on the properties of polyconjugated polymer systems[18,41,76].

It is interesting that the thermal stability and several physical properties of aromatic polyamides and polyimides correlate with their effective conjugation, to which attention has been directed repeatedly[17,18,22]. The effect of polyconjugation may not be apparent in the initial state of polymers containing disconnected aromatic or heteroaromatic rings systems, as in several saturated acyclic polymers capable of eliminating groups when sufficiently stressed. Under various powerful influences, however, such systems are converted into polyconjugated systems with more or less substantial structuring and contraction, depending on the nature and structure of the polymers and the conditions of treatment.

We have thus directed attention to the role of polyconjugation—electron delocalisation through extended fragments of macromolecules and their association complexes—which in the Reviewer's opinion determines the thermal stability and other properties of polymers. This does not mean, of course, that the Reviewer denies the connection discussed in the literature between the structure of a unit, the presence of so called "weak bonds", and thermal stability, or the effect of chain rigidity on the resistance to degradation and the strength of polymers. However, none of this represents a foundation on which specific aspects of the degradation of highly thermostable polymers could be understood, and methods developed for their planned synthesis.

Progress in the Search for Chemical Protective Agents against Radiation

V.G.Yashunskii

Information published during 1968–1973 on the search for protective agents, capable of preventing or diminishing the harmful action of ionising radiation, is discussed and analysed. Only synthetic monomers belonging to various classes of organic compounds are considered: the search for protective compositions is not discussed. The bibliography comprises 168 items.

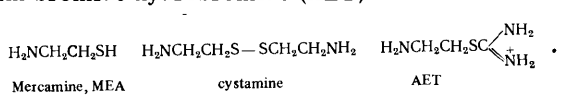
I. INTRODUCTION

A quarter of a century has elapsed since the first demonstration that chemical protection of animals from ionising radiation was possible[1,2]. During this period an immense amount of work has been done on synthesising and studying the prophylactic radiation-protective action of several thousands of synthetic and natural substances of diverse structure. Among them have been discovered extremely effective protective agents, capable under experimental conditions of preventing the death of a considerable proportion of animals subjected to X-rays and γ-rays. It can be concluded from the results that the living organism can in principle be protected by means of chemotherapeutic agents from ionising radiation, but considerable difficulties arise in applying such protection to man, since there is no proof that the doses of these agents that he can tolerate are able to protect him from the action of radiation. The whole 25-years' period of development can be arbitrarily divided into three stages.

The initial stage, from 1949 to the mid-1950s, saw the discovery of protection by chemicals and the start of the search for such agents among various classes of chemical compounds. The second stage, from the mid-1950s to 1968, extended the search for substances which would diminish radiation damage in animals, with a deeper study of compounds showing the greatest protective effect in experiments and attempts to bring the most effective of them to clinical application. An achievement of this stage was the production of such protective preparations as 2-aminoethanethiol (mercamine, MEA), the corresponding disulphide (cystamine), and *S*-2-aminoethylthiouronium bromide hydrobromide (AET)



However, the considerable toxicity and the narrow therapeutic spectrum of these products made it urgently necessary to find more efficient protective agents. By the end of the 1960s, after many different chemical compounds had been studied (~ 3000 by 1965), the impression was created that chemical protection from radiation was of only theoretical importance, and preparations better than the above three could not be obtained. It was even suggested that the whole idea of protection from ionising radiation by means of chemical substances was unpromising.

In this connection one of the pioneers of chemical protection (Bacq) wrote: "... a tendency has become evident to overlook the possibility that new protective chemicals might appear and to focus attention on studying the most active of known agents. However, it is not impossible that more active and far less toxic chemical protective agents will be discovered in the near future".[3] These words of Bacq's have proved to be prophetic: indeed, publication started to appear in 1968 which marked the beginning of the current stage in the development of chemical protection of the living organism from ionising radiation. This stage has seen considerable advances in the production of protective agents and, most importantly, the establishment of confidence in the reality of the practical application of chemical prophylactic radiation-protective agents. The number of substances that have been synthesised and studied as potential protectors has been rapidly increased by slight variations on the optimum chemical structures discovered previously. The main aim has been to find agents of great therapeutic spectrum; the results up to 1971 have been covered in brief reviews[4,5].

The present Review studies and analyses results, published from 1968 to 1973 inclusive, of the search for monomeric synthetic prophylactic protective agents. The greatest attention has been paid during this period, as in previous years, to the search among compounds based on the 2-aminoethanethiol structure. Interesting results have been obtained also for other sulphur-containing compounds and heterocycles.

Before the main subject of the Review is discussed, brief consideration must be given to the quantitative assessment of the efficiency of radiation-protective agents, a problem which has been faced repeatedly[3,6]. American authors[7] have suggested a "protective index"

$$I = \frac{LD_{50}}{ED}\left(1 + \frac{a}{100}\right),$$

representing both the degree of protection and the therapeutic spectrum for a given substance, where LD_{50} is the dose of the agent causing the death of 50% of the animals and a is the percentage survival of the animals with the given effective dose ED and complete mortality in a control group. This parameter has limited application,

since it permits comparison of the efficiencies of substances only under identical experimental conditions (mode of introduction, time of administering substance before irradiation, species of animal, dose and dosage rate of radiation, etc.). However, since the experimental conditions have been adequately standardised during recent years, the protective index can in many cases be used to estimate the practical prospects. Table 1 gives a scale of efficiencies of protective agents based on the protective index and adopted by several American authors.

Table 1. Scale of efficiency of protective agents.

I	0—1	2—5	6—10	11—44	⩾ 15
	0* ineffective	+ relatively ineffective	++ moderately efficient	+++ efficient	++++ highly efficient

* It is assumed that $I = 0$ when protection is below 20%.

The protective index will be used where possible in the present Review. Since the vast majority of experiments with protective agents have been made on mice with the substances introduced 15–30 min before irradiation at 40–400 rad min^{-1}, and the survival rate of the animals was determined after 30 days, these conditions may not be satisfied in the text of the Review.

II. SULPHUR-CONTAINING COMPOUNDS OF AMINOTHIOL STRUCTURE

Among the sulphur-containing compounds studied during the past five years as prophylactic protective agents the vast majority are *N*-substituted derivatives and analogues of 2-aminoethanethiol–thiols, disulphides, thiosulphates, thiophosphates, thiazolidines, etc.—as well as similar compounds in which the ethylene chain has been modified. A considerably smaller number of other sulphur-containing compounds have been studied. They will be discussed in this sequence.

1. *N*-Substituted 2-Aminoethanethiols

Although 2-aminoethanethiol itself has a fairly high protective effect under experimental conditions, its practical use is prevented by its narrow therapeutic latitude of action. With intraperitoneal (ip) injection LD_{50} = 250 mg kg^{-1}, and in the optimum dose ED = 150 mg kg^{-1} it protects 87% of mice when a control batch shows complete destruction; with oral (or) introduction LD_{50} = 615 mg kg^{-1}, ED = 300 mg kg^{-1}, and a = 73%: hence for mercamine

$$I_{ip} = \left(1 + \frac{87}{100}\right)\frac{250}{150} = 3.1,$$

$$I_{or} = \left(1 + \frac{73}{100}\right)\frac{615}{300} = 3.6.$$

On the above scale [Table 1] mercamine must be regarded as a relatively ineffective protective agent. Naturally, therefore, numerous attempts have been made in recent years to vary the structure of mercamine in every possible way in order to obtain a product with the same level of protection against radiation but with a greater latitude of action, i.e. one which is less toxic and better tolerated.

Earlier investigations on the effect of the anion on the protective activity of mercamine have been continued by a detailed examination of its adenosine triphosphate salt [9]. This agent, termed Tsitrifos, was closely similar to aminoethanethiol hydrochloride in activity, but exhibited a protective effect on prolonged irradiation at 10.7 and 3.75 rad min^{-1}.

Various workers have prepared and studied many derivatives of the type

$$RHNCH_2CH_2SH$$

(I)

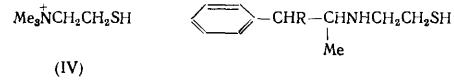
with different *N*-substituents, but most of them were relatively inactive or possessed a weak protective action. Replacing an amino-hydrogen atom by a straight- or branched-chain alkyl results in disappearance of the protective activity [10]. Compounds having a long normal alkyl chain (I: R = C_8H_{17}, C_9H_{19}, $C_{10}H_{21}$) exhibit a protective effect [11]. Polymethylene-*NN'*-bis-2-aminoethanethiol derivatives (II) containing n = 6–8 CH_2, [12] as well as their sulphone analogue (III), [13]

$$HSCH_2CH_2NH{-}A{-}HNCH_2CH_2SH$$

(II) A = $(CH_2)_n$ (III) A = SO_2

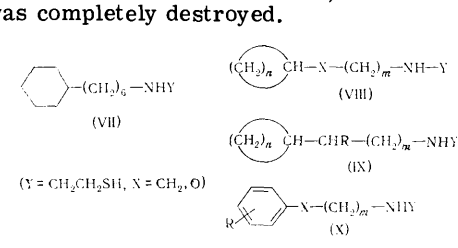
increase very slightly the radiation resistance of mice on prophylactic application. Quaternisation of the nitrogen atom produced a sharp increase in toxicity and a loss of activity, as has been observed with thiocholine (IV). [14]

$Me_3\overset{+}{N}CH_2CH_2SH$ (IV)



(V, R=H); (VI, R=OH)

Little or no protective effect is shown by aminoethanethiol derivatives containing alicyclic, aryl, and heterocyclic substituents attached to the nitrogen atom either directly or through 1–4 methylene groups [10,15]. Similar results were obtained in a study of *N*-substituted derivatives containing hydroxy-, alkoxy-, and aryloxy-alkyl substituents, and of aminoethanethiols with structures (V) and (VI) based on amphetamine and ephedrine [10]. Only one of the 58 such compounds examined in this work, 2-*N*-6'-cyclohexylhexylaminoethanethiol (VII), showed high protection against radiation: an intraperitoneal dose of 30 mg kg^{-1} given 15 min before irradiation provided almost complete protection for mice, whereas a control group was completely destroyed.



(VII) (Y = CH_2CH_2SH, X = CH_2, O)

(VIII) (IX) (X)

It was probably on the basis of these results that a group of investigators headed by Westland studied in 1972 [16] a series of compounds of type (VII) in which the substituent was an alicyclic ring (VIII) and (IX) or a benzene ring (X) attached by a polymethylene chain (C_3–C_6) either directly or through an oxygen atom to the amino-group, in some of which the polymethylene chain was branched (IX). Cycloalkylalkyl derivatives (VIII) were

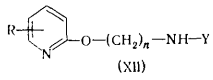
considerably more toxic than aminoethanethiol itself and its closest analogues. Most of them, however, had a protective action in smaller doses (25–50 mg kg^{-1}, only 33–17% of the effective dose of 2-aminoethanethiol). Replacing a five-membered by a six-membered ring and varying the length of the polymethylene chain from three to six units had no significant effect on the protective activity of such compounds. Branching in the hydrocarbon chain leads to loss of or diminution in activity. The protective index of the most active does not exceed 3.5, which corresponds to the efficiency of aminoethanethiol itself.

The sole exception among compounds of this type was the cyclo-octyloxypentyl derivative

(XI)

While possessing considerably lower toxicity (LD_{50} = 180 mg kg^{-1}) than the other cycloalkylpolymethylene analogues, a 50 mg kg^{-1} dose of this compound protected 83% of mice when destruction in the control group was 100%, and its protective index I = 6.6.

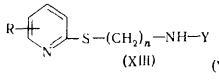
Aryloxyalkyl derivatives (X: X = O) were on the average rather more effective than their alicyclic analogues[16,17]. Among them compounds having n = 4–6 were the most active: the ethylene and trimethylene derivatives did not protect animals[13]. Increasing the number of alkyl substituents in the benzene ring diminishes the protective activity.



(XII)

(XIV)

(XVI)



(XIII)

(XV)

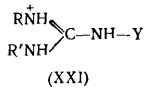
(Y = CH_2CH_2SH)

(XVII)

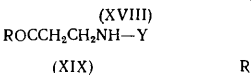
Among the 25 pyridyloxyalkyl derivatives of aminoethanethiol of type (XII) Westland and his coworkers[8] were unable to discover one which would have merited attention as a protective agent. Nor did the pyrid-2′-ylthioalkyl (XIII) and phenylthioalkyl (XIV) analogues, the N-mercaptoethyl (XV)[18] and N-trimethylsilylpropyl (XVI)[19] derivatives, possess a protective action.

(XVIII)

(XX)



(XXI)



(XIX)

R = R′ = Me; R = H, R′ = C_8H_{17}

R = H, R′ = $PhCH_2CH$ (Me)

R = R′ = H, Me

Y = CH_2CH_2SH

A few compounds have been studied whose alkyl substituent contains a secondary amino-group (XVII), but no active substance was discovered among them[20,21]. The oxamido-derivative (XVIII) had a slight protective effect[22]; replacing a hydrogen atom in the terminal carbamoyl group by phenyl, cyclohexyl, or pyridyl led to a loss of activity. A protective action was evident with derivatives containing a propionic acid residue attached to the amino-group (XIX)[21]; the most active was the amide (R = NH_2), which was followed by the acid (R = OH), the nitrile, and the ethyl ester (R = OC_2H_5). Replacing the amino-group in 2-aminoethanethiol by hydrazino (XX) leads to a loss of protective activity[10]. N'-Methylated derivatives (XXI) showed a considerably weaker protective action than did guanidinoethanethiol[24].

Thus in only one case, N-cyclo-octyloxypentylaminoethanethiol (XI) (I = 6.6), did the wide variation in the structure of the substituent attached to the nitrogen atom in 2-aminoethanethiol (~ 130 such compounds were studied) yield a considerably more effective protective agent.

(XXII, R=H) $(RNHCH_2CH_2S)_2$

(XXIII, R= –A

a A=CH(Me)$(CH_2)_3$–; b A=$CHCH_2$(Et),

(XXIV)

Aminoalkyl disulphides have aroused considerably less interest in investigators during recent years. The first member of this group, cystamine (XXII), while having several advantages over the corresponding amino-thiol (mercamine), must also be regarded as a relatively ineffective radiation-protective agent (with LD_{50} = 320 mg kg^{-1}, in the optimum dose (intraperitoneal) of 220 mg kg^{-1} it protects ~ 70% of mice[3]: i.e. I = 2.5). During the past 5–6 years great attention has been paid to the preparation and study of derivatives of (XXII) containing N-alkyl substituents substituted by cycloalkyl and cycloalkoxyl, aryl and aryloxyl, pyrid-2-yloxyl and quinol-2-yloxyl. Active compounds have been found among the cycloalkyl and aryl derivatives[13,16,17]; their heterocyclic analogues possessed no protective action[8]. The highest protective efficiency was found with bis-2-N-4′-cyclohexylpentylaminoethyl (XXIIIa)[16] and bis-2-N-4′-p-methoxyphenylbutylaminoethyl (XXIV)[17] disulphides, with the respective protective indices 8.4 and 11.0. It is interesting that the disulphide (XXIIIb), a close analogue of (XXIIIa) whose N-substituent differs by only one methylene unit, has no protective effect[16].

Table 2. Protective properties of amino-thiols and disulphides.

R	$RHNCH_2CH_2SH$				$(RHNCH_2CH_2S-)_2$				Ref.

2,3,6-$Me_3C_6H_2O-(CH_2)_4-$	130	100	33	1.7	56	32	50	2.2	16
4-$MeOC_6H_4-(CH_2)_4-$	70	40	15	0	240	60	83	11.0	17
Br– –$O-(CH_2)_6-$	140	60	87	4.4	78	20	0	0	8

Table 2 reveals no regular variation in toxicity and protective activity on passing from an amino-thiol to the corresponding disulphide: either an increase or a decrease in toxicity, accompanied by an increase, a decrease, or maintenance of the protective activity, may be observed depending on the nature of the substituent.

Kostyukovskii et al.[14] found that increasing the degree of substitution of the amino-groups in cystamine leads to an increase in toxicity, while protection is maintained at the same level. Quaternisation of the nitrogen makes the compound extremely toxic and almost inactive.

$RR'NCH_2CH_2SH$ (XXV)

R = R′ = H; R = H, R′ = Me

$RR'NCH_2CH_2S-SCH_2CH_2NRR'$ (XXVI)

R = R′ = Me; R = H, R′ =

Tank and Zherebchenko[25] compared the toxicity and the protective activity of several thiol–disulphide pairs such as 2-aminoethanethiol (XXV) and cystamine (XXVI), and found that these properties vary with the species of animal. Thus with mice no relation could be established between the toxicity and antiradiation activity and the thiol or disulphide structure. Experiments on rats showed greater toxicity and a somewhat higher protective efficiency with disulphides than with the corresponding thiols.

$(AcNHCH_2CH_2S-)_2$ (XXVII)

$AcNH-(CH_2)_n-S-S-CH_2CH_2NHC_{10}H_{21}$ (XXVIII)

a $n=2$; b $n=3$

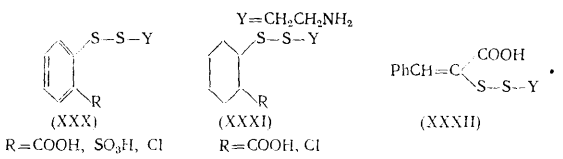
$AcNHCH_2CH_2-S-S-(CH_2)_4-X$ (XXIX)

a $X=SO_3Na$; b $X=SO_2Na$

Field and his coworkers[26-29] have made interesting investigations on the synthesis of symmetrical and unsymmetrical disulphides based on 2-aminoethanethiol and have studied their protective activity. It was discovered that *NN'*-diacetylcystamine (XXVII)[29], like its unsymmetrical analogue (XXVIIIa) having a long *N'*-alkyl substituent[26], does not protect mice from radiation. The homologue of the latter compound with three methylene units between the sulphur atom and the acetamido-group (XXVIIIb) showed a medium protective action[26].

The sulphonate (XXIXa) has a weak protective effect[27], whereas the corresponding sulphinate (XXIXb) proved to be an efficient protective agent. An intraperitoneal dose of the latter sodium salt of 172 mg kg^{-1} (LD_{50} = 800 mg kg^{-1}) protected 93% of mice when destruction of a control group was complete (I_{ip} = 9.0). The degree of protection given by oral introduction of (XXIXb) was also high: a dose of 278 mg kg^{-1} with LD_{50} = 1050 mg kg^{-1} gave 100% survival of the animals (I_{or} = 7.5).

Substances having protective properties have been discovered also among unsymmetrical disulphides of the types[28]

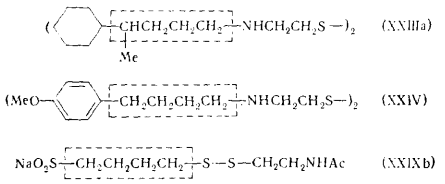


(XXX) R=COOH, SO_3H, Cl

(XXXI) R=COOH, Cl

(XXXII)

It is extremely interesting that the most active disulphides



* Presumably these formulae had originally been numbered (XXXIII)–(XXXV) (Ed. of Translation).

are structurally similar, for they all contain a chain of four carbon atoms. Unfortunately, the lack of data do not allow a reason to be suggested for the role of this factor in the protective effect.

Although less interest has evidently been taken during recent years in disulphides as potential protective agents than in the amino-thiols from which they are derived (a total of ~ 45 such compounds have been studied), highly efficient products have been discovered among them, such as bis-2-*N*-4'-*p*-methoxyphenylbutylaminoethyl disulphide (XXIV) and sodium 4-2'-acetamidoethyldithiobutanesulphinate (XXIXb), the latter showing considerable effectiveness when administered orally. This suggests that the potentialities of 2-aminoethyl disulphides as protective agents are by no means exhausted, and that still more efficient products may be expected to appear in this series.

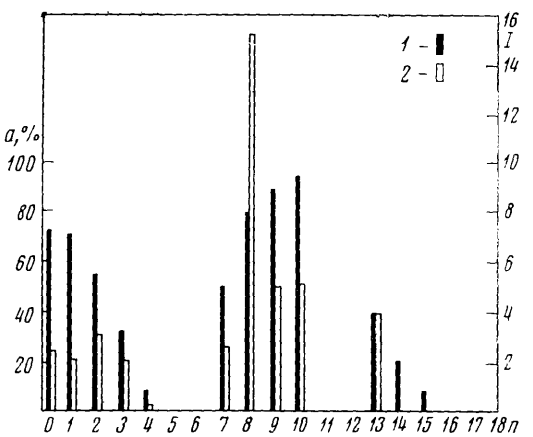
2. *N*-Substituted Aminoethyl Thiosulphates (Bunte's Salts)

In the search for protective agents containing the 2-aminoethanethiol structure the greatest attention has been paid during the past five years to derivatives of aminoethyl thiosulphates, Bunte's salts. The discovery in 1968 of extremely high protective action among these compounds[7] was in effect a turning point in the search for chemical means of protection from ionising radiation.

$H_3\overset{+}{N}CH_2CH_2SSO_3^-$ (XXXVI)

$R\overset{+}{N}H_2CH_2CH_2SSO_3^-$ (XXXVII)

The primogenitor of this series of compounds—2-aminoethyl thiosulphate (XXXVI)—possesses a high protective effect, but in doses which are almost toxic[30]. With LD_{50} = 450 mg kg^{-1} the optimum protective effect of 73% survival was observed with an intraperitoneal dose of 350 mg kg^{-1} in mice. Thus I = 2.2 for (XXXVI): i.e. the compound is relatively inefficient.



Effect of number n of carbon atoms in alkyl group in the compounds $C_nH_{2n+1}N^+H_2.CH_2.CH_2.SSO_3^-$ on: 1) percentage survival of mice a; 2) protective index I.[31]

Klayman et al.[31] studied the prophylactic protective action against radiation of many *N*-alkylated aminoethyl thiosulphates (XXXVII), and discovered an interesting relation between the protective effect and the size of the alkyl group, clearly illustrated by the diagram. Three peaks of activity can be seen, and it is interesting that activity does not always vary in parallel with toxicity. Several Bunte salts containing branched-chain alkyls attached to the nitrogen atom have quite a high protective effect. This is most clearly shown by the 1-methylheptyl derivative (XXXVIII), which in a dose of 75 mg kg^{-1} protects all animals from an absolutely lethal dose of radiation (I_{ip} = 3.7). Among the more than 30 *N*-alkylated

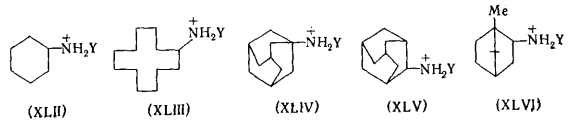
derivatives (XXXVII) studied the most effective protective agent was *N*-octylaminoethyl thiosulphate (XXXIX): at a dosage of 15 mg kg^{-1} with LD_{50} = 125 mg kg^{-1} (intraperitoneal) the survival rate of mice was 80% (I_{ip} = 15.0). Another compound of this series, decylaminoethyl thiosulphate, showed a protective action of ~ 50% at doses of 10–30 mg kg^{-1} in monkeys [32].

$Y{=}CH_2CH_2SSO_3^-$ $C_6H_{13}CH(Me)-\overset{+}{N}H_2-Y$ (XXXVIII) $n-C_8H_{17}-\overset{+}{N}H_2-Y$ (XXXIX)

The encouraging results obtained in the study of *N*-alkylated aminoethyl thiosulphates stimulated an intense search for protective agents among various *N*-substituted derivatives and other amino-thiol compounds. Polymethylene-*NN'*-bisaminoethyl bisthiosulphates (XL) were relatively inactive [12]. A quite well defined protective action was shown by certain compounds containing higher hydroxyalkyl and methoxyalkyl groups (XLI). [7]

$Y{=}CH_2CH_2SSO_3^-$; $Y-\overset{+}{N}H_2-(CH_2)_n-\overset{+}{N}H_2-Y$ (XL), n=6–9; $RO-(CH_2)_n-\overset{+}{N}H_2-Y$ (XLI), R=H, Me; n=4, 7–10

Several workers [7,15,16] have studied the protective properties of Bunte salts having alicyclic substituents in the amino-group. The antiradiation activity of compounds in which the alicyclic substituent is attached directly to the nitrogen atom depends on the size of the ring and the bulk of the substituent. Thus the cyclohexyl derivative (XLII) is inactive [7], whereas the cyclododecyl analogue (XLIII) possesses a moderate protective action [15]; the 1- and 2-adamantyl (XLIV) and (XLV) and the 2-bornyl (XLVI) derivatives are considerably more active [15].



(XLII) (XLIII) (XLIV) (XLV) (XLVI)

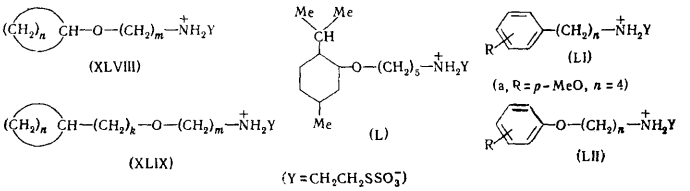
($Y = CH_2CH_2SSO_3^-$)

It was shown for cyclopentane and cyclohexane derivatives that introducing a polymethylene chain between the alicyclic substituent and the nitrogen atom leads to the appearance or enhancement of activity with a diminution in toxicity [7]. The optimum length was pentamethylene. Activity was found among compounds containing four-, five-, six-, and seven-membered rings.

It is interesting that, in a series of derivatives with straight-chain alkyl substituents, maximum efficiency is found with the C_8 group, whereas in cycloalkylalkyl derivatives this occurs in most cases when the substituent contains a total of nine or ten carbon atoms. Branching in the hydrocarbon chain joining the alicycle to the amino-group improves the efficiency of the protective action while having diverse effects on the level of toxicity, as is shown by Table 3 for cyclohexylalkyl derivatives (XLVII). [7]

It is worth noting that Westland et al. reported [16] that the *L*-form of *N*-cyclohexylbutylaminoethyl thiosulphate (XLVIIa), while possessing the same toxicity as the racemate, is almost trebly efficient as a protective agent. The laevorotatory isomer has the very high protective index I_{ip} = 30.

Analogues of the above compounds containing an ethereal oxygen atom between the alicycle and the hydrocarbon chain (XLVIII) or in the chain itself (XLIX) also have a protective action against radiation [7,16]. Among them (XLVIII: n = 7; m = 4) [7] and 5'-*L*-menth-3''-yloxypentylaminoethyl thiosulphate (L) [16] are distinguished by their activity, with protective indices I_{ip} of 9.0 and 8.0 respectively.



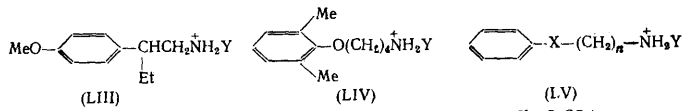
(XLVIII) (XLIX) (L) ($Y = CH_2CH_2SSO_3^-$) (LI) (a, R = *p*-MeO, n = 4) (LII)

Table 3. Protective properties of cyclohexylalkyl derivatives.

(XLVII)

A	LD_{50}, mmole kg^{-1}	ED, mmole kg^{-1}	Protection, %	I
CH_2	1.36	0.43	20	0
$(CH_2)_2$	0.34	0.19	27	2.3
$(CH_2)_3$	0.58	0.39	86	2.8
$(CH_2)_4$	0.17	0.034	87	9.4
$(CH_2)_5$	0.03	0.015	7	0
$(CH_2)_6$	0.028	0.014	53	3.2
$CHMeCH_2$	0.43	0.18	40	3.4
$CHEtCH_2$ (a) (racemate)	1.00	0.17	80	10.8
$CH(Me)-CH_2CH_2CH_2$	0.25	0.08	100	6.3
$CH(Et)-CH_2CH_2-$	0.48	0.08	60	9.6
$CH_2CH(Et)-CH_2$	0.45	0.048	73	16.3

Equally detailed studies have been made on *N*-arylalkyl (LI) and *N*-aryloxyalkyl (LII) derivatives of aminoethyl thiosulphate [7,17,33]. Among the former type (LI) the most active were the mono- and bis-methoxyphenyl derivatives having n = 4 or 5, and the greatest attention has been attracted to *N*-4'-*p*-methoxyphenylbutylaminoethyl thiosulphate (LIa). A dose of 30 mg kg^{-1} with LD_{50} = 120 mg kg^{-1} gave 87% protection to mice, whereas a control group underwent complete destruction (I_{ip} = 7.5). It is interesting that its isomer (LIII) with the same branched chain as in the most active cyclohexane analogue (XLVIIa) was inactive [17]. Introducing an ethereal oxygen atom between the benzene ring and the polymethylene chain has no significant effect on the toxicity or the protective action of the compounds. The nature of the substituent in the benzene ring is also almost without effect on the activity. Branching in the chain removes the protective action.

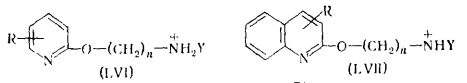


(LIII) (LIV) ($Y{=}CH_2CH_2SSO_3^-$) (LV) (X=S, SO_2)

The most efficient protective agent of this series of compounds is 2''',6'''-dimethylphenoxybutylaminoethyl thiosulphate (LIV). With LD_{50} = 250 mg kg^{-1} a dose of 100 mg kg^{-1} provides 100% protection for mice, and a dose of 25 mg kg^{-1} gives 73% protection. The protective index is I_{ip} = 17.3.

Analogues (LV) of the above compounds in which a sulphur atom or a sulphonyl group has replaced the oxygen

atom in the chain exhibited no appreciable protective action[13].



(LVI) (LVII)

(Y = $CH_2CH_2SSO_3^-$)

Heterocyclic analogues of cycloalkoxy- and aryloxy-alkylated derivatives containing a pyridine (LVI) or a quinoline (LVII) ring have also been synthesised, and their protective action has been studied[8]. The former contained as substituents R halogen, nitro, and cyano at positions 3‴, 5‴, and 6‴, with the number of methylene units varying from 2 to 7. The quinoline derivatives contained methyl, trifluoromethyl, methoxyl, and chlorine in the ring, with 2–6 methylene units. Highly efficient protective agents having a large therapeutic spectrum of action were discovered among compounds of this type (Table 4).

Table 4. Protective properties of pyridine and quinoline derivatives.

Compound	R	n	Dose, mg kg^{-1}		Survival, %	I_{ip}
			LD_{50}	ED		
LVI	5-Br	4	180	100	93	
				50	60	5.8
LVI	5-Br	5	90	25	73	6.2
LVI	5-Cl	5	225	19	87	20.0
LVI	5-Cl	6	120	30	67	6.7
LVI	3,5-Br_2	5	163	25	67	11.0
LVII	H	3	220	25	93	17.0
LVII	4-Me	3	180	25	80	13.4
LVII	4-Me	4	225	50	93	8.7
LVII	6-MeO,4-Me	2	100	12	73	14.4
LVII	4.6-Me_2	3	125	19	93	12.7

By analogy with the thiol derivatives, studies were made on several Bunte salts with an aminoalkyl chain attached to the nitrogen atom (LVIII) and containing the terminal amino-group either unsubstituted[34] or with aryl[20], oxamide[22], or other[21] substituent. However, none of them protected mice from radiation. Several derivatives of 2-aminoethyl thiosulphate containing a propionic-acid residue attached to the nitrogen atom (LIX) were studied[23] and all found to exhibit a weak protective effect against radiation. The trimethylsilylpropyl derivative (LX) was also inactive[19]. Klayman et al.[35] examined several derivatives of guanidylethyl thiosulphate of type (LXI), and found most of them to possess a pronounced protective action. The most active was the derivative in which the nitrogen atoms were unsubstituted (LXI: R = R′ = H): a dose of 100 mg kg^{-1} (LD_{50} = 275 mg kg^{-1}) protected 80% of mice: I_{ip} = 5.0.

(LX)

(LXI)

It had been thought earlier that derivatives of aminoethyl thiosulphate had no protective action on mice when given orally. Westland et al.[7,17] disputed this opinion, having discovered moderate activity on the oral introduction of several of the above *N*-cycloalkyl- and *N*-arylalkylated derivatives showing the greatest protective effect on intraperitoneal administration. Oral introduction diminished the toxicity of these compounds by 90–99%, but considerably larger doses were required to achieve a protective effect.

Among the above compounds *N*-*p*-methoxyphenylbutylaminoethyl thiosulphate (LIa) showed the greatest protective action. When introduced 30 min before irradiation, it protected up to 87% of mice; shortening the period to 15 min led to a sharp decrease in the survival of the animals.

The above experimental results for ~ 300 aminoethyl thiosulphate derivatives as protective agents administered intraperitoneally lead to certain conclusions on the effects of the structure of the *N*-substituents on toxicity and protective activity. Alkyl and cycloalkyl-, aryl-, and heteryl-alkyl substituents, in several cases with some increase in toxicity, led to an appreciable decrease in the protective dose and thereby widened the therapeutic spectrum. The optimum structure in this series must evidently be regarded as that in which the *N*-substituent in the aminoethyl thiosulphate contains 8–12 carbon atoms, one or two of which may be replaced by nitrogen or oxygen atoms. If the substituent is not purely aliphatic, the number of methylene groups joining the cyclic fragment to the amino-group should be 3–5.

* *L*(–)-isomer.

Table 5 gives comparative data for the most efficient protective agents—*N*-substituted aminoethyl thiosulphates—which clearly demonstrate the advantage of these compounds over their primogenitor—2-aminoethyl thiosulphate itself. The protective efficiency of such compounds is evidently determined not so much by the length of the group, which may influence the surface-active properties of the compounds, as by the "weight" of the substituent (around 100–200), its configuration, and other factors. The broadened therapeutic latitude in these substances must be attributed to "dilution of the active fragment" by the increase in molecular weight. Table 5 shows that introducing a substituent increases the toxicity by factors 3–6 but at the same time diminishes the effective protective dose to a still greater extent, by factors of 20–40.

3. Derivatives of *S*-2-Aminoethyl Dihydrogen Phosphorothiolate

The first member of this series—*S*-2-aminoethyl dihydrogen thiophosphate (LXII)—whose sodium salt has since been termed Cystaphos, was first described in 1961 as an effective protection against radiation[36]. Cystaphos and its simple derivatives were shown to possess quite low toxicity while being highly active[36,37]. Thus with LD_{50} = 930 mg kg^{-1} Cystaphos itself in a dose of 400 mg kg^{-1} protects 95% of mice from an absolutely lethal dose of radiation[36]: i.e. its I_{ip} = 4.5. These were high values for the 1960s, and this series of compounds might have been expected to engross the attention of research workers. However, the literature indicates that fewer aminoethyl thiophosphates than thiosulphates and even thiols have been studied during the past five or six years as potential protection against radiation.

$H_2NCH_2CH_2SPO_3H_2$ (LXII) $RHNCH_2CH_2SPO_3H_2$ (LXIII)

The further search in this series for more efficient protective agents than Cystaphos was directed at complicating the molecule by introducing various hydrocarbon and other groups at the nitrogen atom. Most of the compounds synthesised were isolated and used as the sodium and other salts (formulae in the text will be given for the dihydrogen esters). More than 40 compounds of type (LXIII) have been described containing various substituents—alkyl, carboxyalkyl, carbamoylalkyl, etc.[38]—but data are not given on their protective activity against radiation.

$Y=CH_2CH_2SPO_3H_2$

$YHN-(CH_2)_n-NHY$ (LXIV), n=7–10

$YHN-(CH_2)_n-C_6H_{10}-(CH_2)_n-NHY$ (LXV), n=0,1

Some activity has been found with the polymethylenebisaminoethyl bisthiophosphoric esters (LXIV) and their *cis*- and *trans*-cyclohexane analogues (LXV).[12] Replacing an amino-hydrogen atom by bornyl and norbornyl groups diminishes the protective effect found in Cystaphos[15]. The adamant-1-yl derivative (LXVI), although more toxic, gave protection in a smaller dose: with LD_{50} = 560 mg kg^{-1} a dose of 80 mg kg^{-1} showed a protective effect of ~ 80% (I_{ip} = 12.5).[15] Weak protection or none at all was shown by compounds having a heterocyclic *N*-substituent (LXVII)[15] and by the *N*-phenoxy-, *N*-phenylthio-, and *N*-phenylsulphonyl-alkylaminoethyl esters (LXVIII)[13].

$R-HNCH_2CH_2SPO_3H_2$

(LXVI) R =

(LXVII) R =  X=O, S

(LXVIII) R =  $X-(CH_2)_n-$, X = O, S, SO_2; n = 2, 3

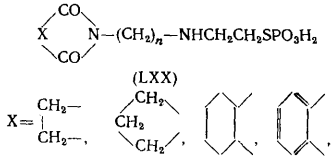
(LXIX) $R = R'HN-(CH_2)_n-$; n = 2–6

Attention was directed mainly at seeking protective agents among *N*-aminoalkyl derivatives of the *S*-aminoethyl thiophosphate (LXIX)[20,21,34]. Introduction of an aminoalkyl chain of 2–6 units terminating in a free amino-group (R′ = H) produces a significant increase in protective efficiency above that of Cystaphos[34]. All *N*-aminoalkyl derivatives other than the first member of the series (LXIX: R′ = H, n = 2) are more toxic than Cystaphos but protect animals in considerably smaller doses. Table 6 shows that most of them have protective indices exceeding that of Cystaphos by about 50%. The protective activity of certain compounds of type (LXIX) is maintained when a hydrogen atom of the terminal amino-group is replaced by methyl or ethyl (R′ = CH_3, C_2H_5); the introduction of an octyl or a cyclohexyl substituent (R′ = C_8H_{17}, C_6H_{11}) deprives the compound of activity[20]. The *N*-aminopropylaminoethyl ester (LXIX: R′ = H, n = 3)—known by the number WR-2721 or the name Gammafos—has been subjected to a more thorough and detailed study as a potential protective agent[39–42]. These investigations enabled the advantage of this agent over Cystaphos to be shown up more boldly.

Table 6. Protective properties of derivatives of (LXIX).

LXIX R′	n	Doses, mg kg^{-1}		Protection, %	I_{ip}
		LD_{50}	ED		
Cystaphos		930	400	95	4.5
H	2	1300	400	100	6.5
H	3	700	300	86	4.3
H	4	800	200	80	7.2
H	5	550	150	100	7.3
H	6	550	150	93	7.1
Me	3	800	200	87	
			100	46	11.7

Various *N*-imidoalkyl derivatives of the aminoethyl ester (LXX) (formed from the imides of succinic, glutaric, cyclohexane-1,2-dicarboxylic, and phthalic acids) have been studied in the search for more effective compounds[21,43,44]. Most of these compounds showed weak or moderate action against radiation. The most active was the cyclohexane derivative, which gave protection even when administered through the mouth[44].



(LXX)

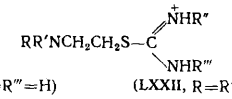
X = n=2–4

The above discussion can be summed up in the conclusion that, among the > 100 *N*-substituted aminoethyl dihydrogen thiophosphates described during the past six years, the most effective protective agents were the adamant-1′-yl (LXVI) and methylaminopropyl (LXIX: R′ = CH_3, n = 3) derivatives, with protective indices reaching ~ 12.

4. Aminoethylthiouronium Derivatives

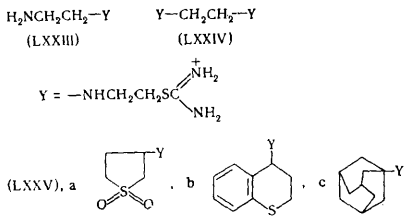
The search for protective agents has been considerably less intense among aminoethylthiouronium derivatives (LXXI), which, while possessing a high protective action, is itself an extremely toxic substance (I = 1.5–2.0). Japanese workers[45,46] examined systematically all possible

N-methyl derivatives (LXXII), but gave no data on their biological activity.

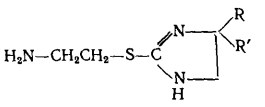


(LXXI, R=R′=R″=R‴=H) (LXXII, R=R′=R″=R‴=Me, H)

The aminoethyl derivatives (LXXIII) and (LXXIV) are inferior in protective activity[47] to the original aminoethylthiouronium.



Elliott and his coworkers[15] discovered that derivatives of (LXXI) having heterocyclic residues such as dioxothiophanyl and thiachromanyl attached to the chain nitrogen atom (LXXVa, b) possess no protective activity, whereas the adamant-1′-yl analogue (LXXVc) develops some action.



(LXXVI)

(R=R′=H; R=R′= Alk, cycloAlk)

Derivatives of (LXXI) have been synthesised with amino-acid and dipeptide residues in the thiouronium group[48], but, like the cyclic analogue (LXXVI)[47,49], these compounds were inferior to aminoethylthiouronium itself in protective activity against radiation.

5. Thiazolidines

Increasing interest has been taken during recent years in thiazolidines, cyclic analogues of 2-aminoethanethiol. The search for protective agents was continued in the traditional direction—among 2-substituted thiazolidines (LXXVII), which are usually regarded as a long lasting, less toxic form of aminoethanethiol because of their ability to break down gradually in the organism with liberation of the latter product. Among compounds of this type studied, several exhibited moderate protective activity—unsubstituted thiazolidine (LXXVIIa), the 2-alkyl and 2-aryl[50], also the 2,2-dimethyl (LXXVIIb) and 2-trichloromethyl (LXXVIIc) derivatives[51], and 2,2-spiroquinuclidylthiazolidine (LXXVIII)[52].

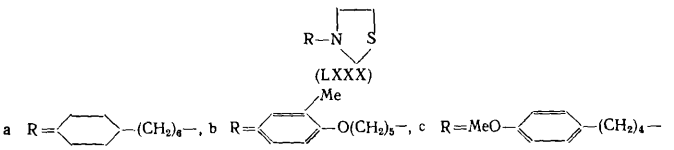
b R=H, R′=COOR‴ (R‴=H, C_1-C_{18}), R″=COOR‴ (R‴=H, Me);
c R=Me, R′=Et, R″=COOH

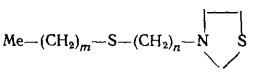
Yakovlev et al.[53] have shown that 2-glycosyl derivatives of thiazolidine protect yeast cells and *Escherichia coli* from the action of ionising radiation. Thiazolidine-2-carboxylic and -2,4-dicarboxylic acids and esters (LXXIXa, b), obtained by condensing glyoxylic acid and its esters with 2-aminoethanethiol and cysteine respectively[54,55], showed slight protective activity, as did compounds containing acetic-ester residues at position 2 (LXXVIId, e).[56] Among 2,2-dialkylthiazolidine-4-carboxylic acids a protective effect was observed only in (LXXIXc)[57]; 5,5-dimethylthiazolidine-4-carboxylic acid—a cyclic analogue of penicillamine—was inactive[51].



(LXXX)

a R=—$(CH_2)_6$—, b R=—O$(CH_2)_5$—, c R=MeO—$(CH_2)_4$—

The most important and interesting results were obtained in a study of the protective properties of *N*-substituted thiazolidines (LXXX). Westland et al.[16] investigated the action against radiation of fifteen 3-cycloalkylalkyl- and 3-aryloxyalkyl-thiazolidines. Several of them showed moderate activity, e.g. 3-6′-cyclohexylhexyl- and 3-5′-*o*-tolyloxypentyl-thiazolidines (LXXXa, b), whose protective indices were respectively 6.0 and 8.0. As among the amino-thiol derivatives containing an *N*-*p*-methoxyphenylalkyl substituent[17], only 3-4′-*p*-methoxyphenylbutylthiazolidine (LXXXc) showed sufficiently high protection, with I_{ip} = 7. Compounds with a branched polymethylene chain or with a 2-methyl group in the thiazolidine ring were devoid of activity. The thiazolidine derivative (LXXXc) gave weak protection when administered through the mouth.

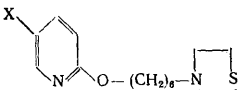


(LXXXI)

m=0—8, *n*=2—7

a *m*=5, *n*=6; b *m*=3, *n*=7; c *m*=4, *n*=5; d *m*=5, *n*=5

Most of the 3-alkylthioalkylthiazolidines (LXXXI) studied (> 25) afforded weak or no protection to irradiated mice on intraperitoneal administration, and only two compounds (a and b) had a moderately protective effect[58]. Oral introduction gave similar results, but (LXXXIa) protected weakly, then (LXXXIb). Furthermore, compounds (LXXXIc, d), relatively inactive on intraperitoneal administration, proved to be efficient when given orally: thus an oral dose of (LXXXIc) of 125 mg kg^{-1}, with LD_{50} = 650 mg kg^{-1}, protected 92% of mice, and its protective index was I_{or} = 10.



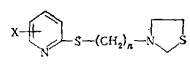
(LXXXII)

a X=5-Cl, b X=5-I

In contrast to pyrid-2″- and quinol-2″-yloxyalkylaminoethyl thiosulphates, among which protective agents of high efficiency on intraperitoneal introduction were discovered, their thiazolidine analogues (> 50 studied) were almost inactive with this method of administration[8]. However, two of them—3-6″-5‴-chloro- and 3-6″-5‴-iodo-pyrid-2‴-yloxyhexylthiazolidines (LXXXIIa, b)—were quite effective on oral administration, with protective indices respectively of ~ 7.0 and 6.0.

Compounds providing efficient protection on oral introduction were discovered also among 3-halogenopyrid-2'''-ylthioalkylthiazolidines (LXXXIII)[56] containing 3–10 methylene groups. The most active of them afforded no protection on intraperitoneal introduction (Table 7).

Table 7. Protective properties of the derivatives.



(LXXXIII)

X	n	Intraperitoneal administration				Oral administration			
		doses, mg kg^{-1}		survival, %	I_{or}	doses, mg kg^{-1}		survival, %	I_{or}
		LD_{50}	ED			LD_{50}	ED		
5-Br	5	275	100	93	5.3	800	200	73	6.9
5-Cl	7	56	30	20	0	650	75	60	14.0
5-Cl	8	125	70	8	0	500	125	80	7.2
3,5-Cl_2	7	275	125	60	3.5	1000	800	0	0

Thus quite efficient protective agents, which develop their activity predominantly on oral introduction, have been discovered among the > 140 thiazolidine derivatives studied, primarily among those substituted on the nitrogen atom. These results may provide some support for the hypothesis that thiazolidine compounds may act as long lasting forms of the corresponding 2-aminoethanethiol derivatives. However, it is still difficult, on the basis of existing data, to reach conclusions on the general effects of substituents in the thiazolidine ring on the protective action of these compounds and on differences in activity between intraperitoneal and oral administration.

6. 2-Aminoethanethiol Derivatives modified in the Hydrocarbon Chain

The structure of 2-aminoethanethiol—the primogenitor of protective agents—can be varied, not only by substitution at the amino and thiol groups, but also by modification of the hydrocarbon chain. Early studies had been made[3,59] of the effect of chain lengthening and branching on the protective activity. These investigations have recently been continued, and novel, more radical changes have been made in this part of the molecule.

$H_2N-(CH_2)_n-SX$ a X=H, n=2,6; b X=SO_3H, n=3,6–10;
(LXXXIV) c X=PO_3H_2, n=3

$H_2N-(CH_2)_m-NH-(CH_2)_n-SPO_3H_2$
(LXXXV)

A decrease in the protective effect until it completely disappears is confirmed on passing from the two-unit (ethylenic) chain in 2-aminoethanethiol to chains of three to six units (LXXXIVa)[60]. A similar rule is observed for the aminoalkyl thiosulphates (LXXXIVb)[15,30]. A sharp drop in protective activity is found also in the trimethylene analogue of Cystaphos (LXXXIVc)[34].

A rather different rule is found in *N*-aminoalkylaminoalkyl phosphorothiolates (LXXXV)[34]. Depending on the length m of the polymethylene chain in the substituent, increase in the distance between the sulphur and nitrogen atoms from two to three methylene units may either enhance or diminish the protective efficiency (Table 8).

The compound (LXXXV: $n = m = 3$) is one of the most efficient protective agents among derivatives of aminoalkyl phosphorothiolates.

Gandacek and Swartz[61] tried to discover a connection between the protective activity of amino-thiols and the possibility of intramolecular hydrogen bonding between the nitrogen and sulphur atoms. They showed that such a bond can be formed only in the first member of the series, 2-aminoethanethiol, which in the crystalline state has the gauche conformation. In their view, however, it is improbable that this fact will be significant in the establishment of a protective effect, since the conformation will certainly change under physiological conditions—in solution.

4	800	200	80	7.2	225	100	13	0

Investigations have continued during recent years on the effect of branching in the ethylene chain in compounds having the 2-aminoethanethiol structure on their toxicity and protective activity. Attachment of a methyl group to the carbon atom adjacent to the nitrogen atom in *S*-aminoethyl thiosulphate (LXXXVIa) maintains both activity and toxicity, whereas the isomer having the methyl group attached to the carbon adjacent to the sulphur atom (LXXXVIIa) is considerably less toxic, but completely devoid of protective action. It is interesting that the opposite relation is observed with the two analogous amino-thiols (LXXXVIb) and (LXXXVIIb)[30]. The trimethylene analogue of aminoethylthiouronium and certain derivatives substituted on the second carbon atom were less active than itself[62].

