The extraction of complexes in the presence of hydrophobic organic bases is especially important in analytical chemistry. Studies have shown, for example, that the chelate complex of molybdenum and catechol can be extracted from the aqueous phase by organic solvents in the presence of tetraphenylarsonium (as well as in the presence of pyridine) [87]. In this case the occurrence of extraction has been explained by a synergic effect, but the latter is based on the formation of a heteroligand complex. The use of tetraphenylarsonium as well as tetraphenylphosphonium for the extraction of niobium proved to be a fairly effective procedure. In the presence of tetraphenylarsonium niobium also forms with thiocyanate ions the heteroligand complex $[(C_6H_5)_4As]_2[NbO(NCS)_5]$, which can be extracted by organic solvents. The formation of this complex constitutes the basis of the extraction-photometric method for the determination of niobium [88]. Compounds formed by dioctylaminoethanol (DOAE) and fluoride ions with niobium or tantalum are similarly extracted by chloroform as $(DOAE)_2[NbOF_5]$. [89]

In particular complexes of the type $MX_mY_n^0$ or $[MX_m(RY)_n]^0$, where Y is the organic base, can be formed in the extraction process. Whereas in the former case Y provides an electron-donating atom for the formation of an electron pair, coordinating the metal ion, in the latter case Y enters into the association complex in the form of an 'onium compound. Anionic complexes which become capable of forming hydrates by combining with the SO_3H

group form solvates with ammonium, arsonium, or phosphonium cations and are extracted in the form of associated ionic species. A number of extraction-photometric methods based on the extraction of these two types of heteroligand complexes are described below.

In combination with diphenylguanidine, the chlorosulphophenol described above has been used in the extraction-photometric determination of niobium with the aid of 1-butanol. Iron, molybdenum, and zirconium are bound by thioglycolic acid and the complexone [90].

The extraction of complexes containing sulpho-, carboxy-, or hydroxy-groups is based on the fact that alkyl- and aryl-amines and their salts form with niobium complexes substituted ammonium salts (R_3NR) which are readily extracted. Thus heteroligand complexes which are extracted by chloroform are formed in the niobium–salicylic acid–organic base systems [91].

An extraction-photometric method has been proposed for the determination of niobium in the presence of tantalum, titanium, uranium, zirconium, iron, and tin; it is based on the formation of a 1 : 2 : 2 extractable heteroligand complex with SCN^- ions and pyrrolidinedithiocarbamate [92].

The usual catechol and pyrogallol methods for the determination of niobium have been improved by the extraction of polyphenol complexes of niobium in the presence of quaternary ammonium bases having a long hydrocarbon chain, with a consequent sharp increase of the sensitivity of the determination of niobium [93,94]. The influence of tantalum, which is also extracted by the above reagents, was eliminated by selecting optimal conditions. Best results were achieved in the extraction of niobium by polyethoxy-15-stearylmethylammonium chloride [Ethoquad 18125].

A large group of niobium complexes containing two organic reagents, one of which forms with niobium a soluble inner complex and the other a sparingly soluble complex, has been investigated [95,96]. The following compounds (with 1 : 2 : 2 component ratios) are of interest: niobium–pyrrolidine dithiocarbamate–catechol, niobium–BPHA–catechol, niobium–BPHA–pyrrogallol, niobium–cupferron–catechol, and niobium–catechol–diantipyrinylpropylmethane. The compounds are almost completely extracted by chloroform. The method is also interesting because niobium can be determined in the presence of a 20-fold excess of titanium and tantalum. The molar extinction coefficient is $\epsilon = 1.4 \times 10^4$.

The extraction of a number of metals forming heteroligand complexes with Arsenazo I and diphenylguanidine has been studied [97,98]. Niobium, tantalum, titanium, zirconium, hafnium, and thorium can be extracted from acid solutions by pentyl, isopentyl, and butyl alcohols; iron, aluminium, beryllium, scandium, yttrium, lanthanum, and copper can be extracted from weakly acid and neutral solutions. The extraction of niobium and a number of other elements in the form of heteroligand complexes which they form with *o*-carboxy-, *oo'*-dihydroxy-, and hydroxyazo-compounds (Acid Chrome Dark-blue, Eriochrome Black T, Magneson, Acid Chrome Red, and others) and organic cations has been investigated [99]. The extraction takes place over a wide pH range. It has been suggested that ionic association complexes in which inner complexes behave as anions are extracted.

The heteroligand complexes of a large group of metals, including niobium, with Chromazurol and diphenylguanidine are readily extracted and permit the determination of many elements with a high sensitivity [100,101]. Peroxo-complexes of niobium and tantalum react with oxalate ions to form compounds which can be extracted by trioctylamine [102]. Niobium and tantalum can be separated in this way from iron, titanium, manganese, vanadium, aluminium, and other elements. Trioctylamine and certain *N*-substituted amines have been used in inorganic acid solutions for the separation of niobium and tantalum by extraction using chloroform [103–105].

An extraction-photometric method, based on the formation of a heteroligand niobium complex with catechol (CA) and thenoyltrifluoroacetone (TTFA) in the proportions Nb : CA : TTFA = 1 : 2 : 3, which can be extracted by chloroform, has been developed for the determination of niobium. The complex absorbs at 414 nm ($\epsilon_{414} = 7.7 \times 10^3$) and the sensitivity is 2 μg/ml Nb. [106] It was shown recently that mixed niobium–catechol–phenylbenzoylpyrazolone and niobium–thiocyanate–phenylbenzoylpyrazolone complexes with component ratios of 1 : 2 : 1 are readily extracted by organic solvents [107].

The extraction of heteroligand organic complexes of niobium and tantalum by oxine in chloroform [108] or by isobutyl methyl ketone from citrate and chloride solutions and also by 50% solutions of tributyl phosphate in chloroform or cyclohexane [109] is used in the radiometric analysis of tantalum–niobium preparations.

It was pointed out above that quaternary heteroligand complexes are used in spectrophotometric analysis, particularly when extraction processes are resorted to. A typical example is provided by the extraction of niobium in the form of a heteroligand complex with Catechol Violet (CV), pyridine, and potassium bromide [110]:

$$2Nb(OH)_2^{3+} + PyH^+ + H_3CV^- + 3Br^- \rightarrow \{[Nb(OH)_2]_2CVPyH\}^{3+}Br_3^- + 3H^+.$$

In this compound pyridine is bound to the sulpho-group of Catechol Violet, and Br^- is an outer-sphere anion, which neutralises the positive charge of the complex formed. A quaternary system is produced with the component ratios Nb : CV : Py : Br = 2 : 1 : 1 : 3. The coloured compound is formed immediately after mixing the solutions and remains stable for 32 h. The coloured solutions obey Beer's law in the presence of 15–100 μg of niobium in 25 ml ($\epsilon = 3 \times 10^4$).

2. EXTRACTION-PHOTOMETRIC METHODS FOR THE DETERMINATION OF TANTALUM

The extraction-photometric methods for the determination of tantalum are based on the use of heteroligand ionic association complexes. Such association complexes are formed when tantalum fluoride complexes interact with basic dyes. The coloured heteroligand complexes formed can be extracted by inorganic solvents, such as benzene, toluene, xylene, chloroform, etc. Under certain conditions, the pure dye is hardly extracted by these solvents. The formation reactions of the extractable ionic association complexes are fairly sensitivity and specific. The following dyes are used as the reagents: triarylmethane dyes (Methyl Violet, Brilliant Green, Crystal Violet, Malachite Green, etc.), xanthene dyes (Rhodamine 6G, Rhodamine S, and Rhodamine 3B), oxazine dyes (Nile Blue, Meldola's Blue, New Blue, etc.), and thiazine dyes (Methylene Blue, Methylene Green, etc.). In the association complexes formed tantalum in the form of the negatively charged fluorotantalate ion substitutes the acid residue (Cl^-, HSO_4^-) in the dye. A number of studies have been made on the use of triarylmethane dyes (TAMD) and xanthene dyes for the determination of tantalum in various materials. These procedures have been reviewed in detail in a monograph [28].

Recently much attention has been devoted to the problem of the mechanism of the formation of association complexes of fluorotantalate with triphenylmethane dyes (TPMD). Most investigators tend to regard the complex anion TaF_6^- as the reactive species in the interaction of fluoride solutions of tantalum with TPMD.[111,112] Elemental analysis of the organic phase in the extraction of the fluorotantalate of Brilliant Green with chloroform established that the compound extracted has the formula $RTaF_6$,[113] where R is the cation of the basic dye. This was confirmed in other investigations.

It was suggested previously that the extractability of ionic association complexes depends on the charge, the relative dimensions of the anion and cation, and the presence of hydrophobic groups in one or both ions. The ratio of the charge to the number of atoms in the ion was proposed as a criterion of extractability. The extractability of the association complex should improve with decrease of "the specific charge". Lomonosov and coworkers[114-117] demonstrated the inadequacy of these ideas, which fail to take into account the individual characteristics of the cation and anion structures. They showed that the overall effective positive charge in the region of the dye cation involved in association can serve as a criterion governing the choice of TAMD for extraction. It was suggested that the part of the cation bounded by the two most basic parts of the dye is responsible for association. The substituents in the amino-groups in the *para*-positions relative to the central carbon (or nitrogen) atom play an important role here. The presence of such substituents leads to an increase of the positive charge at the ends of the molecule and to the stabilisation of the ionic association complexes formed by the reagent with these substituents. Two reagents of the group of oxazine dyes proposed recently for the extraction-photometric determination of tantalum can serve as typical examples, namely Capri Blue[118] and Meldola's Blue[119]. With Capri Blue, which contains a much greater number of substituents than Meldola's Blue, a more stable structure is produced: the fluorotantalate interacts simultaneously with two substituted groups and this is accompanied by a greater localisation of the positive charge than in Meldola's Blue.

The basicity of the dye, which in the case of TAMD is determined by the electron density at the central carbon atom, can serve as a criterion of the extractability of ionic association complexes. The extractability of TPMD increases steadily in the series Crystal Violet < Malachite Green < Brilliant Green, i.e. with increase of the overall positive charge on two dialkylamino-groups. In extraction at high pH values the conversion of the ionic form of the dye into a carbinol is very important, while at high acidities (2 M H_2SO_4) the influence of protonation becomes more marked. In the case of Brilliant Green, which has more positive electron-donating groups than Malachite Green, this factor has a decisive influence on the extraction. Brilliant Green proved to be the most sensitive dye in the TPMD group and has recently been used widely not only for the extraction-photometric determination of tantalum[28,120,121] but also for the extraction-gravimetric determination of large amounts of this metal[122].

The assortment of reagents used in the form of ionic association complexes with fluorotantalate has been greatly extended during the last 5–6 years as a result of the employment of thiazine dye cations, namely those of Methylene Blue and Methylene Green[123], dimethylthionine, trimethylthionine, and Toluidine Blue[124,125].

The use of oxazine dyes (Capri Blue, Meldola's Blue) has already been discussed[118,119]. Studies are being continued on the Rhodamines (Rhodamine 6G) and the TPMD group is being expanded as a result of additions to the TAMD group—Victoria Blue 4R and B[126] and others. The association complex formed by fluorotantalate and tetra-n-pentylammonium bromide $[(C_5H_{11})_4N][TaF_6]$, is used for the gravimetric determination of tantalum[127].

IV. HETEROLIGAND COMPLEXES IN TITRIMETRIC AND GRAVIMETRIC METHODS FOR THE DETERMINATION OF NIOBIUM AND TANTALUM

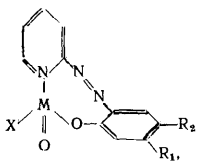
Classical gravimetric and titrimetric methods involving complex processes for the separation of niobium and tantalum and their separation from other elements do not meet modern requirements for production control and only spectrophotometric methods employing organic reagents are widely used nowadays. Nevertheless, as a result of the application of heteroligand complexes, gravimetric and volumetric methods for the determination of niobium and tantalum are again resorted to, albeit not very frequently. The methods where the precipitants are quaternary ammonium and tetraphenylarsonium salts, which permit the development of highly selective and sensitive gravimetric procedures, are of special interest. Thus a method has been devised for the precipitation of niobium or tantalum from fluoride solutions (1–8 M) with the aid of tetraphenylarsonium chloride, which permits a quantitative separation of these elements from those in adjacent Groups: tungsten, molybdenum, titanium, and zirconium[128].

Niobium can be separated from tantalum in the form of the complex $[Fe(o\text{-phen})_3][NbO_2(C_4H_4O_5)_2]$ with the aid of ferroin in a solution containing tartrate ions; a gravimetric method for the determination of niobium has been developed on this basis[129]. In the presence of H_2O_2 niobium forms with complexones (ethylenediaminetetraacetate and nitrilotriacetate) ternary complexes with the component ratios Nb : H_2O_2 : complexone = 1 : 1 : 1. Optimal conditions for the existence of these complexes obtain at pH 2–7. In the titrimetric determination niobium peroxide is titrated with nitrilotriacetic acid using Xylenol Orange as an indicator[130]. Owing to the low stability of niobium complexonates, complexometric methods cannot be regarded as sufficiently accurate.

---o0o---

In the theory and practice of the application of heteroligand complexes there are still many obscure and unsolved problems, which are particularly complicated in the analytical chemistry of niobium and tantalum, bearing in mind the complexity of their ions and compounds and their unusual behaviour when present jointly in solutions and in the presence of other metals and organic ligands. Koch and Ackermann[131] showed in a number of instances that the addition of an auxiliary complex-forming agent leads to an appreciable improvement of the reproducibility of the photometric reactions. In particular, referring to a study of niobium–tartrate–PAAC ternary complexes by Elinson and Mal'tseva[55], they suggest that the formation of the heteroligand complex plays an important role in the suppression of the hydrolysis of niobium. The auxiliary ligand can also influence the kinetics of the complex formation reactions and can promote the formation of coloured ions by reaction with the metallochromic indicator.

It has been shown[56] that the niobium complexes formed with pyridylazo-compounds and tartrate or oxalate ions have the following structure:



where $X=C_4H_4O_6^{2-}$ or $C_2O_4^{2-}$;

$R_1=-OH, -N\langle^{H}_{C_2H_5}$ or $-N\langle^{C_2H_5}_{C_2H_5}$;

and $R_2=-H, \quad -CH_3$.

This structure of the complex, involving the formation of the two most probable stable five-membered rings, is justified from the standpoint of the energy state of the system. It has been stated in the literature that in the synthesis of heteroligand complexes five- and six-membered complexes are formed in most cases. Accurate measurements of the dependence of the stability of the complexes on the number of rings formed have not so far been made in relation to binary systems. The number of experimental data is still less adequate for the solution of this problem in relation to heteroligand complexes.

The affinity of the metal ions for specific electron-donating atoms of the complexing agents (usually for O, N, and S) found for binary chelates applies also to heteroligand complexes, but in this case account must be taken of the more complicated interaction with the third component.

Studies have shown[28] that compounds containing hydroxypyridylazo-, *oo'*-dihydroxyazo-, and complexone groups are the most sensitive and selective reagents for niobium. These groups, which are involved in colour reactions with the niobium present in heteroligand complexes, contain two OH groups in the *ortho*-position relative to the azo-group (*oo'*-dihydroxyazo-compounds) or one OH group with the heterocyclic nitrogen atom playing the same role as the second OH group (pyridylazo-compounds), while in compounds containing complexone groups, which play the role of azo-groups, there are two OH groups in the *ortho*-positions in relation to them.

Sensitive colour reactions with niobium are undergone only by those reagents which contain, apart from ring-forming groups, also auxochromes; many electron-donating and electron-accepting substituents, frequently in the *para*-position relative to the azo-group, behave as auxochromes.

The most sensitive and selective reagents for tantalum are those capable of forming heteroligand complexes in the form of associated ionic species with fluorotantalate. These include basic triarylmethane dyes and their analogues.

Studies on heteroligand niobium and tantalum complexes with the above groups of reagents led to the development of precision methods for the determination of niobium and tantalum in various materials in the presence of many elements without their separation.

Reactivity and Transmission of Electronic Effects in Bridged Bicyclic Systems

L.M.Litvinenko, R.S.Popova, and A.F.Popov

Analysis of data for the transmission of electronic effects in various biaryl systems has shown that the introduction of a bridge group between two benzene rings can both weaken and enhance the interaction between a substituent and a functional centre located in different rings. The nature and mechanisms of the enhanced transmission of electronic influences in bridged systems, called the positive bridge effect (PBE), have been examined and the principal conditions for the manifestation of PBE have been formulated.
The bibliography includes 192 references.

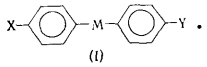
I. INTRODUCTION

Extensive experimental data have now accumulated whose interpretation led to the discovery of certain general relations between the structure and properties of organic substances, which are very important for a quantitative theory of organic reactions [1-9]. The corresponding relations for benzene derivatives have been established from a large amount of data [1-6], but more complex systems have so far been inadequately studied. Investigation of aromatic compounds, which can be represented by structures of type (I), is of undoubted interest for the elucidation of quantitative relations governing the transmission of electronic effects in extended molecular systems:



(I)

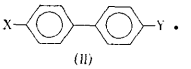
Here X is a substituent which influences the functional group Y and M is a bridge which consists either of a carbon-containing group ($-CH_2-$, $-CH_2-CH_2-$, $-CH=CH-$, $-C\equiv C-$, etc) or a heteroatomic unit (-O-, -S-, -Se-, -NH-, -N=N-, etc).

These compounds are now the subject of very comprehensive studies directed to the elucidation of both their detailed properties and the transmission of electronic effects in their molecules. Various chemical (determination of thermodynamic constants, kinetic measurements, and polarography) and physical (electron diffraction, ultraviolet, infrared, and Raman spectroscopy, NMR, and ESR) methods have been used for the solution of these problems. It is noteworthy that the experimental results themselves and their interpretation in various studies are sometimes contradictory. We therefore believe that it is extremely desirable to compare and discuss together the entire data concerned with the present problem.

It is important to note that compounds of type (I) are now used in a wide variety of fields of practical organic chemistry: in the manufacture of semiconductor materials [10], dyes [11], and physiologically active substances in pharmaceutical preparations [12-14], for the preparation of polymeric materials and their stabilisers [15,16], in the synthesis of reagents for analytical chemistry [17], etc.

II. THE BIPHENYL SYSTEM

The non-bridged biphenyl system (II) is interesting because it can serve as a standard for the comparison of transmission efficiencies in the series of bridged bicyclic systems (I).



(II)

When the problem of the reactivity of biphenyl derivatives was considered, it was initially assumed that the benzene rings act independently in the chemical sense: substituents in one ring do not influence the chemical reactivity of the other ring [18,19]. This conclusion was reached almost exclusively on the basis of the directing influence of substituents in biphenyl and its derivatives in electrophilic substitution reactions. However, this postulate was disproved by the results of Berliner and Blommers [20], who showed in a study of the dissociation of various derivatives of biphenyl-4-carboxylic acid that there is a relation, described by Hammett's equation, between the dissociation constant of the carboxy-group in one benzene ring and the electronic nature of the substituent in the other.

Systematic studies on the transmission efficiencies of biphenyl and other extended molecular systems have been made [21-32], the transmission efficiency being estimated from data for the reactions of the corresponding amines [Y = NH_2 in (I) and (II)] with *p*-nitrobenzoyl chloride (PNBC) and picryl chloride (PC) in benzene. These reactions are interesting because they are extremely sensitive to structural changes in the molecule of the amino-derivative (the ρ^0 for substituted anilines in the above reactions are respectively -3.10 [21,22] and -4.98 [21,23,34]).

Table 1. Transmission coefficients in benzene and biphenyl systems.

No.	Reaction series[a]	X-C$_6$H$_4$-Y standard ρ_{st}	System (II) ρ	System (II) π'
1	ArCOOH ⇄ ArCOO$^-$ + H$^+$; 20°, 50% butylcellosolve-water[20,35]	1.32	0.49	0.37

[a]Here and henceforth the reactions of compounds Ar − Y are considered, Ar being groups corresponding to various derivatives of the standard and given systems (in the present instance X−C$_6$H$_4$ and X−C$_6$H$_4$−C$_6$H$_4$). [b]The coefficient π' was calculated for the *p*-terphenyl system relative to the biphenyl system. [c]Determined from two points for X = H and NO$_2$.

The constants ρ for various reactions involving biphenyl derivatives are presented in Table 1, which includes for comparison the analogous quantities for similar reactions of benzene derivatives. Comparison of the results makes it possible to estimate the transmission efficiency of the system as its length is increased by one benzene ring. The coefficient of transmission of electronic effects $\pi' = \rho/\rho_{st}$ (or ρ^0/ρ^0_{st}), where $\rho(\rho^0)$ is the transmission efficiency in the given system and $\rho_{st}(\rho^0_{st})$ the transmission efficiency in the standard system, is used to characterise quantitatively the above change. It was found that regardless of the nature of the reaction series and its sensitivity to the influence of the substituents (the values of ρ for benzene derivatives vary in the range from +2.88 to −4.98), the second benzene ring invariably decreases the effectiveness of the substituent approximately by a factor of three ($\pi'_{av} = 0.31 \pm 0.01$). A similar change in the transmission of electronic effects has been observed also following the introduction of a third benzene ring (on passing from biphenyl to terphenyl; Table 1, No. 7).

The steric structure of the system can influence significantly its transmission efficiency. A convincing illustration of this is provided by the study of the reactivity of compound (II) with Y = NH$_2$, containing in addition two pairs of permanent substituents in the 3,3′- and 2,2′-positions (reactions with PNBC in benzene at 50°C)[22,23,25-30]. 3,3′-Substituents are known to have little influence on the steric disposition of the benzene rings in biphenyl[52-54] and $\rho = -1.30$ is therefore found to be almost equal to that for system (II) ($\rho = -1.34$). On the other hand, the introduction of 2,2′-substituents of different types increases the dihedral angle φ (the angle between the planes of the benzene rings) from 35–40°[55-59] to about 90°[52-54], which decreases the transmission of effects in the biphenyl system containing 2,2′-substituents such as Cl, Br, CH$_3$, CH$_3$OCO, and i-C$_3$H$_7$OCO approximately by a factor of 1.5 ($\rho \simeq 0.92$). A similar result was obtained also for the introduction of a single bulky substituent in the 2-position, as shown by the basicities of 4-aminobiphenyl ($\rho^0 = -0.52$) and 4′-amino-*o*-terphenyl ($\rho^0 = -0.35$†)[60] derivatives in 50% aqueous ethanol at 20°C.

A study of the same reaction of similar aminofluorene derivatives [Y = NH$_2$ in (II); the 2,2′-positions are linked by methylene units], where the system is coplanar, showed that the transmission efficiency ($\rho = -1.65$) is in this case only 20% higher than in compounds of this type (II)[22,29]. This suggests that the increased planarity of the system entails hardly any increase in its transmission efficiency, since on taking into account the second pathway for the transmission of effects (via the methylene unit) one would expect an increase of ρ approximately by 50% (see the transmission efficiency of diphenylmethane‡ in Table 2). The insignificant influence of the coplanarity of the benzene rings in the fluorene system on the transmission of electronic effects is indicated also by other data[45,46,61].

Apart from the above investigations, undertaken to estimate the transmission of electronic effects via the molecular system of (II) from reactivity data (Table 1), there have also been studies where attempts were made to solve the above problem with the aid of, for example,

†We calculated ρ^0 from the literature values[60] using $\sigma^0_{p\text{-}NO_2} = 0.73$.

‡It is assumed to a first approximation that the transmission efficiencies of the 3,3′- and 4,4′-diphenylmethane systems are approximately the same.

measurements of dipole moments, polarographic reduction (oxidation) half-wave potentials, and ESR, NMR, ultraviolet, and infrared spectra of the corresponding compounds.

Comparison of the dipole moments of 4- and 4,4′-substituted biphenyls revealed[62-64] that there is an appreciable interaction between substituents of different electronic types, which is somewhat reduced compared with the corresponding interaction in benzene. However, it is fairly difficult to estimate quantitatively this weakening from the results of the above studies owing to the difficulty of allowing for different kinds of structural factors (configuration of the system, distance between the substituents), which influence the measured dipole moments. This is even more difficult in systems (I) which will be considered below. Therefore in the present review we shall not deal with these investigations in detail.

The study of the polarographic reduction of various 3′- and 4′-derivatives of 4-nitrobiphenyl to the corresponding radical-anions[65,66] and of their ESR spectra showed that the influence of substituents on their first half-wave potential ($E_{1/2}$) and on their spin densities is satisfactorily consistent with the Hammett equation. Comparison with the analogous results for nitrobenzene derivatives indicates a decreased transmission of electronic effects in the bicyclic system compared with the monocyclic system. A similar conclusion was reached also in a study of the polarographic reduction of a number of 4′-derivatives of 4-acetylbiphenyl.[67] However, we believe that data of this kind should be treated with caution, since it is not altogether clear to what extent the quantity ρ can characterise in this case the transmission efficiency of the system. The point is that in polarographic reduction the electron enters the first vacant orbital of the entire molecule and is only then localised in a particular fragment of the latter. For this reason, the system as a whole must be considered as the reaction centre[68,71]. Therefore the experimental results for the polarographic reduction (oxidation) as well as the ESR spectra of substituted biphenyls probably do not characterise unambiguously§ their ability to transmit electronic effects.

To the same extent the above considerations apply also to the electronic spectra of the compounds. Although numerous studies have been made of the spectra of biphenyl and its various derivatives[72-76], one may conclude on their basis only whether or not there is conjugation between the fragments of the system but nothing can be inferred about the nature of the transmission of electronic effects through the system.

On the other hand, the study of both infrared and NMR spectra, where the "reaction centre" is clearly revealed, makes it possible, in principle, to derive definite information about the transmission of electronic effects in such systems. Indeed it has been established from the N–H stretching vibration frequencies in (II) (Y = NH_2)[43] that the biphenyl system transmits such influences much less effectively than the benzene system. The coefficients π', calculated from the shift of the absorption band maxima corresponding to the symmetric (ν_S) and asymmetric (ν_{as}) stretching vibrations, are 0.31 and 0.37 respectively, i.e. close to the values listed in Table 1. Unfortunately the accuracy of the above investigation is not always very high as yet, so that the experimental errors are sometimes comparable to the measured quantities. For example, in a study of the stretching vibration frequencies of the NO_2 group it was found that the difference $\Delta\nu$ between the wavenumbers of 4-nitrobiphenyl and its 4,4′-dinitro-analogue is only 1 cm^{-1}, which is actually less than the error in the determination of the wavenumbers (usually to within 2 cm^{-1}).[77] Because of this, the choice of a functional group sufficiently sensitive to the substitution is an important problem in such studies[43], since the reliability of the results depends significantly on it. Hence it follows that not all the investigations of infrared spectra are of equal value for a quantitative determination of the transmission efficiencies of the systems considered.

Comparison of the NMR spectra of a series of different benzene and biphenyl derivatives shows quite clearly the attenuating effect of the second benzene ring. This, according to ^1H NMR, this influence for the OH group in phenol derivatives (ρ = 1.54)[78,79] and 4-hydroxybiphenyl derivatives (ρ = 0.712)[80] is reflected by the value π' = 0.46. On the other hand, it is difficult to determine unambiguously the coefficient of transmission of electronic effects through the second benzene ring from the ^{19}F chemical shifts δ for the corresponding derivatives. The point is that the influence of the 4′-substituent is in this case described by the two-parameter equation[81-84]

$$\Delta\delta = \rho_I\sigma_I + \rho_R\sigma_R. \qquad (1)$$

The relation between the constants ρ_I and ρ_R, characterising the sensitivity of a series of compounds to the inductive and conjugation effects of substituents, changes on passing from one series to another. Therefore it is necessary to calculate separately the values of π' for the inductive and resonance effects on the basis of data of this kind[85-87]. It was found that the inductive transmission of effects through the second benzene ring in system (II) (π'_I) changes from 0.50 (in cyclohexane) to 0.33 (in dimethyl sulphoxide). The transmission coefficient of this ring π'_R, estimated from the ρ_R, is almost independent of the solvent and amounts to 0.15.

Thus NMR data (and in many cases infrared spectroscopic data) for benzene and biphenyl derivatives show that, on passing from the former systems to the latter, there is an appreciable weakening of the interaction between the substituent and the functional centre. This weakening is approximately equal to that found from the results of other studies (Table 1). However, there is one factor which somewhat restricts the application of spectroscopic data in a quantitative estimation of the transmission efficiency of extended molecular systems. The sensitivity of the reaction series to the influence of substituents is usually determined by comparing the measured quantities with σ constants. The latter characterise in essence[1-8] the differences between the effects of the substituent on the initial and final (or transition) states of the reaction centre. Therefore, despite the large number of successful applications (Zhdanov and Minkin[6], Chapter VII), the problem of a direct comparison of σ constants with spectroscopic data characterising only one (initial, final, or excited) state of the functional centre still remains open[84,88].

Bearing in mind all the foregoing considerations, we shall concentrate attention primarily on the results obtained in the study of equilibria or reaction rates and those of other investigations will be quoted only whenever convenient.

---

§The complexity of the situation can be illustrated, for example, by the following fact. Two straight lines with different slopes and separated by an appreciable distance have been obtained[65,66] on the $E_{1/2}$–σ correlation graph for 4′-substituted derivatives of 4-nitrobiphenyl.

6	$HON_2ArN_2OH \leftrightarrows HON_2ArN_2O^- + H^+ \leftrightarrows 2H^+ + {}^-ON_2ArN_2O^-$; 18°, H_2O [93]	−1.70[c]	−0.80[c]	0.47	−0.60[c]	0.35
		π'_{av}	0.53±0.06		0.40±0.06	

[a, b] Determined from two points for X = H and NO_2 (a) or H and NH_2 (b). [c] The difference $pK_1 - pK_2$, proportional to ρ, is quoted, since ρ cannot be calculated owing to the lack of the values of σ for the 4'-N_2OH^- and 4'-N_2O groups.

III. SYSTEMS WITH CARBON-CONTAINING BRIDGE GROUPS

The entire data referring to the transmission efficiency of bicyclic systems with carbon-containing bridges can be usefully divided into two conventional groups. One of these includes systems with bridges consisting of saturated hydrocarbon units and the other systems with bridges incorporating multiple bonds.

1. Saturated Groups

The results of studies of the transmission of electronic effects in diphenylmethane and bibenzyl systems, where the benzene rings are separated by $-CH_2-$ and $-CH_2-CH_2-$ groups, are presented in Table 2, which includes also the coefficients π' calculated for them relative to system (II), which clearly indicate the insulating role of the hydrocarbon units. The transmission coefficient of the methylene unit in diphenylmethane (0.53 or 0.58 if the extremely low value of π' for series No. 3 is excluded) proved to be somewhat higher than in aliphatic systems (0.350, [94] 0.360, [3] and 0.388 [7]). This may be due to some involvement of the σ, π conjugation of the C–H bonds of the methylene unit with the benzene rings [32,95]. However, one should bear in mind that, when the capacity of the methylene unit for the inductive transmission of electronic effects ($Z^*_{CH_2}$) is estimated from data for aliphatic compounds where the amino-group is the reactive centre (as in the majority of the series in Table 2), the coefficient increases to 0.470–0.554 [94,96,97] and becomes almost equal to π'_{av} in Table 2. The observed transmission efficiency of a single methylene unit in bibenzyl hardly differs from that in the diphenylmethane system.

The compounds considered were also investigated by other methods. The available ultraviolet spectroscopic [98–100], ESR, and polarographic [101,102] data indicate the insulating effect of the methylene units in these systems. However, for the reasons stated, such data can only yield a qualitatitive idea about the properties of these compounds in which we are interested. As regards the estimation of the transmission of electronic effects in these compounds from infrared spectra, there is a full analogy¶, as for benzene and biphenyl derivatives, with the results obtained in studies on the reactivity of the compounds [43].

The values of π' for M = $-CH_2-$ in Table 2 agree with those determined from NMR data for a series of diphenylmethane derivatives (Y = ^{19}F) [86,87,103]. Thus the coefficients π' for M = $-CH_2-$, $-CHPh-$, $-CH(OH)-$, $-CCH_3(OH)-$, $-CPh(OH)-$, and $-CCF_3(OH)-$, calculated from the ρ_I, are in the range from 0.41 to 0.55 and those calculated from the ρ_R are between 0.34 and 0.50. But, when the transmission coefficient is estimated by a direct comparison of the chemical shifts in the spectra of compounds (I) and (II), then it is found to be in the range from 0.30 to 0.62 for systems of this kind. On the other hand, $\pi' = 0.18$, determined from NMR spectra (Y = ^{19}F) [87] for the two-unit bridge group $-CH_2-CH_2-$, proved to be much lower than the value in Table 2.

2. Groups Containing Multiple Bonds

The transmission coefficients π' for bicyclic systems with unsaturated bridge units such as $-C\equiv C-$, $-CH=CH-$, $-CH=\overset{+}{N}-$, $-N=CH-$, $-N=N-$, $-C_6H_4-$, $-CH=\overset{+}{N}(CH_3)-$, and $-\overset{+}{N}(CH_3)=CH-$ (the reaction centre is to the right of the bridge and the substituent is to the left) are compiled† in Table 3.

Comparison of these data leads to the conclusion that any uncharged two-unit bridge with a multiple bond reduces the ability of the system to transmit electronic effects approximately by a factor of 1.7. Bridges containing only carbon atoms behave in almost exactly the same way as those consisting of one or even two heteroatoms (cf. the coefficients π' for the $-CH=CH-$, $-CH=N-$, $-N=CH-$, and $-N=N-$ bridges).

It is interesting that, on passing from bibenzyl, where there is a two-unit $-CH_2-CH_2-$ bridge (Table 2), to the stilbene and tolane systems, where M = $-CH=CH-$ and $-C\equiv C-$ respectively (Table 3), the influence of the substituents increases only by a factor of 1.5, although the last two compounds represent a classical instance of π, π conjugation of multiple bonds, which is interrupted in bibenzyl by the saturated bridge group.

As regards the ability to transmit electronic effects, the stilbene and tolane systems (Table 3) hardly differ

¶Data [77] where the nitro-group is used as the functional centre constitute the only exception. Here it is almost impossible to reach any conclusions owing to the low sensitivity of this centre to the effect of the substituent [43].

†The azobenzene system, which has no carbon atoms in the bridge, is considered here in view of its structural similarity to stilbene.

[a]Determined from two points for X = H and NO_2. [b]ρ_{st} estimated from the values of ρ for benzene derivatives and the coefficient π'_{av} in Table 1. [c]Since the —CH=C(CN)— group is the bridge, this result was disregarded in the calculation of π'_{av}. [d]The difference $pK_1 - pK_2$ is quoted (see footnote c to Table 2).

quantitatively from the diphenylmethane system (Table 2). On this basis, one may conclude that the familiar rule of vinylogy, according to which the electronic influence of the substituent in conjugated systems is transmitted to the reaction centre without appreciable decay (Reutov[112], p. 85) is not confirmed in quantitative studies on this problem (at least in a series of molecular systems resembling those described). This is apparently caused by the decisive role of the inductive mechanism in the transmission of electronic effects in systems of this kind.

When the structure of tolane is compared with those of stilbene and biphenyl, then, in contrast to stilbene which has a *trans*-configuration and a non-coplanar structure[113–116] and in contrast to biphenyl where the hydrogen atoms in the 2,2′-positions hinder the rotation of the benzene ring about the single bond joining them[56–58,117], the tolane system offers the smallest steric hindrance to the electronic interaction between the benzene rings on either side of the acetylene bridge, owing to its linearity and the appreciable distance between the 2,2′-hydrogen atoms[118]. However, this interaction is less pronounced in tolane than in the biphenyl system and is the same as in stilbene. This is most probably due to the fact that the carbon–carbon triple bond in organic molecules has no particular advantages over a similar double bond as regards transmission of electronic effects, despite its greater degree of unsaturation and shorter length.

The coefficient π' for system (I) with M = $-C_6H_4-$ (the *p*-terphenyl system) (Table 3) has the smallest value (0.31), which is consistent with the greatest length of the above bridge. As already mentioned, it is equal to π' for the biphenyl system relative to the benzene system (Table 1).

Data on the transmission of electronic effects in a series of bicyclic systems containing the charged bridges $-\overset{+}{N}(CH_3)=CH-$ and $-CH=\overset{+}{N}(CH_3)-$ (Table 3) require special consideration. Here the π' are significantly greater than unity (1.94 and 3.23 respectively), while the transmission coefficients for the analogous uncharged bridges —CH=N— and —N=CH— are small and virtually equal to the values for other diatomic bridges with a double bond (Table 3). The sharp increase in the transmission efficiency of azomethine bridges following the quaternisation of their nitrogen (by a factor of 4–5) was initially explained[110,111] by a transition from the non-coplanar structure of the Schiff bases, due to the competing interaction of the π electrons of one of the benzene rings both with the double bond and with the lone electron pair of the nitrogen[119–122], to the coplanar structure in the case of the charged bridges, where the above competition does not occur and the benzene ring is conjugated only with the double bond. However, this fact hardly plays a decisive role because in the stilbene, tolane, and azobenzene systems, where the conditions for conjugation are better than in the systems considered here (in the latter there is no steric interaction of the *N*-methyl group with the *ortho*-hydrogen atoms of the benzene ring), the transmission efficiency is virtually the same as in the benzylidene anil systems (cf. the values of π' in Table 3).

The enhancement of the electronic interaction of the substituent with the reaction centre in systems (I) containing unsaturated two-unit bridges relative to system (II) was also observed by Frankovskii and coworkers, who investigated the acidity of the corresponding phenol derivatives (Table 4).

The phenomenon of enhanced transmission efficiency ($\pi' > 1.0$) was observed for the first time in a study of bicyclic systems containing bridge heteroatoms (see the next Section). We shall therefore return somewhat later to the explanation of the "anomalously" high transmission efficiency (Tables 3 and 4). However, here one should note that the introduction of substituents (OH or Cl) into phenol derivatives (Table 4) in the 2- or 2′-position relative to the bridge unit, which influence the steric structure of these compounds, leads to an increase of transmission efficiency. This is manifested particularly

clearly in derivatives of 2,4-dihydroxyazobenzene, where the system becomes more coplanar as a result of the formation of an intramolecular hydrogen bond[50,124,125] and yet another pathway for the transmission of the influence of the substituent on the activity of the reaction centre appears:

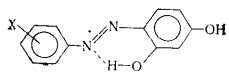

Table 4. Transmission coefficients in the azobenzene system [R and R′ are the substituents in X – (2′-R′) $-C_6H_3-N=N-C_6H_3-$(2-R)–OH-4].

5	$-CH=\overset{+}{N}H-$	1.08[d]	0.62[d]	1	—	—
6	$-\overset{+}{N}H=CH-$	1.47[d]	0.98[d]	1	—	—

[a]The number of solvents in which compounds of types (I) and (II) were investigated (average values of π' are quoted for $n > 1$). [b]Estimated by a direct comparison of the values of Δδ. [c]The chemical shift of the hydroxyl protons were measured and compared. [d]Measurements for compounds of types (I) and (II) were made in FSO_3H and CH_3OH respectively.

Table 5 shows that the transmission efficiency of the system with the –N=N– bridge (No. 4), which has been estimated from the chemical shifts of the hydroxyl protons, agrees well with the efficiency determined from different chemical data (Table 3). On the other hand, the ability of the above bridge to transmit electronic effects determined from the ^{19}F chemical shifts proved to be higher by a factor of 1.5 and its value approached that in Table 4. Hence it follows that the transmission efficiency of the bridge system depends significantly on the nature of the functional centre. The reasons for this will be discussed a little later.

Comparison of the data in Table 5 for the transmission efficiencies of systems (I) with different bridge units, estimated with the aid of the π'_I (for Y = ^{19}F), leads to the conclusion that the efficiency increases steadily on passing from the –CH=CH–, –CH=N–, and –N=CH– bridges, where it does not differ significantly from the value determined for other reaction series (Table 3), to the –N=N–, –CH=NH–, and –NH=CH– bridges. The series based on the transmission efficiency (the bridges are indicated) $-\overset{+}{C}H=CH- \simeq -CH=N- \simeq -N=CH- < -N=N- < -CH=\overset{+}{N}- < =\overset{+}{N}=CH-$ agrees well with the series found from the dissociation data for the corresponding hydroxy-derivatives (No. 6 in Table 3 and Table 4).

IV. SYSTEMS WITH BRIDGE HETEROATOMS CAPABLE OF ELECTRON DONOR CONJUGATION

1. The Positive Bridge Effect (PBE)

In studies on the transmission of electronic effects in a series of systems (I) with bridge heteroatoms on the basis of acylation reactions of the corresponding amino-derivatives (Y = NH_2), the above property was initially estimated in terms of the value of f, [21,126] which is equal to the ratio of the rate constants for the unsubstituted amine and its nitro-derivative (X = H or NO_2). The results (Table 6) show that the introduction of a bridge heteroatom with lone electron pairs between two benzene rings (Nos. 2–5) can not only weaken the electron influence of the substituent on the functional activity of the reaction centre relative to the biphenyl system without a bridge (No. 1) but can also significantly increase it. This phenomenon has been called the positive bridge effect (PBE)[129].

Table 6. The factors f (at 25°C) and ΔpK_a for systems (I) with bridge heteroatoms.

*p-nitrobenzoyl chloride (Ed. of Translation).

The first publications dealing with the manifestation of PBE [21,126,129,130] aroused a lively discussion [49,131–138], since they conflicted with the view, established at the time, that the introduction of any bridge unit between a substituent and the reaction centre must lead to the weakening of the electronic interactions between them. Furthermore, the above phenomenon was initially observed

Table 7. Transmission coefficients in systems (I) with bridge heteroatoms (M).

			π'_{av}	1.06±0.05		1.23		1.30±0.06		1.37±0.11		1.73±0.13

[a], [b], [c], [d] Determined from two points for X = H and NO_2 (a), H and NH_2 (b), NH_2 and NO_2 (c), or NH_2 and $\overset{+}{N}H_3$ (d). [e] ρ^0_{st} was estimated from ρ^0 for benzene derivatives and the coefficient π'_{av} in Table 1. [f] The difference $pK_1 - pK_2$ is quoted.

only for certain properties (nucleophilic reactivity and basicity) of bridged amino-compounds (Table 6) and was not confirmed when other characteristics of the same substances (for example ultraviolet and Raman spectra) were considered[132,133]. However, it was found subsequently that an enhanced transmission efficiency is observed not only for the bridges listed in Table 6 but also for others (Table 4 and 5) when a large number of compounds (I) are investigated.

Table 7 (Nos. 1–7) presents data on the ability of amino-compounds to transmit electronic effects estimated from the values of ρ^0. The relations governing the variation of π'_{av} thus obtained agree well with the results in Table 6. As in the previous case, the maximum transmission of electronic influences is observed for diphenylamine derivatives. On passing from the biphenyl system to methyldiphenylamine, the sensitivity of the reaction centre to the influence of the substituent increases almost by a factor of two ($\pi'_{av} = 1.73 \pm 0.13$). The systems can be arranged in the following sequence (the bridges are indicated) in terms of their ability to transmit electronic effects: $-N(CH_3)- > -NH- > -S- > -Se- > -O-$. This is consistent (see below) with the ability of the above bridge groups to be involved in electron donor conjugation (p,π interaction).

2. The Nature and Mechanism of the Manifestation of PBE

Together with the increase of transmission efficiency of systems (I) with increase of the electron-donating capacity of the bridge heteroatom[143], mentioned above, the fact that the reactivity of these compounds correlates better with the σ^0,[43,140,143–145] characterising the influence of the substituted phenyl group $X-C_6H_4$, than with the Hammett constants σ is of great importance. On this basis, one may conclude that PBE is due to a combined transmission of the electronic influence, namely simultaneously via the inductive mechanism from one ring to the other and via the mechanism based on the conjugation of the bridge heteroatom with each benzene ring. This conjugation should depend on the inductive effect of the substituted phenyl group. The possibility of a change in the conjugation effects of various groups under the influence of the inductive effects of the substituents attached to them has been confirmed by numerous linear correlations between quantities characterising these effects (Zhdanov and Minkin[6], p. 375)[81,146–150].

Some information about the nature of the conjugation of the bridge heteroatom with the benzene rings in compounds (I) can be obtained by examining their geometrical structures. The molecules of these compounds are nonlinear, since the valence angles at the bridge heteroatom are much smaller than 180°[151–155] and, in consequence of their mutual repulsion, the *ortho*-hydrogen atoms in the benzene rings move apart, forming a dihedral angle φ. Their separation can be achieved in two ways[156,157]: (1) both rings are rotated relative to the C–M–C plane by the same angle $\varphi/2$; (2) one of the rings lies in this plane, while the other deviates from it by an angle φ. The problem of which situation actually obtains still remains open. In many instances[152,153,158–161] the first version appears to be preferred. Certain properties of symmetrical bridged bicyclic compounds calculated on this hypothesis agree fairly well with experimental data[159–161].

At the same time interest has been aroused by studies where it was concluded on the basis of an investigation of microwave[156], infrared, and Raman spectra[157] and dipole moments[156,162,163] that the two rings are equivalent in phenyl ether, diphenyl sulphide (and possibly diphenylamine[156], and their derivatives, i.e. that the second situation applies. It is natural to suppose that under these conditions the bridge heteroatoms can be preferentially conjugated first with one and then with the other

benzene ring and that this transition should be fairly rapid. Therefore methods where the duration of the measurement is longer than the lifetime of one of these states will yield averaged results [164], apparently indicating the equivalence of the conjugation of the bridge atom with the benzene rings. These methods include primarily electron and X-ray diffraction measurements [151]. On the other hand, in those cases where the duration of the measurement of the properties of the substance is shorter than the lifetime of the above molecular "species" the results must indicate their existence, which is consistent with certain spectroscopic data [156,157,165,166].

The satisfactory correlation of the reactivities of various bridged compounds with the σ^0 (Table 7) indicates the absence of a direct conjugation between the substituent and the reaction centre in the compounds. On the other hand, the conjugation in (I) between M and X and between M and Y is quite possible. Therefore the results in Table 7 agree best with the view that in systems (I) the bridge heteroatom is not conjugated simultaneously with both benzene rings.

Table 8.

[a]Abbreviations: PC = picryl chloride; BC = benzoyl chloride; PNBSB = p-nitrobenzenesulphonyl bromide.

Thus the manifestation of PBE in bridged amino-compounds is to a large extent due to the ability of the unshared electrons of the heteroatom to enter into electron-donor conjugation with the electronic system of the benzene rings. The constants σ_R^+ (Table 8), which reflect the ability of the p-CH_3-M group to enter into electron-donor conjugation with substituents R via the benzene ring, can be used as quantitative characteristics.

Fig. 1 shows that, for systems with single-unit bridges, there is a definite relation (with a correlation coefficient $r = 0.97$) between their transmission coefficient π'_{av} and σ_R^+. It is interesting to note that the point corresponding to the CH_2 group, where there are no unshared p electrons, also fits satisfactorily on the overall straight line. This most probably indicates that the above bridges interact similarly with the benzene rings in compounds (I). The σ, π conjugation of the methylene group can probably play a role, albeit to a much smaller extent, analogous to that of the p, π conjugation in systems with heteroatoms. The point corresponding to the sulphide bridge in Fig. 1 also fits on the overall straight line, despite the fact that the sulphur atom has vacant d orbitals, which may be involved in conjugation [167-173]. In this case it is probable that this property of the sulphur atom is hardly manifested or contributes in any way to σ_R^+ for the CH_3–S– group.

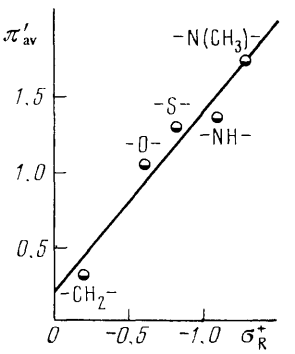

Figure 1. Variation of π'_{av} (Tables 2 and 7) for systems (I) with σ_R^+ (Table 8).