$H_2NCH_2CHCH_2-S-C(=\overset{+}{N}H_2)-NH_2$

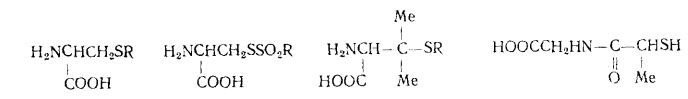
R=H, OH, Cl, Br

$H_2N-(CH_2)_3-NH-CRR'-CH_2S-X$
(LXXXIX)
X=H, SO_3H, PO_3H_2

Detailed study of the effect of methylating the carbon atom adjacent to the nitrogen atom in the compounds (LXXXIX) on their protective activity and toxicity revealed no general rule[34]. Introducing a single methyl group into these compounds with X = H, SO_3H hardly affects the toxicity or activity, whereas when X = PO_3H_2 it increases the toxicity and decreases the activity. Replacing a second hydrogen atom by methyl leads to a sharp increase in toxicity and loss of activity when X = H; with X = SO_3H, PO_3H_2, however, the toxicity diminishes, while the

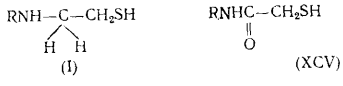
Bunte salt remains inactive, whereas the phosphorothiolate becomes even more effective than the first member of the series (R = R′ = H).



(XC, R=H) (XCI, R=SO_3H) (XCII) R=Me, *p*-MeC_6H_4 (XCIII) a R=$MeSO_2$ (XCIV) (Thiola)

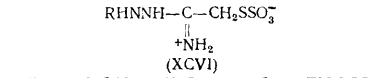
The search for protective agents has continued among derivatives of cysteine (XC), which was the first to protect animals from ionising radiation[3]. Japanese workers[63] made a detailed study of the antiradiation action of the ethyl ester, administered both intraperitoneally and orally. This relatively non-toxic compound was similar to cysteine in protective action, but did not protect mice from an absolutely lethal dose of radiation. The Bunte salt (XCI) was less active than cysteine itself[30]. Among the more complicated derivatives (XCII)[64] and (XCIII)[65], moderate protective activity was shown only by (XCIIIa).

Interesting results have been obtained during recent years from more fundamental changes in the hydrocarbon chain of amino-thiols. Sugahara et al.[66,67] discovered that α′-mercaptopropionylglycine (XCIV), which they termed "Thiola", while being relatively non-toxic (intraperitoneal LD_{50} = 2000 mg kg^{-1}), has an effect against radiation when small doses (20–40 mg kg^{-1}) are given in experiments on mice. However, it protects animals only at radiation doses leading to destruction of at most 70% in a control group. According to these workers[67] Thiola exerts a curative effect, both with parenteral and with oral application, on humans subjected X-radiotherapy: chromosome breakages in leucocytes become fewer after administration of this preparation. A Swedish patent[68] described the production not only of Thiola but also of several other derivatives of this type.



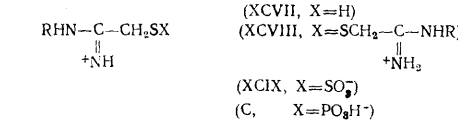
(I) (XCV)

The above work continued earlier investigations of the protective action of mercaptoacetamides (XCV)[69,70], which can be regarded as derived from 2-aminoethanethiol (I) in which the methylene adjacent to the nitrogen atom has been replaced by a carbonyl group. In 1969 Fridinger and Robertson[71] published a study of the protective action of four substituted acetamidrazone thiosulphates (XCVI). They provided weak protection from radiation for mice. It is readily seen that these compounds can be regarded as having the same type of modification of the ethylene chain: two hydrogen atoms have now been replaced not by carbonyl but by the isosteric imino-group.



(XCVI)
R=*p*-$NO_2C_6H_4$, *o*-MeC_6H_4, *p*-FC_6H_4, $EtOOCCH_2$

This latter work was probably the origin of studies by American workers headed by Westland[72] on the protective activity of 84 derivatives of mercaptoacetamidine (XCVII) and its *S*-functional substitution products—disulphides (XCVIII), thiosulphates (XCIX), and phosphorothiolates (C)—with various substituents attached to the nitrogen atom.



(XCVII, X=H) (XCVIII, X=SCH_2—C(=$^+NH_2$)—NHR) (XCIX, X=SO_3^-) (C, X=PO_3H^-)

The simplest compounds of this type—mercaptoacetamidines (XCVII)—far exceeding the corresponding aminoethanethiols in toxicity, were quite effective both with intraperitoneal and with oral administration. The most active among them was the compound with a free amino-group (XCVIIa: X = H), as well as the adamant-1-ylmethyl and 3,5-dimethyladamant-1-ylmethyl derivatives (XCVIIb, c). It is interesting that they were more effective when administered orally (Table 9). The distance of the bulky adamantyl group from the amidine nitrogen atom had little effect on the activity.

The oxidised forms of the mercaptoacetamidines—the corresponding disulphides (XCVIII)—are somewhat inferior in efficiency on intraperitoneal administration, but rather better when introduced orally. Data on the most efficient compounds of this series—the *N*-unsubstituted disulphide (XCVIIIa), adamant-1-ylmethyl, 3,5-dimethyladamant-1-ylmethyl, and cycloheptylmethyl derivatives (XCVIIIb-d)—are included in Table 9. It is noteworthy that the adamantyl derivatives are inactive on intraperitoneal administration. The compound (XCVIIIb) is the most effective of all known oral protective agents studied on mice: its therapeutic index is ~ 13, and its protective index ~ 20.

The largest group among the compounds studied (56) comprised the Bunte salts (XCIX) with cycloalkyl-, aryl-, heteryl-, and hydroxy-alkyl substituents attached to the nitrogen atom. Most of them were considerably more toxic than the corresponding aminoethyl thiosulphates, and had a medium and low protective effect. Only three compounds—the 3′,4′-dimethoxyphenylethyl, indol-3′-ylethyl-, and *cis*-2-myrtanyl-acetamidine thiosulphates (XCIXe-g)—showed high efficiency as intraperitoneal protective agents (Table 9). It is interesting that the immediate homologue of (XCIXf), with three methylene groups between the indole ring and the nitrogen atom, is completely inactive. The vast majority of Bunte salts studied did not protect mice from radiation when given orally, and only one compound—the *N*-born-2-yl derivative (XCIXh)—showed a fairly high protective effect with this mode of introduction.

The paper[72] gives results for only four guanylmethyl phosphorothiolates (C). Three of them—the unsubstituted compound (Ca), cycloheptylmethyl (Cd), and cyclooctylmethyl derivatives—exhibit slight protective activity with both methods of administration. Unique behaviour was exhibited by *S*-N^1-3′,5′-dimethyladamant-1′-ylmethylguanylmethyl dihydrogen phosphorothiolate (Cc), which under the experimental conditions was considerably more efficient than all known protective agents on intraperitoneal introduction (Table 9): its therapeutic index exceeded 30, and its protective index was $I_{ip} \simeq 50$. Its protective effect was not so high when used orally.

Comparison of the most efficient protective agents of acetamidine structure indicates that activity is increased by the introduction of the bulky adamantyl group attached to the nitrogen atom by a single methylene unit. However, no general rules could be derived for the influence of substituents in the amidino-group or of various functional

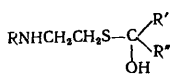
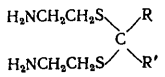
derivatives involving substitution at the sulphur atom. The data cited here demonstrate that the most efficient protective agents in experiments with both intraperitoneal and oral introduction into mice occur among compounds of mercaptoacetamidine structure.



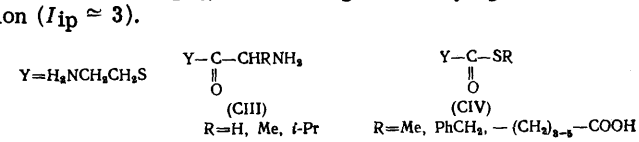
(CI)

R=H, Ac; R'=H, CF_3; R"=CCl_3, CBr_3, CF_3
a R=R'=H, R"=CCl_3; b R=R'=H, R"=COOR"' (R"'=C_1–C_{18}); c R=R'=H, R"=COOMe



(CII)

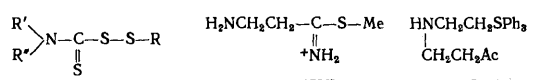
A few other groups of 2-aminoethanethiol derivatives, differing significantly in structure from the above, have been studied as protective agents. This applies primarily to products formed by reaction with carbonyl compounds. Field et al.[73] studied a series of monothiohemiacetals (CI), and found that one of them (CIa) developed a strong protective action, but in doses close to toxic. French workers[54,55] discovered an extremely efficient protective agent—the hydrochloride of methyl *S*-2'-aminoethylthioglycollate (CIc)—among a large number of condensation products (CIb) of aminoethanethiol with glyoxylic esters. In its prophylactic protective effect in an intraperitoneal dose of 450 mg kg^{-1} ($\frac{1}{2}LD_{50}$) it surpasses 2-aminoethanethiol and aminoethylthiouronium, while being considerably less toxic. Among mercaptals (CII)[51] a single compound (R = R' = $COOC_2H_5$) showed slight activity against radiation ($I_{ip} \simeq 3$).



(CIII) R=H, Me, *i*-Pr

(CIV) R=Me, $PhCH_2$, $-(CH_2)_{3-5}-COOH$

Rachinskii et al.[74] prepared and studied the protective action of several aminoethanethiol derivatives (CIII) *S*-acylated by amino-acids—glycine, alanine, leucine, etc.—which were less toxic than aminoethanethiol but exhibited the same protective effect in considerably larger doses. The dithiocarbonates (CIV) were relatively ineffective[75], and trithiocarbonates (CV) showed no activity[76].

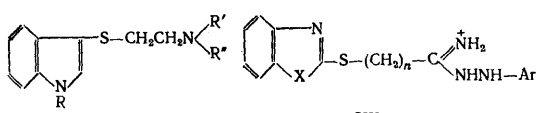


(CV) R=CH_2CH_2NHAc; R'=R"=H, Me

(CVI)

(CVII)

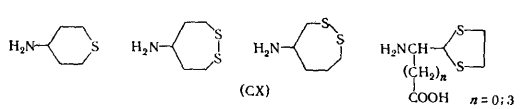
A slight protective effect was shown by the thioimidic ester (CVI)[77] and by the *S*-triphenylmethyl derivative (CVII)[23], for the latter of which a prolonged protective action was assumed. A few *S*-indol-3'-yl derivatives of the type (CVIII) have been synthesised in which R = R' = R'' = H or CH_3, but no results are reported for the protective activity[78].



(CVIII)

(CIX) X=S, NH; *n*=1, 2

Interesting investigations were made by Pantev et al.[79,80] in a search for protective agents among *S*-benzazol-2'-ylthioalkanoamidrazones (CIX). The most active was the benzimidazole derivative (CIX: X = NH, *n* = 2, Ar = *p*-$CH_3C_6H_4$): a dose of 120 mg kg^{-1} protected 56% of mice.



(CX)

a b c d

Several cyclic analogues of amino-thiols with one or two sulphur atoms in the ring (CXa–d) were studied[18,81,82], and all proved to be inactive.

Thus the most efficient protective agents for intraperitoneal and/or oral use under experimental conditions have been found among the almost 150 compounds of amino-thiol structure and having a modified hydrocarbon chain that have been studied.

The information surveyed above shows that more than 900 compounds of amino-thiol structure have been studied during recent years, and among them several highly efficient protective agents under experimental conditions have been discovered. A characteristic feature of the chemical structure of most of them is the presence of a cycloalkyl, adamantyl, aryl, or pyridyl substituent attached to the nitrogen atom through an alkyl, oxyalkyl, or thioalkyl chain.

No data or hypotheses have been published on the role of these structural factors in the development of protection from radiation. The presence of a sufficiently heavy, bulky substituent, usually containing 9–13 carbon atoms, may be supposed to strengthen intermolecular interactions and steric effects and to change the conditions of fixation of such compounds in cells and tissues of the living organism, which will undoubtedly influence the permeability to, the transport, and the distribution of these substances. All this evidently leads in aggregate to an increase in the biological activity of such compounds, when the decrease in the effective protective dose is usually greater than that in the toxic dose (e.g. LD_{50}), which increases the interval between them, i.e. the therapeutic latitude of these substances.

With regard to the thiol function in protective agents of this type, the phosphorothiolate and the disulphide groups must be regarded as optimal for intraperitoneal introduction, and the disulphide and thiazolidine groups for oral administration.

An extremely promising line of research has been fundamental modification of the hydrocarbon chain. The most efficient protective agents have been found among compounds of this type—*S*-N^1-3′,5′-dimethyladamant-1′-ylmethylguanylmethyl dihydrogen phosphorothiolate (Cc) on intraperitoneal administration and bis-N^1-adamant-1′-ylmethylguanylmethyl disulphide (XCVIIIb) when given orally.

X—CH_2CH_2SH (CXI)

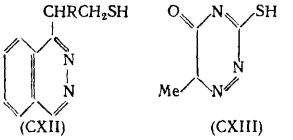
a—X=NH_2, b X=—C(=$\overset{+}{N}H_2$)—NH, c X=—NH—C(=$\overset{+}{N}H_2$)—NH_2, d X=SO_3H, e X=SO_2Et

All the results that have accumulated during recent years compel us to change our existing view[3] that the presence of a free amino-group is a necessary condition for the development of high protective activity in compounds having an amino-thiol structure. Kostyukovskii et al.[83] have recently shown that the amino-group in 2-aminoethanethiol (CXIa) can be replaced by several other electron-accepting groups—e.g. amidino, guanidino, sulpho, and sulphonyl (CXIb–e)—without a significant decrease in protective activity. These authors concluded that the protective activity of compounds of type (CXI) is due to the reactivity of the mercapto-group, which can be represented quantitatively by the dissociation constant K_a^{SH}: effective compounds with this structure should have pK_a^{SH} = 7.7–8.7 (the value of this exponent for 2-aminoethanethiol is 8.2).

The information in the following Section may serve to confirm that the presence of an amino-group or other nitrogen-containing function is not necessary for the development of a high protective effect, not only in the aminoethanethiol type of compound but also in sulphur-containing compounds in general.

III. OTHER SULPHUR-CONTAINING COMPOUNDS

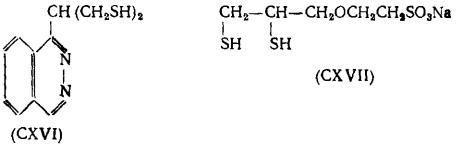
Protective agents have been found during recent years among sulphur-containing compounds of non-aminothiol structure—thiols, thiosulphates, sulphides, di- and trisulphides, dithiocarboxylic acid derivatives, sulphoxides, sulphones, etc.



(CXII) (CXIII) (CXIV) (CXV)

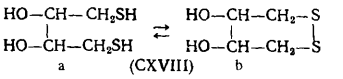
a R=CN, b R=Ph, c R=COOEt

Mercaptoalkyl derivatives of phthalazine (CXII) exhibit slight protective activity[84]. The 5,6-dihydro-3-mercapto-5-oxotriazine (CXIII) is moderately protective[85].



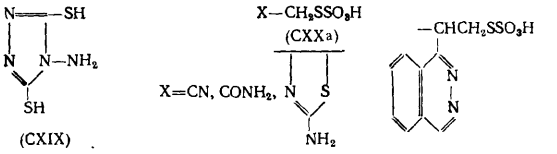
(CXVI) (CXVII)

Several studies have been made of the action of various dithiols against radiation. Foye showed[86] that, in contrast to the inactive dimercaptomethylenemalononitrile (CXIVa), the unsaturated mononitriles (CXIVb, c) develop appreciable protective activity. A slight increase in the survival rate of irradiated mice was produced by the prophylactic administration of racemic dimercaptosuccinic acid and its *meso*-form (CXV)[87]. A comparatively slight protective effect was observed with the dithiols (CXVI)[84] and (CXVII)[88].



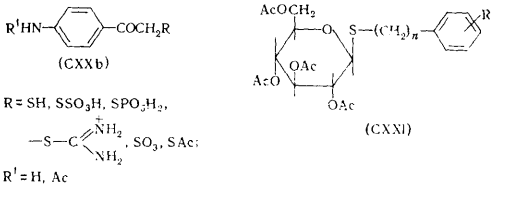
a (CXVIII) b

The attention of radiobiologists has been attracted during recent years to dithiothreitol (CXVIIIa)[89–92], which exists in the less toxic[90] cyclic form (CXVIIIb). It was relatively ineffective as a protective agent. Better results were obtained by its medicinal use under the experimental conditions. The *D*-isomer is more active than the *L*-form[91]. The di-*O*-acetyl derivative of (CXVIII) has a weak protective action[92].



(CXIX) (CXXa)

Some increase in the survival rate of irradiated mice was observed when the aminotriazoledithiol (CXIX) was used[93].

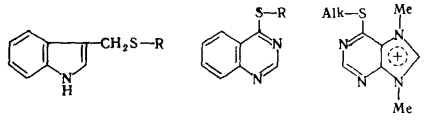


(CXXb) (CXXI)

R = SH, SSO_3H, SPO_3H_2, —S—C(=$\overset{+}{N}H_2$)—NH_2, SO_3, SAc;

R′ = H, Ac

No activity has been discovered among various types of compounds (CXXa) containing a thiosulphuric acid residue[30,79,84]. Kostyukovskii et al.[94] showed that, in a series of *p*-aminobenzoylmethanethiol derivatives (CXXb), a pronounced protective action was exerted by the phosphorothiolate and the compound containing an *S*-acetyl group.

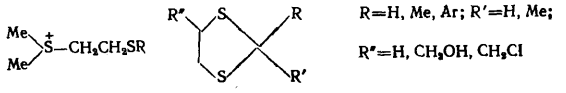


(CXXII) (CXXIII) (CXXIV)

Several compounds of sulphide structure have been studied. Ishiguro et al.[95] found moderate protective action in certain thioglycosides of type (CXXI), of which the most active had R = H and $n = 1, 2$. In the search for protective agents several sulphides were synthesised with heterocyclic and aryl groups of the types (CXXII)–(CXXIV)[96–98].

(CXXV) (CXXVI)

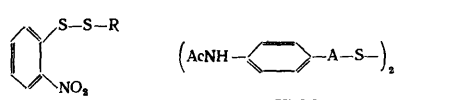
Thien-2-ylmethanol (CXXV), a cyclic analogue of mercaptoethanol, can be included formally among sulphides. A freshly prepared specimen has a weak protective action[99], but after standing for 1 month or exposure to a 1000-W lamp for 18 h this substance shows a fairly strong protective effect. It was assumed[99] that polymerisation occurred under these conditions. Bitoun et al.[100] prepared 13 cyclic analogues of mercaptoethanol of a different type: among these oxathiolans (CXXVI) only the 2,2-dimethyl, 5-chloro-2,2-dimethyl, and spirocyclohexane derivatives exhibited a protective effect of 20–50% on mice.



(CXXVII) (CXXVIII)

R=H, Ac

Prophylactic introduction of ethane-1,2-dithiol derivatives (CXXVII) produced a slight increase in survival rate of irradiated mice[14]. A detailed investigation of the protective properties of > 30 dithiolans (CXXVIII)—cyclic analogues of ethane-1,2-dithiol—has shown[101] that they include compounds that ensure 50–80% survival of mice after intraperitoneal doses close to $\frac{1}{2}LD_{50}$, when animals in a control group are completely destroyed. These are aryl derivatives (R′ = R″ = H; R = Ar) containing a phenyl, a *p*-chloro-, *p*-hydroxy-, or *p*-methoxy-phenyl, or a *p*-tolyl substituent at the 2 position in the ring.



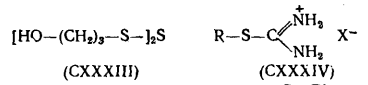
(CXXIX) (CXXX)

A=CH_2CH_2, CH_2CO, COCH(Me)

Several disulphides and their derivatives have been prepared, and their protective activity has been studied. The absence of biological data prevents assessment of the prospects for unsymmetrical aryl disulphides (CXXIX)[102], disulphides of type (CXXX)[103], or disulphides of the pyrimidine series[104] as protective agents.

(CXXXI) (CXXXII)

High protective activity in experiments on mice was shown by the symmetrical disulphide (CXXXI), which is a derivative of butanesulphinic acid[29]. An intraperitoneal dose of 200 mg kg^{-1} (LD_{50} = 800 mg kg^{-1}) protects 73% of mice that have been irradiated with the absolutely lethal dosage ($I_{ip} \simeq 7$). The corresponding trisulphide (CXXXII) was a still more efficient protective agent[29]. While possessing low toxicity (both intraperitoneal and oral LD_{50} = 900 mg kg^{-1}), this compound at an intraperitoneal dose of 38 mg kg^{-1} is claimed to protect 78% of mice when a control group undergoes absolute destruction ($I_{ip} > 41$), and an oral dose of 300 mg kg^{-1} ensures complete survival of the animals ($I_{or} \simeq 6$). Bis-3-hydroxypropyl trisulphide (CXXXIII) has shown[105] a slight protective effect in experiments on mice.



(CXXXIII) (CXXXIV)

a—R=Et

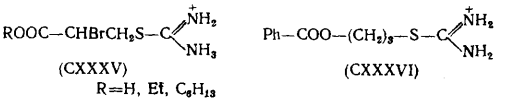
Several papers have appeared on the search for protective agents among alkylthiouronium derivatives, analogues of ethylthiouronium (Etiron, CXXXIV), which exerts a quite pronounced effect. According to Zherebchenko and his coworkers[106] the size of the alkyl group in compounds of this type has a significant influence on the protective activity (Table 10), whereas the nature of the anion plays no special part. It was suggested that Etiron differs from amino-thiols in the mechanism of its protective action. Mukhin et al.[107] supposed that tissue hypoxia underlay the mechanism of protection by Etiron. They report that, in experiments both on mice and on rats, this compound considerably surpasses *S*-2′-aminoethylthiouronium in efficiency.

Table 10. Effect of size of alkyl group in compounds (CXXXIV) on their protective properties[106].

CXXXIV R	Survival of mice, %
Me	40.0
Et	49.0
n-Pr	37.6
n-C_9H_{19}	2.8
Control	1.8

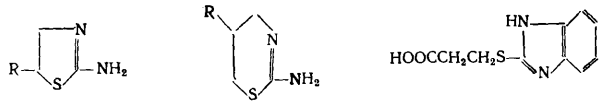
In order to examine the effect of the structure of the *S*-alkyl substituent and of the anion Mizrakh et al.[108] studied several phosphorus-containing alkylthiouronium derivatives both at a cellular level and in experiments on mice with prolonged irradiation (dosage rate 5.8 rad min^{-1}). All the compounds were significantly superior in protective activity to Etiron, which hardly protected the animals at all under these conditions; it was thought that this might be due to the duration of irradiation. The most active compounds were *S*-n-butylthiouronium n-butyl

hydrogen phosphite (CXXXIV: R = C_4H_9 and X = $C_4H_9OPHO_2$) and *S*-ethylthiouronium diethyl orthophosphate (CXXXIV: R = C_2H_5 and X = $(C_2H_5O)_2PO_2$), which ensured the protection of 70–80% of mice and acted against radiation at the chromosomal and cellular level[108].



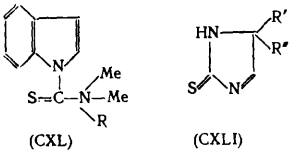
(CXXXV) R=H, Et, C_6H_{13} (CXXXVI)

Slight activity was shown by thiouronium derivatives of α-bromopropionic acid and its esters (CXXXV)[82,109] and also by 3′-benzoyloxypropylthiouronium (CXXXVI)[109]. 2-Acyloxypropyl and other derivatives of thiouronium were inactive.



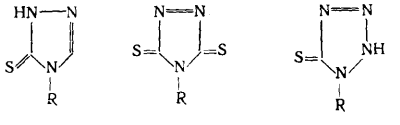
(CXXXVII) R=H, Me, CH_2OH, Br (CXXXVIII) R=H, Cl, Br (CXXXIX)

The protective action of several cyclic analogues of thiouronium of the types (CXXXVII) and (CXXXVIII)[82,110] and (CXXXIX)[79] has been studied. The most interesting results were obtained with 2-aminothiazoline (CXXXVII: R = H)[110]—a possible conversion product of aminothiouronium in the organism—and also for certain of its 5-substituted derivatives, which approach aminoethylthiouronium in efficiency on prophylactic intraperitoneal administration.



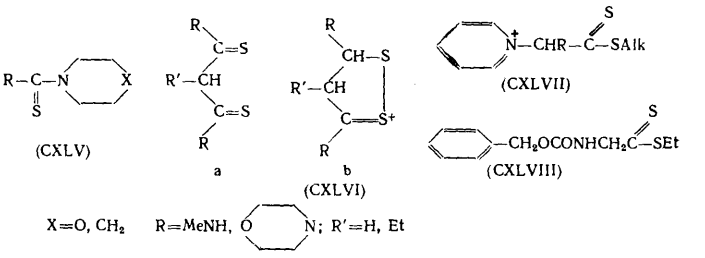
(CXL) (CXLI)

Thiourea derivatives containing a quaternary nitrogen atom (CXL), which are similar in structure to thiouronium compounds, were prepared by Tulecki et al.[111] to study their action against radiation. Here we can also mention cyclic analogues of thiourea—derivatives of imidazole (CXLI)[49,112], triazole (CXLII) and (CXLIII), and tetrazole (CXLIV)[113]—which are able to exist in the tautomeric thiol form. The most efficient were the *p*-halogenoaryltetrazolethiones (CXLIV: R = *p*-HalC_6H_4).



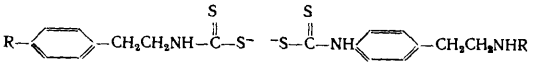
(CXLII) (CXLIII) R=Ar (CXLIV)

Several other compounds containing a thiocarbonyl group were studied in the search for protective agents. Bitoun et al.[114] studied the action against radiation of several morpholino- and piperidino-thioamides (CXLV), and found that only a few of them had a slight protective effect. Similar results were obtained for a series of dithioamides (CXLVIa). Cyclic analogues of the latter—1,2-dithiolium derivatives (CXLVIb)—only slightly surpass in activity (survival of mice at most 30–40%) the initial thioamides[115].



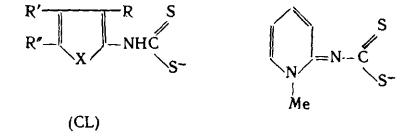
(CXLV) a b (CXLVI) X=O, CH_2 R=MeNH, O N; R′=H, Et (CXLVII) (CXLVIII)

Great attention has been paid during recent years to the search for protective agents among dithiocarboxylic acid derivatives. This line of attack was developed especially intensely by Foye and his coworkers, who showed that substituted derivatives of pyridinodithioacetic acid (CXLVII)[116] and the analogue (CXLVIII)[93] were moderately active in experiments on mice.

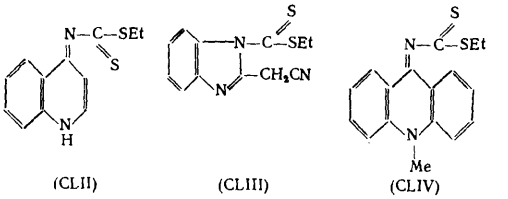


a (CXLIX) b

Several dithiocarbamates have been prepared and studied. No protective activity was detected in two types of derivatives of dithiocarbamic acid based on phenylethylamine (CXLIXa, b)[117], as well as in furan and thiophen derivatives (CL)[118]. It was shown for 1′-methylpyrid-2′-yldithiocarbamic acid (CLI)[119] that dithiocarbamates of the stronger bases have a more pronounced protective effect, though the percentage survival of mice when this compound is used as the 2-amino-1-methylpyridinium salt is not high. Dithiocarbamates of the corresponding 4-imino- and 2-imino-1-methyl-pyrimidines exhibit no protective activity. Among dithiocarbamic esters of 4-amino-2-methylquinoline (CLII), benzimidazole (CLIII), and 9-amino-10-methylacridine (CLIV) only the last showed action against radiation[120].

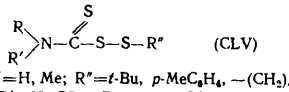


(CL) X=O,S; R=CN, COOEt; R′=H, Me, Ph (CLI)



(CLII) (CLIII) (CLIV)

Field and his coworkers found[76,121] that some of the trithiocarbamates studied by them (CLVa, b) possess quite pronounced protective activity when introduced in large doses.



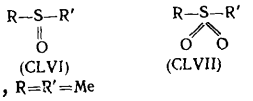
(CLV)

R=R′=H, Me; R″=*t*-Bu, *p*-MeC_6H_4, $-(CH_2)_4SO_2Na$

a R=R′=H, R″=*t*-Bu; b R=R′=Me, R″=*t*-Bu

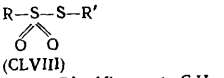
Tulecki et al.[111,122] synthesised several heterocyclic arenesulphinamide derivatives, but gave no data on their protective action.

Studies have continued on the protective action of diammonium phosphoramidothioate[123-125] and its analogues[123], which exhibited little or no activity.



(CLVI) a, R=R′=Me (CLVII)

Compounds containing quadrivalent and sexivalent sulphur have also been studied—as well as bivalent compounds—for use as protective agents. It had earlier been shown[3] that dimethyl sulphoxide (CLVIa) has a protective action against the general irradiation of mice. Arzamastsev et al.[126] studied 40 analogues of this compound (CLVI) and of sulphones (CXVII) with alkyl, ethylenic, vinyl, and acetylenic groups. Only three of these compounds—(CLVI: R = CH_2:CH and R′ = CH_2:CH.SO.$[CH_2]_2$), (CLVI: R = R′ = t-C_4H_9), and (CLVII: R = CH_3 and R′ = CH_2:CH)—had a moderate action against radiation in doses of 33–50% of LD_{50}. Certain thiosulphones (CLVIII) were inactive[64].



(CLVIII) R=Me, p-MeC_6H_4; R′=Alk, cyclo-C_6H_{11}

A comparative study has been made during recent years of the protective action of the selenium analogues of certain sulphur-containing agents[127-129]. Selenourea protects mice more effectively than does thiourea. The protective action of the selenium analogue of cysteine and certain other selenium compounds is at the same level or even higher, but they are considerably more toxic than the corresponding sulphur compounds.

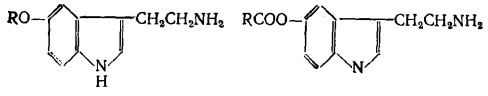
Thus a few highly efficient protective agents, developing activity on intraperitoneal and oral administration in an experiment, have also been discovered among the many (~ 300) sulphur-containing compounds of non-aminothiol structure studied as protective agents against radiation.

IV. HETEROCYCLIC COMPOUNDS

The search for protective agents has been made among nitrogen-containing heterocycles during the past five or six years, as in previous years. Among them derivatives of indole have attracted the greatest attention.

Indolylalkylamines

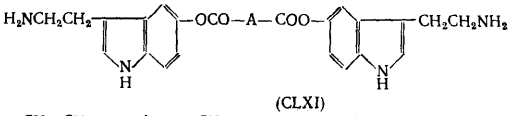
Comprehensive investigations on methods for the synthesis of indolylalkylamines and on their antiradiation properties, made in our country during recent years by Suvorov, Zherebchenko, Semenov, Ermonenko, Shashkov, Antipov, and others[130], led to the production of the protective preparation Mexamine (CLIXa), a close analogue of serotonin (CLIXb), and formed the basis for a further successful search for protective agents in this series of compounds. The study was continued of *N*-peptide derivatives of indolylalkylamines, which showed a marked protective effect (survival of mice 40–60%).[130]



(CLIX) (CLX)

a R=Me (Mexamine)
b R=H (Serotonin)
c R=Et

Investigation of the protective properties of a large number of *O*-acyl derivatives of serotonin (CLX)[130-133]—acyl analogues of Mexamine—showed that the introduction of residues of saturated aliphatic acids at the phenolic hydroxyl does not diminish the protective action in comparison with serotonin or Mexamine. Lengthening of the carbon chain in the acyl substituent is accompanied by enhancement of toxicity. Both in the pronounced character of their protective effect and in its duration these compounds are hardly distinguishable from serotonin. Also, like serotonin, they possess little antiradiation activity when taken. *O*-Aroyl and urethane derivatives (CLX: R = CH_3NH, p-ClC_6H_4NH) have a weaker protective effect.

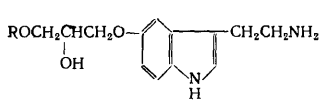


(CLXI)

a A = —CH=CH—, b A = $-(CH_2)_2-$, c A = $-(CH_2)_4-$, d A = $-(CH_2)_8-$

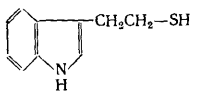
e A =  , f A = 
Several other derivatives of serotonin have been prepared and studied in order to find among indolylalkylamines protective agents of prolonged action and active on oral administration. Interesting results have been obtained for diesters (CLXI) formed by dicarboxylic acids—fumaric, adipic, sebacic, terephthalic, and biphenyl-*pp*′-dicarboxylic—with serotonin[132]. These compounds also are the equal of serotonin and Mexamine in protective activity. Their toxicity is on the average several times higher than that of the latter. When introduced into mice at different times before irradiation, they exhibited more prolonged action against radiation than did serotonin or Mexamine. Data for several of these compounds show (Table 11) that the most efficient as a protective agent is that derived from succinic acid (CLXIb), with $I_{ip} = 20$. Compounds (CLXId, e) retain their high protective properties for 1 h, in contrast to Mexamine and serotonin. When taken orally the bis-*O*-acyl derivatives, like the monoacyl compounds, exert a slight protective effect.

Addition of a glycerol molecule to tryptamine at position 5 of the indole ring (CLXIIa)[132] enhances the effectiveness of tryptamine against radiation. Prophylactic application of this compound gives 60% survival of mice with 92% mortality of animals in a control group. Replacement of the γ-hydroxyl by an alkoxy-group (CLXIIb) does not enhance the antiradiation properties, and introduction of a hydroxyethyl group (CLXIII) leads to a loss of activity. The *O*-glucoside of serotonin and derivatives of 3-dialkylamino-3-deoxy-analogues of 1-indol-3′-ylglycerol were ineffective[133].

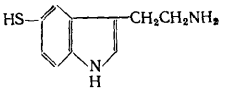


(CLXII) a R=H, b R=Alk
(CLXIII) R=HO—$(CH_2)_2$—

Comparing protective activities in experiments under the same conditions, Deanovič showed[134] that serotonin somewhat surpasses Mexamine, and 5-ethoxytryptamine (CLIXc) is inferior to both. He even[135] discovered that the thiol analogue of tryptophol (CLXIV) and the corresponding disulphide exerted no strong action against radiation, whereas 5-mercaptotryptamine (CLXV) protected mice only slightly more weakly than did serotonin, even with a superlethal dose of radiation.



(CLXIV)



(CLXV)

Table 11. Protective properties of serotonin, Mexamine, and their analogues (CLXI)[132].

CLXI A	Doses, mmole kg^{-1}		Time to irradiation, h	Survival, %	I_{ip}

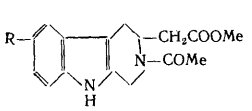
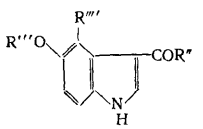
		0.30	0.3	33.3±12.2	
		0.10	0.3	0	
Serotonin		0.04	0.1	64.0±11.3	
		0.150	0.3	0	
		0.40	0.3	6.7±6.5	

From tryptophol Japanese workers[136] prepared several compounds of tryptamine structure, including tricyclic compounds, e.g. (CLXVI), but they did not report results of their biological tests.



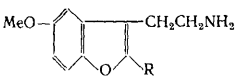
(CLXVI)



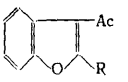
(CLXVII)

Among the many (~ 100) indole compounds studied of type (CLXVII), containing a 3-carbonyl group, Shadurskii and Maksimenko[137] were unable to find any which would protect irradiated mice by more than 20–30%. These workers and also Il'yuchenko et al.[138] studied the protective activity of several types of benzofuran compounds (CLXVIII–CLXX), which are isosteric with indole compounds and include an analogue (CLXVIII) of Mexamine.

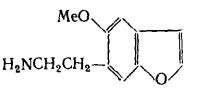
Most active among them (40% protection) was the aminoethyl derivative (CLXX)[138].



(CLXVIII)

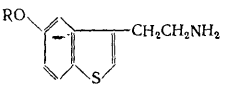


(CLXIX)

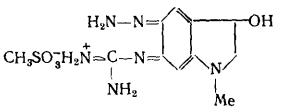


(CLXX)

According to Deanovič[135] the benzothiophen analogue (CLXXIa) of Mexamine has no action against radiation at all, whereas the isostere (CLXXIb) of serotonin is closely similar in efficiency to the latter, becoming inferior only at superlethal radiation doses[135,136].



(CLXXI a R=Me, b R=H)

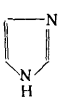


(CLXXII)

Japanese workers[139,140] made a detailed study of the protective properties of 5-hydrazonoadrenochrome-6-guanidinium methanesulphonate (CLXXII), which is a modification of an indoline metabolite. This relatively non-toxic compound (subcutaneous LD_{50} = 1834 mg kg^{-1}) shows a pronounced action against radiation in small doses of ~ 5 mg kg^{-1}. Under the name "S-adchnon" this protective agent, which acts on haemapoietic organs, has been proposed for clinical application to diminish the harmful effect of irradiation during the X-radiotherapy of human beings.

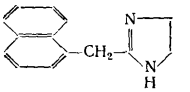
Other Nitrogen-containing Heterocycles

Investigation of the protective activity of imidazole (CLXXIII) and its derivatives has continued during recent years[141–143]. An intraperitoneal dose of imidazole itself of 350 mg kg^{-1} introduced 5 min before irradiation protects ~ 80% of mice; introduction 4½ h before and 1 min after irradiation halves the protective effect. Benzimidazole (CLXXIV) and 2-naphth-1'-ylmethylimidazoline (CLXXV)—the latter is the well known medicinal Naphthisin—are just as active[143].



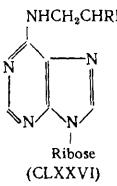
(CLXXIII)

(CLXXIV)

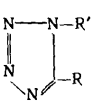


(CLXXV)

It has been reported that diphenylhydantoin improves the radiation resistance of mice[144], and that 3-hydroxypyridine derivatives have high protective activity[145].



(CLXXVI)



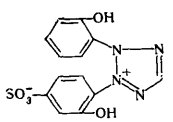
(CLXXVII)

a R=H, R'=ClC$_6$H$_4$;

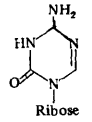
b R=NHNH$_2$, R'=Ph

Interesting results were obtained for the protective action of 6-substituted adenine ribosides (CLXXVI)[146]. In small doses compounds of this type with various substituents in the ethylamino-chain (R = H, CH_3; R' = CH_3, OH, NH_2, SH, CH_2NH_2, CH_2OH) show a well defined effect against radiation. Ribosides of 6-hydrazino- and 6-methylthio-purines were inactive, as were analogues

(CLXXVI) having the ethylamino-chain at position 8 in the ring system.



(CLXXVIII)



(CLXXIX)

Action against radiation has been observed also among tetrazoles. The most active were 1-chlorophenyl derivatives (CLXXVIIa), as well as 5-hydrazino-1-phenyltetrazole (CLXXVIIb)[146] and 2-*o*-hydroxyphenyl-3-2'-hydroxy-4'-sulphophenyltetrazole (CLXXVIII).

Czech workers[147] showed that certain aza-derivatives of pyrimidine have a protective effect in small doses. The highest survival rate of mice (55%) was observed with 5-azacytidine (CLXXIX) introduced 24 h before irradiation. The protective action was attributed[147] to a favourable effect on the proliferation of the stem cells responsible for repopulating bone marrow.

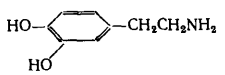
Protective action has been reported for thiamine[148], which contains pyrimidine and thiazole rings, derivatives of tetrahydropteridine[149], and haematoporphyrin[150].

V. COMPOUNDS OF DIVERSE STRUCTURE

Amino-compounds

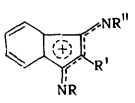
Protective action has been reported[151] in propylenediamine and in 2-methylpropylenediamine. *p*-Alkoxyphenylethylamines (CLXXX) exhibit activity against radiation[152], which diminishes with increase in the length of the hydrocarbon chain from C_4 onwards. The most active was *O*-methyltyramine (CLXXXa), which in an intraperitoneal dose of 50 mg kg^{-1} gave survival rates of 47–75% of irradiated mice (dosage rate 400–600 rad min^{-1}). Oral administration of this compound protects up to 40% of animals. The protective activity disappears when one or two amino-hydrogen atoms are replaced by alkyl or acyl. Il'yuchenko et al.[153] found that *O*-methyltyramine has the average action against radiation when mice are irradiated at rates of 2400, 216, and 65 rad min^{-1}, and they investigated the prophylactic protective activity of tyramine and its *O*-alkyl derivatives when mice were exposed to 10 rad min^{-1}. Under these conditions the *O*-pentyl and *O*-dodecyl derivatives (CLXXX: R = $C_5H_{11}O$, $C_{12}H_{25}O$) were more effective.

(CLXXX) a R=MeO

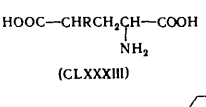


(CLXXXI)

Detailed investigation of the prophylactic protective action of dopamine (CLXXXI) showed[154] that a dose of 100 mg kg^{-1} protects ~ 60% of irradiated mice.



(CLXXXII)



(CLXXXIII)

R = F, Et_2NCH_2–, , $(HOCH_2CH_2)_2N$–

Salts of 1-amino-3-iminoind-2-enes (CLXXXII) diminish the genetic damage in *Drosophila* caused by irradiation[155].

Protective activity was observed in certain γ-substituted glutamic acids (CLXXXIII)[84].

(CLXXXIV) a R=H, b R=OH

The study of analogues of *p*-aminopropiophenone (CLXXXIVa) has continued during recent years. *p*-Hydroxyaminopropiophenone (CLXXXIVb), a possible metabolite of (a), possesses approximately the same protective effect[156]. Vladimirov et al.[157] studied several aminopropiophenone and aminobenzophenone derivatives (Table 12), and showed that the action of most of them against radiation was directly dependent on their ability to form methaemoglobin, which requires the presence of a free amino-group in the molecule. These compounds include substances with a moderate protective action without causing the development of methaemoglobinaemia in the animals. Table 12 lists some of the most active compounds of this type.

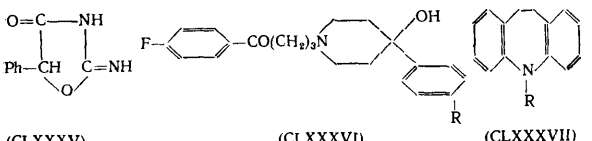
Table 12. Protective properties of aminopropiophenones[157].

Compound	Dose, mmole kg^{-1}	Survival, %
CLXXXIV a	0.2	60
CLXXXIV b	0.2	65
p-$H_2N-C_6H_4C(=NOH)Et$	0.25	60
o-$H_2N-C_6H_4COEt$	1.5	45
p-$H_2N-C_6H_4COEt$	0.5	75

Intraperitoneal introduction of phenylhydrazine 5–8 days before irradiation of mice resulted in a high survival rate[158].

Psychotropic Agents

These agents include compounds of diverse chemical structure exerting a prophylactic effect against radiation and those which are psychotropic medicinals. Slight protection is shown by the magnesium complex of Azoxodone (CLXXXV), a stimulant of the central nervous system[159]. The activity drops sharply in the absence of magnesium. Uray and his coworkers[160,161] studied the protective activity against radiation of tranquilisers of the Haloperidol series (CLXXXVIa). Intravenous injection of one of these preparations—Movotren (CLXXXVIb), which contains *p*-tolyl instead of a *p*-chlorophenyl substituent—into mice after 30 and 60 min protects up to 60–70% of the animals. The same workers[162] discovered that antidepressants—Imipramine and Trimipramine (CLXXXVIIa, b)—are able to increase the survival rate of irradiated mice.



(CLXXXV)

(CLXXXVI) a R=Cl, b–R=Me

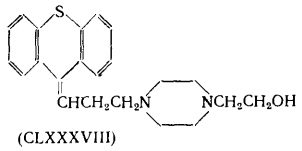
(CLXXXVII) a R=$-CH_2CH_2CH_2N(Me)_2$ b R=$-CH_2CH(Me)CH_2N(Me)_2$

According to Locker et al.[163,164] certain thymoleptics of phenothiazine and thioxanthen structure develop a marked

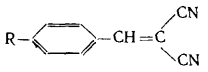
protective effect against radiation, which is strongest with Sordinol (CLXXXVIII). The effectiveness of this preparation was found to increase up to a certain limit with increase in the time between administration and irradiation.

Various Compounds

Among the > 40 nitriles and isothiocyanates studied, only the malononitrile derivative (CLXXXIX) exhibited a weak protective action in experiments on mice[165]. Activity against radiation was shown by diphenylmethanol derivatives with dimethyl- and diethyl-amino-groups in one and two benzene rings[166] and by 1-hydroxy-2-dimethylallylmethylamino-4-butylphenol[167]. *cis*-Dichlorodiammineplatinum develops a protective action in small doses: introduction into mice 1 and 24 h before irradiation produced a survival of 70%.[168]



(CLXXXVIII)



(CLXXXIX)
R=H, OH, Cl

Summarising, we may conclude that a vigorous search for protective agents against radiation has been made during the past 5–6 years among compounds of diverse structure. Most of the almost 1500 substances studied were sulphur-containing compounds, predominantly of amino-thiol structure. Considerable progress has been made during these investigations, the most important advances being listed below.

1. Compounds of high activity against radiation under the experimental conditions and possessing great therapeutic latitude have been prepared.
2. Highly efficient protective agents for oral administration have been found under the experimental conditions.
3. Comprehensive information has accumulated on the influence of the chemical structure of various classes of compound on their protective activity.

The main result must be to confirm and to provide a firmer basis for the possibility and promise of chemical protection of the living organism from ionising radiation.

Negative Ions of Tetrapyrrole Compounds

A.N.Sidorov and V.G.Maslov

The mechanism of the formation of negative ions of phthalocyanine, porphyrins, and their metal derivatives is discussed, together with the effects of the tetrapyrrole ligand and the metal atom on the properties of the ions. The nature of the metal has a significant influence on the electronic structure of the negative ion, and thus on its properties, in particular its protonation, photoelimination of an electron from the ion, and its catalytic activity. Photodetachment of an electron combined with the spectral characteristics of the ions is considered as a method for investigating ionic forms. The Review concludes with a list of 132 references.

I. INTRODUCTION

Ideas on intermolecular charge transfer in organic systems and on the properties of ions of aromatic compounds developed in a comparatively orderly sequence: extensive experimental results fitted well into the framework of theoretical concepts, quantum-mechanical calculations consistent with observation were made for the simplest and most characteristic cases, and comprehensive reviews and monographs were written[1-13]. The structural features of porphin molecules—the presence of heteroatoms and a tetrapyrrole ring of conjugated bonds, high symmetry, the possibility of coordinating a metal atom into the molecular structure—combined with the well known role of certain naturally occurring members of the series in biochemical processes have invariably attracted the attention of research workers to charge-transfer phenomena involving porphin derivatives. However, it is these structural features, which are obviously responsible for the extraordinary variety of properties of porphin derivatives, that make their investigation difficult and prevent the application to them of the general ideas developed from the examination of ions of aromatic compounds. Without considering all aspects of the problem we shall make a preliminary summary of researches on the negative ions of some of the simplest porphyrins. We shall not make a systematic survey of all the relevant literature but shall reply predominantly on recent results, which are relatively free from the errors and discrepancies inevitable in the early work.

The negative molecular ion Por^{n-} is formed from the neutral molecule Por of a porphin derivative by the successive addition of electrons. These ions can be generated by the same methods as the anions of aromatic compounds [2,6,9]. A chemical method is most often adopted, by introducing into the solution as electron donor either an alkali metal or an anion formed by its interaction with an aromatic compound possessing a smaller electron affinity than the porphin molecule. Almost 100% yields of anions have been obtained by this method from phthalocyanine, several porphyrins, and their metal derivatives. Good results are obtained by the electrochemical method, equally applicable to the generation of negative and of positive molecular ions. The method is almost indispensable when alkali-metal ions must not be present.

The first experiments on negative ions of porphins were made by Shablya and Terenin, who measured the electronic absorption spectra of the monoanions formed when magnesium phthalocyanine was treated with sodium in oxolan [14,15]. Almost simultaneously Watt and Dawes [16] examined by X-ray diffraction the products formed by copper phthalocyanine with potassium in liquid ammonia. These workers said nothing about the ionic character of the products, although now, of course, this is not open to doubt. The investigations were subsequently extended to anions of other metal phthalocyanines, and also to metal tetraphenylporphins and metal aetioporphyrins. In spite of several correct observations and conclusions in the early papers, the latter were often contradictory, which can be attributed to unavoidable errors due to the absence of reliable criteria of the purely ionic character of the reduction products of tetrapyrrole compounds, criteria of their purity, and reliable methods for identifying them. A difficulty in identifying and investigating tetrapyrrole anions was that electron spin resonance—one of the main methods for investigating ions of aromatic compounds—provided relatively little information. The e.s.r. spectra of tetrapyrrole anions are usually narrow singlet lines devoid of hyperfine structure [17-21]. In the few cases in which structural e.s.r. spectra were obtained [22-24] their interpretation gave rise to difficulties. Nevertheless, detection of a structureless e.s.r. signal is useful as proof of the radical (though not necessarily ionic) nature of the product, and is regarded as evidence of delocalisation of the electron in the conjugated system of the tetrapyrrole ligand [18]. Many uncertainties and contradictions were removed by a series of investigations in which spectral examination of negative tetrapyrrole ions *during their formation* were immediately followed by experiments on the photochemical detachment of an electron from the resulting ions [20,21,25,26].

II. PHOTOCHEMICAL DETACHMENT OF AN ELECTRON FOR THE STUDY OF NEGATIVE IONS

Like anions of aromatic compounds [27] those of tetrapyrrole derivatives are able to eliminate electrons photochemically [25]:

$$Por^{n-} \xrightarrow{h\nu} Por^{(n-1)-} + e^{-} .$$

This process converts a molecular anion either into an anion of smaller charge or (when $n = 1$) into a neutral molecule. For example, ultraviolet exposure of a solution of magnesium phthalocyanine monoanions in a mixture of oxolan and diethyl ether at −196°C (this mixture freezes as a transparent, vitreous mass) converts them into neutral molecules, which can easily be followed from the variation in the absorption spectra: disappearance of the bands due to the monoanion and the appearance of those due to the neutral molecule are accompanied by the appearance of a characteristic broad band with its maximum at 1240 nm, corresponding to electrons detached from the monoanions and stabilised in intermolecular potential traps in the matrix [28].

Photoelimination of an electron from an anion is reversible: when the frozen solution melts, the stabilised electrons escape from the traps and charge the molecules to the original level. The reverse reaction can also be achieved photochemically by illuminating the frozen specimen in the region of absorption by the stabilised electron ($\lambda > 700$ nm). Such exposure results in complete disappearance of the band due to the stabilised electron, but only a proportion of the electrons liberated from the traps add to magnesium phthalocyanine molecules. Some of the electrons probably fall into deeper traps, in which they do not exhibit their own absorption bands (at least in the experimentally accessible spectral region). Electrons captured in such traps also escape when the specimen melts, add to magnesium phthalocyanine molecules, and charge the latter to the original level.

Photoelimination of the first electron from a multicharged ion usually requires a smaller light quantum than does photoelimination from a monoanion. However, complete discharge of the magnesium phthalocyanine dianion to the neutral molecule is far more difficult than discharge of the monoanion. Detachment of the first electron obviously results in a net positive charge in the matrix cell formed by the molecular anion, the positive gegenions interacting with it, and the solvate sheath surrounding them, and it is now considerably more difficult to remove a second electron. Tetra-anions of certain metal phthalocyanines split off the first electron even under the influence of visible light, ultraviolet exposure gives dianions, but no further photoelimination of electrons is observed. These experiments indicate that the matrix potential traps in which the photoeliminated electron is located lie outside the ionic association complex comprising the anion, positive gegenions, and the solvate sheath surrounding them.

Photorelease of an electron has been observed also in other vitreous matrices, e.g. in an equimolecular mixture of oxolan and dimethylformamide. Here the photodischarge of ions was not accompanied by the appearance of a band due to the stabilised electron, and the reverse reaction occurred only when the specimen was thawed [26]. The liberated electrons may be localised in intramolecular traps due to the presence of vacant molecular orbitals in the dimethylformamide molecules.

Photodetachment of an electron, similar to that described above for multicharged magnesium phthalocyanine anions, has been observed also with negative ions of several other metal phthalocyanines and metal porphyrins [20,21,25,26].

The appearance of stabilised electrons in the matrix accompanied by formation of neutral magnesium phthalocyanine molecules when monoanions are irradiated is sufficient proof that these monoanions are a purely ionic species, differing from the neutral molecules only in the presence of an additional electron. The purely ionic structure of multicharged magnesium phthalocyanine ions is proved by a comparison of the absorption and e.s.r. spectra of products of successive stages of one-electron reduction and their photochemical discharge.

More detailed investigations have established several special features of the photodetachment of an electron [26]. The longer-wavelength threshold of photodetachment

differs markedly with ions of different compounds. Impurities can be distinguished and sometimes identified from the absence of synchrony in the variation of absorption bands on photoelimination of an electron. Thus this phenomenon will give the missing proof of the ionic character of products of the reduction of tetrapyrrole compounds by alkali metals, and will yield reliable spectral characteristics for their identification and analysis.

A method of photoinduced dichroism is based on the photoelimination of an electron. It enables both the relative positions of the molecular oscillators in the anion (polarisation of electron transitions) and their distribution relative to those of the neutral molecule to be determined [29-33]. Such results are important for interpreting the electronic absorption spectra of the anions.

The essence of photoinduced dichroism is that, if a photochemical reaction (in the present case photoelimination of an electron from negative ions in a frozen solution) takes place in an isotropic solid medium under the influence of plane-polarised light, the medium becomes dichroic, since molecules (ions) appropriately oriented relative to the electric vector of the plane-polarised light are preferentially subject to photoconversion. Photoinduced dichroism lasts for a fairly long time in a frozen matrix, and it becomes possible to determine the spectral dependence of its characteristic parameter $\Delta D = D_{\parallel} - D_{\perp}$, where $D_{\parallel}$ and $D_{\perp}$ are the optical densities of the specimen measured in light polarised respectively parallel and perpendicular to the direction of polarisation of the light causing the photoreaction. If only three mutually perpendicular directions of polarisation of electronic transitions are possible owing to symmetry in the molecules (ions) (as occurs with porphyrins, phthalocyanine, and their metal derivatives), the direction of polarisation of transitions corresponding to absorption bands both of the starting material and of the photoreaction product can be determined in a coordinate system coincident with the molecular axes of symmetry. For this it is usually sufficient to determine the sign of ΔD in the given absorption band. This method has been used to determine the orientation of the dipole moments of electronic transitions in the monoanions of disodium complexes of chlorin and tetraphenylbacteriochlorin with respect to transitions of the neutral molecules (in a coordinate system unique to the molecule and the ion) [32,33].

III. ELECTRONIC STRUCTURE AND THE SPECTRA OF NEGATIVE IONS OF METAL PHTHALOCYANINES

The most detailed investigations have been made on the negative ions of metal phthalocyanines. Kholmogorov and Shablya [18] were the first to measure the e.s.r. spectrum of magnesium phthalocyanine monoanions and, from the form of the structureless narrow signal, suggested that the extra electron was delocalised over the cyclic conjugated-bond system of the tetrapyrrole ligand. Taube and his coworkers showed [34-41] that a metal phthalocyanine molecule may add successively 1–4 electrons on reaction with an alkali metal or with a benzophenone anion. They measured the magnetic susceptibility of the ions, made an elementary analysis of them, undertook LCAO-MO calculations to determine the electronic configurations of the metal phthalocyanine monoanions, and also studied the Mössbauer spectra of iron phthalocyanine anions. Unfortunately, none of their papers gives either optical or e.s.r. spectra. This omission makes it difficult either to compare the results with those of other workers or to reproduce them. Use of such a simple method as molecular orbitals for theoretical calculations of electronic configurations of complicated species containing transition-metal atoms is open to sceptism. In almost every individual case the calculations must be confirmed by experiment, which larely deprives the calculations of their predictive value. A recent attempt [42] to interpret the spectra of the mono-, tri-, and tetra-anions of magnesium phthalocyanine on the basis of calculations by the Pariser–Parr–Pople method, allowing for limited configuration interaction, omitted calculation of the intensities of the electronic transitions. Furthermore, agreement between calculated and experimental spectra of the mono- and trianions was obtained only on the hypothesis that the band of longest wavelength does not correspond to the transition of lowest energy among those predicted as allowed. There are no experimental grounds for such a hypothesis. Therefore the interpretation of the electronic spectra of the ions given by these workers cannot be accepted as reliable. Thus at the present stage theory plays only an ancillary part in relation to tetrapyrrole ions, and all the main conclusions, being based on a comparison of experimental results, are predominantly qualitative in character.

The problem in the electronic structure of metal phthalocyanine ions is essentially the location of the added electrons, since the nuclear configurations of ions and neutral molecules can be regarded to a first approximation as the same. The excess charge of the anion can in principle be located either on the central atom M or on the tetrapyrrole ligand, or shared between them in certain proportions. The hypothesis that the charge of the magnesium phthalocyanine monoanion is located on the ligand, which was based on e.s.r. data [18], has since found direct experimental confirmation in the close similarity between the electronic absorption spectra of the monoanions of magnesium and of metal-free phthalocyanines [43-45]. Comparison of the results of absorption spectroscopy, e.s.r. spectroscopy, and theoretical calculations shows that the electron is also located on the ligand in the monoanions of zinc, copper, and nickel phthalocyanines [19,22,23,37,43-48]. The monoanion of cobalt phthalocyanine has a different structure: although it is diamagnetic and therefore inaccessible to e.s.r. investigation, the close similarity of the electronic absorption spectra of the complex and its monoanion is sufficient to suggest that the electron is located on the cobalt atom in the latter [44,48,49]. The energy states of the principal chromophore of the molecule—the tetrapyrrole ligand—show little change, and the spectrum of the monoanion retains the main features of the neutral molecule. (Addition of an electron to the magnesium, copper, and nickel phthalocyanine molecules leads to significant spectral changes.) Taube's calculations [37] support the postulated location of the electron in the monoanion of cobalt phthalocyanine based on spectral data.

The absorption spectra of the dianions of metalfree, magnesium, nickel, and copper phthalocyanines, like those of the monoanions, depend little on the nature or even the presence of the metal atom in the molecule. This means that both electrons in the dianions are located in the tetrapyrrole system of the ligand [44-46,48]. The absorption spectra of cobalt phthalocyanine dianions are closer to those of the monoanions than those of phthalocyanine dianions (and the analogous metal phthalocyanine dianions). It may be assumed, in agreement with calculation, that one electron is located on the cobalt atom, and the other on the ligand.

The electronic structure of the monoanion of iron phthalocyanine may be considered separately. According

to Taube [37] the location of the extra electron in a metal phthalocyanine anion depends on the electronegativity of the metal atom. Thus nickel is the most electronegative of the iron-group metals, and in conformity with this its atom remains unchanged when its phthalocyanine complex is converted into a mono- or a di-anion, since both electrons are located on the ligand. Cobalt is intermediate in electronegativity, so that on reduction of its phthalocyanine complex the first electron goes to the cobalt atom, and the second to the ligand. Since the iron atom is the least electronegative, both electrons should be located on the iron atom when the phthalocyanine complex is reduced. However, the properties of a metal atom, including its electronegativity, may obviously change on coordination into the tetrapyrrole molecule. The absorption spectra of iron phthalocyanine anions show [49] that their electronic structure does not fit a simplified theoretical scheme: the spectrum of the monoanion in oxolan alone or mixed with diethyl ether differs both from that of the cobalt monoanion with its electron on the metal atom and from that of the nickel monoanion with a negatively charged ligand. It was suggested that the negative charge is shared between the iron atom and the ligand. In quantum-mechanical terms this may imply e.g. that the electron is located on a d-level of the iron atom, which is strongly mixed with a vacant π-electron level of the ligand as a result of their proximity. This suggestion has found experimental support, including aspects of the photodetachment of electrons from monoanions of various metal phthalocyanines. Ultraviolet exposure easily detaches the electron from the nickel phthalocyanine monoanion, in which it is situated on the ligand. Detachment of the electron does not occur with the complex cobalt monoanion. Iron phthalocyanine monoanion occupies an intermediate position: although photoelimination occurs, far more work is required than with the complex nickel anion.

Convincing evidence for the suggested location of charge in the iron phthalocyanine monoanion is given by the phenomenon of thermochromism which we have discovered with these ions [26,49]. In solution at temperatures close to $-196°C$ these ions are able to form unstable complexes with molecules of organic bases (pyridine, N-methylpiperidine, diethylamine, triethylamine), which decompose with rise in temperature and are re-formed on subsequent cooling. The changes in temperature are accompanied by changes in colour—blue at $-196°C$, but red at $-100°C$ and above (thermochromism). The absorption spectrum of the red solution is identical with that of iron phthalocyanine monoanion in the absence of bases. However, the spectrum of the blue solution, in which the ions are present as complexes with the molecules of bases, become similar in detail to that of the monoanion of nickel phthalocyanine, in which the negative charge is located on the ligand, as already stated. The molecules of the base, being oriented with their dipoles directed towards the iron atom on formation of the complex with iron phthalocyanine monoanion, obviously make complete localisation of the extra electron at the π-electron level of the ligand energetically favourable. Such a phenomenon would hardly have been possible if the electron were located on the metal atom; in any case, the presence of bases in solution produces no spectral changes in cobalt phthalocyanine ions involving localisation of the electron on the metal atom. As was to be expected, the iron phthalocyanine monoanion in the complex with a molecule of a base, while having the extra electron on the ligand, eliminates it on exposure just as easily as does the monoanion of nickel phthalocyanine.

A recent investigation of the Mössbauer spectra of the singly and doubly charged anions of iron phthalocyanine also indicates some distribution of negative charge between ligand and metal atom in these ions. These results were explained in terms of mixing of the d-orbitals of the iron atom with the π-orbitals of the ligand [40,41].

A point in connection with terminology and the nature of the problem is that it was supposed in some of the early publications [16,35] that the reduction of a metal phthalocyanine (MPhth) involves a change in valency ("state of oxidation") of the central metal atom. This was represented by such notation as

$$Co^{II}\,Phth \xrightarrow{e^-} Co^{I}\text{-}Phth;$$

$$Fe^{II}\text{-}Phth \xrightarrow{e^-} Fe^{I}\text{-}Phth \xrightarrow{e^-} Fe^{0}\text{-}Phth.$$

Watt and Dawes supposed [16] that the initial product of the reduction of copper phthalocyanine CuPhth by potassium is $Cu^{I}Phth$, followed by $Cu^{0}Phth$, the copper atom in the latter being coordinated with the ligand, not combined covalently. The results discussed above show that in actual fact the copper atom in the phthalocyanine complex plays no decisive part in the addition of electrons. Even when the electron is actually located on the metal atom, as in the formation of $[CoPhth]^-$, there are no grounds for assuming that this involves a change in the valency of the cobalt atom or the nature of its bond with the ligand. It would therefore be logical to cease denoting the primary reduced form of cobalt phthalocyanine by the formula $Co^{I}Phth$, as is done even now in certain papers, and to use the formula $[CoPhth]^-$ or even, when the location of the charge is to be emphasised, the formula $[Co]^-Phth$. Analogous notation should be used also for negative ions of all other tetrapyrrole compounds.

The problem of the electronic structure of multicharged metal phthalocyanine ions has been solved only in general outline. Absorption spectroscopy, e.s.r. spectroscopy, and electron photoelimination have shown that the molecules of most metal phthalocyanines are able to add successively up to four electrons with the production of purely ionic forms [25,26]. The possibility of adding such a number of electrons is attributed to the doubly degenerate lowest vacant π-orbital in the metal phthalocyanine molecule [47]. The presence of the central metal atom with a more or less independent system of energy levels also permits the addition of extra electrons. It is assumed, for example, that an additional vacancy on the cobalt atom makes it possible for cobalt phthalocyanine to exist in five negatively charged ionic forms [37,48]. We have previously cast doubt [44] on the existence of the fifth ionic form. Recently we have been able to obtain a fifth reduced form of this compound, having the same absorption spectrum as given by Clack and Yandle [48]. In contrast to most other $[MPhth]^{n-}$ ions investigated, including tri- and tetra-anions of cobalt phthalocyanine, however, this fifth reduced form was incapable of photoelimination of an electron, which gave serious grounds for doubting whether it actually had a purely ionic structure.

Calculations by the LCAO-MO method showed [36-41,47,50] that the third and fourth electrons added to a metal phthalocyanine molecule to form tri- and tetra-anions should be located in a doubly degenerate π-electron level of the ligand. However, experimental studies of the Mössbauer spectra [40,41] and electronic absorption spectra [44] suggest that the charge in multicharged metal phthalocyanine ions is distributed between the metal atom and the ligand. The close similarity of the absorption spectra of tetra-anions of different metal phthalocyanines (magnesium, nickel,

cobalt, iron) shows that the charge distribution in them is little affected by the nature of the metal.

Clack and Yandle assume that the presence of paramagnetism in trebly charged magnesium phthalocyanine anions indicates that all three extra electrons are located on the ligand. The corresponding cobalt complex anion has similar electronic absorption spectra and hence the same electronic configuration[48]. Thus these workers conclude that, on passing from the doubly to the trebly charged cobalt phthalocyanine anion, not only does the third electron add to the ligand, but the electron located on the metal in the singly and doubly charged anions also passes to the ligand. Such a phenomenon can actually result from change in the relative positions of the π-orbitals of the ligand and the d-orbitals of the metal atom when an electron is added to the system, where the raising of the d-orbitals should exceed that of the π-orbitals. As yet, however, such a change in the relative positions of the orbitals has neither a theoretical nor an experimental basis. It is more reasonable to postulate that the π-orbitals undergo a greater rise than do the d-orbitals on addition of an electron, and that localisation of the electron in the d-orbitals will become possible at some stage. Such a process can be assumed in the formation of trebly charged anions of magnesium and similar metal phthalocyanines, and it is then easy to explain the spectral similarity of the trianions of magnesium and cobalt phthalocyanines: they have the same electronic configurations, with (the larger) part of their charge located on the ligand, and the other part on the metal atom.

Without analysis of the structure of the e.s.r. spectra neither the presence nor the absence of paramagnetism will give any information on the location of the charge in an anion. For example, the unpaired electron in the paramagnetic copper phthalocyanine molecule is located on the copper atom, and the extra electron of the singly charged anion on the ligand, but, despite such spatial separation of the electrons, the monoanion as a whole is diamagnetic. The trebly charged magnesium phthalocyanine anion must be assumed to be paramagnetic independently of the location of the extra electrons, since they are distributed within a single system of energy levels.

Peculiarities may be noted in the behaviour of certain metal phthalocyanines on conversion into negative ions. The metal-free compound reacts with sodium to give a disodium complex, which can be reduced to ionic forms analogous in spectra and structure to those of the magnesium and zinc complexes[47]. Singly and double charged phthalocyanine anions could be obtained and examined spectroscopically during the photochemical reduction of phthalocyanine by hydrazine[43]. Copper in its phthalocyanine complex has a tendency to be replaced by sodium on reaction with the latter, but substitution occurs when the molecule adds a third electron. The optical and e.s.r. spectra of singly and doubly charged copper phthalocyanine anions indicate that their electronic structures are similar to those of the corresponding complex magnesium and zinc anions[46,47]. The replacement of copper by sodium at the third stage of reduction is indirect confirmation of the hypothesis that localisation of the charge on the metal atom takes place at this stage[44].

Manganese phthalocyanine, like the cobalt complex, yields five reduced forms on interaction with an alkali metal in oxolan[51]. The metal atoms in manganese and chromium phthalocyanines are able to change their valency easily and reversibly by adding various out-of-plane groups or molecules (hydroxyl, cyano, acetate, pyridine, etc.)[52]. This greatly complicates investigation of their ionic forms[26]. It was observed in particular that the reduction of chromium phthalocyanine by sodium in oxolan gives a paramagnetic product whose e.s.r. spectrum contains nine lines, which means that the unpaired electron interacts with the four inner nitrogen atoms. When the complex is reduced in hexamethylphosphoramide, a signal comprising seventeen lines is observed, which corresponds to interaction of the unpaired electron with the eight nitrogen atoms[23,53]. Such behaviour of chromium phthalocyanine is obviously due to a different distribution of electron density in the resulting ion, which depends on the out-of-plane ligand, as in the interaction of iron phthalocyanine monoanions with bases[49].

We have not hitherto specified how the charge is actually distributed in the tetrapyrrole system of the ligand. Yet this distribution determines the chemical properties of the ion. Unfortunately, theoretical and experimental information is at present insufficient to solve this problem. Published data can be found permitting comparison of the distribution of π-electron density in certain molecules and their ionic forms. For example, theoretical calculations showed that, on formation of the negative ion of tetracyanoquinodimethane, the π-electron density increased most strongly on those atoms on which it was highest even in the neutral molecule (on the cyano-nitrogen atom and on the carbon atom linking the cyano-group with the quinoid ring). In neutral molecules the π-electron density has its minimum value on the cyano-carbon atom. Subsequently it diminishes still more strongly (though slightly) on conversion of the molecule into the singly and doubly charged anions[54,55]. In just the same way the increase in charge density on a carbon atom accompanying formation of radical-anions of polyacenes is greater the higher the π-electron density on the atom in the neutral molecule[56,57]. The physical reason for such a charge distribution in a negative molecular ion is obviously that the added electron, merging with the π-electrons of the neutral molecule, obeys the same distribution laws as do the latter in the force field of the given atomic configuration, which changes little on transformation of the molecule into an ion.

It may be supposed as working hypothesis, by analogy with polyacenes and tetracyanoquinodimethane, that the charge of an electron added to a metal phthalocyanine molecule is distributed (if it is located on the ligand) mainly between both inner and outer nitrogen atoms, which in the neutral molecule bear a considerable excess charge relative to the carbon atoms of the benzene rings[58-61].

IV. NEGATIVE IONS OF PORPHYRINS AND METAL PORPHYRINS. PROTONATION OF NEGATIVE IONS

The structural features distinguishing metal porphyrins from metal phthalocyanines are responsible for the distinctive physicochemical properties both of their neutral molecules and of their ions. Negative ions could be obtained by the same methods as those of the latter, but significant differences between them were immediately discovered: metal porphyrins form only singly and doubly charged anions, although their lowest vacant π-orbital is doubly degenerate, as in metal phthalocyanines, and the addition of four electrons is formally possible[50]. Reports of the formation of more highly charged ionic forms[17,22,62-64] have since been disputed. Experiments on the photodetachment of an electron and on the protonation of ions have shown[20,25,26,65,66] that partly protonated multicharged anions had erroneously been

regarded as purely ionic forms. It is not yet clear why metal porphyrins do not form multicharged ions.

As with metal phthalocyanines, the formation of negative ions of metal porphyrins and their structure depend significantly on the presence and on the nature of the central metal atom. Porphyrins and their copper derivatives resemble phthalocyanine and copper phthalocyanine in being converted into disodium complexes at the first stage of interaction with alkali metals or with negative anthracene ions, and these complexes yield ionic forms at later stages [46,64]. This transformation slows down with fall in temperature, and both monoanions and dianions could be obtained by running together solutions of a porphyrin (aetioporphyrin or tetraphenylporphin) and singly charged anthracene anions at −70°C. [26,64,67] An electrochemical method can also be used to obtain and investigate negative ions of metal-free porphyrins [68-70].

Zinc and magnesium combined with porphyrins are not replaced by alkali metals, and their valency is not changed by redox reactions, so that the first successful experiments on the preparation and spectral investigation of ions of metal porphyrins were made with zinc tetraphenylporphin by Closs's method [17,62]. Later experiments [20,26] with photodetachment of an electron from anions of this complex confirmed the correctness of the spectral characteristics predicted for these anions.

The close similarity of the electronic absorption spectra of the singly charged anions of tetraphenylporphin and its zinc complex, which contain comparatively few bands and, it may be said, are unique [67-70], demonstrate, when combined with e.s.r. measurements [17,19,20,22] and theoretical conclusions [50], that the extra electron is delocalised in the cyclic bond system of the tetrapyrrole ligand. Charge is similarly distributed in the singly charged anions of metal-free, zinc, magnesium, and disodium aetioporphyrins and of metal-free, copper, tin, magnesium, and disodium tetraphenylporphins. The second electron in the doubly charged anions of aetioporphyrin, tetraphenylporphin, and their zinc, magnesium, and copper derivatives is probably also located on the ligand, although the only evidence is a comparison of the absorption spectra of the doubly charged anions of porphyrins and of their metal derivatives. Cobalt and iron atoms introduce a significant anomaly into the charge distribution in the ions of metal porphyrins. Many experimental results indicate that the negative charge in the monoanion of cobalt tetraphenylporphin is located on the cobalt atom [19,71,72]. Information is lacking on products of the further reduction of cobalt porphyrins. Hush and Woolsey report [73] that, when an analogue of cobalamin is reduced with sodium, the first electron is located on the cobalt atom, but on addition of the second electron the whole of the excess charge shifts to the ligand. On formation of singly and doubly charged anions of the corresponding nickel complex both electrons are localised on the ligand. These conclusions were based on a comparison of the absorption spectra of ionic forms and the neutral molecules of the compounds.

Iron porphyrins occupy a special position among other metal porphyrins by virtue of their exceptional capacity for complex formation with out-of-plane ligand molecules and the readiness with which the state of the iron atom changes between bivalent and tervalent. The metal atom in iron(III) porphyrins binds outside the plane of the tetrapyrrole ring with CN, OH, Cl, etc. This ability of iron derivatives of the porphin series, which is responsible for the important part played by individual representatives in biological processes and on which numerous publications have appeared, greatly complicates investigation of their ionic forms. According to spectral data the first stage of interaction between ClFe^{III}AeP and negative pyridine ions is reduction of the central iron atom to the bivalent state [64]. Subsequent stages of this interaction are dissimilar in spectral characteristics from the changes undergone by other metal aetioporphyrins under the same conditions, and no data are yet available on the structure of the ionic forms of iron aetioporphyrin. Three reduction products have been characterised spectroscopically when oxybis[iron(III) tetraphenylporphin] (two molecules of the iron complex bound by an oxygen atom between the iron atoms) is treated with sodium amalgam in oxolan. The first stage is assumed to involve formation of a singly charged iron tetraphenylporphin anion with localisation of the charge on the metal [72].

Singly charged anions and cations of many metal derivatives of octaethylporphin have been obtained by electrochemical reduction. The potentials at which addition or removal of an electron takes place have been measured. Comparison of the absorption spectra of ionic forms and neutral molecules indicated whether the ionic charge was located on the metal atom or on the ligand [74]. Metals which are not involved in redox reactions when present in octaethylporphin complexes (the whole of the ionic charge is localised on the ligand) include alkali and alkaline-earth metals, the bivalent metals palladium, copper, zinc, and cadmium, tervalent antimony, scandium, aluminium, gallium, indium, and thallium, quadrivalent silicon, germanium, and tin, and also the metals present in vanadyl and titanyl. Among metals which change their valency under these conditions are—(*a*: I ⇌ II) cobalt; (*b*: II ⇌ III) manganese, iron, cobalt, chromium, and silver; (*c*: II ⇌ IV) lead; (*d*: III ⇌ IV) chromium and iron; and (*e*: IV ⇌ V) molybdenyl—where a metal atom undergoes a real change in valency only when a redox reaction involves a change in the number of atoms with which it forms valency bonds. If this number remains unchanged [as in the interconversion of cobalt(I) and cobalt(II) porphyrins], it is preferable to regard this as a change not in valency but in the population of the orbitals of the metal atom.

An interesting distinction between the ions of metal porphyrins and those of metal phthalocyanines is the enhanced tendency of the former to protonation. Slight contamination with proton-donating impurities (alcohols, weak acids) may result in conversion of the ionic forms of a metal porphyrin into partly or completely protonated ionic forms [17,20,25,26,66,68,69,75]. The protonation of doubly charged anions is represented by the scheme

$$Por^{2-} \xrightarrow{H^+} PorH^- \xrightarrow{H^+} PorH_2$$

(where Por represents a molecule of a neutral tetrapyrrole compound).

Products of the protonation of zinc tetraphenylporphin ions obtained by this method [20] were identical in absorption spectra and other properties with products of the photochemical reduction of the complex by hydrazine [76]. Protonation of doubly charged zinc aetioporphyrin anions follows by removal of zinc atoms from the protonated ions yielded reduced products spectrally identical with products of the photochemical or dark reduction of metal-free porphyrins to the corresponding dihydro-derivatives [77]. This gave independent confirmation of the structure of the photoreduced forms of porphyrins and their metal derivatives, while the reduction of a metal porphyrin to its hydrogenated form was separated experimentally into two stages: primary addition of an electron was followed by protonation of the resulting negative molecular ion.

The form $PorH^-$ can be obtained in an oxolan solution of zinc aetioporphyrin anions by reaction of Por^- or Por^{2-} with a comparatively weak proton donor, e.g. methanol. The monoanion Por^- is converted into $PorH^-$ by disproportionation:

$$2\,Por^- + H^+ = PorH^- + Por\ .$$

Interaction with a strong proton donor—acetic acid—yields the dihydro-derivative[66]. Protonation of the anions of metal porphyrins leads, of course, to significant changes in their spectral characteristics: the electron delocalised in the tetrapyrrole system of the ion becomes localised near the added proton, forming a valency bond with it. If the proton adds to a methine bridge, as is assumed to occur, the cyclic conjugation in the tetrapyrrole system will break down, and the whole system of energy levels will change. Addition of a second proton will lead to further spectral changes[20,66].

It proved impossible to effect photoelimination of an electron from the forms $PorH^-$ and $PorH_2$. Nor were attempts to obtain neutral radicals PorH· by the protonation of monoanions successful.

Partly protonated ionic forms $PorH^-$ of zinc and magnesium aetioporphyrins and tetraphenylporphins, like the neutral molecules, are able to add electrons on reaction with sodium, with the successive formation of $PorH^{2-}$ and $PorH^{3-}$. The first of these forms is paramagnetic and capable of photoelimination of an electron with regeneration of $PorH^-$, which is proof of its structure $[PorH^{2-}]$. In the presence of methanol the form $PorH^{3-}$, which can be termed a partly protonated trianion, is converted via a disproportionation stage into diamagnetic protonated tetra-anions, which exist in two spectroscopically distinguishable forms containing different numbers of excess protons[26,66].

The form $PorH_2$ is easily converted by loss of a proton into $PorH^-$, a reversible change governed by the acid–base equilibrium conditions. For example, a critical review, in the light of later results, of earlier work[76] on the photoreduction of zinc tetraphenylporphin shows that the presence of ammonia or hydrazine in pyridine solution leads to conversion of the dihydro-derivatives into the form $PorH^-$. Evaporation of the solution and dissolving the precipitate in pure pyridine again yields the $PorH_2$ form. In frozen solutions in organic bases a proton can be detached photochemically from the dihydro-derivative of zinc aetioporphyrin. The resulting $PorH^-$ form is again converted into $PorH_2$ when the solution melts[78].

Parly protonated anions and hydro-derivatives of metal porphyrins were repeatedly observed earlier in experiments on the dark and photochemical reduction of these compounds[76,79–84]. Successful attempts have recently been made to determine the structure of the products by nuclear magnetic resonance. Thus the added hydrogen atoms in the dihydro-form were shown to be situated on two opposite methine bridges, and in $PorH_3^-$ (or $PorH_4$) three of the four methine bridges were hydrogenated[84,85]. The form $PorH^-$ was regarded by the Closs's[17] on the basis of n.m.r. data as a metal phlorin, in full agreement with spectroscopic results.

In an optically excited state the capacity of negative ions of metal porphyrins for protonation is considerably increased, as is indicated by the possibility of accomplishing the photochemical protonation of metal aetioporphyrin ions in the presence of negative ions of pyridine. Here the pyridine ions act as proton donors, being converted into bipyridyl during the reaction[75].

Negative ions of metal-free porphyrins can also be converted into protonated forms. Experiments on the electrochemical reduction of tetraphenylporphin, the dimethyl ester of deuteroporphyrin, and the dimethyl ether of mesoporphyrin yielded not only singly and doubly charged anions but also the form $PorH^-$ having a phlorin structure, protonated tetra-anions $PorH_n^{(4-n)-}$ with a porphomethene structure, and protonated hexa-anions $PorH_n^{(6-n)-}$ with a porphyrinogen structure. The exact number of protons n in these forms was not determined[68,69]. Highly reduced colourless products formed from zinc aetioporphyrin by interaction with sodium had been observed earlier[63,64], probably containing six extra electrons and an unknown number ($n \leq 6$) of protons.

The protonated ions of porphyrins and of their metal derivatives exhibited closely similar absorption spectra at the same state of reduction. This similarity provides hints for determining the structure of the reduction products of porphyrins, in particular the location of hydrogen atoms added to the molecule.

Like porphyrins, their hydrogenated derivatives—chlorins and bacteriochlorins—are able to form singly and doubly charged anions. Negative ions of tetraphenylchlorin and tetraphenylbacteriochlorin have been obtained electrochemically and investigated by means of their absorption spectra[69]. In the presence of proton donors tetraphenylchlorin ions are converted into protonated forms: partly protonated dianions and protonated tetra-anions with an unknown number of protons have been recorded spectroscopically, but protonated hexa-anions are not formed by tetraphenylchlorin. In general the same final reduction product, porphyrinogen, is obtained from the tetraphenyl derivatives of porphin, chlorin and bacteriochlorin[65,69]. The bacteriochlorin molecule requires only two electrons and two protons for conversion into porphyrinogen, and the chlorin and porphyrin molecules require respectively four and six electrons and protons each. Partly protonated ions are intermediate stages in the reduction of these molecules to porphyrinogens.

Singly charged anions of disodium complexes of tetraphenylchlorin and tetraphenylbacteriochlorin have been obtained by the action of sodium on the metal-free compounds in dimethylformamide. They were proved to possess a purely ionic structure by photoelimination of an electron[32,33]. Singly charged anions of bacteriochlorophyll and of zinc tetraphenylbacteriochlorin were obtained by an electrochemical method[86]. The absorption spectra of the latter are similar to those of mono-anions of the corresponding disodium derivatives[33], which indicates that the extra electron is located on the ligand.

The effects of the central metal atom and of the charge distribution on protonation of the anion have not been investigated, although the charge distribution in the tetrapyrrole system of the ligand probably determines both the capacity of the ion for conversion into a protonated form and the structure of the latter (location of added protons). In support of the suggested role of the distribution of negative charge in an ion on its protonation we can consider the photochemical reduction of various metal phthalocyanines, involving as initial stage formation of a negative ion and a subsequent protonation stage. The ability of these complexes to form photoreduced varieties is substantially dependent on the nature of the metal. Magnesium and zinc phthalocyanines are converted into dihydro-derivatives when their pyridine solutions are exposed in the presence of hydrazine[87], whereas all cases investigated[44] of the photoreduction of cobalt phthalocyanine led merely to the formation of singly charged

anions $[CoPhth]^-$. Photoreduction of iron phthalocyanine has not yet been achieved[88]. These differences can be explained in terms of the electronic structures of the singly charged anions. In the magnesium complex ion the electron is located on the ligand, and a proton readily interacts with this ion to give a hydro-derivative, forming a valency bond with one of the outer nitrogen atoms. (It is on these atoms that the excess charge of magnesium phthalocyanine anions is presumably located.) A proton interacting with the complex cobalt anion is located near the cobalt atom, on which almost all the negative charge of the ion is situated; the conjugated system of the ligand remains unchanged, and the proton forms a purely ionic bond with the singly charged anion. The inability of iron phthalocyanine to be photoreduced can also be explained by peculiarities of the charge distribution in its monoanion (see above). We have recently been able to achieve the photoreduction of this complex in *N*-methylpiperidine by exposure to ultraviolet radiation at a low temperature, with formation of a photoproduct spectrally similar to the product of the photoreduction of magnesium phthalocyanine, and obviously also a dihydro-derivative. A possible explanation of the photoreduction of iron phthalocyanine is that the singly charged anion formed in the first stage of the photoreaction acquires in this medium an electronic structure with the charge localised on the ligand in virtue of the above redistribution of charge in the ion on formation of a complex with a molecule of a base.

Ions of metal phthalocyanines are not so sensitive as those of metal porphyrins to contamination with proton-donating impurities, and are protonated only at comparatively high concentrations of protons. Singly and doubly charged magnesium phthalocyanine anions are converted into the dihydro-derivative on treatment with acetic acid, as are the corresponding ions of metal porphyrins, but they probably retain their ionic structure in the presence of methanol, which leads merely to a change in the solvate sheath of the ions and to replacement of positive alkali-metal gegenions by protons, as is indicated by the comparatively small spectral differences. Nor can the possible formation of complexes between the metal phthalocyanine anion and the alcohol molecule be excluded. Such complexes have recently been discovered in experiments with fluorenyl anions[89]. Protonation of quadruply charged magnesium phthalocyanine anions by methanol or acetic acid yields new products, not yet identified, which may include both tetrahydro-derivatives and partly protonated tetra-anions[21].

V. PHOTOCHEMICAL GENERATION OF NEGATIVE IONS IN SOLUTION

The photochemical generation of ions not only supplements existing methods (chemical and electrochemical) but also gives indications of the reasons for the photochemical activity of molecules and the mechanism of the photo-transfer of an electron, the primary act in any redox reaction. Attempts were made long ago to obtain photochemically ionic forms of tetrapyrrole compounds, especially chlorophyll and its analogues, but only recently have positive results been obtained in isolated cases thanks to the development of methods for the spectroscopic identification of ions and to the selection of appropriate experimental conditions. The problem of the photogeneration and stabilisation of negative ions of porphyrins and their metal derivatives in liquid solutions is complicated by the high proton-accepting activity of these ions. When this property was established, the requirements of the medium in which they could exist became obvious—absence of those proton-donating and electron-accepting impurities causing oxidation of the ions and their discharge to neutral molecules, as well as adequate solvating power to stabilise the ionic forms.

One of the most suitable solvents for the photogeneration and stabilisation of anions of tetrapyrrole compounds was dimethylformamide with hydrazine added as reductant, provided that the reagents had been reliably freed from the above impurities. Almost complete conversion of magnesium phthalocyanine into stable singly charged anions could be achieved in this medium by exposure to visible light at $-50°C$.[43,90] Absorption and e.s.r. spectra showed that the photogenerated monoanions were identical with those obtained by interaction with alkali metals. Similar transformation on illumination occurred in this medium also with metal-free phthalocyanine. Ultraviolet irradiation of solutions of monoanions of phthalocyanine or its magnesium complex led to their further reduction to dianions[43].

Singly charged anions of magnesium phthalocyanines can be obtained in almost 100% yield also by exposing solutions of this complex in piperidine, which acts also as an electron donor. Radical-cations of piperidine could not be detected in the e.s.r. spectrum, probably owing to dimerisation of the cations or some other process leading to their neutralisation. In combination with the good solvating properties of piperidine as a solvent this ensures relatively high stability of the radical-anion of magnesium phthalocyanine in the liquid solution[91]. The presence of a proton donor—ascorbic acid—in a piperidine solution of the complex leads to the formation on exposure, not of monoanions, but of a dihydro-derivative which has been observed many times in previous work on the photoreduction of magnesium phthalocyanine[87]. Nevertheless, there are no grounds for doubting that monoanions are formed at the initial stage even in this case, subsequently add a proton, and pass through a stage of disproportionation with conversion into the dihydro-derivative.

N-Methylpiperidine in dimethylformamide can also be used as reductant for the photochemical production of singly charged anions of magnesium phthalocyanine. In this system illumination with visible light at $-60°C$ gives initially monoanions, then a dihydro-derivative with an absorption band at 560 nm, and finally a new product with a band at 780 nm.[26] This latter spectrum was identical with that of a protonated form of tetra-anions of the complex[21], and the product was probably a tetrahydro-derivative.

Monoanions of several other metal phthalocyanines can be obtained in dimethylformamide with hydrazine or *N*-methylpiperidine as reducing agent[26]. Those of the lead and cadmium complexes obtained in this way were spectroscopically indistinguishable from singly charged phthalocyanine anions. These compounds probably lose their metal atoms immediately after addition of an electron: i.e. a phenomenon takes place analogous to the photophaeophytinisation of chlorophyll on reduction[92]. Copper and nickel phthalocyanines on exposure form monoanions with the typical absorption spectrum characteristic of localisation of the added electron on the ligand. Cobalt phthalocyanine is reduced to a monoanion with localisation of the charge on the cobalt atom. In the presence of *N*-methylpiperidine in dimethylformamide alone or in an equimolecular mixture with oxolan at $-60°C$ iron phthalocyanine is reduced photochemically to monoanions having an absorption spectrum indicating a distribution of charge between the ligand and the iron atom, as in

the reduction of the metal complex by an alkali metal. Cooling a solution of monoanions of iron phthalocyanine to −196°C changes the spectrum, and the charge shifts to the ligand (thermochromism—see above).

Application of this method for the photogeneration of ions in liquid solutions to tetraphenylporphin and its zinc derivative [67,93] also yielded monoanions at −60°C, although their yield was only 60%. This may have been due to the photoinduced reverse reaction. When heated to 20°C these monoanions are converted partly into a dihydro-derivative and partly into the original compound. Protonation was not observed with ions of phthalocyanine and metal phthalocyanines, probably owing to their greater stability towards protonation.

The ionic character and the magnitude of the charges on the products of the above photoprocesses have been confirmed by e.s.r. measurements [91] and by photoelimination of an electron leading to regeneration of neutral molecules of the original tetrapyrrole compound (or its monoanion if the electron has been detached from the dianion) [43,67].

Sufficient data are not yet available to settle the mechanism of the photogeneration of molecular ions, and only certain general considerations can be expressed. The act of electron transfer occurs between a photoexcited molecule of the tetrapyrrole compound Por* and an electron-donating molecule Don:

$$Por^* + Don \rightarrow Por^- + Don^+ .$$

The electron donor may be either a solvent molecule (as occurred in the reduction of magnesium phthalocyanine by piperidine) or an added reactant molecule (hydrazine in dimethylformamide); these cases may differ significantly in reaction kinetics. The excited molecule Por* is most often present in the lowest triplet state, but activity in the charge transfer may be exhibited both by a singlet state and by excited states due to the presence of the d-shell of the central metal atom [94]. A special case is the photogeneration of iron phthalocyanine monoanions and also of dianions of phthalocyanine and the magnesium complex. These reactions do not occur on exposure in the region of long-wavelength absorption bands but require short-wavelength bands, which suggests that higher excited states are involved in these photoreactions. Since the lifetimes of such states are usually brief, diffusion processes must play an insignificant part, and the electron donors must be either solvent molecules from the solvate sheath or out-of-plane added molecules present in a complex with the Por* molecule.

The stability of photogenerated negative ions of tetrapyrrole compounds in liquid solutions is determined firstly by the solvating properties of the solvent and secondly by the ability of the positive gegenions Don^+ formed in the photoreaction to be deactivated in time to prevent electron transfer in the opposite direction. The actual occurrence of such deactivation is confirmed by the absence from the e.s.r. spectra of signals due to radical-cations. The most probable mechanism of deactivation is interaction with solvent molecules or with neutral molecules of the donor.

In solid solutions (predominantly solutions frozen at −196°C, but polymerised matrices can in principle be used) the general mechanism of the phototransfer of an electron is the same as in liquid solutions, but conditions for stabilisation of the ions differ considerably. Molecular diffusion is slowed down, and the presence of proton-donating and electron-accepting impurities does not affect the stability of negative ions provided that these impurities do not form complexes with molecules of the tetrapyrrole compound and do not enter their solvate sheaths.

Krasnovskii and his coworkers [95] reported the possibility of the photochemical generation and stabilisation of radical-ion forms of porphin in acidified alcoholic solutions at −196°C. Gribova detected radical-ions on irradiating frozen alcoholic solutions of magnesium aetioporphyrin [96]. The hypothesis that these radical-ions were monoanions of the complex was not supported by later work: exposure of frozen solutions of zinc and magnesium aetioporphyrins in mixtures of diethyl ether with ethanol or with oxolan results in detachment of an electron from the molecules of these compounds and formation of their monocations. Negative ions may also be formed in subsequent stages of the reaction as a result of migration of the freed electrons [97,98]. Magnesium phthalocyanine, in contrast to magnesium aetioporphyrin, is converted into monoanions on exposure in a frozen ethereal oxolan matrix [90]. The porphyrin ring is obviously a better electron donor than is the phthalocyanine ring. Monoanions of zinc tetraphenylporphin may be photogenerated in frozen pyridine, and were recorded in photoconductivity experiments [99].

An interesting case of electron phototransfer from negative pyridine ions to zinc aetioporphyrin molecules has been observed in a frozen mixture of oxolan and ether [75]. When solutions of these species are mixed, they form a complex which in the frozen state is highly photosensitive: brief exposure in any of the absorption bands of zinc aetioporphyrin converts it into monoanions, which with increase in exposure eliminate the extra electron and regenerate the neutral molecule. Magnesium, copper, nickel, and disodium aetioporphyrins do not form complexes with pyridine ions under similar conditions, and in frozen solutions possess no photosensitivity to visible light. Thus slight individual peculiarities of different tetrapyrrole compounds may be efficacious under certain conditions.

In acid medium two protons add to a molecule of a metal-free porphyrin, with formation of a porphyrin dication [100]. The presence of the positive charge enhances its electron affinity: the acid dicationic form of a porphyrin can be reduced not only in the presence of typical reducing agents but even by anions of mineral acids. Photochemical reduction of the acid cationic forms in frozen solutions may yield either ionic or hydrogenated forms. The photoprocesses can be directed towards either reduction or oxidation by varying the composition of the incident radiation by introducing typical oxidants or reductants into the solution [25,101,102].

Frozen solutions enable molecular ions to be generated by γ-radiolysis, which effects electron transfer between solvent and solute molecules. Depending on the properties of the solvent the solute molecules can be converted into either anionic or cationic forms. The advantage of this method is that the resulting ions do not interact with the gegenion. Though widely used for investigating ions of aromatic compounds, γ-radiolysis has hardly been applied at all to the generation of tetrapyrrole ions. Only one paper has been published, on the radiolysis of chlorophyll: irradiation in frozen methyloxolan gave monoanions, and exposure in isobutyl chloride yielded monocations [103].

VI. COMPLEXES. IONIC ASSOCIATION

The formation of molecular complexes (association) is a widespread phenomenon with neutral molecules, and has been investigated in detail. The presence of the excess

charge in a molecular ion, by introducing a specific character into its interaction with the medium, not only does not prevent but rather promotes such interaction. The specific character of a molecular ion governs the association of ions of opposite sign. In solution this phenomenon leads to the formation of ion-pairs (e.g. comprising a molecular anion and an alkali-metal cation) or larger aggregates. In the solid state ionic association leads to the formation of saltlike products. Another feature of interaction of a molecular ion with the medium is its enhanced capacity for solvation in solution. The excess charge of the ion ensures a more stable orientation of the molecular dipoles surrounding it and deeper potential wells formed by the solvating dipoles. This ability of ions to form stable solvates makes it possible to stabilise the ions in liquid solutions.

Furthermore, molecular ions can also be involved in the interactions usually observed between neutral molecules. For example, monocations of perylene and tetracene form dimers by donor–acceptor interaction [104]. We have discussed above complexes comprising a negative ion and a neutral molecule, which are probably weak charge-transfer complexes in which the negative ion obviously acts as electron donor. Such are the complexes between the iron phthalocyanine monoanion and a neutral molecule of an organic base, whose formation leads to a redistribution of charge in the monoanion, and the complex between a negative ion of pyridine and a neutral molecule of zinc aetioporphyrin. The latter complex is not formed if the component solutions are mixed and kept at or below −100°C: complex formation takes place only around −60°C. The need to raise the temperature for complex formation to occur is obviously due to the necessity of rearrangement of the solvate sheaths surrounding the pyridine ions and the zinc aetioporphyrin molecules. The sheath around the pyridine ions, which bear an excess negative charge and therefore exert an enhanced orienting effect on the surrounding dipoles, exhibits especially great stability, which increases the lower the temperature. Once the complex has been formed at −60°C, of course, it does not decompose when the temperature is subsequently lowered [75]. Exposure entails electron transfer within the complex, with formation of the zinc aetioporphyrin monoanion—not dianions—so that the complex must be regarded as equimolecular.

Returning to the phenomenon of ionic association, we note that in general an equilibrium is established in solution between ion-pairs of various types (contact, separated) and dissociated ions [1-3,9,105]. The solvating properties of the solvent become stronger with fall in temperature, and the equilibrium shifts towards separated and dissociated ion-pairs. The position of equilibrium depends on the solvating power of the solvent, the dimensions of anion and cation, and the charge on the molecular ion: a multicharged ion retains gegenions more firmly than does a singly charged ion. In methyloxolan, in particular, the monolithium salts of anthracene, tetracene, and pentacene, both at 20 and especially at −196°C, are dissociated or form separated ion-pairs differing little in properties from dissociated ions. Monosodium and monopotassium salts of polyacenes exist in this solvent at 20°C predominantly as contact ion-pairs, which are converted into separated pairs or dissociated ions when the temperature is lowered. Dianions of polyacenes are associated with two positive ions at 20°C, but in most cases with one such ion at −196°C. [3,106,107]

No detailed investigations have been made on the association of negative ions of tetrapyrrole compounds. Preliminary data show that they obey the same laws as do the ions of aromatic compounds. Although it was suggested that ionic association was strengthened by lowering the temperature of solutions of singly charged magnesium phthalocyanine anions, the grounds for such a hypothesis were insufficient [21], and it must be abandoned in the light of later results. As in the general case, lowering the temperature of solutions of metal phthalocyanine anions probably displaces the equilibrium towards the dissociation of ion-pairs.