Taking into account the combined transmission of electronic influences in bridged systems, the observed value of ρ^0 for such systems should be linked with the transmission efficiency ρ_1^0 of the monocyclic system (for the same functional group and reaction conditions) by the relation (Palm [7], p. 231)

$$\rho^0 = \rho_1^0 (Z_p^* Z_M^* + \alpha Z_p^R). \qquad (2)$$

This equation reflects quantitatively the fact that the influence of the substituent in systems (I) with PBE is transmitted via both the inductive ($\rho_1^0 Z_p^* Z_M^*$) and conjugation ($\rho_1^0 \alpha Z_p^R$) mechanisms. The quantities Z_p^* and Z_M^* characterise the transmission of the inductive effect by the p-phenylene system and the M bridge, Z_p^R characterises the transmission of the conjugation effect by the p-phenylene system, and α is a measure of the change in the effect of the conjugation of the bridge group with the benzene rings due to the inductive effect of the substituent in the given reaction series.

The quantity ρ_1^0 can be obtained from the reactivities [34,35,44,174] of benzene derivatives by the equation

$$\lg k = \lg k_0 + \rho_1^0 \sigma^0 + \rho_R^+ \sigma_R^+ + \rho_R^- \sigma_R^-, \qquad (3)$$

where ρ_R^+ and ρ_R^- are constants characterising the sensitivity of the reaction series to the conjugation effect of the substituents of the type +R and –R, while $\sigma_R^+ = \sigma^+ - \sigma^0$ and $\sigma_R^- = \sigma^- - \sigma^0$.

The validity of Eqn. (2) was demonstrated using four reaction series for which the required values of ρ^0 (Table 7, Nos. 1 and 3–5) and ρ_1^0 (Table 1, Nos. 6, 8, 10, and 11) are available. Here it is important to stress that in the case of the corresponding monocyclic compounds (aniline derivatives) the effect of the electron-donor conjugation of the substituents ($|\rho_R^+| \gg 0$) [34,35,44] is shown to quite

an appreciable extent for all these series. The values of α calculated for single-unit bridge groups‡, subject to the condition that $Z_p^* = 0.11$, $Z_p^R = 0.43$, [175] and $Z_M^* = 0.40$ (Palm[7], p. 231), are listed in Table 8, which includes also the analogous data for the diphenylmethane system (calculated from the results of Table 2) and the non-bridged biphenyl system ($Z_M^* = 1.00$ according to the data in Table 1).

The α for single-unit bridges increase steadily with increasing capacity of the bridge groups for electron-donor conjugation. However, for a direct comparison of these quantities with the σ_R^+, it is necessary to subtract from them the constant α_0, which is due to the presence in the σ^0 of a resonance component equal to 0.145 σ^* (Palm[7], p. 236). The quantity $\alpha_0 = 0.145 Z_M^*/Z_p^R$ has a numerical value of 0.34 for systems (II) and 0.13 for systems (I) with single-unit bridges.

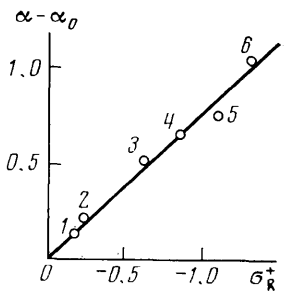

Figure 2. Variation of $\alpha - \alpha_0$ with σ_R^+ ($r = 0.99$) for the reactions of amines [Y = NH_3 in (I)] with picryl chloride. The symbols are numbered as in Table 8.

Comparison of the differences $\alpha - \alpha_0$ with the σ_R^+ (Table 8) shows that, for all the reaction series considered, there are linear relations (see the example in Fig. 2) which pass through the origin of coordinates, i.e. the relation given by the equation

$$\alpha - \alpha_0 = \beta\sigma_R^+. \qquad (4)$$

holds. It is noteworthy that the quantity $\alpha - \alpha_0$ for system (II) is positive (Table 8, No. 1) and the corresponding point in Fig. 2 fits satisfactorily on the common straight line for bridged systems. It is as yet difficult to explain this finding. However, the hypothesis that the inductive effect of the substituent influences the degree of conjugation (in the present instance the electron-donor conjugation) between the benzene rings does not lack justification.

‡It is assumed to a first approximation that the ability of the bridges to transmit electronic effects by the inductive mechanism is independent of their nature (Palm[7], p. 233). This conflicts with data on the correlation of the NMR spectra of fluoro-derivatives (Tables 5, 10, 11), for which the values of π'_I vary appreciably as a function of the nature of the bridge. The latter is probably due to the fact that, when the ^{19}F chemical shifts for such compounds are correlated, ρ_I is a more complex function than would appear from a formal examination of Eqn. (1).

Thus the results can serve as a quantitative confirmation of the above hypothesis that the influence of substituents on the functional activity of the reaction centre in type (I) amino-compounds is transmitted both by the inductive mechanism and by the mechanism based on electron-donor conjugation of the bridge heteroatom with each benzene ring. Here it is particularly significant that in the latter case the relative change in conjugation[176] under the influence of the substituent, defined by the product $\beta\sigma_R^+$ in Eqn. (4), and not its absolute magnitude, plays the principal role.

3. The Limits of the Manifestation of PBE

Since the capacity of the bridge group for electron-donor conjugation is not limitless, it follows that, as the electron-accepting properties of the substituents X in (I) become more pronounced, a situation may arise where this capacity has been completely exhausted. Subsequently the electronic influence on the reaction centre by the ring with the substituent must be transmitted preferentially via the inductive mechanism. In this case the plot of lg k against σ^0 will consist of two linear sections: one with a larger slope, where PBE is manifested, and one with a smaller slope, where there is no PBE. The abscissa (σ^0) of the break point may be designated by σ_{cr}^0 (Palm[7], p. 237).

The reactivities of 4-aminodiphenylamine with several electron-accepting substituents in the benzene ring without the reaction centre have been examined from this standpoint[177,178]. The findings agree qualitatively with the above considerations, but are somewhat complicated by the possibility of forming an intramolecular hydrogen bond between the imino-bridge and the *ortho*-substituent (nitro-group)[179-181].

More definite data were obtained in a study of the reactivities of triphenylamine derivatives with various substituents in the 4′- and 4″-positions[178,182,183]. The corresponding correlation graph, based on basicity data (Fig. 3*A*), agrees fully with the prediction. This suggests that in these systems the capacity of the bridge nitrogen for conjugation is already exhausted following the introduction of one nitro-group. On the other hand, in the reactions of these amines with *p*-nitrobenzenesulphonyl bromide (PNBSB) this situation is attained following the introduction of two nitro-groups (Fig. 3*B*), while the reaction with picryl chloride could not be achieved in the experimental $\Sigma\sigma^0$ range (Fig. 3*C*).

Comparison of the ρ^0 for different sections of the correlation graph in Fig. 3 with the analogous values for aminobiphenyl derivatives [system (II)] in the same reaction series makes it possible to estimate the ability of the bridge group to transmit electronic effects in its various states. In those cases where the capacity of the bridge nitrogen atom for conjugation has not been fully exhausted (the left-hand branches *A* and *B* and straight line *C*), PBE is clearly manifested (the π' are respectively 1.17, 1.29 and 1.24)[34,41,182]. After σ_{cr}^0 has been reached (the right-hand branch *A*), the transmission coefficient of the nitrogen atom ($\pi' = 0.21$) [178] is much smaller than for the methylene unit in system (I) (Table 2). Furthermore, it is smaller by a factor of two than the coefficient defining the capacity of this unit for transmission of electronic effects by the inductive mechanism alone (0.388). The extremely low transmission coefficient obtained for the electron-deficient nitrogen atom agrees satisfactorily

with π' for the positively charged nitrogen atom in *N*-protonated derivatives of *N*-arylglycines (0.22) [183,184] and the nitrogen atom in the amide group (0.23) [185].

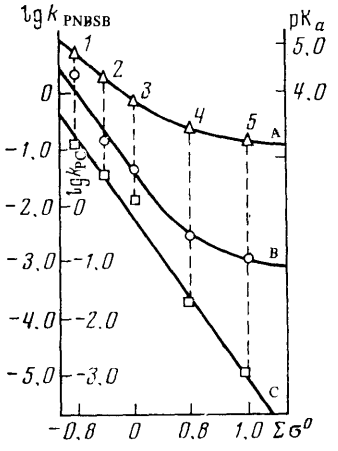

Figure 3. Variation with $\Sigma\sigma^0$ of pK_a (A) for triphenylamine derivatives [4′-X-C_6H_4-N(Ar)-C_6H_4-NH_2-4] in 45% aqueous dioxan [162] and of lg *k* for the reactions of these amines with nitrobenzenesulphonyl bromide (B) in nitrobenzene and with picryl chloride (C) in benzene [166] at 25°C; X and Ar in the formula: 1) 4′-NH_2, 4″-NH_2. .C_6H_4; 2) 4′-NH_2, C_6H_5; 3) H, C_6H_5; 4) H, 4″-$NO_2C_6H_4$; 5) 4′-NO_2, 4″-$NO_2C_6H_4$.

All these findings show that PBE can be manifested only in those cases where the reaction series investigated (for benzene derivatives as an example) is sufficiently sensitive to electron-donor conjugation [ρ_R^+ in Eqn. (3) differs significantly from zero] and the bridge group M in compounds (I) has unshared electrons capable of being involved in such conjugation.

o0o

On the basis of the principles formulated above, it is interesting to examine data describing the ability of systems (I) with bridge heteroatoms to transmit electronic effects, which have been obtained from other reaction series (Y ≠ NH_2). Since the reaction of benzoyl chloride derivatives with aniline is fairly sensitive to the electron-donor conjugation of substituents [186], the manifestation of PBE in the phenyl ether system for Series No. 8 (Table 7) becomes quite understandable. For the same reason (high sensitivity to the above conjugation [137], an enhanced transmission efficiency of systems (I) with M = –O– and –S– is observed in Series No. 9 (Table 7).

It is interesting that, in a study of the transmission efficiencies of systems (I) on the basis of acid dissociation data (Y = OH), Frankovskii and coworkers [49,50,135–137] concluded that the bridge heteroatoms have an insulating influence. At the same time their results (Table 9) show that in this case the transmission efficiency increases in the sequence (the bridges M are indicated) –O– < –S– < –NH–, while in the case where M = –NH– it virtually coincides with that of system (II). The parallel variation of the π' in Table 9 and the σ_R^+ for CH_3–M groups (Table 8) suggests that in this case the capacity of the bridge atom for electron-donor conjugation plays a significant role. Since the acid dissociation of phenols is almost insensitive to such conjugation ($\rho_R^+ = 0$) [44], it follows that the higher values of π'_{av} in Table 9 compared with the coefficient giving the transmission efficiency for a single-atom bridge solely by the inductive effect (0.388) is due to the conjugation of the bridge heteroatom with the benzene ring containing this substituent and not with the ring in which the reaction centre is located. This constitutes direct confirmation that the manifestation of PBE requires that the bridge heteroatomic group should enter into electron-donor conjugation with each benzene ring.

Table 9. Transmission coefficients in systems (I) (Y = OH) with bridge heteroatoms.

No.	Reaction series	System (II)	M=—O—		M=—S—		M=—NH—	
		ρ_{st}	ρ	π'	ρ	π'	ρ	π'

		π'_{av}	0.43±0.03		0.68±0.04 0.81±0.10[a]		0.93±0.02	

[a] The X-(2′-Cl)-C_6H_3-S-C_6H_4-Y-4 system is considered.

Comparison of the chemical shifts (Table 10) in the NMR spectra of compounds of type (I) shows that, as expected, there is no full correspondence between the series being compared. For fluorobenzene derivatives, where the chemical shift depends significantly on the effect of the electron-donor conjugation of the substituents (Zhdanov and Minkin [6], p. 375), the introduction of bridge heteroatoms between the benzene rings (Table 10, Nos. 1–3) leads to an increased influence of the substituent on the given property, i.e. PBE is clearly manifested in this instance. On the other hand, measurements of the chemical shifts due to the proton in the hydroxy-group have shown that, although the ability of bridge groups to transmit electronic effects does increase on passing from oxygen to nitrogen, it does not exceed that of system (II). As for the acid dissociation of the above compounds (Table 9), the absence of PBE in this case is caused by the insensitivity of the proton chemical shifts in the series of phenol derivatives to the electron-donor conjugation of substituents [78].

An enhanced transmission coefficient of the heteroatom ($\pi' > 1.0$) has been observed in a study of NMR spectra also in other series where the bridge heteroatom was incorporated between two π-electron systems (for example a benzene ring and a vinyl group) [171–173,188]. The transmission coefficient of the system with M = –S– then proved to be greater than for M = –O–.

The full analogy between the results obtained in measurements of the reactivities of amino-compounds

(Table 7) and the ^{19}F chemical shifts (Table 10) for compounds of type (I) with bridge heteroatoms suggests that Eqns. (2) and (4) are applicable to the latter case. Indeed, Fig. 4 shows that the relation between the α calculated from the data in Table 10 and the σ_R^+ (Table 8) is described by a straight line passing through the coordinate origin, in accordance with Eqn. (4). The point for diphenylmethane fits on the same line, as in Fig. 2. However, the point for system (II) deviates appreciably from the general line, which is probably due to the characteristic features of the transmission of electronic influences in the series of fluoro-derivatives (see below).

Table 10. Transmission coefficients estimated from NMR spectra in systems (I) with bridge heteroatoms.

No.	Bridge M in (I)	Y=^{19}F[86,103]			Y=^{19}F[87]	Y=OH[50,80]
		π_I'	π_R'	n[a]	π'	π'
1	—O—	1.00±0.01	1.08±0.01	9	1.10[b]	0.52[c]

4	—$\bar{C}$Ph—	3.34	2.86	1	—	—
5	—N=$\bar{C}$—	2.74	1.80	1	—	—

[a]The number of solvents in which bridged compounds of types (I) and (II) were investigated. [b]Estimated by a direct comparison of the values of $\Delta\delta$. [c]The chemical shifts of the hydroxyl proton were measured and compared.

The highest transmission coefficient in the series of fluoro-derivatives has been observed for the $-\bar{C}$Ph– bridge (Table 10, No. 4) bearing an integral negative charge, which maximises its capacity for electron-donor conjugation. An enhanced transmission coefficient has also been observed for the $-N=\bar{C}-$ bridge (No. 5) whose capacity for conjugation should be fairly high.

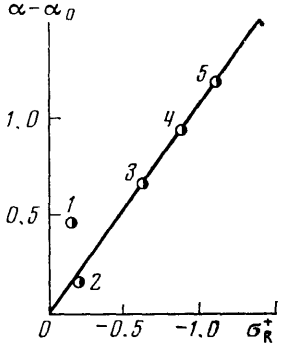

Figure 4. Variation of $\alpha - \alpha_0$ with σ_R^+ ($r = 0.99$) for systems (I) with M = $-CH_2-$ (*2*), –O– (*3*), –S– (*4*), and –NH– (*5*) and for system (π) (*1*) on the basis of NMR (Y = ^{19}F) [86,103].

Analysis of the corresponding infrared spectroscopic data for a series of benzoic acid derivatives (the C=O stretching vibration frequencies) indicates their high sensitivity to electron-donor conjugation by the substituents ($\rho_R^+ \gg 0$). This is precisely why PBE was observed in studies by this method of compounds of type (I) with Y = $COOCH_3$ and M = –O–. [145,189]

PBE was also observed in a study of the stretching vibration frequencies of N – H in compounds (I) with Y = NH_2 in the presence of bridges such as –O–, –S–, –NH–, and $-N(CH_3)-$. [43] This is fully consistent with the above considerations, since the frequencies for aniline derivatives [190] depend significantly on the capacity of the substituents for electron-donor conjugation.

Thus data derived from NMR spectra (Table 10) and infrared spectra of compounds of type (I) fully confirm the conclusions reached about the mechanisms and characteristics of the manifestation of PBE obtained in studies on the reactivities of the corresponding compounds (Tables 7 and 9).

V. SYSTEMS WITH SINGLE-UNIT BRIDGE GROUPS CAPABLE OF ELECTRON-ACCEPTOR CONJUGATION

The data examined above concerning the manifestation of PBE refer mainly to systems (I) where the bridge consists of heteroatoms capable of electron-donor conjugation. It is reasonable to suppose that, in those cases where the reaction series is characterised by a high sensitivity to the electron-accepting effect of the substituents ($|\rho_R^-| \gg 0$), PBE can also be manifested in systems (I) with bridge groups capable of electron-acceptor conjugation.

For reactions involving substituted anilines, ρ_R^- in Eqn. (3) is fairly high. This is in fact why studies on the nucleophilic reactivity of 4'-derivatives of 4-aminobenzophenone [21,191] yielded $\pi'_{av} = 0.91$ (for reactions with *p*-nitrobenzoyl chloride and picryl chloride). This shows that system (I) with M = –CO– hardly differs from system (II) in its ability to transmit electronic effects, i.e. an enhanced transmission efficiency was observed for the first time in bycyclic systems with bridge groups capable of electron-acceptor conjugation.

Subsequently enhanced transmission efficiencies of systems (I) with the above bridge groups were observed in studies of the acid dissociation of the corresponding hydroxy-compounds (Tables 3 and 4) and the NMR spectra of fluoro-derivatives (Table 5). Here it is important to emphasise that in the cases examined PBE is shown only for fairly powerful electron-accepting bridge groups and varies in the sequence $-NR=CH- > -CH=NR- > -N=N-$, i.e. in the same sequence as the electron-accepting capacity of these bridges. For groups with weaker electron-accepting capacities, such as –CH=N–, –N=CH–, –C≡C–, and –CH=CH– (Tables 3–5), the coefficients π' are appreciably less than unity.

These bridges do not show high transmission efficiencies for systems (I) (Tables 3–5), although all the reaction series examined (with the exception of Nos. 7 and 8 in Table 3) are sensitive to electron-acceptor conjugation [when data for benzene derivatives are interpreted in terms of Eqn. (3), the ρ_R^- are non-zero]. This shows that PBE is observed only after the attainment of a specific capacity of the bridge group for electron-acceptor conjugation and when the reaction centre is highly sensitive to such conjugation. This is confirmed also by measurements of the transmission coefficients of systems (I) with M = $-SO_2-$. Whereas according to the dissociation data for 4-hydroxy-derivatives $\pi' = 1.24$ in the

diphenyl sulphone system[50] (i.e. PBE is clearly manifested), the study of the nucleophilic reactivities of the corresponding 4-amino-derivatives with respect to picryl chloride in nitrobenzene showed that $\pi' = 0.68$ (PBE not observed)[192].

Since the NMR spectra of fluorobenzene derivatives are fairly sensitive to both electron-donor and electron-acceptor conjugation (Zhdanov and Minkin[6], p. 375), it is quite reasonable that, in NMR studies of compounds of type (I) (Y = ^{19}F), PBE is observed for both electron-donating (Table 10) and some electron-accepting (Table 5) bridge groups. As already stated, in the latter case, PBE is not observed in all cases but only for the most electron-accepting bridges§. This hypothesis is confirmed particularly clearly by the data in Table 11, where the transmission coefficients for bicyclic systems with single-unit bridges increase steadily as the electron-accepting properties of the bridge group and its capacity for electron-acceptor conjugation become more marked, reaching a maximum value ($\pi'_I = 13.9$) for the powerful acceptor $-\overset{+}{C}(CF_3)-$ (No. 11).

Table 11. Transmission coefficients estimated with the aid of NMR in systems (I) with single-unit electron-accepting bridges.

[a]Estimated by a direct comparison of the values of $\Delta\delta$.

Unfortunately, owing to the lack of $\sigma_{\bar{R}}$ constants, characterising the capacity of the CH_3-M- groups for electron-acceptor conjugation, it was not possible to interpret the data considered in the present section in terms of equations analogous to Eqns. (2) and (4).

It is interesting that the coefficients π'_R calculated from the corresponding ρ_R constants increase in parallel with increase of the π'_I (Tables 5, 10, and 11). The reasons for the observed variation of these constants as the bridge M in (I) is varied are not yet altogether clear. Nevertheless, it is noteworthy that the very appearance of the constants ρ_R, which usually characterise the interaction between the substituent and the functional centre via the conjugation mechanism, can hardly be caused here by this interaction. The point is that the ρ_R are not zero even in series such as p-X-C_6H_4-CH_2-^{19}F, p-X-CH_2-C_6H_4-^{19}F, and p'-X-C_6H_4-CH_2-C_6H_4-^{19}F-p,[103] where such conjugation should not occur.

The above data permit the conclusion that in bridged bicyclic systems of type (I) the electronic interaction between the substituent and the reaction centre can be not only weaker than in the non-bridged biphenyl system (II) but in some cases can also be several times stronger. This enhancement of the interaction, i.e. the positive bridge effect, is manifested distinctly only when the following conditions are observed:

1. The reaction series investigated (Ar–Y) is fairly sensitive for benzene derivatives to electron donor (or electron-acceptor) conjugation, i.e. the constant $\rho_{\overset{+}{R}}$ (or $\rho_{\bar{R}}$) in Eqn. (3) is appreciably different from zero.
2. The bridge group can be involved in the above conjugation, i.e. $\sigma_{\overset{+}{R}}$ (or $\sigma_{\bar{R}}$) for the CH_3-M- group is much smaller (or greater) than zero.
3. The bridge group is conjugated with each benzene ring to an extent which varies as a result of the inductive effect of the substituted ring.

§The deviation of the point for system (II) in Fig. 4 (No. 1) is probably caused by the enhanced transmission efficiency due to the capacity of the benzene ring for electron-acceptor conjugation.

Silylation of Organic Compounds

M.V.Kashutina, S.L.Ioffe, and V.A.Tartakovskii

The mechanism of the silylation reaction and the methods of synthesis and properties of silylating agents are discussed together with the silylation of various classes of compounds in relation to the most characteristic substances. The bibliography includes 186 references.

I. INTRODUCTION

The silylation reaction (particularly the trimethylsilylation reaction) is nowadays widely used in organic synthesis. "Silylation" is usually understood as the introduction of the silyl group in place of a labile hydrogen atom or a metal atom substituting the latter and it is essential that the group thus introduced can be readily removed with reintroduction of active hydrogen.

Silylation makes it possible to modify widely various properties of the starting materials: it alters the reactivity of the products and, in particular, makes it possible to block certain reaction centres, it improves the solubility of compounds in non-polar solvents and increases the volatility of products as the result of the disappearance of hydrogen bonds, thus permitting their analysis and separation by gas–liquid chromatography and mass spectrometry. Finally, in certain cases the stability of the initial substances increases after silylation, for example $(CH_3)_3SiN_3$ is more stable than HN_3.

Pierce's monograph[1] surveys data on the silylation of organic compounds up to 1967. Furthermore, there are a number of reviews dealing with individual aspects of silylation[2-6] and also with the use of silyl derivatives in gas–liquid chromatography[7,8]. However, we believe that, in view of the relative inaccessibility of the majority of the above sources to the Russian reader and also the publication in recent years of many new and interesting data, it is desirable to publish the present review.

II. THE MECHANISM OF THE SILYLATION REACTION

The majority of investigators believe that the silylation reaction is reversible and proceeds via a mechanism involving bimolecular nucleophilic substitution at the silicon atom[1]:

$$HY + R_3SiX \rightleftarrows \overset{\delta-}{Y} \cdots \underset{\displaystyle H \quad R}{\overset{R\ R}{Si}} \cdots \overset{\delta-}{X} \rightleftarrows HX + R_3SiY, \qquad (1)$$

where Y is the nucleophilic component of the molecule of the compound being silylated and X is the group substituted in the silylating compound.

According to another view[9], the silylation reaction proceeds via a many-centre transition state:

$$HY + R_3SiX \rightleftarrows \begin{matrix} R_3Si{-}X \\ \vdots\ \ \vdots \\ Y{-}H \end{matrix} \rightleftarrows R_3Si{-}Y + HX. \qquad (2)$$

In many instances the rate-limiting stage of the reaction is believed to be the protonation of the silylating agent, preceding nucleophilic attack on the silicon atom[10]:

$$HY + R_3SiX \overset{\text{slow}}{\rightleftharpoons} [R_3SiX \cdots H]^+ \rightarrow \xrightarrow{Y^- \text{ or } HY} R_3SiY + HX. \qquad (3)$$

There are two criteria whereby it is possible to choose between particular silylation mechanisms. One of these is based on a kinetic study in which the order of the reaction with respect to the reactants and the rate-limiting stage are determined. The second is based on the study of silylation by agents containing an asymmetric silicon atom. This procedure for elucidating the mechanism has become possible as a result of detailed studies by Sommer[11], who obtained a set of optically active compounds with an asymmetric silicon atom and determined their true configurations.

The "optical" criterion makes it possible to investigate directly the mechanism of the substitution stage at the silicon atom even if it is not rate-determining. Sommer suggests[11] that silicon is capable of giving rise to transition structures in the silylation reaction as a result of the involvement of its vacant *d* orbitals. Three possible versions are considered.

1. The inversion of the optical configuration at the silicon atom (here and henceforth we shall designate this process, following Sommer[11], as S_N2–Si). In this case the group X is replaced by Y via a bimolecular mechanism and the transition state has the geometry of a trigonal bipyramid (Fig. 1).

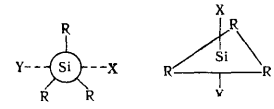

Figure 1. Geometry of the transition state in an S_N2–Si reaction.

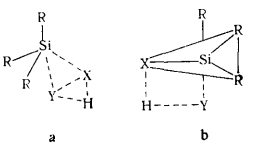
2. The retention of the optical configuration at the silicon atom (we shall designate this process by S_Ni–Si)[11]. Here the reaction is also bimolecular but the geometry of the transition state changes. It is either a tetragonal

pyramid (Fig. 2*a*) or a trigonal bipyramid in which the relative positions of X and Y are not the same as in Fig. 1 (Fig. 2*b*).

3. The loss of optical activity. In this case the reaction either proceeds via the S_N1–Si mechanism involving the formation of a planar siliconium cation:

$$R_3Si{-}X \rightleftarrows R_3Si^+ + X^- \overset{HY}{\rightleftarrows} R_3SiY + HX\,,$$

or it proceeds simultaneously via the S_N2–Si and S_Ni–Si mechanisms. Evidently a choice can be made between these two versions kinetically using the order of the reaction with respect to each reactant.



a b

Figure 2. Geometry of the transition state in a S_Ni–Si reaction.

Since the siliconium cation R_3Si^+ is relatively unstable[12], and the silylation reaction is usually carried out in aprotic solvents of low polarity, we believe that "racemisation" is most probably a consequence of a bimolecular reaction mechanism intermediate between S_N2–Si and S_Ni–Si.

1. Reaction Kinetics

It has been shown that in many cases the rate determining stage in the silylation reaction is nucleophilic substitution at the silicon atom. Thus Grubb[13] established that silylation of trimethylsilanol in methanol proceeds with participation of the solvent and is catalysed by acids or bases. It was found that the reaction is of first order with respect to the silanol, chlorotrimethylsilane, and the catalyst. The following reaction mechanism was proposed:

$$(CH_3)_3SiOH + CH_3OH \rightleftarrows (CH_3)_3SiOCH_3 + H_2O\,.$$

Then, in the presence of an acid catalyst we have

$$(CH_3)_3SiOCH_3 + CH_3\overset{+}{O}H_2 \rightleftarrows (CH_3)_3Si\overset{+}{O}CH_3 + CH_3OH,$$

$$(CH_3)_3SiOH + (CH_3)_3Si\overset{+}{O}CH_3 \overset{slow}{\rightleftarrows} \left[(CH_3)_3SiO \cdots \overset{CH_3\ CH_3}{Si} \cdots OCH_3\right] \rightleftarrows$$

$$\rightleftarrows [(CH_3)_3Si]_2O + CH_3\overset{+}{O}H_2\,,$$

and in the presence of a basic catalyst

$$(CH_3)_3SiOH \overset{OH^-}{\rightleftarrows} (CH_3)_3SiO^- + H_2O,$$

$$(CH_3)_3SiO^- + (CH_3)_3SiOCH_3 \overset{slow}{\rightleftarrows} \left[(CH_3)_3SiO \cdots \overset{CH_3\ CH_3}{Si} \cdots OCH_3\right] \rightleftarrows [(CH_3)_3Si]_2O + CH_3O^-.$$

The kinetics of the reaction of methanol with silylamines having the general formula  —NHSiR$_3$

(where X = H, CH_3, OCH_3, C_2H_5, Cl, or F and R = alkyl) have been studied[14]. The reaction was carried out in an excess of methanol in the presence of or absence of acid catalysts. It was shown that it is irreversible and is of first order with respect to silylamine and the catalyst. For substituents X in the *meta*- and *para*-positions, a linear relation was observed between $\lg K = \lg(k_1/k_0)$ and the Hammett constants σ of the substituents (the sensitivity coefficient $\rho = -2.52$). Very rapid deuterium exchange between methanol and the silylamine was observed. Bearing in mind the data concerning the reaction order, the sign and magnitude of the sensitivity coefficient ρ, and the high activation entropy, the authors[14] suggested a mechanism for this process in which the rate-determining stage is the interaction of the protonated silylamine with methanol:

$$\begin{gathered} ArNHSi(iso\text{-}C_3H_7)_3 + (CH_3\overset{+}{O}H_2) \overset{fast}{\rightleftarrows} Ar\overset{+}{N}H_2Si(iso\text{-}C_3H_7)_3 + CH_3OH\,, \\ Ar\overset{+}{N}H_2Si(iso\text{-}C_3H_7)_3 + CH_3OH \rightarrow ArNH_2 + (iso\text{-}C_3H_7)_3Si\overset{+}{O}CH_3\,, \\ \qquad\qquad\qquad\

2. Stereochemistry of the Reaction

The silylation of compounds containing a mobile hydrogen atom with the aid of optically active trialkylhalogenosilanes proceeds as a rule with almost complete inversion of the configuration of the R_3Si fragment[20-25]. The silylation of water and methanol by silylamines[25-27] and the silylation of methanol by alkoxycarbonylsilanes proceed similarly[28]. On the other hand, the interaction of organic acids and HCl with silylamines can proceed both with and without inversion of optical configuration[26,29]†.

Examination of the kinetic and stereochemical data for the silylation reaction shows that it usually proceeds via the S_N2–Si mechanism. The silylating agent can interact in both neutral and protonated forms, the latter being apparently preferable. The silylated compound reacts either as an anion or as a neutral molecule. However, in many instances the silylation reaction proceeds via the S_Ni–Si mechanism or simultaneously via the S_N2–Si and S_Ni–Si mechanisms.

3. Additional Data on the Silylation Mechanism

In addition to the kinetic and stereochemical studies already discussed, it is necessary to consider certain investigations which also provide information about the mechanism of the silylation reaction.

A hypothetical S_Ni–Si mechanism involving a many-centre transition state has been postulated for some reactions. In particular, such a mechanism has been suggested for the silanolysis of silylamines[10]:

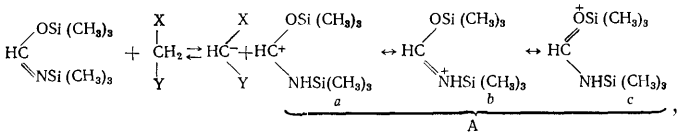
$$R_3SiOH + R'_3SiNR''_2 \rightarrow R_3Si{-}O{-}H \rightarrow R_3SiOSiR'_3 + R''_2NH.$$
$$\vdots$$
$$R'_3Si{-}NR''_2$$

According to Becke-Gochring and Wunsch[30], the interaction of hexamethyldisilazane with compounds containing a mobile hydrogen atom may be accompanied by the formation of an intermediate complex‡:

$$[(CH_3)_3Si]_2NH + HX \rightarrow [(CH_3)_3Si{-}\underset{\uparrow\ \downarrow}{N}HSi(CH_3)_3] \rightarrow (CH_3)_3SiX + [(CH_3)_3SiNH_2],$$
$$X{-}H$$

where X = Cl, OC_2H_5, or OC_6H_5.

In their study of the silylation of weak C–H acids by *N O*-bis(trimethylsilyl) formamide Kentlenner et al.[10] suggested that the silylating agent is initially protonated with formation of an ambident cation A§:



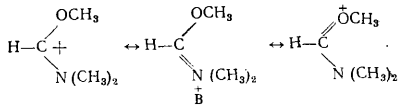
where X = RCO for R = CH_3 or C_6H_5 and Y = $CO_2C_2H_5$, for R = CH_3OCOCH_2 and Y = CO_2CH_3, or for R = C_6H_5 and Y = $COCH_3$ and X = CN for Y = CN, $CO_2C_2H_5$, or CO_2CH_3.

---

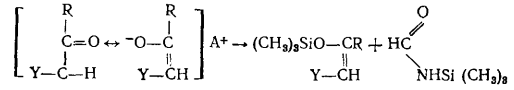
† These results are explained in the next section of this review.

‡ However, the authors do not rule out also other reaction mechanisms.

§ The cation A can be regarded as the silylated analogue of the ambident cation B:[31]

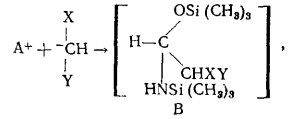


When the anion formed from the C–H acid is capable of tautomerism, the ambident cation A reacts with it in form (*b*) or (*c*), giving rise to an *O*-silylation product:



where Y = $COOC_2H_5$, $COOCH_3$, or $COCH_3$.

When the anion of the C–H acid is incapable of tautomerism, the cation A reacts with this "hard" anion in form (*a*) to form compounds of type C, which are unstable and undergo further reactions:



where X = CN and Y = CN, $COOCH_3$, or $COOC_2H_5$.

Thus several different mechanisms have been proposed for the silylation reaction¶. We believe that this process should not be always treated from the standpoint of any one mechanism, since the reaction mechanism can probably change under the influence of many factors.

4. The Influence of the Nature of the Group X Substituted in the Silylating Agent R_3SiX

Examination of Eqn. (1) shows that the rate of silylation must depend on the properties of the substituent X as the group to be eliminated†. Firstly, it is desirable that X should be capable of delocalising the negative charge arising on it in the transition state. Secondly, the weaker the $(d-p)_\pi$ interaction between the silicon atom and the group X, the greater the ease of nucleophilic attack on the silicon atom and the dissociation of the Si–X bond. In many cases the rate of the silylation reaction depends on the ease of protonation of the compound R_3SiX [Eqn. (3)] and the role of protonation should become more important as X becomes more difficult to eliminate.

Certain ideas about the influence of the nature of the group X on the ease of substitution are provided by the series of conversions deduced by Eaborn[33] and Anderson and Fischer[34] on the basis of studies of the reactions of certain silver salts with triorganosilanes:

$$\rightarrow \text{SiI} \rightarrow (\text{Si})_2\text{S} \rightarrow \text{SiBr} \rightarrow \text{SiH} \rightarrow \text{SiNC} \rightarrow \text{SiCl} \rightarrow \text{SiNCS} \rightarrow \text{SiNCO} \rightarrow$$
$$\rightarrow (\text{Si})_2\text{O}, \text{SiF}.$$

In this series the reactions of the compounds $\rightarrow$SiX with the salt AgY proceed only from left to right.

The most thoroughly investigated silylating agents are compounds with an Si–N bond. These organosilicon derivatives have been arranged in the following sequence in terms of their silylating capacity[1,15]:

$$R_3Si{-}N\begin{matrix}R'\\R''\end{matrix} < R_3SiNR'CONR''R''' \sim R''CONR'SiR_3 < R''C(OSiR_3){=}NSiR_3.$$

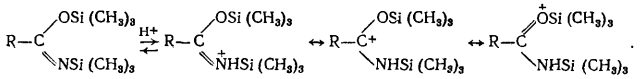
¶ In addition to the foregoing, we may mention that a radical-anion mechanism has been put forward for the silylation of ketones in the presence of an alkali metal[32].

† X must be more electronegative and less nucleophilic than Y in the compound HY being silylated. Otherwise HX must be removed from the reaction sphere in order to shift the equilibrium towards the silylation products.

Silylamines are less effective donors of the trimethylsilyl group than silylated ureas and amides. *NO*-Bis-(trimethylsilyl)amides are the best silylating agents for the majority of compounds to be silylated, among those known at the present time.

The explanation is that, firstly, the introduction of the carbonyl group at the nitrogen atom linked to the silicon atom weakens the $(p - d)_\pi$ interaction between them and facilitates nucleophilic attack on the silicon atom. The introduction of a second trimethylsilyl group into silylated amides weakens still further the double-bond character of the linkage between the silicon atom and the group X to be substituted. Secondly, on passing from silylamines to silylated amides and ureas, there is an increase of the capacity of the group X being eliminated for the delocalisation of the negative charge due to the carbonyl group.

Furthermore, *NO*-bis(trimethylsilyl)amides are more readily protonated than silylamines and silylureas, since the resulting positive charge is more effectively stabilised:



The substituent at the nitrogen atom in the group $-CO-N(X)-Si$ also influences the reactivity of *N*-silylamides.

The study of the methanolysis of *N*-methyl-*N'*phenyl-*NN'*-bis(trimethylsilyl)urea showed that the trimethylsilyl group at the nitrogen atom linked to the more electronegative substituents is more mobile[15]:

$$C_6H_5N[Si(CH_3)_3]CON(CH_3)Si(CH_3)_3 \xrightarrow{CH_3OH} C_6H_5NHCON(CH_3)Si(CH_3)_3.$$

It is noteworthy that the ease of protonating of silylamides depends very markedly on the contribution of the amide formed to the structure of the amide and on the energy barrier between the amide and imide forms (see Section III). A decrease of the barrier and an increase of the content of the form C in the mixture should facilitate the protonation of silylamines (in consequence of the resonance stabilisation of the cation $R-C(OSi<)(\overset{+}{N}HR')$) and hence improve the silylating capacity of these compounds.

In conclusion we shall consider briefly the influence of the group X being substituted in silylating agents with an Si–O bond. Sommer et al.[23] investigated the rate of solvolysis of alkoxy- and acyloxy-silanes R_3SiOR' and $R_3SiOCOR'$. Trialkylacyloxysilanes are more reactive, owing to the greater stabilisation of the charge by the group $(-OCOR')^-$ compared with $(OR')^-$ and the smaller amount of double bond character of the linkage between the silicon atom and the group being substituted in acyloxysilanes compared with alkoxysilanes.

5. The Influence of the Nature of the Compound HY Being Silylated

The silylation mechanism may be also determined by the properties of the compound being silylated. If the compound HY has pronounced nucleophilic properties, then reaction (1) should be favoured. An increase of the acidity of HY with retention of fairly marked nucleophilic properties should lead to a many-centre cyclic transition state, in accordance with Eqn. (2). Under these conditions, when the acidity of HY is of decisive importance, the rate-limiting stage becomes the protonation of the silylating agent [Eqn. (3)].

Hydroxy-compounds are known to be more readily silylated than compounds with an N–H bond[35]. Possibly this is because alcohols are stronger acids than amines. For this reason, they, on the one hand, protonate more readily the silylating agent (see acid catalysis) and, on the other hand, they are themselves more readily deprotonated, the anion RO^- being more nucleophilic than the amine.

The rate of silylation decreases in the series of alcohols $CH_3OH > n\text{-}C_3H_7OH > n\text{-}C_6H_{13}OH$ in parallel with the decrease of their acidity[36,37]. The decrease of the rate of silylation in the series $RNH_2 > R_3CONH_2 > RCONHSi(CH_3)_3$ takes place in parallel with the decrease of the nucleophilicity of these compounds[35].

6. Steric Effects

In many cases the mechanism and rate of silylation are determined by the steric factors associated with the silylating agent or the compound being silylated. Thus, in the interaction of organic acids with silylamines, the change in reaction mechanism may be caused by the steric hindrance in the compound being silylated. In particular, the silylation of benzoic acid proceeds via the S_Ni–Si mechanism. When substituents are introduced into the *ortho*-position, the mechanism changes to S_N2–Si.[26]

Secondary amines with a branched chain in the α-position relative to the nitrogen atom are silylated with greater difficulty than primary amines, which is due to steric hindrance[38]. Bulky substituents in certain primary amines and aminoacids preclude the introduction of a second trimethylsilyl group at the nitrogen atom when the starting materials are treated with diethyltrimethylsilylamine in the presence of ammonium sulphate[39].

According to some investigators[36,37], the decrease of the rate of hydrolysis and alcoholysis of chlorotriorganosilanes in the series water > methanol > propanol > 1-hexanol > isopropyl alcohol is due to the steric hindrance in the compound being silylated.

A study of the rate of hydrolysis of various disilazanes showed that bulky substituents at the silicon atom retard the reaction[40]. The same causes are probably responsible for the resistance to hydrolysis of alkoxyisopropyldimethyl- and alkoxy-t-butyldimethyl-silanes[41,42]. A steric effect of the substituents at the nitrogen atom was also observed in a study of the rate of methanolysis of silylamines: $C_6H_5(C_2H_5).NSi(C_2H_5)_3$ silylates methanol more slowly than does $C_6H_5NHSi(C_2H_5)_3$.[14]

7. The Influence of Catalysts

The role of the acid catalyst in the silylation reactions proceeding via Eqns. (1) and (3) reduces to the protonation of the silylating agent R_3SiX, which in its turn weakens the $(p - d)_\pi$ interaction between the silicon atom and the group X. Examples of acid-catalysed silylation reactions are quoted below.

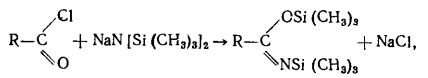
Alcoholysis of silylamines is as a rule an acid-catalysed reaction[14,26]. Grubb showed[13] that the condensation of a silanol in ethanol is catalysed by acids (see Subsection 1 of the present Section).

The following mechanism has been proposed for the silylation of alcohols and amines by hexamethyldisilazane[43]:

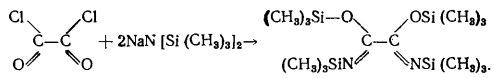
$$[(CH_3)_3Si]_2NH \overset{H^+}{\rightleftarrows} [(CH_3)_3Si]\overset{+}{N}H_2 - Si(CH_3)_3;$$

$$[(CH_3)_3Si]_3\overset{+}{N}H_2 + HY \rightleftarrows \{(CH_3)_3SiNH_2{-}Si(CH_3)_3\} \rightarrow (CH_3)_3SiY + (CH_3)_3Si\overset{+}{N}H_2,$$
$$\quad\quad\quad

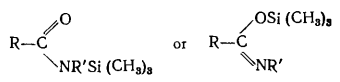
Another method for the synthesis of *NO*-bis(trimethylsilyl)amides was proposed by Pump and Rochow[65]:



where R = C_6H_5, C_5H_4N, or $(CH_3)_3C$. A trimethylsilyl derivative of oxalic acid diamide was obtained similarly[65]:

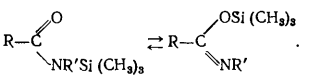


The structure of silylated amides. Silylation of amides can result in the formation of two isomeric products:



A B

^{1}H NMR data for a number of monotrimethylsilylated amides indicate the migration of the $(CH_3)_3Si$ group between oxygen and nitrogen atoms[15,66]:

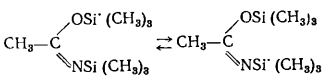


The equilibrium position in this process depends on the electronegativity of the substituents R and R′. The rate of migration of the $(CH_3)_3Si$ group varies in the following sequence of a function of R (R′ = C_6H_5):[66]

$$CF_3 \simeq CCl_3 < CHCl_2 < CH_2Cl < CH_3 \leqslant C_2H_5 < \text{iso-}C_3H_7 \ll \text{t-}C_4H_9 .$$

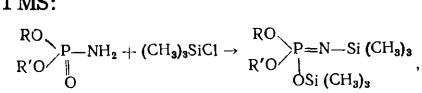
With increase of the electronegativity of the substituent at the nitrogen atom, the content of the *O*-trimethylsilyl imidate rises[15].

A study of the ^{1}H NMR and infrared spectra of bis(trimethylsilyl)acetamide (BSA) led Pump and Rochow[65] to the conclusion that this compound is *NO*-bis(trimethylsilyl)acetamide and that there is a rapid intramolecular exchange of $(CH_3)_3Si$ groups¶.



In recent years studies of the infrared and ^{1}H NMR spectra of mono- and bis-(trimethylsilyl)amides enriched in ^{15}N established rigorously that BSA and other bis(trimethylsilyl) derivatives having the general formula $[RCON][Si(CH_3)_3]_2$, where R = iso-C_3H_7, t-C_4H_9, or CF_3, exist exclusively in the imidate form, while bis(trimethyl)formamide and the monosilylacetamides CH_3CONR–$Si(CH_3)_3$ (R = H or alkyl) are true amides[67–69].

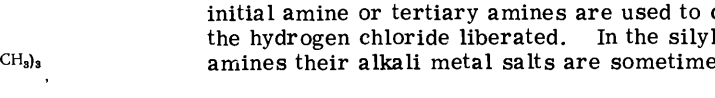
Dialkyl trimethylsilyl *N*-trimethylsilylphosphorimidates are formed on silylation of the corresponding amides of dialkyl phosphoric acids with an excess of CTMS:[70]



where R = R′ = CH_3; R = C_2H_5, R′ = CH_3; R = n-C_4H_9; R′ = CH_3. These compounds are very sensitive to moisture.

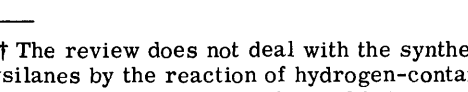
¶ We believe that the evidence supporting intramolecular rather than intermolecular exchange of $(CH_3)_3Si$ group is inadequate.

Vinyloxysilanes are formed when the corresponding enolates are acted upon by CTMS:[71]†



where R = H and R′ = C_6H_5, R = H and R′ = CH_3, R = CH_3 and R′ = $COCH_3$, or R = H and R′ = HC = $C(CH_3)_2$.

Lutsenko and coworkers[72] reported the synthesis of 2-trimethylsiloxyprop-1-ene by the exchange reaction between α-tripropylstannylacetone and CTMS:



Certain vinyloxysilanes have been obtained by treating α-mercurated aldehydes and ketones with chlorosilanes[73]. In addition we may note that, in the silylation of certain ketones with a BSA–*N*-trimethylsilylimidazole–CTMS mixture, trimethylvinyloxysilanes are also formed[74].

Silylating agents were already compared to some extent in the discussion of the mechanism of the silylation reaction. The most convenient are the trimethylsilyl derivatives of ureas and amides. To some extent, this can be accounted for by the fact that, as a result of the silylation reaction, ureas and amides, compounds which are usually inert with respect to silylation products, are formed. To investigate substances containing the NH,, OH, and SH groups with the aid of gas–liquid chromatography (GLC), they are silylated with trifluoro-*N*-methyl-*N*-trimethylsilylacetamide[57] and trifluoro-*NO*-bis(trimethylsilyl)acetamide[61], since the fluorinated derivatives are more volatile than their non-fluorinated analogues. Mixtures of several silylating agents have been recommended in several studies, CTMS being added to such compositions as the catalyst[7,75–77]. This version of the silylation reaction is used particularly frequently in GLC.

The employment of 2-trimethylsiloxyprop-1-ene for the silylation of compounds with the OH, NH, COOH, and SH groups showed that it is less effective than BSA and silylation with its aid is not always satisfactory[78]. *N*-Trimethylsilylimidazole, which readily silylates oxygen linked to mobile hydrogen, is at the same time relatively unsuitable for the silylation of the N–H bond[76].

The usefulness of a particular silylating agent is determined by the nature of the compound to be silylated. For this reason, examples illustrating conditions governing the silylation of various functional groups are quoted below.