Comparison of the absorption spectra of negative ions of metal phthalocyanines at 20°C and at −196°C shows that in an ether–oxolan mixture all ions—from monoanions to tetra-anions—change their state of association with change in temperature. An exception is the cobalt phthalocyanine monoanion, in whose spectrum no change was observed over the above temperature range. An explanation of the absence of change is that the absorption bands of this anion are due to transitions between energy levels of a ligand not bearing a negative charge that, on interaction with the positive charge of a cation, might cause a displacement of levels and bands as occurs with anions of other metal phthalocyanines [44]. The absence of spectral changes with variation in temperature does not mean, of course, that the equilibrium between aggregates and dissociated ions does not shift.

Since an obvious difference is observed [21,44] between the absorption spectra of solutions of metal phthalocyanines at 20°C and at −196°C, it must be supposed that in the former case they are associated with alkali-metal cations, but in the latter case are present as separated ion-pairs or in a dissociated state. The state of association of monoanions of other tetrapyrrole compounds—zinc tetraphenylporphin [20,93], zinc aetioporphyrin [26], disodium chlorin [32]—changes similarly when the temperature is lowered.

On the basis of available experimental data it is difficult to say anything definite on the state of association of multicharged ions of tetrapyrrole compounds, other than that this state changes when the solutions freeze. Comparison with the properties of anions of aromatic compounds suggests that, in oxolan at 20°C, the multicharged ions form aggregates in which the number of alkali-metal cations is equal to the anionic charge. With fall in temperature these aggregates partly dissociate, eliminating one alkali-metal cation—or less probably two cations—as a consequence of the strengthening solvating power of the solvent. It is to be hoped that a detailed study of electron photoelimination from multicharged ions will enable the structure of aggregates in frozen solutions to be refined, since the spectral threshold of such photoelimination should depend significantly on the state of association of the ions: the more complete is dissociation, the more easily can photoelimination be accomplished right up to conversion of the multicharged anion into a neutral molecule.

Electron photoelimination enables ionic aggregates of unusual composition to be obtained in a frozen solution. Thus in methyloxolan at −196°C monoanions of terphenyl and tetracene are usually present in the dissociated state. By detaching an electron from the dianion, which at this temperature is associated with one sodium cation, it was possible to obtain under these conditions associated monoanions clearly distinguishable by their absorption spectra from the dissociated monoanions [107]. Detachment of an electron from magnesium phthalocyanine dianion in a frozen ether–oxolan mixture gave a monoanion with a spectrum similar to that of the monoanion at room temperature [21]. Comparison of this experiment with those on the photodischarge of dianions of terphenyl and tetracene

indicates that the same phenomenon is observed even in this case, i.e. that magnesium phthalocyanine dianion is associated with one sodium cation in frozen solution. The photodetachment of one electron from the dianion gives the associated monoanion, which does not normally exist in frozen solution. Complete photodischarge of the dianion should result in formation of the neutral magnesium phthalocyanine molecule in direct contact with the alkali-metal cation. The photodischarge of tetra-anions may yield a metal phthalocyanine molecule surrounded by two or three cations, which opens up the possibility of investigating the properties of a molecule in the field of contiguous charged species.

VII. CATALYTIC ACTIVITY OF NEGATIVE IONS OF METAL PHTHALOCYANINES

Although molecular ions are involved as intermediate structures in most redox reactions, their use as reactants is still fairly limited. The ability of negative ions to transfer an electron to compounds of greater electron affinity makes possible their use for reductions, including the initiation of anionic polymerisation [108]. Anions of aromatic hydrocarbons, obtained on interaction with alkali metals, can be employed in metallations [109]. Use of the protonation of negative ions to obtain hydrogenated derivatives of the compounds is a promising possibility. It must be supposed that negative ions of tetrapyrrole compounds can be employed in the same reactions as ions of aromatic compounds. The existence of multicharged ions of metal phthalocyanines and the localisation of the negative charge either on the tetrapyrrole ligand or on the complexing metal atom may extend significantly the potential use of ions of metal phthalocyanines and porphyrins as selective reactants. Hitherto, however, hardly any investigations on these lines have been made on ions of tetrapyrrole compounds. Information is available only on a series of Japanese studies in which negative ions of tetrapyrrole compounds, mainly metal phthalocyanines, were used as catalysts.

Neutral metal phthalocyanines catalyse, for example, hydrogen exchange, the conversion of para- into ortho-hydrogen, the oxidation of cumene to its hydroperoxide, and the dehydrogenation and decomposition of formic acid [110,111]. In several cases the catalytic activity is determined by the nature of the central metal atom, but with heterogeneous catalysis the rate of reaction is significantly affected by the crystalline modification of the metal phthalocyanine, which indicates the part played by the π-conjugated system of the tetrapyrrole ligand [110]. Polymeric metal phthalocyanines, which have an extended π-electron system, exhibit catalytic activity towards reactions involving activation of hydrogen atoms that exceeds the activity of the monomeric complexes by an order of magnitude [111].

The negative ions of metal phthalocyanines, which are distinguished from the neutral molecules by a higher π-electron density in the tetrapyrrole ring, exhibit a significantly higher catalytic activity than the latter. In 1966 Ichikawa et al. discovered [112,113] that "donor–acceptor complexes" formed on contact between a sublimed film of a metal phthalocyanine and sodium vapour effectively catalyse hydrogen exchange between molecular hydrogen and deuterium, and between acetylene and deuteroacetylene. These "donor–acceptor complexes" were later identified with ionic salts of the metal phthalocyanines [114,115], and were found to catalyse several other chemical reactions, in particular the hydrogenation of alkenes in isomerisations, the synthesis of ammonia from hydrogen and nitrogen, and that of hydrocarbons from carbon monoxide and hydrogen [114,116,117]. It was found also that two central hydrogen atoms in sodium phthalocyanine were replaced by deuterium in the presence of molecular deuterium or deuteroacetylene. Negative ions of metal phthalocyanines also exchange their hydrogen for deuterium atoms [118,119]. This implies that hydrogen exchange takes place even in the benzene rings of metal phthalocyanine ions [113]. The excess negative charge of the ion, being distributed over the phthalocyanine ring, obviously covers the benzene rings also, whence the latter become more protophilic, which makes possible hydrogen exchange between magnesium phthalocyanine ions and deuterium molecules (or deuteroacetylene). This conclusion is supported directly by the increased rate of isotopic exchange between molecular deuterium and the metal phthalocyanine ion with increase in the ionic charge, but only slight variation with the nature of the central metal atom [115]. Exceptions are the monoanions of cobalt and iron phthalocyanines and the dianion of the latter, which do not exchange their hydrogen atoms for deuterium and catalyse neither exchange in a mixture of hydrogen and deuterium molecules nor the hydrogenation of alkenes by hydrogen [120,121]. The reason for such exceptions becomes clear from the electronic structure of these ions (see above): almost all the excess charge in the complex cobalt monoanion is concentrated on the cobalt atom, and a considerable proportion is localised on the iron atom in the complex iron monoanion. Multicharged ions of cobalt and iron phthalocyanines exhibit catalytic activity, as do the ions of other metal phthalocyanines.

The possibility of isotopic exchange between metal phthalocyanine ions and molecular deuterium of deuteroacetylene opens up a route for obtaining under laboratory conditions completely deuterated metal phthalocyanines, which are necessary for spectroscopic investigations on these compounds.

Whereas isotopic exchange between molecular deuterium and metal phthalocyanine ions is little affected by the nature of the metal atom, the hydrogen exchange between molecular hydrogen and deuterium catalysed by these ions depends significantly on the metal atom. The two reactions obviously have different mechanisms. Dissociative chemisorption of the hydrogen (deuterium) molecule in the vicinity of the central metal atom is assumed to be a stage in the latter reaction [115]. The mechanism of isotopic exchange in the benzene ring is obscure: it may be effected either by direct contact between the ring and a deuterium molecule or by contact with atomic deuterium formed by dissociative chemisorption on a neighbouring metal phthalocyanine ion.

The above series of papers on the catalytic action of negative metal phthalocyanine ions contain insufficient spectroscopic data, without which it is difficult, firstly, to monitor the identity of the ionic forms and their stability during an experiment, and secondly, to compare the results with those of other investigations on such ions made predominantly by spectral methods. An unsuccessful attempt was made to obtain infrared absorption spectra of negative ions of phthalocyanine: the spectrum of the initial phthalocyanine film remained unchanged after contact with sodium vapour. Hence it was concluded that formation of ions and catalysis take place only in the surface layer of the film [118,119]. This seems to us a dubious result, as the colour of metal phthalocyanine films was changed by con-

tact with sodium vapour[119]. Using the same method as the Japanese workers, we obtained without special difficulty the electronic and infrared absorption spectra of various ionic forms of magnesium phthalocyanine after films of the neutral complex had been kept in an alkali-metal vapour[122]. This means that the alkali-metal atoms are able to penetrate inside microcrystals of the metal phthalocyanine. Furthermore, comparatively thick films of a metal phthalocyanine are permeable to such small and even large molecules as water, ammonia, phenylhydrazine, aniline, diphenylamine, pyridine, indole, etc.[123,124] This implies that catalysis can occur not only on the surface of films of metal phthalocyanines and their ionic forms but also inside the layer.

Catalytic activity towards various chemical reactions is not an exceptional property peculiar to ions of metal phthalocyanines, as was to be expected. Such activity has been observed with negative ions of metal tetraphenylporphins[125-127], as well as with negative and positive ions of several other organic compounds—tetracyanopyrene[128], phenothiazine[129], polyacenes, quinones, nitriles, and several other aromatic compounds[114,116,120].

Detailed investigation (kinetic and spectroscopic) of the mechanism of the interaction of negative ions of anthracene with hydrogen showed that the product was an anthracene carbanion (the anion of 9-hydroanthracene)[116,130-132]. Carbanions of anthracene are probably formed also in hydrogen exchanges catalysed by anthracene ions and in the hydrogenation of alkenes. The kinetics of the sorption of hydrogen on metal phthalocyanine ions resembles that of the interaction of hydrogen with anthracene ions, but no changes were detected in the electronic absorption spectrum of a film of nickel phthalocyanine tetra-anions in the presence of molecular hydrogen, which was assumed[115] to exclude the suggested possibility of the formation of protonated anions of nickel phthalocyanine.

Polymeric Charge-transfer Complexes

S.I.Peredereeva, I.G.Orlov, and M.I.Cherkashin

Research results on polymeric donor-acceptor complexes both in the solid state and in solution are summarised. Solid polymeric charge-transfer complexes (crystals, films) are semiconducting materials satisfying the requirements of various branches of science and technology. Study of such complexes in solution reveals several specific features of complex formation in polymer systems and approaches an explanation of the electrophysical characteristics of layers of these complexes in terms of the mechanism of complex formation in solution. A brief account is given of the theory of charge-transfer complexes. Methods for determining and calculating the equilibrium constants of the polymeric complexes are critically examined. A list of 172 references is included.

I. INTRODUCTION

According to modern ideas charge-transfer complexes are compounds formed by the interaction of two valency-saturated molecules—an electron donor D and an electron acceptor A—the former possessing a filled molecular orbital of quite high energy and a low ionisation potential, while the acceptor has a fairly low vacant molecular orbital and considerable electron affinity[1-7]. The transfer of charge from donor to acceptor forms an intermolecular donor-acceptor bond, probably together with various other types of interaction, including polarisation, dipole-dipole, and also van der Waals forces[8].

The properties and the structure of charge-transfer complexes depend in considerable measure on which donor and acceptor orbitals are involved in forming the intermolecular bond. This principle constituted the basis of Mulliken's classification of these complexes[9], in which he divided all donors into three groups—n, σ, and π— according to a structural criterion. The energetically highest orbital in the first group is a lone pair of n-electrons of a heteroatom (R_2O, R_2S, R_3N, etc.), in the second group the electron pair forming an σ-bond (R-Hal), and in the third group a pair of π-electrons in an unsaturated or an aromatic compound. Acceptors are also divided into three groups—v, σ, and π— containing as lowest molecular orbitals respectively a vacant v-valent orbital of the metal atom (metal halides, certain organometallic compounds), a non-bonding σ-orbital (molecular iodine and bromine, iodine monochloride, etc.), and a system of π-bonds (aromatic and unsaturated compounds containing electron-accepting substituents).

Typical organic acceptors-nitro-derivatives of hydrocarbons, anhydrides and chlorides of di- and poly-carboxylic acids, cyano-derivatives of hydrocarbons, and also quinones and their derivatives—belong mainly to the third group Typical organic donors are present in all three groups in Mulliken's classification.

Combining these types of compounds gives a whole variety of donor-acceptor complexes:

nv ($R_2O \cdot MX_3$)	σv ($RX \cdot MX_3$)	πv ($ArH \cdot MX_3$)
$n\pi$ ($R_2O \cdot ArH$)	$\sigma\sigma$ ($RX \cdot I_2$)	$\pi\sigma$ ($ArH \cdot I_2$)
$n\sigma$ ($R_2O \cdot I_2$)	$\sigma\pi$ ($RX \cdot ArH$)	$\pi\pi$ ($Ar_1H \cdot Ar_2H$) .

At the present time $\pi-\pi$ and $\pi-\sigma$ complexes have been most thoroughly studied, whereas the smallest amount of work has been done on complexes with σ-donors.

Brieglev and Checalla divide charge-transfer complexes into strong and weak[10]: the weaker the donor and acceptor properties of the components, the smaller the gain in energy when they interact, the smaller the fraction of charge transferred, and hence the weaker the complex. The tendency to donor-acceptor interaction increases with decrease in the difference $I_D - E_A$ between the ionisation potential and the electron affinity of the molecules[10]. With very strong donors and acceptors complete transfer of an electron from donor to acceptor is possible in the ground state, with the formation of compounds termed strong complexes or radical-ion salts.

Blyumenfel'd et al. divide charge-transfer complexes into weak and strong on the basis of the decisive role of polar states in the appearance of paramagnetism and current carriers[11]. McConnell's classification of complexes into strong (ionic) and weak (non-ionic) is based on the type of packing of the molecules in crystals[12].

II. THEORY OF CHARGE-TRANSFER COMPLEXES

The most characteristic criterion of the formation of a charge-transfer complex is the appearance of a charge-transfer band, in addition to the absorption bands due to the initial components, in the electronic spectrum. The attempt to explain this band led to the development of several theories of donor-acceptor interaction[14-17], among which Mulliken's quantum-mechanical theory[1,13,18-22], which he developed for weak charge-transfer complexes, is now generally accepted. In this theory the ground state of an equimolecular charge-transfer complex is described by a wave function ψ_N, which can be represented approximately by a linear combination of two functions:

$$\Psi_N = a\Psi_0(D, A) + b\Psi_1(D^+ - A^-) \quad (1)$$

where ψ_0 is the wave function corresponding to the structure of the complex with van der Waals interaction (the wave

function of the non-bonded state), and ψ_1 is the wave function of the dative (bonded) state. With weak complexes $a \gg b$, and with strong complexes $b > a$. The lowest excited state of the complex is described by the wave function ψ_E, also a linear combination of wave functions ψ_1 and ψ_0 corresponding to the ionic and neutral states:

$$\Psi_E = a^*\Psi_1(D^+ - A^-) - b^*\Psi_0(D, A) \,. \qquad (2)$$

For weak complexes $a^* \simeq a$ and $b^* \simeq b$. Transition of the complex from the ground to an excited state is responsible for the appearance of the additional band in its absorption spectrum. The energy of such a transition is

$$E_{chtr} = h\nu_{chtr} = W_E - W_N \,. \qquad (3)$$

Fig. 1 gives a diagram of the energy transitions for weak charge-transfer complexes[30].

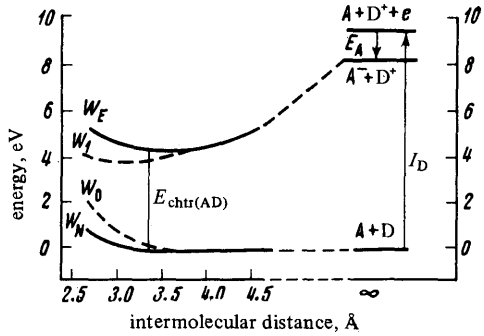

Figure 1. Energy relations of weak charge-transfer complexes between a donor D and an acceptor A, where W_N is the energy corresponding to the ground state of the wave function $\psi_{N(AD)}$ and W_E is the energy corresponding to an excited state of the wave function $\psi_{E(AD)}$, with W_0 and W_1 the corresponding energies in the absence of resonance stabilisation, and $E_{chtr(AD)}$ the energy of the optical intermolecular transition with transfer of charge[22].

The quantum-mechanical expression for the charge-transfer energy is

$$E_{chtr} = h\nu_{chtr} = \frac{(W_1 - W_0)}{(1 - S_{01}^2)}\left[1 + \frac{4\beta_0\beta_1}{(W_1 - W_0)^2}\right]^{1/2} \qquad (4)$$

where W_1 and W_0 are the energies of the dative and non-bonded structures,

$$S_{01} \equiv \int \Psi_0\Psi_1 d\tau$$

is an overlap integral, and

$$\beta_0 = (H_{01} - S_{01}W_0), \quad \beta_1 = (H_{01} - S_{01}W_1), \quad H_{01} = \int \Psi_0 H \Psi_1 d\tau,$$

where H is the Hamiltonian for the whole system of nuclei and electrons. Mulliken showed that, for interaction to occur between the structures ψ_0 and ψ_1, both S_{01} and H_{01} should differ from zero, which means that, in all cases other than strong spin–orbital coupling, the functions ψ_0 and ψ_1 have the same spin. He confirmed by quantum-mechanical calculations that electron transfer takes place with retention of spin.

Phenomenological examination of the transfer of charge leads to the formula

$$h\nu_{chtr} = I_D - E_A - \frac{e^2}{R_{D^+,A^-}} \qquad (5)$$

where I_D is the ionisation potential of the donor, E_A the electron affinity of the acceptor, and $e^2/R_{D+,A-}$ the Coulombic attraction.

Many empirical equations for the energy of charge transfer in complexes of different donors with a particular acceptor have the general form[23]

$$h\nu_{chtr} = cI_D - e_A \qquad (6)$$

where c and e_A are constants.

Further advances in the theory of charge-transfer complexes entail the description of the energy of complex formation by the method of molecular orbitals[24] and also the application of the free-electron model to these complexes[25].

III. CHARGE-TRANSFER COMPLEXES BASED ON POLYMERS AND THEIR ELECTROPHYSICAL PROPERTIES

Numerous research results on the properties of donors and acceptors, conditions for the preparation of pure charge-transfer complexes, and their structure, stability, and role in organic reactions and biochemical processes have been summarised in monographs[1–5,26]. Special mention need be made only of work during recent years on the use of such complexes as initiators in the polymerisation of monomers exhibiting donor properties, e.g. *N*-vinylcarbazole[27–36] and propylene sulphide methylthi-iran[37].

Special attention has been paid to investigating the semiconductor properties of charge-transfer complexes[38–42]. The complexes exhibit exhanced electrical conductivity[43–46], the activation energy of which (1.5–0 eV) varies linearly with the energy of charge-transfer[45–47]. The theoretical and practical interest in new highly conducting materials has recently stimulated a great development of work on charge-transfer complexes based on polymers. The principle of introducing a polymeric molecule into the complex has been used for example, to prepare a series of chelate compounds, with polymeric phthalocyanine[48], polypyromellitimide[49], and polymeric tetracyanoethylene[50] as ligands. Interest in polymeric complexes is connected with the possibility of improving the conductance by increased intermolecular interaction on complex formation by chain molecules[51] and with use of the film-forming properties of polymers in semiconductor technology.

All the polymeric donors studied can conveniently be classified according to the structure of the repeating unit: (I) polystyrene and its derivatives; (II) polymers with aromatic ring systems in a side-chain; (III) polymers with a heteroatom (usually a nitrogen atom) in a side-chain; and (IV) polymers having a conjugated system in the main chain (Table 1). The acceptors usually studied have been benzoquinone derivatives (chloranil, bromanil, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, and 7,7,8,8-tetracyanoquinodimethane), 1,3,5-trinitrobenzene, silver perchlorate, molecular bromine and iodine, and tetracyanoethylene.

All the complexes (Table 1) exhibit an exponential temperature dependence of electrical conductivity:

$$\sigma = \sigma_0 \cdot \exp(-\epsilon/kT) \qquad (7)$$

where ϵ is the activation energy, which has values of 0.8–0 and 1.5–0.01 eV according to Knoesel[52] and Paushkin[53] respectively. The corresponding conductivity ranges are

5×10^{-2}–3×10^{-14} [52] and 10^{-2}–10^{-15} [53] $ohm^{-1}\ cm^{-1}$. Radical-ion salts of tetracyanoquinodimethane possess the highest conductivity[69,74], as also charge-transfer complexes based on polymers having a conjugated system[69,75–79,83]. In most cases a parallelism is observed between the electrical and magnetic properties of charge-transfer complexes having the character of radical-ion salts.

Table 1. Charge-transfer complexes based on polymeric donors.

Polymeric donor	Acceptor	Ref.
	Group I	
Polystyrene	tetracyanoethylene	54, 55
Polystyrene	chloranil	54
Polystyrene	2,3-dichloro-5,6-dicyano-1,4-benzoquinone	54
Polystyrene	silver perchlorate	54
Polystyrene	iodine, bromine	56
Poly-*p*-dimethylaminostyrene	chloranil, bromanil	57, 58–60
Poly-*p*-dimethylaminostyrene	7,7,8,8-tetracyanoquinodimethane	61–63
Polyvinyltoluene	iodine, bromine	56
Styrene–α-methylstyrene copolymer	iodine, bromine	56
Styrene–2-vinylnaphthalene copolymer	iodine, bromine	56
Polyvinylmesitylene	tetracyanoethylene, chloranil, dichlorodicyano-*p*-benzoquinone	54
	Group II	
Polyvinylnaphthalene (atactic)	tetracyanoethylene, chloranil	54, 65
Polyvinylnaphthalene (atactic)	dichlorodicyano-*p*-benzoquinone	54
Polyvinylnaphthalene (atactic)	tetracyanoquinodimethane	63
Polyvinylnaphthalene (atactic)	1,3,5-trinitrobenzene	65
Polyvinylnaphthalene (isotactic)	chloranil	54
Polyvinylanthracene	trinitrobenzene, iodine, bromine	66
Polyacenaphthylene	tetracyanoethylene, chloranil	54, 67
Poly-2-vinylnaphthalene	tetracyanoquinodimethane	62
Poly-2-vinylnaphthalene	various	62
	Group III	
Poly-4-vinylpyridine	various	69
Poly-4-vinylpyridine	tetracyanoquinodimethane, antimony pentachloride	70, 64
Poly-4-vinylpyridine	iodine	68
Poly-4-vinylpyridine	chloranil, iodine, tetracyanoquinodimethane	74
Poly-2-vinylpyridine (atactic)		
Poly-2-vinylpyridine (isotactic)	tetracyanoquinodimethane	74, 63
Poly-*N*-vinylcarbazole	tetracyanoquinodimethane	71
Poly-*N*-vinylcarbazole	antimony trichloride, iodine	72
Poly-*N*-vinylcarbazole	iodine	73
Poly-*N*-vinylcarbazole	tetracyanoethylene, chloranil, trinitrobenzene	65
	Group IV	
Polydiphenylamine	tetracyanoethylene, chloranil, iodine	75
Polymeric Schiff bases	iodine, bromine	76
Polyphenylenes	iodine	77
Polyethynylnaphthalene	tetracyanoquinodimethane, iodine	78
Radiation-thermal polyethylene	iodine	81
Polyphenylacetylene	iodine	80
Polyethynylpyridine	tetracyanoquinodimethane	69

Studies have been made not only on the systems listed in Table 1 but also on charge-transfer complexes from polymers obtained by polycondensation, polymers containing ferrocene (with iodine, picric acid, and tetracyanoethylene as acceptors)[82], polyesters of aryliminodiethanols (with tetracyanoethylene, chloranil, and dichlorodicyano-*p*-benzoquinone)[83], and albumen (with chloranil)[84]. Systems have also been examined in which the polymer was an electron acceptor, while a compound of low molecular weight served as donor[85], e.g. complexes of poly-2,4-dinitrostyrene with amines[55]. Stable charge-transfer complexes possessing semiconductor properties have been reported[86] from the copolymerisation of monomers having strongly electron-accepting groups (trinitrostyrene) and electron-donating groups (4-vinylpyridine, *p*-dimethylaminostyrene). Among the most interesting polymers are polyphenylenaminochloranils, which contain both electron-donating and electron-accepting groups in the macromolecular chain[87].

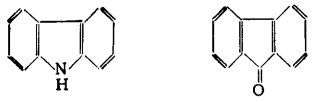
Highly photoconducting systems are of the greatest interest among polymeric semiconductors[88]. Although all insulators and semiconductors are photosensitive, the number of substances suitable for practical use as photosemiconductors is extremely limited. The reason is that many factors governing the photosensitivity of a substance depend on defects in its crystal structure, and only in certain materials and structures is the nature of these defects such that the excited current carriers are sufficiently long lived[88]. Polymers, in particular, are characterised by an immense number of defects in the solid state (regions of differing orientations of crystallites, irregularities in the packing of sheets and strips, etc.). The photosensitivity of many polymers has been studied, including polyconjugated polymers[83], biopolymers[89], polystyrene[90], and polyvinylcarbazole[91]. The mechanism of photoconduction in polymers probably involved as first step excitation of the macromolecule by an absorbed photon, followed by migration of the excited state (exciton) until it encounters a structural or chemical defect, on which a free pair of photocurrent carriers is formed[92].

Polyvinylcarbazole obtained in the presence of a Lewis acid as initiator is more strongly photosensitive than is the thermal polymer[91]. Thus the photosensitivity of the polymer is sensitised by the formation of a charge-transfer complex between the acceptor (the Lewis acid) and the electron donor (the polymer). It has been reported that various chemical compounds sensitise several polymers[91], in particular polyacenaphthylene[93], polyvinylpyridine[74], polystyrene[90], polydiphenylbutadiyne[94], β-iodophenylacetylene[95], and polyvinylcarbazole, which has been the most thoroughly studied during recent years[96–100]. This last polymer possesses thermoplasticity, forms photosensitive, transparent films, and currently finds practical application in electrophotography[91,101–105] (this process consists in producing an electrostatic image in the photosensitive memory layers and then developing it with dyes[106–108]).

A fundamental aspect of the study of the functioning of polymeric charge-transfer complexes under electrographic conditions is to ascertain the mechanisms of complex formation and of photoconduction. Weigle, for example, considers that, on excitation with a light quantum, the complexes inject holes into the valency band of the polymer, whose chains become conducting[109]. Hoegl discusses the mechanism of photoconduction in terms of the types of donor and acceptor[91]. However, the plethora of polymer systems has hitherto prevented the development of a unified view on the mechanism of photoconduction. An important problem is to establish a correlation between the photoconductance and the physicochemical properties of the components of the electrographic layer as well as its structure. Many authors relate the photoconductance to the electronic properties of the acceptor. Thus Meier and Albrecht[110] studied the effect of electron acceptors on the photosensitivity of thin *p*-type merocyanine and phthalocyanine films, and found only a rough correlation between the electron affinity of an acceptor and its ability to sensitise photoconduction. Smith and Weigle[111] tried to correlate spectral photosensitivity with the electron affinity of the acceptor. They conclude in a series of papers that the photosensitivity and the stability of charge-transfer complexes are influenced not so much by the electron affinity as by the spatial dimensions of the components. Thus the complexes of two similar π-systems are more stable than those formed by a donor and an acceptor differing in size[112]. Pyrene forms stronger complexes with tetracyanoquinodimethane than with tetracyanoethylene (K = 78.4 and 29.5 M^{-1}). Hayashi et al. found that the sensitising power of acceptors of the series

—*p*-benzoquinone, 1,4-naphthaquinone, 9,10-anthraquinone—diminishes with increase in their electron affinity[97]. Since these acceptors differ comparatively little in electron affinity (0.5, 0.7, and 0.77 respectively), the size of the π-system is an important factor in their sensitising power. This may be an indication that the stability constant of the complex is a more important parameter in the choice of an effective additive for a given electron-donating photoconductor than is the electron affinity of the acceptor.

Interesting results were obtained by Wagner and Gasner[113], who studied the photosensitivity of polyvinylcarbazole with several acceptors, including nitro-derivatives of fluorenone, an important feature of whose structure (II) is its similarity to that of carbazole (I):



(I) (II)

All the fluorenone derivatives, while differing in electron affinity, fitted on a straight line when the rate constant of the decay of the photocurrent was plotted against electron affinity, whereas points departing from the correlation, and enclosed by the full line in Fig. 2, correspond to acceptors differing in molecular size of the carbazole unit. Thus the photoconductance correlates with the electronic properties of the acceptor only in a homologous series of acceptors with the steric factors of the components taken into account. No correlation is found[114] between the thermodynamic characteristics of charge-transfer complexes of polyvinylcarbazole and of polystyrene with various acceptors and the photoelectric sensitivity under electrographic conditions.

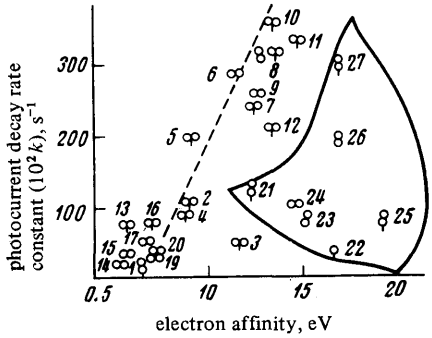


Figure 2. Dependence of photocurrent decay rate constant in charge-transfer complexes of polyvinylcarbazole on electron affinity of a series of acceptors[113]: *1*)–*20*) nitrofluorenone derivatives; *21*) 3,3′,5,5′-tetramethyldiphenoquinone; *22*) *o*-chloranil; *23*) *p*-chloranil; *24*) 2-dicyanomethylenindane-1,3-dione; *25*) 2,3-dichloro-5,6-dicyano-1,4-benzoquinone; *26*) tetracyanoethylene; *27*) 7,7,8,8-tetracyanoquinodimethane.

Recently investigators have increasingly arrived at the conclusion that the photosensitivity of a layer should be influenced by its physical macrostructure. Kryszevski, for example, regards all structural defects as traps within a forbidden energy band[115,116]. Electron microscopy has shown the appearance of supermolecular structures of dendritic type in films of charge-transfer complexes based on poly(phenyl methacrylate), poly-(2-naphthyl methacrylate)[117], polyvinylcarbazole, and polystyrene[118]. Such dendritic structures are absent from films of pure polymers. The formation of supermolecular structures is attributed to the increase in chain rigidity of polymeric charge-transfer complexes during complex formation in solution.

IV. PHYSICAL CHEMISTRY OF POLYMERIC CHARGE-TRANSFER COMPLEXES IN SOLUTION

The technology of the production of electrographic layers based on polymeric charge-transfer complexes involves solutions of polymers, so that a study of molecular aspects of the formation of such complexes in solution followed by interpolation of the results into the solid complexes is of great theoretical and practical value. A fair number of publications on the chemistry of polymeric charge-transfer complexes in solution have appeared recently.

In a study of the formation of complexes by poly-2-vinylpyridine and by its styrene copolymer with halide ions in 0.5*N* sulphuric acid Slough[119] noted that both π- and n-charge transfer is possible in heteroaromatic systems, so that they yield stronger complexes than do purely aromatic systems. The intensity of the charge-transfer band at 280–400 nm increased in the sequence—chloride < bromide < iodide—in parallel with the polarisability of the halide ions. The differing force of interaction of ions with a polymer can be used for the production of selectively anion-permeable membranes[120].

Klöpffer and Willicks[121] made a broad spectroscopic investigation of complexes formed by several polymeric donors and by their low-molecular weight analogues with various electron acceptors. Complexes of tetracyanoethylene with poly-10-methyl-3-vinylphenothiazine and with *N*-methylphenothiazine have a double absorption band in the region of 9600 cm^{-1}, which they attribute to splitting of the energy level of the donor in the ground state, so that two ionisation potentials are observed. The complex of poly-*p*-dimethylaminostyrene with tetracyanoquinodimethane exhibits in solution a double band in the range 11 750–13 200 cm^{-1}, which is assigned to the radical-anion of the acceptor. Absorption bands in the range 25 000–23 800 cm^{-1} for the complex formed by the same polymer with tetracyanoethylene indicate the formation of a pentacyanopropanide anion, a conversion product of the radical-ion of tetracyanoethylene. The band in the region of 25 600 cm^{-1} in the spectrum of the complex of this polymer with dichlorodicyano-*p*-benzoquinone is also ascribed to absorption by the radical-anion of the acceptor. The stability of the complexes is not always determined by the difference $I_D - E_A$: thus the ionisation potential of poly-10-methyl-3-vinylphenothiazine (7.0 eV), which forms only a weak complex with tetracyanoethylene, is lower than that of poly-*p*-dimethylaminostyrene (7.2 eV), which gives a strong radical-ion complex with the same acceptor. This is probably due to a difference between the energies of polarisation of individual states.

In a study of radical-ion salts Japanese investigators found[70,74] that tetracyanoquinodimethane (TCQDM) forms with polyvinylpyridines two types of complexes—simple $H^+(TCQDM)_2^-$ and double $BH^+(TCQDM)_2^-$.—where B is the radical of the organic base. The absence from the ultraviolet spectra of the absorption band due to the neutral acceptor indicates that the molecule and the radical-anion of the

acceptor form an intermolecular bond in the double complex and add to the same unit in the polymer. The ratio $\epsilon_{\lambda 842}/\epsilon_{\lambda 395}$, where $\epsilon_{\lambda 842}$ and $\epsilon_{\lambda 395}$ are the extinction coefficients of the radical-anion and of the molecule respectively, shows that only every fourth unit of the polymer forms the double complex. When the complexes are kept in the air, $\epsilon_{\lambda 395}$ decreases, while the ratio increases, which corresponds to conversion of the double into the simple complex[70].

In a spectrophotometric study of complexes of poly-*p*-dimethylaminostyrene with chloranil Knoesel[58] observed that in freshly prepared solutions the charge-transfer bands for complexes of this polymer and of its low-molecular analogue coincide, but after some time the band due to the polymeric complex shifts to the red range. This was explained by compaction of the packing of the acceptor between donor groups of the polymer, a phenomenon on which the authors termed "the polymer effect". The displacement of the charge-transfer band of this polymer with chloranil and also with dichlorodicyano-*p*-benzoquinone was confirmed by Klöpffer[121].

Hallensleben isolated[122] and studied[123] complexes of poly-4-vinylpyridine with tetracyanoethylene in solution in methanol and in chlorinated hydrocarbons. The variation in the ultraviolet spectra of the complexes correlated with the time variation of the viscosity. At low polymer concentrations the viscosity tended to constant values, and at high concentrations passed through a maximum. The extinction coefficients of solutions of the complex increased to a constant value. The experimental results were explained by conformational changes in the macromolecular chain on interaction with the acceptor.

Zwick's spectrophotometric study of complexes of polyvinyl alcohol with iodine in the presence of boric acid is distinguished by its elegance and completeness[124]. He showed that the position of the principal absorption maximum of the complex in the range 580–700 nm depends on the relative concentrations of iodine ions, boric acid, and polymer, as well as on the temperature, which is all evidence of the complexity of the process. In the presence of boric acid the polyvinyl alcohol molecule emerges from the coiled conformation and forms helices, which associate and finally crystallise, during which process the channels within the helices of the polymer molecule fill with polyiodide chains and become longer and more regular, all these changes being accompanied by a characteristic blue coloration. A limiting intensity of colour is reached when one iodine molecule is associated with 24 monomer units (two turns of the helix) in the polyvinyl alcohol macromolecule.

The thermodynamics of complex formation in polymer systems was not considered in the work discussed above, although the thermodynamic properties of the lower-molecular-weight charge-transfer complexes have been studied very carefully[1–6]. The most important thermodynamic characteristic of complex compounds in general and of macromolecular compounds in particular is the equilibrium (instability, stability) constant, which is a measure of the free energy of complex formation, although the reliability of this parameter is disputed in several cases (Ref. 5, p.383).

Equilibrium constants of polymeric charge-transfer complexes (formed by iodine with polystyrene and with rubber) were first determined by Evans by the Benesi-Hildebrand method[126], earlier used for low-molecular-weight complexes. According to Evans equilibrium constants and extinction coefficients have the same values for polymers as for model compounds (ethylbenzene, propylbenzene, *cis*- and *trans*-butenes) owing to the isolation of the electron-donor groups in the polymer and the absence of additional steric hindrance in the polymer complexes.

Kryszewski[127] obtained different equilibrium constants for complexes of polymers and of their low-molecular analogues with silver perchlorate. The equilibrium constants for charge-tranfer complexes of atactic and isotactic polystyrene and poly-α-methylstyrene with iodine are respectively 0.14, 0.18, and 0.26 M^{-1}; those for toluene, benzene, styrene, and ethylbenzene agree well with Evan's results[126] and are respectively 0.16, 0.14, 0.15, and 0.17 M^{-1}. It is assumed that complexes of various configurations are formed in solution, the least symmetrical of which is unstable. Therefore complexes based on low-molecular analogues and atactic polystyrene possess the lowest equilibrium constants. In conformity with the theory of contact charge-transfer[128] lower intensities of absorption correspond to higher stability constants:

$$K_{\text{pst,atact}} < K_{\text{pst,isotact}} < K_{\text{pamst}} \cong \epsilon_{\text{pst,atact}} > \epsilon_{\text{pst,isotact}} > \epsilon_{\text{pamst}} .$$

It was shown spectrophotometrically that charge-transfer complexes of *p*-benzoquinone with nitrogen-containing monomers, such as poly-2- and 4-vinylpyridines, poly-2-methyl-5-vinylpyridine, and poly-*NN*-dimethylmethacrylamide, are more stable than the corresponding complexes of their model compounds[120]. However, Markova[69] found from kinetic data that the equilibrium constant for the complex of poly-4-vinylpyridine with tetracyanoethylene is rather smaller than that for 4-ethylpyridine (0.5 and 0.6 M^{-1}). Rembaum et al. studied the charge-transfer complexes of *N*-ethylcarbazole and poly-*N*-vinylcarbazole with tetracyanoethylene in dichloromethane (K = 5.83 and 1.3 M^{-1}), and attributed the lower equilibrium constant for the polymeric complex to steric hindrance in the polymer chain[130]. A similar explanation is given for the complexes of polystyrene and polyvinylcarbazole with quinonoid acceptors, which have smaller equilibrium constants than those of the complexes of model analogues—ethylbenzene, cumene, *N*-isopropylcarbazole[131].

Smets et al. studied complexes formed by polyvinylcarbazole, poly-2-vinylnaphthalene, poly-2-naphthylmethylene, and their simple analogues with several organic acceptors[65]. The equilibrium constants were always smaller for the polymeric complexes than for the model compounds. This relation was preserved even when the constants were determined by nuclear magnetic resonance[132].

An original approach to polymeric donor-acceptor complexes was adopted by Braun and Sterzel[133], who studied the formation of donor-acceptor complexes of a styrene-*p*-dimethylaminostyrene copolymer with chloranil and with dichlorodicyano-*p*-benzoquinone, and found the equilibrium constants calculated by the Benesi–Hildebrand method to be functions of the copolymer composition, the highest values being observed for the complex of the copolymer containing 80 mole % of *p*-dimethylaminostyrene (Fig. 3). From these results it was concluded that the thermodynamic parameters (equilibrium constant $\overline{K}$ and free energy of formation of the complex ΔG) are significantly affected by solvation of donor, acceptor, and complex. On complex formation the mobility of the polymer chain diminishes, the entropy decreases, and hence the absolute value of ΔG increases. The equilibrium constants for the complexes with dichlorodicyano-*p*-benzoquinone exceed those for the chloranil complexes by factors of 10^4–10^5, which is attributed to the difference in electron affinity between these acceptors (1.95 and 1.37 eV respectively).

Iwatsuki and Arai[134] used complexes of the same copolymer with several acceptors (chloranil, trinitrotoluene, iodine, maleic anhydride) to elucidate the "polymer effect".

They observed a bathochromic shift in the charge-transfer band maximum and an increase in the equilibrium constant with lengthening of the continuous sequence of *p*-dimethylaminostyrene units and increase in their mole fraction in the copolymer (Fig. 4). The bathochromic shift was attributed to a fall in the ionisation potential *I* of the polymeric donor resulting from $\pi-\pi$ interaction of the dimethylaniline groups with the phenyl rings. The two-stage character of the variation in equilibrium constant was ascribed to the contribution by the energy of Brownian movement of the polymer chain of the donor to the total free energy of complex formation.

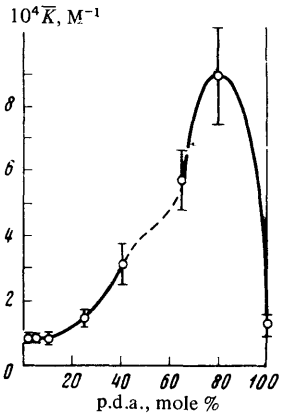

Figure 3. Dependence of equilibrium constant $\bar{K}$ on *p*-dimethylaminostyrene (p.d.a.) content of its styrene copolymer with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone as acceptor and cyclohexanone as solvent[133].

The influence of conformational changes in the macromolecular chains on complex formation has been examined[114,135]. Complexes formed by polystyrene, poly-α-methylstyrene, and polyvinylcarbazole of various molecular weights with several quinonoid acceptors and with tetracyanoethylene showed that the temperature dependence of the equilibrium constant depends on the molecular weight of the polymeric donor. With polymers of comparatively low molecular weight (e.g. polyvinylcarbazole having $\bar{M}_n$ = 1000) the equilibrium constants of the complexes decrease with rise in temperature, as with simple charge-transfer complexes. Complexes of polymers of intermediate molecular weight (polyvinylcarbazole with $\bar{M}_n$ = 30 000) the constants vary very little with temperature. Charge-transfer complexes of polymers of high molecular weight (polyvinylcarbazole with $\bar{M}_n$ = 460 000, polystyrene with $\bar{M}_n$ = 10 000–860 000) have equilibrium constants which increase with rise in temperature (Fig. 5). The occurrence of conformational transitions in polystyrene, polyvinylcarbazole, and their charge-transfer complexes in solution is confirmed by the temperature dependence of the dielectric loss angle. For the temperature variation of the conformation of polymers and the effect of these conformational transitions on complex formation these workers conclude that the van't Hoff method for calculating change in enthalpy during complex formation is incorrect when high molecular weights characterise one or both components. Methods ensuring isothermal experimental conditions, e.g. microcalorimetry in solution, must be used to determine the enthalpies of such processes.

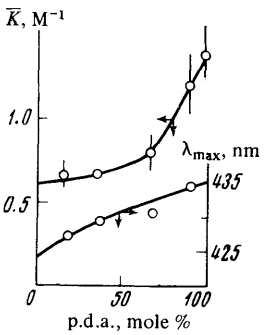

Figure 4. Dependence of $\bar{K}$ and λ_{max} of charge-transfer complex of styrene–*p*-dimethylaminostyrene copolymer with maleic anhydride on composition of copolymer in benzene as solvent[134].

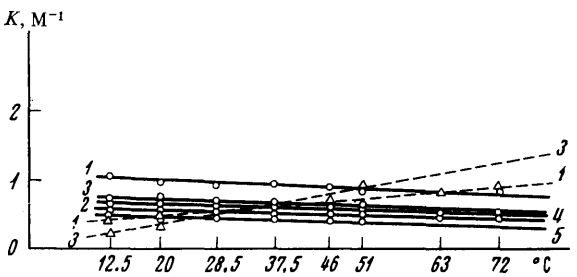

Figure 5. Temperature dependence of equilibrium constants in dichloroethane of charge-transfer complexes of polyvinylcarbazole varying in molecular weight M_n: –o–) 30 000; –Δ–) 460 000 with several acceptors: *1*) tetracyanoethylene; *2*) 7,7,8,8-tetracyanoquinodimethane; *3*) chloranil; *4*) bromanil; *5*) fluoranil[135].

Kinetic investigations of polymeric charge-transfer complexes have begun recently. Boudevska and Neitchev[137] used the "stopped flow" spectrometric method to study the kinetics of complex formation by tetracyanoethylene with polyvinylcarbazole, poly(naphthyl methacrylate), and the corresponding simple analogues in chloroform solution. All the complexes showed high rate constants ($\sim 10^4$ + M^{-1} s^{-1}), which were independent of the molecular weight of the donor. The rate constants of complex formation by tetracyanoethylene with polyvinylcarbazole and with *N*-ethylcarbazole were somewhat higher than with poly(naphthyl methacrylate) and naphthyl methacrylate, from which it was concluded that the rate of complex formation depended on the electron-donating power of the complexing unit.

The reversibility of the equilibrium of polymeric donor-acceptor complexes can be utilised for the chromatographic separation of complicated mixtures of chemical compounds, in particular to separate nitrated polystyrene[125].

Table 2.

Donor	Donor concn., M	Acceptor	Acceptor concn., M	K_{eq}, M^{-1}	ε_{max}	$\delta_0 - \delta_{AD}$ n.m.r.	Solvent	Ref.

* Model compound of poly-*p*-dimethylaminostyrene.

Thus the main lines of research on polymeric charge-transfer complexes have been connected with applied problems of semiconductor technology and electrography, with the physical chemistry of the formation and behaviour of the complexes in solution. Microcalorimetry and nuclear magnetic resonance, ultraviolet, visible, and infrared spectroscopy have been used to study the polymeric complexes[138]. Thermodynamic parameters calculated by the van't Hoff method and obtained for the same polymeric complexes in different laboratories do not agree (Table 2). Since macromolecules in solution may undergo complicated conformational transformations depending on the temperature and influencing the thermodynamics of complex formation, all thermodynamic characteristics of such processes will be functions of temperature, so that the van't Hoff method for determining enthalpies cannot be accepted as valid. Microcalorimetric methods must be used, enabling heats of formation to be determined under isothermal conditions. The main problem—the relation between the equilibrium constants of the polymeric complexes and those of their low-molecular analogues—is not always definitely solved. It is quite likely that such a state of quantitative data on polymeric charge-transfer complexes is due to a series of inaccuracies in the generally accepted methods for determining equilibrium constants. We shall therefore examine briefly the general principles of the calculation of equilibrium constants for complex formation in solution.

V. GENERAL PRINCIPLES OF THE CALCULATION FROM SPECTROPHOTOMETRIC DATA OF THE EQUILIBRIUM CONSTANTS OF CHARGE-TRANSFER COMPLEXES

In the investigation of charge-transfer complexes in solution, where they may undergo dissociation, the observed parameters characterise not the individual complex but an equilibrium mixture with the starting materials. Several monographs have been published on methods for the investigation of equilibrium mixtures[5,139–141]. When only one equilibrium

$$q[D] + p[A] \rightleftarrows [D]_q[A]_p \qquad (8)$$

is established, the problem of the simultaneous determination of physicochemical parameters and equilibrium constants has been solved for the simplest and most frequent case of unit coefficients $p = q = 1$.

On the assumption of unit activity coefficients of all species present in solution, the equilibrium constant expressed in molar concentrations is

$$K = \frac{[AD]}{[D][A]} . \qquad (9)$$

The material balance of the system is represented by the relations

$$[A]_0 = [A] + [AD] , \qquad (10)$$

$$[D]_0 = [D] + [AD] , \qquad (11)$$

where $[A]_0$ and $[D]_0$ are the initial concentrations of the components A and D. If the optical density D is additive, we have

$$D = \varepsilon_{AD}[AD] + \varepsilon_A[A] + \varepsilon_D[D] + \varepsilon_S . \qquad (12)$$

Equations (9)–(12) contain five unknowns—[A], [D], [AD], ϵ_{AD} and K_{AD}—for the spectrophotometric case. Only simultaneous solution of equations for two experimental points obtained under different concentration conditions will enable ϵ_{AD} and K_{AD} to be determined. Owing to the cumbersome form of the equation obtained, various approximations are used depending on the stability of the complex.

For weak complexes Eqns. (9) and (12) reduce to a single equation containing the two unknowns ϵ_{AD} and K_{AD}. The coefficients ϵ_A and ϵ_D are determined experimentally, and then simplifying functions concerning the experimental conditions are introduced to bring this equation to a form which can be solved graphically. The simplifying condition in the deduction of the Benesi–Hildebrand equation

$$\frac{[A]_0}{D} = \frac{1}{K_{AD}\cdot\varepsilon_\lambda^{AD}}\cdot\frac{1}{[D]_0} + \frac{1}{\varepsilon_\lambda^{AD}} \qquad (13)$$

is that $[D]_0 \gg [A]_0$. This method[142] requires extrapolation to concentrated solutions. Scott[143] suggests the preferable variant

$$\frac{[D]_0[A]_0}{D} = \frac{[D]_0}{\varepsilon_\lambda^{AD}} + \frac{1}{K_{AD}\cdot\varepsilon_\lambda^{AD}} \qquad (14)$$

which entails extrapolation to dilute solutions for the estimation of ϵ_λ^{AD} and K_{AD}. Several modifications of Eqn. (13) are available depending on specific experimental conditions[143–147].