IV. METHODS FOR THE SILYLATION OF VARIOUS CLASSES OF ORGANIC COMPOUNDS

1. Silylation of Amines

A general method for the silylation of amines involves their reaction with CTMS [2] (Table 1). An excess of the initial amine or tertiary amines are used to combine with the hydrogen chloride liberated. In the silylation of amines their alkali metal salts are sometimes used.

† The review does not deal with the synthesis of vinyloxysilanes by the reaction of hydrogen-containing silanes with αβ-unsaturated aldehydes and ketones.

Another method for the silylation of amines involves the transamination of silylamines, first investigated by Larson and coworkers[86]:

$$(CH_3)_3SiNR_2 + R'NH_2 \rightleftarrows (CH_3)_3SiNHR' + NHR_2.$$

Table 1. Silylation of amines by chlorotrimethylsilane.

Amine	Reaction product	Yield, %	Refs.
Ammonia	Hexamethyldisilazane	45-70	51,79
Methylamine	Methyltrimethylsilylamine	38-55	51
Ethylamine	Ethyltrimethylsilylamine	25	51
Diethylamine	Diethyltrimethylsilylamine	32	51
Aziridine	*N*-Trimethylsilylaziridine	44	80,81
Pyrrolidine	*N*-Trimethylsilylpyrrolidine	65	82
Piperidine	*N*-Trimethylsilylpiperidine	72	82
Pyrrole (K salt)	*N*-Trimethylsilylpyrrole	71	82,83
Indole (K salt)	*N*-Trimethylsilylindole	55	82
Aniline	*N*-Trimethylsilylaniline	60-80	84,85

Hexamethyldisilazane, trimethylsilylamine, and diethyltrimethylsilylamine are usually employed as donors of the trimethylsilyl group (Table 2). The rate of this reaction increases following the distillation of the amine NHR_2 formed or after the addition of catalytic amounts of ammonium salts, CTMS, or $ZnCl_2$, which promote the condensation to silazanes of the silylamines formed initially[38] (Table 3):

$$2\,(CH_3)_3SiNHR' \xrightarrow{(NH_4)_2SO_4} [(CH_3)_3Si]_2NR' + R'NH_2\ .$$

For sterically hindered amines, only the monosilyl derivatives have been obtained[38].

Table 2. Transamination of silylamines.

Amine	Silylating agent	Reaction product	Yield, %	Refs.
Imidazole	$[(CH_3)_3Si]_2NH$	*N*-Trimethylsilylimidazole	85	82
Pyrazole	$(C_2H_5)_3SiNH_2$	*N*-Trimethylsilylpyrazole	72	82

*The position of the $(CH_3)_3Si$ group in the ring is not indicated.

The silylation of primary amines containing a branched alkyl substituent in the α-position with *N*-methyl-*N*-trimethylsilylacetamide yields monosilyl-substituted products[38]. In other cases silylation with this agent leads to the corresponding silazanes.

N-Methyl-*N*-trimethylsilylamides have been used to silylate secondary amines when the latter were analysed by GLC:[88]

$$RCON(CH_3)Si(CH_3)_3 + R'_2NH \rightarrow RCONHCH_3 + (CH_3)_3SiNR'_2,$$

where R = H or CH_3.

At an elevated temperature primary amines can be silylated by a trialkyl- or triarylsilane in the presence of catalytic amounts of metal hydrides[89]:

$$RNH_2 + R'_3SiH \xrightarrow[\sim 100^\circ]{\text{Met-H}} RNHSiR'_3 + H_2,$$

where R and R' is an alkyl or aryl group. Triarylsilanes react more readily in this process than trialkylsilanes. Likewise alkylamines are silylated less effectively than arylamines.

Table 3. Transamination of silylamines in the presence of catalysts[39].

Amine	Silylating agent	Catalyst	Reaction product	Yield, %

2. Silylation of Alcohols

Alcohols are usually silylated with the aid of CTMS (in the presence of tertiary amines) or hexamethyldisilazane. The reactions have comparatively low rates, but the desired products are formed in high yields. Best results were obtained when monosilylacetamides, BSA, and *N*-trimethylsilylimidazole were used. The rate of silylation of alcohols depend on their acidity and on steric factors (see Section II, Subsections 5 and 6).

Individual examples of the silylation of polyhydric alcohols and alcohols with other functional groups are quoted below. Prey and Gump[48], who silylated certain monosaccharides with CTMS in the presence of pyridine, obtained bis-, tris-, and tetrakis(trimethylsilyl)derivatives of monosaccharides. Schwartz et al.[52] reported the synthesis of incompletely silylated D-glucose with chlorotriethylsilane in pyridine. In the presence of a deficiency of the silylating agent the product is *O*-tris(triethylsilyl)-D-glucose, while in the presence of an excess of the silylating agent a mixture of tris- and tetrakis-(triethylsilyl)-D-glucoses is formed. Pentakis(trimethylsilyl)-glucose can also be obtained by silylating glucose with CTMS.[47]

Derivatives with all the hydroxy-groups trimethylsilylated were obtained by treating uronic acids with CTMS in the presence of pyridine[90]. Alcohols with sulphur-containing functional groups, for example $(C_3H_7S)_2C(CH_3).CH_2OH$, were silylated with CTMS in the presence of triethylamine[91]. Halogenophenols react with CTMS to form the corresponding trimethylsilyl derivatives[92]. Acetone cyanohydrin is also silylated with CTMS.[93,94]

Certain nitro- and halogeno-alcohols were recently silylated with the aid of halogenosilanes[19,95,96]:

$$(CH_3)_3SiCl + ROH \xrightarrow{C_5H_5N} (CH_3)_3SiOR,$$
$$R=CH_2CH_2NO_2,\ CH(CH_3)CH_2NO_2,\ CH_2NO_2,$$
$$CH(NO_2)C_2H_5,\ C(CH_3)_2CH_2NO_2,\ CH(CH_3)C(NO_2)(Br)CH_3,$$
$$CH_2C(Br)(NO_2)CH_3,\ CH(CH_2Cl)CH_2NO_2.$$

The silylation of sugars[97] and phenols[46,98] by hexamethyldisilazane gave high yields of the corresponding derivatives with all the hydroxy-groups trimethylsilylated. The silylation of alcohols, including steroid alcohols[77], by the BSA–CTMS–*N*-trimethylsilylimidazole mixture has been investigated at 60–80°C in several studies[74,77]. The resulting trimethylsilyl derivatives were analysed by GLC. It was found that this mixture of silylating agents is in some cases more effective than BSA.

The silylation of glucose and its derivatives by *N*-trimethylsilylacetamide has been reported[99]. The reactions proceed at high rates and with satisfactory yields. The silylation of polyhydric alcohols and sugars by *N*-methyl-*N*-trimethylsilylacetamide makes it possible to separate these compounds by GLC.[88] BSA readily silylates 2′-hydroxy-*m*-terphenyl, while 2,6-di-t-butylphenol reacts with BSA only on refluxing in acetonitrile[100]‡. The silylation of alcohols by trimethylvinyloxysilanes takes place with high yields in the presence of catalytic amounts of CTMS.[78]

3. Silylation of Aminoalcohols

Aminoalcohols are silylated by CTMS (in the presence of triethylamine)[101], hexamethyldisilazane[102], or dimethyltrimethylsilylamine[39]. These reactions have been mainly investigated for ethanolamine, the hydroxy-group being silylated first[101,102]:

$$HOCH_2CH_2NH_2 \xrightarrow[(C_2H_5)_3N]{(CH_3)_3SiCl} (CH_3)_3SiOCH_2CH_2NH_2$$

or

$$HOCH_2CH_2NH_2 \xrightarrow{[(CH_3)_3Si]_2NH} (CH_3)_3SiOCH_2CH_2NH_2.$$

Under more severe conditions and in the presence of an excess of the silylating agent, the *NO*-bis(trimethylsilyl) derivative of ethanolamine is produced[101]:

$$HOCH_2CH_2NH_2 \xrightarrow[(C_2H_5)_3N]{(CH_3)_3SiCl} (CH_3)_3SiOCH_2CH_2NHSi(CH_3)_3.$$

Ethanolamine has been silylated to *NN*-bis(trimethylsilyl)-*O*-trimethylsilylethanolamine with the aid of diethyltrimethylsilylamine in the presence of $(NH_4)_2SO_4$ as the catalyst[39].

It has been shown that the BSA–*N*-trimethylsilylimidazole mixture can silylate selectively the OH group in aminoalcohols in the presence CTMS.[74]

4. Silylation of Organic Acids

Trimethylsilyl esters of organic acids are usually obtained when the acids are treated with hexamethyldisilazane[98] or CTMS in the presence of pyridine[103]. For example, bis(trimethylsilyl) esters of terephthalic, fumaric, and sebacic acids have been obtained by treating the dibasic acids with CTMS.[103] Trimethyl acetate, propionate, and adipate have been synthesised with the aid of hexamethyldisilazane[98]. The silylation of derivatives of certain hydroxyacids has been studied[103].

When sodium tartrate is acted upon by CTMS, a mixture of products is formed: 2,3-bis(trimethylsilyl) derivatives of tartaric acid, polytartrate esters, trimethylsilanol, and hexamethyldisiloxane. The reaction of CTMS with strontium lactate results in the formation of polylactate esters, trimethylsilanol, and α-trimethylsiloxylactic acid, which the authors believe is obtained as a result of a rearrangement of monotrimethylsilyl lactate[103]:

$$\left[\begin{matrix}HOCHCOO\\ |\\ CH_3\end{matrix}\right]_2 Sr + 2(CH_3)_3SiCl \rightarrow SrCl_2 + 2\{CH_3CH(OH)COOSi(CH_3)_3\}$$
$$(CH_3)_3SiOCH(CH_3)COOH\ (65\text{—}70\%) + [-CH(CH_3)COO]_n + n(CH_3)_3SiOH.$$

In order to identify certain acids, their trimethylsilyl esters, which are suitable for infrared spectroscopic studies, are prepared with the aid of dialkyl trimethylsilyl *N*-trimethylsilylphosphorimidates[70]§:

$$RCOOH + (C_2H_5O)_2P[OSi(CH_3)_3]{=}NSi(CH_3)_3 \rightarrow (C_2H_5O)_2P(O)NHSi(CH_3)_3 + RCOOSi(CH_3)_3.$$

5. Silylation of Aminoacids

Aminoacids can be silylated by various agents: CTMS, hexamethyldisilazane, silylamines, and silylamides. In many cases best results were obtained when CTMS was used in the presence of triethylamine[104].

CTMS reacts with both the free acids and with their derivatives. The hydrogen of the carboxy-group is the first to be substituted in free aminoacids. It was found that monoaminoacids are converted into the corresponding hydrochlorides of their trimethylsilyl esters after only brief heating in the presence of an excess of CTMS.[105]:

$$H_2NCHRCOOH + (CH_3)_3SiCl \rightarrow HCl \cdot H_2NCHRCO_2Si(CH_3)_3,$$

where R = CH_3 or $CH_2CH(CH_3)_2$.

Aminoacids with several functional groups also form the hydrochlorides of *O*-trimethylsilyl esters on interaction with CTMS.[105] In particular, the hydrochlorides of the trimethylsilyl esters of glutamic acid, serine, and cystine have been obtained[105]. It is noteworthy that under these conditions lysine forms a mixture of mono- and tris(trimethylsilyl) derivatives[105]:

$$3H_2NCH_2(CH_2)_3CH(NH_2)COOH + 5(CH_3)_3SiCl \rightarrow 2\underset{\underset{NH_2\cdot HCl}{|}}{CH_2(CH_2)_3CHCO_2Si(CH_3)_3} + \underset{\underset{NH_2\cdot HCl}{|}}{}$$
$$+ \underset{\underset{NHSi(CH_3)_3}{|}}{CH_2(CH_2)_3CHCO_2Si(CH_3)_3}\ \underset{\underset{NHSi(CH_3)_3}{|}}{}.$$

The difficulty of silylating certain free aminoacids by chlorosilanes has been explained in a review[5] by the existence of inactive betaines. *O*-Trialkylsilyl esters of aminoacids sometimes disproportionate on heating[106]:

$$2RCH(NH_2)COOSiR'_3 \rightarrow RCH(NHSiR'_3)COOSiR'_3 + RCH(NH_2)COOH.$$

When the hydrochlorides of trimethylsilyl esters of aminoacids are treated with CTMS and triethylamine, *NO*-bis-(trimethylsilyl) derivatives of the aminoacids can be isolated in low yields[105].

---

‡ CTMS and hexamethyldisilazane do not enter into this reaction[100].

§ The use of silylamides for this purpose is ruled out, because the reaction results in their conversion into carbonyl compounds[70].

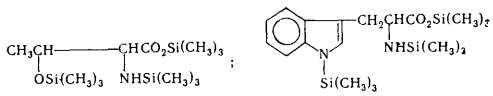
The silylation of aminoacids by hexamethyldisilazane leads to the formation of *NO*-bis(trimethylsilyl) derivatives and in this case too the hydrogen of the carboxy-group is the first to be substituted[106,107]§. A mixture of diethyltrimethylsilylamine, CTMS, and triethylamine is sometimes used to synthesis *NO*-bis(trimethylsilyl) derivatives of aminoacids[106].

Satisfactory results were obtained in the silylation of aminoacids by diethyltrimethylsilyl- or dibutyltrimethylsilyl-amines in the presence of catalytic amounts of $(NH_4)_2SO_4$. *NO*-Bis(trimethylsilyl) derivatives of valine, alanine, phenylalanine, leucine, and isoleucine were isolated in this way[39,108]. It was possible to introduce three $(CH_3)_3Si$ groups only into the sterically unhindered glycine molecule[39]:

$$H_2NCH_2COOH + 3(CH_3)_3SiN(C_2H_5)_2 \xrightarrow{(NH_4)_2SO_4} [(CH_3)_3Si]_2NCH_2CO_2Si(CH_3)_3 + 3NH(C_2H_5)_2.$$

A number of aminoacids with functional groups and their hydrochlorides have been silylated with the aid of diethyltrimethylsilylamine. In particular, derivatives of glutamic acid, sarcosine, alanine, histidine, proline, norvaline, tyrosine, hydroxyproline, and aspartic acid with all the functional groups trimethylsilylated have been obtained[109].

Klebe et al.[110] separated aminoacids by gas–liquid chromatography after silylating them with the aid of BSA. They investigated the silylation of more than 20 aminoacids, including alanine, valine, and serine. They were the first to describe the fully silylated threonine and tryptophan:



Trifluoro-*NO*-bis(trimethylsilyl)acetamide has also been proposed as a silylating agent for aminoacids[64]. Because of its volatility, it is more suitable for the gas–liquid chromatographic analysis of aminoacids than BSA.

The effects of silylating agents of different classes on certain aminoacids (phenylalanine, lysine, and tyrosine) were compared under the conditions of gas–liquid chromatography[76]. They were arranged in the following sequence in terms of the rate of silylation: dialkyltrimethylsilylamines > BSA ≫ monosilylacetamide. *N*-Trimethylsilylimidazole proved to be inactive under these conditions. It is interesting that the addition of dimethylformamide or dimethylformamide and CTMS to BSA impaired the silylating capacity of the latter, while pyridine facilitated silylation. Trifluorobis(trimethylsilyl)-acetamide was regarded as equal to BSA in its silylating capacity. The authors arranged in the following sequence the aminoacids investigated in terms of the rate of silylation: tyrosine ≥ phenylalanine > lysine. The above series do not involve the absolute kinetic characteristics of the process, since they reflect not only the rate of silylation but also the stability of the derivatives formed in solution.

It has been shown[75] that properties of the solvent have a significant influence on the degree of silylation of polyfunctional aminoacids. With increase of solvent polarity the degree of silylation of these products usually rises.

By treating alkyl esters of aminoacids with CTMS, Birkofer and Ritter[111,112] obtained their *N*-trimethylsilyl derivatives:

$$H_2NCHR(CH_2)_nCO_2C_2H_5 \xrightarrow{(CH_3)_3SiCl} (CH_3)_3SiNHCHR(CH_2)_nCO_2C_2H_5,$$

where $n = 0$ and R = H, n-C_3H_7, or s-C_4H_9 and $n = 1$ and R = H or CH_3.

N-Benzoyl derivatives of aminoacids react with CTMS to form *N*-benzoyl-substituted trimethylsilyl esters[113]:

$$C_6H_5CONHCHRCO_2H + (CH_3)_3SiCl \xrightarrow{C_5H_5N} C_6H_5CONHCHRCO_2Si(CH_3)_3,$$

where R = H, CH_3.

On silylation with CTMS in the presence of pyridine and formamide, glutamic acid gives rise only to the mono-*O*-trimethylsilyl derivatives, because (according to the authors) the amino-group and the second carboxy-group form an inner salt[113].

Ruhlmann[114] obtained trimethylsilyl-substituted aminoacids by treating alkali metal salts of the aminoacids with CTMS and triethylamine. He then isolated fully trimethylsilylated glycine, alanine, phenylalanine, and ϵ-aminocaproic, *p*-aminobenzoic, anthranilic, and glutamic acids. Treatment of glycine, alanine, and isoleucine hydrochlorides with CTMS and triethylamine led to the formation of the corresponding *NO*-bis(trimethylsilyl) derivatives of the aminoacids[115].

6. Silylation of Peptides

Like aminoacids, peptides have been silylated by treatment with CTMS,[111] hexamethyldisilazane[116], silylamines[117], and silylamides[104]. Both the carboxy- and amino-groups were silylated in the resulting products. When hexamethyldisilazane was used, only dioxopiperazines were isolated from the reaction mixture[116].

7. Silylation of Ketoximes and Aldoximes

These compounds are silylated by CTMS in pyridine[118-120]:

$$RR'C{=}NOH + (CH_3)_3SiCl \xrightarrow{C_5H_5N} RR'C{=}NOSi(CH_3)_3$$
$$R{=}R'{=}CH_3;\ R{=}R'{=}\text{iso-}C_5H_7;\ R{=}C_6H_5,\ R'{=}CH_3;$$
$$R{=}H,\ R'{=}CH_3;\ R{=}H,\ R'{=}C_6H_5;\ R{=}H,$$
$$R'{=}o\text{-}C_6H_4OH;\ R{=}H,\ R'{=}o\text{-}(CH_3)_3SiOC_6H_4.$$

8. Silylation of Hydroxylamine

When hydroxylamine is silylated by an equimolar amount of CTMS, *O*-trimethylsilylhydroxylamine is formed[121]. When the reaction is carried out in the presence of triethylamine and an excess of CTMS, the product is *NO*-bis(trimethylsilyl)hydroxylamine[121]:

$$NH_2OH + 2(CH_3)_3SiCl \xrightarrow{(C_2H_5)_3N} (CH_3)_3SiNHOSi(CH_3)_3.$$

The second hydrogen atom at the nitrogen atom can be substituted by the trimethylsilyl group only via the lithio-derivative[121]:

$$(CH_3)_3SiNH \xrightarrow[OSi(CH_3)_3]{C_4H_9Li} (CH_3)_3SiNOSi(CH_3)_3 \xrightarrow[Li]{(CH_3)_3SiCl} [(CH_3)_3Si]_2NOSi(CH_3)_3.$$

When CTMS was allowed to react with *O*- and *N*-alkyl derivatives of hydroxylamine, products with both one and two hydrogen atoms substituted by the $(CH_3)_3Si$ group were obtained[122].

¶*O*-Trimethylsilyl derivatives of aminoacids can be obtained by treating the *NO*-bis(trimethylsilyl) derivatives with ammonia of the free aminoacid[107].

9. Silylation of Hydrazines

When *O*- and *N*-alkyl derivatives of hydroxylamine are treated with CTMS, the product is 1,2-bis(trimethylsilyl)-hydrazine[123,124]. Under more severe conditions, a mixture of 1,2- and 1,1-bis(trimethylsilyl)hydrazines is isolated[124-126]. It has been suggested[124] that both isomers are formed as a result of the interaction of CTMS with intermediate monosilylated hydrazine. It has also been found that 1,2-bis(trimethylsilyl)hydrazine rearranges to 1,1-bis(trimethylsilyl)hydrazine in boiling benzene in the presence of N_2H_4.HCl or triethylamine.

1-Methyl-2-trimethylsilylhydrazine was obtained from methylhydrazine and CTMS.[127] Other trimethylsilyl derivatives of hydrazine were synthesised from this compound[126]:

$$CH_3NHNHSi(CH_3)_3 \xrightarrow[2.(CH_3)_3SiCl]{1.C_4H_9Li} CH_3N[Si(CH_3)_3]NHSi(CH_3)_3 + CH_3NHN[Si(CH_3)_3]_2.$$

On heating above 100°C in the presence of $N_2H_3(CH_3)$.HCl, the resulting mixture isomerises[127]:

$$(CH_3)_3SiN(CH_3)NHSi(CH_3)_3 \rightleftarrows CH_3NHN[Si(CH_3)_3]_2 .$$

10. Silylation of Acetylenes

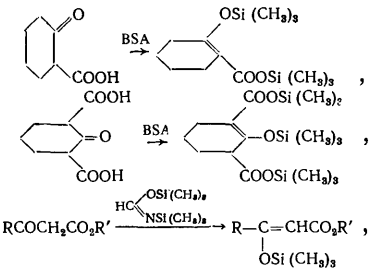
The silylation of free acetylenes has not been described, but there have been a number of studies dealing with the silylation of lithium, sodium, or magnesium derivatives of acetylenes by trialkylhalogenosilanes. Since it is comparatively difficult to remove the trialkylsilyl group from the acetylene silylation products, the term "silylation" is not used in the present sections strictly in the sense employed elsewhere in the review. However, since silylation is nowadays widely used to protect the terminal C≡C bond in order to use the resulting derivatives as intermediates in organic synthesis, we thought it desirable to include some information on this problem. The main data on the silylation of acetylenes up to 1960 have been compiled in a monograph[128]. Later a series of studies dealing with the silylation of metallated arylacetylenes (see for example, Eaborn et al.[129]), halogenoacetylenes[130], and unsubstituted acetylene (see, for example, Eastmond and Walton[131] and Krüerke[132]) were carried out.

11. Silylation of Ambident Systems

Bearing in mind the appreciable hardness of silyl cations[133], the interaction of silylating agents with ambident compounds may be expected to result in the silylation of the hardest anionic centre in these systems. However, in view of the relative lability of the silicon–element bonds, one can also postulate that both kinetically and thermodynamically favoured products of the silylation reaction should be detected in this case.

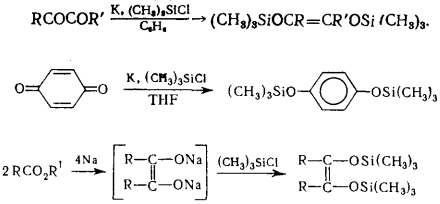
Silylation of ketones. As already mentioned, when carbonyl compounds are treated with a mixture of *N*-trimethylsilylimidazole with BSA and CTMS at an elevated temperature, the hardest centre in the ambident system—the oxygen atom—is silylated[74,77].

Silylation of α- and β-keto-acids and β-ketoacid esters. When these compounds were silylated by *NO*-bis(trimethylsilyl)amides, the corresponding *O*-trimethylsilyl derivatives were obtained[10,80]:

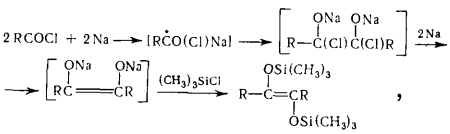


where R = CH_3, C_6H_5, or CH_3OCOCH_2 and R′ = CH_3 or C_2H_5.

Silylation of *O*- and *C*-metallo-derivatives of carbonyl compounds. The silylation of enolates usually leads to the formation of *O*-silylated products. When hydroxyketones[134], diketones[135], and carboxylic acid esters and chlorides[136-140] react with CTMS in the presence of alkali metals, it is suggested that the corresponding enolates are formed initially and then give rise to *O*-silylation products having the general formula $R'C[OSi(CH_3)_3]=CR[OSi(CH_3)_3]$, where R and R′ are alkyl substituents in the initial compounds. Several examples of this reaction are given below:

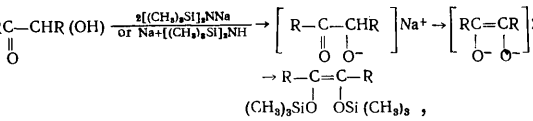


where R = CH_3, C_2H_5, C_3H_7, iso-C_3H_7, n-C_4H_9, $(CH_3)_2CH(CH_2)_2$, or n-C_7H_{15} and R′ = C_2H_5 or n-C_4H_9;



where R = H, CH_3, C_2H_5, or C_3H_7.

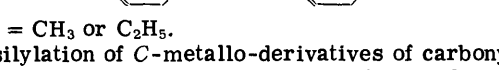
The sodium salt of hexamethyldisilazane may be used to synthesise *O*-metallo-derivatives of α-hydroxyketones[134]:



where R = H, CH_3, C_6H_5 or β-furyl and R′ = H, CH_3, C_6H_5, or β-furyl.

The interaction of carbonyl compounds capable of enolisation with the sodium salt of hexamethyldisilazane or of sodium enolates of carbonyl compounds with CTMS leads to the corresponding *O*-trimethylsilyl derivatives[71,141]. The reactions of alkyl- and alkylalkoxy-halogenosilanes with the sodio-derivatives of acetoacetic ester[142-144] or acetylacetone[145] leads to the formation of the corresponding *O*-silylated derivatives. The exchange reaction

of trialkylchlorosilanes with tributylstannoxycyclohex-1-ene provides a convenient method for synthesising trialkylsiloxycyclohex-1-enes[146,147]:



where R = CH_3 or C_2H_5.

The silylation of *C*-metallo-derivatives of carbonyl compounds also involves the formation of *O*-silylated products[148-151]. The reaction of *C*-metallo-derivatives of acetone with trialkylhalogenosilanes led to the formation of the corresponding alkoxysilanes[72,151]:

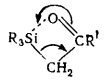
$$R_M CH_2COCH_3 \xrightarrow{R_3SiHal} CH_2=C(CH_3)OSiR_3 + R_MHal,$$

where R_M = $HgCH_2COCH_3$, HgCl, HgI, $(C_4H_9)_3Sn$, $(C_3H_7)_3Sn$, or $(C_3H_7)_3Ge$, R = CH_3, C_2H_5, or C_3H_7, and Hal = Cl, Br, or I.

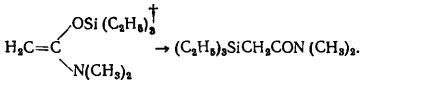
When trialkylhalogenosilanes were allowed to react with α-metallated carboxylic acid esters, only the *O*-silylation products were also isolated[72,151,152]:

$$(C_2H_5)_3SiI + Hg(CH_2COOCH_3)_2 \rightarrow CH_2=C(OCH_3)OSi(C_2H_5)_3 + HgCH_2COOCH_3;$$
$$(C_2H_5)_3SnCH_2COOCH_3 + (C_2H_7)_3SiI \rightarrow (C_2H_5)_3SnI + CH_2=C(OCH_3)OSi(C_3H_7)_3.$$

There is an equilibrium between the *O*- and *C*-silyl derivatives of carbonyl-containing compounds, which is usually displaced towards one of the products[150]. Isomerisation of silyl derivatives of carbonyl-containing systems can be an intramolecular[153-155] or an intermolecular[153,156] process. Since in the former case the optical configuration at the silicon atom is retained[155], it has been suggested that the reaction proceeds via a four-unit cyclic transition state:



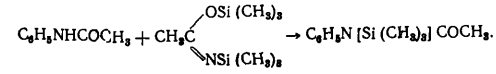
Intermolecular isomerisation is accelerated by trialkyliodosilanes or mercury salts[153-156]. The rate of isomerisation and the equilibrium position depend on the nature of the carbonyl compound and the substituents at the silicon atom. The introduction of electronegative substituents at the silicon atom facilitates the conversion into *C*-silylated products[157]. Substituents at the carbonyl group with a positive mesomeric effect also promote the rearrangement of *O*-derivatives into *C*-derivatives[158]:



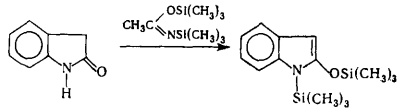
O-Silyl-derivatives are comparatively more favoured by thermodynamic factors, probably because of the $(p-d)\pi$ interaction between the oxygen and silicon atoms[150].

Silylation of amides, ureas, and urethanes. The silylation of amides has already been discussed. It was noted that the formation of these products is reasonable on thermodynamic grounds. Depending on the nature of the substituents at the carbonyl groups and at the nitrogen atom, the amide or imide form of the products predominates or their equilibrium mixture is formed.

In addition we may quote the study by Klebe et al.[100], who showed that amides can be silylated by BSA:



Under these conditions oxindole is immediately converted into the bis(trimethylsilyl) derivative[100]:



The silylation of phenyl esters of phosphoramidic acids with the aid of hexamethyldisilazane or methyltrimethylsilylamine yielded the corresponding trimethylsilyl derivatives[30,159]:

$$RN[Si(CH_3)_3]H + (NH_2)_nP(O)(OC_6H_5)_{3-n} \rightarrow [(CH_3)_3SiNH]_nP(O)(OC_6H_5)_{3-n},$$

where R = CH_3 or $Si(CH_3)_3$ and n = 1 or 2.

Some data on the silylation of ureas were presented above. Only the *N*-silylation products have been isolated. In addition to the foregoing, we may mention that urea can be silylated also by hexamethyldisilazane[88]:

$$CO(NH_2)_2 + [(CH_3)_3Si]_2NH \rightarrow [(CH_3)_3SiNH]_2CO + NH_3.$$

Mono-*N*-trimethylsilyl derivatives have also been obtained by treating the corresponding ureas with BSA.[100]

A number of studies have been made on the silylation of various urethanes by CTMS in the presence of triethylamine[160-162]:

$$RNHCOOR' \xrightarrow[(C_2H_5)_3N]{(CH_3)_3SiCl} RN[Si(CH_3)_3]COOR',$$

where R = alkyl[160,161] or C_6H_5 [162] and R' = CH_3, [160] $(CH_3)_3Si$, [161] or C_2H_5. [162] Kricheldorf[162] demonstrated rigorously by spectroscopic investigations that the products isolated are exclusively *N*-trimethylsilyl derivatives.

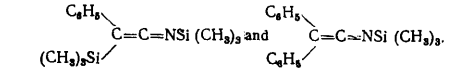
Silylation of compounds in which the mobile hydrogen atom has been replaced by a metal. When halogenosilanes react with silver cyanide[163-165], mixtures of silyl-substituted cyanides and isocyanosilanes, in equilibrium with one another, are formed. According to infrared spectroscopic data[166], the cyanide formed predominates the usual temperature, but with increase of temperature its content in the mixture falls.

The silylation of the corresponding silver salts by bis(trimethylsilyl) sulphide yielded $(CH_3)_3SiNC$ and $(CH_3)_3SiNCO$.[34] Trimethylsilyl nitrite is formed from silver nitrite and CTMS.[167]‡ The reaction of CTMS with silver cyanamide yields *NN*-bis(trimethylsilyl)carbodiimide, $(CH_3)_3SiN=C=NSi(CH_3)_3$, which is isomeric with cyanohexamethyldisilazane[169].

The tris(trimethylsilyl) derivative was obtained from the trisodium salt of acetonitrile and CTMS:[140]

$$Na_3[N\equiv C-C \leftrightarrow C=C=N] \xrightarrow{(CH_3)_3SiCl} [(CH_3)_3Si]_2C=C=N-Si(CH_3)_3.$$

The corresponding trimethylsilylated products were isolated similarly after the reaction of the sodium salts of phenylacetonitrile and diphenylacetonitrile with CTMS:[140]



Similar results were obtained by Klebe[170] in the silylation of malonotrile.

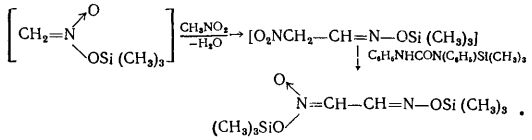
†H_2C = $CNR'_2(OSiR_3)$ is obtained by the interaction of $R_3SiNR'_2$ with keten[158].

‡ $(CH_3)_3SiONO_2$ was obtained similarly[168].

Silylation of diazoacetic ester. Schollkopf and coworkers[171,172] obtained diazo-*C*-trimethylsilylacetic ester by the interaction of diazoacetic ester salts with CTMS or bis(trimethylsilyl) sulphide:

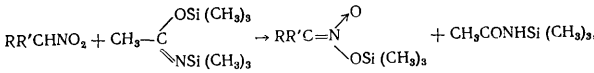
Silylation of nitro-compounds. Since nitro-compounds exhibit a dual reactivity[153], the formation of *O*-silylation products may be expected in their silylation reactions.

After allowing nitromethane to react with *NN'*-diphenyl-*N*-trimethylsilylurea, Klebe[170] isolated the bis(trimethylsilyl) derivatives of methazonic acid. The author suggests that this product is formed via the intermediate trimethylsilyl ester of methanenitronic acid:

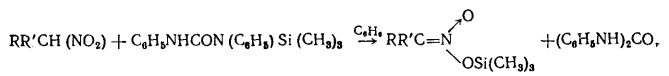


After the reaction of nitromethane with CTMS in pyridine, Manzur and Zamudio[174] isolated hexamethyldisiloxane, which they believe is also formed via the intermediate trimethylsilyl ester of methanenitronic acid. However, no evidence is adduced[170,174] in support of the formation of this intermediate.

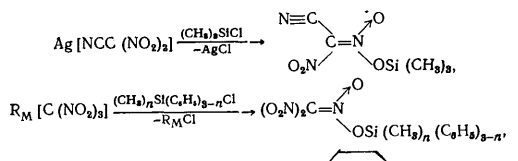
The first clear-cut experimental confirmation of the *O*-silylation of nitro-compounds was obtained by Tartakovskii and coworkers[155-159]. On silylation of nitroalkanes (nitromethane, nitroethane, etc.) by BSA, these investigators isolated (or detected) the trimethylsilyl esters of the corresponding alkanenitronic acids in nearly quantitative yields[175]:



where R = R' = H (20°C)§, R = CH_3 and R' = H (60°C), R = C_2H_5 and R' = H (80°C), R = R' = CH_3 (100°C), or R = C_6H_5 and R' = H (20°C). *O*-Trialkylsilyl derivatives of aliphatic nitro-compounds with other functional groups have been obtained by treating the free nitro-compounds with *NN'*-diphenyl-*N*-trimethylsilylurea[176-179]:



where R = R' = $COOCH_3$, R = $COOCH_3$ and R' = H, R = NO_2 and R' = H, or R = R' = NO_2, or by the interaction of the silver or mercury salts of the nitro-compounds with alkylchlorosilanes[176-179]:

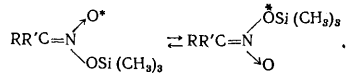


where n = 0, 1, or 3 and R_M = Ag.  or n = 3 and R_M = $Hg[C(NO_2)_3].CH_3NO_2$.

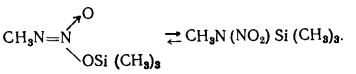
§ The silylation temperature is indicated in brackets.

The structure of the silyl esters of nitronic acids has been confirmed by making them undergo the 1,3-dipolar cycloaddition reaction with olefins and also by infrared, ultraviolet, and NMR spectroscopic data[176-180].

It has been shown[180] that there is a rapid intramolecular exchange of the $(CH_3)_3Si$ group between the oxygen atoms in the  fragment:



The silylation of methylnitramine by methyltrimethylsilylamine, BSA, or *NN'*-diphenyl-*N*-trimethylsilylurea as well as the silylation of the silver salt of methylnitramine by CTMS leads to a tautomeric mixture of *O*- and *N*-trimethylsilyl derivatives of methylnitramine[181]:



The presence of tautomers is indicated by low-temperature NMR data for the products[182]. It has been shown that, with increase of temperature, the equilibrium is displaced towards the *O*-trimethylsilyl derivative. The introduction of bulky substituents at the silicon atom has the same influence on the equilibrium position[182].

---o0o---

The present review does not have as its aim the discussion of the problem of the applications of trimethylsilyl derivatives in organic synthesis. However, it is necessary to emphasise yet again that silylation makes it possible to expand significantly and modify the sphere of applications of particular products in organic reactions.

As examples, one can quote the interaction of silyldiamines with phosgene[87,183], the use of trimethylsilyl azide in the synthesis of tetrazoles[184,185], the thermal decomposition of silylated urethanes with formation of isocyanates[161], and the involvement of nitroalkane derivatives in dipolar 1,3-cycloaddition[178]. Furthermore, the uses of silyl derivatives in peptide synthesis[1,5] and in the synthesis of nucleosides and nucleotides[186] have been examined in detail.

Indolizines

N.S.Prostakov and O.B.Baktibaev

The methods of synthesis and properties of indolizines—bicyclic condensed heterocylic compounds with a bridgehead nitrogen atom—are examined. The bibliography includes 201 references.

III. Properties of indolizines 748

I. INTRODUCTION

The studies on indolizines, which have been fairly vigorously prosecuted in recent years, are associated with the development of methods of synthesis and the investigation of this condensed system of pyridine and pyrrole with a bridgehead nitrogen atom as well as the search for physiologically active substances among indolizine derivatives.

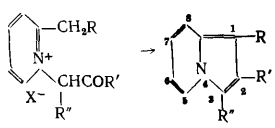
At the present time the chemistry of indolizines constitutes a fairly thoroughly investigated branch of the chemistry of heterocyclic compounds, which was founded by Scholtz and Chichibabin. Scholtz was the first to obtain 1,3-diacetylindolizine from α-picoline and acetic anhydride. He then converted it into indolizine (pyrrocoline).[1-4] Chichibabin elucidated the mechanism of this reaction[5,6]. He also developed one of the general and most convenient methods for the synthesis of indolizines from 2-methyl-*N*-β-oxoalkylpyridinium salts[7,8].

The chemistry of indolizines has been reviewed by Borrows and Holland[9] and a chapter in Mosby's monograph[10] is devoted to it. The present review surveys data on individual sections of indolizine chemistry and deals with recent studies which yielded new information both about the methods of synthesis and properties of indolizines.

II. SYNTHESIS OF INDOLIZINES

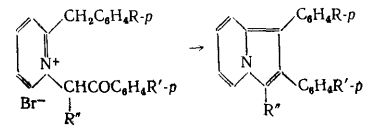
The Preparation of Indolizines from 2-Alkyl-*N*-(β-oxoalkyl)pyridinium Salts (The Chichibabin Method)

The closure of the five-membered ring of the indolizine system takes place on treating the salts formed from α-picoline (α-picoline substituted in the methyl group) and α-halogenoketones with sodium bicarbonate and certain other bases in aqueous, alcoholic, or acetone solutions:



Chichibabin obtained in this way 2-methyl, 2-phenyl, 2,5-dimethyl-, and 2-methyl-1-phenylindolizines[7,8].

This reaction was carried out both with and without isolation of the corresponding pyridinium salts. When α-bromoketones are used, substituted indolizines are formed in high yields—up to 90% for aryl-substituted derivatives[7,8,11-15]. A series of indolizines where the 2-position is occupied by a substituted phenyl or naphthyl group (with alkyl, halogeno-, nitro-, amino-, hydroxy-, alkoxy-, alkylthio-, phenylthio-, and other substituents)[16-26] as well as the *p*-arylphenyl[27], *p*-cyclohexylphenyl[28], 2-thienyl[29], 5-aryl-2-thienyl[30], *m*-(2,5-dimethylpyrrolyl)phenyl[31], 9-ethyl-3-carbazolyl[32], 2-dibenzofuryl[33], and 3-phenoxathiinyl[34] groups were obtained by this method, which was also used to synthesise 4,4-di-(2-indolizinyl)biphenyl from α-picoline and 4,4-di-(ω-bromoacetyl)biphenyl[35]. Indolizines with a methyl group in the 1-position were obtained from α-ethylpyridine[36,37]. α-Benzylpyridines with substituents in the benzene ring were used to synthesise 1,2-diaryl- and 1,2,3-triarylindolizines[38,39]:



In the synthesis of indolizines of this type quaternisation products were isolated[12,14]. It was not possible to isolate the quaternary salt formed from α-halogenoketones and 2-*p*-chlorobenzylpyridine, since it cyclises spontaneously to the corresponding substituted indolizine[38,40].

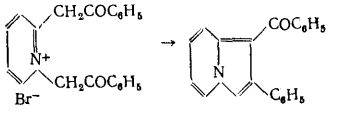
Only a limited number of studies have been made on the synthesis by this method of indolizines with substituents in the six-membered ring owing to the comparatively low availability of substituted α-picolines. 2,5-Dimethylindolizine was obtained by Chichibabin from αα′-lutidine and bromoacetone[7]. 2,6-Dimethyl-7-phenyl- and 6-methyl-2,7-diphenyl-indolizines[41], were obtained from 2,5-dimethyl-4-phenylpyridine[42]. 7-Benzyloxy-5-methyl-2-phenylindolizine was obtained in a very low yield from 4-benzyloxy-2,6-dimethyl-*N*-phenacylpyridinium bromide[43]. In the synthesis of 8-ethoxycarbonyl-2-methylindolizine (in 30% yield) ethyl 2-methylnicotinate and bromoacetone were used; the conversion of the resulting ester into 2-methylindolizine-8-carboxylic acid has been described[44].

Indolizines are formed from α′-substituted α-picolines in a lower yield than from α-picoline itself owing to steric hindrance due to the substituents at the $C_{(6)}$ atom of the pyridine ring[36]. A similar influence on the yield of indolizines was discovered for the sterically hindered

carbonyl group in halogenoketones[14,15,25]. The corresponding indolizine could not be synthesised from α-picoline and ω-bromo-4-(t-butyl)-2,6-dimethylacetophenone or ω-bromo-6-methoxy-2,4-dimethylacetophenone[25].

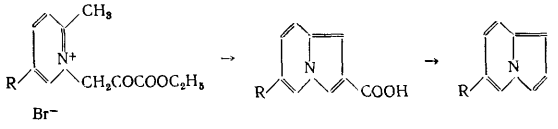
Vinylindolizines—2,3-dimethyl-6-vinyl- and 2-methyl-6-vinyl-derivatives—were obtained from 2-methyl-5-vinylpyridine and α-bromoethyl methyl ketone and bromoacetone respectively. The latter indolizine is resistant to polymerisation and oxidation in air[45,46]. 2-Methyl-5-vinylindolizine could not be isolated, because it polymerises during the reaction[47].

The synthesis of many indolizines with functional groups was achieved by the Chichibabin method. 1-Acetylindolizine could not be obtained from 2-acetonylpyridine and bromoacetophenone, because the corresponding quaternary salt is not formed[48]. However, 1,2-diphenacylpyridinium cyclises exclusively with formation of 1-benzoyl-2-phenylindolizine[49,50]:

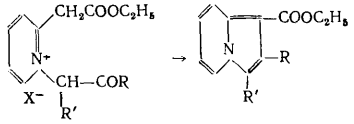


2-(*o*-Acetamidophenyl)-1-acetyl-indolizine was obtained in a yield of more than 40% by the cyclisation of 1-(*o*-acetamidophenacyl)-2-acetonyl-pyridinium salts[51]. 6-Ethoxycarbonyl(carbamoyl, cyano)-2-methyl- and 7-acetamidomethyl(cyano)-2-methyl-indolizines substituted in the six-membered ring were obtained by the cyclisation of 1-acetonyl-2-methylpyridinium bromides with the corresponding substituents in the pyridine ring[52].

Several versions of the synthesis of indolizinecarboxylic acids with carboxy-groups in the five-membered ring have been developed. The cyclisation of the quaternary salt formed from α-picoline and ethyl bromopyruvate gives a 30% yield of indolizine-2-carboxylic acid[14,53]. 6-Ethylindolizine-2-carboxylic acid was obtained in the same way from 5-ethyl-2-methylpyridine[54]. Indolizine[55,56] and 6-ethylindolizine were obtained by the decarboxylation of these acids[53]:



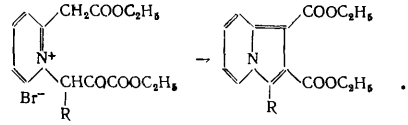
The cyclisation of the quaternary salts obtained from 2-ethoxycarbonylmethylpyridine and α-halogeno-substituted aldehydes and ketones leads to indolizine-1-carboxylic acids[57,58]. The above pyridine base and chloroacetone were used to synthesise 2-methylindolizine-1-carboxylic acid[59]. Salts obtained from the same pyridine base were used in the analogous condensation reaction with bromoacetaldehyde, α-bromopropionaldehyde, and bromophenylacetaldehyde. The corresponding indolizine-1-carboxylic acids are formed in comparatively low yields in the above reactions[49,57]:



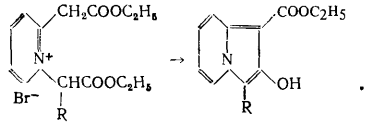
R=CH_3, R′=H; R=R′=H; R=H, R′=CH_3; R=H, R′=C_6H_5.

The synthesis of the methyl ester of 2-(*o*-acetamidophenyl)indolizine-1-carboxylic acid from 1-(*o*-acetamidophenacyl)-2-methoxycarbonylmethylpyridinium bromide has been described[60]. 1-Acetonyl-2-β-ethoxycarbonylethylpyridinium bromide and its analogue with a methoxy-group in the 4-position have been cyclised to 1-ethoxycarbonylmethyl-2-methyl- and 1-ethoxycarbonylmethyl-7-methoxy-2-methyl-indolizines. 1-(α-Ethoxycarbonylethyl)-2-methylindolizine was obtained from 2-(β-ethoxycarbonylpropyl)pyridine and bromoacetone in acetone, after which it was successively acetylated (benzoylated) at $C_{(3)}$ and then hydrolysed to 3-acetyl-(benzoyl)-1-(α-carboxyethyl)-2-methylindolizine[61]. The cyclisation of 2-(β-carbamoylethyl)-1-phenacylpyridinium bromide results in the formation of 1-carbamoylmethyl-2-phenylindolizine[43].

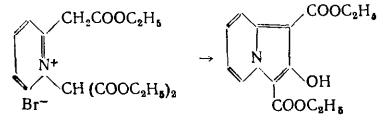
The diethyl ester of indolizine-1,2-dicarboxylic acid is formed in 95% yield in the Chichibabin cyclisation of the pyridinium salt obtained from 2-ethoxycarbonylmethylpyridine and bromopyruvic acid[49]. 2-Methoxycarbonylmethylpyridine was used in a similar condensation[58]. The esters of indolizine-1,2-dicarboxylic acids were also obtained with substituents in the 3-position[57]:



The reactions of quaternary salts formed from 2-ethoxycarbonylmethylpyridine and α-bromopropionate and bromophenylacetate esters are examples of syntheses of hydroxy-acids of the indolizine series. The ethyl esters of 2-hydroxy-3-methyl(phenyl)indolizine-1-carboxylic acids were obtained in this way[49].



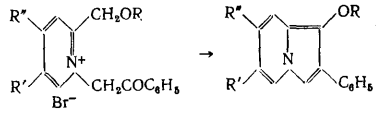
When the cyclisation is carried out in ether, the ethyl ester of 2-hydroxyindolizine-1-carboxylic acid is formed from 1,2-di(ethoxycarbonylmethyl)pyridinium bromide. When this reaction is carried out in the absence of a solvent, the ethyl esters of 3-ethoxycarbonylmethyl-2-hydroxyindolizine-1-carboxylic acid and 3-(1-ethoxycarbonyl-2-indolizinyl)-2-hydrozyindolizine-1-carboxylic acid are formed as a result of secondary reactions[49]. The diethyl ester of 2-hydroxyindolizine-1-carboxylic acid was obtained from 2-ethoxycarbonylmethylpyridine and bromomalonic ester[49]:



Indolizines with a cyano-group in the 1-position were obtained by the cyclisation of quaternary salts derived from 2-cyanomethylpyridine with α-bromoketones[49,62]. The ethyl ester of 3-cyano-2-methylindolizine-1-carboxylic acid was synthesised from 1-(α-cyanoacetonyl)-2-ethoxycarbonylmethylpyridinium bromide[63].

When 2-hydroxymethyl-1-phenacyl- or 2-acetoxymethyl-1-phenacyl-pyridinium bromide is treated with sodium bicarbonate, the product is 1-hydroxy-2-phenylindolizine—an unstable compound which rapidly darkens in air[63]. The cyclisation of 1-acetonyl(phenacyl)-2-ethoxymethyl-(phenoxymethyl)-5-methyl-4-phenylpyridinium bromide

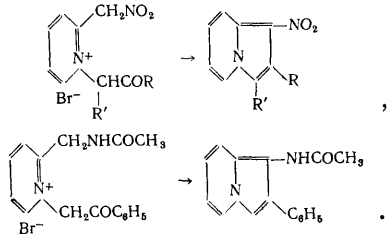
gave the corresponding substituted indolizines with an ethoxy- or phenoxy-group in the 1-position[41]:



R=R′=R″=H; R=C_2H_5, R′=CH_3, R″=C_6H_5; R′=CH_3, R=R″=C_6H_5.

An instance of the synthesis by the Chichibabin method of an indolizine with the hydroxymethyl group in the five-membered ring has been described. 1-Hydoxymethyl-2-methylindolizine was obtained in high yields by the cyclisation of 1-acetonyl-2-(β-hydroxyethyl)pyridinium bromide in sulpholan[52]. However, the cyclisation of 2-(β-hydroxypropyl)-1-phenacylpyridinium resulted in the formation of 2-phenylindolizine instead of the expected hydroxyalkylindolizine. It has been suggested that the hydroxyethyl group is split off during the reaction as a result of retro-aldol condensation[48].

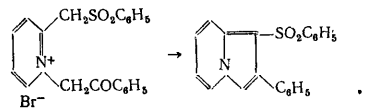
3-Nitroso-2-phenylindolizine is formed in the cyclisation of an α-picolinium salt with ω-chlorohydroxyimine-acetophenone[64]. The cyclisation of quaternary salts obtained from 2-nitromethylpyridine (hydrate) and bromoacetaldehyde, bromophenylacetaldehyde, bromoacetone, and bromoacetophenone results in the formation of 1-nitroindolizines in yields up to 50%.[63] 1-Acetamido-2-phenylindolizine was obtained in the same way from 2-acetamidomethyl-1-phenacylpyridinium bromide[63]:



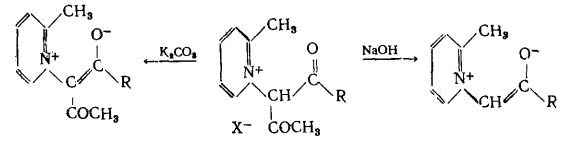
When 1-[2-(2-furyl)-1-isonitroso]-2-oxoethyl-2-picolinium chloride was treated with a 30% sodium hydroxide solution, 2-(2-furyl)-3-nitrosoindolizine was obtained in 87% yield[65].

A number of 1-aminomethyl-, 1-(β-aminoethyl)-, and 1-(γ-aminopropyl)-2-phenylindolizines with CH_3, $(CH_3)_2$, $COOC_2H_5$, and $CON(C_2H_5)_2$ substituents in the amino-group have been synthesised. The quaternary salts obtained from bromoacetophenone and the corresponding pyridines with ω-aminoalkyl-substituted amino-groups in the α-position were cyclised. Indolizines of this type with an alkylated amino-group were obtained by the reduction of an alkylcarbamoyl group with lithium tetrahydroaluminate after ring closure[50,66].

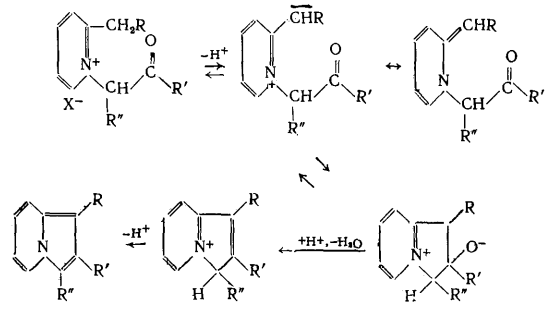
A sulphur-containing indolizine, phenyl 2-phenyl-1-indolizinyl sulphone, was synthesised from phenyl 2-picolinyl sulphone and bromoacetophenone[54,67]:



The mechanism of the formation of indolizines by the Chichibabin method has not as yet been fully elucidated. It has been discussed in detail by Bragg and Wibberley[49]. One of the initial factors serving as a basis for conclusions concerning the mechanism of this reaction was the difficulty encountered in the synthesis of certain indolizines by the Chichibabin method. It was not possible to cyclise salts obtained from α-picoline and α-chloroacetylacetone, α-bromobenzoylacetone, and ethyl α-bromobenzoylacetate[14,53]. Under the conditions of the cyclisation reaction, these salts, which are formed with difficulty, are converted into "enol-betaines". Then, depending on the nature of the salt and the base employed, either the acyl (ester) group splits off ("acid cleavage") or the enol-betaine is retained[68-72]:

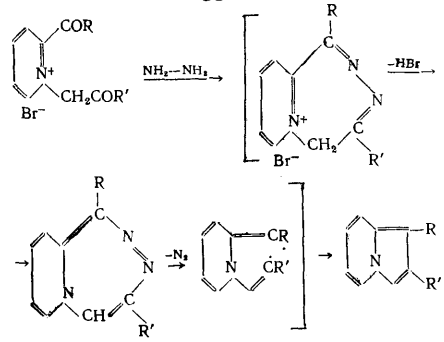


It has been suggested that fairly stable enol-betaines cannot cyclise and that indolizines are formed via a stage involving the condensation of the 1,3-ylid formed from the pyridinium salt when the latter is treated with a base[49]:



The formation of the ylid is facilitated when the substituent at the methyl group (at the carbon atom in the 2-position) has electron-accepting properties; it is also promoted by the use of sodium bicarbonate. The ylid cyclises intramolecularly via a reaction of the aldol type; the subsequent elimination of water from the betaine formed under these conditions followed by irreversible dehydrogenation of the 3*H*-indolizinium cation results in the formation of a substituted indolizine. Another hypothesis concerning the conversion of the ylid into a cyclic betaine has also been put forward: the methine obtained from the ylid cyclises[44].

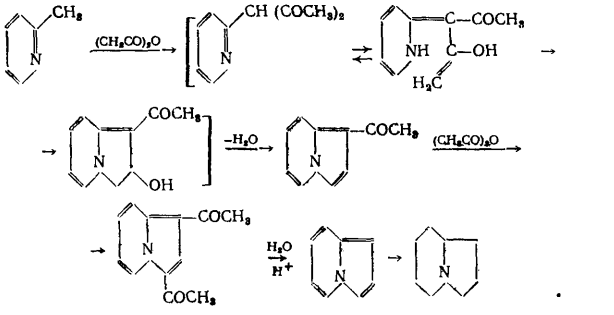
Hitherto the Chichibabin method has been one of the fundamental procedures for the synthesis of various indolizines. 1,2-Disubstituted indolizines, described by Kröhnke and Weis[73], were obtained by a different method from 2-acyl-1-(β-oxoalkyl)pyridinium salts. They were synthesised from 1-acetonyl(phenacyl)-2-acetyl(benzoyl)-pyridinium bromides and hydrazine hydrate. The following mechanism has been suggested for these reactions:



1,2-Disubstituted indolizines with a methyl or phenyl group in the 1-position and with a methyl or aryl group in the 2-position were synthesised by this method.

The Synthesis of Indolizines from α-Picoline (Substituted in the Methyl Group) and Acetic or Propionic Anhydride (the Scholtz Method)

The mechanism of the formation of 1,3-diacetylindolizine from α-picoline and acetic anhydride as well as the structure of the indolizine were elucidated by Chichibabin[1-7,74]:



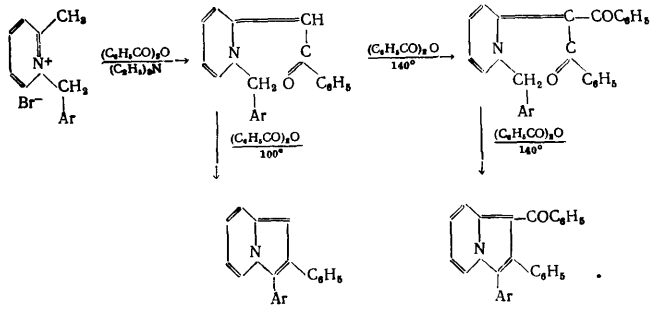
α-Picoline is acetylated to 2-diacetylmethylpyridine, the cyclisation of a tautomeric form of which gives rise to 1-acetyl-2-hydroxy-2,3-dihydroindolizine. Further dehydration leads to 1-acetylindolizine and the latter is acetylated to 1,3-diacetylindolizine. Deacetylation takes place on acid hydrolysis. Indolizine has been converted by catalytic hydrogenation into octahydroindolizine—δ-coniceine[55].

1,3-Diacetyl-5-methyl- and 1,3-diacetyl-5-phenylindolizines were obtained by the Scholtz method from the corresponding substituted α-picolines[3,75]. Only propionic anhydride as well as acetic anhydride can be used in this reaction[4,76]. The structure of the resulting 3-methyl-1-propionylindolizine was demonstrated by acetylating it to 3-methylindolizine[11].

The synthesis of 3-acetyl-1-(*p*-chlorophenyl)indolizine from 2-(*p*-chlorophenyl)methylpyridine by this method has been described[77]. 1-Acetyl-3-ethoxyindolizine were obtained by heating ethoxymethyl α-picolinyl ketone with acetic anhydride[78].

The Synthesis of Indolizines from 2-Alkyl-1-Benzylpyridinium Salts

When 1-benzyl-2-methylpyridinium salts are treated with acetic, propionic, or benzoic anhydrides in the presence of bases (for example triethylamine), the five-membered ring is closed at the $C_{(2)}-C_{(3)}$ bond, resulting in the formation of substituted indolizines. When the reaction is carried out at 100°C, 2,3-disubstituted indolizines are formed and at 140°C also 1,2,3-trisubstituted indolizines:



The pyridinium salt is benzoylated at the α-methyl group with simultaneous elimination of hydrogen bromide. This results in the formation of 2-benzoylmethylene-1-benzyl-1,2-dihydropyridine substituted in the benzene ring of the benzyl group. Its cyclisation at 100°C, which is an intramolecular aldol condensation, leads to the formation of 3-aryl-2-phenylindolizine. When the reaction is performed at 140°C, the methine derivative is benzoylated to 2-dibenzoylmethylene-1-benzyl-1,2-dihydropyridine, the cyclisation of which leads to 3-aryl-1-benzoyl-2-phenylindolizine. Since direct benzoylation of 3-aryl-2-phenylindolizine can be achieved only at 200°C, it is believed that a dibenzoylmethine derivative is formed as an intermediate in the above reactions[50,63,67,79,80]. In many cases monosubstituted methine derivatives were isolated and their conversion into indolizines was investigated. Methines are obtained on simultaneous acylation and dehydrohalogenation of 1-benzyl-2-methylpyridinium bromides[72,81,82].

1-Benzyl-2-phenacylidene-1,2-dihydropyridine was prepared in two ways: by the Schotten-Baumann benzoylation of 1-benzyl-α-picolinium bromide[81,83,84] and by the quaternisation of 2-phenacylpyridine[50,81]. On treatment with acetic anhydride in the presence of triethylamine, 2-benzoylmethylene- and 2-acetylmethylene-1-benzyl-1,2-dihydropyridine are converted in yields up to 90% into 1-acetyl-2,3-diphenyl- and 1-acetyl-2-methyl-3-phenylindolizines respectively[50,67]. Triethylamine can be successfully replaced in this reaction by sodium acetate[85]. When propionic anhydride was used in the first instance, the analogous indolizine with the propionyl group in the 1-position was obtained.

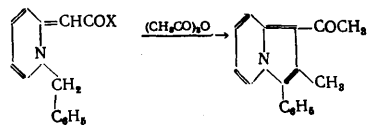
Methine derivatives are cyclised on being heated in formamide[79]. 6-Methyl-2,3,7-triphenylindolizine was obtained in this way from 1-benzyl-5-methyl-2-phenacylidene-4-phenyl-1,2-dihydropyridine; its cyclisation in the presence of acetic anhydride leads to its 1-acetyl-substituted analogue[82].

The corresponding indolizines with *p*-nitro- and *p*-chloro-phenyl groups in the 3-position were obtained, without the isolation of the methine derivatives, from 2-methyl-1-[*p*-nitro(*p*-chloro)]benzylpyridinium bromides and acetic or benzoic anhydride at 140°C with and without the acyl group in the 1-position in each case[79,80]. The influence on the yield of indolizines of the nature of the substituent in the *p*-position of the *N*-benzyl group which affects the reactivity of the *N*-methylene group was investigated. The following sequence of substituents in terms of increasing yields of indolizine caused by their introduction has been established: $p\text{-}NO_2C_6H_4 < C_6H_5 < p\text{-}CH_3OC_6H_4$.

1-Acetyl-2,3-dimethylindolizine was obtained in 9% yield from 1-ethyl-2-phenacylidene-1,2-dihydropyridine after heating for 12 h with acetic anhydride. The corresponding indolizine could not be obtained from 1-methyl-2-phenacylidene-1,2-dihydropyridine and benzoic anhydride. The product isolated in this case was 2-dibenzoylmethylene-1-methyl-1,2-dihydropyridine, which was also obtained by the direct benzoylation of 1-methyl-2-phenacylidene-1,2-dihydropyridine[80].

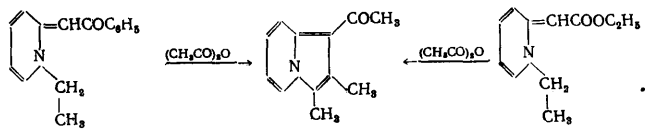
1,2,3-Triphenylindolizine[38] was synthesised by this method from 1,2-dibenzylpyridinium bromide and benzoic anhydride, while the use of acetic anhydride led to the isolation of 2-methyl-1,3-diphenylindolizine[79].

1-Acetyl-2-methyl-3-phenylindolizine is formed from 1-benzyl-2-cyanocarbonyl(carbamoyl, phenylcarbamoyl, acylcarbonyl)methylene-1,2-dihydropyridines and acetic anhydride[50]:

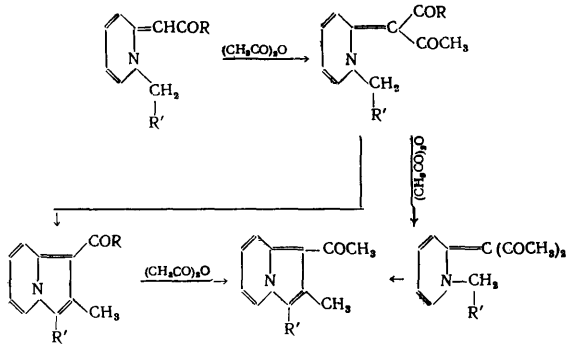


X=CN, NH_2, NHC_6H_5, COR.

1-Acetyl-2,3-dimethylindolizine was obtained similarly from 2-benzoyl(ethoxycarbonyl)methylene-1-ethyl-1,2-dihydropyridine:



It is believed that the first reaction stage is *C*-acetylation of the ketoenamine to a diacylmethine, which can then be converted into indolizine in two ways:



Initially the diacyl derivative undergoes transacylation and then cyclises. The second pathway involves the cyclisation of the diacylmethine derivative via the acetyl group followed by transacetylation at the 1-position. This is less likely because 1-ethoxycarbonyl- and 1-cyano-indolizines are stable in relation to acetic anhydride and ethoxycarbonyl and cyano-groups are not replaced by the acetyl group in these substances[50].

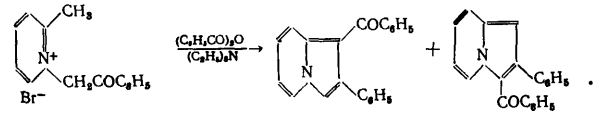
The occurrence of transacylation in the formation of indolizines from diacylmethines is confirmed to some extent by the following results obtained in the synthesis of indolizines from 1-benzyl-2-ethoxycarbonylmethylene-1,2-dihydropyridine[50,86]. When this methine was treated with acetic anhydride, 2-acetoxy-1-acetyl-3-phenylindolizine, 1-acetyl-2-methyl-3-phenylindolizine, and 1-ethoxycarbonyl-2-methyl-3-phenylindolizine were obtained in proportions of approximately 14 : 8 : 1. When this reaction was carried out in acetic acid, the ratios of the indolizines changed sharply and became 4 : 20 : 1. Thus the ethoxycarbonyl group is split off during the reaction (transacylation), which is promoted by an increase of the acidity of the medium[86].

Two methods have been described for the cyclisation of 1-(*p*-nitrobenzyl)-α-picolinium chloride to 3-(*p*-nitrophenyl)indolizine. This indolizine is formed in a low yield on heating the above picolinium salt with *s*-triazine in a pyridine–piperidine mixture; it is suggested that the intermediate in this reaction is 2-(β-aminovinyl)-1-(*p*-nitrobenzyl)pyridinium chloride. The second method involves heating the same picolinium salt in a pyridine–piperidine mixture with triethyl orthoformate: it is suggested that in this case the intermediate is 1-[β-ethoxy-α-(*p*-nitrophenyl)vinyl]-2-methylpyridinium chloride. 3-(*p*-Nitrophenyl)indolizine was obtained by the second method in 67% yield[87].

Synthesis of Indolizines from 2-Alkyl-1-(β-oxoalkyl)-pyridinium Salts and Acid Anhydrides

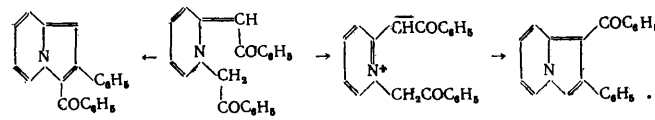
This method, as it were, combines two procedures for the synthesis of indolizines: their preparation by treating 2-alkyl-1-(β-oxoalkyl)pyridinium salts with bases and by treating 2-alkyl-1-benzylpyridinium salts with acid anhydrides, also in the presence of bases.

In one of these methods a 1-(β-oxoalkyl)pyridinium salt is treated with acetic anhydride in the presence of triethylamine. A mixture of 1-benzoyl-2-phenylindolizine and 3-benzoyl-2-phenylindolizine was obtained in this way in a satisfactory yield in proportions of 1 : 2 from 2-methyl-1-phenacylpyridinium bromide, benzoic anhydride, and triethylamine at 140°C.[44,79,80] The same indolizines were obtained in the same proportions when the initial pyridinium salt was treated with benzoic anhydride in the presence of sodium benzoate[44]:

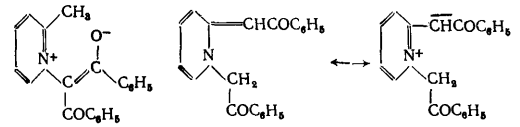


3-Acetyl-2-methylindolizine (58%) and 1,3-diacetyl-2-methylindolizine (27%) were obtained from 1-acetonyl-2-methylpyridinium bromide, acetic anhydride, and sodium acetate[44]. The synthesis of analogues of the same indolizines with substituents in the six-membered ring was achieved by the same procedure.

1-Ethoxycarbonyl-3-methylindolizine was obtained in 47% yield on heating 2-ethoxycarbonylmethylpyridine with α-bromopropionaldehyde in acetic anhydride[88]. The following syntheses of 1-benzoyl-2-phenyl- and 3-benzoyl-2-phenyl-indolizines, mentioned above, and also 2-phenylindolizine apparently constitute important evidence which can be used for the solution of problems concerning the mechanisms of the formation of indolizines from 2-alkyl-1-(β-oxoalkyl)pyridinium salts and acid anhydrides. The first two indolizines were formed (in proportions of 1 : 5) when 1-phenacyl-2-phenacylidene-1,2-dihydropyridine was treated with acetic anhydride. It was suggested that 3-benzoyl-2-phenylindolizine is formed directly from the methine derivative (ring closure at the 2–3 positions) and 1-benzoyl-2-phenylindolizine is formed from the intermediate ylid (ring closure at the 1–2 positions[49,50]:

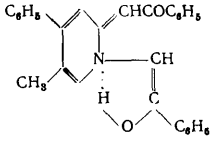


Different structures have been attributed to the product formed on benzoylation of 2-methyl-1-phenacylpyridinium bromide: enol-betaine[71,80] as well as 1-phenacyl-2-phenacylidene-1,2-dihydropyridine and its mesoform as the betaine-anion (ylid)[50]:



The enol-betaine was synthesised from α-picoline and dibenzoylmethyl bromide. It was established that hydrobromic acid cleaves it to benzoic acid and 2-methyl-1-phenacylpyridinium bromide.

An enolic structure with an intromolecular hydrogen bond was attributed to 5-methyl-1-phenacyl-2-phenacylidene-4-phenyl-1,2-dihydropyridine on the basis of its spectroscopic characteristics:

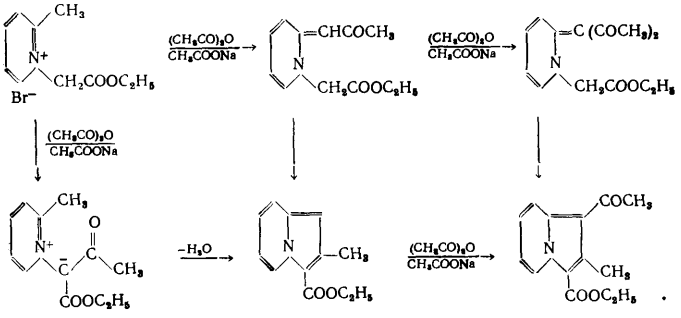


When this methine derivative was heated with acetic anhydride, 3-benzoyl-6-methyl-2,7-diphenyl-, 1-benzoyl-6-methyl-2,7-diphenyl-, and 1-acetyl-3-benzoyl-6-methyl-2,7-diphenyl-indolizines were obtained. The second indolizine is formed on cyclisation of the methine derivative in the presence of formamide[89]. 3-Benzoyl-2-phenyl- and 1-benzoyl-2-phenyl-indolizines were synthesised from the stable 2-methylpyridinium dibenzoylmethylid on brief heating with acetic anhydride[79,80].

Analysis of the type of substitution in the indolizines formed on treatment of 2-alkyl-1-(β-oxoalkyl)pyridinium salts with acid anhydrides in the presence of triethylamine or the sodium salt of the acid led Dainis[44] to the hypothesis that the first reaction stage involves the conversion of the pyridinium salt into ylids. The Table[44] illustrates examples of this reaction.

The method of synthesis of indolizines from 2-alkyl-1-(β-oxoalkyl)pyridinium salts with the aid of acetic anhydride and sodium acetate (as well as propionic anhydride and sodium propionate) has been used in the synthesis of indolizinecarboxylic acids. A mixture of the ethyl ester of 2-methylindolizine-3-carboxylic acid (the main product) and the ethyl ester of 1-acetyl-2-methylindolizine-3-carboxylic acid was obtained by this method in a good yield from 1-ethoxycarbonylmethyl-2-methylpyridinium bromide (3-cyanosubstituted analogues of these indolizines were also obtained from 1-cyanomethyl-2-methylpyridinium). The ethoxycarbonyl group in these indolizines is readily removed on acid hydrolysis[85].

The following explanation has been proposed for the formation of substituted indolizines by this method, which is illustrated by the syntheses of the above indolizines.



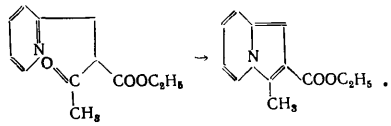
Bearing in mind that 3-ethoxycarbonyl-2-methylindolizine greatly predominates in the mixture of indolizines obtained and that direct acetylation of this indolizine with acetic anhydride in the presence of sodium acetate gives rise to 1-acetyl-3-ethoxycarbonyl-2-methylindolizine in a low yield (12%, the remainder consists of the initial indolizine), it is suggested that kinetically the rate-limiting stage is the formation of the diacylmethine[85]. Quantitative data for the synthesis of indolizines from 1-methoxycarbonylmethyldimethylpyridinium salts are consistent with this conclusion. When the methyl groups in the pyridine ring are in the 2,4- and 2,5-positions, a mixture of indolizines non-acylated and acylated at $C_{(1)}$ is formed; on the other hand, when the methyl groups are in the 2,3-positions, only 3-acetyl-2,8-dimethylindolizine is produced (70% yield). The explanation is that the methyl group at $C_{(3)}$ in the pyridine ring causes steric hindrance to the acylation of the intermediate acylmethine to the diacylmethine.

Cyclisation of 2-(γ-oxoalkyl)pyridines

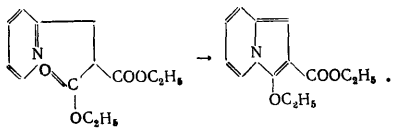
The initial substituted pyridines of this type are obtained from 2-bromomethylpyridine and sodio-derivatives of acetoacetic and malonic esters as well as acetylactone[90]. The cyclisation is achieved by heating 2-(γ-oxoalkyl)pyridine with acetic anhydride for a short time[63].

Indolizines obtained from 1-acetonyl-2-methyl(2,6-dimethyl)pyridinium bromides.

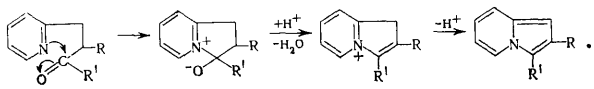
Starting compound	Method	Indolizines isolated			
	$(CH_3CO)_2O$ + CH_3COONa	 (58%)	—	 (27%)	—
	$(CH_3CO)_2O$ + $(C_2H_5)_3N$	 (23%)	 (8%)	—	—
	$(CH_3CO)_2O$ + CH_3COONa	 (38%)	 (23%)	 (24%)	
The condensation of 2-($\beta\beta$-diacetylethyl)pyridine leads to the formation of 2-acetyl-3-methylindolizine. The more active carbonyl group enters into cyclisations of this type, which has been shown in the conversion of 2-(β-acetyl-β-ethoxycarbonylethyl)pyridine into the ethyl ester of 3-methylindolizine-2-carboxylic acid:



As expected, bearing in mind the foregoing considerations, the cyclisation of 2-[$\beta\beta$-di(ethoxycarbonyl)ethyl]-pyridine to the ethyl ester of 3-ethoxyindolizine-2-carboxylic acid proceeds with greater difficulty and with a lower yield under comparable conditions:



It is believed that the cyclisation reaction begins with nucleophilic attack by the nitrogen atom on the carbonyl group in the side chain, which leads to ring closure with formation of a betaine. The protonation of the latter and subsequent dehydration result in the formation of an indolizinium cation, which is converted into a substituted indolizine by acid-catalysed dehydrogenation:

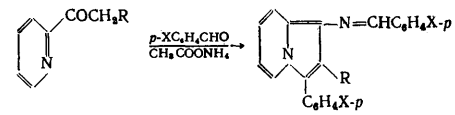


An indolizine is probably formed similarly (in 50% yields) from 3-(2-pyridyl)-1-propanol when it is heated in the presence of palladium on charcoal, since the intermediate should be 3-(2-pyridyl)propanol. 5-Methyl-2-phenylindolizine was obtained by the same procedure from 3-(6-methyl-2-pyridyl)-2-phenylpropanol[75]. It is suggested that 3-(2-pyridyl)indolizine is formed in the same way from 1,1-diacetoxy-1,3-di-(2-pyridyl)propane when it is heated *in vacuo*[91]. Pyrolysis of 2-($\alpha\gamma$-diacetoxypropyl)pyridine leads to the formation of indolizine[92]. 5-Methylindolizine was obtained similarly in a low yield by the pyrolysis of 2-($\beta\gamma$-diacetoxypropyl)-6-methylpyridine. The same indolizine was formed in 30% yield on pyrolysis (at 450°C) of 2-(α-acetoxypropenyl)-6-methylpyridine[75].

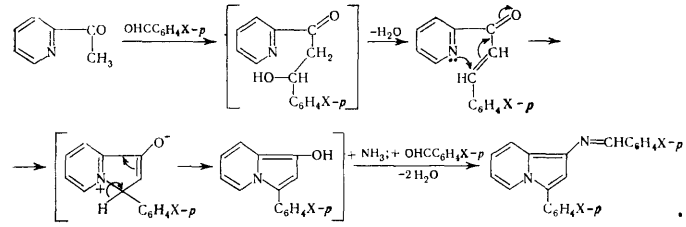
When 2-(γ-hydroxypropyl)pyridine *N*-oxide is treated with acetic anhydride, the product is 2-(γ-acetoxy-α-acetylpropyl)pyridine, which cyclises to an indolizine at 480°C with elimination of two acetic acid molecules[92]. On treatment with concentrated sodium hydroxide, 2-(γ-chloro-β-hydroxypropyl)pyridine, formed in a low yield on partial reduction of 2-(γ-trichloro-β-hydroxypropyl)pyridine with zinc in dilute sulphuric acid, is converted into an indolizine in a low yield[93]. The reaction of 2-pyridyl-lithium with epichlorohydrin leads to 2-hydroxy-3*H*-indolizinium chloride from which an indolizine was obtained on treatment with sodium hydroxide[94].

The Cyclisation of 2-Cinnamoylpyridines

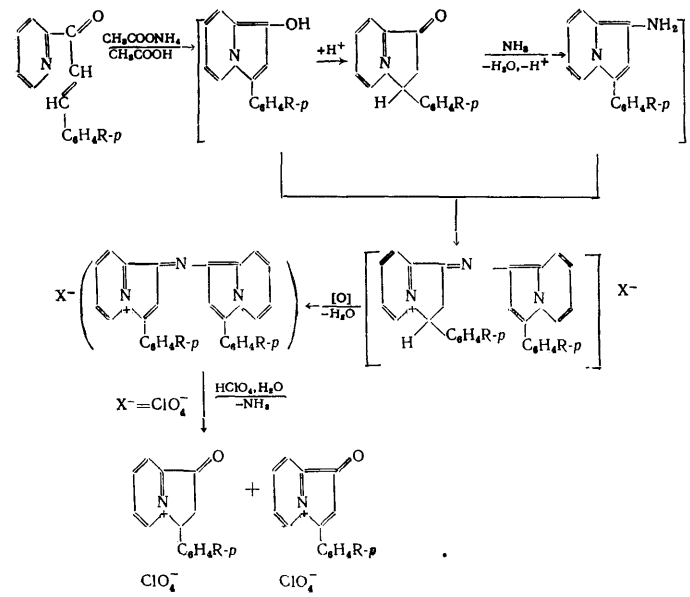
When 2-acetyl(propionyl, benzoyl)pyridines are heated with aromatic aldehydes in glacial acetic acid in the presence of ammonium acetate (with an acylpyridine : aldehyde ratio of 1 : 2), azomethines derived from 1-aminoindolizines are formed in yields up to 50%:[95-97]



The first stage of this reaction is the aldol condensation of 2-acylpyridine with the aromatic aldehyde, which results in the formation of 2-cinnamoylpyridine. Its intramolecular condensation leads to the formation of 3-aryl-1-hydroxyindolizine. On interaction of the latter with ammonia, the hydroxy-group is replaced by the amino-group and 1-amino-3-arylindolizine then condenses with the aromatic aldehyde[97-101]:



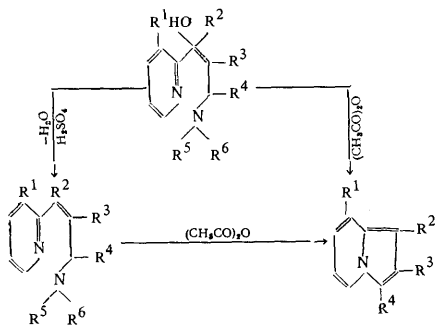
When 2-cinnamoylpyridines and ammonium acetate are heated in glacial acetic acid in the presence of air, the products are also azocyanines, but this time with two indolizine rings, which can be isolated in the form of salts. It is suggested that 3-aryl-1-hydroxyindolizine, whose salt has the 3-aryl-1-oxo-2,3-dihydro-1*H*-indolizinium structure, and 1-amino-3-arylindolizine formed from it condense. The intermediate dihydroazomethine is then oxidised further by atmospheric oxygen to the azomethine:



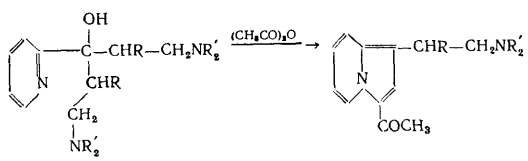
When the perchlorate of such an azomethine ($X^- = ClO_4^-$) is heated with 70% perchloric acid, it is cleaved with formation of 3-aryl-1-oxo-2,3-dihydro-1*H*-indolizinium and 3-aryl-1-oxo-1*H*-indolizinium perchlorates[102].

Deamination and Cyclisation of 2-(γ-dialkylamino-α-hydroxyalkyl)pyridines

On heating with acetic anhydride, the aminoalcohols formed from 2-lithiopyridines and β-dialkylaminoketones[103] are converted into substituted indolizines in yields up to 60%. The same indolizines are formed under the same conditions from the dehydration products of 2-(γ-dialkylamino-α-hydroxyalkyl)pyridines. When R^4 = H (see the reaction scheme), indolizines acetylated in the 3-position are obtained[77,104-106]:

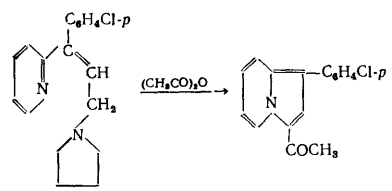


3-Acetyl-1-(*p*-chlorophenyl)indolizine together with a number of side products were obtained in this way from 1-(*p*-chlorophenyl)-1-(2-pyridyl)-3-(1-pyrrolidinyl)-1-propanol. The use of diaminomethanols (symmetric and asymmetric) in these reactions permitted the synthesis of aminoalkylindolizines[106]:



3-Acetyl-2-methyl(ethyl)-1-(β-dimethylaminoethyl)-indolizines, whose structure has been established by ultraviolet spectroscopy, were obtained from asymmetrically substituted carbinols of the following type: 2-methyl(ethyl)-1,5-bis(dimethylamino)-3-(2-pyridyl)-3-pentanols. The formation of the isomeric indolizines unsubstituted in the 2-position could not be observed.

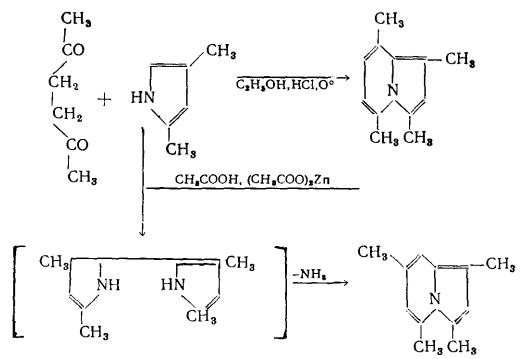
It is believed that the alkenylamines formed on dehydration of the aminomethanols are not intermediates in the conversion of the aminomethanols into indolizines, although they are converted into substituted indolizines under the same conditions. Thus 3-acetyl-1-(*p*-chlorophenyl)indolizine, mentioned above, was obtained from *cis*-1-(*p*-chlorophenyl)-1-(2-pyridyl)-3-(1-pyrrolidinyl)-prop-1-ene:



The *trans*-isomer does not cyclise under analogous conditions (refluxing for 30 min), more severe conditions being required for this purpose, and the yield of the substituted indolizine is low. In these reactions an appreciable amount of 3-acetoxy-1-(*p*-chlorophenyl)-1-(2-pyridyl)prop-1-ene is formed as a side product.

The Conversion of Alkylpyrroles into Indolizines

When 2,4-dimethylpyrrole is heated with acetonylacetone in acetic acid in the presence of zine acetate, 1,3,5,7- and 1,3,5,8-tetramethylindolizines are formed[107,108]. Later it was established that the second indolizine is formed from 2,4-dimethylpyrrole and acetonylacetone in alcoholic solution at 0°C in the presence of hydrogen chloride. It is suggested that the formation of 1,3,5,7-tetramethylindolizine proceeds via a pyrrolinylpyrrole stage[109]:

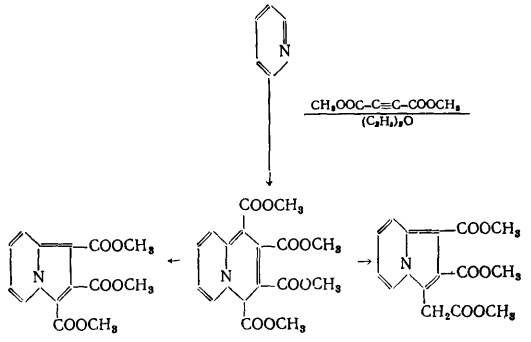


1,2,6,7-Tetraethylindolizine was obtained similarly in 24% yield from 3,4-diethylpyrrole in the presence of zinc acetate and the condensation of the same substituted pyrrole with acetonylacetone led to the isolation of 1,2-diethyl-5,8-dimethylindolizine. 3,4-Dimethylpyrrole was also converted into 1,2,6,7-tetramethylindolizine[110]. The interaction of pyrrole with hexane-2,5-dione in acetic acid containing zinc acetate leads to the formation of a mixture of various condensation products containing more than 10% of 5,8-dimethylindolizine and also substituted indole, carbazole, and other substances[111].

The Conversion of 1,2,3,4-Tetra(methoxycarbonyl)-4*H*-quinolizine into Indolizine-1,2,3-tricarboxylic Acid Esters

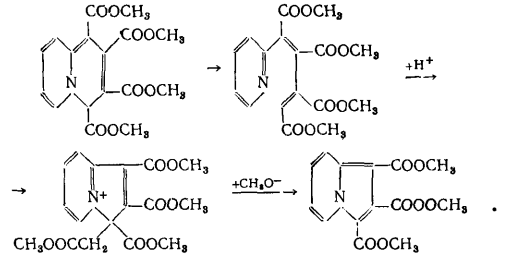
One of the substances formed in the interaction (in ethereal solution) of pyridine with acetylenedicarboxylic acid dimethyl ester is the tetramethyl ester of 4*H*-quinolizine-1,2,3,4-tetracarboxylic acid (the yellow "stable product") to which the structure of 1,2,3,4-tetra(methoxycarbonyl)-9*aH*-quinolizine was attributed previously. When this tetramethyl ester is treated with bromine and then hydrolysed, or when it is oxidised with dilute nitric acid or chromic acids, or when it is irradiated with light from a 450 W mercury lamp, the trimethyl ester of

indolizine-1,2,3-tricarboxylic acid is formed (on irradiation the yield is only 5%). When the above dihydroquinolizine is heated with phenol or formic acid, 1,2-di(methoxycarbonyl)-3-methoxycarbonylmethylindolizine is also formed[53,55,56,112-119]:

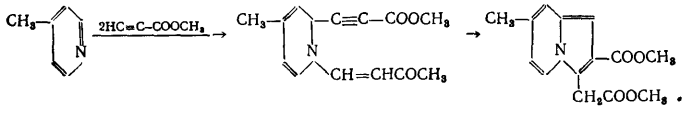


α-Picoline[120], β-picoline[115,121], isonicotinonitrile[122], and stilbazole[118,123] were introduced into the reaction with acetylenedicarboxylic acid dimethyl ester with the formation of tri(methoxycarbonyl)indolizines with the corresponding substituents in the six-membered ring.

It has been suggested that irradiation of a methanolic solution of 4*H*-quinolizine-1,2,3,4-tetracarboxylic acid tetramethyl ester (the experiment is carried out in a stream of nitrogen) leads to the opening of the 4*H*-ring with formation of a substituted α-pyridylbutadiene, which subsequently undergoes cyclisation[119]:



The substances formed in the interaction of 2-, 3-, and 4-methyl and 3,5-dimethylpyridines with methyl propiolate have been studied[124-126]. It was established (mainly by spectroscopic methods) that this involves the formation of compounds of two types: substituted cyclo-[3,2,2]azines and indolizines. The formation of 2-methoxycarbonyl-3-methoxycarbonylmethyl-7-methylindolizine from γ-picoline and a propiolate ester was observed:



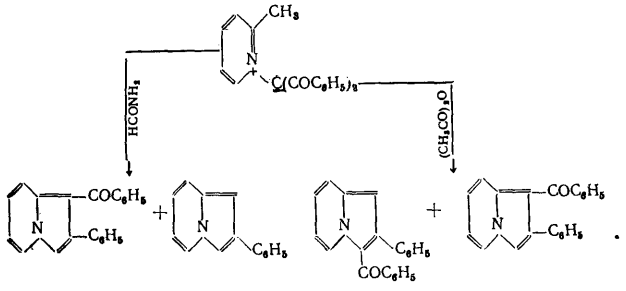
It is suggested that 2-(methoxycarbonylethynyl)-1-(β-methoxycarbonylvinyl)-4-methyl-1,2-dihydropyridine is formed as an intermediate. This method was extended to the synthesis of benzoindolizine systems[127].

The interaction of 2-phenylethynylpyridine with acetylenedicarboxylic acid dimethyl ester in acetonitrile leads to the formation of the tetramethyl ester of oxy-bis-(1-phenylmethyleneindolizine-2,3-dicarboxylic acid), whose treatment with bromine in chloroform led to a quantitative yield of 1-bromoindolizine-2,3-dicarboxylic acid dimethyl ester[128].

The Synthesis of Indolizines from Ylids

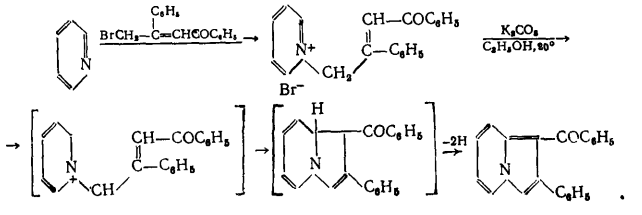
Ylids are converted into indolizines either by the cyclisation of the ylids themselves or by their interaction with acetylenic compounds, i.e. via 1,3-dipolar cycloaddition.

A mixture of 1-benzoyl-2-phenyl- and 3-benzoyl-2-phenyl-indolizines in proportions of 1 : 2 and a small amount of 2-phenylindolizine are formed from the stable 2-methylpyridinium dibenzoylmethylid when it is heated for a short time with acetic anhydride[44,79,80]. When the same ylid was refluxed in formamide, the main reaction product proved to be 1-benzoyl-2-phenylindolizine, but when the refluxing was continued only for a very short time (about 1 min), 2-phenylindolizine was obtained quantitatively:



3-Benzoyl-1-methyl-2-phenylindolizine and 3-benzoyl-1,2-diphenylindolizine were obtained in quantitative yields on refluxing 2-ethyl- and 2-benzyl-pyridinium dibenzoylmethylids respectively in acetic anhydride. The latter ylid was converted quantitatively into 3-benzoyl-1,2-diphenylindolizine when it was heated to the melting point (170–172°C) or to 200°C for 1 min in formamide[44].

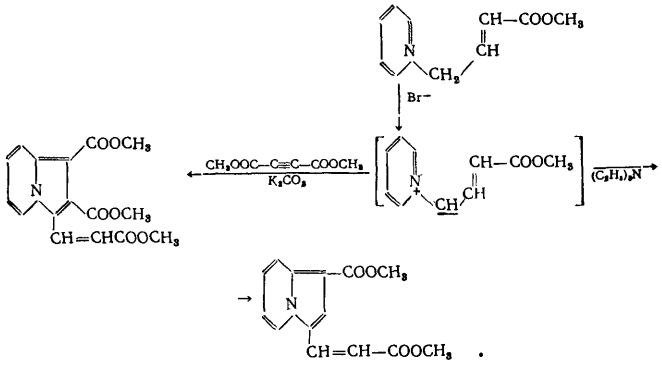
The syntheses of certain substituted indolizines where 4-bromo-1,3-diphenylbut-2-en-1-one was used for the preparation of pyridinium salts have been described. The synthesis of 1-benzoyl-2-phenylindolizine is illustrated below[129]:



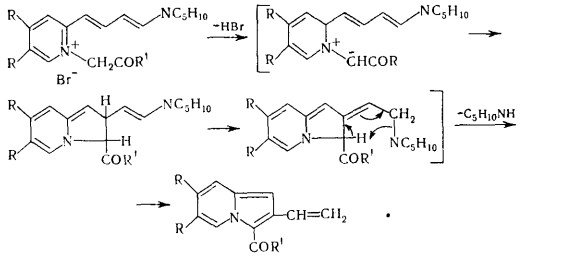
The ylid formed under the conditions of base catalysis cyclises with formation of dihydroindolizine, which is aromatised during the reaction with elimination of hydrogen.

The formation of a substituted indolizine from the analogous pyridinium salt—1-(γ-methoxycarbonylallyl)-pyridinium bromide—when the latter is heated with triethylamine apparently proceeds in a different way. Instead of the expected ester of indolizine-1-carboxylic acid, the product consisted of a 20% yield of 1-methoxycarbonyl-3-(β-methoxycarbonylvinyl)indolizine, the hydrogenation of which in the presence of palladium on charcoal led to its conversion into 1-methoxycarbonyl-3-(β-methoxycarbonylethyl)-indolizine. It is suggested that the reaction proceeds via a γ-methoxycarbonylallylid stage. This is confirmed indirectly by the formation of

1,2-di(methoxycarbonyl)-3-(β-methoxycarbonylvinyl)-indolizine from the same pyridinium salt and acetylenedicarboxylic acid dimethyl ester in dimethylformamide[88]:

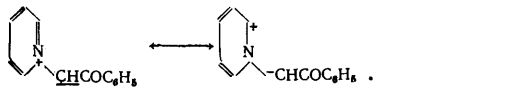


When 2,3-disubstituted quinolizinium bromide (with CH_3, C_6H_5, or H substituents) react with piperidine or morpholine, conjugated tetramethines are formed: 4,5-disubstituted 2-[4-piperidino(morpholino)buta-1,3-dienyl]pyridines. Their salts formed by reaction with bromoacetone or bromoacetophenone undergo intramolecular cyclisation when their chloroform solution is passed through a column containing alumina (Grade III activated alumina). This results in the formation of 6,7-disubstituted 3-acetyl(or benzoyl)-2-vinylindolizines[130]. The mechanism of this reaction is illustrated below:

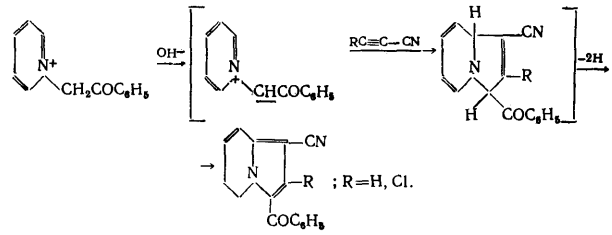


A mechanism similar to that described above was considered by Mörler and Krohnke for the formation of these indolizines[130]. The first indolizine is formed when *N*-vinylpyridine is split off from the intermediate dihydroindolizine and the second is formed via the acetylation of the dihydroindolizine in the 1-position and the elimination of piperidine. In the next communication, dealing with the study of the reactions of a salt of 4,5-disubstituted 2-(4-piperidinobuta-1,3-dienyl)piperidine and ethyl bromoacetate in the presence of acetic anhydride and triethylamine, two 6,7-disubstituted indolizines were reported: 1-(β-formylvinyl)-2-methyl- and 3-ethoxycarbonyl-1-(β-formylvinyl)-2-methylindolizines[131].