All approximate methods yield[148] an overall equilibrium constant K relating to all the isomeric equimolecular complexes, including contact complexes, together with an average extinction coefficient.

$$K_{AD} = \Sigma K_i \ , \qquad \varepsilon_\lambda^{AD} = \Sigma K_i \varepsilon_{\lambda i} / K \ . \tag{15}$$

The concept of contact complexes or contact charge transfer was introduced by Orgel and Mulliken[148] to explain the discrepancy arising in the relation between equilibrium constants and extinction coefficients. Mulliken had remarked[19] that increase in the equilibrium constant should be accompanied by an increase in the quantum-mechanical dipole moment and in the oscillator strength of the transition in the transfer of charge. A corresponding strengthening of the charge-transfer band may be expected[149]. However, the calculated equilibrium constants and extinction coefficients for weak complexes show the opposite relation[150]. Orgel and Mulliken suggested that the exchange of electrons occurring in the absorption of light could occur not only between donors and acceptors combined in a complex but also on the random collision of the free donors and acceptors. The weaker the complex the more significant the contribution of contact charge transfer to the total absorption by the complex. When the whole of the absorption characteristic of donor–acceptor interaction results from contact charge transfer, the Benesi–Hildebrand method yields $K = 0$ and $\epsilon = \infty$. Thus the chief defects of approximate graphical methods of calculation for weak systems are due to the "conspiracy of errors effect", when the total experimental inaccuracies distort the true values of K and ϵ[151–155].

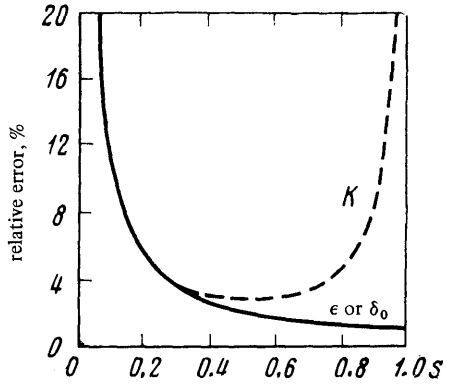

Figure 6. Dependence of relative error on concentration ratio S of components[162].

The literature on weak charge-transfer complexes has recently been overflowing with critical investigations of two-parameter equations used to determine equilibrium constants and extinction coefficients[156–163], in which various criteria of reliability were suggested for determining equilibrium constants of weak complexes. Person, for example, stated[161] that the most accurate values are obtained when the concentration of the donor lies in the range (0.1 to 9)K^{-1}. At donor concentrations below $0.1K^{-1}$ graphical solution of Eqns. (13) and (14) will give negative values. Derenleau[162] analysed theoretically the minimum error as a function of the concentration ratio S of the components, and showed that the most reliable values of K and ϵ are formed in the range $S = 0.2–0.8$ (Fig. 6). This diagram shows also that the relative errors for experiments conducted within the range $S = 0.01–0.1$ will correspondingly vary by 100–101%, and attempts to obtain accurate values of K and ϵ by a graphical method are meaningless.

Further, as shown above, the deduction of the Benesi–Hildebrand equation assumes the presence of only one equilibrium, but the linearity of Eqn. (13) by no means implies the absence of a complicated equilibrium[164,165]. This simplification may lead to inadequacy of the suggested reaction mechanism and of the equation describing the reaction.

VI. USE OF ELECTRONIC COMPUTERS TO CALCULATE COMPLEX-FORMATION EQUILIBRIA IN POLYMER SYSTEMS

A method of trial and error entailing use of an electronic computer has recently been suggested, in contrast to approximate methods for estimating equilibrium constants and extinction coefficients. A graphical variant is Drago's method[166], in which arbitrary component concentrations are chosen and appropriate equilibrium constants are calculated for each series of experiments, after which graphs are plotted of equilibrium constant against extinction coefficient. In the ideal case the lines representing all series of experiments should intersect in a single point, which gives the true values of K and ϵ. However, such a procedure is extremely laborious.

The method of trial and error using a computer[167–172] has several advantages over approximate methods: a solution can be found for complexes other than equimolecular, approximation becomes unnecessary, and the restriction to the extremal conditions $[D]_0 \gg [A]_0$ is removed. For example, Conrow[168] finds the concentration of the complex from initial calculation of the equilibrium constant. This concentration is then used to find the most suitable value of the extinction coefficient ϵ^{AD} in Eqn. (12). The required equilibrium constant K and extinction coefficient ϵ are found by calculating the absorption at every experimental point and accumulating the sums of the squares of differences between calculated and experimental values. The computation is terminated when the change in the difference

$$F_{min} = \sum_{i=1}^{N} (D_{calc.} - D_{exp.})^2 \tag{16}$$

becomes arbitrarily small. The non-linear methods described for calculating equilibrium parameters have hitherto been applied to systems of low molecular weight[167–172]. The complexity of the equilibrium of polymer systems due to the possible presence of several complexes and the irreproducibility of published data make resort to electronic computers necessary.

The method of minimisation of the function for polymer systems has hitherto been applied only to solutions of complexes of poly(phenyl methacrylate), poly(naphthyl methacrylate), polyvinylcarbazole, and their model analogues

with tetracyanoethylene[136]. Equimolar initial concentrations of the components were taken, and the reaction was thus regarded as a simple one-stage formation of an equimolecular complex. However, the values obtained[136] for the equilibrium constants were hundredfold the usual values, which is inconsistent with our ideas on weak complexes. Furthermore, the relations between equilibrium constants for polymeric and low-molecular complexes were opposite to those found by Rembaum[130] and by Smets[65].

The survey of methods for investigating charge-transfer complexes in solution reveals the complexity of the study of equilibrium complex formation in polymer systems, where the usual phenomena for the simple complexes (contact charge transfer) are accompanied by the specific behaviour of chain molecules (variation in configuration of the macromolecule, mobility of the chain, etc.).

The study of complex formation between polymeric donors and low-molecular acceptors obviously requires further deepening of research using the latest achievements of physicochemical methods and of calculations by means of electronic computers.

Promotion of Aluminosilicate Catalysts by Reactants and Additives

I.M.Kolesnikov

Experimental results are given on the promotion of aluminosilicates—amorphous and crystalline—by components of the reaction mixture (alkenes, halogen-containing compounds) and by molecules (water, nitrogen, carbon dioxide, etc.) not involved in the reaction stoichiometry. The effect of additives or reactant molecules on the catalyst depends on their structure and composition, as well as on the concentration of the promoter. A suggested mechanism of promotion of aluminosilicates and zeolites is considered. A list of 160 references is included.

I. INTRODUCTION

Artificial and naturally occurring aluminosilicate catalysts and zeolites (constructed on an aluminosilicate frame) have found wide use in the petroleum-processing and petrochemical industry for the cracking of petroleum fractions, the alkylation of aromatic hydrocarbons, the polymerisation of alkenes, the isomerisation of alkylated aromatic hydrocarbons, *trans*-alkylation, and other processes[1-5]. The aluminosilicate catalysts are built of interconnected polyhedra such as $[AlO_4]$, $[AlO_5]$, and $[AlO_6]$ groups and the $[SiO_4]$ tetrahedron. They contain also hydroxy-groups and water molecules, either sorbed or structural. In zeolites aluminium is present in $[AlO_4]$ tetrahedra "stabilised" in the lattice by $[SiO_4]$ tetrahedra and by other groups. "Isolated" $[AlO_4]$ tetrahedra present in the structure of aluminosilicates and zeolites are the most active in catalysing the reactions of hydrocarbons, alcohols, and other compounds[6,7]. Zeolites are used also as matrices in the production of new zeolite-containing catalysts possessing excellent operating properties.

The efficiency of the industrial or laboratory conversion of various hydrocarbons and other compounds depends not only on the composition and structure of the catalyst but also on the composition of the initial mixture of reactants under otherwise similar experimental conditions, i.e. temperature, pressure, type of process, duration of continuous operation of the catalyst, and other variables. The activity of solid catalysts can be increased considerably (promoted) by the addition of reactant molecules or by introducing non-reactants into the reaction mixture. Such enhancement of the activity of a catalyst by oxygen molecules was first observed for liquid-phase hydrogenation[8]. In the Soviet Union work on the promotion of catalysts by reactant molecules was undertaken by Roginskii[9], who suggested that promotion of the solid surfaces was due to change in their structure and electronic state, departure of their compositions from stoichiometric, and the trapping of the promoting additives in surface defects on a metallic or oxide solid catalyst. More recently the idea has developed that promotion involves action on a solid surface by molecules of a promoter acting as a non-stoichiometric component in the catalysis[10]. This concept is phenomenological in character, like the ideas of variation in composition and properties of the catalyst under the influence of the reaction mixture[11] and like the deductions based on the formal kinetics of the interaction of a catalyst with reactant molecules[12].

The above paper[10] gave several examples of the activation of various catalysts by components of the reaction mixture or by molecules of substances specially added thereto. However, no systematic survey has been made of information on the change in activity and selectivity of aluminosilicates, varying in composition and structure, under the influence of reactant molecules or on the control of the activity and selectivity of catalysts by changes in the composition of the reaction mixture. It has now been shown that certain compounds present in a hydrocarbon reaction mixture promote the action of an aluminosilicate when they are present at certain concentrations, but deactivate the catalyst when present at other concentrations. Roginskii termed this phenomenon *modification*, and the additives themselves *modifiers*[9].

II. PROMOTION OF ALUMINOSILICATES BY ALKENES IN CRACKING, ALKYLATION, POLYMERISATION, AND HYDROGEN EXCHANGE

It was established as early as 1948 that alkenes act as promoters[13] in the isomerisation of hydrocarbons in the presence of halide catalysts. Later it was observed[14] that small (0.1—0.35 mole %) additions of octene to the reaction mixture on the cracking of n-octane enhance the activity of an aluminosilicate catalyst, with an increase in the conversion of the alkane approximately from 21% to 27%. Additions of more than 0.4 mole % of the alkene diminish the quantity of n-octane decomposed (Fig. 1): i.e. the catalyst is deactivated. The alkene itself may undergo partial conversion. However, it had undergone repeated preliminary involvement in the main process.

Experiments in which 0.27 mole % of radioactive ethylene $^{14}C_2H_4$ was added to the reaction mixture were made in order to obtain a more precise idea of the mechanism of the action of the alkene on the catalyst and on the conversion of n-octane. Radiometric analysis established[14] that at most 20% of the ethylene mixed with octane underwent transformation, and the molecular ratio of conversion of the former to that of the latter was ~1 : 100. This suggests that the effect of the alkene molecules is to change the energy state both of the catalytic centres and of the reactant molecules. The behaviour of alkene molecules mixed with alkanes and a catalyst probably differs from their behaviour in the purely thermal cracking of hydrocarbons, where unsaturated hydrocarbons inhibit breakdown of saturated hydrocarbons, which occurs by a radical—chain mechanism[15].

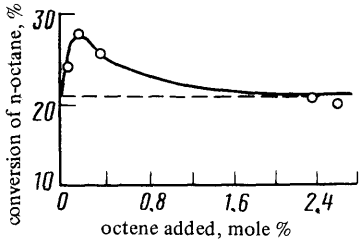

Figure 1. Effect of additions of unsaturated compounds on the cracking of n-octane at 518°C for 18 s. The broken line represents a blank experiment.

The promotion of an aluminosilicate catalyst by extremely small quantities (<0.01%) of alkenes was observed in the alkylation of aromatic hydrocarbons by alcohols[16-22]. Table 1 shows that, if a starting material isolated from the products of catalysis (which may contain alkenes) is subjected to alkylation, the yields are higher than those from the alkylation of the pure raw material (alkenes were detected by treating the catalysate with bromine water or potassium permanganate solution)[22].

Small additions of alkenes to the reaction system have a favourable effect on the hydrogen—deuterium exchange between isobutane and deuterium oxide in the presence of an aluminosilicate catalyst[23]: the rate of exchange in the presence of 0.5 vol.% of isobutene in the mixture was higher than in the absence of the alkene, although the activation energy of exchange was 17 kcal mole^{-1} in both cases. After alkenes had been removed from the mixture by hydrogenation, the rate of exchange decreased nearly to one-third[23] or exchange ceased completely[24] at high temperatures, in spite of the presence of alkenes.

Alkenes formed during the dehydrogenation of alkanes promote a catalyst containing platinum. Thus pure n-pentane does not undergo isomerisation in the presence of pure alumina under 7 atm at 220°C.[25] If a small quantity of platinum is deposited on the aluminium oxide, rapid isomerisation takes place. It was assumed[25] that platinum causes the formation of a small quantity of an alkene (or a carbonium ion), which is now able to isomerise on the acid carrier and again be hydrogenated to an alkane. We may suppose that the alkene itself is able to promote the platinum—alumina catalyst and enhance its isomerising activity.

Nevertheless, some alkenes tend to inhibit the conversion of others[26,27]. In the presence of an aluminosilicate catalyst containing nickel monoxide, for example, the polymerisation of ethylene is inhibited by 3—5% of propene or butene in the mixture. Yet the isomerisation of cyclopropane in the presence of an aluminosilicate or a cobalt oxide—aluminosilicate catalyst gives far higher yields in the presence of added ethylene or propene than in the absence of alkenes[28].

Table 1. Alkylation of benzene, toluene, phenol, bromobenzene, and chlorobenzene by propan-2-ol with a space velocity v = 0.2 cm^3 cm^{-3} h^{-1} at 250°C*.[22]

Molar C_6H_6R reactant ratio	Yield of alkylation products, mass%									
	cumene		cymenes		isopropylphenol		isopropylbromobenzene		isopropylbenzene	
	I	II	I	II	I	II	I	II	I	II
2:1	29.6	29.8	39.0	40.8	39.0	—	16.5	19.5	13.0	14.5
4:1	53.0	58.6	60.0	62.6	58.0	58.7	31.0	37.0	31.0	33.0

8:1	60.2	68.5	74.3	82.5	70.0	—	42.0	53.5	40.0	50.5
20:1	73.5	94.0	79.5	96.3	81.0	98.0	69.0	92.0	63.3	81.0

*(I) Fresh starting material; (II) starting material isolated from products of catalysis.

The above experimental results obviously indicate that small doses of alkenes added to a reaction mixture act as promoters of aluminosilicates. The optimum content of alkenes exerting an activating effect on catalytic centres is probably below 1%. Higher concentrations of alkenes usually tend to deactivate the catalyst, as shown by a decrease in the rate of the process.

III. PROMOTION OF ALUMINOSILICATES BY "INERT" CHEMICAL COMPOUNDS

It has been established experimentally that water, carbon dioxide, and other molecules added in certain quantities to the reaction mixture are able to promote aluminosilicates, zeolites, and γ-alumina in the reactions of hydrocarbons and other compounds or else to change their adsorptive capacity[29-51]. In turn, heating aluminosilicates and zeolites to a certain temperature enhances their activity towards deuterium—hydrogen exchange[41], polymerisation[7], cracking[29], etc.

The activity of an artificial aluminosilicate catalyst towards the cracking of cumene[29,30] varies with the quantity of water introduced into the system, passing through a maximum whose position depends on the composition of the catalyst, its method of preparation, and the drying conditions[52]. Thus Kaliko and Pervushina[30] first heated an aluminosilicate catalyst in a vacuum at 700°C for 700 h, then cooled it in the vacuum to 400°C, and passed cumene vapour through it. If the catalyst were absolutely dry, it exhibited no catalytic activity on contact with isopropylbenzene. The adsorption of 0.00035 mass % of water conferred considerable activity on the aluminosilicate, which increased with the sorption of additional quantities to reach a maximum at 0.2 mass % of water. Similar results were obtained when an aluminosilicate was treated with caesium hydroxide solution, ignited at 750°C, and then treated with water[30].

Table 2 shows that the catalytic activity of an aluminosilicate in the cracking of cumene passes through a maximum with variation in its water content[53]. This was attributed[54] to variation in the relative quantities of protic and aprotic centres. The promotion of aluminosilicates by water has been observed also [31,32,35] in cracking, isomerisation, deuterium–hydrogen exchange[24,51], and polymerisation[55].

Table 2. Effect of dehydration on the activity of an aluminosilicate catalyst in the cracking of cumene[53].

Time of treatment of catalyst at 700°C, h	Water remaining in catalyst, mass %	Relative activity
Initial	1.40	1
12	1.63	1
15	0.53	1.3
30	0.42	2.1
40	0.37	1.7
50	0.16	1.6

The reactions undergone by 2,2,3-trimethylpentane, 2-methylpentane, and n-heptane in the presence of an aluminosilicate catalyst, with and without addition of water to the reaction vessel, are mainly of the cracking and isomerisation type[48]. The activity of the catalyst passes through a maximum at different quantities of water vapour absorbed by the aluminosilicate in the two reactions: maximum cracking and isomerisation were observed with 2,2,3-trimethylpentane, 2-methylpentane, and n-heptane with water contents in the catalyst of respectively 0.1, 0.047, and 0.15 mass %. The results for the isomerisation of 2-methylpentane were identical with those of Ref. 26. With rise in temperature from 162 to 180 and then to 200°C the yields of products from n-heptane for the "dry" catalyst were respectively 7.53, 21.83, and 52.83 [%]; the corresponding yields for the "wet" catalyst (with the optimum water content of 0.1 mass %) were 44.30, 53.41, and 77.23 [%].

Table 3. Effect of water (supplied at 0.03 $cm^3\ cm^{-3}\ h^{-1}$) on yield of xylenes from the isomerisation of *m*-xylene fed at 0.3 $cm^3\ cm^{-3}\ h^{-1}$.[56]

Temp., °C	Yields, mass %			
	toluene	*m*-xylene	*p*-xylene	*o*-xylene
400	trace	67.8	14.7	9.3
450	2.5	51.1	16.7	18.5
470	9.7	47.2	12.5	17.5
450	3.7	55.0	13.6	13.6 (no water)

Aluminosilicates exhibited their maximum activity when they had adsorbed 0.05 mass % of water[31]. Yet the addition of water vapour[56] to ethylene diminishes its rate of polymerisation in the presence of an aluminosilicate catalyst containing nickel monoxide, and the yield of products of the isomerisation of *m*-xylene and its dismutation into toluene increases on the introduction of water into the reaction system (Table 3).

Nitrogen and carbon dioxide also promote aluminosilicates, as was observed in a study by a pulse method of the disproportionation of toluene[57] in currents of these gases in gas–liquid chromatographic apparatus. The kinetic results were processed quantitatively by the method of Refs. 58 and 59. The rate of disproportionation of toluene was higher in nitrogen than in hydrogen, as is shown by the equations—in a stream of hydrogen

$$K \cdot k = 34 \cdot 10 \exp(-30\,000/RT)$$

and in a stream of nitrogen

$$K \cdot k = 0.2 \cdot 10^{-1} \exp(-20\,000/RT)$$

where k (in s^{-1}) is the rate constant and K (atm^{-1}) the adsorption equilibrium constant. These indicate that conducting the disproportionation in hydrogen increases the activation energy, whereas in nitrogen fewer catalytically active centres function, but the process has a smaller activation energy. Thus hydrogen molecules slightly deactivate the aluminosilicate, whereas nitrogen molecules activate it. The pre-exponential factor is proportional to the number of active centres[60]. These results are supported also by data[61] on the polymerisation of hex-1-ene on aluminosilicate catalysts containing cobalt oxide. Thus the yield of liquid polymerisation products in the presence of hydrogen at 190°C is 7.6%, which rises to 22.6% when 7.0 vol.% of carbon monoxide is added. Crystalline aluminosilicates are promoted also by carbon dioxide[62,63].

IV. PROMOTION OF ALUMINOSILICATES BY GASEOUS HYDROGEN HALIDES

Artificial and native aluminosilicate catalysts were activated by pretreatment in a gaseous halogen or by a continuous supply of a hydrogen halide to the reaction zone. If a stream of gaseous hydrogen chloride is passed through a mixture of benzene, propene, and a catalyst, for example, alkylation can be effected with high yields at temperatures below the boiling point of benzene[64]. It is interesting that alkylation takes place more efficiently when the catalyst has first been completely dehydrated at temperatures above 500°C..

Gaseous hydrogen chloride also increases the yield when benzene is alkylated by alkyl halides at relatively low temperatures. This indicates that hydrogen chloride is a promoter of aluminosilicates in different reaction media, so that promotion is probably not due to formation of a protonated centre but to additional activation of the catalytic polyhedra.

In the absence of hydrogen chloride hardly any alkylation of benzene by ethylene occurs on aluminosilicate catalysts right up to 500°C.[65] Introduction of the gas into the stream of benzene and ethylene leads to an appreciable rate of alkylation to give a yield of 0.285 mole of ethylbenzene per mole of ethylene (at 450°C, with liquid benzene supplied at 0.075 mole $cm^{-3}\ h^{-1}$). Such alkylation is described[65] by the kinetic equation for a second-order irreversible heterogeneous reaction. The temperature dependence of the rate constant is

$$k = 2.77 \cdot 10^3 \exp(-90\,100/8.313T)\ . \qquad (1)$$

Increase in activity of an aluminosilicate on the addition of gaseous hydrogen chloride to the reaction mixture has been observed also in the isomerisation of n-butene[66] and in the alkylation of toluene by propene[67,68]. In these experiments the aluminosilicate had undergone preliminary treatment

with the gas for 1 h. The alkylation was conducted with molar proportions of toluene and propene of 2.3 : 1, a rate $v = 1.1$ cm^3 cm^{-3} h^{-1}, and the catalyst functioning at 200°C for 1 h.

Table 4. Alkylation of toluene by propene[67,68].

Reaction products	Yields (× 100), mole mole^{-1}			
	aluminosilicate activated with HCl (gas)			Unactivated aluminosilicate
	initial	first regeneration	second regeneration	
Cymenes (total)	26.5	25.8	29.1	22.0
o-Cymene	23.5	25.0	23.4	25.8
m-Cymene	36.0	34.2	36.8	33.4
p-Cymene	40.5	40.7	39.8	40.8
Di-isopropyltoluenes	22.1	20.2	21.1	13.7
Hexenes	17.9	14.2	14.6	13.2

Table 4 shows that the high activity of an aluminosilicate treated with gaseous hydrogen chloride is preserved even after several cycles of regeneration in a current of air at 550°C for 3 h, but that the products of the alkylation of toluene by propene on activated aluminosilicates contain more *m*-xylene than is obtained with unactivated catalysts.

Other results[69,70] confirm the stable character of the centres produced in aluminosilicates by the action of gaseous hydrogen chloride. It was suggested[71] that the effect of the gas was to increase activity by forming more active centres than in the original aluminosilicate. Experimental data on the change in catalytic activity indicate that a gaseous hydrogen halide transforms $[AlO_n]$ polyhedra in the surface layer of the catalyst into polyhedra of mixed type $[AlO_nHal_m]$, with a change both in the composition of the polyhedron and in its acceptor power ($n = 1-6$ and $m = 1-3$). The $[AlO_4]$, $[AlO_5]$, $[AlO_6]$, and $[AlO_nH_m]$ polyhedra may undergo a change not only in symmetry and composition but also in energy state, which may influence the stability of intermediate complexes of reactant molecules with catalytic centres, and hence favour easier conversion of the reactant molecules.

V. PROMOTION OF ALUMINOSILICATES BY ALKYL HALIDES AND OTHER HALOGENATED COMPOUNDS

The alkylation of aromatic hydrocarbons by alkyl halides in the presence of aluminosilicates gives higher yields than do the pure alkenes[72-78]. This may be due to higher reactivity of the alkyl halides and to the promoting effect of these compounds themselves or of their decomposition products[79] on the catalytic centres of the aluminosilicates.

Carbon tetrachloride exerts a strong promoting effect on aluminosilicates in the alkylation of benzene by ethylene[80]: thus the temperature dependence of the rate constant in its absence is

$$k = 1.41 \cdot 10^{-6} \exp(-10\,000/RT) \qquad (2)$$

but on the addition of 0.3 mass % CCl_4 this becomes

$$k_1 = 2.63 \cdot 10^{-6} \exp(-10\,600/RT) \ . \qquad (3)$$

These results show an increase in rate of alkylation of some 80% in the presence of carbon tetrachloride. The higher pre-exponential term in the latter equation suggests that the intermediate complex of the catalytic centre with reactant and promoter molecules is "looser" than in the absence of tetrachloromethane, while the energy state of the complexes is almost the same in the two cases. Experimental results for the promotion of a catalyst by carbon tetrachloride are listed in Table 5. Termination of the supply of carbon tetrachloride to the reaction mixture results in a sharp decrease in the conversion of ethylene in the alkylation of benzene, whereas in the presence of 0.3 mass % CCl_4 raising the pressure and the molar ratio of benzene to ethylene increases the proportion of starting material converted.

Table 5. Effect of quantity of tetrachloromethane on conversion of ethylene on aluminosilicate catalyst under 20 atm at 250°C with molar velocity $n_0 = 0.0357$ mole g^{-1} h^{-1}*.[80]

Tetrachloromethane added to benzene, mass %	Conversion of ethylene, %
0.0	35
0.1	42
0.2	50
0.3	75
0.5	75

* Molar ratio of benzene to ethylene $\gamma = 2.7 : 1$.

It is interesting that aluminosilicates differing in composition are unequally activated by an alkyl halide (ethyl chloride) in the alkylation of benzene by ethylene. Fig. 2 shows that an aluminosilicate containing 30 mass % Al_2O_3 + 70 mass % SiO_2 is most strongly promoted by ethyl chloride or its decomposition products. These results will be explained[81-83] in Section VIII.

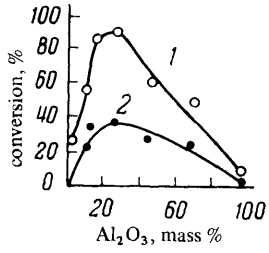

Figure 2. Activity of aluminosilicate catalysts, differing in composition, in the alkylation of benzene by ethylene with the addition of ethyl chloride (benzene supplied at $n_0 = 0.0357$ mole g^{-1} h^{-1} under 3.0 atm): 1) 0.3 mass % C_2H_5Cl added to benzene; 2) pure $C_6H_6 + C_2H_4$ mixture.

The character and the magnitude of the effect of alkyl halides on aluminosilicate catalysts depend also on the composition and structure of the compound introduced into the reaction mixture. Table 6 shows that hydrocarbons in which geminal hydrogen atoms have been replaced by halogen atoms activate aluminosilicates more strongly than do their isomers with a different arrangement of

halogen atoms. The greater the number of geminal halogen atoms in a compound, the stronger usually is its promoting action on a catalyst. Compounds containing bromine or fluorine atoms have a weaker activating effect on an aluminosilicate than have compounds containing only chlorine atoms. Halogen-containing compounds of vicinal structure generally lower the activity of an aluminosilicate catalyst towards alkylation.

Table 6. Alkylation of benzene by ethylene in presence of an aluminosilicate catalyst (containing 16 mass % Al_2O_3) with $\gamma = 2.7:1$ and $v = 1.2$ cm^3 cm^{-3} h^{-1} at 300°C.[80]

Halogenated compound	Quantity added to benzene, mmoles $(100\ g)^{-1}$	Ethylene converted, %	Ethylbenzene in products, %
CCl_4	1.95	93.5	96.5
$CHCl_3$	2.50	77.8	90.8
CH_2Cl_2	3.52	47.0	83.2
C_2H_5Cl	4.65	89.5	96.0

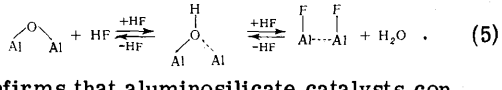
1,2-$C_3H_6Cl_2$	2.66	25.2	—
$FCCl_3$	2.18	83.4	98.3

The data in Table 6 suggest that the promoting or deactivating effect of additives on a catalyst is due to undecomposed hydrogen halide molecules. However, decomposition products of halogenated compounds—alkenes and hydrogen halides—may play some part. The activity of an aluminosilicate catalyst towards the conversion of hydrocarbons passes through a maximum depending on the quantity of alkyl halide added to the reaction mixtures[67,68]. Thus in the alkylation of toluene by propene under 1 atm at 240°C the maximum growth in activity of the catalyst was obtained on addition of 1.4 vol.% of isopropyl chloride to the reaction mixture. Gaseous hydrogen chloride and propene were detected among the reaction products. This confirms that aluminium silicate can be promoted in a high-temperature reaction not only by the reactant molecules but also by gaseous hydrogen chloride and by an alkene. It is assumed also that hydrogen chloride molecules can be sorbed by catalytic centres of the aluminosilicate, thereby displacing products or impeding the sorption of compounds responsible for the formation of "carbon" and other highly condensed products. This preserves accessibility to catalytic centres for the initial reactant molecules and thereby maintains high catalytic activity in the aluminosilicate for a longer time. This suggestion has found confirmation[84,85].

It is also possible that polyhedra of novel chemical composition may be formed by interaction between gaseous hydrogen chloride molecules and the aluminium—oxygen polyhedra:

(4)



(5)

Scheme (4) confirms that aluminosilicate catalysts containing fluorine but no hydroxy-groups[86] are extremely active in the isomerisation and the polymerisation of hydrocarbons, despite the diminished acidity of the centres. The appearance of centres of the type AlO_nHal_m in an aluminosilicate under the influence of gaseous hydrogen chloride is indicated by data on the isomeric composition of products of the alkylation of toluene by propene in the presence of an aluminosilicate catalyst and aluminium chloride. Table 7 shows that increase in the isopropyl chloride content of the mixture in the presence of the catalyst is accompanied by an increase in the *m*-cymene content of the products, until the equilibrium concentration is reached. A similar pattern is observed with rise in temperature of the alkylation of toluene by propene in the presence of aluminium chloride. The increase in the *m*-cymene content of the mixture in the former case is probably due to an increase in the number of halogenated catalytic centres formed in the aluminosilicate by scheme (4), which affect the isomerisation of *o*- and *p*-cymenes into the *meta*-isomer. This is evident from the fact that the composition of the cymene fraction in the former case approaches the composition obtained in the presence of aluminium chloride.

Table 7. Isomeric composition of products of the alkylation of toluene by propene.

	20	—	—	17	44.2	38.8	88

* Alkylation by pure isopropyl chloride.

The promoting action of halogenated compounds—not of their decomposition products—on the catalytic centres of aluminosilicates can be revealed by an investigation at relatively low temperatures, at which the molecules of the halogenated compounds remain unchanged.

VI. PROMOTION OF ALUMINOSILICATES IN LOW-TEMPERATURE REACTIONS

Examples of low-temperature reactions are the polymerisation of pentenes and the liquid-phase alkylation of benzene by propene. In the presence of aluminosilicate catalysts quite high rates of polymerisation are observed[89-93] even between −20 and +60°C, with 60—70% conversion. The activity of an artificial catalyst can be further enhanced by the action of carbon tetrachloride introduced into the reaction mixture. In Fig. 3 the relative conversion of a mixture of pentenes is plotted against the quantity of tetrachloromethane added to the mixture[79]. Every point was obtained from the dependence of the yield of reaction products on time of contact at 20°C. Fig. 3 shows that the addition of up to 0.5 vol.% of carbon tetrachloride to the reaction mixture increases the proportion of pentene converted by roughly 50%.

Dichloroethane and diethyl ether have a similar effect on aluminosilicates[79]. Addition of 0.2 mass % of the former or 0.1 mass % of the latter increases the yield of polymerisation products from a mixture of pentenes at room temperature by 100—200% in comparison with the pure pentenes. Fig. 4 shows that the activity of the catalyst depends on the quantity of dichloroethane or ether added to the reaction mixture, and may pass through a maximum. In the presence of dichloroethane the activity of a promoted catalyst is higher than that of an unpromoted catalyst at all the concentrations studied. With ether, however, increasing its quantity above an optimum value entails strong deactivation of the catalyst. This indicates that alkyl halides and ether have different effects on the aluminosilicate centres and on the reactants.

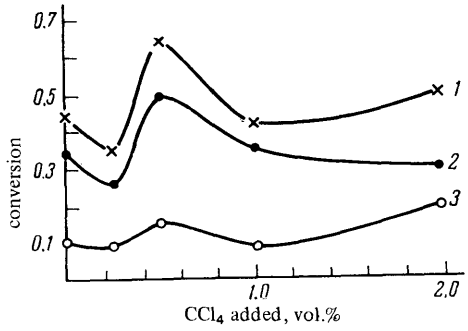

Figure 3. Effect of quantity of carbon tetrachloride added on the polymerisation of a mixture of isopentenes at 20°C for 120 min: 1) conversion of monomers; 2) yield of dimers; 3) yield of trimers.

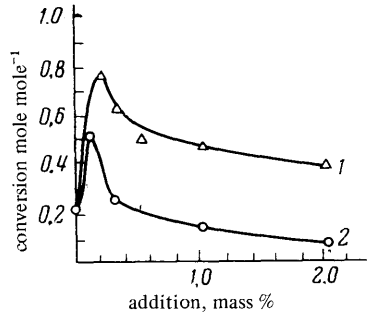

Figure 4. Dependence of conversion of a mixture of isopentenes at 20°C with time of contact 130 min on quantity of: 1) 1,2-dichloroethane; 2) diethyl ether.

Industrial aluminosilicate catalysts (including those containing zeolites) are contaminated by compounds of sodium, potassium, calcium, and other cations, which may have diverse effects on the catalytic activity[93,94]. Alkali-metal ions usually lower the activity of aluminosilicates towards the conversion of hydrocarbons. Halogenated compounds enhance considerably the activity of catalysts containing alkali-metal ions, probably in polyhedra of the type $[MO_4]$. This applies to reactions of hydrocarbons both at high and at low temperatures.

Aluminosilicates containing sodium and potassium ions are obtained by treatment with aqueous solutions of the chlorides[95]. Table 8 summarises results on the polymerisation of pentenes in the presence of such catalysts at 20°C, with and without the addition of carbon tetrachloride to the reaction mixture. It shows that aluminosilicates containing sodium and potassium ions exhibit less intense catalytic activity towards the polymerisation of pentenes than do those not containing such ions, and that potassium ions deactivate the catalyst more strongly than do sodium ions. The addition of 0.5 vol.% of tetrachloromethane to the reaction mixture almost completely restores the activity of a "poisoned" aluminosilicate, a potassium aluminosilicate being promoted more strongly than the sodium compound.

Table 8. Initial rates of polymerisation of a mixture of pentenes at 20°C.[95]

Soln. to treat catalyst	CCl_4 added, vol.%	Initial rate (× 10⁴) of conversion, moles g^{-1} h^{-1}	Soln. to treat catalyst	CCl_4 added, vol.%	Initial rate (× 10⁴) of conversion, moles g^{-1} h^{-1}
—	0	3.37	1.0*N* NaCl	—	1.33
—	0.25	2.57	0.3*N* NaCl	0.5	2.53
—	0.5	4.57	0.5*N* NaCl	0.5	2.96
—	1.0	3.24	1.0*N* NaCl	0.5	2.30
—	2.0	1.78	0.1*N* KCl	—	0.21
0.1*N* NaCl	—	2.44	0.1*N* KCl	0.5	3.21
0.5*N* NaCl	—	1.44			

An aluminosilicate treated with sodium chloride solution exhibits low catalytic activity also towards the alkylation of benzene by propene[96]. With a molar ratio of benzene to propene of 2.56 and v = 0.44 cm^3 cm^{-3} h^{-1} at 320°C the yield of isopropylbenzene is 38.7%, which falls to 3.7% on an aluminosilicate catalyst poisoned by sodium ions. The introduction of 3 mass % of propyl chloride into the reaction mixture with the "poisoned" aluminosilicate enables the yield to be raised again to 20.5%.

Thus halogenated compounds promote aluminosilicates both in high-temperature reactions of various hydrocarbons and in low-temperature reactions. The halogen compounds activate not only ordinary industrial aluminosilicate catalysts but also catalysts that have been "poisoned" by alkali-metal salts and other compounds.

VII. PROMOTION OF ZEOLITES

Original papers and reviews have been published on the structure of zeolites[97,98] and on their catalytic activity[99-103], showing that the latter depends on the nature, composition, and structure of the crystal lattice, as well as on the type of cations present in the polyhedra[104-106]. Alkali-metal ions usually deactivate a zeolite towards the reactions of hydrocarbons, and change the selectivity in isomerisation and in other reactions; but ions of bivalent and tervalent metals enhance the catalytic activity of zeolites. The activity of zeolites of various types can be changed (increased or decreased) by introducing into the hydrocarbon mixture halogen-containing compounds[71], carbon dioxide[115], certain organic acids, and other compounds of donor[96] or acceptor type.

Thus an NaY-type zeolite does not catalyse the transformation of hydrocarbons, in particular the isomerisation of *o*-xylene into *p*- and *m*-xylenes, at temperatures below 500°C.[107] Addition of gaseous hydrogen chloride up to a partial pressure of 0.05 gauge atm in the stream of hydrocarbons ensures 10% conversion of *o*-xylene, which can be increased to 15% by raising the partial pressure to 0.1 gauge atm. A zeolite of type MnY can be promoted for the alkylation of toluene by methanol when gaseous hydrogen chloride is supplied continuously into the flow of reactants (Fig. 5).[108]

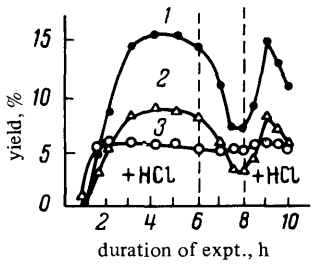

Figure 5. Effect of gaseous hydrogen chloride on activity of MnY-type zeolite in the alkylation of toluene by methanol ($\gamma = 2:1$) at 225°C as shown by yields (%) of: 1) *p*-xylene; 2) *m*-xylene; 3) *o*-xylene.

The activity of an NaX-type zeolite[109] is determined by the partial pressure of gaseous hydrogen chloride and depends on the degree of exchange of sodium for calcium or cerium(III) ions. When such ionic substitution reaches 30%, the zeolite is not activated by gaseous hydrogen chloride. The yield of cumene formed by alkylation is increased from 15% to 25% when 40% of the sodium ions in the zeolite have been replaced. Some of the hydrogen chloride molecules are strongly sorbed, while others are weakly sorbed. The rate of reaction is assumed to be proportional to the number of weakly sorbed molecules, which are responsible for promoting the zeolite.

The action of hydrogen bromide, water, and hydrogen chloride molecules on the catalytic centres in an REX-type zeolite (RE = rare-earth element) in the alkylation of benzene by ethylene can be traced from published data[110]. The zeolite was first ignited at 400°C and kept in a vacuum of 0.2 mmHg for 0.5 h, after which hydrogen bromide, water, or hydrogen chloride (1.85 mg-equiv.g^{-1}) was introduced into the system, and benzene was alkylated with ethylene at 177°C ($C_6H_6 : C_2H_4 = 12$ and $v = 8.5\ s^{-1}$). Fig. 6 shows that, with short times (<50 min) of contact of the reaction mixture with the zeolite, the sequence of activating effects of the additives is $HCl > H_2O > HBr$; on prolonged (>100 min) operation of the zeolite this sequence changes to $H_2O > HBr > HCl$; and if the catalyst had operated for <25 min, added water and hydrogen bromide tended to deactivate the catalytic centres. It may be supposed that the catalytic centres on the fresh zeolite already possess the highest activity, so that the above three polar molecules are first sorbed on them. This leads to some diminution in acceptor power and hence in catalytic activity of the $[AlO_4]$ tetrahedron. With increase in duration of operation of the zeolite its catalytic centres become covered with condensation products of high molecular weight or "carbon". Under these conditions the sorption of water, hydrogen bromide, or hydrogen chloride on them preserves[110,111] their enhanced catalytic activity in the transformation of hydrocarbons.

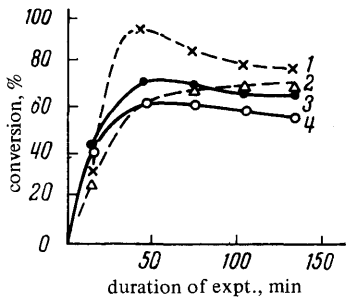

Figure 6. Variation of activity of REX-type zeolites with additions of: 1) H_2O; 2) HBr; 3) HCl; 4) pure zeolite.

Faujasite of NaY type is completely inactive in the cracking of cumene[112]. Quite high activity results from the introduction of gaseous hydrogen chloride, when the yield of cracked products is proportional to the surface coverage of the catalyst with the halide. It is assumed that a new catalytic centre is formed[113]:

$$M^+Z^- + HCl \rightleftarrows \begin{matrix} M^{+\delta'} \ldots Z^{-\delta''} \\ | \qquad\quad | \\ Cl^{-\delta_1} \quad H^{+\delta_2} \end{matrix}$$

However, the increased chlorine content of the mixture[114] is insufficient to increase the activity of the zeolite significantly. The formation is probably necessary of centres with a definite structure and composition, i.e. a definite polyhedron, e.g. $[AlO_nCl_m]$. Polyhedra of this type have been detected by nuclear magnetic resonance when a zeolite is treated with chlorine at high temperatures[115].

The activity of zeolites, like that of aluminosilicates, can be enhanced by the action of alkyl halides and other compounds[96]. Table 9 shows that propyl chloride promotes zeolites of types NaX, NaY, CaX, and HX, but tends to deactivate CaY. The activity of a zeolite passes through a maximum, whose height and position depend on the type of zeolite, with increase in the quantity of propyl chloride added to the reaction mixture. The HX zeolite is almost twice as active as CaX towards the alkylation of benzene by pure propene. When propyl chloride is added to the reaction mixture, the yields of cumene on CaX approach those on an HX type. The NaY zeolite does not catalyse the alkylation of benzene by pure propene, but a markedly different picture is obtained when 3.0 mass % of propyl chloride is added to the system: the yield of cumene is then 0.173 mole per mole of the alkylating agent, which increases to 0.55 mole $mole^{-1}$ in the presence of 10 mass % of propyl chloride (calculated on the benzene). The alkylation of benzene by pure n-propyl chloride gives a yield of isopropylbenzene of only 0.104 mole $mole^{-1}$.

It is interesting that the activity of zeolites used in the alkylation of benzene by propene to which propyl chloride has been added remains fairly high after regeneration.

As mentioned above, this effect is connected with the appearance of new polyhedra in the zeolite under the influence of decomposition products of alkyl halides. The activity of the promoted zeolite diminishes after several regeneration cycles, but remains above that of the initial zeolite. This indicates that regeneration of a promoted zeolite by atmospheric oxygen and other molecules entails the breakdown of a number of chlorine-containing catalytic centres.

The activity of an NaY-type zeolite towards the alkylation of benzene by propene[98,116] depends on the molecular structure and type of additive. Table 10 shows that molecular chlorine, tetrachloromethane, n-propyl chloride, propionaldehyde, and acetone activate the zeolite. They can be arranged in the sequence

$$Cl_2 > CCl_4 > n\text{-}C_3H_7Cl \gg (CH_3)_2CO > C_3H_7CHO,$$

according to their activating effect on the zeolite. Propionic acid, nitropropane, and chlorobenzene have no activating effect on an NaY-type zeolite.

The presence of up to 3 mass % of water almost doubles the activity of zeolites also towards the cracking of isopropylbenzene[117-119], but the introduction of large quantities of water either has no effect or diminishes the activity. The activation of zeolites by carbon dioxide and by water is explained by surface protonation or by the formation of hydroxy-groups attached to silicon in the lattice, which are assumed to act as catalytic centres[118,119]. The promotion of zeolites by water has been observed also in the isomerisation of cyclopropane, the dehydration of alcohols[119,120], the disproportionation of toluene[121], the isomerisation of butenes[122] and xylenes[113], the alkylation of toluene by alcohol[123], and the polymerisation of ethylene and propene[124]. In many cases the change in catalytic activity of the zeolites when heat-treated at various temperatures depended on the quantity of residual water in the zeolite[110,111,120,123,125,126]. Promotion was explained by the action of molecules on "acidic" centres in the zeolite, although the structure of these centres and their energy state were not discussed.

Table 10. Alkylation of benzene by propene on NaY-type zeolite with various additives[116].

Alkylating agent and additive	Rate of supply of liquid benzene, $cm^3\ cm^{-3}[h^{-1}]$	Molar ratio, benzene: alkylating agent	Yield (× 100) based on alkylating agent, moles $mole^{-1}$

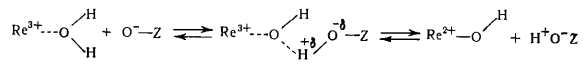
VIII. MECHANISM OF THE PROMOTION OF ALUMINOSILICATES AND ZEOLITES

Polymeric complexes, formed after adsorption of alkene molecules on catalytic centres, are assumed to play a definite part in the mechanism of the promotion[127-130] of aluminosilicate catalysts by alkenes. These hydrocarbons (propene, butenes) undergo rapid transformation with formation of a polymeric complex on an "acidic" centre of the aluminosilicate having degrees of polymerisation of 2–5.

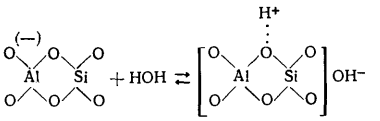
To establish the role of polymeric complexes in catalysis on aluminosilicates experiments were made on the isomerisation of but-1-ene[130] on an aluminosilicate containing polymeric perdeuteriobutene on the catalytic centre. On such a centre isomerisation yielded a large quantity of products in which the hydrogen atoms had been replaced in considerable number by deuterium. Yet hydrogen–deuterium exchange with an aluminosilicate surface that had undergone exhaustive deuteriation was comparatively small.

At low partial pressures of the alkene its degree of polymerisation in the complex is small and the activity of the catalyst also low. Both degree of polymerisation and catalytic activity increase with rise in partial pressure. Hence the effect of an alkene on an aluminosilicate catalyst depends on its degree of polymerisation with complex formation on an "acidic" centre. The optimum degree of polymerisation of ~3 units ensures the most active catalyst. The promotion of an aluminosilicate by an alkene may lead also to a change in the mechanism of isomerisation of alkenes, which is probably anionic at not very high temperatures.

The promoting effect of water molecules on aluminosilicate catalysts and zeolites is usually attributed to their ability to supply protons[131] to the surface. The transfer of protons is caused by the polarising effect of the cations, e.g. of a rare-earth metal, replacing ions in the zeolite:



A proton appears in the aluminosilicate catalyst by the mechanism



According to these schemes the catalytically active centre is a proton of a hydroxy-group attached to aluminium[131] or to silicon[35,66]. Nevertheless, direct experimental evidence has been published that the catalytically active centres in high-temperature and low-temperature reactions of hydrocarbons are aluminium—oxygen polyhedra[71,81,91,132-138], while the hydroxyl proton is able only to strengthen the accepting power of these polyhedra[137]. Furthermore, it is well known that silica has a high content of Si—O—H groups (even after ignition at temperature above 500°C), while their catalytic activity in the conversion of hydrocarbons is almost zero.

The promotion of zeolites by carbon dioxide is presumably[62,115] due to chemisorption of its molecules by sodium or calcium ions with activation of the catalytic centre. Chemisorption of carbon dioxide on a zeolite is regarded[115] as increasing the number of protons per unit surface, and hence enhancing the catalytic activity.

Kaliko and Pervushina[29,30] assume that water in aluminosilicates is present in both structural and adsorbed forms. Promotion is effected only by molecules adsorbed on catalytic centres. Catalysis of the conversion of hydrocarbons by aluminosilicates is supposed to involve active Lewis centres (aluminium three-coordinated with oxygen) or Brønsted centres[33]. However, such a view of the structure of the catalytic centre is incomplete and inconsistent with the geometrical limits of stability of the polyhedra. A coordinated triangle of type $[AlO_3]$ is unstable in aluminosilicates[139]. The ratio of the radii $r_{Al}/r_O = 0.418$ characterises the stability of $[AlO_4]$ and $[AlO_6]$ polyhedra. Triangular coordinated groups are stable only when this ratio is 0.15—0.22. The value 0.418 is the lower limit of stability of a coordinated octahedron. Hence only $[AlO_4]$ tetrahedra and $[AlO_6]$ octahedra are able to exist in aluminosilicates. The presence of such groups has been demonstrated in native aluminosilicates[97], artificial aluminosilicates, and zeolites[139,140].

Absorption of a water molecule is assumed to convert a Lewis centre into a Brønsted centre, a source of a proton which may be captured by hydrocarbon (e.g. alkene) molecules with formation of a carbonium ion, converted into the final products with regeneration of a proton. However, such an interpretation leads to difficulties in explaining the mechanism of the conversion of alkanes. Furthermore, it was shown experimentally that the activity of an aluminosilicate catalyst passes through a maximum with increase in the quantity of water introduced into the reaction zone, although most of the "aprotic" centres remain unoccupied by water molecules[141,142]. Danforth postulates[143] that water in an aluminosilicate acts as a cocatalyst, moving from centre to centre if the latter are contiguous. This results in displacement of the hydrocarbon from the complex catalyst and facilitates regeneration of the catalytic centre.

It must again be noted that heating aluminosilicate catalysts above 800°C leads to irreversible loss of their catalytic activity. The activity cannot be increased by addition of any quantity of water, so that the promotion of aluminosilicates involves catalytic centres having a different structure, which will be discussed below.