Pyridinium phenacylid[71b,132] in acetonitrile solution reacts exothermically with cyanoacetylene and also with chlorocyanoacetylene (with a 1 : 2 ylid : substituted acetylene reactant ratio), which results in the formation of substituted indolizines with a cyano-group at $C_{(1)}$ and a benzoyl group at $C_{(3)}$ in yields ranging from 5 to 25%.[133-135] Indolizines are formed from ylids and substituted acetylenes via a 1,3-dipolar cycloaddition reaction, owing to the presence of the stabilised mesomeric form of the 1,3-zwitterion of the ylid[136]:



The following explanation has been proposed for the formation of the indolizine system in the above reactions:

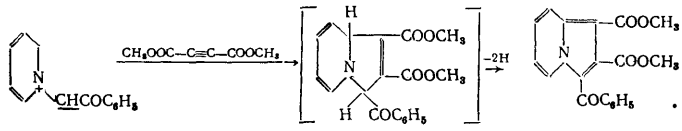


An intermediate in these reactions is an unstable dihydroindolizine, which is dehydrogenated to the final product. The substituted acetylene, which is introduced into the reaction in a molar excess, serves in this case as the hydrogen acceptor in the aromatisation of the dihydroindolizine. The formation of acrylonitrile and *trans*-β-chloroacrylonitrile as side products of these reactions was confirmed experimentally. The nitrile of 3-benzoyl-8-methylindolizine-1-carboxylic acid was obtained similarly in 10% yield from 3-methyl-1-phenacylpyridinium bromide.

3-Benzoyl-1-cyano-1,2,3,8*a*-tetrahydroindolizine, which is dehydrogenated at room temperature in the presence of palladium on charcoal to the similarly substituted 2,3-dihydroindolizine, was obtained from 1-phenacylpyridinium bromide via a stage involving the formation of an ylid. If the reaction of the ylid with acrylonitrile is carried out at an elevated temperature or for a long time, 3-benzoyl-1-cyanoindolizine, which was obtained also in the dehydrogenation of the corresponding 2,3-dihydroindolizine, is formed immediately[137].

The reaction of pyridinium phenacylid with acetylene dicarboxylic acid dimethyl ester has been investigated in fair detail. When this reaction is carried out in the presence of 5% of palladium on charcoal, 3-benzoylindolizine-1,2-dicarboxylic acid dimethyl ester is formed in 18% yield; its structure was demonstrated by converting it via acid hydrolysis and subsequent decarboxylation into indolizine-2-carboxylic acid[138]. It has been shown[139] that the use of a dehydrogenation catalyst in this reaction is not obligatory. The same indolizine was obtained in 32% yield when the reaction was performed in dimethylformamide in the presence of sodium hydride.

The intermediate in the reaction of pyridinium phenacylid with acetylene dicarbocylic acid dimethyl ester is also the corresponding dehydroindolizine, which is converted into a substituted indolizine via 1,4-elimination:



A similar mechanism has been proposed to account for the reaction of pyridine with acetylenedicarboxylic acid dimethyl ester, which leads to the formation of 1,2,3-tri(methoxycarbonyl)indolizine and 1,2-di(methoxycarbonyl)-3-[methoxy(methoxycarbonyl)methyl]indolizine[140].

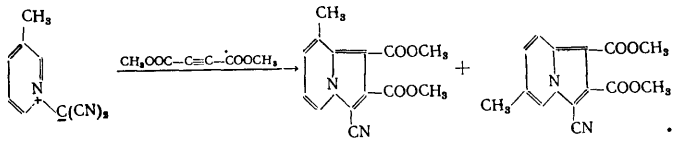
As expected, 3-substituted pyridinium phenacylids give rise to isomeric indolizines as regards the position of the substituent in the six-membered ring. 3-Benzoyl-1,2-di(methoxycarbonyl)-6-methyl(cyano)- and 3-benzoyl-1,2-di(methoxycarbonyl)-8-methyl(cyano)-indolizines were obtained in this way from 3-methyl(cyano)pyridinium phenacylids. Isomeric indolizines were also synthesised from 3,4-dimethylpyridinium phenacylid. However, as

was to be expected, 3-benzoyl-1,2,7-tri(methoxycarbonyl)-indolizine was obtained from 4-methoxycarbonylpyridinium phenacylid[135]. Ylids obtained from quaternary pyridinium salts and bromoacetone, bromoacetate esters, and bromoacetonitrile were also introduced into the reaction with acetylenedicarboxylic acid dimethyl ester. The indolizines thus obtained contain a group in the 3-position, which is linked to the methine carbon atom of the ylid. Indolizines are not formed by the above procedure from *N*-methyl(ethyl, allyl, benzyl)pyridinium salts.

When the reaction of pyridinium phenacylid with acetylenedicarboxylic acid dimethyl ester is carried out in the presence of iodine, 1,2,3-tribenzoylindolizine is formed. Bearing in mind the above mechanism, this mode of reaction has been explained by postulating the formation of dibenzoylacetylene during the reaction, although this could not be demonstrated experimentally[139]. Only 3-benzoyl-1,2-di(methoxycarbonyl)indolizine is formed from pyridinium dibenzoylmethylid and acetylenedicarboxylic acid dimethyl ester. The formation of 3-ethoxycarbonyl-1,2-di(methoxycarbonyl)indolizine from the corresponding di(ethoxycarbonyl)methylid proceeds with analogous elimination of the ethoxycarbonyl group[139].

Pyridinium dicyanomethylid is formed from pyridine and tetracyanoethylene and its interaction with acetylene dicarboxylic acid dimethyl ester at room temperature gives rise to a 48% yield of 3-cyanoindolizine-1,2-dicarboxylic acid dimethyl ester[141].

To elucidate the mode of the 1,3-dipolar cyclisation in the interaction of methylids with acetylenedicarboxylic acid dimethyl ester 3-methylpyridinium dicyanomethylid was also used:



It was established that 8- and 6-substituted indolizines are formed in this reaction in proportions of 3 : 1.[135,142]

The Synthesis of Indolizines from Heterocyclic Compounds in Their Catalytic Reactions

When furan and ammonia are passed over alumina at 350–400 °C, pyrrole and traces of indole, carbazole, and indolizine are formed[143–145]. Indolizine is also present in the products of the pyrolytic decomposition of pyridine. Octahydroindolizine could not be aromatised in the presence of palladium on charcoal or with the aid of selenium[146].

The Synthesis of a Substituted Indolizine from α-Picoline and Sulphur

Prolonged refluxing of α-picoline with sulphur leads to the formation of a substance $C_{36}H_{24}N_6S_2$, which is converted into 1,2-di(2-pyridyl)indolizine on reduction with hydriodic acid in the presence of phosphorus and into 3-nitro-1,2-di(2-pyridyl)indolizine on nitration[147].

III. PROPERTIES OF INDOLIZINES

The physical and chemical properties of indolizine and its derivatives have been described fairly completely[9,10]. In the present review we shall consider mainly studies on the properties of indolizines carried out in recent years.

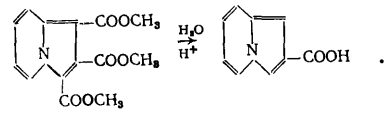
Electrophilic substitution reactions constitute a characteristic chemical feature of indolizines. Nucleophilic substitution—amination of indolizine with sodamide—could not be achieved[9].

Electrophilic Substitution

Indolizine is more reactive than benzene with respect to electrophilic agents owing to the delocalisation of the lone electron pair of the nitrogen atom. An estimate of the distribution of π-electron density and of the bond orders in the indolizine molecule by the molecular orbital method[148] and also calculation of the frontal electron density in the molecule in relation to electrophilic substitution[149] have shown that its fundamental mesoforms consist of structures with maximum electron density in the 3-position and then in the 1-position[9]:

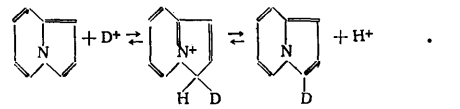
Therefore electrophilic substitution in the indolizine system should take place primarily in the 3-position and then in the 1-position; in the presence of substituents further substitution takes place in the 2-position. In electrophilic attack on indolizine substitution takes place only in the five-membered ring[150]. Substitution of the pyridine ring of indolizine cannot be achieved.

The enhanced electron density in the 3-position of the indolizine ring is indicated by the stepwise decarboxylation of indolizine-1,2,3-tricarboxylic acid. On hydrolysis (by heating with dilute hydrochloric acid) of its trimethyl ester, decarboxylation in the 1- and 3-positions takes place. Indolizine-2-carboxylic acid thus formed was decarboxylated by pyrolysing its calcium salt[53,56]:



Calculations by the LCAO-MO method[151] have shown that the 1- and 3-positions are almost equally effective in relation to electrophilic substitution with a slight preference for substitution in the 1-position. However, examination of resonance structures shows that electrophilic attack should take preferentially on the 3-position.

The calculated data were confirmed in a study of the deuteration reaction. It is suggested[152] that in the deuteration of indolizine the formation of a cation identical with a π complex constitutes an intermediate stage:



The rate of deuteration of indolizine itself in the 3-position is fives times faster than the rate of deuteration in the 1-position. Similar relative rates of deuteration in the 3- and 1-positions hold also for 2-methylindolizine. The reactivities of different positions of the

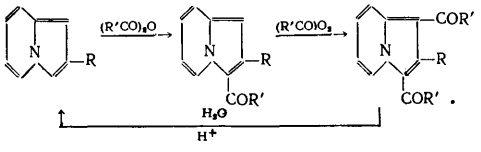
indolizine system were determined[153] with the aid of electrophilic hydrogen exchange and were compared with calculated data. The distribution of π-electron density agrees with the experimental reactivities of different positions in the indolizine system, which decrease in the sequence $3 > 1 \gg 2 > 5 \simeq 7 > 6 > 8$. Contradictions, which still remain controversial, were encountered when these results were compared with the calculated electron localisation energies.

Similar conclusions concerning the different reactivities of various positions in the indolizine ring in relation to electrophilic attack were reached on the basis of a determination by ^{1}H NMR of the degrees of protonation of the $C_{(1)}$ and $C_{(3)}$ positions in a number of methylindolizinium perchlorates in trifluoroacetic and hydrochloric acids. The protonation of indolizines without a methyl group at $C_{(3)}$ involves almost exclusively the 3-position[154]. 100% of the 3*H*-cations was detected in the protonation of 3,5-dimethyl-, 1,2,3-trimethyl-, and 1,3-dimethyl-2-phenyl-indolizines. The amounts of the 3*H*-cations and the 1*H*-cations in the case of 2,3-dimethylindolizine were 41 and 59% respectively[155].

Acylation of Indolines and the Reactions of Acylindolizines

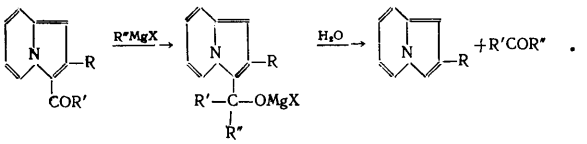
On heating with acid anhydrides in the presence of the sodium salts of the corresponding acids, indolizines are readily acylated to 3-acylindolizines[3-6,14,15,44,74,156,157]. When monoacyl derivatives are heated with the anhydride at a higher temperature, 1,3-disubstituted indolizines are formed. Acetylation of the nitrile of 2-methyl-(phenyl)indolizine-1-carboxylic acid also leads to the formation of the 3-acetyl derivative[5,14]. 3-Alkoxycarbonyl-2-methylindolizines are extremely resistant to acetylation; the yield of their 1-acetyl derivatives on acetylation with acetic anhydride in the presence of sodium acetate is only slightly more than 10%.[85]

Certain characteristic features are observed in the interaction of indolizines with acyl halides. 2-Methylindolizine is acetylated with difficulty by acetyl chloride (by the Friedel–Crafts reaction) in carbon disulphide to 1,3-diacetyl-2-methylindolizine. Acetylation of 3-acetyl-2-methylindolizine[158] and particularly 2-phenylindolizine (the phenyl group is partly acetylated)[14] proceeds more readily in the presence of aluminium chloride. In the absence of a catalyst 2-phenylindolizine does not react with acetyl chloride or bromide, but is benzoylated by benzoyl chloride in the 3-position and then in the 1-position under more severe conditions[38,44,69,79,157,159-161]. In the absence of a catalyst indolizine itself does not react with benzoyl chloride[4]:

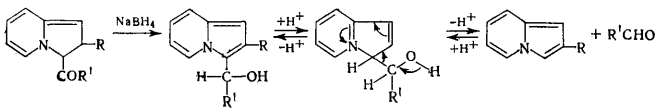


The reaction of aroylacetic acid esters with indolizine and also with 2-methylindolizine at 140°C leads to the formation of 3-(β-aryl-β-oxopropionyl)indolizines[162]. Substituted indolizines, obtained by treating indolizine with oxalyl chloride in benzene using different proportions of the reactants, have been described. 3-Carboxycarbonylindolizine and di-(3-indolizinyl)glyoxal were obtained in yields of 80% and 15% respectively[151]. 3-Ethoxycarbonyl-2-methylindolizine was synthesised from 2-methylindolizine and chlorocarbonic acid ester[85].

The acyl groups in the pyrrole ring of indolizine are readily removed by acid hydrolysis[1,3,5,14,50,76,105,106,134]. Diacyl derivatives are hydrolysed with greater difficulty than monoacyl derivatives. Acylindolizines with a nitro-[74,156] or nitroso-group[64] in the five-membered ring are not hydrolysed in this way. The acyl group is eliminated from 3-acylindolizines when they interact with organomagnesium compounds. The initial and deacylated indolizines and a ketone are present in the reaction products[48,163]:

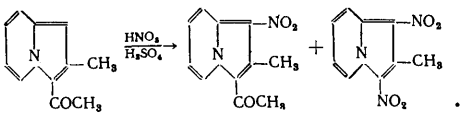


When the products of the reaction of 3-acetyl-2-methylindolizine with sodium tetrahydroborate were treated with D_2O in alcohol, 2-methylindolizine deuterated in the 3-position to an extent greater than 75% was obtained. Consequently the intermediate carbinols are readily protonated in the 3-position. These experimental findings were used to account for the mechanism of the elimination of the acetyl group from the 3-position in indolizines on treating the latter with sodium tetrahydroborate[164]:



It has been shown in many instances that the elimination of the acetyl group with the aid of sodium tetrahydroborate is selective. The acyl group is not split off from the 1-position under these conditions[164].

Nitration of acetylindolizines results in partial substitution of the acetyl group for the nitro-group. Thus nitration of 3-acetyl-2-methylindolizine in the presence of sulphuric acid leads to the formation of a mixture of 3-acetyl-2-methyl-1-nitroindolizine (59%) and 2-methyl-1,3-dinitroindolizine[156]:



3-Ethoxycarbonyl-2-methyl-1-nitroindolizine was obtained in a yield exceeding 30% by the nitration of 1-carboxymethyl-3-ethoxycarbonyl-2-methylindolizine[85]. When 3-acetyl-2-phenylindolizine is treated with iodine, the acetyl group is partly substituted by iodine and the reaction products contain 3-acetyl-1-iodo-2-phenylindolizine and 1,3-diiodo-2-phenylindolizine[48]. 3-Acylamino-2-methylindolizines are formed by the Schmidt reaction from 3-acyl-2-methylindolizines[157]. Several 1-acetamido-3-aryl-2-methylindolizines have been synthesised by this method from 1-acetyl-3-aryl-2-methylindolizines[97].

1- and 3-Acylindolizines are reduced by lithium tetrahydroaluminate to 1- and 3-alkylindolizines[67,78,82,157,165,166]. The reduction of 3-methoxycarbonyl indolizine with lithium tetrahydroaluminate leads to the formation of 3-hydroxymethylindolizine[52] and 2,3-dimethylindolizine was obtained from 3-methoxycarbonyl-2-methyl indolizine in a yield exceeding 70%.[164]

1- and 3-Acylindolizine behave differently in the reactions with hydroxylamine and phenylhydrazine. The corresponding derivatives involving the carbonyl group

are formed under the usual conditions only from 1-acylindolizines. In 1,3-diacylindolizines only the acyl carbonyl in the 1-position enters into these reactions[1,3-5,14,165]. The condensation (in the presence of alkali) of 1,3-diacetylindolizines with aromatic aldehydes leads to the formation of mono- and di-cinnamoylindolizines[1,3,14,15].

Nitrosation of Indolizines and the Reactions of Nitrosoindolizines

Direct nitrosation of indolizines with the 3-position free leads to 3-nitrosoindolizines. When the 3-position is occupied, 1-nitroso-derivatives are formed[14-16,25,27-29,64,79,167-169]. When 1-methyl-2-phenyl, 1-acetyl-5-methyl-2-phenyl-, 3-methyl-2-phenyl-, and 3-acetyl-2-phenylindolizines were nitrosated with sodium nitrite in concentrated hydrochloric acid to which glacial acetic acid or acetone had been added, the first two indolizines gave rise to 3-nitroso-derivatives and the last two gave rise to 1-nitroso-derivatives.

Careful oxidation of nitrosoindolizines with nitric, acetic, and peracetic acids converts them into nitroindolizines[64,156]. When 1-nitrosoindolizines are treated with nitric oxide in the cold, diazonium salts, stable in the solid state and in solutions, are formed in high yields. 3-Methyl-2-phenyl-1-indolizinyldiazonium nitrate was obtained in this way from 3-methyl-1-nitroso-2-phenylindolizine. After coupling it with β-naphthol, the corresponding azo-compound was isolated[168,170]:

3-Nitrosoindolizines do not react with nitric oxide even after prolonged treatment, which has not so far been explained[168]. Aminoindolizines are unstable in air and therefore cannot be used for diazotisation[50,63]. Azocyanine dyes are formed on condensation of nitrosoindolizines with heterocyclic compounds containing an active methylene group. Some of these azocyanines are used in the manufacture of photographic emulsions[171].

Formylation of Indolizines

Indolizines are formylated in the 3- and 1-positions by the Vilsmeier method using methyl- and dimethylformamides[157,165,166]. 3-Formyl-2-methylindolizine was obtained from 2-methylindolizine and then reduced by the Wolff–Kishner method to 2,3-dimethylindolizine[165]. When the formyl derivative is heated with hydrochloric acid, the formyl group is split off. 1,3-Diformyl-2-methylindolizine was obtained from 2-methylindolizine by the Reimer–Tiemann method and then reduced to 1,2,3-trimethylindolizine[165].

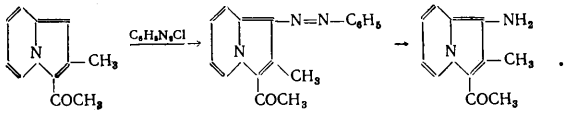
Formylation of indolizine in the presence of sodium hydrogen sulphide led to the formation of 3-thioformylindolizine[172].

Nitration of Indolizines

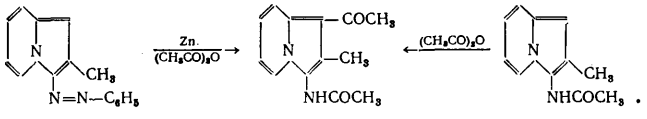
In order to suppress oxidation processes, substituted indolizines are nitrated in sulphuric acid at a reduced temperature or in nitric acid at an elevated temperature, but for a short period. Nitration results in a mixture of isomers. 2-Methyl-1-nitroindolizine and 2-methyl-3-nitroindolizine were obtained in 62 and 1.5% yields respectively by nitrating 2-methylindolizine in the presence of sulphuric acid[156]. 2-Methyl-1,3-dinitroindolizine is formed much more readily on nitration of 2-methyl-3-nitroindolizine than 2-methyl-1-nitroindolizine.

Indolizines in Azo-coupling Reactions

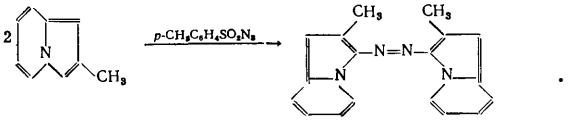
Azo-coupling of indolizine and 2-substituted indolizines involves the 3-position. When it is occupied, the 1-position is involved in azo-coupling[4,68-71,157,167]. 3-Acetyl-2-methyl-1-phenylazoindolizine was obtained by coupling phenyldiazonium chloride with 3-acetyl-2-methylindolizine and its catalytic reduction gave rise to 3-acetyl-1-amino-2-methylindolizine, which is unstable in air[167]:



The reduction of 2-methyl-3-phenylazoindolizine with zinc in acetic anhydride led to the isolation of 3-acetamido-1-acetyl-2-methylindolizine, which is resistant to acid and alkaline hydrolysis and which is formed also on acetylation of 3-acetamido-2-methylindolizine[120]:



3,3′-Azobis(2-methylindolizine) is formed in the reaction of 2-methylindolizine with tosyl azide[173]:

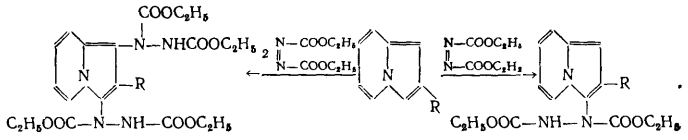


Similar azo-compounds coupled at the 1-position in the indolizine ring have been obtained from 2,5-dimethyl- and 3-methyl-2-phenyl-indolizines. 2-Phenylindolizine does not react with tosyl azide even on heating[174]. It has been confirmed[175] that 3,3′-azobisindolizines are formed from 2-methylindolizine and from 1,2-dimethylindolizine, both on treatment with tosyl azide and with picryl azide in ethyl acetate. Under the same conditions, 1,1′-azobis-(2,3-dimethylindolizine) is formed from 2,3-dimethylindolizine. This condensation takes place particularly readily with 2-methyl- and 1,2-dimethyl-indolizines. Fast dyes for polyamide and polyester fibre with tints ranging from yellow to violet have been found among 3-(1-indolizinylazo)-2-phenylindoles, 2,3-disubstituted in the indolizine ring, and 2-substituted 3-(3-indolizinylazo)-2-phenylindoles[176].

Condensation of Indolizines with Certain Dienophiles and with Azodicarboxylic Ester

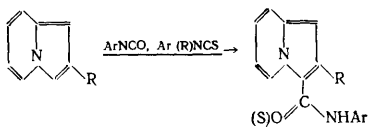
Adducts formed by indolizines with malic anhydride[123,177] and with quinone[4] have been described. 2-Phenyl(methyl)-indolizine is involved in a Diels–Alder type of reaction in benzene at room temperature with the diethyl ester of azodicarboxylic acid, forming a monoadduct—the diethyl

ester of [2-phenyl(methyl)-3-indolizinyl]hydroazodicarboxylic acid, while on refluxing a di-adduct is formed[178]:

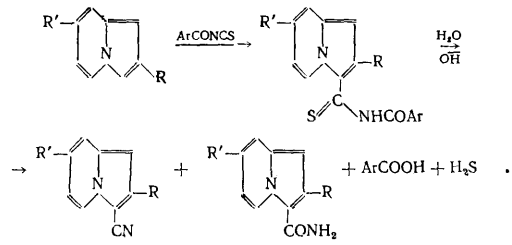


Similar addition products were obtained from 1-methyl-2-phenyl-, 3-methyl-2-phenyl-, and 2,3-dimethylindolizines. As a rule, the 3-adducts are formed more readily and in higher yields than the 1-adducts.

The carbamoylation and thiocarbamoylation of indolizines can be included among reactions of a similar type. When equimolar amounts of 2-methylindolizine and phenyl isocyanate, formed on decomposition of benzoyl azide under these conditions, are refluxed in toluene, the *N*-phenylamide of indolizine-3-carboxylic acid is obtained[179]. The thiocarbamoyl group is introduced similarly into the 3-position of 2-methyl- and 2,7-dimethyl-indolizines when these interact with isothiocyanates[180]:

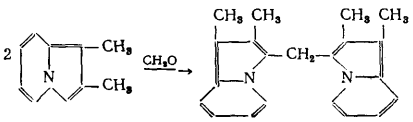


N-Aroylthioamides of the corresponding indolizine-3-carboxylic acids were synthesised from 2-methyl-, 2-aryl-, 2,7-dimethyl-, and 2-aryl-7-methyl-indolizines and aroyl isothiocyanates[181,182]; on being refluxed in an alkaline alcoholic solution, they give rise to nitriles and amides of indolizine-3-carboxylic acids (in yields up to 15%):[183]

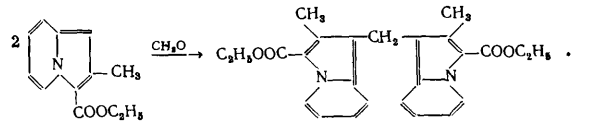


Alkylation of Indolizines

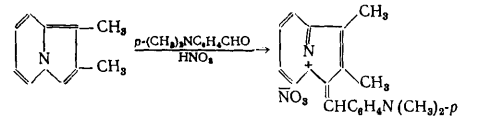
Alkyl groups, which may be substituted by functional groups, can be introduced into the 3- and 1-positions of indolizines in several ways. (3-Benzoyl-1-indolizinyl)-acetic acid was synthesised by the condensation of 3-benzoylindolizine with diazoacetic ester[184]. Condensation of indolizines containing free 1- or 3-positions with formaldehyde and other aldehydes leads to diindolizinylmethanes[1,3,4,93,105,157,165]. Di-(1,2-dimethyl-3-indolizinyl)-methane was obtained in a yield exceeding 90% from 1,2-dimethylindolizine and 40% formaldehyde solution[185]:



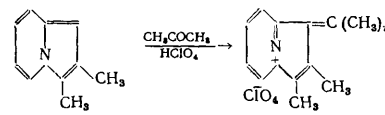
A similar condensation product involving the 1-positions of the indolizines rings was obtained from 2,3-dimethylindolizine[165]. The condensation of 3-ethoxycarbonyl-2-methylindolizine with formaldehyde gave a 75% yield of di-(3-ethoxycarbonyl-2-methyl-1-indolizinyl)methane[85]:



The condensation of 1,2- and 2,3-dimethylindolizines with *p*-dimethylaminobenzaldehyde in alcoholic solution in the presence of nitric acid led to the formation of 1,2-dimethyl-3-(*p*-dimethylaminobenzylidene)indolizinium and 2,3-dimethyl-1-(*p*-dimethylaminobenzylidine)-indolizinium nitrates respectively[37]:



A similar dye was synthesised by the condensation of 2-methylindolizine hydriodide with *p*-dimethylamino-benzaldehyde[36]. Methine derivatives of indolizines have been synthesised by condensing them with aromatic ketones containing the *p*-dimethylamino-group in one of the benzene rings[37] and also with aliphatic ketones. The condensation of 2,3-dimethylindolizine with acetone in the presence of perchloric acid led to the isolation of 1-isopropylidene-2,3-dimethylindolizinium perchlorate[165]:

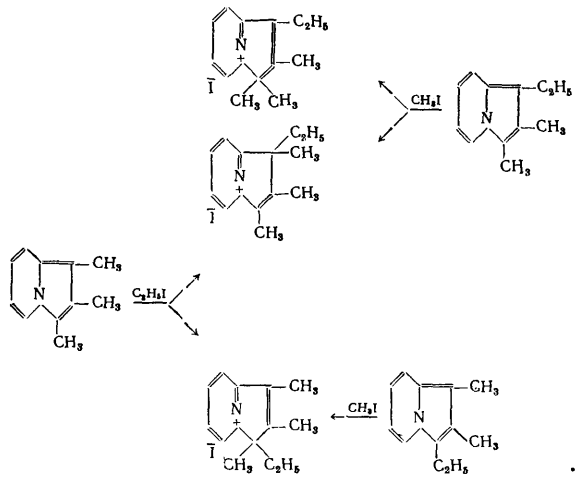


The products of the condensation of 2-aryl-1-methylindolizines with *p*-dimethylaminobenzaldehyde and with di-(*p*-dimethylaminophenyl) ketone were isolated as the perchlorates or the tetrafluoroborates[186].

The condensation of 5-methyl-2-phenylindolizine with *NN*-dimethylacetamide in the presence of phosphoryl chloride results in the formation of a mixture of 1- and 3-(α-dimethylaminoethylidene)indolizines, which were isolated as the perchlorates. After treating a mixture of these perchlorates with sodium hydroxide, 1-acetyl-5-methyl-2-phenylindolizine and an enamine [3(α-dimethylaminovinyl)-5-methyl-2-phenylindolizine] were obtained. If there is no substituent causing steric hindrance at $C_{(5)}$ in the indolizine ring, then condensation with *NN*-dimethylacetamide proceeds almost wholly with formation of the 3-(α-dimethylaminoethylidene) derivative[187].

The interaction of indolizines substituted by alkyl groups in the five-membered ring with certain alkyl iodides has been studied[10,36]. The alkyl halide adds to 1,2,3-trialkylindolizine with formation of an indolizinium salt, the alkyl group entering both the 3- and 1-positions.

In 2,3-dialkylindolizines the alkyl group enters the 3- and 1-positions:



3-Phenacyl-2-phenylindolizine was obtained from 2-phenylindolizine and bromoacetophenone semicarbazone in the presence of triethylamine[188]. The reaction of 2-methylindolizine with ethyl iodoacetate in the presence of aluminium chloride results in the formation of a mixture of 3-ethoxycarbonylmethyl-2-methylindolizine, 1,3-di(ethoxycarbonyl methyl)-2-methylindolizine, and the initial indolizine. The attempt to introduce the ethoxycarbonylmethyl group into 2-methylindolizine with the aid of bromoacetic and diazoacetic esters was unsuccessful[161].

2,3-Dimethylindolizine was aminomethylated via the Mannich reaction. On treatment with dimethylamine, 2,3-dimethyl-1-dimethylaminomethylindolizine was obtained[165]. A number of similar 3-aminomethyl-1,2-diphenylindolizines substituted in the amino-group have been described[189]. 1-Aminomethyl derivatives with dimethyl- and diethyl-amino-groups and also with an *N*-pyrrolidinyl substituent have been synthesised from 3-alkyl-2-phenylindolizines[190,191]. A number of 1,3-bis-(dialkylaminomethyl)-2-phenylindolizines were synthesised from 2-phenylindolizine for pharmacological study[192]. The synthesis of unsubstituted aminomethylindolizines is difficult. Reduction of the amide of indolizine-2-carboxylic acid (which was obtained by heating the methyl ester of this acid with ammonia in methanol at 155°C) with lithium tetrahydroaluminate led to the isolation of an unstable substance to which the structure of 2-aminomethylindolizine was attributed on the basis of infrared and NMR spectra[52]. 1-Aminomethylindolizine is also very unstable; it was characterised as the *N*-acetyl derivative[50]. 3-(1-Hydroxy-2-dimethylaminoethyl)-2-phenylindolizine was obtained in a low yield by the reduction of *NN*-dimethyl-(2-phenyl-3-indolizinyl)glyoxylamide with lithium tetrahydroaluminate[43]. The reduction of the nitrile of 2-methylindolizine-7-carboxylic acid with lithium tetrahydroaluminate led to the isolation of 7-aminomethyl-2-methylindolizine[52].

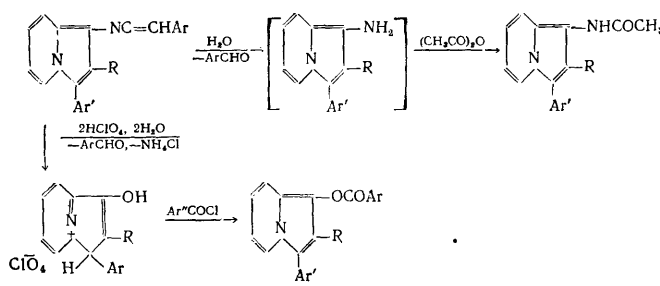
2-Hydroxymethyl-, 3-hydroxymethyl-, and 6-hydroxymethyl-2-methyl-indolizines were obtained in fairly high yields by the reduction of the corresponding indolizinecarboxylic acid esters with lithium tetrahydroaluminate[52]. However, the reduction of the ethyl ester of 2-methylindolizine-1-carboxylic acid with $LiAlH_4$ in tetrahydrofuran led to the isolation of only one product—1,2-dimethylindolizine[52].

The methyl group in the 5-position of the indolizine ring system is analogous to the methyl group of α-picoline. When 5-methylindolizine and 5-methyl-2-phenylindolizine are treated with butyl-lithium and then with a carbonyl compound, the corresponding 5-(β-hydroxyalkyl) derivatives are formed[193]. After treating 5-methyl-2-phenylindolizine with butyl-lithium and then with dimethylbenzamide, 5-phenacyl-2-phenyl-indolizine was obtained. 5-Formylmethyl-2-phenylindolizine was synthesised similarly using dimethylformamide. The same reactions were achieved also with 5-methylindolizine[194].

Amino- and Hydroxy-indolizines

1-Aminoindolizines, which are formed on reduction of 1-nitroso- and 1-nitroindolizines, could not be isolated since they are unstable in air[113,167]. 1-Amino-2-phenylindolizine hydrochloride, obtained by the reduction of 1-nitro-2-phenylindolizine with hydrogen in the presence of palladium on charcoal, is unstable like the base itself[63]. 3-Acetamido-1-acetyl-2-methylindolizine[157], 1-acetamido-(propionamido, benzamido)-2,3-dimethyl- and 1-acetamido-(propionamido, benzamido)-2,3-diphenyl-indolizines[67], and 1-acetamido-2-phenylindolizine were synthesised in various ways. The last compound is resistant to alkali, but on acid hydrolysis is readily converted into 1-hydroxy-2-phenylindolizine[50,63]. The unstable hydrochloride of 1-hydroxy-2,3-diphenylindolizine was obtained by the hydrolysis of 1-benzamido-2,3-diphenylindolizine in the presence of hydrochloric acid[50]. The conversion of 1-amino-2-phenylindolizine into 1-acetamido-2-phenylindolizine and the acid hydrolysis of both indolizines to the unstable 1-hydroxy-2-phenylindolizine have been described[63].

1-Azomethines, formed when 2-acylpyridines interact with aromatic aldehydes in acetic acid in the presence of ammonium acetate, are hydrolysed in the presence of acetic anhydride with formation of 1-acetamidoindolizines. After such 1-azomethines have been heated for a long time with 70% perchloric acid, 1-hydroxyindolizinium perchlorate can be isolated and then benzoylated by the Schotten–Baumann method at the hydroxy-group to give the benzoyl derivative[97,102]:



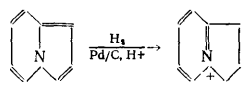
1-Hydroxy-3-phenyl-(*p*-chlorophenyl, *p*-anisyl)-indolizinium and 1-hydroxy-2-methyl-3-phenyl-(*p*-chlorophenyl, *p*-anisyl)indolizinium *p*-nitrobenzoates were obtained in this way.

Reduction and Oxidation of Indolizines

Indolizine[9] and substituted indolizines[66] are not reduced by zinc in acid[1] and on hydrogenation under the usual conditions in the presence of palladium on charcoal. Alkylindolizines are hydrogenated in the presence of

Raney nickel or the Adams catalyst at room temperature to 5,6,7,8-tetrahydro-derivatives and on heating to octahydroderivatives[9,11,14,15,25,54-56,66,92,109,114,195,196]. When 6-ethylindolizine was hydrogenated in glacial acetic acid on a platinum oxide catalyst (at 20°C and 7 atm), 6-ethyloctahydroindolizine was obtained in 80% yield[54]. The hydrogenation of 3-acetyl-2-methyl(phenyl)indolizines in the presence of the Adams catalyst at room temperature also stops at the stage of the 5,6,7,8-tetrahydroderivatives[15,196]. 1-(ω-Aminoalkyl)-2-phenylindolizines are not hydrogenated on a palladium catalyst, while on Raney nickel the reduction also involves the six-membered ring and yields the tetrahydroderivatives[56].

However, in 2*N* hydrobromic acid in the presence of palladium on charcoal indolizine is hydrogenated in the five-membered ring with formation of 1,2-dihydro-3*H*-indolizinium bromide in 85% yield:



It is suggested that in an acid solution there exists a mesomeric form of indolizine, which contains a pyridine ring conjugated with a double bond in the five-membered ring and that this species is hydrogenated[197].

Alkylindolizines are readily oxidised even by atmospheric oxygen[1,2]. Electrophilic substituents in the five-membered ring stabilise indolizines with respect to oxidants; indolizine-1,2,3-tricarboxylic acid is not oxidised by either nitric or chromic acid[48,55,56]. The final product of the oxidation of indolizines by peracetic acid or hydrogen peroxide in acetic acid is picolinic acid *N*-oxide or its homologues[55].

Physiological Properties of Indolizines

The research on indolizines is to a great extent concerned with the study of their physiological properties in addition to synthetic and theoretical investigations of this heterocyclic system. The hydrogenated indolizine system is contained in strychnine, securinine, and veratrine alkaloids: cevine, germine, and protoverine. There are some similarities between indolizines and serotonine.

It has been reported that certain alkylindolizines resemble convulsants in their physiological action; they paralyse muscular and respiratory activity[198]. Mannich bases obtained from 1,2-diphenylindolizine, formaldehyde, and ephedrine as well as a deoxy-analogue of the last compound have a depressant effect on the central nervous system[199]. 3-Dialkylaminomethyl-1,2-diphenylindolizines[192,200] and 1-aminoalkyl-2-phenylindolizines[66,190,191] also influence the central nervous system. 2-Furylindolizines exhibit antimicrobial activity[169]. Indolizine-1-acetic acid is an analgesic. 3-Acetyl(benzoyl)-1-(α-carboxyethyl)indolizines have been patented as analgesic and anti-inflammation agents[61].

3-Benzoylindolizine-1-acetic acid (the structural analogue of heteroauxin) exhibits an auxin-like activity[184]. β-(1-Indolizinyl)alanine is a tryptophan antimetabolite[201]. 1-Carboxymethyl-3-(*p*-chlorobenzoyl)-7-methoxy-2-methylindolizine and 3-carboxymethyl-1-(*p*-chlorobenzoyl)-6-methoxy-2-methylindolizine exhibit anti-inflammatory activity but are less effective than indomethacin [1-(*p*-chlorobenzoyl)-5-methoxy-2-methylindole] although less toxic than the latter[161]. It has been established that 2-arylindolizines are not carcinogenic[28].

Structure and Properties of Heat-resistant Polymers

A.A.Askadskii and G.L.Slonimskii

The influence of the chemical structure of heat-resistant aromatic polymers on their physical properties is discussed mainly in relation to mechanical properties. Methods for determining the heat resistance of polymers and their mechanical performance are described, and the calculation of the principal physical characteristics from the chemical structure of the repeating unit is explained. A detailed account is given of the effect of chemical structure on the glass point of heat-resistant aromatic polymers and on relaxation transitions within the temperature range of the vitreous state. A list of 131 references is included.

I. INTRODUCTION

The multitude of scientific publications appearing during recent years are testimony to the attention paid by specialists to the synthesis and the properties of heat-resistant polymers. A widely used route to such polymers is the synthesis of various polyheteroarylenes. Saturation of the polymer chain with aromatic ring systems and ladder-like fragments leads to increases in both skeletal and kinetic rigidity of the macromolecules, and hence to significant rises in the glass point and in the modulus of elasticity, with improvements in the strength and other properties of the polymer systems.

We attempt to summarise published information on the effect of the chemical structure and the supermolecular structure of the broad class of polyheteroarylenes and certain other heat-resistant polymers on their various physical properties, including mechanical (relaxation and strength), electrical, etc. properties. Special attention is paid to the nature of the heat resistance of polymers. These problems have recently been dealt with in several monographs [1-7] and reviews [8-10]. The present Review, therefore, will discuss the most recent research results, not covered in the above publications.

II. CHARACTERISTICS OF THE HEAT RESISTANCE OF POLYMERS

Before discussing results we must examine the very concept of the "heat resistance of polymers". According to one definition [11] "heat resistance is the ability of a polymer to retain at high temperatures the hardness necessary for the performance of articles made from it". In practice heat resistance is often measured in terms of certain temperatures, at which deformation of the polymer by a strictly defined amount occurs under a specified load (e.g Vicat or Martens heat resistance). With such a measure it is not always borne in mind that actual softening† of a material (i.e. loss of heat resistance) may take place not only at the glass point, determined under certain mechanical conditions, but also at any point within a range of temperatures if other stresses are applied.

In this connection Korshak [1,2] understands by heat resistance the "limiting temperature at which a polymer loses its mechanical strength under the influence of a particular load". It is very significant that this limiting temperature is influenced not only by the magnitude but also by the duration of the mechanical stress. Small stresses acting for a long time may produce the same breakdown of the material as do large stresses, when softening or fracture takes place rapidly. The same applies also to the temperature: fracture or softening occurs after a longer time at a comparatively low temperature than at a comparatively high temperature under otherwise similar conditions. The heat resistance of a plastic, i.e. retention of shape and integrity by the solid, can therefore be characterised physically either by a time [12] (under specified mechanical and thermal conditions),

†Since the softening of a material may present two different aspects—softening of a solid (i.e. an abrupt decrease in Young's modulus) and the appearance of fluidity—the concept of "softening temperature" requires refinement. If the decrease in Young's modulus is important, the softening temperature of a vitreous polymer coincides with the glass point, and that of a crystalline polymer with the melting point. If, however, the appearance of fluidity is significant, the softening temperature is usually defined as that at which a substance in a capillary begins to flow under its own weight, and then coincides with the pour point (in the absence of degradation). If a solid polymer (vitreous or crystalline) undergoes chemical degradation when heated, its softening temperature coincides with the beginning of intense thermal degradation.

by a maximum performance temperature (with a definite mechanical constraint acting for a specified period), or by a maximum permissible stress (acting under specified temperature and time conditions).

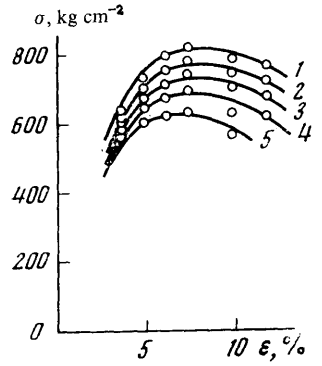

Figure 1. Isochronous dependence of stress σ on deformation ϵ for a polyimide of anilinefluorene and oxy-4,4′-diphthalic dianhydride (POI-10) at 130°C for different relaxation times t_r (min): 1) 1; 2) 3; 3) 10; 4) 60; 5) ∞.

If the conditions of service of the material require that its deformation should not exceed a specified value, the heat resistance will be characterised by the time of retention of shape t_{sh}, during which deformation under load (under certain temperature conditions) does not exceed this specified value. If, however, the stress in a material must not fall (owing to relaxation) below a required value, the heat resistance will be characterised by the time t_r during which this condition is satisfied (under specified temperature conditions).

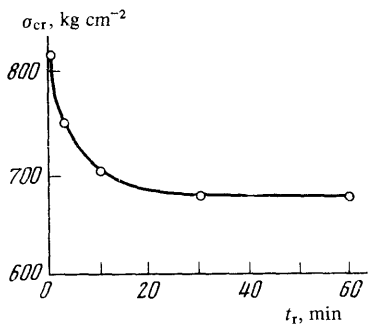

Figure 2. Dependence of σ_{cr} on t_r for POI-10 at 130°C.

To determine the maximum stresses that can be retained in a polymer for a specified time after the beginning of relaxation it is necessary to plot the stress σ against the deformation ϵ, when each curve corresponds to a definite duration of relaxation, i.e. is an isochronous dependence. Such relations usually pass through a maximum (Fig. 1). This maximum stress σ_{cr} depends significantly, of course, on the duration t_r of relaxation, as is illustrated by Fig. 2 for the polyimide of anilinefluorene and the dianhydride of the 3,3′,4,4′-tetracarboxylic acid of diphenyl ether. The dependence of σ_{cr} on t_r shows a monotonic decrease and conforms closely to Kohlrausch's equation.

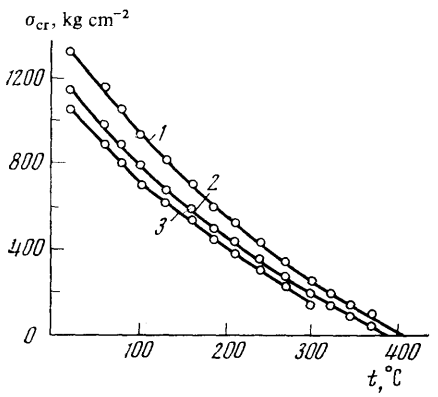

Figure 3. Temperature dependence of σ_{cr} for POI-10 after different relaxation times: 1) 1 min; 2) 60 min; 3) ∞.

From this equation we can determine the relaxation parameters, among which the most interesting is the maximum stress $\sigma_{cr,\infty}$ produced in a polymer by the completion of relaxation. It is a structural characteristic of the material, depending only on the chemical structure and the supermolecular structure. The temperature dependence of σ_{cr} determined for different relaxation times provides a complete description of the heat resistance of the polymer material (Fig. 3). These graphs also enable the period t_r of retention of the relaxing stress to be determined as a function of lg σ_{cr}. When the times are short these relations are linear (Fig. 4) and are described by the equation

$$t_r = A\sigma_{cr}^{-(\alpha_0 - \kappa T)} e^{U/RT}, \qquad (1)$$

where A, α_0, κ, and U are parameters of the material, R is the universal gas constant, and T is the absolute temperature. A more complicated relation applies for longer relaxation times [12]. The temperature dependence of $\sigma_{cr,\infty}$ and the dependence of t_r on σ_{cr} have since been used by several workers in assessing the influence of the chemical structure of a polymer on its heat resistance (see below).

Lengthy experiments are required to characterise heat resistance by the measurement of stress relaxation throughout the ranges of possible temperatures and deformations for each polymer. Such a determination should therefore be reserved for assessing the heat resistance only of the most promising individual representatives of a given class of polymers. More rapid assessment can be made by a widely used method [13-16] in which stress relaxation is examined under non-isothermal

conditions. For this purpose prismatic monolithic specimens of the polymer are placed between the working plates of a relaxometer and are deformed a certain amount, after which the temperature is raised linearly with time. In fixed specimens under such conditions, of course, compressive stresses arise as a consequence of the tendency to thermal expansion. With rise in temperature the stress increases to a certain limit, after which it falls as a result of accelerating relaxation, to reach zero at the glass point. By imposing different initial deformations on a specimen, we can obtain a series of such relaxation curves, each with its maximum (Fig. 5).

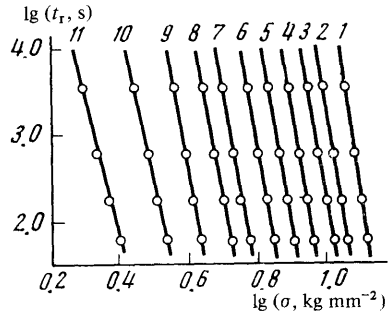

Figure 4. Dependence of lg t_r on lg σ_{cr} for POI-10 at various temperatures (°C): 1) 20; 2) 60; 3) 80; 4) 100; 5) 130; 6) 160; 7) 185; 8) 210; 9) 240; 10) 270; 11) 300.

The geometrical locus of these maxima delimits the region of stresses and temperatures within which the polymeric material remains effective, i.e. preserves heat resistance. The curve bounding the region of effectiveness obeys the equation

$$\ln \frac{\sigma}{\sigma'_\infty} = \frac{U_{r,0} - \gamma_r \sigma}{RT}, \qquad (2)$$

where $U_{r,0}$ is the initial activation energy of relaxation, and γ_r and $\sigma'_\infty = E\alpha\tau_{r,0}$ are parameters of the material, in which E is the Young's modulus, $\tau_{r,0}$ the pre-exponential factor in the temperature dependence of the stress-relaxation time, and $\alpha = \beta K$ the rate of deformation due to thermal expansion, β being the rate of temperature rise with time and K the coefficient of linear thermal expansion.

Experiment shows that, with a rate of heating of ~1.50 deg min^{-1}, the curve bounding the performance region almost coincides with the temperature dependence of σ_{cr} (Fig. 2) determined at a relaxation time t_r = 5 min. At longer relaxation times the bounding curves will, of course, be displaced to lower temperatures, but not very greatly (as in Fig. 3).

A thermomechanical method is also widely used for assessing the heat resistance of polymers. It is noteworthy that, over quite a wide range of molecular weights, many heat-resistant polymers do not exhibit rubberlike elasticity, passing directly from a vitreous solid to a viscous fluid when heated. In this case the temperature dependence of deformation (the thermomechanical curve) was described[17,18] in terms of Maxwell's model of a viscoelastic material. With a non-linear rise in temperature with time

$$T = a/(b - t), \qquad (3)$$

where a and b are constants, the thermomechanical curve will be represented by the equation

$$\varepsilon = \frac{\sigma a R}{E\tau_{r,0}U_r} e^{-U_r/RT}, \qquad (4)$$

in which ϵ is the relative deformation, σ is a constant stress, $\tau_{r,0}$ and U_r are parameters characterising the relaxation properties of the polymeric material, and E is the Young's modulus.

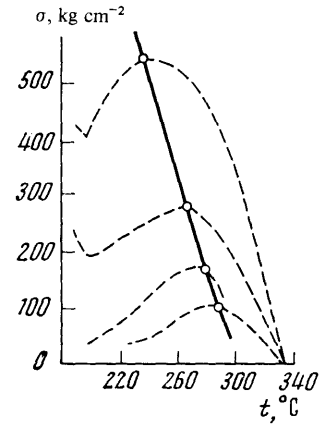

Figure 5. Performance range of polyamide of terephthalic acid and anilinephthalein.

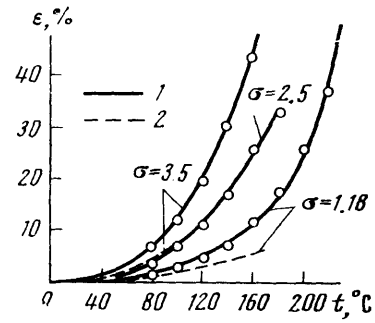

Figure 6. Thermomechanical curves (σ in kg mm^{-2}) for polyester of isophthalic acid and phenolphthalein having different structures: 1) fibrillar; 2) globular.

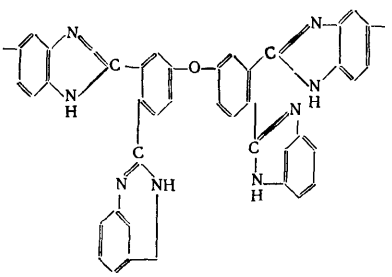
Fig. 6 shows thermomechanical curves obtained when films of a globular and a predominantly fibrous polyester of isophthalic acid and phenolphthalein are subjected to uniaxial extension. Only slight deformation is possible in the former polymer, but quite large deformation in the latter, which can thus pass into a viscous fluid under the

influence of mechanical stress. Experiments and calculations showed that the activation energy of relaxation U_r is rather larger for a globular than for a fibrous structure.

The relative simplicity of the relaxation process is indicated by the adequate description of the transition from solid to viscous fluid by Maxwell's method, i.e. by means of a single relaxation time that depends on temperature and stress. Softening in other heat-resistant systems, e.g. in various polybenzazoles, does not take place by one simple mechanism[19]. Fig. 7 shows thermomechanical curves (plotted as lg ϵ against $1/T$) for the polybenzimidazole



Since the relation is non-linear, relaxation is not described in this case by the usual temperature dependence of a single relaxation time.

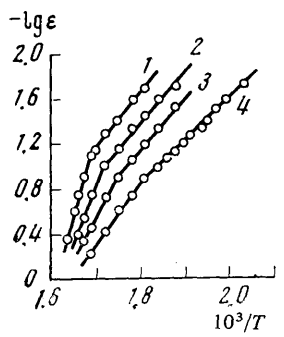


Figure 7. Thermomechanical curves for polybenzimidazole determined under different stresses (kg cm^{-2}): 1) 100; 2) 200; 3) 300; 4) 400.

In characterising the mechanical performance of polymers in general and their heat resistance in particular we must bear in mind the occurrence of several transitions at lower temperatures in addition to the main relaxation corresponding to transition from a vitreous solid into a state of rubberlike elasticity or of viscous flow. They are not revealed by the usual dynamic (mechanical and electrical) test methods but by examination of the relaxation properties of polymers under static conditions. Heat-resistant rigid-chain polymers are the most suitable subjects, since they exist in a vitreous state over an extremely wide temperature range, within which forced rubberlike elasticity develops: in other words, such polymers do not soften over a wide temperature range and do not exhibit brittle fracture.

These relaxation transitions were discovered earlier by Lazurkin[20] in a study of the temperature dependence of the limit of forced rubberlike elasticity for several polymer glasses and by Bartenev[21,22] in an investigation of the temperature–time dependence of strength for several systems over a wide temperature range. Transition from one substate to another entailed a change not only in its durability but also in its stress dependence. Thus, even before reaching the brittle point, the region of the vitreous state can be subdivided into at least two substates, in which different types of relaxation processes occur.

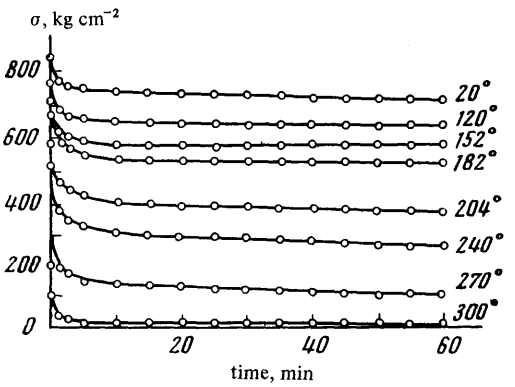

Figure 8. Stress-relaxation curves for polyester of terephthalic acid and phenolphthalein (ϵ = 4.4%).

Relaxation transitions detected by static methods of investigation are also very clearly developed in heat-resistant polymers. They have been studied[12,14,15,23] by examining the relaxation of stress at constant deformation under isothermal conditions. This yields a series of relaxation curves—the time dependence of stress—each corresponding to a certain chosen temperature. Fig. 8 shows that the relaxation curves are quite close together at low temperatures, and begin to shift rapidly down towards low stresses only after a certain temperature has been reached. A clearer idea of the temperature dependence of relaxation properties can be obtained from several properties, of which the simplest and most convenient is the relative decrease in stress after a specified relaxation time

$$\beta = \frac{\sigma_d - \sigma_t}{\sigma_d}, \qquad (5)$$

where σ_i is the stress on completion of deformation and σ_t the stress after relaxation for a certain time (e.g. 1 h).

The temperature dependence of $1/\beta$ is very characteristic (Fig. 9): it remains constant over a wide temperature range, after which it drops sharply, and then decreases smoothly with rise in temperature, to reach unity at the glass point. This means that the range of the vitreous state for a given system can be subdivided into two regions, differing in the temperature dependence of the relaxation parameters. At the lower temperatures the rate and extent of relaxation are relatively insensitive to temperature. The higher-temperature region shows a

sharp acceleration of relaxation processes, which is typical of many of the polymers studied earlier, not possessing high-glass points.

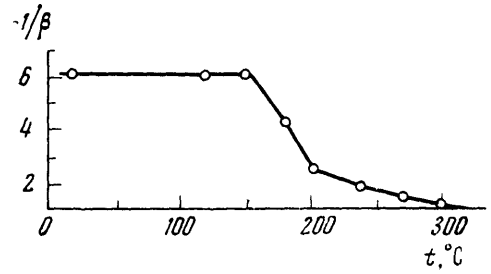

Figure 9. Temperature dependence of β^{-1} for polyester of terephthalic acid and phenolphthalein.

Without discussing the mechanism of the transition from one substate to the other, we note that such transition must be taken into account for an objective assessment of the heat resistance of a polymer. The glass point is usually regarded as the upper temperature limit of heat resistance: i.e. it is assumed that the polymer can be used right up to this temperature. This may be valid under very small loads for very short times. But even that is not the point. If a polymer material is functioning under variable temperatures, its transition from one substate to another, involving a sharp acceleration of relaxation processes, may lead to a complete loss of performance at temperatures far below the glass point. This is apparent, for example, in an abrupt increase in the coefficient of friction and in the seizing of moving parts[24]. Thus the zone of stable performance lies in the temperature range corresponding to the first substate, in which the rate of relaxation is insensitive to temperature. The real temperature range within which heat resistance is maintained therefore extends only to a temperature far below the glass point.

The above features are evident when the heat resistance of polymers is investigated by the measurement of stress relaxation. Prolonged creep tests under various loads must also be made for a more detailed assessment of the mechanical properties of heat-resistant polymers and for a comparison of their deformation behaviour under load. The isochronous stress–deformation curves obtained from these tests enable the rigidity of the systems to be judged more objectively[25].

III. CHEMICAL STRUCTURE AND PROPERTIES OF HEAT-RESISTANT AROMATIC POLYMERS

Before discussing the effect of the chemical structure of heat-resistant polymers on their properties, we must consider briefly the processing of such systems. Heat-resistant polymers whose glass point lies considerably below the temperature at which they begin to decompose can be processed[26] by the usual methods of injection moulding at high temperatures. The properties of monolithic specimens of poly(phenylene sulphide) have been reported[27]: specimens obtained by injection moulding possess moderate breaking stress (770 kg cm^{-2}), and extremely slight deformability (ϵ_r = 3%), but a considerable bending modulus of elasticity (E = 42 200 kg cm^{-2}); the maximum temperature limit to the performance of poly(phenylene sulphide) is assumed[27] to be 260°C.

Application of the usual methods of injection moulding and hot extrusion to process into monolithic articles highly heat-resistant polymers, in particular polyheteroarylenes, is made extremely difficult by the intensity of the accompanying thermal degradation and cross-linking. However, monolithic articles can be obtained from such polymers if processing is conducted below the limiting temperature at which thermal degradation takes place. By using high pressures and extruding at a temperature a few dozen degrees below that at which loss in weight begins we can obtain monolithic specimens from such heat-resistant systems as polytriazoles and polypyrazoles[28], polyphenylenes[29], aromatic polyimides[30–32], etc. This enables us to examine the effect of the chemical structure of polyheteroarylenes on their mechanical properties, in particular to specify the effect of the heterocycle.

If the heterocycle occupies a comparatively small volume, as e.g. in the case of poly(oxydi-*p*-phenylene–1,3,4-oxadiazole), appreciable crystallisation may occur, which in turn will tend to extend the performance range. With a more bulky ring system, e.g. poly(oxydi-*p*-phenylene–4-phenyl-1,2,4-triazole), the kinetic rigidity of the chain is increased, but crystallisation does not take place, the former factor tending to increase the performance range, and the latter to diminish it. Although the two effects are mutually competitive, experience shows that, with polyoxadiazoles and polytriazoles, crystallisation leads to a greater extension of the stress and temperature limits within which the polymer is effective. Competition between two processes—degradation and cross-linking—also occurs, however, if the polymer undergoes physical changes during processing. Cross-linking may have a favourable influence, promoting consolidation of the specimen at temperatures below the softening point (under the influence of high pressures). Thus the processing of poly-*p*-phenylene-1,2,3-triazole at 360°C yields monolithic specimens, whose performance range extends far above the processing temperature (Fig. 10).

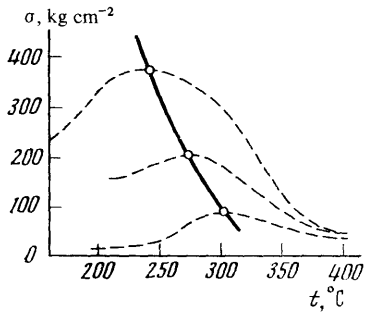

Figure 10. Performance range of poly-*p*-phenylene–1,2,3-triazole.

An especially interesting heat-resistant polymer is polyphenylene, from which monolithic specimens have also been obtained[29]. Although thermo-oxidative degradation occurs at ~400°C, monolithic polyphenylene is able

to function at far higher temperatures (Fig. 11). Moulded polyphenylene remains effective under a stress of 200 kg cm^{-2} at 300°C. Raising the temperature to 400°C lowers the working stress to 80 kg cm^{-2}, and even at 600°C the stress in monolithic polyphenylene is not completely relaxed to zero: i.e. performance is maintained at this temperature, but only under very small stresses.

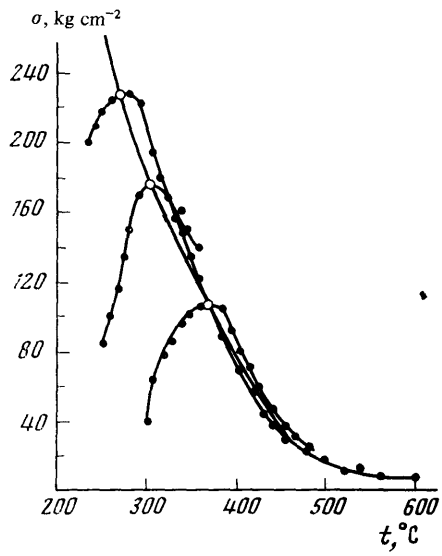

Figure 11. Performance range of polyphenylene.

The extrusion of heat-resistant polymers even at very high temperatures and pressures does not always yield true monoliths, since the extrusion temperature lies below the pour point. Despite this, such caked material is able to function in rigid structures. Thus the aromatic polyester Ekonol 301 is extruded under pressure to yield machinable monolithic material[33]. Articles made of Ekonol retain good mechanical and dielectric properties up to 315°C.

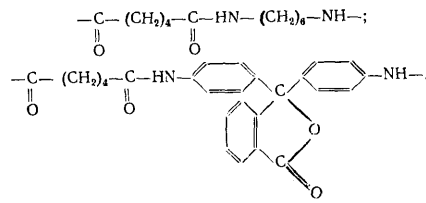
Mechanical properties under hydrostatic pressure have been studied[34] in connection with the problem of obtaining monolithic articles from rigid-chain polyimides at comparatively low temperatures. Under these conditions the polyimide exhibits large plastic deformations and collapses with formation of a neck, so that the polyimide can be processed by cold moulding. The application of hydrostatic pressure to polyimides may tend to raise the limit of forced elasticity and the elongation at rupture, and also to increase Young's modulus[35].

One route for obtaining heat-resistant plastics is the use of oligomers having reactive end-groups[36]. Fibres of a filler (e.g. graphite fibres) are impregnated with solutions of the oligomers and aromatic diamines, and then dried at a high temperature, after which the products are extruded. The resulting plastics possess good mechanical properties.

In the above processing methods the heat-resistant polymers are subjected to high temperatures and pressures, which is often undesirable and may lead to thermal degradation. This can be avoided by producing goods (in particular, films) from solution. In this connection the synthesis of the card type of heat-resistant systems has made a significant contribution to polymer science[37-41]. Such systems contain bulky side-rings, often possessing appreciable polarity, with one of the cyclic elements forming part of the main polymer chain. Thus without loss of heat resistance the polymer acquires good solubility in many readily available organic solvents, so that strong transparent films, whose properties will be described below, can be obtained. Enhancement of solubility can be achieved by the synthesis of "spiral-staircase" polymers containing ladderlike fragments[42].

The production of polymeric goods directly from monomers is currently a leading line of advance in polymer processing. The accompanying polymerisation or polycondensation results ultimately in formation of a finished article. This is sometimes the only possible method for heat-resistant systems, since many heat-resistant polymers do not possess fluidity. Morgan et al[43-45] have shown that it is entirely possible to process the monomers of pyrrones to give articles possessing adequate strength, elasticity, and several other valuable properties. Equimolecular mixtures of the monomers are compressed in a mould at temperatures up to 450°C for 1 h. In this way pyrrones have been obtained from pyromellitic dianhydride, benzophenone-3,3',4,4'-tetracarboxylic acid and biphenyl-3,3',4,4'-tetra-amine, etc. The optimum temperature, pressure, and time can be chosen to give specimens of maximum density, which in this case possess the greatest strength (up to 1475 kg cm^{-2}).

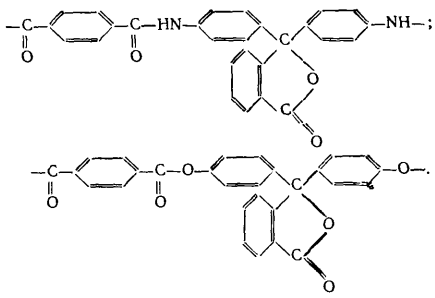
In assessing the effect of the chemical structure of heat-resistant polymers on their properties it must be borne in mind that a change in chemical structure quite often leads to a change in the state of aggregation (e.g. crystallisation), with significant changes in all the properties. The phase must therefore be taken into account. In order to examine the effect of chemical structure and state of aggregation on the mechanical properties of several polyesters and polyamides we shall compare the performance ranges of a few pairs of such polymers[46]. In the first pair of polyamides



the polymethylene segment in the amine component is replaced by an anilinephthalein residue. The performance regions of these polymers (Fig. 12) show that, although their softening temperatures are about the same, the polyamide based on an aromatic diamine withstands far greater stresses at all lower temperatures. Whereas polyhexamethylenadipamide is crystalline, while polyanilinephthaleinadipamide is amorphous, the latter forms a far more rigid monolith, capable of withstanding considerable mechanical loadings.

Comparison of the mechanical properties of an aromatic polyamide and an aromatic polyester in which the diol

residue has the same chemical structure as the diamine residue



permits assessment of the contributions by ester, peptide, and intermolecular (hydrogen) bonds in establishing the set of mechanical properties of the polymer over a wide temperature range. Fig. 13 shows that the curves bounding the performance regions of polyamides lie at considerably higher temperatures than the corresponding curves for polyarenecarboxylates. The largest displacement is found with polymers of aliphatic dicarboxylic acids, since hydrogen bonds continue to "function" at low temperatures, and undergo appreciable cleavage at high temperatures.

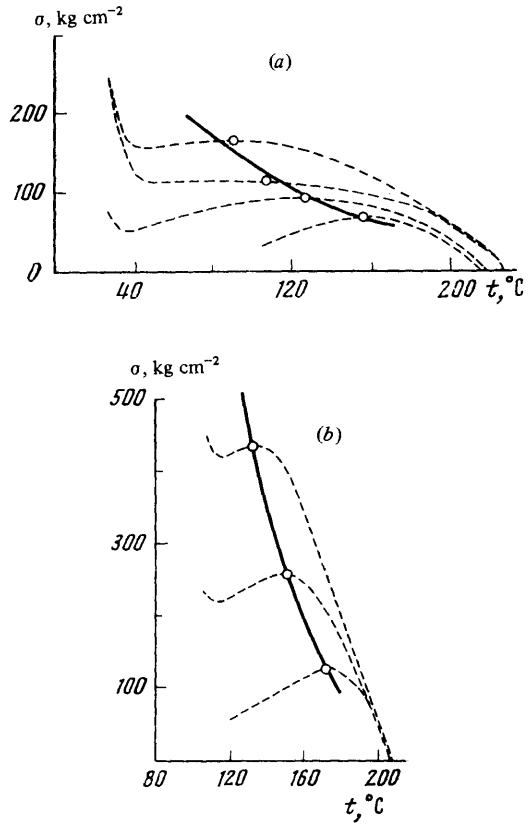


Figure 12. Performance ranges of: *a*) polyhexamethylenadipamide; *b*) polyamide of adipic acid and anilinephthalein.

A clearer idea of the effects both of chemical structure and of intermolecular interaction on the mechanical properties of such polymers can be obtained from the curves bounding the performance regions of polysebacamides and the corresponding polysebacates (Fig. 14). The polyamide formed by sebacic acid and anilinephthalein possesses the largest performance region. The bounding curve undergoes only a slight displacement to lower temperatures on passing to the analogous polyester, but a completely aliphatic polyester based on sebacic acid exhibits a sharp decrease in the mechanical stress limits. Thus the presence of intermolecular (hydrogen) bonds with a repeating unit of almost identical structure shifts the boundaries of the performance region only with respect to temperature, but changing the chemical structure (in the presence of hydrogen bonds) produces displacements with respect both to temperature and to stress.

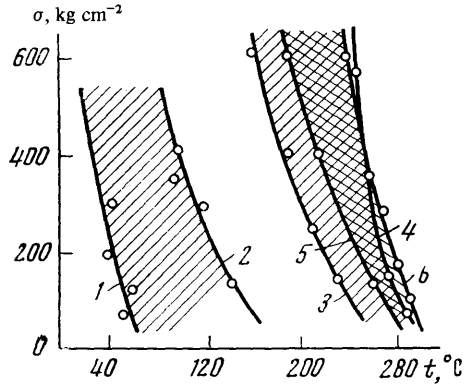

Figure 13. Curves bounding performance regions of various polyamides and polyesters: 1) polyester of sebacic acid and phenolphthalein; 2) polyamide of sebacic acid and anilinephthalein; 3) polyester of isophthalic acid and phenolphthalein; 4) polyamide of isophthalic acid and anilinephthalein; 5) polyester of terephthalic acid and phenolphthalein; 6) polyamide of terephthalic acid and anilinephthalein.

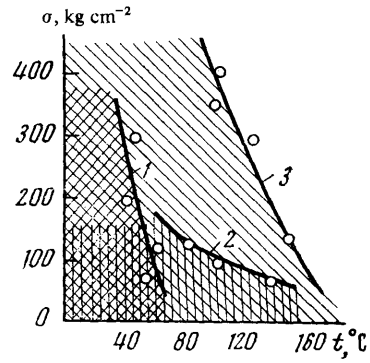

Figure 14. Curves bounding performance regions of polyamides and polyesters based on sebacic acid: 1) polyester with phenolphthalein; 2) polyamide with hexamethylenediamine; 3) polyamide with anilinephthalein.

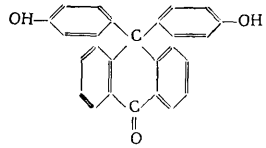
The difference in softening point between aromatic polyamides and polyesters was used[47] to determine the energy of the hydrogen bonds as 6.6 kcal mole^{-1}. Special attention has been paid[48,49] to the influence of substitution isomerism on the properties of aromatic polyamides[50].

The above systems belong mainly to the group of card polymers containing bulky side-rings. The presence of such rings confers solubility on the polymers, but often prevents their crystallisation, especially if the rings are unsymmetrical. In some cases, however, the presence of a bulky side-ring does not prevent crystallisation, and polyarenecarboxylates based on 9,9-bis-*p*-hydroxyphenylanthrone



are interesting in this respect[51-53]. Like analogous polymers they dissolve readily in many of the usual organic solvents, from which strong, transparent films can be obtained. Such polyesters show a pronounced tendency to crystallise. The structure of poly(hydroxyphenylanthrone terephthalate) and its properties can be changed by varying the conditions of preparation[52]. The use of different methods of polycondensation (at high and low temperatures in solution, interfacial) or different conditions of high-temperature polycondensation (reaction temperatures, rates of heating and cooling of the reaction mass, concentrations of starting materials, nature of the solvent) enabled this polyester to be obtained in crystalline form, in amorphous form, and as a mixture of the two forms‡. The polyester of hydroxyphenylanthrone and terephthalic acid is obtained in the most crystalline form by polycondensation at 220°C in chlorinated biphenyl, 1,2,4-trichlorobenzene, nitrobenzene, and 1-chloronaphthalene. The structure of this polyester can be varied not only by changing the conditions of preparation but also by appropriate treatment—reprecipitation, heating in specially selected solvents—of the finished polymer. The crystallisation of aromatic polyesters based on hydroxyphenylanthrone is accompanied by a deterioration in their solubility.

The presence of an anthrone ring system in a polymer chain favours crystallisation of the aromatic polyesters, and thereby provides further opportunities for improving their heat resistance, and perhaps that of other classes of rigid-chain polymers. Examination of a monolithic, partly crystalline polyester of hydroxyphenylanthrone and terephthalic acid showed a peculiar influence of order on heat resistance. Determination of the performance region of this polyester showed[52] that relaxation processes accelerate sharply, i.e. the material begins to soften, at the same temperatures with a partly crystalline specimen as with the amorphous material (Fig. 15), which suggests that softening involves the amorphous part of the polymer.

‡In the discussion of structure formation in polymers the terms "crystallinity", "crystalline and amorphous parts", etc. must be employed with some caution, especially when applied to aromatic polymers having bulky side-chains. In such case it is better to speak of the ordering of the system, since polyesters of this type cannot be obtained in the usual crystalline form. However, we shall not enter into questions of terminology here, but use these terms with this reservation.

However, the maximum temperature limits of performance become much higher with weakly stressed, partly ordered specimens.

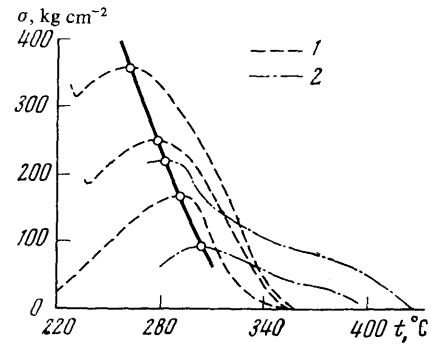


Figure 15. Performance ranges of monolithic specimens of polyester formed by hydroxyphenylanthrone and terephthalic acid: 1) amorphous specimen; 2) partly crystalline specimen.

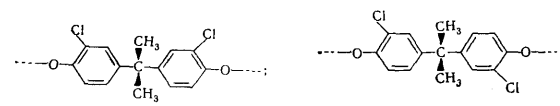
Interesting results have been obtained[54,55] for the mechanical properties of aromatic polyesters of 3′,3″-dichloro-2,2-diphenylpropane-4′,4″-diol prepared by acceptor-catalysed polycondensation. The chlorine-35 nuclear quadrupole resonance spectra of such systems are characterised by comparatively narrow signals belonging to different crystallographic forms. The reason may be that the chlorine atoms in the diol permit in principle the existence of two rotational isomers.



whose presence in the polyester chain may lead to two isomeric types of macromolecules. Polyesters of this diol and terephthalic acid obtained under various conditions of acceptor-catalysed polycondensation (different reaction media, temperatures, etc.) exhibit several abnormalities of mechanical behaviour. The thermomechanical investigation of films reveal a transition, apparent in a rapid development of deformation at temperatures below the softening range and in the establishment of a plateau (Fig. 16). It was found that the increase in deformation was not due to the usual transition to a state of rubberlike elasticity.

Another interesting abnormality is evident in the determination of performance regions for monolithic specimens of such polyesters. The non-isothermal stress-relaxation curve under conditions of uniaxial compression passes not just through one maximum (as is usual) but through two maxima, which appear in the temperature range of the first increase in deformation on thermomechanical curves obtained at the corresponding stress. Detailed analysis of this phenomenon, based on nuclear quadrupole resonance and on the measurement of heat capacity, suggests[55] that all these anomalies may be due to a transition between

rotational isomers in the residue of the diol, with a consequent conversion of one isomeric form of macromolecule into the other. This transition is activated by mechanical stresses, since increase in stress lowers the transition temperature (Fig. 16).

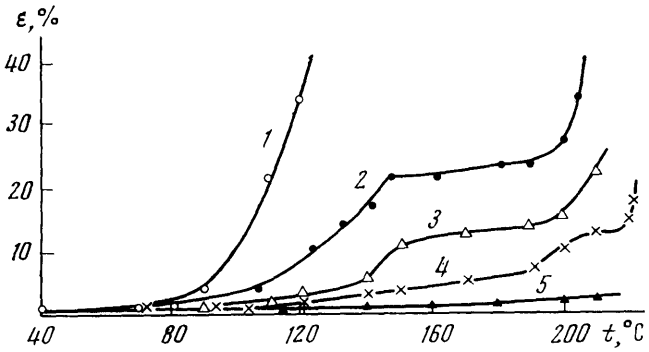


Figure 16. Thermomechanical curves obtained for polyester of 2,2-di-*m*-chlorophenylpropane-*pp'*-diol and terephthalic acid determined at constant tensile stresses (kg cm^{-2}): 1) 200; 2) 100; 3) 50; 4) 25; 5) 100 (repeat test).

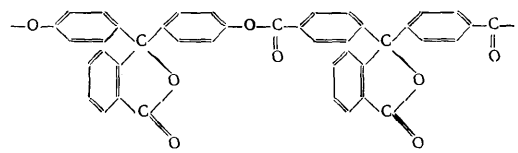
It appeared from the above considerations that the rotational isomers of aromatic polyesters of the dichlorodiphenylpropanediol were quite stable. This opens up the theoretical possibility of synthesising stereoregular polycondensed systems simply by varying the conditions. It also becomes obvious that the structure and properties of rigid-chain polymers can be most efficiently varied during synthesis, since the resulting macromolecular conformations are "frozen", remaining stable on subsequent treatment of the polymer[54,55]. Strength and deformation characteristics were published[56-58] for aromatic polyester films prepared in various media.

Strength cannot be fully assessed from the breaking stress, which merely provides a comparison of the strength properties of polymers differing in chemical structure. To obtain a more complete measure of the strength properties of polymers we must determine the parameters in Zhurkov's durability equation

$$\tau = \tau_0 e^{\frac{U_0 - \gamma\sigma}{RT}}, \qquad (6)$$

where τ_0 is the pre-exponential factor, U_0 the initial activation energy of fracture, γ a structure-sensitive parameter, and σ the constant stress. Numerical values of U_0 and γ were determined[17,59] by a modified thermomechanical method and by the application of Bailey's criterion to tests with uniaxial stretching at various temperatures. The initial activation energy of fracture was found to be low (U_0 = 30 kcal mole^{-1}) for globular polyesters of phenolphthalein with isophthalic and terephthalic acids. This indicates that the bonds between the globules forming a film or a monolithic body are fairly weak. The type of supermolecular structure of such systems has an appreciable influence also on the relaxation processes accompanying deformations remote from fracture. Greater rigidity at comparatively low temperatures and larger equilibrium stresses are obtained with a globular than with a fibrous structure. With rise in temperature the opposite situation is found, for the ease of rupture of the weak bonds between globules leads to premature breakdown of the material. Globular material is more homogeneous in structure, which results, in particular, in well defined temperature dependence of the relaxation parameters[60].

The effect of bulky side-rings in conferring solubility is confirmed by the synthesis of soluble, extremely heat-resistant polyesters of 4,4-diphenylphthalide-*pp'*-dicarboxylic acid with various diols (resorcinol, quinol, biphenyl-*pp'*-diol, etc.)[61]. Among them the polyester of this acid with phenolphthalein



is especially interesting, its performance range surpassing those of other aromatic polyesters with respect both to temperature and to stress at a given temperature. Thus the introduction of an additional bulky, polar ring not only improves the solubility but also extends the ranges of stresses and temperatures over which the polymer remains solid and able to function in rigid structures.

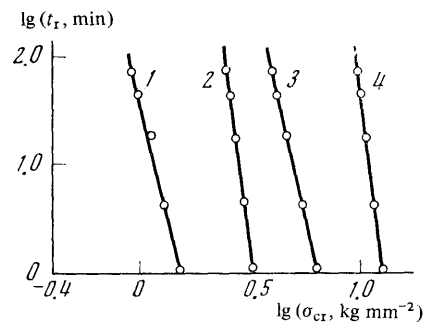


Figure 17. Dependence of lg t_r on lg σ_{cr} at 20°C for the polymers: 1) polyethylene glycol (M = 20 000); 2) poly(ethylene glycol sebacate); 3) polyester of sebacic acid and phenolphthalein; 4) polyester of terephthalic acid and phenolphthalein.

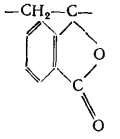
In concluding our account of the structure and properties of polyesters we must pay special attention to their relaxation properties, which largely determine the heat resistance. Measurement of these properties over a wide temperature range has enabled[62] the effect of chemical structure on heat resistance to be studied for a series of polyesters. Comparison of the relaxation parameters of the sequence from aliphatic polyethers to polyesters containing different numbers of aromatic rings in the repeating unit shows that, under otherwise similar conditions, an aromatic polyester (polyarylate F-2) retains the relaxing stress for a far longer period than any other polymer in this sequence (Fig. 17). As we pass

from polyethers to polyesters and as the latter become saturated with benzene rings the above relations shift regularly to greater critical stresses. Thus extension not only of the temperature ranges of mechanical performance but also of the range of working stresses themselves can in practice be achieved by controlled variation of the chemical structure of the polymer to increase the relative proportion of aromatic rings in the repeating unit.

Special importance must be attached to the presence of bulky (polar) groups, whose beneficial effect on solubility and heat resistance when in the side-chain is especially clearly demonstrated with cardlike carbon-chain polymers, an example of which is polymethylenephthalide[63,64]



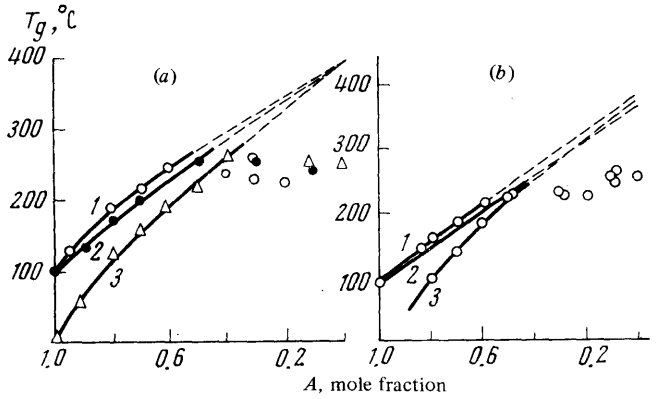


Figure 18. Dependence of glass point determined: *a*) by thermomechanical method; *b*) from performance regions on composition of copolymers [of methylenephthalide] with (*A*, mole fraction): 1) styrene; 2) methyl methacrylate; 3) methyl acrylate.

This polymer can usefully be regarded as a substituted polyethylene possessing incomparably greater heat resistance than either polyethylene itself or its other derivatives. Thus the glass point of polyethylene is −130°C, and that of polystyrene is 100°C, whereas thermomechanical curves suggest that polymethylenephthalide has a glass point of 300°C. However, this last polymer undergoes intense thermal degradation at these temperatures, so that the true softening temperature may be still higher. Calculation by means of Eqn. (8) gave a softening point of 390°C. Calculated and experimental softening points were tested by examining a series of copolymers with styrene, acrylonitrile, methyl methacrylate, methyl acrylate, and other monomers, which showed[64] a smooth rise to 250°C with increase in the methylenephthalide content (Fig. 18). Further increase produced no further rise in softening point of the copolymer, which remained constant in the range 220–250°C. The observed constancy of the softening temperature with variation in the composition of a copolymer is evidently due to thermal degradation at this temperature. The softening point of polymethylenephthalide itself can be determined only by extrapolating the composition dependence of the glass point of the copolymers to zero concentration *c* of the second comonomer, which yields a glass point lying in the range 370–380°C, in good agreement with the calculated temperature.

Thus the presence of card groups in a carbon-chain polymer leads to a sharp increase in heat resistance, as in heterochain polymers. In such systems the heat resistance exceeds the thermal stability, and the latter thus limits their performance. This has extremely important practical consequences. With a large margin of heat resistance present, the polymer can be modified by copolymerisation, plasticisation, etc. without danger of lowering its actual softening temperature. In particular, the quantity of plasticiser or the concentration of phthalide groups on copolymerisation with other monomers can be varied within wide limits. Nevertheless, the introduction of even a small quantity of phthalide segments into an ordinary carbon-chain polymer leads to a considerable improvement in its heat resistance.

Polyimides currently form one of the most important classes of heat-resistant polymers, since they form the basis of plastics, films, fibres, coatings, and other objects which retain their performance at high temperatures. Aromatic polyimides when heated often pass from a vitreous state directly into a viscous fluid, but in several cases they may develop rubberlike elasticity, as do polymers having flexible macromolecules. A characteristic of heat-resistant systems is that the range of such elasticity is displaced significantly to higher temperatures, which its upper limit determined by the intensity of thermal degradation and cross-linking. Furthermore, the modulus of rubberlike elasticity is substantially greater for heat-resistant systems than for flexible-chain polymers. Polyimides may yield either non-softening rigid polymers or softening polymers having normal Young's moduli of 50–100 kg cm^{-2}, depending on the proportion of flexible units in the polymer chain[65]. The thermomechanical properties of several polyimides were explained[66] by the formation of a labile network, whose presence was especially apparent above 250°C.

Determination of the temperature range of rubberlike elasticity from the thermomechanical curve without further verification of the reversibility of deformation may lead to substantial errors. The presence of a plateau on this curve is a necessary but not a sufficient condition for the development of rubberlike elasticity, since it may be due to thermal degradation and several other secondary processes: verification of the reversibility of deformation in the region of the plateau is therefore absolutely necessary. Fig. 19 shows thermomechanical curves, determined on uniaxially stretched films[31], for polyimides of oxy-*pp'*-dianiline and oxy-4,4'-diphthalic acid (curves *1* and *1'*) and of anilinephthalein and sulphonyl-4,4'-diphthalic acid (curves *2* and *2'*). The broken curves represent the properties of the polymers subjected to a constant stress, whereas the full (primed) curves apply to periodic loading. Fig. 19 shows that part of the deformation in the region of the plateau is reversible (rubberlike elasticity), while part is irreversible (viscous flow). The former polymer (curve *1*) possesses a wide range of rubberlike elasticity (280–500°C). Curve *1'*, determined under a variable load, shows that the modulus of rubberlike elasticity $E = \Delta\sigma/\Delta\epsilon$, where $\Delta\sigma$ is an increment of stress and $\Delta\epsilon$ the

consequent increment of reversible deformation, increases continuously with rise in temperature (from 30 to 100 kg cm^{-2} from 300 to 430°C). The specimen does not exhibit rubberlike elasticity above 460°C, which, like the increase in the modulus, is attributed to chemical cross-linking. A similar modulus (20 kg cm^{-2}) was observed in the transition zone for the second polyimide. The specimen had an extremely high glass point and hence a narrow range of rubberlike elasticity (430–470°C), bounded by the intensity of degradation and cross-linking.

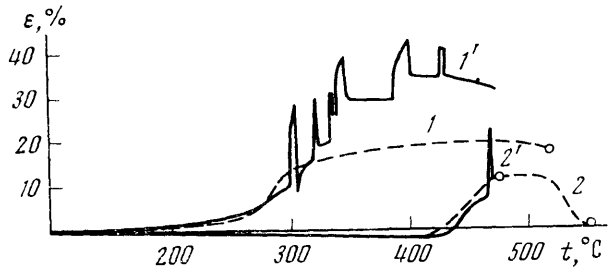

Figure 19. Thermomechanical curves for polyimide films.

Many types of aromatic polyimides are roughly equivalent in thermal stability, from which follows the conclusion of practical importance that the range of the state of rubberlike elasticity can be extended significantly by lowering the glass point either by introducing oxa, carbonyl, etc. groups into the polymer chain or by diminishing the number of fused rings. We again stress that, despite the sharp drop in glass point, the thermal stability remains almost undiminished; thus there is no direct link between the glass point and the temperature at which loss in weight begins. Rubberlike elasticity is exhibited not only by polyimides but also by other heat-resistant polymers, e.g. polybenzoxazoles[67]. The thermal stability of these systems is also little affected by the introduction of oxa, thia, or carbonyl groups into the main chain.

When the thermomechanical properties of these polymers are determined in the presence of small mechanical stresses, the glass points are often close to the decomposition temperatures. The former can conveniently be sought by making thermomechanical tests with comparatively large stresses. This lowers the glass point considerably, but a plateau is still formed on the thermomechanical curve because of the high moduli of rubberlike elasticity, and it is easy to determine both the glass point and the pour point T_{fl}. The true temperatures of these points can be determined by plotting T_g and T_{fl} against stress and extrapolating to zero stress. This procedure enables glass and pour points to be found when they lie above the decomposition temperatures of the polymers.

On the whole the introduction of "hinge" atoms into the repeating units of polybenzoxazoles, polyimides, and other heat-resistant polymers permits control not only of the glass point but also of strength and deformation properties. A suggested classification of polyimides was based[68,69] on the presence and site of hinge bonds. The resulting classes differed in physical properties. A physical model shows[69] that the rearrangement and introduction of "flexible" bonds, allowing for interaction between chains through transverse groups, controls the number of degrees of freedom of such a system. This classification can be applied also to other systems[70,71]. The introduction of various hinge groups—oxa, thia, carbonyl, peptide, carboxylate, etc.—not only enhances the deformability of heat-resistant systems but also facilitates their fabrication into monolithic articles by hot extrusion, injection moulding, etc. to yield polymeric materials having excellent mechanical properties[5]. However, the main advantage of many aromatic polymers—their high heat resistance—is in considerable measure lost.

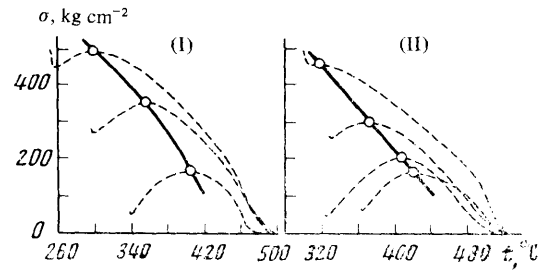

Figure 20. Performance ranges of monolithic specimens of polypyromellitimides (I) and (II).

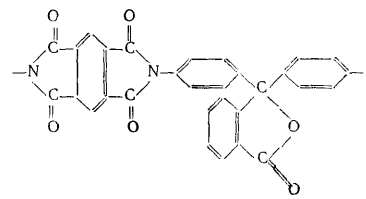
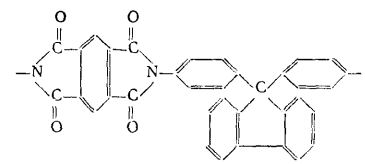
More detailed consideration of this problem in relation to aromatic polyimides shows that, on introduction of the above groups, the heat resistance of the polymers will differ little from that of aromatic polyesters, aromatic polyamides, and other polyheteroarylenes. The performance ranges of monolithic specimens of the polyimides



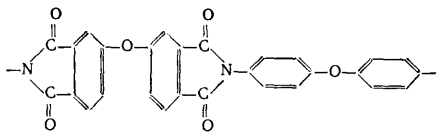
(I)



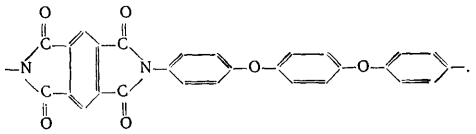
(II)

which do not contain the above groups, are extremely wide with respect both to temperature and to stress (Fig. 20)[32]. Thus at 300°C these plastics can function under a load of 500 kg cm^{-2} for a short time, and at 400°C they withstand 200 kg cm^{-2} (most structural plastics are completely devoid of performance at this temperature, owing both to degradation and to softening or flow). The maximum performance limits for the polyimides (I) and (II) are respectively 490 and 515°C. To compare the performance of these polyimides with that of polyimides containing "hinge" groups and also of several traditional polymers, we plot on the same diagram (Fig. 21) the curves bounding the performance regions of these systems.

The heat resistance of the polymeric materials increases significantly as the main polymer chain becomes saturated with aromatic rings and with other heterocycles. Some of the solid polyimides represented on Fig. 21 are not true monoliths (Nos. 9–11), and their performance ranges might be extended further if true consolidation of the material were achieved. The heat resistance can be improved also by crystallisation. Not only the number but also the relative arrangement of rings is no less important for the heat resistance of polyimides and other systems [31,32,72]. With identical numbers of imide rings, benzene nuclei, and all other groups and elements, the heat resistance is enhanced by a greater degree of ring fusion. Thus the polyimide



is considerably less heat-resistant than is



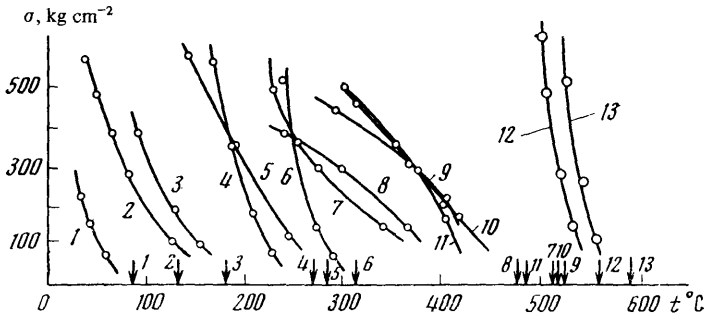


Figure 21. Curves bounding the performance regions of representatives of various polymer series: 1) poly(methyl methacrylate); 2) poly(2,2-diphenylpropane-*pp'*-diol carbonate); 3) poly(propane-2,2-di-*p*-phenylene isophthalate); 4) poly(phenolphthalein isophthalate); 5) polyimide of oxy-*pp'*-dianiline and oxy-4,4'-diphthalic acid; 6) polyamide of isophthalic acid and anilinephthalein; 7) polypyromellitimide of oxy-*pp'*-dianiline (amorphous); 8) polypyromellitimide of *p*-diphenoxybenzene-*p'p''*-diamine; 9) polypyromellitimide of oxy-*pp'*-dianiline (partly crystalline); 10) polypyromellitimide of 9,9-diphenylfluorene-*p'p''*-diamine; 11) polypyromellitimide of 3,3-diphenylphthalide-*p'p''*-diamine; 12) sodium silicate glass; 13) potassium silicate glass. The arrows indicate the softening points of the polymers. Specimens 5, 7, and 8 were obtained by formation from a preliminary polymer (polyamino-acid).

In conclusion we again direct attention to the possibility of obtaining extraordinarily heat-resistant organic polymers (polyimides). In this respect they approach quite closely to inorganic glasses, which many authors [73] now regard as polymeric in structure. Fig. 21 includes curves bounding the performance regions of two inorganic glasses, which are displaced to higher temperatures than the corresponding curves for polyimides based on anilinefluorene and on anilinephthalein, but not so greatly. In the preparation of polymers capable of functioning at high temperatures it must be borne in mind that the upper temperature limit of their performance may be governed not by loss of heat resistance (softening) but by the beginning of intense thermal degradation, i.e. loss of thermal stability. In several cases, therefore, it may be important to determine the thermal stability rather than the heat resistance.

Considering in greater detail the relaxation properties[30] of block specimens of one of the most important aromatic polyimides—the polypyromellitimide of oxy-*pp'*-dianiline—we note that the properties of its films have been studied in some detail[6], but different views are held on several of its principal physical properties. Results for the glass point are especially contradictory, for temperatures of 250, 380, and >500°C have been found [6,66,74]. The temperature dependence of the parameter α in Eqn. (1) for block specimens of this polymer shows (Fig. 22) two relaxation transitions (at 270 and 400°C), which may be due to devitrification. Extrapolation to $\alpha = 0$ yields [12] $T_g = 520$–530°C. However, this polymer exhibits a tendency to crystallise, which may be responsible for the break in the temperature dependence near 400°C.

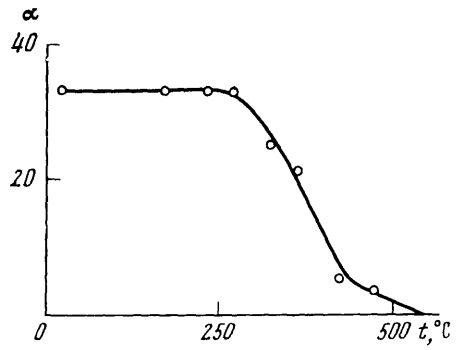

Figure 22. Temperature dependence of α for block specimens of the polypyromellitimide of oxy-*pp'*-dianiline.

The temperature dependence of $\sigma_{\infty, cr}$ exhibits a similar pattern: Fig. 23 shows that this critical equilibrium stress remains approximately constant over a wide temperature range, after which it decreases smoothly with rise in temperature. The curve bounds the region of stresses and temperatures in which the solid polymeric material can function under conditions of stress relaxation for a long time. With the above polypyromellitimide this region is quite large with respect both to temperature and to stress, although polyimides having a card structure are able to operate under far larger stresses at the same temperatures (cf. Figs. 23 and 20).