A convincing explanation of the promotion and deactivation of catalytic centres in aluminosilicates varying in type, structure, and composition was based on the view[71,81,91,132-138] that $[AlO_4]$ and $[AlO_6]$ polyhedra act as catalytic centres, with $[AlO_4]$ tetrahedra distributed as "islands" in a solid lattice, probably of defect (unsymmetrical] structure, catalytically the more active. Among artificial aluminosilicates the highest concentration of such tetrahedra is found in a catalyst containing 35—40 mass % of alumina and 65—60 mass % of silica[82]. Aluminosilicates of various compositions may contain "isolated", "island" $[AlO_4]$ tetrahedra, "condensed" $[AlO_4]$ tetrahedra, and "isolated" and "condensed" $[AlO_6]$ [octahedra].[82,83] The above aluminosilicate contains the maximum number of "isolated" $[AlO_4]$ tetrahedra. Artificial and natural aluminosilicates containing the largest number of such tetrahedra possess the greatest catalytic activity[134-138,144,145].

The degree of promotion of aluminosilicates by halogenated hydrocarbons depends on their alumina and silica contents[80]. Maximum promotion by ethyl chloride is observed[80] precisely with aluminosilicates containing 35—40 mass % of alumina, possessing maximum activity, and containing the maximum number of $[AlO_4]$ tetrahedra of "island" type. These results suggest that the promotion of aluminosilicates by halogenated and other compounds depends firstly on the content of $[AlO_4]$ tetrahedra of "isolated" type, secondly on the change in structure of the catalytic centre, and thirdly on the change in energy state of the catalytic centre and the reactant molecules.

The promotion of aluminosilicates by water, carbon dioxide, nitrogen, and other molecules may be attributed to a change in the acceptor properties of the $[AlO_4]$ tetrahedron or the $[AlO_nH_m]$ polyhedron in general, and to a change in the occupancy of unfilled $3d$ levels, possibly also in the symmetry of the tetrahedron. With small quantities of water, carbon dioxide, nitrogen, and other activating molecules sorbed on the catalyst surface the acceptor power of the catalytic aluminium—oxygen polyhedron may be increased by a change in the energy level of a vacant $3d$ orbital, which facilitates polarisation of a carbon—hydrogen bond in the hydrocarbon molecule, its cleavage, and reaction by a definite mechanism.

Andrianova and Roginskii considered[14] that the conversion of hydrocarbons on catalysts, whether promoted or not, had a radical—chain mechanism. Hansford[37] suggested a carbonium-ion mechanism, but this was not confirmed[142].

The promotion effect when halogen-containing compounds interact with catalytic centres in a zeolite or an aluminosilicate containing alkali-metal ions as $[MO_n]$ polyhedra (n = 4--6) can be attributed primarily to the action of the promoter molecule on the state of this polyhedron. Hence the increase in the activity of the catalyst under the influence of activating molecules may be due to the electronic (orbital) promotion of surface centres. The same phenomenon may occur under the influence of reactant molecules, with additional excitation of the catalytic centre. Interaction of activator with reactant molecules may further excite the latter. When activating

molecules of acceptor type interact with alkenes or with aromatic hydrocarbons, charge-transfer complexes are formed[146]. Such a complex has been observed with a mixture of chloroform and benzene[147,148].

Stepwise transfer of excitation energy along a layer of reactant and additive molecules sorbed on the catalyst surface may also occur. This is confirmed by the fact that a considerable proportion of benzene and carbon tetrachloride molecules (3% and 13% respectively) are already in excited vibrational states at room temperature[149]. This excitation may be transmitted to catalytic centres or reactant molecules and may promote these centres, changing their energy state and destroying the symmetry.

New catalytic centres resulting from chemical substitution may play some part in activating the catalyst[150]. Treatment of aluminosilicates or alumina with hydrogen halides produces Brønsted centres[151,152]. Partial replacement of hydroxy-groups by halogen atoms may also occur, with the formation of new active centres of Lewis[153] or Brønsted [154] type. However, treating aluminium oxide with fluorine compounds diminishes the acidity of the surface, while the catalytic activity towards the conversion of hydrocarbons increases sharply[155,156]. As mentioned above, the charge-transfer complexes themselves, e.g. that of an alkyl halide with an aromatic hydrocarbon, may have a considerable effect on the catalytic activity of the $[AlO_n]$ polyhedra. Transfer of charge may be effected from a 3*d* orbital of the halogen to a vacant π-orbital of the aromatic hydrocarbon or conversely; some compounds of this type are able to promote, whereas others deactivate, the catalytic centres.

Mixing benzene with molecules of considerable acceptor power, such as tetrachloromethane, hydrogen chloride, chloroform, and perchloroethane, yields associated charge-transfer complexes[157-159]. Associated complexes can be formed only with a certain acceptor concentration in the mixture, e.g. when the concentration of hydrogen chloride or chloroform does not exceed 0.02 mole per mole of benzene, above which concentration the resulting complexes already dissociate. The composition of the complex depends on the concentration of the solution. The stability of the complexes is connected not only with charge transfer but also with the stepwise migration of a proton. The latter is governed by the thermal motion and force fields of the benzene molecules.

Aromatic hydrocarbons mixed with ammonia, ether, dioxan, and other compounds of the same type form complexes in which the former act as acceptors and the latter as donors. Here the hydrocarbons have the role of aprotic acids, and the other reactants that of bases. These results can be related to the conversion, in the presence of aluminosilicates, of hydrocarbons mixed with acceptor or donor additives.

Certain acceptor additives to the reaction mixture may enhance the activity of aluminosilicates. Their activating effect, ability to form complexes with hydrocarbons, and promoting action are interrelated, as has been observed in the low-temperature[79,93,95] and high-temperature[68,116,104] reactions of hydrocarbons.

Donor molecules added in certain amounts to a reaction mixture usually lower the activity of aluminosilicates, although activation by donor molecules may be observed. Molecules of the reaction mixture may have a synergistic effect on the aluminosilicates in both cases: adsorption of a hydrocarbon on an aluminosilicate surface may lead to the formation of both radical-cations and radical-anions[160], the former by electron transfer from a molecular orbital of the donor molecule to a vacant atomic or molecular orbital of an aluminium—oxygen polyhedron, and the latter by electron transfer from a donor aluminium—oxygen polyhedron to a vacant molecular orbital of the hydrocarbon molecule. These centres may be adjacent, and it was assumed[160] that a donor catalytic centre contains an excess of oxygen atoms and favours conversion of an acceptor molecule into a radical-anion. With simultaneous or successive sorption of donor and acceptor molecules on the catalytic centres the catalytic activity of one centre may be strengthened by the other. Sorption of a donor molecule on an acceptor centre tends to strengthen the donor power of the donor centre. Conversely, sorption of an acceptor molecule on a donor centre will tend to strengthen the acceptor properties of the acceptor centre. This may be one reason why some concentrations of an additive will promote a catalyst, whereas other concentrations will deactivate it.

Metal-catalysed Oxidation of Organic Compounds by Hydroperoxides

G.A.Tolstikov, V.P.Yur'ev, and U.M.Dzhemilev

Information on the oxidation of various alkenes by hydroperoxides, as well as that of nitrogen- and sulphur-containing compounds, is summarised. Aspects of the catalysis of such oxidations are considered, and their mechanism and stereochemistry are discussed. A list of 166 references is included.

I. INTRODUCTION

The oxidising properties of hydroperoxides have long attracted the attention of research workers. Their great reactivity promises the development of highly effective methods of preparative organic chemistry and potentially successful industrial processes. We shall not attempt to survey all the reactions of hydroperoxides, especially in view of the vastness of the literature on this subject[1-7]: we shall restrict our discussion to reactions of various organic compounds with hydroperoxides in the presence of metals to yield oxidised products. Attention will be paid only to work published during the past 5–8 years. In particular, Section II will give a detailed account of the oxidation of alkenes by hydroperoxides in the presence of metals to give α-oxides, alcohols, ketones, and other oxygen-containing compounds. The mechanism and the stereochemistry of the hydroperoxide epoxidation of alkenes will be discussed.

The rest of the Review will examine hydroperoxide oxidation as an extremely promising method of organic chemistry. A reagent comprising a hydroperoxide with a metal salt resembles a peroxy-acid in its mode of action, but also exhibits several interesting novel features. Oxidations of the peroxy-acid type include the epoxidation of enol ethers, the *N*-oxidation of amines, the formation of oxaziridines from azomethines, and the oxidation of organosulphur compounds. Among reactions of a second type are the direct formation of α-hydroxyketones from alkenes, the oxidation of alcohols and quinols, the dehydrogenation of 1,4-dihydropyridines, and others.

II. EPOXIDATION OF ALKENES BY HYDROPEROXIDES CATALYSED BY METALS

1. History

Hawkins[8] discovered in 1950 that cyclohexene oxide was obtained when the cycloalkene was treated with cumenyl hydroperoxide in benzene solution in the presence of vanadium pentoxide. Under the same conditions oct-1-ene was converted into 1,2-epoxyoctane. However, the yields of the oxides were low. Their formation was explained by the addition of $RO_2^{\bullet}$ radicals at the double bond[9].

Investigation of the thermal breakdown of hydroperoxides in solutions of alkenes established[10,11] that the yields of the oxides were independent of the structure of the alkene. The effective activation energy of the reaction of oct-1-ene with t-butyl hydroperoxide was 30 kcal mole^{-1}, from which it was concluded that the reaction had a polar mechanism.

A little later the same workers[12], studying the epoxidation of oct-1-ene, 4-vinylcyclohexene, oct-2-ene, and 2,2,4-trimethylpent-1-ene by t-pentyl hydroperoxide in the presence of metal acetylacetonates, found that the highest yields of α-oxides could be obtained if the reaction were catalysed by the acetylacetonates of vanadium, molybdenum, and chromium. Significantly, the cobalt, copper, and manganese complexes were far less active. Aluminium, iron, nickel, titanium, zinc, magnesium, and zirconium acetylacetonates decompose the hydroperoxide completely, with no formation of α-oxides.

The above work formed a starting point for researches by Halcon International Inc.[13], who patented the production of α-oxides by oxidising alkenes with hydroperoxides in the presence of compounds of molybdenum, vanadium, tungsten, titanium, zirconium, tantalum, and other metals.

2. Catalysts

Compounds of molybdenum, vanadium, tungsten, and chromium are recognised to be the best catalysts for epoxidation, but even among these metals differences in activity are clearly evident. Table 1 shows the dependence on the type of catalyst of the rate and extent of the epoxidation of 2-methylpent-2-ene by cumenyl hydroperoxide[14]. The most active catalysts are hydrocarbon-soluble compounds of molybdenum, e.g. the octanoate, naphthenate[15], di-t-butylbenzoate[16], molybdic esters[17,18], and also the tetra- and para-molybdenates of pyridine and piperidine[19]. A porous ceramic obtained by sintering the oxides—alumina, silica, and molybdenum sesquioxide—has been patented as a catalyst[20]. Metallic molybdenum

can serve as catalyst when it forms the walls of the reaction vessel [21,22]. Molybdenum compounds including other active elements, e.g. heteropolyacids [23], cobalt molybdate [24], etc., have given good results.

Table 1. Epoxidation of 2-methylpent-2-ene by cumenyl hydroperoxide.

Catalyst	Time, min	Yield of oxide, %
None	930	29
$NaMoO_3$	930	70
$NaVO_3$	930	52
MoO_2	90	88
$NaSiMo_{12}O_{40}+NaMoO_3$	45	85
$MoO_2(C_5H_7O_2)_2$	45	86
$VO(C_5H_7O_2)_2$	60	75

Some patents, however, must be approached with caution. In particular, the statement that a mixture of molybdenum and nickel acetylacetonates must be used for successful epoxidation, as these catalysts are inactive when used separately [25], does not correspond to reality. Molybdenum, while more active than vanadium in the oxidation of alkenes, retreats to second place as catalyst for the epoxidation of allyl alcohols, where vanadium compounds are most active [26].

With regard to other catalysts, mention may be made of patents describing the use of compounds of tungsten [27,28] as well as of titanium, chromium, niobium, zirconium, tellurium, rhenium, and other elements [29]. It is extremely interesting that boric esters catalyse the reactions [30,31] with metaborates the most active [32]. A recent paper [33] has described the use of carbonyl and phosphine complexes of rhodium, ruthenium, and iridium as catalysts.

Table 2. Effect of solvent on oxidation of oct-1-ene.

Solvent	Conversion of t-BHP*, %	Yield of oxide, %
Ethyl acetate	100	89.3
Di-isopropyl ketone	98.7	88.0
Acetophenone	98.6	67.8
Benzene	99	63
Methanol	69.6	42.4
Acetone	50.4	23.8
Dioxan	29.6	21.2

*t-BHP = t-butyl hydroperoxide.

3. Solvents

A hydrocarbon or a tertiary alcohol is generally used as solvent for epoxidation. Primary alcohols and ketones inhibit oxidation [14]. As illustration Table 2 lists results obtained for the epoxidation of oct-1-ene by t-butyl hydroperoxide [in various solvents] in the presence of sodium molybdophosphate.

The percentage conversions of ethylbenzene hydroperoxide in the oxidation of propene varies [35] in different solvents—ethylbenzene 99, 2-phenylpropanol 98.8, methanol 54.7, ethanol 62.8, propan-1-ol 67.8, n-butanol 78.0, and n-octanol 87.5.

Thus the successful choice of solvent depends on the specific conditions and should take into account the structure of the alkene and the hydroperoxide, together with the type of catalyst.

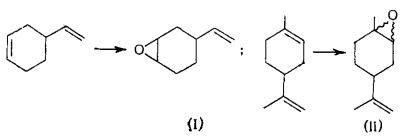
4. Effect of Structure of the Alkene and of the Hydroperoxide

Investigations on epoxidation have been reported mainly in patents and have been concerned with relatively simple alkenes. Only during the past three or four years have papers begun to appear in journals. The rate of epoxidation increases with the number of electron-donor substituents adjacent to the double bond. Table 3 illustrates the dependence of rate of oxidation on degree of branching of the alkene [14,34]. Both structural and geometrical isomers differ in reactivity. Thus the relative reactivities of *cis*-but-2-ene, *trans*-but-2-ene, and but-1-ene are 36.6, 14.2, and 1.0. [35,36]

Table 3. Oxidation of alkenes by t-butyl hydroperoxide.

Alkene	Yield of oxide, %
$C_6H_7-C(CH_3)=CH_2$	63.2
$C_6H_{11}-CH=CH-CH_3$	72.7
	76
$(CH_3)_3C=CH-CH_3$	80.5

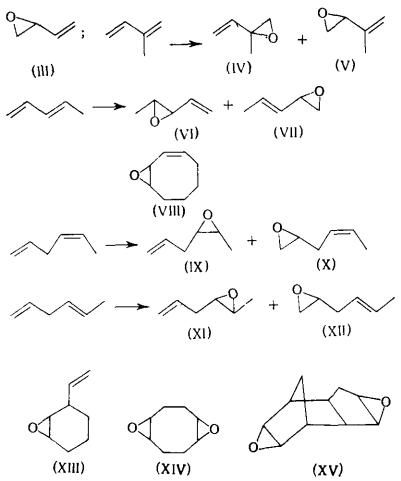
A cyclic double bond usually reacts more readily, as is shown by the epoxidation of alkenylcyclohexenes. Thus 4-vinylcyclohexene gives the theoretical yield of 1,2-epoxy-4-vinylcyclohexane (I) when oxidised with t-butyl [34], t-pentyl, or cumenyl [37] hydroperoxide. Under the same conditions *p*-mentha-1,8-dienes give the monoxides (II). [38]



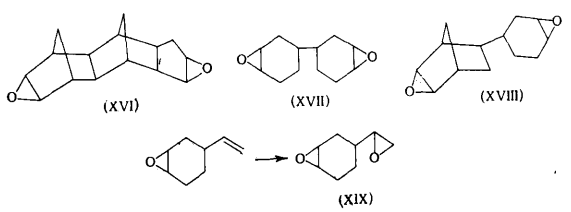
(I) (II)

Examination of the oxidation of dienes has established several empirical rules linking the completeness of oxidation with the structure of the alkene. Conjugated dienes form only monoxides [26]. Thus butadiene gives (III), [26,29] while isoprene and penta-1,3-diene form mixtures of structural isomers (IV)–(VII). [26,40] A monoxide (VIII) has been reported from cyclo-octa-1,3-diene [34]. Aliphatic 1,4-dienes, e.g. *cis*- and *trans*-hexa-1,4-dienes, are able to give only isomeric monoxides (IX)–(XII). A dioxide

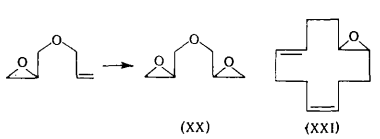
could not be obtained from 3-vinylcyclohexene, since reaction ceases at the monoxide (**XIII**) stage.



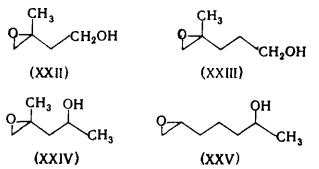
However, 1,5-dialkenes are able in most cases to react with two moles of a hydroperoxide. Cyclo-octa-1,5-diene, for example, is converted into the dioxide (XIV) by t-butyl hydroperoxide in the presence of trisodium dodecamolybdophosphate or tetrasodium dodecamolybdosilicate. The farther apart are the double bonds, the more complete is the epoxidation. This is well illustrated by bi- and tercyclopentadienes, bi(cyclohexenyl), and cyclohexenylnorbornene, which give the dioxides (XV)–(XVIII) in almost quantitative yields when oxidised by t-pentyl hydroperoxide in the presence of molybdenum pentachloride[41]. 4-Vinylcyclohexene dioxide (XIX) cannot be obtained by the direct reaction of two moles of the hydroperoxide with one mole of the diene, since the process is completely inhibited after formation of the monoxide. However, epoxidation of the latter, freed by distillation from inhibiting impurities, will give a satisfactory yield of the dioxide. The same procedure was used to obtain the dioxide of diallyl ether (XX).[26]



The oxidation of trienes by hydroperoxides has not been investigated systematically. It is known merely that *cis*,*trans*,*trans*-1,5,9-cyclododecatriene forms a monoxide (XXI).[42]



Smooth progress of the reaction is not prevented by polar groups and heteroatoms sufficiently remote from the double bond. Thus oxides of unsaturated alcohols



have been obtained by the action of t-butyl hydroperoxide in the presence of hexacarbonylmolybdenum. The best catalysts for the oxidation of allyl alcohols were vanadium compounds, but satisfactory yields of oxides can be obtained also with molybdenum catalysts (Table 4)[26]. Allylic diols are oxidised quite smoothly[26] to the oxides

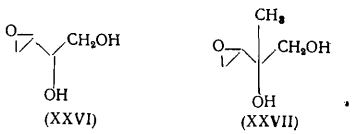


Table 4. Oxidation of allyl alcohols and ethers.

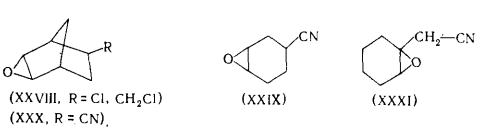
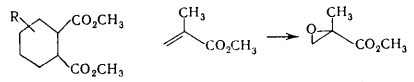
Compound*	Catalyst	Temp., °C	Time, min	Conversion of t-BHP, %	Yield of oxide, %
ROH	$Mo(CO)_6$	100	60	100	70
ROH	$V(C_5H_7O_2)_3$	100	25	92	93
$CH_2=C(CH_3)CH_2OH$	$V(C_5H_7O_2)_3$	80	30	97	100
$CH_2=C(CH_3)CH_2OH$	$Mo(CO)_6$	80	30	82	69
ROEt	$Mo(CO)_6$	95	120	73	77
R_2O	$Mo(CO)_6$	95	120	89	85
R_2O	$Mo(CO)_6$	100	180	88	58

*R = $CH_2:CH.CH_2$–.

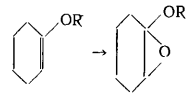
Oxidation of chlorine-containing alkenes gives yields of oxides depending on the position of the chlorine atom relative to the double bond. Thus allyl and methylallyl chlorides are converted into α-oxides in moderate yield. *trans*-1,4-Dichlorobut-2-ene is oxidised with great difficulty to give a 20% yield of the oxide[26]. However, 2-chloro- and 2-chloromethyl-norbornenes form the oxides (XXVIII) in high yield[43].

Epoxidation is not appreciably impeded by the presence of a nitrile group sufficiently remote from the double bond. In t-butyl alcohol solution at 80°C, for example, 4-cyanocyclohexene is oxidised by t-butyl hydroperoxide to give an 89% yield of the oxide (XXIX).[44] 2-Cyanonorbornene is oxidised smoothly to the oxide (XXX), and cyanomethylcyclohexene is converted not quite so well into (XXXI). Acrylonitrile is not epoxidised at all[26].





(XXXII, R = H, Me) (XXXIII)



R = Et, $COCH_3$ (XXXIV)

Few data are yet available on the epoxidation of unsaturated acids and their derivatives. However, quantitative yields of derivatives of cyclohex-4-ene-1,2-dicarboxylic acid (XXXII) have been obtained by means of t-pentyl hydroperoxide in the presence of molybdenum pentachloride or hexacarbonylmolybdenum [39,45]. A process for the epoxidation of vegetable oils has been patented, but details are not reported [46].

Mention must be made of the formation of methyl epoxymethylpropionate (XXXIII) from methyl methacrylate [26], an observation of fundamental importance, since it indicates the powerful oxidising properties of a reagent comprising a hydrogen peroxide and a molybdenum salt. Incidentally, ordinary peroxy-acids do not oxidise esters of $\alpha\beta$-unsaturated acids: only such strong oxidants as trifluoroperacetic and *m*-chloroperbenzoic acids are sufficiently reactive.

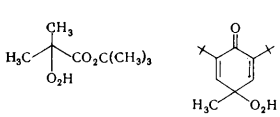
Enol ethers give high yields of oxides. Thus ethoxycyclohexene and cyclohex-1-enyl acetate are converted into the oxides (XXXIV). [47]

The influence of the structure of the hydroperoxide on the rate and the completeness of the epoxidation of alkenes has been less fully studied. Thus alkylated aromatic hydroperoxides have exhibited high activity in the epoxidation of oct-2-ene in benzene solution catalysed by hexacarbonylmolybdenum [14]. In particular, the percentage conversion of *p*-nitrocumenyl, cumenyl, and t-butyl hydroperoxides was respectively 83, 60, and 54. Hence an electron-accepting substituent in the benzene ring tends to increase the rate of oxidation.

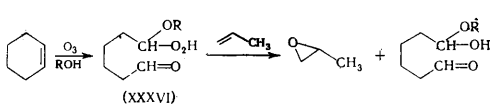
The relative reactivities of ethylbenzene, t-butyl, and cumenyl hydroperoxides in the epoxidation of propene have been given [48] as 2.4 : 1.3 : 1. t-Butyl α-hydroperoxy-α-methylpropionate (XXXV), obtained by oxidising t-butyl isobutyrate [49], is an excellent reagent for obtaining methyloxiran [50]: in the presence of molybdenum and sodium naphthenates the yield of the oxide is 78–84%.

Application of the hydroperoxides of ionol (XXXVa), di-isopropyl ketone, and tetralin has been patented [34], but their activities were not compared.

It has recently been established that smooth epoxidation of propene and cyclohexene is accomplished by means of alkoxy-ω-formylalkyl hydroperoxides (XXXVI), which are formed when cyclohexene is ozonised in solutions of primary alcohols [51].

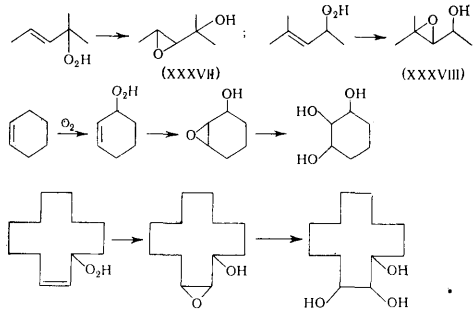


(XXXV) (XXXVa)



(XXXVI)

An interesting variety of hydroperoxide oxidation is based on the principle of the "self-epoxidation" of alkenyl hydroperoxides. In particular, the epoxyalkanols (XXXVII) and (XXXVIII) have been obtained from the hydroperoxides of 4- and 2-methylpent-2-enes:



(XXXVII) (XXXVIII)

The best catalysts for the process are compounds of tungsten [52] and vanadium [53]. Processes for obtaining cyclohexanetriols and cyclododecanetriols (above) have been based on the same principle [54,55].

5. Mechanism and Stereochemistry

Kinetic aspects of epoxidation have recently been surveyed quite fully [56]. Certain fundamental principles may be recalled here to provide a link with the above discussion. Over the range of cyclohexene concentrations 0.087–1.79 M reaction with t-butyl hydroperoxide in the presence of molybdenum acetylacetonate is initially first order with respect to the substrate and the hydroperoxide [57]. In contrast to earlier work [12] the first order with respect to the catalyst was established. Over the temperature range 24–51 °C the activation functions are $\Delta H = 12.7 \pm 0.4$ kcal mole^{-1} and $\Delta S = -19.8 \pm 1.9$ e.u. The Michaelis–Menten equation has been applied [58,59] to the initial stages of formation of an α-oxide on the basis of the considerable analogy with enzymic catalysis.

Epoxidation has been considered [57-60] to comprise the stages—(1) oxidation of the metal by the hydroperoxide to a higher (most probably the highest) valency with an increase in the number of vacant 4*d* orbitals, (2) coordination of the hydroperoxide with the catalyst involving a lone pair of electrons on an oxygen atom in the hydroperoxide and 4*d* orbitals of the metal, (3) weakening of the oxygen–oxygen bond with migration of electron density to the metal as a result of coordination, the enhancement of the electrophilic character of the hydroperoxide facilitating rupture of this bond as a result of nucleophilic attack on the alkene, (4) redistribution of the proton, (5) exchange of ligands, and (6) competitive inhibition due to the formation of catalytically inactive molybdenum–inhibitor complexes.

Epoxidation is inhibited by water, ketones, and alcohols. In particular, the inhibiting effect falls in the sequence—water, 1-phenylethanol, t-butyl alcohol, 2-phenylpropan-2-ol—and is greater the greater the stability of the molybdenum–inhibitor complex, which is determined by the nature of the inhibitor as ligand. More highly polar alcohols form more stable complexes, a relation which has been expressed quantitatively: for aliphatic alcohols the polar Taft factors σ^* were found to correlate with the dissociation constants of the complexes (Scheme 1). Thus there is no doubt about the electrophilic character of the

reaction. This conclusion was supported by a kinetic investigation of the oxidation of *para*- and *meta*-substituted styrenes, which showed that the rate-determining stage was electrophilic attack on the alkene (Table 5). This is indicated by the negative value of the constant $\rho = 1.4 \pm 0.6$.[59]

Scheme 1

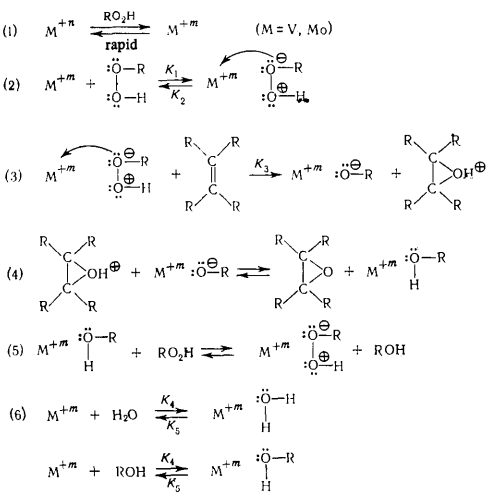


Table 5. Rate constants of the oxidation of *meta*- and *para*-substituted styrenes by t-butyl hydroperoxide

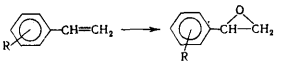


Substituent R	H	*m*-Cl	*p*-Cl	*m*-Br	*p*-Br	*m*-NO_2	*p*-CH_3
10^4 x rate constant, M^{-1} min^{-1}	26.7	21.8	30.5	26.1	31.0	3.10	89.6

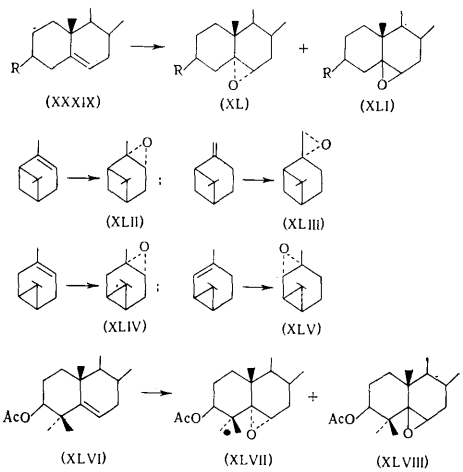
The present Reviewers had found that the initial rates of oxidation by t-pentyl hydroperoxide of a series of norbornene derivatives in the presence of molybdenum pentachloride varied with the electronegativity of the 6-substituent. Table 6 shows that compounds having electron-donating substituents show higher initial rates of oxidation, whereas electron-accepting substituents lower the rate[43].

The activation energy of epoxidation can vary with the structure of the alkene and the hydroperoxide, as well as with the type of catalyst. Thus the oxidation of propene by ethylbenzene, t-butyl, and cumenyl hydroperoxides has effective activation energies of 15–15.5 kcal $mole^{-1}$,[48] but the corresponding value for the reaction between 2-methylpent-2-ene and cumenyl hydroperoxide is 23.8 kcal $mole^{-1}$.[60] The very low activation energy of 5.6 ± 0.5 kcal $mole^{-1}$ was found[43] for the reaction between norbornene and t-pentyl hydroperoxide in the presence of molybdenum(V) chloride. Introduction of an electron-accepting group into the hydroperoxide lowers the effective activation energy; in particular, a value of 11.7 ± 0.5 kcal $mole^{-1}$ was obtained[49] for the oxidation of propene by t-butyl α-hydroperoxy-α-methylpropionate [(XXXV)]. The catalyst may cause very marked changes in activation energy. In the oxidation of oct-1-ene by t-butyl hydroperoxide, for example, use of different metal acetylacetonates gave the values (in kcal $mole^{-1}$)—Cr^{III} 23, VO^{II} 15, MoO_2 12, and V^{III} 9.[12] Aspects of the mechanism of hydroperoxide epoxidation are discussed also in several other papers[61–63].

Table 6. Rates of oxidation of 6-substituted norbornene derivatives by t-pentyl hydroperoxide

Substituent R	H	CH_3	OH	OAc	*endo*-CN	*exo*-CN	CH_2OH	CH_2OAc	CO_2CH_3	Cl
$10^7 W$, $M\,s^{-1}$	35	116	7	6	9	8	23	5	2	15

An all-round assessment of a reagent is unthinkable without examination of the stereochemistry of its reactions. Among epoxidising agents the stereochemistry of epoxidation by peroxy-acids has been most widely investigated. It has been reliably established that peroxy-acids attack an alkene mainly on the less shielded side. The configuration of the resulting oxide coincides with the direction of attack by the reagent. These principles can be seen especially clearly with cyclic alkenes, such as steroids, terpenes, etc. For example, the epoxidation of Δ^5-steroids (XXXIX) by peroxy-acids produces a mixture of oxides in which the 5α,6α-isomer (XL) predominates[64,65]. Relatively slight shielding of the double bond permits the peroxy-acid to approach the opposite side also, with formation of the 5β,6β-oxide (XLI). Until recently almost nothing was known of the stereochemistry of epoxidation by hydroperoxides. It has been reported only that *cis*- and *trans*-but-2-enes formed the corresponding oxides[14].

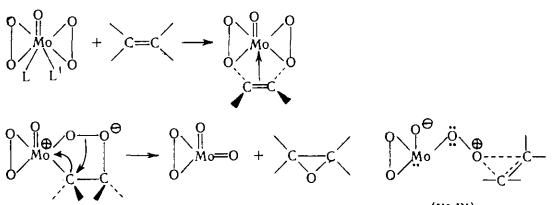


The present Reviewers investigated the stereochemistry of the epoxidation of certain steroids and terpenes[38,66], and established that it depends both on steric factors and on the presence of complexing groups in the reactant molecule. In the oxidation of unsaturated cyclic hydrocarbons and alkenes not containing these groups near the double bond

the stereospecificity of epoxidation by t-pentyl hydrogen peroxide is limited only by steric factors. Thus epoxidation of Δ^5-steroids (XXXIX: R = H, Cl, OH) occurs mainly by attack by the reagent at the less shielded α-side, which as in the experiments with peroxy-acids leads to predominance of the 5α,6α-oxides (XL) in the mixture of epimers. The bicyclic hydrocarbons—pin-2-ene, pin-2(10)-ene, car-2-ene, and car-3-ene—have such effective shielding of the double bond that, when oxidised with t-pentyl hydroperoxide in the presence of molybdenum pentachloride, only the oxides (XLII)–(XLV) are formed, whose configuration coincides with the direction of attack by the reagent. The same oxides were obtained by oxidising these monoterpenes with perbenzoic acid [66-70].

Thus epoxidation by a hydroperoxide involves a stage in which the double bond is attacked by a "molybdenum–hydroperoxide" complex, whose size governs control of the reaction solely by steric factors. This stage, it seems to us, can be modelled on the oxidation of cycloalkenes by the molybdenum pentoxide–hexamethylphosphoramide MoO_5.HMPA complex [71]. This reagent quantitatively epoxidises Δ^5-steroids (XXXIX: R = H, Cl, OH, OCOCH), to form the almost pure 5α,6α-oxides [72,73]. The above monoterpenes undergo stereospecific oxidation, being converted by this complex into the oxides (XLII)–(XLV). [74] Epoxidation by this reagent is evidently still more strictly controlled by steric factors, which follows also from experiments on 3β-acetoxy-4,4-dimethylsteroids (XLVI), also not oxidised by the reagent owing to steric hindrance by the geminal methyl groups. Hydroperoxides in the presence of molybdenum pentachloride or hexacarbonylmolybdenum are also unable to oxidise compounds of type (XLVI), whereas perbenzoic acid reacts quite readily to give a mixture of the 5α,6α- and 5β,6β-oxides (XLVII) and (XLVIII) in the proportions 82 : 18 [Table 7].

The highly stereospecific action of the MoO_5.HMPA reagent is an important argument, in the opinion of the Reviewers, for interpreting the mechanism of epoxidation as ambipolar 1,3-addition [75]. In any case, it is difficult to accept the possibility of completely stereoselective oxidation if the recently suggested [76] scheme



(XLIX)

involving a three-membered transition state (XLIX), is adopted. Anomalous results were obtained when Δ^5-steroids having oxygen-containing groups attached to $C_{(3)}$ were oxidised with t-pentyl hydroperoxide in the presence of molybdenum pentachloride (or hexacarbonylmolybdenum). Thus 3β-acetoxy-Δ^5-steroids (L) were converted mainly (55–80%) into 5β,6β-oxides. Owing to conformational distortions of rings A and B the double bond in 3-ethylenedioxy-Δ^5-steroids (LI) is accessible to attack on the β-side. Oxidation by perbenzoic acid therefore yields mainly the 5β,6β-oxides (proportions of 5α,6α- and 5β,6β-oxides 35 : 65). The ethylene acetal (LI) undergoes completely stereospecific β-epoxidation both with t-pentyl hydroperoxide in the presence of molybdenum pentachloride and with the peroxide complex MoO_5.HMPA: both reagents give the pure 5β,6β-oxides (LII).

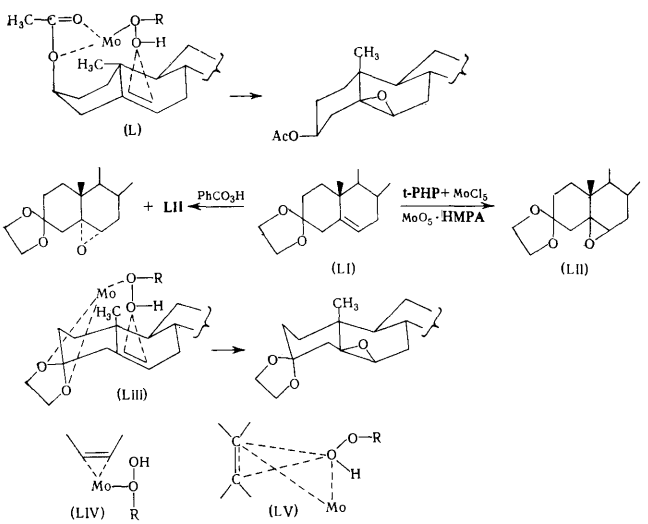


Table 7. Composition of mixtures of 5,6-oxides obtained by the epoxidation of Δ^5-steroids.

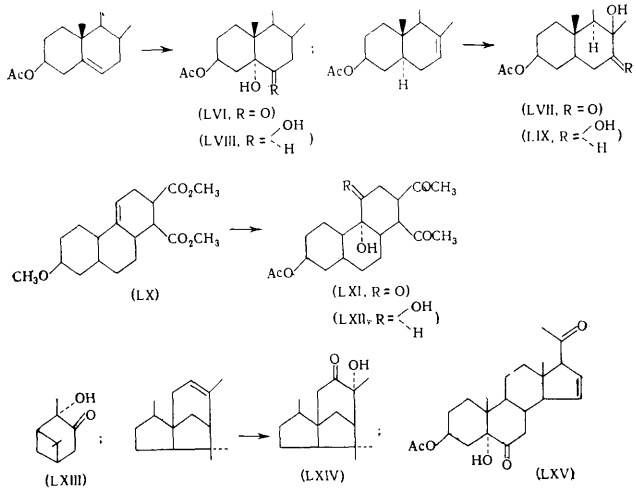
Δ^5-Steroid	Oxidising agent					
	C_6H_5COOH		t-PHP + Mo		MoO_5 + HMPA	
	5α, 6α	5β, 6β	5α, 6α	5β, 6β	5α, 6α	5β, 6β
3β-Acetoxyandrost-5-en-17-one	65	35	20	80	100	0
3β-Acetoxycholest-5-ene	70	30	45	55	80	20
3β-Acetoxyspirost-5-ene	65	35	35	65	95	5
3β-Acetoxypregna-5,16-dien-20-one	65	35	35	65	90	10
3β-Acetoxy-4,4-dimethylcholest-5-ene	82	18	no reaction takes place			
Cholest-5-ene	90	10	55	45	100	0
3α-Chlorocholest-5-ene	85	15	60	40	95	5
Cholest-5-en-3β-ol	90	10	70	30	90	10
Spirost-5-en-3β-ol	90	10	55	45	90	10
3-Ethylenedioxyspirostene	35	65	0	100	0	100

Whereas the results of epoxidation by MoO_5.HMPA can be explained by stereospecificity in the action of the reagent, the outcome of the experiments with 3-pentyl hydroperoxide and molybdenum pentachloride is somewhat unexpected. Formation of the "anomalous" 5β,6β-oxides in the oxidation of 3β-acetoxy-Δ^5-steroids and that of the "normal" 5β,6β-oxides by the epoxidation of ethyleneacetals most probably have the same origin: complexing groups combine with the metal and thereby orient the hydroperoxide for attack on the β-side. This is especially clearly evident with ethylene acetals, where steric factors and the orienting effect of the oxygen group act in harmony (LIII).

Thus the stereochemistry of the epoxidation of unsaturated cyclic hydrocarbons and of compounds containing no metal-complexing groups is determined by the direction of attack by the "metal–hydroperoxide" complex. Such attack occurs predominantly on the less shielded side and involves the formation of π-complexes of type (LIV) [63-73] or (LV). [62]

III. "HYDROXYKETONISATION" OF ALKENES

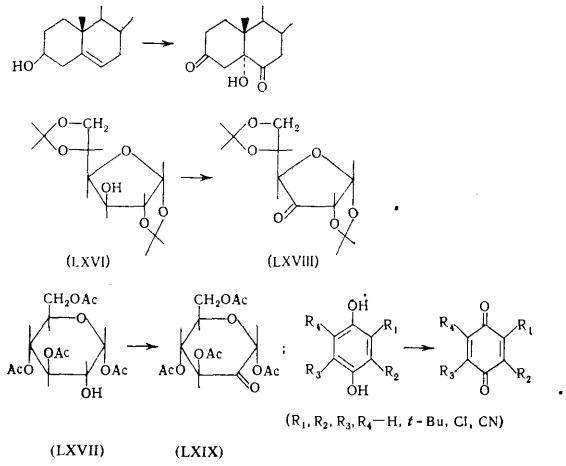
It has recently been shown [38,66,77,78] that trisubstituted alkenes can be converted directly into α-hydroxy-ketones by excess of a hydroperoxide in the presence of molybdenum, tungsten, and vanadium compounds. The yields are usually 60–90%. Thus Δ^5- and Δ^7-steroids are converted in one stage, when treated with two moles of t-pentyl hydroperoxide, into 85–90% yields of 5α-hydroxy-6-ones (LVI) and 8β-hydroxy-7-ones (LVII) respectively. The glycols (LVIII) and (LIX) were found as by-products. A double bond conjugated with an aromatic ring readily undergoes this reaction. For example, the compound (LX) gives a mixture of the hydroxy-ketone (LXI) and the glycol (LXII). It is significant that the new method enables the hydroxy-ketones (LXIII) and (LXIV) to be obtained from pin-2-ene and cedr-8-ene, whose oxides isomerise very readily [67,79].



The reaction has its limitations, since it extends only to trisubstituted alkenes. Attempts at the hydroxyketonisation of compounds containing a disubstituted double bond have been unsuccessful. Oxidation does not affect the double bond in αβ-unsaturated ketones, as is exemplified by the conversion of dehydropregnenolone acetate into 3β-acetoxy-5β-hydroxypregn-16-ene-6,20-dione (LXV).

IV. OXIDATION OF SECONDARY ALCOHOLS AND QUINOLS

Although the formation of ketones from secondary alcohols by the action of hydroperoxides is well known [80], this method has no preparative value. However, it has recently been established [38,81] that diverse secondary alcohols are easily oxidised by t-pentyl hydroperoxide in the presence of a catalyst (molybdenum pentachloride), without which hardly any oxidation occurs. The completeness of conversion varies between 40% and 90% depending on the structure of the alcohol. The new method of oxidation can be regarded as preparative in view of the high selectivity of the process. Among oxidations achieved in this way are those (percentage conversion indicated in parentheses) of cyclohexanol into cyclohexanone (95), cholestanol into cholestanone (85), 5α,22α-spirostan-3β-ol into the spirostanone (85), 18β-methyl glycyrrhetate into 3-oxomethyl glycyrrhetate (40), cholest-4-en-3β-ol into cholesten-3-one (60), *trans*-cyclohexanediol into hydroxycyclohexanone (85), pinane-2β,3α-diol into hydroxypinocamphone (80), and 3β-acetoxy-5α,6α-dihydroxysteroids into 3β-acetoxy-5α-hydroxy-6-oxosteroids (85). Oxidation of a hydroxy-group may be combined with hydroxyketonisation: thus 3β-hydroxy-Δ^5-steroids are converted in a single stage into 5α-hydroxy-3,6-diones:

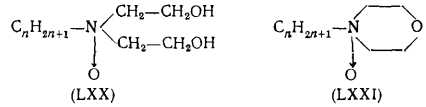


Hydroperoxide oxidation is extremely promising as a convenient method of obtaining keto-sugars [82,83], e.g. the smooth conversion of glucofuranose (LXVI) and glucopyranose (LXVII) derivatives into ketones (LXVIII) and (LXIX). Quinols are oxidised to quinones in high yields (70–95%). [38]

V. OXIDATION OF NITROGEN-CONTAINING COMPOUNDS

1. Aliphatic Amines

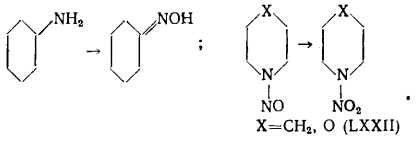
Tertiary aliphatic and cycloaliphatic amines are converted by hydroperoxides in the presence of vanadium, molybdenum, and titanium compounds into 75–80% yields of *N*-oxides [84]. *N*-Oxidation goes smoothly with bis-hydroxyethylamine and morpholine derivatives



The influence of the catalyst and of the solvent on the completeness of conversion of amines has been investigated with the oxidation of tributylamine, triethylamine, and dimethylaminoethanol by t-butyl and cumenyl hydroperoxides as examples [85]. The best catalysts are vanadium and molybdenum compounds, tungsten and niobium compounds are less active, chromium salts exhibit little activity, and cobalt, manganese, and iron salts are almost inactive. It is noteworthy that the latter completely decompose the hydroperoxide, but the yield of *N*-oxides is only 3–10%.

The oxidation of tertiary amines is less demanding on the choice of solvent. Thus in the presence of vanadium compounds high (84–96%) yields of *N*-oxides were obtained by using t-butyl alcohol, methanol, oxolan, ether, and acetone as solvents.

According to the patent literature [86] primary amines are converted by hydroperoxides, in the presence of molybdenum, vanadium, and titanium, into ketoximes, the most satisfactory results being obtained with cyclohexylamine:



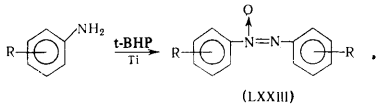
X=CH_2, O (LXXII)

The reaction of cyclohexylamine with ethylbenzene and t-butyl hydroperoxides obeyed a second-order rate equation [87]; oxidation to the ketoxime took place with high yields in the presence of titanium, vanadium, molybdenum, and tungsten compounds.

The interesting potentialities of the hydroperoxide method are demonstrated by the recently reported [45,88] examples of the conversion of nitrosamines into nitramines. In particular, nitramines (LXXII) have been obtained by the action of t-pentyl hydroperoxide on *N*-nitroso-morpholine and -piperidine in the presence of molybdenum pentachloride.

2. Aromatic Amines

Depending on the dosage of the oxidant, primary aromatic amines can be converted into azoxy-compounds or nitro-derivatives. In the presence of titanium compounds aniline, *o*- and *p*-toluidines, and *m*-nitroaniline are converted by t-butyl hydroperoxide almost quantitatively [89] into the corresponding azoxy-compounds (LXXIII):



(LXXIII)

p-Chloro-, 2,4,6-tribromo-, and *o*- and *p*-nitroanilines give unidentified products under the same conditions.

Kinetic investigation of the oxidation of *para*- and *meta*-substituted anilines to nitrobenzenes has shown [90] that the best catalysts are vanadium compounds, molybdenum being less active, and tungsten and cobalt salts completely inactive. Under optimum conditions (with t-butyl hydroperoxide and vanadyl trisacetylacetonate) the rates of oxidation of the anilines correlate well with the Hammett σ-constants and the Brown–Okamoto σ^*-constants, the values found for the ρ-constant being respectively -1.63 and -1.42. It is significant that a value of ρ of the same order (-1.86) was found for the oxidation of substituted anilines by peracetic acid [91]. The reaction mechanism in Scheme 2 has been suggested [90].

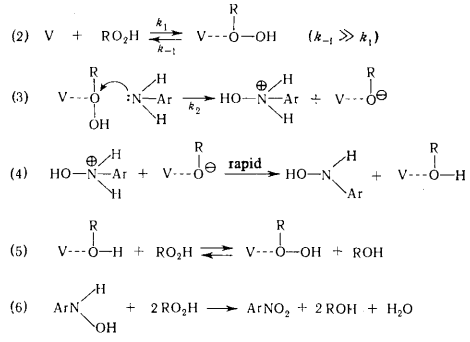
The oxidation of secondary aromatic amines has been investigated with cobalt salts as catalyst. Under these conditions the oxidant is $RO_2^{\cdot}$, which makes such reactions fundamentally different from ionic oxidation [92,93].

3. *N*-Oxidation of Aromatic Nitrogen Heterocycles

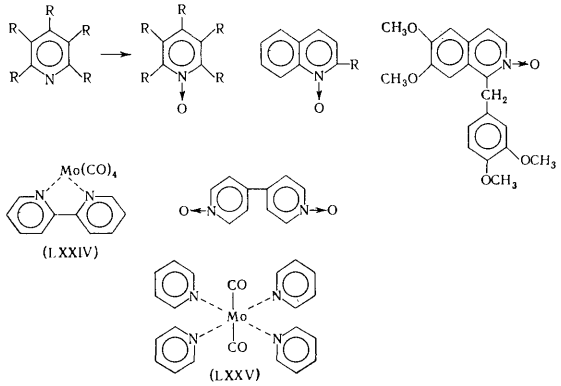
The oxidation of diverse compounds of this class has been investigated [38,45,88,94]. Almost quantitative *N*-oxidation is possible with pyridines containing one to five substituents, including such difficultly oxidisable compounds as 3,5-dibromopyridines and acetamidopyridines. The reaction is conducted in benzene solution in the presence of t-pentyl hydroperoxide with molybdenum pentachloride or hexacarbonylmolybdenum. The advantages of the proposed method can be demonstrated by the oxidation of acridine, which is converted quantitatively into the *N*-oxide after only 2 h, whereas perbenzoic acid gives merely 50% conversion after several days. Derivatives of quinoline, isoquinoline (papaverine), and naphthoquinoline are oxidised very smoothly. The possibility of obtaining the dioxides in at least 85% yield in a single stage has been shown for the oxidation of 4, 4′-bipyridyl, 2,3,5,6-tetramethylpyrazine, and phenazine.