Investigation of the effect of chemical structure on the properties of polyimides must take into account their possible tendency to crystallise. This tendency varies in complicated fashion with the rigidity of the chain [75–77],

which is determined by the presence of aromatic nuclei: increase in the content of such rings initially prevents crystallisation, and at a certain content the tendency to crystallise becomes minimal; but after this the strengthening of intermolecular interaction intensifies the tendency, leading to an infusible polymer. The crystallisability is significantly affected by the position of the aromatic ring in the chain and by the presence of a solvent [75,76].

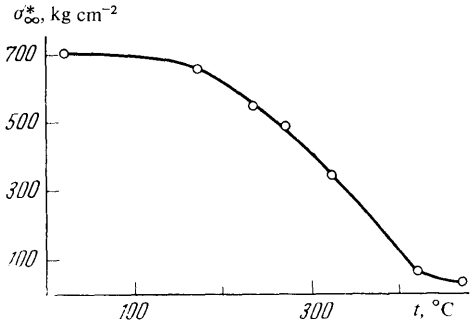

Figure 23. Temperature dependence of $\sigma^*_{\infty,cr}$ for block specimens of the polypyromellitimide of oxy-*pp'*-dianiline.

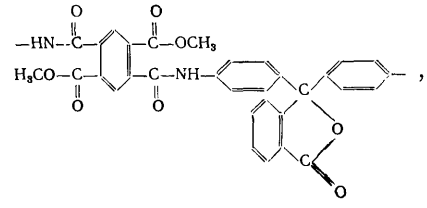
Close attention has recently been paid to the hydrolytic stability of polyimide films. Keeping such a film in water produces a rapid fall in tensile strength and in elongation at break. This phenomenon is characteristic both of polyalkyl-imides (based on pyromellitic dianhydride) and of completely aromatic systems. With the former the elongation at break falls rapidly from 200 to 100–40% after immersion in water at 70–100°C for 50–100 h. [78] A film of poly(oxy-*pp'*-dianiline pyromellitimide) [79] exhibits the same peculiarities, although the quantity of water absorbed is about 4%, compared with 0.4% for polyalkyl-imides.

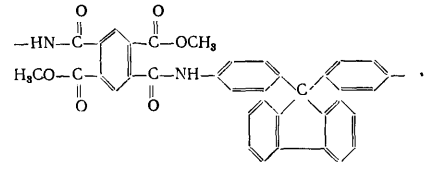
It is possible [80] to restore the strength and deformation properties of Kapton polyimide film after they have been sharply reduced by hydrolysis in distilled water at 100°C. The tensile strength of 1860 kg cm^{-2} and elongation of 62% of the initial film had fallen to 1050 kg cm^{-2} and 6.3% after standing in water at 100°C for 12 days. Heat-treatment of the hydrolysed film at 224–310°C for a few hours increases the tensile strength to 1700–1800 kg cm^{-2} and the corresponding elongation to 38–51%. Thus the amino-acid units formed by hydrolysis are recyclised, rapidly in the early stages and slowly in the later stages; this occurs not only in the solid state [81,82] but also in solution [83].

In this connection it is very important, in the two-stage formation of polyimides and other polymers, that cyclisation of the initial polymer should be as complete as possible. The presence of uncyclised units not only diminishes the heat resistance but also sharply decreases the hydrolytic stability and impairs several other properties. It is thus very important to determine the optimum conditions for cyclisation. It was shown in the case of poly(3,3-diphenylphthalide-*pp'*-dicarboxylic hydrazide) that its cyclisation to polyoxadiazole takes place rapidly at temperatures below the glass point of the polyhydrazide [84,85]. Chemical cyclisation is accompanied here by considerable contraction of the repeating unit. Passage through the glass point makes possible, of course, full development of the mobility of the polymer chain, as a result of which the intramolecular cyclisation is considerably accelerated.

In other cases cyclisation is rapid even in the vitreous, solid state, as has been shown for the polyimides resulting from cyclisation of the alkoxycarbonylated polyamides



(III)



(IV)

Detailed examination has shown [86] that, although the glass point of (IV) is 290–300°C, the polymer has undergone intense cyclisation over the range 150–250°C. With certain other polyimides rapid cyclisation takes place above the glass point of their polyamino-acids [87,88]. However, these workers themselves [87,88] admit that the polyamino-acid contained a large quantity of solvent (*NN*-dimethylformamide), which not only lowered the glass point of the system but also changed the whole kinetics of cyclisation. Calculations based on Eqn. (8) gave glass points of these acids considerably higher than the published temperatures [87,88].

Thus heat-resistant aromatic systems can undergo rapid and extensive cyclisation in the solid phase either above the glass point of the initial polymer or in the vitreous state. Both the rate and the extent of cyclisation are determined, not by the physical state of the system (vitreous or rubberlike elastic), but mainly by the chemical structure, which governs the kinetics of the process and the need for a particular contraction of the repeating unit on formation of an intramolecular ring.

The properties of heat-resistant polymer films can be modified by synthesising mixed systems, which often tend to change the structure and improve the mechanical properties of the films. The properties of polyheteroarylenes can be modified by preparing polyamide-imides, whose solutions are more stable (in contrast to solutions of polyamino-acids); stable films can be obtained from them without heat-treatment [89]. The preparation and properties of polyamide-imides and polyester-imides of ordered structure have been described [90–93]. The latter polymers, because of the introduction of an ester group into the dianhydride component, possess several specific properties and characteristics of their state of aggregation. The macromolecules show well defined spontaneous orientation as a consequence of a conformational transition into a more ordered state, occurring in the region of the glass point of the polymer (210–230°C), where the molecular units become sufficiently mobile. The transition is accompanied by the appearance in unoriented films of an axial (in some cases axial-planar) texture with its axis perpendicular to the surface of the film. Polyester-imides undergo extensive crystallisation when heated to

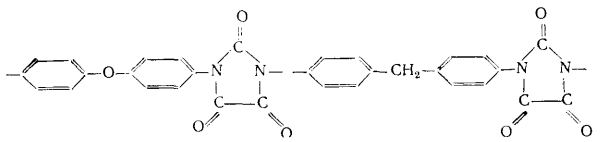
350–380°C. Drawing these polymers at temperatures near the glass point yields a typical amorphous texture, which, together with the spontaneous orientation effect, indicates that considerable order is present in the amorphous state. Further heating enables highly crystalline structures to be obtained, which are stable up to 420–450°C. X-Ray diffraction showed that increasing the number of phenyl rings in the diamide component merely increased the parameter c of the unit cell, without affecting the relative arrangement of the macrochains. The characteristic behaviour of polyesterimides is explained by enhanced rigidity of the macromolecules and interaction between phenyl rings, leading to a non-spherulitic type of crystallisation[91–93]. Films of polyimides and polyamidoimides are able to withstand ultraviolet radiation[94].

Other mixed heat-resistant systems of interest are polyamidoquinoxalines[95] and polybenzoxazolimides, whose mechanical properties have been reported in detail[96]. The tensile strength of films of these polymers lies in the range 1600–2200 kg cm^{-2}, and the elongation at rupture between 5% and 40%. The mechanical properties of films are significantly affected by the solvent in which the polymer had been dissolved. Evaporation of different solvents will yield films possessing appreciably different properties, probably because of differences in structure formation.

The properties of aromatic polymers, including polyimides, can be modified by the introduction of perfluoroalkylene segments[97,98], which is a more efficient method of lowering the glass point than is the introduction of ether links. The glass point can be varied within quite wide limits by changing the length of the perfluoroalkylene chain. Films, monolithic articles, and fibres possessing satisfactory mechanical properties have been obtained from modified polyimides. The glass point can be raised also by the introduction of card groups[10,99], their effect being most marked in an aliphatic chain (e.g. in aliphatic polyesters). Introduction of a card group, of course, increases both the skeletal rigidity of the chain and its kinetic rigidity, because of the large bulk of the group. Hence the significant rise in the glass point in comparison with the initial polyesters.

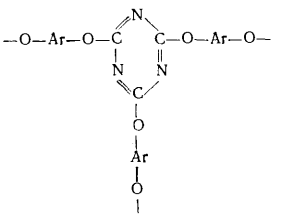
Heat resistance can be improved by cross-linking linear polymers, e.g. polyamidoquinoxalines, containing functional side-groups[100]. The system thereby loses its fluidity, and when filled possesses enhanced strength, which is maintained at very high temperatures. The strength of heat-resistant polymers can be increased by drawing and heat-treating them in a swollen state. Application of this procedure to poly-*m*-phenylenisophthalamide leads to significant increases in Young's modulus, tensile strength, and (with moderate degrees of drawing) elongation at break[101]. A very appreciable improvement in mechanical properties can be achieved by choosing optimum drawing conditions (type of solvent, temperature, duration of drawing, etc.).

A recent paper[102] has described the preparation and properties of polyparabanic acids



which possess high glass points (290–300°C), are readily processed into monolithic articles by stamping or extrusion, and form very strong films possessing good dielectric properties preserved at high temperatures.

An interesting investigation on the preparation and properties of heat-resistant aromatic polymers has been concerned[103,104] with polycyanates, obtained by the polycyclotrimerisation in mass of dicyanates of various aromatic diols. This reaction produces a network



of high regularity resulting from the enhanced selectivity of cyclotrimerisation of O–C≡N groups[103,104]. Polycyclotrimerisation is characterised also by a high conversion of such groups, reaching 98–99%. All these features lead to the formation of systems having a very dense network and possessing increased resistance to mechanical impacts and several other interesting properties[105]. The network systems exhibit not only increased resilience but also appreciable signs of structural order, with almost constant packing coefficients of the macromolecules in the networks close to the mean value (k = 0.681) for amorphous monolithic polymers[15]. Thus three-dimensionally cross-linked aromatic polymers are similarly ordered systems to amorphous and slightly crystallised linear polymers. The heat resistance of such networks is limited by the temperature at which their degradation begins; for many of them the limit is 300–350°C.

Not only monolithic articles and films but also fibres retaining their performance at high temperatures can be obtained from heat-resistant aromatic polymers. Without considering in greater detail this special aspect, we note merely that information has been published on the properties of fibres based on aromatic polyamides and various irregular copolyamides[106] and that fibres have been obtained from alternating polyoxadiazolimides[107], polyamide–hydrazides[108–113], and adamantane[114] and other polymers[115,116], among which considerable interest attaches to poly-2,2′-octamethylene-5,5′-dibenzimidazole, obtained by interaction between biphenyl-3,3′,4,4′-tetraamine and derivatives of sebacic acid. This last polymer forms stable films and fibres, whose crystalline state is affected significantly by the solvent[116]. In particular, replacing the solvent (formic acid by acetic acid) changes the parameters of the unit cell. Experimental results obtained by X-ray diffraction, thermography, and infrared spectroscopy combine to indicate the formation of a crystalline solvate state, which considerably alters the physical properties of this polymer.

IV. RELAXATION TRANSITIONS

Relaxation transitions in polymers are usually detected from the temperature dependence of the tangent of the angle for mechanical and dielectric losses tan δ. Heat-resistant polymers are extremely interesting to investigate, since they exist in the vitreous or crystalline state over a wide range of temperatures, within which many transitions can be discovered. Study of the temperature dependence of tan δ is not only of scientific value for identifying relaxation transitions but also of considerable practical value as a method of quality control of the article

during processing. A still more complete picture is obtained by combining this method with differential thermal analysis. An instrument has been described[117] for the simultaneous determination of dielectric constant and losses, together with differential thermal analysis.

The appearance of particular relaxation transitions will depend on the previous thermal history of the specimens, their crystallinity, and other factors, as well as the method of investigation. It is interesting to trace the transitions in poly-(2,6-diphenyl-1,4-phenylene ether)[118], amorphous specimens of which exhibit a distinct maximum in the temperature dependence of E'' at ~230°C, which corresponds to the glass point. A slight maximum is observed at lower temperatures (~130°C), whose appearance is due to twisting vibrations of the phenylene groups. This transition is more clearly evident in the dilatometric curve, which shows a break near 120°C as the coefficient of cubical expansion increases. The temperature dependence of tan δ for dielectric losses reveals new transitions at 290, 340, and 485°C.

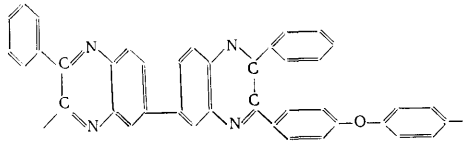
The influence of the previous thermal history on dynamic and static mechanical properties has been studied in detail on polyimides obtained by the cyclisation of polyamino-acids[119]. The temperature dependence of tan δ and that of Young's modulus vary with the rate of heating and the temperature at which cyclisation occurred. The presence of uncyclised units and the possibility of chemical cross-linking at very high temperatures lead to "post-cyclisation" over a certain temperature range during testing, with the appearance of additional peaks in the temperature dependence of tan δ. This applies also to the effect of water and of residual solvent, an aspect which must be discussed in greater detail.

Whether low-temperature transitions in polyimides are due to the molecular nature of the repeating units or to the presence of impurities (e.g. water) has been a matter of debate. A special investigation[120] has revealed three distinct maxima below 130°C in the temperature dependence of tan δ for polyoxy-*pp'*-diphenylenepyromellitimide containing no water: the first, γ-transition occurs at −123°C; the second, at 77°C, is attributed to β°-relaxation; and the third, very weak maximum at −27°C is due to residual moisture in the specimen. Even a small quantity of water (0.225%) changes the picture significantly: a blurred peak is observed from −123 to +77°C, probably owing to the superposition of all the above relaxation processes. Detailed analysis[120] of the temperature dependence of tan δ for samples with different water contents has shown that the transition at −27°C is actually due to the presence of water in the polyimide.

Serious attention must therefore be paid to the importance of removing solvent residues in the investigation of the dynamic mechanical properties of heat-resistant polymers, since its presence may not only distort the temperature dependence of tan δ but also lead to chemical changes at high temperatures. Hence special methods have been developed[121] for examining dynamic mechanical properties, involving attempts at the complete removal of residual solvent. The product of the polycondensation of napthalene-1,4,5,8-tetracarboxylic acid with biphenyl-3,3',4,4'-tetra-amine underwent irreversible chemical changes involving the formation of chemical cross-links, "postcyclisation", etc. even after complete removal of residual solvent[121]. However, the low-temperature peak of tan δ (at −100°C) remained in all cases, so that these irreversible changes do not suppress the mobility of the kinetic units apparent at low temperatures.

The use of dynamic methods to investigate relaxation transitions yields conclusions in several cases as to the mechanism of the relaxation processes accompanying orientation, shrinkage, etc. Thus three temperature regions are found in which a Kapton film shrinks at a maximum rate[122]: the first maximum is observed near 90°C whatever the degree of preliminary drawing at room temperature; a second maximum appears in the region of 200°C only with films that have been stretched by 25%; and the third maximum near 350°C applies to films that are 40% oriented. Each of these maxima occurs roughly at the temperatures of maxima in tan δ for mechanical and electrical losses. Hence the rapid shrinkage after these temperatures have been reached is due to an increase in the molecular mobility of the polyimide macromolecules. Thus a comparative investigation of the temperature dependence of tan δ and of other (static) characteristics—Young's modulus, rate of shrinkage, etc.—may provide valuable information on the establishment of the set of mechanical properties or of polyimides, which has been made for aliphatic and aromatic polyimides[123].

A fundamental investigation of transitions in heat-resistant aromatic polymers was made[124] on a long series of amorphous polyquinoxalines, among which that having the structure



was examined in greatest detail by a variety of methods. Polymers of this type can occur in three isomeric forms, which was regarded[124] as preventing their crystallisation. A single sharp maximum is observed in the temperature dependence of tan δ, E'' and ϵ'', corresponding to vitrification of the polyquinoxalines, the maximum in the dielectric measurements being displaced several tens of degrees to higher temperatures. A weak, additional peak near 210°C is attributed to impurities; in any case, it cannot be explained by the thawing out of the motion of phenyl groups, since it appears even in their absence. The temperature dependence of the heat capacity also showed a transition (vitrification), which was confirmed by dilatometric measurements. Analysis of experimental results obtained by various methods suggested that the appearance of mobility in polyquinoxalines was due not to torsional vibrations but to deformation of the polymer chain itself, which had the form of a tape. The flexibility of such a tape depends on the presence of particular heteroatoms in the main chain.

The most significant transition in a heat-resistant polymer is that involving softening or vitrification. It is therefore extremely important to be able to calculate the glass point T_g solely from the chemical structure of the repeating unit. It was suggested initially[125] that use could be made of the relation

$$\lg T_g = \frac{d}{M}\sum_i K_i' + A', \qquad (7)$$

in which d is the density of the polymer, M the molecular weight of the repeating unit, $\Sigma K_i'$ is its effective volume, comprising the effective volumes of the atoms and groups of atoms forming the unit, and A' is a parameter representing a given series of polymers. This equation holds

well for several series (aromatic polyesters and polyamides, polymethacrylates), Numerical values of K_i' and A' can be found from the original paper [125].

Table 1. Increments K_i^* for various atoms and types of intermolecular interaction.

Atom or interaction	Conventional symbol	Value
Carbon	K_C^*	10.739
Oxygen in side-group	$K_{O,s}^*$	3.925
Oxygen in main chain	$K_{O,m}^*$	−5.244
Hydrogen	K_H^*	−1.248
Nitrogen in side-group	$K_{N,s}^*$	9.520
Nitrogen in main chain	$K_{N,m}^*$	2.185
Chlorine	K_{Cl}^*	7.242
Silicon	K_{Si}^*	19.570
Hydrogen bond	K_h^*	7.333
Dipole-dipole*	K_d^*	7.333
Symmetry coefficient**	K_p^*	10.500

*The coefficient K_d^* is introduced in all cases in which a hydrogen atom is replaced by any type of radical other than phenyl. This rule does not extend to polyisoprene and polychloroprene. When two hydrogen atoms are replaced by identical radicals, the value 0.5 K_d^* is introduced.
**The coefficient K_p^* is introduced if all the aromatic rings in the main chain are substituted in the *para*-position.

Later a general scheme of calculation was proposed [126], applicable to polymers of any series. The glass point was determined from the relation

$$\lg T_g = \frac{\sum_i K_i^*}{N_A \sum_i \Delta V_i} + A, \qquad (8)$$

where $\sum_i K_i^*$ is an additive quantity having the dimensions of a volume and connected with the packing coefficient k and the coefficient α_G of cubical expansion, $\sum_i \Delta V_i$ is the van der Waals volume of the repeating unit, comprising the volumes ΔV_i of all the component atoms, $A = 1.435$ is a parameter of linear polymers of any chemical structure, and N_A is Avogadro's number. The quantities K_i^* occurring in ΣK_i^* are characteristic of each element and each type of intermolecular interaction, and are listed in Table 1. With their values known, it is easy to calculate the glass point of a polymer by means of Eqn. (8) provided that its chemical structure is known. It is first necessary to find [15,127] the van der Waals volume of the repeating unit. Calculated and experimental glass points show good agreement [126] for many polymers of the most diverse structure. Fig. 24, in which the theoretical dependence of the glass point on $\sum_i K_i^*/N_A \sum_i \Delta V_i$ has been drawn, and experimental values have been plotted, confirms that formula (8) holds over a very wide temperature range.

It is thus theoretically possible to calculate the glass point of a polymer before it has been synthesised: the applicability of Eqn. (8) has been subjected to the most detailed verification on heat-resistant polymers. Use of the above scheme of calculation to predict glass points with the aim of synthesising polymers having specified properties has been applied [128] to heat-resistant systems containing fluorine. Other problems can also be solved by this means. Thus, knowing the increment K_d^* representing the effect of intermolecular interaction on the glass point, we can determine from Eqn. (8) the number of chemical groups in the repeating unit that are able to interact in this way and how many are excluded from interaction by steric hindrance. With aromatic polyimides, for example, only two of the four possible carbonyl groups enter into interaction. It is noteworthy also that carbonyl groups enclosed directly between aromatic ring systems are also incapable of intermolecular interaction because of steric hindrance, as has been demonstrated by an independent method [129].

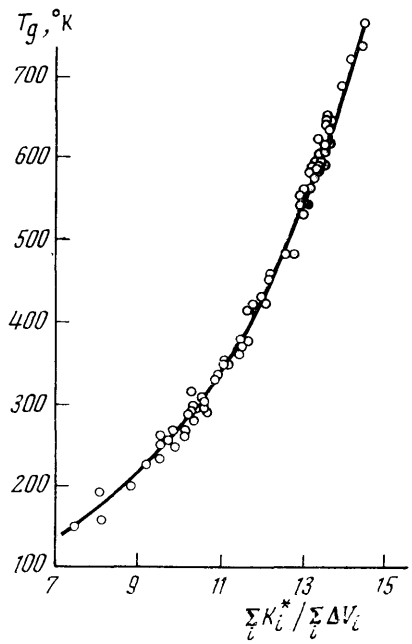


Figure 24. Dependence of T_g for a series of polymers on the ratio $\sum_i K_i^* / \sum_i \Delta V_i$.

Another problem that can be solved by means of formula (8) is the calculation of glass points of polymers whose experimental determination presents great difficulties. Such are systems which undergo various types of chemical changes—thermal degradation, oxidation, cross-linking, cyclisation, etc.—when they are heated. This applies especially to heat-resistant polymers, in which such chemical changes may take place below the glass point. Table 2 gives calculated values for some of them, as well as for certain polyamide-esters, polyamino-acids, etc. that undergo rapid cyclisation.

Yet another use of the above scheme of calculation is to refine the chemical structure of a polymer whose glass

Table 2. Calculated glass points for polymers when experimental determination is difficult.

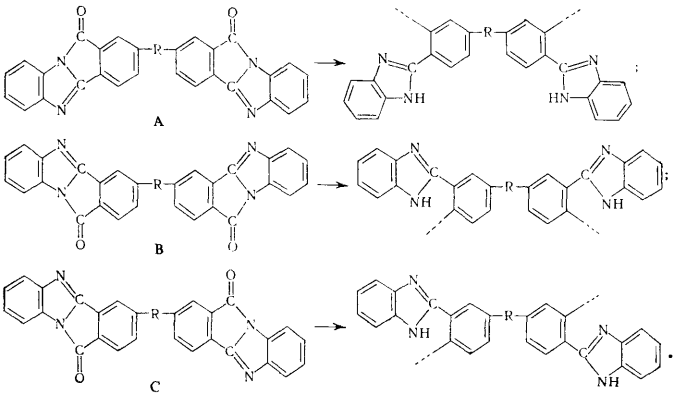
point has been determined experimentally, as in a study [19] of the effect of chemical structure on the properties of polybenzazoles containing bulky substituents. These heat-resistant polymers may have an irregular arrangement of chains because of the possibility of geometrical (*cis–trans*) isomerism in the initial bisbenzoylenebenzimidazoles. With *meta*- or *para*-substitution the resulting polymers may in principle contain the structural units



It is difficult or almost impossible to determine the exact structure of such systems by the usual methods, so that the softening points of all the systems were calculated and compared with the experimental temperatures [19]. Experimental and calculated glass points showed good agreement when substitution occurred either in the *meta*-position or in *meta*- and *para*-positions. The first type of linking into chains may occur with the *cis*-isomer (A), and the second with the *trans*-isomer (B). Thus the polybenzazoles studied [19] evidently contain both structures and are mixtures of isomers. This is supported experimentally by the fairly wide melting range of the initial bisbenzoylenebenzimidazoles, despite their high purity. Analogous problems have also been solved [130].

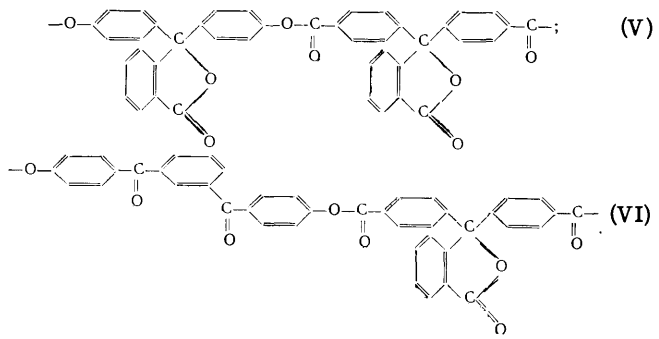
The chemical structure of a copolymer can also be determined by comparing calculated and experimental glass points. In several cases it is sufficient to apply formula (8), deduced on the assumption of approximately the same density of packing of macromolecules within monolithic amorphous systems. Differently constructed copolymers (random, block, various types of addition of units, etc.) may exhibit looser or denser packing of the macromolecules, which must be taken into account in the calculation. For this purpose Eqn. (8) can be rewritten

$$\lg T_g = \frac{k}{k_{av}} \cdot \frac{\sum_i K_i^*}{N_A \sum_i \Delta V_i} + A, \qquad (9)$$

where k is the actual packing coefficient and $k_{av} = 0.681$. Formula (9) will then give glass points higher or lower than the additive values depending on the composition, as is observed fairly often in practice. With copolymers not only the glass point but also the density must be determined experimentally, k calculated, and then T_g found from Eqn. (9). The chemical structure of the copolymer can be determined by comparing calculated and experimental glass points.

Furthermore, it is possible in several cases to estimate the contributions both of intermolecular and of intramolecular interactions to the glass point on passing from one copolymer to another. A series of copolymers and homopolymers was synthesised [129] from phenolphthalein,

3,3-diphenylphthalide-*p'p''*-dicarboxylic acid, and *m*-bis-*p'*-hydroxybenzoylbenzene. The homopolymers had the structures



(V)

(VI)

These polyesters, as well as all the copolymers, contained the same numbers of atoms and benzene residues, differing only in the numbers of attached phthalide rings. Passing from polymer (V) to polymer (VI) entailed not only diminished intermolecular interaction due to the phthalide ring but also a lower glass point because of diminished intramolecular interaction (steric factor). The contributions of each of these factors were estimated by means of formula (9), which for copolymers becomes

$$\lg T_g = \frac{k}{k_{av}} \cdot \frac{x_1\left(\sum_i \Delta V_i\right)_1 (\lg T_{g,1} - A) + x_2\left(\sum_i \Delta V_i\right)_2 (\lg T_{g,2} - A)}{x_1\left(\sum_i \Delta V_i\right)_1 + x_2\left(\sum_i \Delta V_i\right)_2} + A. \quad (10)$$

This showed that only half the difference $\Delta T = T_{g,1} - T_{g,2}$ was due to the decrease in the number of intermolecular bonds corresponding to the smaller number of phthalide groups, the rest being caused by rotation of a phthalide ring. The effective energy of intermolecular interaction in the presence of a phthalide ring was 9.4 kcal mole^{-1}.

o0o

Comparison of the whole set of properties of heat-resistant aromatic polymers with those of ordinary polymers having relatively inflexible chains indicates that increasing the rigidity of the chain and saturating it with aromatic rings lead to the expected rise in the glass point, but this is accompanied by qualitative changes in all the other properties. Passing to heat-resistant aromatic polymers (e.g. various types of polyheteroarylenes) leads to a significant increase in the maximum mechanical stresses that the polymeric material is able to withstand in articles not only at high but also at ordinary temperatures. The explanation is not that the fixed test temperature lies at different distances from the glass point with different compounds: if this were the reason, application of the principle of corresponding states would yield the same tensile strength or limit of forced elasticity at the reduced temperature. However, this does not occur, since the temperature dependence of the forced rubberlike elasticity is indistinct at temperatures sufficiently below the glass point, and these relations cannot be superimposed merely by displacement along the temperature axis. Hence the reason for the increased strength lies in the actual nature of the polymer chain saturated with aromatic rings.

The difference between the mechanical properties of flexible-chain and rigid-chain aromatic polymers becomes especially clear in prolonged observations under conditions of stress relaxation. Such relaxation is considerably less marked with rigid-chain than with flexible-chain systems, which is responsible for the great difference in the mechanical stresses that these systems are able to withstand at a given temperature. Thus the synthesis of heat-resistant aromatic polymers not only extends the temperature range of performance but also increases significantly the mechanical stresses under which performance is maintained at lower temperatures.

Another characteristic feature of heat-resistant systems is an extraordinarily large optical stress coefficient C_σ, whose values for polyheteroarylenes exceed those for ordinary polymeric glasses (polystyrene, polymethacrylates, etc.) by factors of 10–1000. This means that even very small mechanical stresses cause large double refraction in them, which is of great practical importance, since the use of such materials in the photoelastic method enables the pattern of stress distribution to be obtained with extremely small deformations, i.e. under conditions under which Hooke's law is best obeyed.

The next interesting feature of heat-resistant aromatic polymers is a multitude of relaxation transitions, which plays a very important part in shaping the whole set of mechanical and other physical properties. In the Reviewers' opinion, especial interest attaches to the static methods that have been discovered for investigating the transitions, which largely determine the temperature ranges of performance, i.e. the heat resistance of the polymers.

Another curious feature of heat-resistant polyheteroarylenes is their capacity for considerable (10–20%) deformation at very low temperatures (down to that of liquid nitrogen) [5,6,72,131]. Hence heat-resistant aromatic polymers are able to satisfy a requirement for a polymeric material that is capable of non-brittle fracture not only at high but also at low temperatures.

Kinetics and Mechanism of the Decomposition of Organic Hydroperoxides in the Presence of Transition Metal Compounds

I.P.Skibida

The principal features of the homogeneous-catalytic decomposition of hydroperoxides in the presence of variable-valence metal compounds are examined and kinetic and physicochemical evidence for the formation of intermediate catalyst-hydroperoxide complexes and their subsequent decomposition into free radicals and molecular products is presented. Factors influencing the change in the mode of decomposition of the hydroperoxide are analysed and a special section is devoted to the catalysis of the decomposition of hydroperoxides by soluble molybdenum, vanadium, and tungsten compounds and also to the mechanism of the catalytic epoxidation of olefins by bound oxygen.
The bibliography includes 134 references.

I. INTRODUCTION

The theory of liquid-phase oxidation processes of hydrocarbons has been developed in fair detail, to a large extent by Emanuel' and his school[1,2]. The problem of the influence of various additives on the liquid-phase oxidation, the solution of which would permit the inhibition of undesirable oxidation process[3,4] or the acceleration of the oxidation and would make the latter more selective as a result of the employment of homogeneous or heterogeneous catalysts[5,6], has now become of primary importance.

The problems of the mechanism of homogeneous-catalytic oxidation reactions have been analysed fairly recently in a number of reviews[7-9]. The mechanism of one of the principal stages in the oxidation of hydrocarbons —the decomposition reactions of hydroperoxides and chain branching in the presence of homogeneous catalysts— are discussed below. Studies on the mechanism of the homogeneous-catalytic decomposition of hydroperoxides are important not only from the standpoint of the further development of the theory of liquid-phase oxidation but also for the determination of the general characteristics of homogeneous catalysis, since the decomposition of hydroperoxides constitutes a convenient model for a quantitative investigation of the influence of the structures of the hydroperoxide and the catalyst on the rate and mechanism of the process. In view of the extensive data available for the decomposition of peroxide compounds, we shall consider only the most characteristic features of the mechanism of the decomposition of organic hydroperoxides.

II. RADICAL DECOMPOSITION

Modern ideas concerning the mechanism of the catalytic action of transition metal compounds in hydroperoxide decomposition reactions are based on the mechanism proposed by Haber and Weiss[10], according to which the hydroperoxide alternatively behaves as an oxidant and as a reductant in the reaction with the reduced or oxidised form of the metal respectively:

$$ROOH + M^{n+} \rightarrow RO^{\cdot} + OH^{-} + M^{(n+1)+}; \quad (1)$$

$$ROOH + M^{(n+1)+} \rightarrow ROO^{\cdot} + H^{+} + M^{n+}. \quad (2)$$

The alternation of reactions (1) and (2) ensures the constancy of the ratio of the different valence forms of the catalyst in the course of the process and is responsible for the catalytic effect. Depending on the type of the hydroperoxide and the nature of the catalyst, the number of molecules of the hydroperoxide decomposed per catalyst molecule may be up to 1000 and more. This hydroperoxide decomposition mechanism in non-aqueous media has been confirmed in a number of investigations[7,8].

When the compounds of metals which can exist typically in more than two valence states are used as the catalysts, the decomposition of hydroperoxides may involve a more complex mechanism. Thus the decomposition of hydroperoxides in the presence of rhodium compounds can lead to the formation in the system of three valence forms: rhodium(I), rhodium(II), and rhodium(III). It has been suggested that the process is catalysed by the rhodium(II)–rhodium(III),[11] rhodium(I)–rhodium(II),[12] or rhodium(I)–rhodium(III)[13] pairs. However, in the latter case the process does not proceed via the two-electron mechanism proposed by the authors:

$$Rh(I) + 2\,ROOH \rightarrow Rh(III) + 2\,RO^{\cdot} + 2\,OH^{-},$$
$$Rh(III) + 2\,ROOH \rightarrow Rh(I) + 2\,ROO^{\cdot} + 2H^{+},$$

but is accompanied by the formation (at least as an intermediate) of a rhodium(II) species, which may be identified[12] by its ESR spectrum in the decomposition of cumenyl hydroperoxide in the presence of $Rh(I)(PPh_3)_3$.COCl.

The valence forms of the metal do not necessarily change when the hydroperoxide is involved in stages (1) and (2). Metals in the highest valence state can react rapidly with hydroperoxide decomposition products and also with the solvent[1,2,14–16]. Thus it has been suggested[17] that, in the oxidation of aldehydes in an aqueous phase, the cobalt(III) → cobalt(II) transition takes place with participation of benzaldehyde; the reaction of cobalt(III) with C_6H_5COOH is extremely slow, although in a later study[18] the possibility of reducing cobalt(III) by perbenzoic acid was noted. Nickel(III) reacts rapidly with benzaldehyde[18]. The rate of the valence transformation manganese(III) → manganese(II) increases appreciably in the presence of aldehydes[19]. The involvement of aldehydes in the degenerate branching of chains in the catalytic oxidation of alkanes has been postulated[20]. The involvement of alcohols, ketones, and acids in oxidation-reduction reactions with participation of metal ions is also extremely likely. For example, the steady-state concentration of manganese(III) in the catalytic decomposition of t-butyl hydroperoxide falls as the process develops, which may be due to the reduction of manganese(III) by the ROOH decomposition products—methyl alcohol or acetone[19]. It has been shown[21–23] that, in the decomposition of acyl hydroperoxides cobalt(II) is almost wholly converted into the tervalent form. In the decomposition of alkyl hydroperoxides cobalt is also mainly present in the tervalent form, although the rate of the transition cobalt(II) → cobalt(III) is much lower than for acyl peroxides. In the presence of organic acids cobalt is present only in the bivalent form during the reaction. When cobalt(III) is used as the catalyst in the presence of organic acids, the transition cobalt(III) → cobalt(II) takes place rapidly. The oxidation of alcohols, ketones, and acids by cobalt(III) ions has been studied in a number of investigations[24–26].

The ratio of the valence forms of the catalyst is determined by the different reactivities of the oxidised and reduced forms of the metal ion in the reaction with the hydroperoxide or other products[21,27].

The formation of free peroxy-radicals in the decomposition of hydroperoxides in the presence of variable-valence metal compounds has been demonstrated[28–30]. The ESR spectra of free peroxy-radicals have been observed in the decomposition of t-butyl, cumenyl, diphenylethyl, and triphenylmethyl hydroperoxides in the presence of cobalt compounds[31]. The method of inhibitors has been used to identify hydroperoxides and to measure the rates of their radical decomposition[5,31].

Although it has been suggested in the majority of studies that the interaction of the reduced form of the catalyst with the hydroperoxide [reaction (2)] entails the formation of the hydroxide ion and a free alkoxy-radical $RO^{\cdot}$, in some instances, for example in the decomposition of tetralinyl hydroperoxide in the presence of cobalt carboxylates, the composition of the ROOH decomposition products can be explained by simply postulating the formation in this process of an $OH^{\cdot}$ radical and an RO^{-} ion[33–35].

Kinetic studies on the decomposition reactions of hydroperoxides have shown that the overall order of the reaction with respect to the catalyst and the hydroperoxide depends on the solvent and the nature and concentration of the hydroperoxide and the catalyst and can vary from zero to two. Second-order decomposition of hydroperoxide with respect to the catalyst and first-order decomposition with respect to the hydroperoxide have been observed in the decomposition of tetralinyl hydroperoxide in xylene and acetic acid[36–39], in the decomposition of t-butyl hydroperoxide in the presence of cobalt(II) ethylenediaminetetraacetate[40], and in the decomposition of n-decyl hydroperoxide in the presence of cobalt stearate[41].

There have been numerous instances where the order of the reaction with respect to the catalyst proved to be 1 or 1.5;[5,32] in some cases the reaction order varies during the process or depends on the initial concentration of the hydroperoxide or the catalyst. Thus the decomposition of tetralinyl hydroperoxide in the presence of chromium, copper, and cobalt oleates is a first-order reaction with respect to the hydroperoxide, while the order with respect to the catalyst varies from 0.5 to 0.7.[23] The decomposition of cumenyl hydroperoxide in chlorobenzene in the presence of cobalt salts is a first-order reaction with respect to ROOH and the catalyst[42–45]. A linear variation of the rate of decomposition with catalyst concentration was observed in the decomposition of hydroperoxides by cobalt salts in alcohols[46] and by cobalt complexes in chlorobenzene and benzene[47,48]. In the decomposition of t-butyl hydroperoxide in chlorobenzene in the presence of cobalt 2-ethylhexanoate the order of the reaction with respect to the catalyst depends strongly on its concentration. At 20°C the order of the reaction with respect to the catalyst increases from 1 to 1.6 with increase of the salt concentration from 1.3×10^{-5} to 8.4×10^{-5} M and then falls as

the salt concentration rises further. At 0°C the order of the reaction with respect to the catalyst diminishes with increasing salt concentration[36].

In the inhibited decomposition of t-butyl hydroperoxide in acetic and butyric acids and their mixtures with chlorobenzene the order of the reaction with respect to cobalt acetate is close to unity[44,49], while for the non-inhibited reaction it is greater than unity[44]. A reaction order greater than unity has been observed in other investigations[40,43,50-54].

The order of the hydroperoxide decomposition reaction with respect to ROOH also depends on the nature and concentration of the latter. Thus in the decomposition of ethylphenyl hydroperoxide in the presence of copper stearate, the order of the reaction with respect to ROOH was unity[55], while in the decomposition of n-decyl hydroperoxide it was 2, falling to zero with increase of [ROOH].[56,57] In most of the cases investigated the reaction order with respect to ROOH tends to zero with increase of the hydroperoxide concentration[5,47,48,55-58].

Various mechanisms have been proposed for the decomposition of hydroperoxides in the presence of cobalt, copper, and manganese salts[36,49,59-63]. In certain instances the formation of organometallic peroxide compounds decomposing subsequently into free radicals[64]:

$$\mathrm{ROOH} + \mathrm{M}^{n+}\mathrm{X} \rightarrow \mathrm{ROOM}^{n+} + \mathrm{HX}, \quad (3)$$

$$\mathrm{ROOM}^{n+} \rightarrow \mathrm{RO}^{\cdot} + \mathrm{OM}^{(n+1)+} \quad (4)$$

$$\searrow \mathrm{ROO}^{\cdot} + \mathrm{M}^{(n+1)+}, \quad (5)$$

(X represents the anion) or oxidative addition of ROOH to the catalyst:

$$\mathrm{ROOH} + \mathrm{M}^{n+} \rightarrow \mathrm{ROM}^{(n+2)+}\mathrm{OH} \quad (6)$$

with subsequent decomposition of the complex formed were suggested.

The decrease of the order of the hydroperoxide decomposition reaction with respect to ROOH with increasing concentration of the latter was explained in terms of intermediate formation of a complex by the hydroperoxide and the catalyst[5,32]:

$$n\,\mathrm{ROOH} + m\,\mathrm{M}^{n+} \xrightarrow{k_1} n\,\mathrm{ROOH}\cdot m\,\mathrm{M}^{n+}. \quad (7)$$

The resulting complex is unstable and decomposes into the reaction products:

$$n\,\mathrm{ROOH}\cdot m\,\mathrm{M}^{n+} \xrightarrow{k_1} \mathrm{RO}^{\cdot} + \mathrm{OH}^{-} + \mathrm{M}^{(n+1)+} + (n-1)\,\mathrm{ROOH} + m-1)\,M^{n+}. \quad (8)$$

The reduced form of the catalyst also decomposes via the intermediate formation of the complex:

$$n_1\,\mathrm{ROOH} + m_1\,\mathrm{M}^{(n+1)+} \rightleftarrows n_1\,\mathrm{ROOH}\cdot m_1\,\mathrm{M}^{(n+1)+} \rightarrow \mathrm{ROO}^{\cdot} + \mathrm{H}^{+} + \mathrm{M}^{n+} + (n_1-1)\,\mathrm{ROOH} + (m_1-1)\,\mathrm{M}^{(n+1)+}. \quad (9)$$

The mechanism of reactions (7)–(9) yields a simple expression of the Michaelis–Menten type for the variation of the rate of decomposition with the concentrations of the hydroperoxide and the catalyst[5,32]. For $n = m = n_1 = m_1 = 1$, the equation is

$$W = \frac{Kk_1\,[\mathrm{ROOH}]\,[M^{n+}]}{1 + K\,[\mathrm{ROOH}]} \quad (10)$$

and makes it possible to determine the complex formation constant K and the rate constant k_1 for the decomposition of the complex into free radicals.

The second order with respect to the catalyst[41,65] may be due to the two-stage process

$$\mathrm{ROOH} + \mathrm{CoX}_2 \rightleftarrows \mathrm{ROOH}\cdot\mathrm{CoX}_2,$$
$$\mathrm{ROOH}\cdot\mathrm{CoX}_2 + \mathrm{CoX}_2 \rightarrow \mathrm{RO}^{\cdot} + \mathrm{CoX}_2\mathrm{OH} + \mathrm{H}_2\mathrm{O} + \mathrm{CoX}_2.$$

It has been suggested that the first order with respect to the catalyst in acetic acid[38,65] is due to the involvement of the dimeric form of cobalt acetate in the reaction:

$$2\mathrm{CoAc}_3\cdot\mathrm{AcH} \rightleftarrows (\mathrm{CoAc}_3)_2\cdot\mathrm{AcH} + \mathrm{AcH},$$
$$\mathrm{ROOH} + \mathrm{AcH} \rightleftarrows \mathrm{ROOH}\cdot\mathrm{AcH},$$
$$(\mathrm{CoAc}_3)_2\cdot\mathrm{AcH} + \mathrm{ROOH} \rightarrow \text{radicals}.$$

The second-order with respect to the hydroperoxide in the presence of copper salts may be attributed to the formation of the hydroperoxide–catalyst complexes having the composition $\mathrm{CuX}_2.2\mathrm{ROOH}$ [56,57] or $2\mathrm{CuX}_2.2\mathrm{ROOH}$.[66]

The formation of catalyst–hydroperoxide complexes has been confirmed by various physicochemical methods: spectrophotometrically in the decomposition of cumenyl hydroperoxide in the presence of bis-[*N*-(2-hydroxy-3-methoxybenzylidene)aniline] cobalt[47] and of ethylphenyl hydroperoxide in the presence of copper stearate[55], the formation of copper 2-ethylhexanoate complexes with t-butyl hydroperoxide[66] and of bis-(α-thiopicolinanilide)-copper with ethylphenyl hydroperoxide[67] has been demonstrated by ESR, and the formation of complexes of cumenyl hydroperoxide with cobalt and nickel chelates has been demonstrated by NMR.[68,69] In the last case the formation of complexes was inferred from the chemical shifts of the OH protons of the hydroperoxides and it may be regarded as established that (at least for the systems investigated) ROOH does not add as a result of ligand exchange via reactions (3) or (6), as postulated by Waters[64]. The hydroperoxide is coordinated to the central metal ion via the oxygen atom of the hydroxy-group[69].

The equilibrium constants for the formation of the complexes have been calculated by Eqn. (10) for a large number of catalysts and hydroperoxides[70]. It has been shown for the decomposition of cumenyl hydroperoxide in the presence of substituted bis-[*N*-aryl-*N*-(2-hydroxy-3-methoxybenzylidene)amine]cobalt complexes that the introduction of electron-donating substituents into the ligand has only a slight influence on the rate constant for the decomposition of the catalyst–hydroperoxide complex and leads mainly to a change in the equilibrium constant for the formation of the complex[58].

Quantitative evidence for the role of complex formation in the catalytic decomposition of hydroperoxides is provided by the agreement[68] between the equilibrium constants for the formation of cobalt chelates with cumenyl hydroperoxide determined by two independent methods: from the chemical shift of the OH proton of the hydroperoxide in the presence of the catalyst and by a kinetic method from the dependence of the rate of decomposition of ROOH on its concentration using Eqn. (10). This suggested that the formation of the complexes, identified by a physicochemical method, in the catalyst–hydroperoxide system is indeed an intermediate stage in the catalysis.

The decrease of the reaction order with respect to the catalyst with increase of its concentration has been explained in some investigations by the aggregation of the catalyst[38,56,66,71] or by the interaction of one of its valence forms with free radicals[72]. The latter hypothesis can explain the relative decrease of the rate of reaction only in the presence of a chain mechanism of the decomposition of ROOH. The study of the decomposition of cumenyl hydroperoxide in the presence of copper stearate complexes with *o*-phenanthroline (*o*-phen) in benzene and chlorobenzene showed that there is no chain mechanism of the hydroperoxide decomposition reaction and that the decrease of the reaction order with respect to the catalyst from 1 to 0 with increase of [CuSt_2.*o*-phen] is not related to the formation of micelles[73].

It has been suggested that deactivation of the catalyst in the process occurs owing to the formation of inactive dinuclear complexes. The process mechanism involves stages in which copper(I) complexes of the hydroperoxide are formed:

$$\text{Cu(II)} \cdot o\text{-phen} \xrightarrow{\text{ROOH}} \text{Cu(I)} \cdot o\text{-phen} \quad ,$$

$$\text{Cu(I)} \cdot o\text{-phen} + \text{ROOH} \rightarrow \text{Cu}^{\delta+}\text{(I)}\ o\text{-phen}\ \overset{\delta-}{\text{ROOH}} \quad .$$

This is followed by the reactions of the complexes $\overset{\delta+}{\text{Cu(I)}}(o\text{-phen})(\overset{\delta-}{\text{ROOH}})$ with the catalyst (catalyst deactivation) and the hydroperoxide (catalytic stage). The mechanism proposed explained quantitatively the kinetic curves for the decomposition of the hydroperoxide and also the variation of the rate of decomposition of ROOH with the concentrations of the catalyst and the hydroperoxide.

III. MOLECULAR DECOMPOSITION

The so called "molecular" mechanism of the decomposition of the hydroperoxide, which leads to the formation of non-radical products, has been observed in the decomposition of many organic hydroperoxides in the presence of various organometallic catalysts.

This decomposition mechanism was postulated initially on the basis of data for the influence of variable-valence metal compounds on the oxidation of hydrocarbons[74]. The increase of the rate of decomposition of the hydroperoxide via the molecular mechanism lowers the rate of formation of free radicals in the system. In certain cases, where the rate of formation of the radicals in the presence of the catalyst is lower than the rate of their formation in the absence of the catalyst, the introduction of organometallic compounds can lead to the appearance of induction periods. The inhibition of the oxidation of hydrocarbons in the presence of nickel, cobalt, platinum, and palladium dithioketonates, which are effective catalysts of the decomposition of hydroperoxides, is treated from precisely this standpoint[75].