Scheme 2

(1) Activation of catalyst (rapid)



2,2′-Bipyridyl, 1,10-phenanthroline, and 8-hydroxyquinoline stand apart in being completely unoxidised. The catalyst is firmly bound by these reactants, and does not undergo the complex formation which would activate the hydroperoxide. An investigation was therefore made of the dependence of the rate of oxidation of alkenes and pyridine on the strength of binding of the molybdenum, by conducting oxidation in the presence of complexes hexacarbonylmolybdenum, tetracarbonylbipyridylmolybdenum (LXXIV), and dicarbonyldibipyridylmolybdenum (LXXV). The catalytic activity of molybdenum dropped sharply in this sequence: whereas (LXXIV) still had a catalytic effect, the complex (LXXV) was completely inactive. It is readily seen that substituting four coordination positions with such an active ligand as 2,2′-bipyridyl prevents complex formation either with the hydroperoxide or with the substrate.

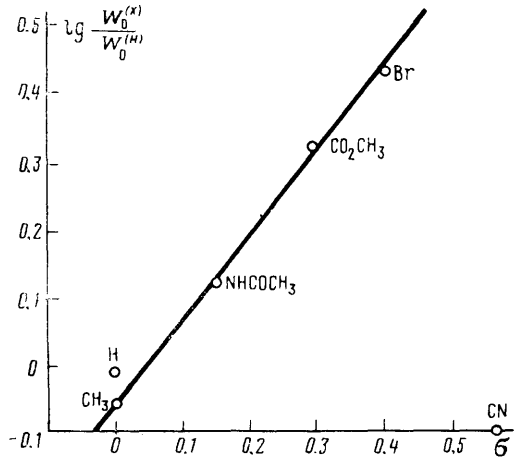


(LXXIV)

(LXXV)

Several quantitative characteristics have been obtained for the *N*-oxidation of pyridine and its 3-substituted derivatives by t-pentyl hydroperoxide in the presence of

molybdenum pentachloride [95]. In particular, it has been established that the reaction is first order with respect to substrate and hydroperoxide on conversion of up to 20% of the former. The activation energies of the oxidation of pyridine and methyl pyridine-3-carboxylate over the range 40–80°C were respectively 9.1 ± 0.2 and 7.7 ± 0.2 kcal mole^{-1}.

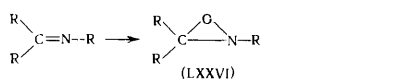


Dependence of rate of oxidation of substituted pyridines on the σ-constants.

The dependence of the rate of reaction of 3-substituted derivatives on the σ-constant was very characteristic. The diagram shows that the rate increases with decrease in the electron density on the reaction centre (series constant $\rho = +1.2$). 3-Cyanopyridine is out of line with the general sequence, and has the lowest rate of oxidation. This was attributed to enhanced complexing activity of the nitrile group, resulting in blocking of the catalyst.

4. Synthesis of Oxaziridines

Oxaziridines are formed in yields of 40–90% when azomethines are oxidised with peroxy-acids [96]. It has recently been shown that these interesting compounds can be obtained by oxidising azomethines with t-pentyl hydroperoxide in the presence of molybdenum compounds [38,45,88]. Azines obtained from aliphatic aldehydes or ketones and amines react especially easily. Reaction goes very smoothly to give at least 80% yields of oxaziridines (LXXVI):



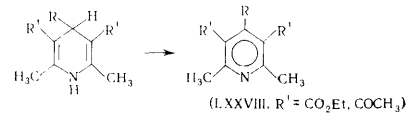
(LXXVI)

(LXXVII)

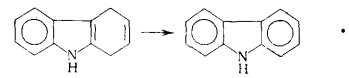
Oxaziridines (LXXVII) containing aromatic and aliphatic substituents are formed smoothly. Attempts to obtain purely aromatic oxaziridines were completely unsuccessful. Thus oxidation of benzylidenaniline is accompanied by vigorous rearrangement to benzanilide.

5. Dehydrogenation of 1,4-Dihydropyridines

One stage in the Hantzsch method for the preparation of pyridines involves the dehydrogenation of 1,4-dihydropyridines by means of various oxidising agents [97,98]. It has recently been found [99] that dehydrogenation by the action of t-pentyl hydroperoxide in the presence of molybdenum pentachloride is far more convenient. For example, diethyl 1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate is converted quantitatively into (LXXVIII):



(LXXVIII, R' = CO_2Et, $COCH_3$)
(LXXIX)

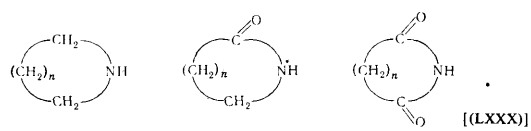


However, the conversion of 4-substituted dihydropyridines into pyridines (LXXIX) requires milder conditions, since in boiling benzene *N*-oxides are formed simultaneously. If excess of the hydroperoxide is used, *N*-oxides of the corresponding pyridines are formed in at least 80% yield in a single stage.

Dihydrocarbazole is converted quantitatively into carbazole.

6. Oxidation of Cyclic Amines to Imides

Interesting new potentialities for hydroperoxide oxidation are revealed by recent publications. It has been shown in particular that piperidine can be converted into 2-oxopiperidine [100], and caprolactam, 2-oxopiperidine, and 2-oxopyrrolidine are oxidised by t-butyl hydroperoxide to the corresponding imides [101] (LXXX)



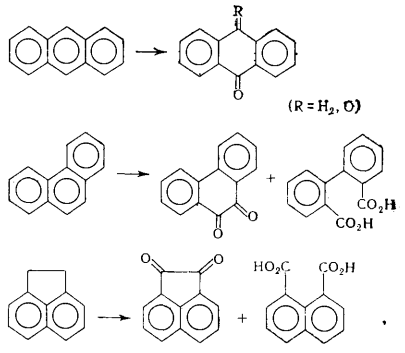
[(LXXX)]

The reactions are catalysed by bivalent and tervalent manganese salts. The yields of the imides are 65–85%, which confers preparative value on the method.

VI. OXIDATION OF FUSED AROMATIC HYDROCARBONS

Anthracene, phenanthrene, and acenaphthene can be oxidised by means of t-pentyl hydroperoxide in the presence of molybdenum pentachloride [102]. Anthracene is converted into a mixture of anthrone and anthraquinone, and phenanthrene and acenaphthene give phenanthraquinone

and acenaphthenequinone together with diphenic and naphthalic acids:

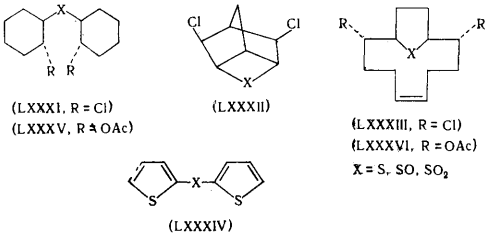


Thus the reaction involves rupture of a carbon–carbon bond. Up to 90% conversion of the hydrocarbons can be achieved by using excess of hydroperoxide. If vanadium compounds are used as catalysts, the same oxidation products are formed, but conversion of the initial compounds does not exceed 25%.

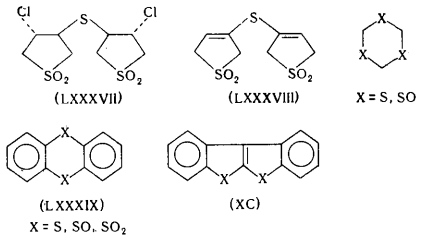
VII. OXIDATION OF ORGANOSULPHUR COMPOUNDS

Inorganic oxidising agents and peroxy-acids are generally employed to oxidise a sulphur atom in an organic compound [103,104]. The reaction between a sulphide and a hydroperoxide is very slow in the absence of a catalyst: for example, cyclohexyl methyl sulphide is converted into the sulphoxide by the action of t-butyl hydroperoxide at 60°C over a period of 64 h. [105] Some years later it was shown that aliphatic sulphides could be oxidised quantitatively to the sulphones by the action of hydroperoxide in the presence of molybdenum acetylacetonate [106]. A process of oxidation of sulphides to sulphoxides and sulphones by the action of hydroperoxides in the presence of metals of Groups IV and VII has been patented, and the partial and complete oxidation of dialkyl (diphenyl) sulphides has been described [107].

The hydroperoxide oxidation of organosulphur compounds has been most fully investigated [28,108,109]. The new method is applicable generally, since it can be used to oxidise organosulphur compounds of diverse structure. Its chief merit is extraordinarily high selectivity, not possible with the usual oxidising agents. The high rate of oxidation and the preparative simplicity are noteworthy. Hydroperoxide oxidation combines mildness of action, permitting the oxidation of compounds which undergo changes in the presence of such a reagent as hydrogen peroxide, with strong oxidising power, allowing the oxidation of sulphides and aromatic sulphur heterocycles that do not react with other oxidants. For example, the dichlorinated sulphides (LXXXI)–(LXXXIII), whose chlorine atoms are extremely labile, and dithienyl sulphide (LXXXIV) give very low yields of sulphoxides and sulphones when treated with hydrogen peroxide, whereas oxidation with t-pentyl hydroperoxide and molybdenum pentachloride in benzene solution produces almost quantitative yields of the oxidised products. The introduction of two acetoxy-groups, as in the sulphides (LXXXV) and (LXXXVI), almost completely prevents oxidation by hydrogen peroxide by shielding the sulphur atom, but high yields of sulphoxides and sulphones were obtained by means of the above hydroperoxide and catalyst.



The advantages of hydroperoxide oxidation are clearly evident from experiments on the sulphides (LXXXVII) and (LXXXVIII). Oxidation of the former with hydrogen peroxide gives a mixture of the sulphoxide and the sulphone, whereas the latter remains completely unoxidised [110]. However, the Reviewers have been able to obtain sulphoxides and sulphones in at least 90–95% yield by the action of t-pentyl or cumenyl hydroperoxide in the presence of molybdenum pentachloride. The possibility of precise control of the degree of oxidation by measuring out the oxidant has been shown with trithian as example, which is converted quantitatively into mono-, di-, and tri-sulphoxides, as well as with thianthren and 3,4,5,10-tetramethylthianthren (LXXXIX), which are converted respectively into mono- and di-sulphoxides, sulphoxidosulphones, and disulphones. Similarly, benzothiopheno[2,3-*b*]benzothiophen (XC) is converted quantitatively into the monosulphoxide and the mono- and di-sulphones; the disulphone could not be obtained by the action of hydrogen peroxide [111].

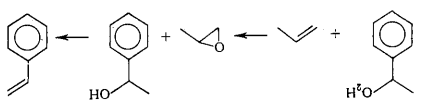


The hydroperoxide method has been applied to the selective oxidation of organosulphur compounds such as dicyclohexyl sulphide, thiadecalin, 13-thiabicyclo[8,2,1]-tridecane, benzothiophen, phenoxathi-in, phenazine, etc.

VIII. POSSIBLE INDUSTRIAL APPLICATIONS OF METAL-CATALYSED HYDROPEROXIDE OXIDATION

The development of processes for the conversion of alkenes originating from the petroleum industry into oxygen-containing compounds—oxides, alcohols, ketones, etc.—is one of the main tasks of petroleum chemistry. From this naturally follows the interest that has been evinced in the hydroperoxide epoxidation of alkenes.

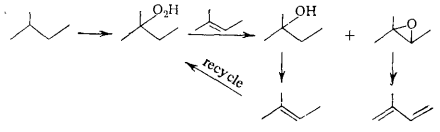
Publication of the firm Halcon International Inc. patents [112–117] on the simultaneous production of methyloxiran and styrene clearly revealed the potentiality of the new method. This process is based on the reactions



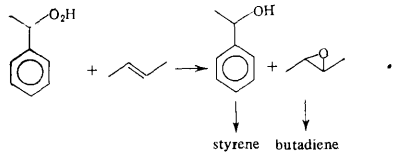
It may compete with the classical method of obtaining styrene by the dehydrogenation of ethylbenzene. A recent report on the starting-up of a plant based on the "Halcon process" states [118] that technical difficulties have been successfully overcome. Information on the production and purification of ethylbenzene hydroperoxide and on the choice of optimum conditions for oxidation will be found in patents [119-127]. The use of cumenyl hydroperoxide enables methyloxiran and α-methylstyrene to be produced together [128,129]. An interesting route has been suggested [50] for the simultaneous production of methacrylic esters and methyloxiran.

The development of improved and economic processes for obtaining isoprene is a most important task of the monomer industry. A process based on isopentane hydroperoxide is undoubtedly of interest in this connection [130-134]; its principle will be clear from Scheme 3.

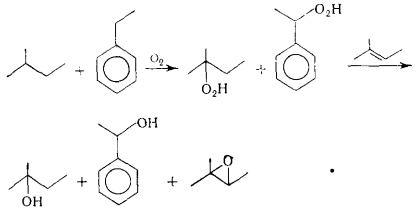
Scheme 3



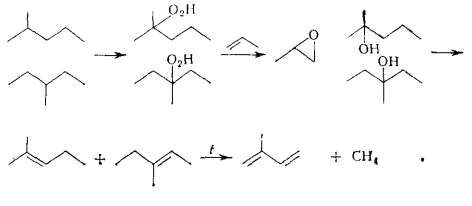
Among processes for the combined production of styrene and dienes—butadiene and isoprene—the first involved oxidation of but-2-ene by ethylbenzene hydroperoxide followed by appropriate reactions [135]:



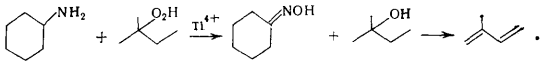
Oxidation of a mixture of isopentane and ethylbenzene is claimed [136] to yield the corresponding hydroperoxides, which are then used to oxidise isopentene to the oxide, after which the reactions are similar to those described above:



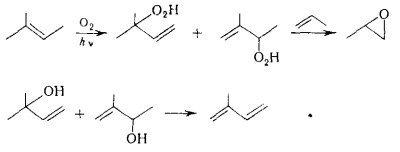
A noteworthy combined process for obtaining isoprene and methyloxiran from 2- and 3-methylpentane hydroperoxides yields tertiary alcohols, which crack to form isoprene [137]:



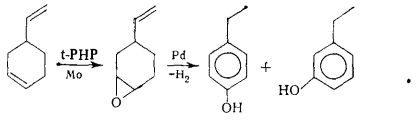
The production of isoprene can be combined with that of cyclohexanone oxime, which is formed by oxidising cyclohexylamine with hydroperoxides in the presence of titanium salts [137,138]:



An extremely interesting process for obtaining isoprene and methyloxiran is based on unsaturated hydroperoxides formed by the photosensitised oxidation of isopentene [139]:

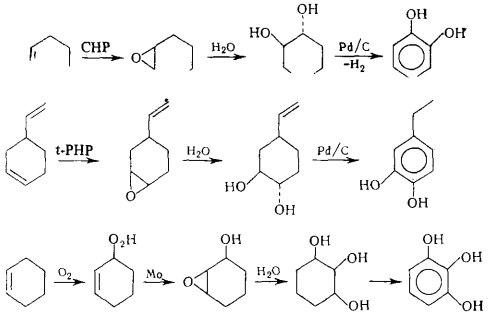


It has been proposed to use hydroperoxide epoxidation as a stage in the production of phenols. In particular, a mixture of *m*- and *p*-ethylphenols is obtained by the scheme [140]

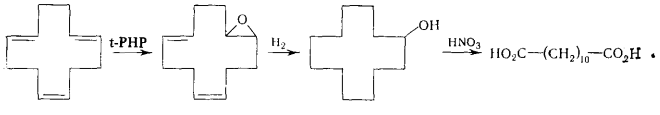


The essential nature of methods developed for obtaining catechol [141,142], ethylcatechol [143], and pyrogallol [144] will be clear from Scheme 4.

Scheme 4



A suggested method for obtaining dodecanedioic acid involves the stages [145]



The application of hydroperoxide epoxidation to the production of various oxygen-containing compounds is considered in periodical communications [146-152] and in patents [153-157].

While the Review was being prepared for press several publications have appeared on the kinetics and the mechanism of hydroperoxide epoxidation [158-163]. Papers clearly showing for the first time that the reaction is catalysed by complexes of sexivalent molybdenum are especially interesting [158,159]. The stereochemistry of oxidation has been examined [164-166].

Effect of a Strained Double Bond on the Behaviour of Hydrocarbons Towards Oxygen

V.V.Voronenkov

The reasons for strain in a double bond are considered, and the effect of the stress on the behaviour of hydrocarbons in liquid-phase oxidation and in oxidative polymerisation is discussed. The list of references contains 39 items.

CONTENTS

I. Introduction 333
II. Oxidation of a double bond with "cisoid repulsive stress" 333
III. Oxidation of a double bond with "torsional stress" 334
IV. Effect of tendency of double bonds to homolysis on the reactivity of hydrocarbons towards oxygen 335

I. INTRODUCTION

The oxidation of hydrocarbons by molecular oxygen is currently attracting the attention of many research workers. The literature on this process [1–4] indicates that the scientific problems of oxidation are indissolubly linked with general aspects of structure and reactivity. I have therefore examined the effect of a strained double bond on the behaviour of hydrocarbons in reactions with oxygen.

All substituents adjacent to a double bond are in the same plane as the alkene group and the angle [5]

is normally taken to be 120°. Departure from this angle requires the consumption of energy: i.e. it increases the internal energy of the system. Thus a strained double bond is understood to be one which, in contrast to the "ideal" geometry, is subject to strong angular distortions with enhanced energy of the system. Such systems were discussed comprehensively in a review by Zefirov and Sokolov [6]. However, they did not consider the effect of a strained double bond on the reactivity of hydrocarbons towards oxygen, a gap to be filled in the present Review.

II. OXIDATION OF A DOUBLE BOND WITH "CISOID REPULSIVE STRESS"

Hecht and Victor [7] found by proton magnetic resonance spectroscopy that rotation of the methyl groups in *cis*-but-2-ene was hindered compared with that in the *trans*-isomer. They also proved that the skew conformation of *cis*-but-2-ene, obtained from the form with the methyl protons shielding the double bond, was energetically the most favourable. Such a conformation exhibits fairly strong overlapping of the van der Waals spheres (Fig. 1), leading into an increase in the angle θ. It must be borne in mind that the deformation of this angle between the bonds is not localised, but distributed over the other angles, as a result of which the energy of the system as a whole is minimised. This involves deformation of the remaining angles and an increase in the strain in the double bond ("cisoid repulsive stress").

The strain in a double bond can be assessed experimentally from thermodynamic data by comparing the negative heats of hydrogenation of the alkenes. Table 1 shows that increase in the volume of *cis*-alkyl groups in an alkene produces an increase in the negative heat of hydrogenation, which corresponds to greater stress in the >C=C< bond, and so to greater deviation of the valency angle θ, which becomes 136° in *cis*-di-t-butylethylene [*cis*-2,2,5,5-tetramethylhex-3-ene]. The main consequence of such stress in the double bond is enhanced reactivity.

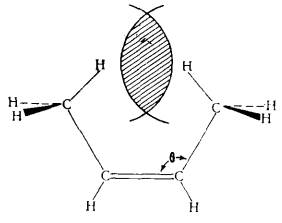

Figure 1. Diagram of overlapping of van der Waals spheres in *cis*-but-2-ene (from proton magnetic resonance data [7]) with distances (Å) C=C 1.38, C–C 1.54, and C–H 1.06 and angles CCC 120° and CCH 109.5°.

Table 1. Negative heats of hydrogenation of isomeric *cis*- and *trans*-alkenes [6].

Alkene	$-\Delta H_{hydr}$, kcal mole^{-1}	Alkene	$-\Delta H_{hydr}$, kcal mole^{-1}
cis-But-2-ene	28.57	*cis*-Methyl-t-butylethylene	30.8
trans-But-2-ene	27.62	*trans*-Methyl-t-butylethylene	26.5
cis-Methylisopropylethylene	28.60	*cis*-Di-t-butylethylene	36.2
trans-Methylisopropylethylene	27.76	*trans*-Di-t-butylethylene	26.87

In the epoxidation of alkenes by hydroperoxides in the presence of a molybdenum catalyst, represented by the general scheme

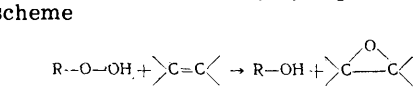

Table 2. Reactivities of isomeric butenes (4.0 M) in epoxidation on a molybdenum catalyst [8] (0.0001 M) at 50°C.

Alkene	Rate constant, $M^{-1}\ s^{-1}$	Relative rate
But-1-ene	$0.076 \cdot 10^{-3}$	1.00
trans-But-2-ene	$1.08 \cdot 10^{-3}$	14.2
cis-But-2-ene	$2.74 \cdot 10^{-3}$	36.0

for example, the reactivity of *cis*-but-2-ene is considerably greater than that of the *trans*-isomer (Table 2). A similar rule is observed in the epoxidation of cycloalkenes: those having a strained double bond (norbornene, cyclopentene) are epoxidised far more readily than are cycloalkenes not containing a strained double bond (cyclohexene) [9]. *cis*-Polybutadiene is oxidised by oxygen more vigorously than is *trans*-polybutadiene [10].

III. OXIDATION OF A DOUBLE BOND WITH "TORSIONAL STRESS"

"Torsional or twisting stress" in a double bond results from a fragment of the molecule turning about the double bond (Fig. 2), which reduces the degree of overlap of the p_z atomic orbitals. Quantum-mechanical calculations show that the energy of a π-bond is greatest with maximum overlap of these orbitals, which occurs when they lie in the same plane. Deflection of the axes of the orbitals from coplanarity decreases their degree of overlap, ultimately with the appearance of a biradical triplet state.

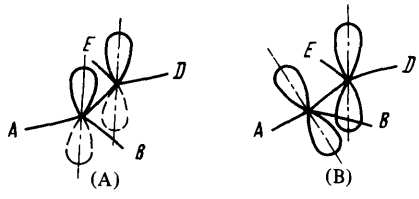

Figure 2. Diagram of the overlap of p_z orbitals in model of: A) coplanar state; B) strained state.

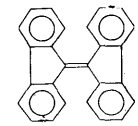
The graph shows (Fig. 3) how the energies of the ground level N, the first triplet level T, and an excited level V in ethylene vary with mutual rotation of the moieties of the molecule [11,39]. With increase in the angle of deflection the $N-V$ transitions require less energy: i.e. excitation occurs at longer wavelengths, and at an angle of 90° the triplet state now becomes energetically more favourable than the singlet state.

One mode of homolysis of an ethylenic bond, i.e. of mutual approach of ground and triplet levels N and T, is a decrease in the degree of overlap of the p_z atomic orbitals of the π-bond (Fig. 2). Such a state arises in ethylenic bonds with "torsional stress", e.g. in 9,9′-bifluorenylidene [12]



(I)

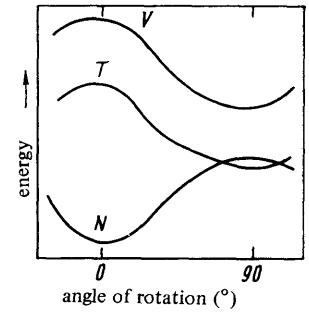


Figure 3. Variation of ground level N, first triplet level T, and excited level V of ethylene during rotation about the double bond [11].

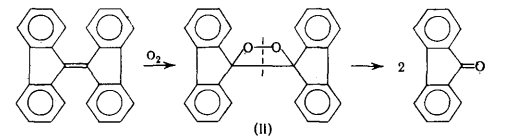
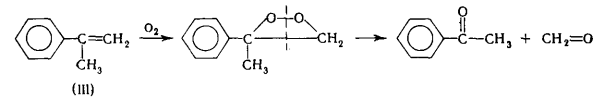
Here the double bond is strained because left-hand and right-hand moieties of the molecules are turned apart by the repulsion of the non-bonded *peri*-hydrogen atoms. This leads to decreased overlap of the p_z atomic orbitals, i.e. to diminished coupling (overlapping) of the electrons forming π-bond and to an increased degree of homolysis of this bond. Such bonds exhibit an enhanced tendency to undergo homolytic (radical) reactions. This is supported by the fact that 9,9′-bifluorenylidene readily terminates reaction chains in the oxidation of benzaldehyde, thereby being oxidised to fluorenone. It is also extremely readily oxidised to fluorenone by atmospheric oxygen in ethereal or alcoholic solution. The sensitised photochemical oxidation of 9,9′-bifluorenylidene occurs highly selectively to give a 91% yield of fluorenone [13]. The oxidation probably involves intermediate formation of 1,2-dioxetans:

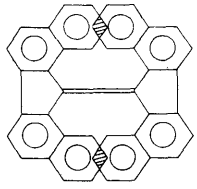


Oxidation of the double bond in α-methylstyrene obviously has the same mechanism:



It is interesting that the rate of oxidation of the double bond in bifluorenylidene exceeds that in *trans*-4-methylpent-2-ene—a compound from whose double bond torsional stress is completely absent—by a factor of 720. [13]

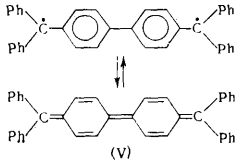
Homolytic reactions are still more characteristic of the double bond in bisdibenzo[*a*,*i*]fluorenylidene



(IV)

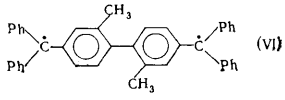
This hydrocarbon inhibits the autoxidation of certain organic compounds, in particular benzaldehyde, slows down the polymerisation of styrene, and in toluene solution readily reacts with oxygen when exposed to ultraviolet radiation [14].

Among compounds with torsionally stressed double bonds is Chichibabin's hydrocarbon [15]



(V)

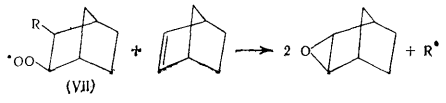
It adds oxygen fairly easily to form a peroxide, but if methyl groups are introduced into the *oo'*-positions of the biphenyl system the product



(VI)

is oxidised still more vigorously to a peroxide [16]. Interaction of the methyl groups results in complete uncoupling of the *p*-electrons of the central π-bond in biphenyl [17].

In cycloalkenes, especially in the bicyclic compounds, e.g. norbornene and its derivatives, serious angular deformations, leading to stress in the double bond, arise from the conditions of ring closure. Zefirov and Sokolov predicted that the study of strained cycloalkenes could lead to the discovery of fundamentally new reactions [6], a forecast which has recently been fulfilled. The oxidation of norbornene and its derivatives by oxygen has shown that the t-C–H bond in them is inert [18–20]. In the presence of azoisobutyronitrile, however, oxidation is fairly vigorous. The oxidation products are not hydroperoxides—as occurs in the oxidation of cycloalkenes whose double bond is unstressed—but cyclic oxides. This was explained [20] by a mechanism in which the epoxidising agent was a peroxy-radical formed by addition of a free radical R$^{\bullet}$ to one end of the double bond and of oxygen to the other end. Such a peroxy-radical (VII) reacts with the initial compound to form two molecules of the oxide:



(VII)

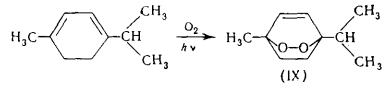
Interaction of the radical with the strained double bond suggests that the stress makes the latter liable to radical dissociation (to become partly homolysed).

IV. EFFECT OF TENDENCY OF DOUBLE BONDS TO HOMOLYSIS ON THE REACTIVITY OF HYDROCARBONS TOWARDS OXYGEN

It will be extremely interesting to examine the oxidation of conjugated diene and polyene systems in terms of homolysis of the double bonds. These systems differ from monoalkenes and unconjugated polyenes in usually not forming hydroperoxides even when a methylene group appears at first glance to be in a position favourable for oxidation, e.g. in elaeostearic ester [21]

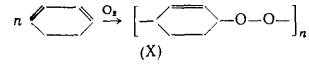
(VIII)

Instead, oxygen tends to add at the ends of a diene segment with formation of an oxygen bridge, as in transannular peroxides [22]:



(IX)

Polymeric peroxides



(X)

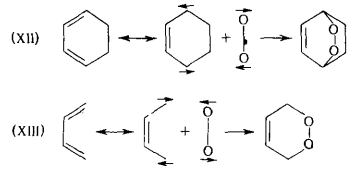
may also be formed [23,24]. All the above published information suggests that the interaction of alkenes and polyalkenes with oxygen is strongly dependent on the liability to homolysis of the bonds in the hydrocarbon.

In conjugated diene systems, e.g. butadiene and cyclohexadiene, neighbouring π-bonds do not remain strictly localised, but interact with partial overlapping of the *p*-electrons of double bonds in positions 2 and 3. As a result of this interaction, the double bonds 1–2 and 3–4 become partly uncoupled (homolysed), which can be represented conventionally by

(XI)

The arrows below the outer carbon atoms on the right-hand side denote single electrons, and their opposite directions indicate opposite spins [25,26]. Thus the uncoupling of the electrons at the ends of a diene system leads to weakening of the terminal bonds, which increases their activity in radical reactions. The right-hand formula obviously corresponds to an excited state of the butadiene molecule.

According to resonance theory, individual resonant structures do not correspond to physically real molecular states [27]. Recognition of the partial uncoupling of electrons in double bonds leads to the conviction that the symbols used by resonance theory can probably represent the excited (real) state of a molecule and—what is most important—predict the course of chemical (homolytic) reactions. This conclusion is confirmed by known oxidations of hydrocarbons, e.g. butadiene, cyclohexadiene, cyclohexene, and elaeostearic ester. Cyclohexadiene (XII) and butadiene (XIII) give with oxygen cyclic peroxides, which can be represented by the scheme

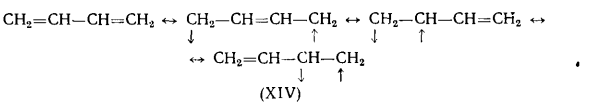


The right-hand formulae for the hydrocarbons have greater energy than the usual formulae on the left. With a planar arrangement of atoms in the molecule the two right-hand formulae have a different distribution of p-electrons and approach a triplet biradical state in which the ethylenic carbon atoms are no longer so double-bonded in character.

The concept of the uncoupling of electrons of a π-bond under the influence of a free electron in an allyl radical was put forward long ago in the early papers by Burton and Ingold[28]. In particular, they regarded stabilisation of a radical as involving interaction of an unpaired electron with the electron pair of a neighbouring π-bond, leading to partial uncoupling of the latter and a redistribution of electrons:

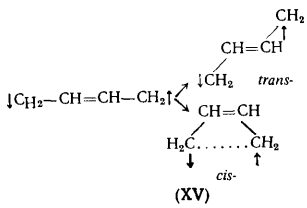
Ingold writes[29]: "In this paper, the main conclusions of which are partly applicable to the whole theory of organic chemistry, reference was first made to the relation between mesomerism and the uncertainty principle and to the fact that the motive force distributing electrons along a conjugated chain is of quantum origin".

The concept of partial uncoupling of electrons of a π-bond suggests that in an excited state butadiene may exist in the forms



(XIV)

The 2–3 bond obviously has one-third double-bond character, so that free rotation is unlikely about this bond. Separate existence of *cis*- and *trans*-forms of butadiene is therefore possible:

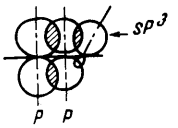


(XV)

Since the outer groups approach very closely in the *cis*-system, a homocomplex may be formed. The increased proportion of the *cis*-form of butadiene with rise in temperature (e.g. in diene synthesis) probably results not from rotational isomerism but from an increase in the statistical weight of the excited *cis*-form.

The above facts suggest that the liability of double bonds in a molecule to homolytic breakdown may well be as important in the oxidation of hydrocarbons as are the properties of the radical. Thus from a comparison of the interaction of peroxy-radicals of α-methylstyrene, styrene, and methyl methacrylate with monomers Mayo concluded[30] that the oxidation of vinyl monomers is governed mainly by the activity of their double bond.

It follows from the above considerations that the hyperconjugation of α-CH bonds in alkenes and alkylated aromatic hydrocarbons can also be explained by their tendency to homolysis (partial uncoupling of the electrons of the α-CH bond). On certain postulates the interaction of an α-CH bond with the π-electrons of a double bond, e.g. in propene, is analogous to the interaction of π-electrons in a conjugated system. This can be represented[31]



Here the hybrid sp^3 orbitals overlap the p_z orbitals of the double bond. Such interaction would probably result in partial uncoupling of the α-CH bond, its partial homolysis. The tendency to such homolysis will be most effective when the axis of the α-CH bond and the axes of the p-electrons are completely or nearly parallel, i.e. when the double bond is not weakened by steric factors. A partly uncoupled (homolysed) α-CH bond has far greater electron affinity for a peroxy-radical than has the unhomolysed bond. Attack by such a radical in the autoxidation of alkenes is therefore directed at an α-CH bond. In monoalkenes the double bond interacts with the α-CH bonds and homolyses them.

In the hyperconjugation effect the interaction of alkyl group and double bond is a reciprocal process. For example, a consequence of replacing an ethyl group in propane by vinyl is that the methyl group in propene reacts considerably more readily with oxygen than does a methyl group in propane. Replacing a hydrogen atom in ethylene by a methyl group makes the double bond in propene more susceptible to epoxidation than is the double bond in ethylene. Thus the relative rates of epoxidation of ethylene, propene, isobutene, trimethylethylene [2-methylbut-2-ene], and tetramethylethylene [2,3-dimethylbut-2-ene] are respectively 1, 21, 30, 5600, and 6000.[32] This is paralleled by a fall in the ionisation potential (Table 3): increase in the number of methyl groups in a molecule leads to a fall in the ionisation potential and an increase in the rate of epoxidation.

Table 3. Ionisation potentials of alkenes[33].

Alkene	$CH_2=CH_2$	$CH_2=CH-CH_3$	$CH_2=C(CH_3)_2$		Ionisation potential, eV	10.62	9.84	9.35	8.85	8.45

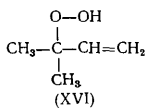
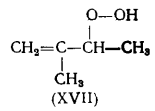
The low-temperature autoxidation of hydrocarbons such as tri- and tetra-methylethylenes involves intermediate formation of an allyl radical. Examination by proton magnetic resonance spectroscopy of the products of the low-temperature oxidation of trimethylethylene has established the formation of two hydroperoxides—tertiary and secondary[34]

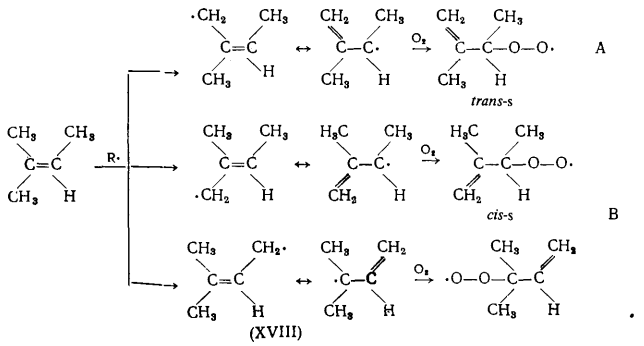


(XVI)



(XVII)

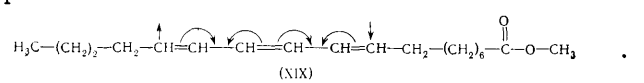
This can be explained in terms of resonance in the hydrocarbon free radicals of the isoalkene in the forms (XVIII) A and B



(XVIII)

All the free radicals indicated are equally likely to react with oxygen, but the probability of forming primary hydroperoxides is small because of the short lifetime of a primary allyl hydrocarbon radical. The more stable tertiary and secondary radicals are formed from the primary radicals. Since the rate of radical abstraction of the hydrogen atom is the same from all three methyl groups in trimethylethylene, the number of resonance structures formed under otherwise similar conditions is twice as great for a secondary radical (*cis*-s, *trans*-s) as for a tertiary radical. Therefore the statistical probability of involvement in reaction with oxygen is considerably greater for a secondary radical (form A) than for a tertiary radical (form B). This evidently explains why the quantity of secondary hydroperoxide formed is double the quantity of the tertiary hydroperoxide. Thus in this example the structure and the proportions of the hydroperoxides are governed solely by the number of resonance structures of the hydrocarbon free radicals.

If a system of conjugated double bonds is present, interaction of the π-electrons will evidently be stronger than that between double and α-CH bonds. In diene systems, therefore, the π-bonds—not the α-CH bonds—are homolysed (uncoupled) first. An example is the oxidation of cyclohexadiene. Elaeostearic esters are oxidised similarly, when uncoupling of the electrons may be represented



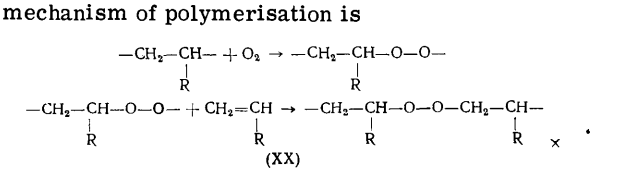
(XIX)

Radical unsaturation appears predominantly at the ends of the diene system, at which the action of oxygen is directed.

It is interesting that the addition of phenyl rings at the ends of a double bond increases the tendency to homolysis and accelerates oxidation of the double bond. For example, the rates of oxidation of the double bond by oxygen with formation of polyperoxides increase in the sequence [35]

styrene < α-methylstyrene < 1,1-diphenylethylene.

The mechanism of polymerisation is



(XX)

Table 4 lists kinetic data on the radical polymerisation of vinyl acetate with the above monomers [36]. This process is interesting because the same radical is interacting with the double bond in monomers having different structures.

The difference in reactivity of the above monomers therefore represents primarily a difference in the electronic nature of their double bond. Weakening of the double bond is greater in 1,1-diphenylethylene than in styrene, probably an effect of the two phenyl rings, which exert a stronger homolysing action on the π-bond. 1,1-Diphenylethylene is a structural analogue of benzophenone, in which the carbonyl π-bond passes considerably more readily into the triplet (biradical) state than does the corresponding bond in benzaldehyde [37]. Thus homolysis of the π-bond in hydrocarbons is promoted by steric factors (torsional or angular stress) and electronic factors (effect of non-polar substituents adjacent to double bonds capable of $\sigma-\pi$ or $\pi-\pi$ conjugation).

Table 4. Stoichiometric coefficient* of vinyl monomers in the polymerisation of vinyl acetate at 50°C. [36]

Monomer	μ_{theor}	μ_{exp}	$\frac{\mu_{exp}}{\mu_{theor}}$
Styrene	2.0	0.065	0.032
α-Methylstyrene	2.0	0.65	0.32
1,1-Diphenylethylene	2.0	1.77	0.88

*μ = stoichiometric coefficient in the equation $t_i = \mu z_0/w_1$, where t_i is the duration of the induction period, z_0 the initial inhibitor concentration, and w_1 the rate of initiation.

The increase in the polarity of the ethylenic bond may even produce an ambipolar ion $\overset{+}{\text{C}}-\overline{\text{C}}$, in which rotation about the central bond does not result in a decrease in the overlap integral between the p-electrons, since they are concentrated in the region of a single carbon atom. This situation diminishes the effect of the double bond on the α-CH bonds. It now becomes clear why, for example, the rate of autoxidation of 2-methylpent-1-ene is one-tenth of that of 2-methylpent-2-ene [38]: the double bond is polarised only in the former hydrocarbon.

Advances in the Synthesis and Investigation of Organofluorine Compounds

I.L.Knunyants and V.R.Polishchuk

Modern data concerning the wide variety of the physical and chemical properties of organofluorine compounds are reviewed. The studies in recent years, carried out using non-empirical quantum-mechanical calculations, photoelectronic spectroscopy, ^{19}F and ^{13}C NMR, as well as other latest research techniques, have introduced a number of refinements into ideas on the effect of fluorine atoms on the properties of both stable molecules and reaction intermediates.
The principal fields of practical application of organofluorine compounds are also examined. New data on the methods of introducing fluorine into organic molecules are presented in the concluding section.
The bibliography includes 227 references.

I. THE SCOPE OF MODERN FLUORINE CHEMISTRY

Classical organic chemistry constituted an elegant system the fundamental components of which were hydrocarbons—not only as the basis for the classification of any compound containing carbon–carbon bonds but also as a class of substances from which all these compounds can be synthesised by an appropriate sequence of experimental procedures.

The problem of the possibility of another non-hydrocarbon system, comparable in its chemical scope to the classical system, evidently arose simultaneously with organic chemistry. In the search for an answer to this problem twentieth century chemists undertook comprehensive studies on compounds in which both or at least one of the fundamental organogenic elements (carbon and hydrogen) is fully substituted by another element.

Saturated fluorocarbons, the study of which began as late as the 1930s, initially attracted attention by their complete chemical inertness. In combination with excellent thermodynamic characteristics, this property made Freons—derivatives of methane or ethane substituted by fluorine and chlorine atoms—ideal cooling agents in refrigeration engineering.

The set of properties of saturated fluorocarbons and fluorinated polymers made them essential materials for the most important branches of industry which arose in the 1940s—atomic and aerospace engineering. Their resistance to the action of the most powerful oxidising agents permitted the employment of fluorocarbons as lubricants for apparatus in contact with uranium hexafluoride or rocket fuel oxidants.

Even a very powerful oxidising agent such as atomic fluorine reacts only slightly with CF_4 (exchange with ^{18}F)[1]; on the other hand, when perfluorocycloalkanes, for example cyclo-C_4F_8, react with ^{18}F, the dissociation of C–C bonds is twice as likely as that of C–F bonds[2]. As a result of the accumulation of C–F bonds in fluoropolymer molecules, they are not only resistant to chemical action (Teflon is not acted upon either by aqua regia or concentrated alkali, which dissolve even platinum) but also have a low coefficient of friction. This property is associated with the very weak intermolecular interactions characteristic of fluorocarbons. Thus the boiling points of the lowest saturated fluorocarbons are close to those of the corresponding hydrocarbons, but, starting with the C_5 compounds, normal fluorocarbons boil at lower temperatures than hydrocarbons. On the other hand, when account is taken of the high molecular weight of fluorocarbons, it is found that the curve relating their boiling points to molecular weight is close to the corresponding curve for the inert gases[3].

In consequence of their high volatility in combination with chemical inertness, fluorocarbons have found extensive applications as components of aerosol compositions; their high vapour density makes them excellent fire-extinguishing agents.

Owing to the lack of polar interactions of the long fluorocarbon chains with the surrounding medium, fluorocarbon derivatives containing ionogenic groups (carboxylic and sulphonic acids, quaternary ammonium salts[4]) proved to be most valuable surface-active substances. Thus the addition of 0.35% of perfluorocaprylic acid lowers the surface tension of water to 15.3 dyn cm^{-1} (cf. the usual carboxylic acids for which the decrease is at most to 24 dyn cm^{-1}). Fluorocarbon residues interact weakly also with hydrocarbon chains. Thus successive substitution of hydrogen atoms in benzene derivatives by fluorine leads to a decrease of the solubility of alkanes in the latter (determined by gas–liquid chromatography[5]).

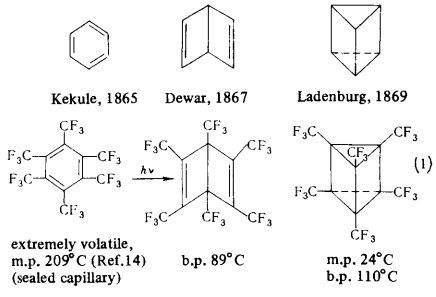
For this reason, impregnation of textiles with fluorocarbon derivatives imparts to them not only hydrophobic but also oil-repellent properties.

Their high breakdown voltage and thermal conductivity have led to the use of fluorocarbons and some of their derivatives as cooling dielectrics.

The industrial applications of fluorocarbons enumerated above (reviewed in detail elsewhere[6-11]) have led to interest in the development of convenient methods for their synthesis and in the 1940s and 1950s there was an explosive growth of the stream of empirical data on organofluorine chemistry. New facts did not always fit within the framework of ideas current at the time, which led to a tendency towards some autonomy in fluorine chemistry. However, progress in theoretical organic chemistry, which was particularly enriched by the method of investigation of electronic effects of substituents by measurements of the chemical shift of the fluorine label (see the review of Emsley and Phillips[12]) and also the adoption by many chemists working in synthetic chemistry of the

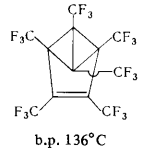
experimental achievements in fluorine chemistry made it a kind of branch of organic chemistry, a distinctive feature of which is the extreme richness of its synthetic possibilities. One may say that fluorocarbons constitute the non-hydrocarbon system which was sought by the chemists of the past, the wide variety of whose reactions surpasses the classical hydrocarbon system in certain respects.

The introduction of fluorine atoms makes it possible to isolate in a pure form structures which were regarded in classical organic chemistry as short-lived or as hypothetical reaction intermediates. Thus the introduction of six trifluoromethyl groups into the benzene ring makes it possible to isolate valence isomers corresponding to the different benzene formulae proposed in the XIXth century[13]:



(1)

The derivative corresponding to benzvalene, the existence of which had not been postulated in the XIXth century, was also isolated:



In this case the valence isomers are thermodynamically much more stable than the non-fluorinated analogues: their free energies of aromatisation are almost twice as small as for the isomers of hexamethylbenzene. The activation energy for this transformation also exceeds the value characteristic of hexamethylbenzene[15]. For comparison, we may point out that prismane C_6H_6, which was recently obtained by an elegant synthesis from benzvalene, has explosive properties[16].

Functional groups with highly oxidising properties can be introduced into fluorocarbons, i.e. it is possible to synthesise compounds whose hydrocarbon analogues are difficult to imagine: organic hypofluorites (CF_3OF)[17], superoxides (CF_3OOOCF_3)[18], derivatives of quinquevalent iodine (CF_3IF_4)[19] or halogenoperoxides (CF_3OOCl)[20].

The stabilising effect of fluorine atoms is also very marked when they are introduced into organometallic compounds. Thus the best method for the purification of fluoroalkyl derivatives of mercury[21] is distillation from concentrated sulphuric acid.

The physical properties of fluoroalkyl derivatives of metals are also sharply different from those of their hydrogen analogues. Whereas dimethylmercury is a mobile liquid with all features of a typical covalent compound, bis(trifluoromethyl)mercury is a solid (albeit volatile), which melts at 163°C in a sealed capillary; it dissolves readily in water forming conducting solutions[22].

Owing to the stabilising effect of fluorine atoms, it is possible to isolate in a pure crystalline form compounds containing a σ bond between the fluoroalkyl residue and the transition metal atom. Hydrogen-containing analogues of such compounds are frequently either unstable at room temperature or their existence as intermediates is merely postulated. Thus dehalogenation by iron pentacarbonyl[23] may involve a stage in which unstable σ derivatives of iron are formed.

On the other hand, when 1,2-dibromotetrafluoro-ethane is introduced into the reaction with $Fe(CO)_5$, the main product is an organometallic compound. Tetrafluoroethylene is isolated only on heating[24]:

$$BrCF_2CF_2Br + Fe(CO)_5 \rightarrow BrCF_2CF_2{-}Fe(CO)_4Br + CO \xrightarrow{\Delta} CF_2{=}CF_2\ (+CF_2{=}CFBr)\,. \qquad (2)$$

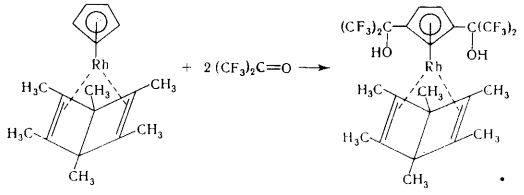
Yet another reaction in which the intermediate formation of σ compounds of transition metals was merely postulated is the synthesis of biphenyls by allowing cobalt salts to react with arylmagnesium halides. When pentafluorophenylmagnesium bromide is introduced into the reaction, the product is a blue solid—bis(pentafluorophenyl)cobalt—stable on long storage in solution. Decafluorobiphenyl is obtained only on heating this compound or on oxidising it with air[25]:

$$C_6F_5MgBr + CoBr_2 \rightarrow (C_6F_5)_2Co \xrightarrow{O_2} C_6F_5{-}C_6F_5\,. \qquad (3)$$

Many organofluorine compounds are extremely reactive. Thus the carbonyl group in fully fluorinated ketones is so electrophilic that hexafluoroacetone is "inserted" in the C–H bond of isobutene at room temperature[26]:

$$(CF_3)_2C{=}O + \begin{matrix} H_3C \\ H_3C \end{matrix}\!\!>\!C{=}CH_2 \rightarrow (CF_3)_2C(OH){-}CH_2{-}C(CH_3)_2{=}CH_2 \qquad (4)$$

or into the bond of cyclopentadiene coordinated to a rhodium atom[27]:

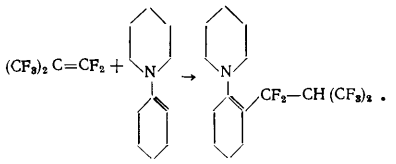


(5)

The immediate proximity of the fluorine atoms results in an extremely marked increase of the electrophilicity of carbon–carbon double bonds too. Thus octafluoroisobutene reacts at room temperature with comparatively weak nucleophilic agents such as alcohols[28]:

$$(CF_3)_2C{=}CF_2 + ROH \rightarrow (CF_3)_2CH{-}CF_2OR + (CF_3)_2C{=}CFOR \qquad (6)$$

or enamines[29]



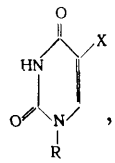
(7)

Evidently the high toxicity of octafluoroisobutene is due precisely to the ease of its reaction with nucleophilic centres and its nature is therefore analogous to that of the toxicity of many alkylating agents[30].

The physiological activity of organofluorine compounds is by no means always manifested by their toxicity. Certain fluorine-containing derivatives of ethane ("fluorotan" $CF_3CHClBr$, "inhalan" $CCl_2HCF_2OCH_3$ and its numerous analogues[31]) are valuable anaesthetics, which are almost free from side effects; fluorotan is used in paediatric surgery.

It is remarkable that the anaesthetic property of these compounds is associated with their low polarity. This property is more pronounced the greater the solubility of the substance in the non-polar lipids forming part of the membrane of the nerve cell[32].

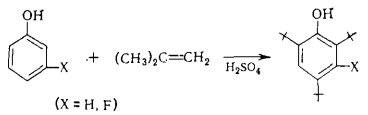
The introduction of fluorine atoms into the molecules of medicinal preparations frequently makes it possible to achieve striking results. Thus the substitution of hydrogen in the 5-position of the uracil molecule by fluorine[33] or the CF_3 group[34] leads to the formation of very effective antitumour preparations:



where X = F and R = H, , or riboside or X = CF_3

and R = riboside. Despite the fact that both preparations are antimetabolites, the mechanisms of their actions are completely different.

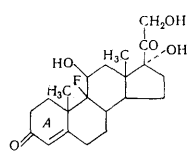
The action of 5-fluorouracil is based on the fact that the small fluorine atom leads to only a slight alteration in the geometry of the molecule, which thus retains its ability to combine the enzymes controlling its metabolic transformations. However, the latter become impossible owing to the presence of the firmly bound substituent in the 5-position. As an illustration of the low degree of steric hindrance associated with the replacement of the hydrogen atom by fluorine, one may quote an instance from the syntheses of hindered phenols: on alkylation with isobutene, three t-butyl groups can be introduced when only hydrogen or fluorine are present in the *m*-position[35]:



(X = H, F) (8)

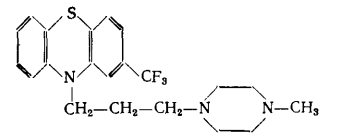
5-Trifluoromethyluridine suppresses the action of enzymes in a different way: the fluorine atoms in its molecules possess some mobility as a result of which it can alkylate the active centres of enzymes[36].

However, in the case of steroids, the slight change in molecular geometry caused by the introduction of a fluorine atom is sufficient to influence their physiological activity very significantly. Thus 9-α-fluorocortisol, whose antitumour activity exceeds that of cortisol by a factor of 7–10, differs from the latter only by the position of the *A* ring in space, which makes its molecular geometry similar to that of 6-methylprednisolone. On the other hand, the electronic defects associated with the introduction of fluorine do not play a significant role, contrary to expectation[37]:



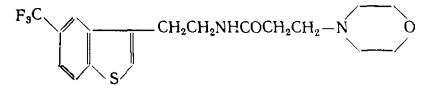
Fluorine-containing derivatives of phenothiazine and benzodiazepine are used as cyclotropic preparations.

According to polarographic data, *N*-substituted phenothiazines, including triphthazine which is used in clinical practice, form complexes with molecular oxygen.

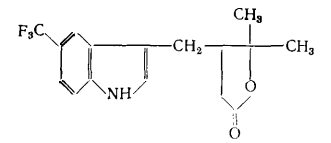


It may be that the mechanism of the action of derivatives of phenothiazine preparations consists in the formation of such complexes, which leads to a change in the energetics of cell respiration[38]. The especially high efficiency of the fluoroalkyl derivative can probably be related to the high solubility of oxygen in fluorocarbons. As a result of this property, solutions of oxygen in inert organofluorine compounds (fully fluorinated ethers, tertiary amines, and others) can find applications as substitutes for blood which, are hardly inferior to the latter in their oxygen capacity[39].

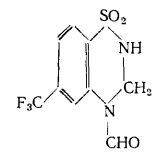
According to patent literature, fluorine-containing heterocycles can exhibit a depressive activity[40]:



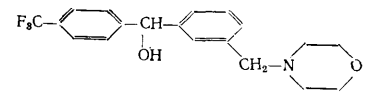
can stimulate the contraction of cardiac muscle[41]:



can reduce blood pressure[42]:



and can exhibit anti-inflammatory and antidiabetic activity[43]:



as well as diuretic[44], antimalarial,[45] and antifungal[46] activity. In addition they can have anticonvulsant properties[47], can reduce appetite[48], and can be used as sugar substitutes for diabetics[49].

The examples enumerated above, chosen from a number of patents published as late as 1972, clearly illustrate the continuous expansion of the applications of organofluorine compounds. As a result of this process, studies in the field of organofluorine chemistry have begun to develop at an ever increasing rate, the rate of growth of the number of publications in this field exceeding the average (which is also very high) for chemical literature as a whole. Thus the number of publications in 1970 on fluorine chemistry was three times greater than in 1960 and the number of new compounds described in these papers was five times greater[50]. On the other hand, the total number of chemical publications (and the compounds synthesised) doubles only every 8.3 years[51].

The available information about organofluorine compounds has been distributed in recent years among a large number of publications, many of which are difficult to obtain. Thus in 1969–1970 90% of the entire information on this field was distributed among 100 publications. Bearing in mind the fact that the role of patent literature has been continuously increasing (24% of the entire information in 1960 and 33% in 1970), the need for a working survey of this field of information becomes evident.

In the present review attention is concentrated on the publications of the 1970s (the earlier data have been largely covered in the monograph of Sheppard and Sharts [52] and also in Paleta's review [53], which include the literature for 1968 and 1969 respectively)—studies of fundamental importance or with an extensive bibliography.

The separate concluding section describes data on methods for the specific introduction of fluorine atoms into organic molecules, which is of specially great importance for investigators interested in applied chemistry.

One should note that the "Fluorine" information-research system, developed at the All-Union Institute of Scientific and Technical Information, significantly aided the authors in the selection of material for the review. A particularly valuable feature of this system is that it makes it possible to retrieve instantly detailed information about patent publications.

Certain references to the patent literature in the present review are based on data obtained from the above system.

II. THE FLUORINE ATOM AS A SUBSTITUENT

This section constitutes an attempt to survey the results of studies on organofluorine compounds by certain physical methods from the standpoint of their value for synthetic chemistry.

1. The Fluorine Atom at a Saturated Carbon Atom

The majority of applications of fluorocarbons and their derivatives enumerated in section I are associated with the extremely low polarity of these compounds and the consequent weakness of their intermolecular interactions. The quantities which determine the non-specific intermolecular interactions are molecular dipole moments and polarisabilities. The dipole moments of fully fluorinated alkanes with both normal and iso-structures are zero [54]. The introduction of only one hydrogen atom in the 1-position of the hexadecafluoroheptane molecule leads to the appearance of a significant dipole moment (1.60 D) and alkanes having the general formula $H(CF_2)_nH$, where $n = 4–10$, have dipole moments in the range 2–2.2 D. [55] On the other hand, 1,2-difluoroethane, a substance containing only two C–F bonds, is a liquid miscible with water. Its dielectric constant is 34.4 at 32 °C. [56] Evidently intermolecular H...F hydrogen bonds play a significant role in the solvation of 1,2-difluoroethane by water. The ability of fluorine atoms to form intramolecular hydrogen bonds is indicated by the infrared spectra of fluorine-containing alcohols and phenols [57] and also by the study of the structure of β-fluoroethanol by electron diffraction (90% of the *gauche*-conformation). [58]

The substitution of hydrogen atoms in alkane molecules by fluorine does not increase significantly their polarisability [59]. The weak solvation of fully fluorinated alkanes by various solvents is also consistent with these findings. It has been shown by ^{19}F NMR that dispersion interactions play a decisive role in this [60]: the dependence of the chemical shifts of CF_4, cyclo-C_4F_8, and cyclo-C_6F_{12} on the SV constant, characterising the properties of the solvent, is the same for both polar and non-polar media. The situation changes when chlorine or bromine molecules are introduced into the fluoroalkane molecule. The variation of the chemical shift in polar solvents becomes more pronounced owing to dipole–dipole interaction. It is significant that the chemical shifts of compounds usually employed as standards also change appreciably on passing from non-polar to polar solvents (the range of variation is 1.79 p.p.m. for CCl_3F, 1.88 p.p.m. for $C_6H_5CF_3$, and even as much as 4.88 p.p.m. for C_6F_6). [60] This fact is extremely important for investigators studying correlations in various solvents. The C_6F_6 chemical shift depends appreciably also on temperature: its change by 10 deg shifts the signal by 0.115 ± 0.021 p.p.m. [61]

Intermolecular interaction plays a significant role also in the chemical properties of organofluorine compounds. Thus the acidity of trihalogenoacetic acids in the gas phase varies in the sequence Br > Cl > F, i.e. in the order opposite to that widely known to hold for an aqueous medium. Evidently this finding is related to the greater polarisability of the bromine and chlorine atoms. On the other hand, in an aqueous medium the tendency of fluorine towards the formation of hydrogen bonds, leading to a more effective solvation of the trifluoroacetate ion, plays a decisive role [62].

Table 1. The binding energies of 1*s* electrons of the carbon atom in substituted methanes (in eV relative to CH_4). [63]

Formula	X = F	X = Cl	X = Br
CH_3X	2.8	1.6	1.0
CH_2X_2	—	3.1	—
CHX_3	8.3	4.3	—
CX_4	11.0	5.5	—

Photoelectronic spectroscopic data for halogenomethanes have shown that, as halogens accumulate, the binding energies of the electrons in the 1*s* level of carbon increase significantly, i.e. the formal atomic charge increases. This is particularly marked on accumulation of fluorine atoms [63] (the perfluoro-effect), which withdraw particularly strongly the valence electrons of carbon (Table 1). Photoelectronic spectroscopy can be used to analyse fluorine-containing polymers. The resolving power of existing instruments is sufficient to obtain resolved signals corresponding to the carbon atoms in the $CF_3–$, $–CF_2–$, $>CF$, and $–CH_2–$ groups. For this reason, it is possible to distinguish polymers with regular and irregular structures and by integrating the spectra one can also estimate the quantitative composition of the copolymers (for example $CF_2=CFCl$ can be distinguished from $CH_2=CF_2$). [64]

Quantum-mechanical calculations by non-empirical methods confirmed the increase of the charge of the carbon atoms in substituted methanes as fluorine atoms

accumulate (Table 2). Despite the appreciable difference between the charges obtained by different workers (the differences arise, in particular, from the choice of the *ab initio* set of wave functions, as shown by a methodological study[68]), the above tendency has been shown quite clearly in all investigations.

Table 2. The results of quantum-mechanical calculations on methane and its fluoro-derivatives.

Formula	Charge of C atom	Charge of H atom	Charge of F atom	References

	+0.68	—	−0.17	69

*Population data are quoted.

Fully fluorinated cycloalkanes behave as electron acceptors albeit to a slight extent. Thus the formation of charge-transfer complexes by these compounds with tetrakis(dimethylamino)ethylene has been demonstrated[70]. The reason for the enhanced (compared with linear analogues) electron-accepting properties of cyclic fluoroalkanes is probably that in their molecules the majority of the fluorine atoms are in the "eclipsed" conformation at short distances from one another. Under these conditions, the role of the interaction of the orbitals of these atoms, which may lower the thermodynamic stability of the molecule, becomes more marked. Nevertheless, owing to the pronounced screening of the positive charge of the carbon skeleton of the molecule by fluorine atoms, its chemical inertness can increase at the same time[71].

As will be shown below, the interaction between fluorine atoms plays an appreciable role also in the properties of fluoro-olefins.

The ability of fluoroalkanes containing bromine or iodine atoms to accept electrons is much more marked. The interaction of these compounds with mercury or amalgams[72], Grignard reagents[73], and the carbonyls of transition metals or their other derivatives in the lowest valence state[74] makes it possible to synthesise the corresponding σ-fluoroalkyl organometallic compounds. Nevertheless, the reaction between tertiary amines and fluoroalkyl iodides is not accompanied by irreversible electron transfer (leading ultimately to the formation of quaternary ammonium salts in the case of the usual halides—see Bubnov et al[75]) but consists merely in the formation of comparatively unstable complexes[76], which have been investigated by infrared[77] and NMR[78] spectroscopy.

Polarographic data have shown that fluoroalkylmercury derivatives are reduced at appreciably lower half-wave potentials than their hydrocarbon analogues (an electrochemical acidity scale has been constructed for hydrocarbons on the basis of these measurements[79,80]). The tendency of fluoroalkyl derivatives of mercury towards the formation of complexes with nucleophilic species is just as pronounced as their oxidising properties[81].

Thus the fluoroalkyl group, which exhibits a high electronegativity, reduces markedly the electron density at the metal atom to which it is linked. The resulting polarisation of the carbon–metal bond is evidently the main cause of the high, compared with non-fluorinated analogues, stability of fluoroalkyl σ derivatives of transition metals. Comparison of the photoelectronic spectra of $CF_3Mn(CO)_5$ and $CH_3Mn(CO)_5$[82] as well as the parameters of the NMR spectra of methyl and trifluoromethyl complexes of platinum[83] led to the conclusion that "back bonding", i.e. supply of the metal *d* electrons to the antibonding orbitals of the C–F bonds, does not play a significant role in the stabilisation of fluoroalkyl complexes.

The study of the relation between the parameters of ^{19}F NMR spectra of fluoroalkyl derivatives of mercury and the nature of the solvent revealed an anomalous behaviour of the *gem* constant for the $^{19}F-^{199}Hg$ spin-spin interaction, which decreases with increase of the solvating capacity of the medium (in contrast to the $^{19}F-^{199}Hg$ vicinal constant and the $^{1}H-^{199}He$ *gem* constant). This behaviour is evidence in support of the coordination of the mercury atom to the unshared electron pairs of the fluorine atom. This coordination, which lowers the capacity of mercury to combine with external nucleophiles, can play a significant role in the chemical behaviour of fluoroalkyl derivatives in metals[84].

The influence of the fluoroalkyl groups on the properties of the hydrocarbon groups bound to them is to a large extent determined by their strong negative inductive effect, which lowers the electron density at the adjacent carbon atoms. Conjugation effects play a certain role in aromatic systems. However, the absolute value of σ_I for fluoroalkyl groups exceeds significantly σ_R, which is of the same sign, the difference increasing with decrease of the number of fluorine atoms in the α-position, i.e. on passing from the CF_3 group to $C(CF_3)_3$, for which $\sigma_R = 0$ (see the review of Yagupol'skii et al.[85]). These data indicate the occurrence of a specific interaction between the π system and the orbitals of the fluorine atoms located in the benzyl position.

2. The Fluorine Atom at an Unsaturated Carbon Atom

The fluorine atom linked directly to an unsaturated carbon atom can both "strip" the multiple bond via the inductive effect and can supply to it electrons from its lone pairs. The acceptance of these electrons by the antibonding π* orbital should reduce the order of the C=C bond in fluoro-olefins, i.e. should lengthen it. However, owing to the inductive effect transmitted via the σ component, the length of the bond should diminish. As a result of the simultaneous action of these effects, the C=C bond in tetrafluoroethylene is nevertheless somewhat shorter than in ethylene[86]. According to photoelectronic spectroscopic data, the first ionisation potential (removal of a π electron) is virtually the same for ethylene and tetrafluoroethylene. Nevertheless the second potential (the removal of a σ electron from the C=C bond) of tetrafluoroethylene is higher by about 3 eV. On this basis, it has been concluded[87] that the filled orbitals of the fluorine atoms are mixed with the bonding π orbitals to an extremely slight extent and that the "perfluoro-effect" influences mainly the σ component of the C=C bond.

Furthermore, the overlapping of the p_X orbitals of the fluorine atoms, for example in the terminal CF_2 group, plays some role in the unusual properties of fluoro-olefins. This leads to the mutual approach of the fluorine atoms and the decrease of the angle between the C–F bonds to a value close to that of the tetrahedral angle[88] (previously this made it possible to attribute sp^3 hybridisation to the CF_2 group regardless of its environment[89]). The greater stability of *cis*-1,2-difluoroethylene compared with the *trans*-isomer has been explained similarly[88].

A chemical consequence of the dual effect of the fluorine atoms on the properties of the multiple bonds is electronic amphoteric properties of fluoro-olefins, i.e. their ability to react with both electrophilic and nucleophilic agents. As electronegative substituents accumulate at the multiple bond, the tendency to undergo nucleophilic reactions increases. A striking example of this is a reversal of the mechanism of the addition of nitrosyl fluoride on passing from tetrafluoroethylene (electrophilic process catalysed by BF_3) to hexafluoropropene (nucleophilic process catalysed by KF)[90]:

$$CF_2=CF_2+FNO \xrightarrow[BF_3,40^\circ]{} [\overset{\oplus}{C}F_2CF_2NO] \rightarrow CF_3CF_2NO\ , \qquad (9)$$

$$CF_3-CF=CF_2+FNO \xrightarrow[KF,80^\circ]{} \left[\begin{matrix}CF_3\\CF_3\end{matrix}\!\!>\!\overset{\ominus}{C}F\right] \rightarrow \begin{matrix}CF_3\\CF_3\end{matrix}\!\!>\!CFNO\ . \qquad (10)$$

In view of the reversal of the mechanism, it is possible to achieve the same reaction with the opposite mode of addition, depending on the nature of the catalyst. Thus, using the fact that perfluoromethyl vinyl ether is attacked by both electrophilic and nucleophilic agents at the CF_2 group, Lur'e et al.[91] succeeded in directing the mercury atom to the α- and β-positions in its molecule:

$$CF_3OCF=CF_2+HgCl_2 \xrightarrow[KF,20^\circ]{} [\overset{\ominus}{C}F_3OCFCF_3] \longrightarrow \underset{\displaystyle HgCl}{CF_3OCFCF_3}\ , \qquad (11)$$

$$CF_3\overset{\curvearrowright}{O}-CF=CF_2+HgF_2 \xrightarrow[HF,150^\circ]{} [CF_3O\overset{\oplus}{C}FCF_2HgF] \longrightarrow (CF_3OCF_2CF_2)_2Hg\ . \qquad (12)$$

Table 3. The full charges of the carbon atoms in fluoroethylenes.

Olefin	Group			References
	CH_2	CHF	CF_2	
$CH_2=CH_2$	−0.064			92
$CH_2=CHF$	−0.112	+0.218		92
	−0.046	+0.078		93
$CH_2=CF_2$	−0.138		+0.478	92
	−0.030		+0.219	93
$CHF=CF_2$		+0.121	+0.446	92
		+0.109	+0.235	93
$CF_2=CF_2$			+0.400	92

Quantum-mechanical calculations have shown that the charge at the olefinic carbon atom increases as fluorine atoms are attached to it, as happens in the series of saturated compounds (Table 3).

The results of the calculations of Borisova et al.[92] have not been confirmed by the familiar series of comparative reactivities of fluoro-olefins in reactions with nucleophilic and electrophilic agents:

ease of electrophilic reactions

$$\longleftarrow CH_2=CH_2 \quad CH_2=CHF \quad CH_2=CF_2 \quad CHF=CF_2 \quad CF_2=CF_2 \longrightarrow$$

ease of nucleophilic reactions

(on the other hand, according to these calculations vinylidene fluoride was the most reactive in any reaction).

Nevertheless the results obtained agree well with the measurements of the ^{13}C chemical shifts of fluoroethylenes, according to which the carbon atom of the CF_2 group of vinylidene fluoride is least shielded, while the carbon atom of the CH_2 group in the same compound is most strongly shielded[94] (Table 4).

Table 4. ^{13}C chemical shifts of fluoroethylenes (in p.p.m., quoted relative to ethylene).

Olefin	Group		
	CH_2	CHF	CF_2
$CH_2=CH_2$	0		
$CH_2=CHF$	+24.0	−24.94	
$CH_2=CF_2$	+58.22		−38.22
$CHF=CF_2$		+2.20	−25.24
$CF_2=CF_2$			−21.20

The calculated data quoted by Jolly and Perry[93] are remarkable in that the calculation of the binding energies of the 1*s* electrons of the carbon atom carried out on their basis makes it possible to estimate (in relation to experimental photoelectronic spectroscopic data) in which direction the calculated charge deviates. The distribution of the charges corresponds in this case to the series of comparative reactivities of fluoro-olefins in ionic reactions. The fairly stable π complexes formed by fluoro-olefins and transition metals are extremely promising from the standpoint of synthesis. The dative interaction, i.e. the supply of the *d* electrons of the metal to the antibonding π orbital of the olefin, makes the main contribution to the formation of the metal–olefin bond in this instance. However, the chemical behaviour of these complexes, frequently resembling that of small rings, and the relevant NMR data are described satisfactorily by formulae with two carbon–metal σ bonds (see Stone's review[95]):

The study of the properties of fluorine-containing dienes has shown that the conjugation of the multiple bonds in fully fluorinated 1,3-dienes is weakened. Thus comparison of the photoelectronic and ultraviolet spectra of 1,1,4,4-tetrafluorobutadiene and hexafluorobutadiene led to the conclusion[96] that there is a significant difference between their properties. Whereas the first compound has a *trans*-planar structure like normal butadiene, the second is not planar according to ultraviolet[96] and NMR[97] spectroscopic data. This conclusion has been confirmed by electron diffraction, which shows that the dihedral angle between the two $CF_3=CF$ groups in hexafluorobutadiene

is 47.4° ± 2.4°.[98] Evidently the breakdown of conjugation is associated with the interactions of the fluorine atoms in the CF groups.

The introduction of fluorine atoms into the aromatic ring also leads to the appearance of a significant positive charge at the carbon atom linked to it. Thus the ^{13}C NMR signal of hexafluorobenzene is displaced downfield by 38.34 p.p.m., compared with the signal of the 1-C atom of pentafluorobenzene[99]. Analysis of the photoelectronic spectra (the 1*s* levels of fluorine) has shown that the charge on this atom, linked to the ring, amounts to −0.15–0.20.[100] This is consistent with quantum-mechanical calculations (the charges in C_6F_6 are +0.132 for carbon and −0.132 for fluorine[93]). The changes in the charges of the carbon atoms which are not linked directly to fluorine are much smaller, amounting to zero for the *p*-position in fluorobenzene[100] and to −0.016 for the 9- and 10-positions in octafluoronaphthalene[101]. The ionisation potentials of the levels of aromatic fluoro-compounds (photoelectronic spectroscopy) differ from the corresponding values for the non-fluorinated analogues fairly slightly[102], i.e. the introduction of fluorine atoms does not prevent the aromatic system from retaining its capacity to behave as an electron donor. Indeed hexafluorobenzene forms charge-transfer complexes both with alkylbenzenes[103], behaving as an electron acceptor, and with the strong Lewis acid MoF_6,[104] behaving as an electron donor. Thus aromatic fluoro-compounds exhibit electronic amphoteric properties like fluoro-olefins.

The properties of the C_6F_5 group as a substituent are determined by the combination of the strong negative inductive effect (which is greater than for the C_6H_5 group but smaller than for CF_3) and the electron-donating properties associated with the presence of the lone electron pairs in the fluorine atoms. The electron-donating properties are manifested particularly clearly in the interaction of the C_6F_5 group with a cationoid reaction centre. The review of Vlasov and Yakobson[105] is devoted to a detailed consideration of these problems.

3. The Fluorine Atom in the Intermediate Species

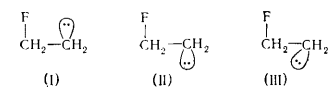
The mode and rate of a chemical reaction depend both on the structure of the reactant molecules and on the stability of the intermediate species formed. These two factors frequently act in different directions: the charge distribution in the attacked molecule can be unfavourable for the orientation leading to the formation of the more stable intermediate species. This effect is shown particularly clearly in reactions of organofluorine compounds: it has been shown that the charge separation between the atoms entering into the composition of their molecules is very pronounced.

For this reason, it is interesting to compare the stabilities of reaction intermediates with the observed mode of the processes, which has in fact been done below—mainly for fluoro-olefins. It is assumed that the findings obtained in the study of kinetically independent ions and radicals are valid also in these extremely common instances, where such species are not formed independently and there exists merely a transition state of the system which is of a type similar to them.

Among organofluorine compounds, reactions involving the intermediate formation of carbanions are most common. Despite their high electronegativity, fluorine atoms do not always stabilise these species, which is due to the presence of lone electron pairs in fluorine.

Thus, being bound directly to a negatively charged carbon atom, they can reduce significantly the stability of the carbanion as a result of the formation of the "back bond" between the electrons of the *p* orbital and the anionic centres. This phenomenon, sometimes referred to as the "Hine effect",[106] is evidently the cause of the decrease of the ionisation constant on passing from $CF_3CH_2NO_2$ to CF_3CHFNO_2[107] and also of the much lower kinetic acidity of $(CF_3)_2CHF$ compared with its analogues $(CF_3)_2CHX$ (X = Cl, Br, or I).[108]

The stabilisation of carbanions by the fluorine atoms in the β-position relative to the charged atom is difficult to account for exhaustively within the framework of the inductive effect. Calculation on the β-fluoroethyl anion, carried out in several versions using various semi-empirical approximations[109], has shown that the preferred conformations of the species are "*syn*" or "*anti*" (I, II), but not the "perpendicular" conformation (III), in which there is evidently a strong repulsion of the lone electron pairs of fluorine and the negatively charged carbon atom.



(I) (II) (III)

Analysis of the charge distribution among orbitals of the C–F bonds indicates a significant contribution of the π component, i.e. confirms the occurrence of "hyperconjugation" (an effect the nature of which requires further investigation). A non-empirical calculation on the FCH_2CH_2 cation, anion, and the radical led to analogous results. The preferred conformations are *syn*- or *anti*- for the anion and the perpendicular conformation for the cation[110]. As a result of the combination of these effects, tertiary monohydroperfluoroalkanes have an extremely "acid" hydrogen atom: according to deuterium exchange data, $pK_a = 11$ for $(CF_3)_3CH$,[108] and the value obtained in terms of the polarographic scale is as low as 7.[80]

It is believed[111] that the comparative reactivity series for the substituted benzenes $C_6F_5R_f$ in the reaction with ammonia [$R_f = (CF_3)_3C > CF_3CF_2 > (CF_3)_2CF > CF_3 \gg F$] indicates the absence of hyperconjugation in the intermediate species. However, since the σ_I for fluoroalkyl groups increase in the same direction[85], it may be that the higher reactivity of benzenes containing secondary and tertiary fluoroalkyl groups as substituents is associated merely with the greater positive charge in the *p*-positions in their molecules, which facilitates nucleophilic attack.

In contrast to carbanions, carbonium ions containing fluorine atoms at a charged carbon atom are stabilised. The lone electron pairs of the fluorine atoms are involved in "back bonding", as a result of which the fluoromethyl cations have a planar structure. The effect decreases somewhat (per fluorine atom) on passing from the CH_2F cation to CF_3. At the same time, the inductive effect of fluorine acting via the σ bond leads to an increase of the charge of the carbon atom from +0.659 in CH_2F^+ to +1.095 in CF_3^+ (calculation via the INDO method†)[112]. The ethyl cation with a fluorine atom in the β-position is less stable than the 1-fluoroethyl cation (the difference between the stabilisation energies is 29.23 kcal mole^{-1}). Its destabilisation compared with $C_2H_5^+$ can be partly compensated by the formation of the "non-classical" onium cation, $CH_2{-}CH_2$ with F which is more favourable on energy grounds than

† INDO = Incomplete neglect of differential overlapping.

the classical cation by 3.58 kcal mole^{-1}. However, in solution the more favourable species may be the more effectively solvated classical β-fluoroethyl cation (non-empirical calculations).[113]

Stabilisation as a result of the formation of a halogenonium cation is much more marked in the case of chlorine—the energy gain then amounts to 15.81 kcal mole^{-1}. This has been confirmed experimentally by the finding that the NMR spectrum of the β-chloroethyl cation at −80°C shows a singlet[114] (the applications of the NMR method in the study of fluorine-containing carbonium ions in highly acid media have been reviewed[115]).

The accumulation of fluorine atoms in the β-position relative to the positively charged carbon atom leads to the destabilisation of the cation compared with CF_3^+: whereas the ionisation potential of the $\dot{C}F_3$ radical does not exceed 9.5 V, it amounts to 9.98 V for $\dot{C}_2F_5$, 10.06 V for n-$\dot{C}_3F_7$, and 10.5 V for $(CF_3)_2\dot{C}F$ (mass spectroscopy).[116]

Quantum-mechanical calculations by the INDO method of the distribution of spin density in the series of radicals $\dot{C}H_3$, $\dot{C}H_2F$, $\dot{C}HF_2$, and $\dot{C}F_3$ showed that the unpaired electron density at the 2*s* orbitals of carbon and fluorine increases following the accumulation of fluorine atoms. This is consistent with the increase of the hyperfine interaction constants with the ^{13}C and ^{19}F nuclei in the ESR spectra of these radicals and also the change in their geometry, which gradually deviates from the planar structure of $\dot{C}H_3$.[117] On the other hand, owing to the high electronegativity of the fluorine atoms, the formal charge of the carbon atom in $\dot{C}F_3$ is +0.402 ($\sigma + \pi$, calculated from population data), while the charge in $\dot{C}H_3$ is 0.574.[118] Thus fluoroalkyl radicals should exhibit strong electrophilic properties. The enhanced stability of $\dot{C}F_3$ leads to a decrease of the energy of the C–C bond in hexafluoroethane to 60–70 kcal mole^{-1} compared with 79–81 established for alkanes. As a result, hexafluoroethane dissociates into radicals when acted upon by a glow discharge. Incidentally $(CF_3)_4Sn$ was synthesised by this unusual procedure (following addition to $C_2F_6SnI_4$), the yield exceeding 90%.[119] (Previously the C–C bond energy in C_2F_6 was assumed to be 94 kcal mole^{-1}; see Errede[120]. Possibly the C–H bond energy in CF_3H requires revision: the activation energy for the reaction of $\dot{C}F_3$ with alkanes, calculated on the basis of the value 106 kcal mole^{-1} adopted at the present time agrees poorly with the experimental results[121].)

In free-radical addition to fluoro-olefins an inconsistency is observed between the charge distribution in the initial molecule on the one hand, and the relative stabilities of the intermediate radicals on the other.

Thus, the addition of fluoroalkyl iodides to vinylidene fluoride or trifluoroethylene proceeds with a high degree of selectivity:

$$R_fI + CH_2{=}CF_2 \rightarrow R_fCH_2\dot{C}F_2I\ , \qquad (13)$$

$$R_fI + CHF{=}CF_2 \rightarrow R_fCHF\dot{C}F_2I\ . \qquad (14)$$

The selectivity increases on passing from $\dot{C}F_3$ to $\dot{C}_2F_5$ and $\dot{C}F(CF_3)_2$,[122] reaching in the latter case 97% for reaction (13) and 96% for reaction (14),[123] i.e. the process proceeds as if its mode were determined by the formation of the more stable radical $R_f\dot{C}H_2CF_2$. However, the opposite orientation is observed in the reaction of trifluoroethylene with the $\dot{C}H_3$ radical: the attack is directed to the CF_3 group to the extent of 88%.[124]

In the light of this finding, it becomes evident that the direction of attack on the olefin is not determined so much by the stability of the intermediate species as by polar effects. In the case of electrophilic fluoroalkyl radicals both factors act in concert, but the nucleophilic radical $\dot{C}H_3$ attacks trifluoroethylene via the carbon atom, which carries a more positive charge. In this connection the extremely high affinity of tetrafluoroethylene for $\dot{C}H_3$, which is ten times greater than in the case of ethylene[125] (the affinity of fluorobenzene exceeds that of benzene by a factor of 1.5)[126], is understandable.

Nevertheless in the reaction with an electrophilic species, such as the fluorine atom, the order of the reactivities of olefins is reversed: $CH_2{=}CHF > CH_2{=}CF_2 > CF_2{=}CF_2$ (kinetic data[127]).

The charge distribution in the ground state of the fluoro-olefin molecule is frequently of decisive importance also in ionic reactions. Thus in electrophilic addition reactions $\alpha\beta\beta$-trifluorostyrene gives rise to a mixture of products instead of the expected unambiguous result determined by the dominant stability of the benzyl cation[128]:

$$C_6H_5{-}CF{=}CF_2 + HBr \rightarrow C_6H_5CHF{-}CF_2Br + C_6H_5CFBr{-}CF_2H\ . \qquad (15)$$

Evidently the appreciable positive charge of the carbon atom in the CF_2 group, which hinders its protonation, has a significant influence in this case.

The stability of the recently synthesised enolic forms of the polyfluorinated ketones $CF_2{=}\underset{\displaystyle OH}{\underset{|}{C}}{-}CF_2X$, where X = F or Cl,[129] is apparently to some extent related to the difficulty of protonating the CF_2 group.

The stabilising effect which fluorine has on anion onoid species is also pronounced in the case of radical-anions:

$$R_2\dot{C}{-}OH \xrightarrow{-H^{\oplus}} [R_2C{=}O]^{\ominus}\ . \qquad (16)$$

Owing to the formation of the more stable ketyl, the acidity of the hexafluoro-2-hydroxyisopropyl radical (R = CF_3) exceeds that of hexafluoroisopropyl alcohol by 8.1 pK units, while the corresponding difference for R = CH_3 amounts to only 5.7 units[130].

The stabilising effect of fluorine leads to an increase of the hyperfine interaction constants for the ESR spectra of the radical-anions of fluorine-containing ketones[131] or nitro-compounds[132]. This constant is appreciably higher than for protons. Evidently the hyperconjugation effect plays a significant role in this[133]. ESR data for fluorocarbon radicals have been reviewed[134]. More recent data, obtained in liquid media, have been surveyed by Lloyd and Rogers[135].

The radical-cations derived from polyfluorinated benzenes are also stable. According to quantum-mechanical calculation (the INDO method), the charge on the carbon atom in $C_6F_6^{+\cdot}$ is +0.24 (cf + 0.132 in C_6F_6) and the unpaired electron density at the carbon atom is 0.12.[136]

The study of voltage–current curves in fluorosulphonic acid has shown that the radical-cations derived from pentafluorobenzene and 1,2,3,5-tetrafluorobenzene have lifetimes of the order of several minutes, while the radical-cations from hexafluorobenzene and octafluoronaphthalene exist in a highly acid medium for a very long time[137]. The formation of such radical-cations, which proceeds readily under the influence of antimony pentafluoride[138], apparently plays an important role in electrophilic reactions of aromatic fluoro-compounds (see, the review of Shteingarts and Yakobson[139]).

The influence of fluorine atoms on the properties of radicals is extremely important, because the radicals or the transition states resembling them are more common in the reactions of real organofluorine compounds than might have been supposed on the basis of traditional ideas

concerning the mechanisms of ionic processes. The transfer of single electrons, leading to the formation of radical species, frequently constitutes a decisive reaction stage. Biradical species (carbenes) and also triplet states of unsaturated systems, whose properties resemble those of biradicals, also play an extremely important role in reactions of organofluorine compounds.

Fluorine-containing carbenes are involved in many reactions of preparative value, particularly in pyrolytic industrial syntheses of fluoro-olefins. According to quantum-mechanical data (the Roothaan method), the positive charge on the carbon atom in carbenes, as in all other species, increases following the accumulation of fluorine atoms ($CF_2 > CHF > CH_2$). However, the presence of an unfilled π orbital in carbenes introduces its own specific features: its population also increases as a result of the interaction with the *p* electrons of the fluorine atoms. Since the interaction of the carbenes with unsaturated systems (the commonest type of reaction undergone by carbenes) probably begins with charge transfer to this orbital, the CH_2 group, in which the orbital is completely vacant, is more electrophilic than CHF. The electrophilicity of CF_2 is lower still and this carbene is one of the most selective[140].

On the other hand, the stability of the triplet states of aromatic fluoro-compounds is lower than for the analogues without fluorine. The study of laser flash photolysis of fluorobenzene has shown that the emission spectrum can be observed in the course of 250 ns (weaker approximately by a factor of two than the benzene spectrum), while the triplet state of pentafluorobenzene exists only in the course of 140 ± 5 ns.[141]

III. THE INTRODUCTION OF FLUORINE INTO ORGANIC MOLECULES

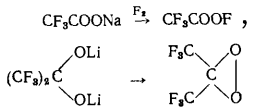
For a long time the introduction of fluorine atoms into organic molecules with the aid of an apparently natural reagent for this purpose such as free fluorine was regarded as virtually impossible in view of its extremely pronounced corrosive properties. Nevertheless, as early as 1933, the possibility of substituting by fluorine one hydrogen atom, for example in cyclohexane and carboxylic acids, or of the "fluorodimerisation" of tetrachloromethylene was demonstrated in a pioneer study by Bockemüller[142]:

$$2\,CCl_2{=}CCl_2 + F_2 \rightarrow FCCl_2CCl_2CCl_2CCl_2F\,, \qquad (17)$$

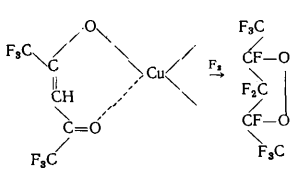
(subsequently this reaction was developed in detail for fluoro-olefins[143]); fluorination by free fluorine has not found extensive applications.

Only in recent years a number of reports have been published indicating the possibility of successful fluorination without degradation even of systems containing heteroatoms. Thus interesting peroxide compounds can be synthesised with the aid of fluorine[144,145]:

$$CF_3COONa \xrightarrow{F_2} CF_3COOF\,, \qquad (18)$$



(19)



(20)

Fluorine atoms have been introduced successfully into the α-position with respect to the nitro-group by treating salts of nitro-compounds with fluorine (see Nagase's review[146]).

Direct fluorination shows promise of wide scale applications also in the synthesis of fully fluorinated fluoroalkanes and their derivatives used in practical applications. The reactor with a highly efficient heat elimination system, which has been developed for this process, makes possible exhaustive fluorination of complex compounds such as $(CH_3)_3C{-}C(CH_3)_3$,[147] $CH_3OCH_2CH_2OCH_3$,[148] or *m*-carborane[149]. The reaction is not accompanied by degradation and the yield of desired products is extremely high in the second and third instants.

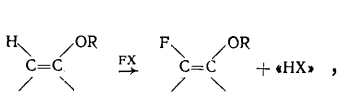
Fluorination by elemental fluorine is evidently a free-radical process. Its extremely high exothermic heat is associated with certain characteristics of the fluorine molecule, in particular with its low dissociation energy (37 kcal $mole^{-1}$ compared with 58 kcal $mole^{-1}$ for Cl_2).[150] In reactions with aromatic systems fluorine behaves as an electrophilic agent: despite the radical mechanism of the process, *ortho–para* orientation is observed predominantly for benzene containing substituents of the first kind[151-154] and *meta*-orientation for substituents of the second kind[151,152]. The selectivity of substitution characteristic of fluorine made it possible to achieve the preparative synthesis of the valuable antimetabolite 5-fluorouracil (see Section I) by direct fluorination of uracil[155].

Apart from direct fluorination, methods for the introduction of fluorine with the aid of a wide variety of fluorinating agents are widely used; in terms of their action on organic molecules, these can be divided into oxidative and non-oxidative.

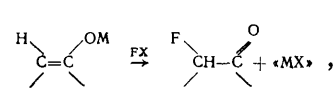
1. Oxidative Methods for the Introduction of Fluorine

The development of methods for the specific introduction of fluorine atoms is clearly important for the synthesis of fluorine-containing physiologically active substances which have been finding increasing application in recent years. The possibility of modifying finished (for example natural) structures by treatment with a fairly mild fluorinating agent is particularly valuable. A number of agents, whose activity varies over a fairly wide range, have been developed for this purpose. Thus perchloryl fluoride ($FClO_3$) has been used successfully to fluorinate steroids[156] or penicillin derivatives[157] in the presence of bases. Comparison of $FClO_3$ with CF_3OF shows that the latter acts more vigorously[156]. Nevertheless fluorine atoms have been introduced successfully with its aid into griseofulvin[158] or an anhydro-sugar[159] (see Lustig and Shreeve[160] for a review of the chemistry of hypofluorites).

The mode of substitution when such agents are employed is usually determined by the presence of an electron-donating substituent at the multiple bond:



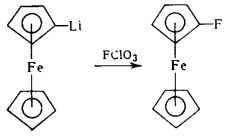
(21)



(22)

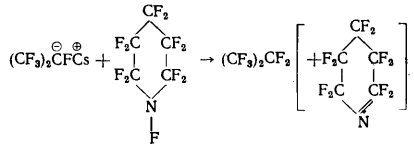
where M = Li or Na and X = OCF_3 or ClO_3.

The reaction with participation of hypofluorites frequently involves an addition–elimination stage[161]. However, direct fluorination of the anionoid centre is also possible[162]



(23)

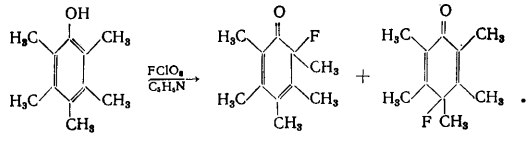
Perfluoropiperidine, a relatively weakly active agent, can act similarly (under severe conditions[163]):



(24)

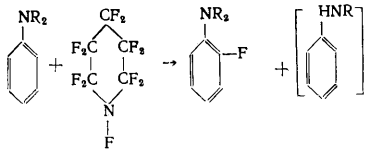
On the other hand, the activity of the bishypofluorite $CF_2(OF)_2$ apparently approaches that of free fluorine: it substitutes by fluorine the hydrogen atoms in acetonitrile or nitrobenzene[164].

Reagents of this type are used successfully also for the introduction of fluorine atoms into aromatic compounds. Thus CF_3OF substitutes one hydrogen atom in benzene or toluene. The reaction yield increases up to preparative values under the influence of intense ultraviolet irradiation. It is remarkable that the substitution in the toluene ring takes place almost exclusively in the *ortho*-position[165]. Xenon difluoride also reacts readily with benzene derivatives C_6H_5X with the preferential formation of *ortho*- and *para*-isomers for X = F, Cl, CH_3, or OCH_3 and *meta*-isomers for X = CF_3 or NO_2.[166] The formation of biphenyls is a side process. IF_4OCH_3 also shows a capacity for the fluorination of benzene rings[167]. In the fluorination by $FClO_3$ of phenols containing substituents in the *ortho*- or *para*-position, fluorodienones are formed[168]:



(25)

Perfluoropiperidine fluorinates *NN*-dialkylanilines exclusively in the *ortho*-position. Dealkylation and the formation of products of the type of Crystal Violet are side reactions[169]:



(26)

where R = CH_3 or C_2H_5.

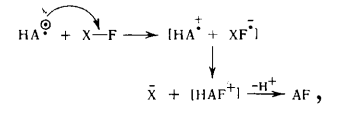
In order to account for the orientation of the reactions enumerated above, a mechanism has been put forward involving substitution of the S_N2 type at the fluorine atom in the fluorinating agent[161,163]. However, the observation by ESR of the formation of radical-cations of aromatic compounds in the course of their fluorination by xenon difluoride[166] or perfluoropiperidine[169] and also the preferential or exclusive *ortho*-orientation of the substitution reaction established in a number of instances require a more detailed examination of this mechanism. Like many nucleophilic substitution reactions (see the review of Bilevich and Okhlobystin[170]), oxidative fluorination probably involves a stage in which a single electron is transferred. Nevertheless the radical-cations which can be detected are involved in the formation of side products only[171]. The fluorination of asymmetric diphenylethylenes by XeF_2 is not accompanied by a rearrangement (of the type usual in the generation of carbonium ions from these compounds) when the reaction is catalysed by CF_3COOH:

(27)

where X = H, F, or CH_3.

In catalysis by a stronger acid (HF) there is a partial rearrangement, which is probably not related to the fluorination process ($C_6H_5COCHXC_6H_5$ is formed)[172].

Thus fluorination can probably be regarded as a cage process, which involves the abstraction of a fluorine atom from the radical-anion formed by the molecule of the fluorinating agent. The process can be represented in the general form as follows (its outcome is indeed "substitution at the fluorine atom"):

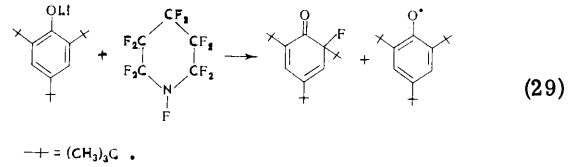


(28)

where HA is the fluorinated substrate with a lone electron pair and HF is the fluorinating agent.

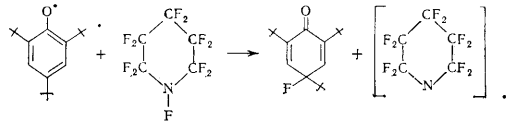
The following facts support this mechanism: if the potassium salt of nitroform is fluorinated by $FClO_3$ in the cavity of the ESR spectrometer in the presence of a radical "trap" (t-butylphenyl nitrone), radicals are formed as a result of the addition of both $(O_2N)_3C^{\cdot}$ and $F^{\cdot}$ to the nitrone. Consequently, the radical-anion $FClO_3$, capable of losing the fluorine atom, is formed after electron transfer[173].

Lithium 2,4,6-tris-t-butylphenoxide is rapidly fluorinated by perfluoropiperidine in the *ortho*-position:



(29)

A stable phenoxy-radical is formed as a side product; it cannot be an intermediate in the *ortho*-fluorination process, since it reacts very slowly with perfluoropiperidine (in the *para*-position):



(30)

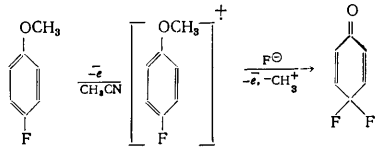
Thus *ortho*-fluorination is probably a process occurring within a cage and *para*-fluorination is a free-radical reaction[174]. The mechanism described is probably common for processes involving "anomalous" electrophilic substitution in aromatic compounds, leading to the preferential formation of *ortho*-isomers (see Pearson's review[175]).

The formation of radical-cations is probably a stage also in the fluorination by traditional agents such as the fluorides of metals in the highest valence state. Quantum-mechanical calculation has shown that the one-electron pathway in the fluorination of C_6F_6 under the influence of CoF_3 is more favourable on energy grounds than direct abstraction of a fluorine atom to an extent of the order of

50 kcal mole^{-1}.[136] Fluorination by lead tetra-acetate in HF is accompanied (as in the case of XeF_2 + HF) by a rearrangement of 1,1-diphenylethylene[176]:

$$(C_6H_5)_2C{=}CH_2 \xrightarrow[HF]{Pb(OCOCH_3)_4} C_6H_5CF_2CH_2C_6H_5 . \qquad (31)$$

The electrochemical generation of radical-cations of aromatic compounds in the presence of the fluoride ion also leads to the introduction of fluorine into the ring. Under these conditions, trifluoromethylbenzene is then substituted in the *meta*-position[177] and fluorobenzene is substituted in the *para*-position[178]. 4,4-Difluorocyclohexadienone is formed from *p*-fluoroanisole[179]:



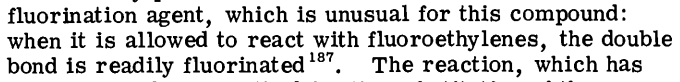
(32)

A similar mechanism may obtain also in the electrochemical fluorination of organic compounds in hydrogen fluoride[180], which is one of the most important industrial methods for the preparation of fully fluorinated organic compounds.

The widely used method for the introduction of fluorine into aromatic systems, involving the decomposition of solid diazonium salts containing the HF_4^-, PF_6^-, and SbF_6^- anions (Schiemann reaction, see Sushitskii's review[181]) probably also involves a one-electron transfer stage like the majority of typical reactions of diazo-compounds[182]. One of the most recent preparative versions of the Schiemann reaction, the photochemical decomposition of diazonium salts, frequently ensures a higher yield of aromatic fluoro-compounds than thermal decomposition[183].

The elimination of CO from benzoyl fluorides catalysed by rhodium complexes[184], the thermal elimination of SO_2F_2 from $C_6H_5OSOF_3$,[185] and also the elimination of groups such as SO_2 from $ArSO_2F$, CO_2 from ArOCOF, or COS from ArSCOF also leads to the introduction of fluorine into the aromatic ring. Examples of reactions of the latter type and also of the action of the fluoride ion on the diaryliodonium cation have been given in a patent[186] devoted to various methods for the synthesis of 4-(4′-fluorophenyl)-salicylic acid. This patent constitutes a kind of compilation of the modern methods for the introduction of fluorine into the benzene ring.

Antimony pentafluoride can behave as an oxidative fluorination agent, which is unusual for this compound: when it is allowed to react with fluoroethylenes, the double bond is readily fluorinated[187]. The reaction, which has been patented as a method for the substitution of the "residual" hydrogen by fluorine in hexafluoroepoxypropane oligomers, may also involve a stage in which the intermediate olefin is fluorinated[188]:



(33)

2. Non-Oxidative Methods for the Introduction of Fluorine