This treatment of the inhibiting effect of variable-valence compounds is not unambiguous, since almost all the compounds employed are radical acceptors and may inhibit the oxidation not only owing to the decomposition of ROOH but also owing to the increase of the rate of chain termination[76-78]. Direct evidence for the occurrence of the molecular mechanism in the decomposition of the hydroperoxide in the presence of the catalyst was obtained with the aid of inhibitors[32,56]. It was shown that, in the decomposition of n-decyl hydroperoxide in the presence of copper stearate, the rate of consumption of ROOH is significantly higher than the rate of consumption of the inhibitor, which is equal to the rate of formation of free radicals. An appreciable molecular decomposition of the hydroperoxide was demonstrated in a study of the decomposition of tetralinyl hydroperoxide under the influence of cobalt salts in various solvents[34,35].

The contribution of the molecular decomposition of the hydroperoxide depends significantly on the nature of the catalyst and the hydroperoxide[79]. Thus in the presence of cobalt stearate t-butyl hydroperoxide decomposes at 50°C in chlorobenzene only into free radicals; the rates of decomposition of tetralinyl[35] and cumenyl[79] hydroperoxides into free radicals under the same conditions are 1.2 and 36% of the overall rate of decomposition of ROOH respectively; the contributions of the radical pathways to the decomposition of α-phenylethyl hydroperoxide in the presence of tin 2,2'-thiobis-[4-methyl-6-(α-methylbenzyl)-phenoxide] and 2,2'-thiobis-(6-t-butyl-4-methylphenoxide) are 0.1 and 3.5% respectively[80]. When the metal in the catalyst is changed, the relative contributions of the molecular and radical mechanisms of the decomposition of ROOH also change. In the presence of $CoSt_2$, n-decyl hydroperoxide decomposes only via the radical pathway[41], while in the presence of $CuSt_2$ the contribution of the molecular decomposition is 20–50% [56,57] of the overall rate of decomposition of ROOH. The contribution of the radical decomposition of t-butyl hydroperoxide is 100% in the presence of $CoSt_2$ [81] and 4–10% in the presence of manganese stearate[19].

The study of the dependence of the rates of decomposition of hydroperoxides and of the consumption of the inhibitor on the catalyst and hydroperoxide concentrations established that in all cases the molecular decomposition of the hydroperoxide proceeds, like the radical decomposition, via a stage involving the formation of catalyst–hydroperoxide complexes. Determination of the thermodynamic characteristics and compositions of these complexes from the rates of the molecular and radical decompositions of ROOH showed that, in the decomposition of cumenyl, n-decyl, tetralinyl, and α-phenylethyl hydroperoxides in the presence of copper, cobalt, and nickel compounds, both mechanisms of the decomposition of the hydroperoxides involve the formation of the same complexes[79,82-84].

Kinetic data for the variation of the rates of decomposition of hydroperoxides with their concentrations and with that of the catalyst made possible in many instances the calculation of the individual rate constants for the decomposition of the catalyst–hydroperoxide complexes into free radicals (k_r) and the molecular products (k). It was found that the k_r are as a rule associated with very low pre-exponential factors[70]. The relative contributions of the molecular and radical mechanisms of the decomposition of the hydroperoxide depend markedly on the viscosity of the medium—with increase of η, the contribution of the molecular decomposition of ROOH increases, but the overall rate remains unchanged. The variation of the ratio k_r/k is described by the Stokes–Einstein formula, which leads to the conclusion that the role of diffusion processes in the mechanism of the catalytic decomposition of ROOH is important[79].

The kinetic data obtained suggested a mechanism for the molecular decomposition of the hydroperoxide in which the "cage effect" of the solvent plays an important role[19,79,82-86]. The radicals formed in the decomposition of the complex MX_2.ROOH can either recombine in the solvent cage (molecular decomposition of the hydroperoxide) or can diffuse from the cage (radical decomposition):

$$MX_2 + ROH \rightleftarrows MX_2 \cdot ROH \rightarrow [MX_2OH,\ RO]$$

$$RO^{\cdot} + MX_2OH \qquad MX_2 + H_2O + R'COR'' \quad .$$

It has been suggested[34] for the decomposition of tetralinyl hydroperoxide in the presence of cobalt salts that ROOH decomposes when the complex MX_2.ROOH reacts with the hydrocarbon as follows:

$$[MX_2 \cdot ROOH] + R'H \rightarrow [MX_2^{\cdot} \ \ldots\ R''] + \text{product.} \qquad (11)$$

The relative contributions of the molecular and radical mechanisms of the decomposition of ROOH are then determined by the ratio of the rates of recombination of the radicals R'' within the cage and by the number of

radicals released from the cage when the complex $MX_2 \ldots R''$ reacts with a second R'H molecule:

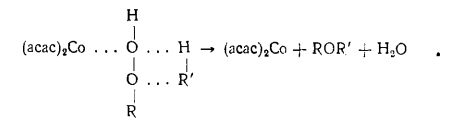
$$[\dot{M}X_2 \ \ldots \ R''] + R'H \rightarrow 2R'' + MX_2 + \text{product}. \qquad (12)$$

In this mechanism of the decomposition of the hydroperoxide an increase of the rate of consumption of ROOH [stage (11)] and of the contribution of the radical ROOH decomposition mechanism [stage (12)] was to be expected with decrease of the C–H bond strength in the hydrocarbon solvent.

This mechanism of the molecular decomposition of the hydroperoxide does not hold in the decomposition of cumenyl hydroperoxide (CHP) in the presence of cobalt acetylacetonate [$Co(acac)_2$].[86] In this case the rate of decomposition of CHP is almost independent of the solvent and the contribution of the molecular decomposition of ROOH increases in the sequence benzene < ethylbenzene < tetralin, i.e. with decrease of the C–H bond strength in the hydrocarbon. This suggested a more complex role of the solvent in the ROOH decomposition mechanism. As in inert solvents, in the presence of hydrocarbons the consumption of hydroperoxides is determined by the stage

$$Co(acac)_2 \cdot ROOH \rightarrow [\overset{\delta+}{Co}(acac)_2; \ \overset{\delta-}{ROOH}].$$

The $[\overset{\delta-}{Co}(acac)_2, \ \overset{\delta+}{ROOH}]$ species formed reacts further with RH to form non-radical products, most probably ethers. Such interaction can proceed via a stage involving the formation of ternary complexes:



This pathway, involving a bimolecular interaction of the hydroperoxide with the hydrocarbon, is a characteristic feature of the catalytic decomposition of the hydroperoxide and is due to the activation of ROOH when it is bound in a complex with the catalyst (probably as a result of partial electron transfer). In the absence of a catalyst the hydroperoxide interacts with the hydrocarbon to form only free radicals as the reaction products[1].

IV. INDUCED CHAIN DECOMPOSITION

The decomposition of the hydroperoxide induced by free radicals (chain decomposition of the hydroperoxide) is largely characteristic of the non-catalytic decomposition, which is probably associated to a considerable extent with the marked increase of the rate of formation of the radicals and the corresponding decrease of chain length in the presence of the catalyst.

The hypothesis of an appreciable contribution of the decomposition of the hydroperoxide induced by free radicals was put forward for the first time in a study of the kinetics of the oxidation of n-decane in the presence of manganese(II) stearate[87]. Direct methods using inhibitors of free-radical processes demonstrated the occurrence of the chain pathway in the decomposition of t-butyl and cumenyl hydroperoxides in the presence of cobalt acetate in a chlorobenzene–acetic acid mixture[88], of cumenyl hydroperoxide in benzene in the presence of substituted *N*-aryl-*N*-(2-hydroxy-3-methoxybenzylidene)aminocobalt complexes[89], and of tetralinyl hydroperoxide in the presence of cobalt acetate in tetralin[38].

The occurrence of the chain pathway in the hydroperoxide decomposition reaction depends strongly on the nature of the catalyst. Thus, according to data obtained by the method of inhibitors using ionol as the inhibitor[72], in the presence of iron-phthalocyanine t-butyl hydroperoxide decomposes via the chain mechanism, while in the presence of cobalt salts there is no chain decomposition of the hydroperoxide.

This influence of the nature of the catalyst on the mode of decomposition of the hydroperoxide may be one of the manifestations of the dual function of the catalyst discovered in 1959 by Emanuel' and coworkers[90], which consists in the ability of the catalyst not only to generate free radicals but also to participate in the chain termination reaction. It was shown in later studies that metal compounds can interact with both peroxy-[77,91] and alkoxy-radicals[92,93] formed in the decomposition of hydroperoxides. In hydrocarbon media, where there is a possibility of chain transfer to the solvent, the interaction of metal compounds with free alkyl radicals may play an important role[94].

Unfortunately in the presence of the catalyst the use of inhibitors greatly alters the properties of the catalyst itself, for example as a result of complex-formation effects. The inhibition of the catalytic decomposition of the hydroperoxide by the addition of the inhibitor can be caused in this case not only by the suppression of the chain decomposition of the hydroperoxide but also by the "poisoning" of the catalyst. Furthermore, there is a possibility of oxidation-reduction reactions between one of the forms of the catalyst and the inhibitor, which leads to a change in the relative amounts of the different valence forms of the catalyst, and hence in the measured rate of decomposition of ROOH. For this reason, the available information in the literature concerning the occurrence of the induced decomposition of ROOH in the presence of the catalyst is frequently contradictory. Thus Skibida et al.[35] showed, in contrast to Kamiya et al.[38], that tetralinyl hydroperoxide does not undergo chain decomposition in benzene in the presence of $CoSt_2$. One cannot rule out the possibility that the ionol employed by Kamiya et al.[38] as the inhibitor interacted with the catalyst in the highest valence state, which has in fact been demonstrated, for example by Gernet et al.[95]

The occurrence of the chain decomposition of ROOH is determined to a large extent by the nature of the alkyl radical and the hydroperoxide. t-Butyl and cumenyl hydroperoxides decompose in the presence of cobalt salts via the chain mechanism, which is apparently not characteristic of the decomposition of triphenylmethyl and diphenylethyl hydroperoxides[30,43,88].

In certain cases conclusions concerning the occurrence of the induced decomposition of the hydroperoxide are reached on the basis of a comparison of the rates of the overall decomposition of hydroperoxides having different structures. The rate of decomposition of the primary n-butyl hydroperoxide in chlorobenzene in the presence of cobalt 2-ethylhexanoate is lower than the rate of decomposition of t-butyl hydroperoxide under the same conditions, which suggested a greater contribution of the chain decomposition of the tertiary hydroperoxide. This hypothesis is consistent with the change in the reactivity of the free radicals: the rate of recombination increases on passing from the t-butyl to the n-butyl-peroxy-radical; consequently the probability of chain propagation diminishes. However, the above influence of the nature of the hydroperoxide on the rate of its decomposition can be caused also by the influence of the structure of the radical

on the rate of the primary decomposition of the hydroperoxide into free radicals. Furthermore, there is also a possibility of a change in the mechanism of the radical decomposition of ROOH. As stated above, the primary step in the hydroperoxide decomposition reaction may lead to the formation of a free hydroxy-radical and an alkoxide anion and not a hydroxide ion and an RO· radical[33,35,36]. The chain decomposition of ROOH can then be induced by the OH· radical[33,36,96]. It has been suggested[97] that the decomposition products of t-butyl hydroperoxide are formed when free peroxy-radicals react with the hydroperoxide–catalyst complex.

The available factual data suggest that the chain decomposition of the hydroperoxide in the presence of the catalyst is mainly characteristic of tertiary hydroperoxides in aprotic media.

V. THE INFLUENCE OF SOLVENTS ON THE CATALYTIC DECOMPOSITION OF HYDROPEROXIDES

As in the thermal decomposition of hydroperoxides, the rate of their decomposition in the presence of catalysts is largely determined by the nature of the solvent. A study of the decomposition of cumenyl hydroperoxide in different solvents catalysed by cobalt abietate[43] showed that the rate of decomposition and the effective activation energy greatly depend on the solvent. The above solvents can be arranged in the sequence nonane < toluene < chlorobenzene < benzene in terms of the rate of decomposition. The activation energies fall in the same sequence from 21 kcal mole^{-1} for nonane to 13 kcal mole^{-1} for benzene.

The rate of decomposition of the hydroperoxide varies even more in the presence of oxygen-containing compounds. The addition of dimethylphenylmethanol to give a concentration comparable to that of t-butyl hydroperoxide reduces the rate of decomposition of the latter by a factor of four in the presence of cobalt abietate[98]. The rate of decomposition of cumenyl hydroperoxide in the presence of dimethylphenylmethanol (25% relative to the hydroperoxide employed) decreases almost by a factor of two, while α-tetralinone strongly inhibits the decomposition of tetralinyl hydroperoxide[36]. In the decomposition of cumenyl hydroperoxide by cobalt salts in alcoholic solutions a deviation was observed from the equation for first-order kinetics with respect to the hydroperoxide[46]. Acetophenone and dimethylphenylmethanol inhibit the decomposition of the hydroperoxide in the presence of copper stearate[55].

Organic acids as a rule strongly inhibit the decomposition of hydroperoxides in the presence of homogeneous catalysts; low-molecular-weight acids exhibit the strongest influence[38,99,100]. The rate of decomposition of tetralinyl hydroperoxide in a mixed solvent consisting of benzene and an organic acid falls in proportion to the square of the concentration of the acid[38,99]. A detailed study of the decomposition of cumenyl hydroperoxide catalysed by cobalt carboxylates in chlorobenzene, organic acids, and their mixtures has been carried out[31]. With increase of the concentration of acid in the solution, the rate constant for the decomposition of the hydroperoxide falls. The hydroperoxide decomposition rate constant in the presence of cobalt(II) oenanthate decreases by a factor of 90 on passing from a solvent containing 6% of butyric acid to pure butyric acid. The apparent activation energy rises from 12 kcal mole^{-1} in chlorobenzene to 22 kcal mole^{-1} in the presence of butyric acid, but depends only slightly on the amount of added acid.

The inhibiting effect of acetic and 2-ethyloenanthic acids on the rate of decomposition of t-butyl hydroperoxide catalysed by cobalt salts has been demonstrated[100]. The decrease of the catalytic activity of nickel stearate in the decomposition of α-phenylethyl hydroperoxide in the presence of acetic acid has also been established[101]. Aliphatic alcohols, ketones, and acids greatly reduce the rate of decomposition of n-decyl hydroperoxide in the presence of copper stearate[102].

The above data show that such influence of the solvent can be due to several causes.

1. Since in the majority of the studies quoted the influence of the solvent on the overall rate of decomposition of the hydroperoxide was considered, the observed influence of hydrocarbon solvents is possibly associated with a change in the contribution of the induced decomposition of the hydroperoxide owing to the change in the reactivity of the radicals caused by the involvement of the solvent in the chain transfer reaction.
2. Many solvents, particularly alcohols, ketones, and acids, can alter the relative amounts of the different valence forms of the catalyst as a result of reaction with the highest valence form of the metal. This effect also leads to an alteration of the rate of decomposition of the hydroperoxide.
3. Finally, the possible formation of complexes by the metal with the solvent may be a significant factor influencing the efficiency of the catalyst. Below we shall consider in somewhat greater detail the role of the formation of complexes of the catalyst and the solvent in the mechanism of the homogeneous-catalytic decomposition of hydroperoxides.

The decrease of the induction period in the oxidation of cyclohexanone catalysed by manganese stearate following the addition of benzoic acid and the acceleration of the oxidation in the presence of butyric acid have been attributed[103] to the formation of a complex of the acid and the catalyst, as a result of which the latter is activated.

The influence of acids on catalytic oxidation processes depends on the structure of the catalyst employed, particularly on the metal ion. For example, the addition of caprylic acid activates cobalt stearate but passivates manganese caprylate in the oxidation of cyclohexane[104]. It has been suggested that the hydroperoxide decomposes via the following mechanism in the coordination sphere of the metal:

$$M[X_5, ROOH]^{n+} \rightarrow M[X_5, (OH^-)]^{(n-1)+} + RO^{\cdot}.$$

In the presence of acids there is a possibility of the simultaneous coordination of hydroperoxide and acid molecules to the metal ion:

$$M[X_5, ROOH, R'COOH]^{n+} \rightarrow M[X_4, (R'COO), (H_2O)]^{(n-1)+} + RO^{\cdot}.$$

Depending on the relative rates of these reactions, the presence of the acid in the coordination sphere of the metal can either inhibit or accelerate the decomposition of the hydroperoxide and can lead to a corresponding retardation or acceleration of the oxidation reaction.

There are many fewer examples of the suppression of the catalytic activity of homogeneous catalysts by the addition of compounds capable of forming complexes with organometallic compounds. The decrease of the rate of oxidation of cyclohexane in the presence of cobalt stearate has been attributed[105] to the formation in the system of polar substances such as cyclohexanol or water, which

block the catalyst molecules and reduce the rate of initiation thereby. The deviation from the bimolecular kinetics of the decomposition of α-phenylethyl hydroperoxide in chlorobenzene in the presence of copper stearate as oxidation proceeds may be caused by the formation of complexes of the decomposition products (acetophenone and methylphenylmethanol) and the catalyst. The occurrence of such complex formation has been confirmed qualitatively by a spectrophotometric method. The formation of cobalt(II) and cobalt(III) complexes with α-tetralinone has been postulated to account for the retardation of the decomposition of tetralinyl hydroperoxide in the presence of cobalt 2-ethylhexanoate when α-tetralinone is introduced into the solution[36].

In the oxidation of *o*-xylene in acetic acid in the presence of cobalt acetate the reaction product (*o*-phthalic acid) forms chelate complexes with cobalt(II) and cobalt(III) ions, which alters the oxidation-reduction potential of the system: there is a considerable increase of the stability and hence of the concentration of cobalt(III) in solution. Terephthalic acid, formed in the oxidation of *p*-xylene, also binds cobalt ions into catalytically inactive complexes[103]. A change in the activity of the catalyst as a result of the formation of complexes with acetic and 2-ethylhexanoic acids has been observed in a study of their influence on the decomposition of t-butyl hydroperoxide in the presence of cobalt carboxylates[100]. The changes in the absorption spectrum of cobalt 2-ethylhexanoate in the presence of acids demonstrate qualitatively the formation of complexes of the acid with the cobalt salt. The formation of dinuclear acid–catalyst complexes is possible.

Polar solvents can form complexes with cobalt stearate[34,39]. The rate of decomposition of the hydroperoxide is determined then by the competition between the complex-formation reactions of the catalyst with the hydroperoxide, its decomposition products, and the solvent[39]. A quantitative confirmation of the role of the formation of complexes by copper salts with alcohols, ketones, and acids in the passivation of the catalyst of the decomposition of hydroperoxides was obtained in a study of the decomposition of n-decyl hydroperoxide in the presence of copper stearate in oxygen-containing solvents[102]. Using the method of inhibitors, it was established that there is no chain decomposition of n-decyl hydroperoxide. Alcohols, ketones, and acids inhibit to an equal extent both the decomposition of the hydroperoxide and the formation of free radicals. The relative contributions of the hydroperoxide decomposition pathways do not change in the presence of the compounds used. Furthermore it was shown that under the experimental conditions copper stearate does not oxidise decanol, decanone, and higher carboxylic acids.

Kinetic data for the dependence of the rate of decomposition of n-decyl hydroperoxide on the concentration of alcohols, ketones, or acids and the hydroperoxide established that the observed inhibition of the decomposition of ROOH by the addition of oxygen-containing solvents (S) can be accounted for if it is supposed that, together with the complexes $CuSt_2.2ROOH$, ROOH.S, and $CuSt_2.S$, mixed-ligand complexes $CuSt_2.2ROOH.S$ are produced in the system. The hydroperoxide in such a complex decomposes at rates several orders of magnitude lower than the rate of decomposition of the hydroperoxide in the complex $CuSt_2.2ROOH$. The stabilisation of the hydroperoxide in the complex $CuSt_2.2ROOH.S$ may be due to the fact that in this case the solvent is incorporated in the inner, rather than outer, coordination sphere of the metal. This entails the decomposition of the hydrogen bond between two ROOH molecules bound in a complex with copper stearate and the rate of decomposition of the hydroperoxide falls.

The equilibrium constants for the formation of the complexes $CuSt_2.S$, ROOH.S, and $CuSt_2.2ROOH.S$ were calculated from the kinetic data for the decomposition of the hydroperoxide. At the same time the equilibrium constants for the formation of $CuSt_2.S$ complexes were determined spectrophotometrically from the change in the optical density of $CuSt_2$ solutions in the presence of S.[106] The agreement between the equilibrium constants for the formation of the $CuSt_2.S$ complexes found by the two independent methods made it possible to establish the following mechanism for the decomposition of n-decyl hydroperoxide in the presence of copper stearate and oxygen-containing compounds:

$$CuSt_2 + 2\,ROOH \rightleftarrows CuSt_2 \cdot 2\,ROOH \rightarrow \text{decomposition of ROOH},$$
$$CuSt_2 + S \rightleftarrows CuSt_2 \cdot S,$$
$$ROOH + S \rightleftarrows ROOH \cdot S,$$
$$CuSt_2 \cdot 2\,ROOH + S \rightleftarrows CuSt_2 \cdot 2ROOH \cdot S.$$

VI. DECOMPOSITION OF HYDROPEROXIDES IN THE PRESENCE OF GROUP V–VI METAL COMPOUNDS AND CATALYTIC EPOXIDATION OF OLEFINS BY HYDROPEROXIDES

There has been a recent increase of interest in the study of the mechanism of the catalytic decomposition of hydroperoxides in the presence of Group V–VI metal compounds in connection with the problem of the catalytic epoxidation of olefins by bound oxygen (hydroperoxides, hydrogen peroxide, and peracids) in the presence of molybdenum, vanadium, tungsten, and chromium compounds[107]. The interaction of olefins with hydroperoxides in the presence of these compounds takes place with a high degree of selectivity. Group IB, VII, and VIII transition metals are as a rule relatively inactive in the epoxidation; metals with a constant valence do not catalyse the epoxidation of olefins by hydroperoxides[108,109].

The absence of an appreciable catalytic effect in the epoxidation of olefins in the presence of cobalt, nickel, copper, and manganese compounds, which are typical catalysts of the radical (homolytic) decomposition of hydroperoxide, led to the hypothesis that, in the presence of molybdenum, vanadium, and tungsten compounds, the heterolytic pathway predominates in the decomposition of hydroperoxides[110].

The experimental studies on the decomposition pathways for cumenyl and cyclohexyl hydroperoxides in the presence of vanadium, vanadyl, molybdenyl, and chromium acetylacetonates and stearates showed that the hydroperoxides decompose (as in the presence of transition metals) via two pathways: molecular and free-radical[111]. Depending on the type of catalyst and temperature, the contribution of the radical decomposition may vary from 1 to 100% relative to the overall rate of decomposition of the hydroperoxide[111]. Thus in the decomposition of cumenyl hydroperoxide in the presence of chromium stearate the yield of radicals increases from 1 to 100% as the temperature is raised from 70° to 120°C; cyclohexyl hydroperoxide decomposes in the presence of chromium, vanadyl, and molybdenyl acetylacetonates at 120–130°C with a 3–12% yield of radicals[111].

The study of the kinetics of the decomposition of hydroperoxides in the presence of such catalysts led to the hypothesis that, in contrast to cobalt, copper, and nickel compounds, the molecular decomposition is not in this case a manifestation of the "cage" effect.

The principal decomposition products are acetophenone, dimethylphenylmethanol, α-methylstyrene, and carbon dioxide for cumenyl hydroperoxide and cyclohexanone and cyclohexanol for cyclohexyl hydroperoxide[111]. Phenol, a typical product of the heterolytic decomposition of cumenyl hydroperoxide, is absent from the reaction products, which throws doubt on a significant contribution of the heterolytic hydroperoxide decomposition reaction.

In many studies dealing with the epoxidation of olefins by hydroperoxides it was noted that the epoxidation process is preceded by the interaction of the catalyst with the hydroperoxide, which converts the catalyst into an active valence form. This hypothesis is supported in the first place by the finding that the catalytic epoxidation is always preceded by an induction period, during which the catalyst is altered, in many cases with a change in the colour of the solution. Preliminary incubation of hydroperoxide solutions with the catalyst as a rule eliminates the induction period.

The study of the catalysis of the decomposition of t-butyl hydroperoxide and hydrogen peroxide by vanadium compounds established that a red complex is formed in the initial stage of the process[110-115] when vanadyl chelate complexes are used as the initial forms of the catalyst: vanadyl bis(acetylacetonate) [$VO(acac)_2$]; vanadyl bis-(hexafluoroacetylacetonate) [$VO(hfac)_2$]; vanadyl bis(dipivaloylmethide) [$VO(dpm)_2$]; vanadyl chloride. The $V(acac)_3$ and $V(t\text{-}C_3H_7O)_3$ catalysts do not form a red complex. The stability of the complex depends on the nature of the catalyst employed. It has been suggested[112] that the red colour of the solution is due to the formation of the vanadium(IV)...ROOH complex the decomposition of which involves the transition of vanadium(IV) $\rightarrow$ vanadium(V).

The stoichiometry of the decomposition of H_2O_2 in aqueous solutions in the presence of $VOCl_2$ corresponds to the equation[113]

$$2\,VO^{2+} + H_2O_2 \rightarrow 2\,VO^{+} + 2\,H^{+} + O_2.$$

The formation of the complex $O{=}V{-}OOH^{+}$ in the first stage via the reaction

$$VO^{2+} + H_2O_2 \rightleftarrows O{=}V{-}OOH^{+} + H^{+},$$

with subsequent decomposition of the peroxo-complex via the mechanism

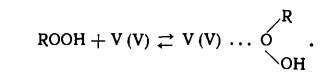
$$O{=}V{-}OOH^{+} \rightarrow VO_2^{+} + OH^{\cdot},$$

$$VO_2^{+} + H_2O_2 \rightarrow VO_3^{+} + H_2O,$$

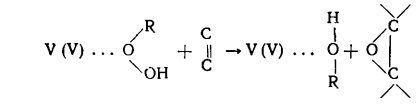
has been postulated.

The VO_3^{+} species can form complexes with free hydroxy-radicals, which ultimately leads to the reduction of vanadium(IV) in the system. The possibility of the interaction of VO_2^{+} with H_2O_2 to form VO_3^{+} has been demonstrated[114]. The disappearance of paramagnetism from the ROOH–$VO(acac)_2$ system suggests that vanadium is in the +5 state in the red complex[111].

The actual nature of the active species in this process has not been established. The virtual independence of the rate of expoxidation of the olefin of the hydroperoxide concentration observed in a kinetic study of the systems allyl alcohol–α-phenylethyl hydroperoxide–vanadium tris-(acetylacetonate)[116], propene–α-phenylethyl hydroperoxide–molybdenum resinate[117], and many others[110,118,119] led to the hypothesis that catalyst–hydroperoxide complexes are formed reversibly:



In this complex there is a possibility of partial polarisation (heterolysis) of the O–O bond[110], which facilitates the subsequent interaction of the hydroperoxide with the olefin:



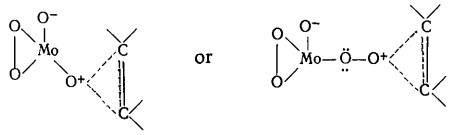
The formation of complexes of t-butyl hydroperoxide with molybdenyl bis(cyclohexanediolate)[120] and molybdenyl bis(acetylacetonate)[121] was observed by NMR from the broadening and partial shift of the signal due to the OH protons of the hydroperoxide in the presence of molybdenum compounds. The existence of two peroxy-species in equilibrium was postulated in this instance[120]:

$$Mo\,(VI)\,ROOH \rightleftarrows Mo\,(V)\,RO_2^{\cdot} + H^{+}. \qquad (13)$$

The formation of the $RO_2^{\cdot}$ radical in the interaction between molybdenum(V) and ROOH has been noted[122].

It has been suggested[123] that molybdenyl peroxo-complexes capable of stoichiometric epoxidation of olefins are formed in the course of the catalytic epoxidation reaction. The capacity of these peroxo-complexes for epoxidation was demonstrated in the epoxidation of olefins[124] and allyl alcohol[125] by the peroxo-complexes $O{=}Mo(O_2)_2L_1L_2$, where L_1 and L_2 are hexamethylphosphoramide and water. Later similar peroxo-complexes [$O{=}Mo(O_2)_2$ and in small amounts $Mo(O_2)_2Cl_2$] were isolated in reactions of organic peroxides with $MoCl_5$ in ethyl alcohol[126].

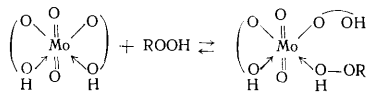
It has been shown with the aid of "labelled" oxygen (^{18}O) that the O=Mo oxo-group is not involved in the epoxidation and that the process proceeds via the formation of intermediate complexes of the type[127]



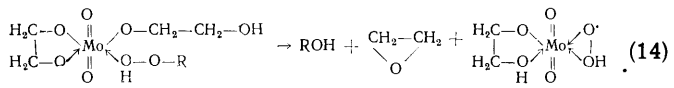
The possibility of the formation of complexes by peroxomolybdenum compounds with an olefin was confirmed[126] by the observation of a change in the colour of $O{=}MoO_4$ from yellow to green in the presence of the olefin. The formation of a complex with allyl alcohol has been demonstrated kinetically for $MoO(O_2)_2L_1L_2$.[125]

Although a peroxomolybdenum(VI) compound has been isolated in the interaction of molybdenum compounds with a hydroperoxide in the absence of an olefin and its capacity for epoxidation has been demonstrated (in stoichiometric proportions of 1 : 1), the mechanism of epoxidation via a successive alternation of stages involving the formation of the peroxo-complex and its reaction with the olefin cannot be regarded as proved. In catalysis by molybdenyl chelate complexes molybdenum bis(diolate) was identified as the main product derived from the catalyst in the presence of an olefin and a hydroperoxide[128,129]. The structure of the diol in the chelate complex corresponds to that of the initial olefin. It has been suggested that such diols can form complexes with hydroperoxides,

probably with dissociation of one of the coordinate bonds between the diol and the molybdenum(VI) ion[120]:

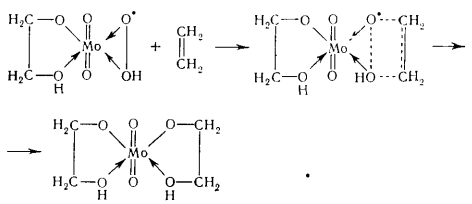


The hydroperoxide in the complex thus formed is activated and can react with the diol in the coordination sphere of the metal to form an oxide (from the diol) and alcohol:



(14)

The initial diolate is reduced and a cyclic catalytic complex is formed via the mechanism



In most investigations of the catalytic epoxidation of olefins the inhibition of the reaction by alcohols was noted. As a rule this effect is attributed to a competitive inhibition mechanism, i.e. the formation of the stable complexes Cat.ROH, which prevent the formation of catalyst–hydroperoxide complexes in the system. Although this mechanism of the inhibition of the epoxidation process by alcohols is extremely probable, it may not be the only one possible.

It has been shown[120] that the introduction of an alcohol into a molybdenum(VI)–ROOH system increases the concentration of the Mo(V).$RO_2^{\cdot}$ species and it has been suggested that the inhibition by alcohols is caused by the acceleration of reaction (13) and the consequent decrease of the concentration of the Mo(VI).ROOH complexes and of the rate of reaction (14). This hypothesis is consistent with the absence of an effect by the alcohol on the kinetics of the formation of the primary red complex in catalysis by vanadyl acetylacetonate and with the increased stability of this complex, if it is supposed that the red complex formed by organic peroxides is analogous to $O{=}VOOH^{+}$. Together with molybdenum(VI) compounds, zero-valent molybdenum carbonyls can serve as active epoxidation catalysts[129–133].

In the absence of an olefin, the hydroperoxide decomposes on $Mo(CO)_6$ via an oxidation-reduction mechanism with a change in the valence of molybdenum. The introduction of phenols into the system leads to the formation of π complexes of the phenol and $Mo(CO)_6$. The decomposition of the hydroperoxide then proceeds without a change in the valence of molybdenum via a synchronous mechanism and involves a reaction between the phenol in the complex and two hydroperoxide molecules[134].

The study of the infrared spectra of molybdenum hexacarbonyl in the presence of an olefin and a hydroperoxide showed that the valence state of molybdenum does not change in the epoxidation reaction[130–133]. The kinetic epoxidation curves nevertheless show a distinct induction period, which suggests the necessity for an $Mo(CO)_6$ dissociation stage. An NMR study of the $Mo(CO)_6$–α-phenylethyl hydroperoxide system in dichloroethane demonstrated the formation of the outer-sphere complexes $Mo(CO)_6$.ROOH with subsequent displacement of CO and the incorporation of the hydroperoxide in the inner coordination sphere:

$$Mo(CO)_6 + ROOH \rightarrow Mo(CO)_6 \cdot ROOH \xrightarrow{-CO} Mo(CO)_5 \cdot ROOH.$$

It is suggested that the epoxidation proceeds via a stage involving the formation of the mixed-ligand complexes $Mo(CO)_{6-1-n}.(olefin)_n.ROOH$.

Short-lived Phenoxy- and Semiquinone Radicals

I.V.Khudyakov and V.A.Kuz'min

The results of the principal studies of the absorption spectra and the kinetics of the destruction of short-lived phenoxy- and semiquinone radicals in the liquid phase are examined. A systematic account is given of the results of investigations of their interaction with metal compounds. Much attention is devoted to the photochemical method of generating phenoxy- and semiquinone radicals from phenolic and quinonoid compounds.
The bibliography includes 205 references.

I. INTRODUCTION

In the vast majority of cases the reactions of phenolic compounds in chemical and biological processes have free-radical mechanisms. The phenoxy- and semiquinone radicals formed under these conditions as intermediates and the related flavosemiquinone radicals are π radicals and belong to the class of aromatic radicals. The study of the characteristics of phenoxy-radicals is an important task in connection with the extensive use of phenols as inhibitor-stabilisers in various branches of theoretical and applied chemistry[1-3] and recently also in experimental biology and medicine[4]. There has been an immense growth of interest in the last decade and a half in this field of research in connection with studies by Emanuel' and his coworkers[4-11].

A number of monographs and reviews are devoted to stable phenoxy- and semiquinone radicals[3,12-16]. As a result of the development of pulse methods, extensive data on the physicochemical properties of short-lived phenoxy- and semiquinone radicals have accumulated during the last 10–15 years.

It is therefore desirable to survey the available literature data for the fundamental reactions of phenoxy- and semiquinone radicals and their physicochemical properties.

II. METHODS FOR THE INVESTIGATION OF THE PHYSICOCHEMICAL PROPERTIES OF SHORT-LIVED RADICALS

Almost all the techniques for the investigation of reactivity can be applied to phenoxy- and semiquinone radicals. In this review the term "unstable" or "short-lived" is applied to a radical whose lifetime is shorter than one second in the absence of oxygen at room temperature in a non-viscous solvent at concentrations in the range 10^{-7} to 10^{-5} M.

For a time the ESR method (in its usual version) was the main procedure for the investigation of the properties of radicals. Its use in the study of short-lived radicals is extremely difficult. In such cases one employs a flow system or the radical precursor is irradiated directly in the cavity of the spectrometer. In certain cases the radicals can be stabilised owing to the characteristics of the solvent—a highly alkaline medium (in the case of semiquinone radicals) or the formation of a complex with the solvent[13]. The method of low-temperature stabilisation[17], in which the radicals are stabilised in a solid matrix and their spectra are recorded, has been widely used. In recent years the absorption spectra of aromatic and other radicals, stabilised in a solid poly(methyl methacrylate) (PMMA) or adamantane matrix, have been recorded at room temperature[18-20].

Pulse methods (flash photolysis and pulse radiolysis) have a considerable scope in the study of the properties of short-lived radicals. The use of flash photolysis with detection of intermediates from their ESR spectra is extremely promising.

The absorption of light by an aromatic molecule, for example phenol, leads to the formation of an unstable excited state, which is deactivated either as a result of a photophysical process, for example fluorescence or phosphorescence, or photochemically, i.e. via dissociation into radicals or ionisation. The radicals or radical-ions thus formed can be detected, for example, from their absorption spectra. The method of pulse radiolysis has been also widely used to study aromatic radicals; it differs from flash photolysis by the fact that the excitation is achieved by a short pulse of high-energy electrons†.

† In order to obtain high non-equilibrium concentrations of phenoxy- and semiquinone radicals, water was subjected to pulse radiolysis in the presence of the initial phenolic or quinonoid compound. The aqueous solutions contained 0.1–10% of organic additives (alcohol, acetone, formate, etc.) and could be saturated with N_2O to remove undesirable water radiolysis products from the reaction mixture. All the experiments were performed at room temperature.

III. THE INVOLVEMENT OF PHENOXY- AND SEMIQUINONE RADICALS IN CHEMICAL AND BIOLOGICAL PROCESSES IN THE DARK

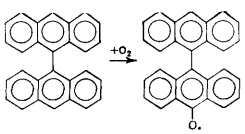
1. Phenoxy-radicals

Phenoxy-radicals are intermediates in various reactions where phenol is oxidised—by inorganic oxidants, oxygen, alkoxy- and peroxy-radicals, oxidation enzymes, anodically, etc. They are formed in hydrocarbon oxidation reactions inhibited by phenol. The mechanism of the action of phenolic inhibitors in free-radical reactions reduces to chain termination owing to the interaction of the phenol (RhOH) with the chain-propagating radicals R$^{\cdot}$ or RO$_2^{\cdot}$:[1]

$$R^{\cdot}\,(RO_2^{\cdot}) + PhOH \rightarrow RH\,(ROOH) + Ph\dot{O}.$$

Aromatic radicals RO$^{\cdot}$ are as a rule incapable of propagating the chain process further and are destroyed by interacting with one another or with the chain-propagating radicals[1,2,21].

Aryloxy-radicals are also formed when condensed aromatic compounds without OH groups are oxidised by oxygen. The oxidation of anthracene leads to the formation of the corresponding aryloxy-radical[22], while the oxidation of bianthryl proceeds via the substitution of its most reactive hydrogen atom by oxygen[23]:



Phenolic compounds are extremely widely distributed in nature. It has been suggested that phenolic substances are involved in the growth, development, immunity, resistance to cold and harmful radiation, respiration, and photosynthesis in plants, i.e. in almost all their vital processes[24,25]. It has been established that certain biologically important phenolic substances are capable of reversible oxidation with formation of the corresponding phenoxy-radicals as intermediates and it has been suggested that these properties constitute the basis of the pharmacological activity of such compounds[25]. Phenolic compounds are incapable of participating in various enzymatic and photochemical oxidation-reduction processes which are of great biological importance[25]. It is nowadays regarded as proved that oxidative coupling of phenols is one of the principal stages in the biosynthesis of natural products[26].

2. Semiquinone Radicals

o- and *p*-Hydroxyphenoxy-radicals and their anions as well as their derivatives constitute the group of semiquinone radicals. As early as the 1930s, Michaelis and coworkers[27] showed that the two-electron oxidation of hydroquinone or the reduction of quinone proceeds via a stage involving the formation of an intermediate containing an odd number of electrons—a semiquinone radical. The existence of semiquinone radicals in quinone reduction or hydroquinone oxidation processes was demonstrated for the first time in measurements of magnetic susceptibility and in potentiometric measurements[27]. *o*- and *p*-Benzosemiquinone radical-anions are relatively stable in an alkaline medium, which makes it possible to record their intense ESR signals in aqueous or alcoholic media at room temperature[28,29].

Like phenoxy-radicals, semiquinone radicals are the primary products of the oxidation of various hydroquinones by inorganic oxidants, by atmospheric oxygen, by enzymes[30], etc. They can probably be formed also in the catalytic oxidation of phenol by oxygen, as shown by the formation of hydroquinone and catechol as the final products of such a reaction[31]. Quinones are well known in organic chemistry as electron acceptors which are reduced to dihydroquinone via the intermediate formation of a semiquinone radical.

A wide variety of numerous quinonoid compounds are encountered in nature and are involved in oxidation-reduction reactions[32,33]. Semiquinone radicals play an important role in biological systems as active agents in electron transfer reactions in living organisms, plants, and microorganisms[34,35]. The simplest quinones (*p*-benzoquinone, chloranil, duroquinone, and naphthoquinone) have aroused interest, because they can be regarded as models for more complex quinones—coenzyme Q, vitamins K, plastoquinones, flavin-adenine dinucleotide, etc. Studies on reversible oxidation reduction reactions of riboflavin (vitamin B$_2$), which also proceed via the formation of flavosemiquinone radicals, are of great interest from the biological point of view.

IV. FUNDAMENTAL PHOTOCHEMICAL PROCESSES OCCURRING ON PHOTOEXCITATION OF PHENOLS AND QUINONES

1. Photolysis of Phenols

The majority of the reactions leading to the formation of phenoxy-radicals are associated with the abstraction of hydrogen from the hydroxy-group of phenol under the influence of oxidising agents. The dissociation of the O–H bonds in phenols (as well as PhO–CH$_3$, PhO–C$_2$H$_5$, and PhO–COR bonds) with formation of phenoxy-radicals can occur also under the influence of ionising and ultraviolet radiation or ultrasonic waves[36–56]. The simplest phenols are photolysed in the gas phase via the reaction[45]

$$PhOH + h\nu \rightarrow PhO^{\cdot} + H^{\cdot}.$$

An energy diagram has been plotted for this decomposition pathway of the phenol molecule[45], according to which the absorption of a photon by the phenol results in its transition from the ground state to the first singlet excited state $^1\pi_1$. This level intersects the dissociative level $^3\sigma_0$, and the system can pass to the $^3\sigma_0$ state, which entails the dissociation of the O–H bond and the formation of the radicals PhO$^{\cdot}$ and hydrogen atoms H$^{\cdot}$.

In the pulse photolysis of phenoxide ions in the liquid phase a phenoxy-radical is formed, as in the photolysis of phenol, which indicates the photoionisation of the anion via the reaction[54,55]

$$PhO^- + h\nu \rightarrow PhO^{\cdot} + e^-_{hydr.}$$

The photoionisation of phenols and their anions in a solid matrix at low temperatures proceeds via a two-photon pathway with participation of the triplet excited state[56–62]. The nature of this process in liquid media, particularly in polar liquids, is less clear. The earlier attempts to observe a non-linear relation between the initial yield of solvated electrons, obtained in the photolysis of *p*-cresol, and light intensity were unsuccessful[50].

It was suggested[64] that in certain cases a one-photon process may proceed via an intermediate semi-ionised state, which is produced directly from the unrelaxed excited singlet state. As a result of the energy gain on solvation, photoionisation can be induced by light the energy of whose quanta is less by 3–4 eV than the ionisation potential in the gas phase[65]. It has been shown[18] that the corresponding naphthoxy-radicals are formed from the molecules of α- and β-naphthols in the excited singlet state in a PMMA matrix.

In the liquid-phase photoexcitation of phenols, phenoxy-radicals are formed via the reactions[51,66,67]

$$\mathrm{PhOH} + h\nu \rightarrow \mathrm{PhOH}^* \begin{cases} \xrightarrow[-\mathrm{H}^+]{(a)} (\mathrm{PhO}^-)^* \rightarrow [\mathrm{PhO}^\cdot + e_{solv}] \rightarrow \mathrm{PhO}^\cdot + e_{solv} \\ \xrightarrow{(b)} [\mathrm{PhO}^\cdot + \mathrm{H}^\cdot] \rightarrow \mathrm{PhO}^\cdot + \mathrm{H}^\cdot \end{cases} , \quad (1)$$

where the solvent "cage" is represented by square brackets.

In the flash photolysis of phenol and cresols the relative yield of hydrated electrons falls when the pH becomes less than the pK of the corresponding unexcited phenol molecule[50]. After the dissociation of the phenol molecule in the singlet excited state (pathway a), the electron is "ejected" with formation of a phenoxy-radical. Subsequent studies confirmed that the pK of phenol and cresols in the first singlet state are smaller by 5–6 units than in the ground state[68,69]. The relative contributions of the decomposition pathways of the excited phenol molecule, a or b, are independent of many factors, primarily temperature, solution pH, and the polarity of the medium[51,66]. A detailed mechanism of the photoionisation of aromatic molecules in liquids has been discussed[64,70].

According to Feitelson and Hayon[51], more than 70% of the radicals generated from phenols are obtained via photoionisation (pH 7.0; 25°C) and the remainder via the dissociation of the O–H bonds. (The quantum yield in the dissociation of the O–H bond amounts to about 0.01 for various media[53].) On the other hand, the photoionisation is much less effective with the phenol than that with the corresponding anion[71]. The photoionisation of phenols and their anions in alkaline media proceeds via two-photon and one-photon processes respectively[65]. The concentration of phenoxy-radicals formed under the influence of the flash is proportional to the light intensity I^n, where n varies from 2 to 1 over a relatively narrow pH range. Absorption due to phenoxy-radicals is observed in air-saturated solutions, the radicals being formed in a somewhat lower yield and $n = 1.5$.

Studies of the photolysis of aqueous solutions of phenols in the absence of oxygen (at 25°C) with added hexa-2,4-diene, a typical quenching agent for the triplet state, showed that in the photolysis of many phenols the electron is also ejected from a long-lived excited state, possibly the triplet state[51].

Either halogenophenoxy-radicals or hydroxyphenyl radicals may be formed in the photolysis of halogenophenols. The photolysis of iodophenols results in the formation of hydroxyphenyl radicals[18,146], as in the photolysis of p-chlorophenol and monobromophenols[48,73].

The photolysis of 2,4-dibromophenol and 2,4,6-tribromophenol yields the corresponding phenoxy-radicals[72,45]. The absorption recorded in the flash photolysis of certain chlorophenols is due to the formation of chlorophenoxy-radicals[45].

2. Photochemical Reactions Leading to the Formation of Semiquinones

Semiquinone radicals may be obtained by the photochemical oxidation of the corresponding hydroquinones or by the photochemical reduction of quinones. The photochemical oxidation of hydroquinones proceeds partly in the same way as the photolysis of phenols [see Eqn. (1)]. Thus the formation of the corresponding semiquinone radicals and hydrated electrons was observed in the flash photolysis of hydroquinone and catechol in water[59].

The photochemistry of quinones has been vigorously investigated in connection with the elucidation at the molecular level of the destructive effect of light on certain biological objects[33] and also the possible initiation of electron transfer in biological systems following the absorption of light by a quinone[74]. It has been shown that certain alkylquinones are bound to chlorophyll in leaf chloroplasts[33,34]. It has been suggested, that, apart from their function as acceptors in the electron-transport chain, these quinones can play a definite role in photophosphorylation[75].

The damaging influence of ultraviolet light on living organisms is associated with photochemical reactions of quinones, which are the most likely targets for radiation[76]. Semiquinone radicals are frequently the primary products of the photochemical excitation reactions of quinones under these conditions[76–78].

The photochemical reduction processes involving quinones have been studied in fair detail. In an excited state quinone molecules abstract a hydrogen atom (or electron) from the solvent molecule or from another hydrogen (or electron) donor present in solution with formation of a semiquinone radical. Depending on the pH, an acid–base equilibrium involving the half-reduced forms of quinones is then rapidly established. The problem arises as to the nature of this excited state of the quinone. Studies on the kinetics of the destruction of the triplet state of duroquinone DQ(T) and the semiquinone radical DQH$^\cdot$ in liquid paraffin[79,80] showed that DQH$^\cdot$ is formed mainly via the reaction

$$\mathrm{DQ}(\mathrm{S}^*) + \mathrm{RH} \rightarrow \mathrm{DQH}^\cdot + \mathrm{R}^\cdot .$$

However, experiments on energy transfer established that DQH$^\cdot$ is formed also by a path involving the triplet state[81]. It was subsequently shown by laser photolysis that the durosemiquinone radical is indeed formed from the triplet state in ethanol[82].

The fact that DQ(T) is destroyed in liquid paraffin, giving rise to DQH$^\cdot$, has not been rigorously demonstrated[82]. Studies of the photochemical reduction of chloranil have also demonstrated that the photoexcited triplet state of chloranil is quenched by ethanol with direct formation of a semiquinone radical-anion[83]. The lifetime of the triplet state of p-benzoquinone in ethanol is 10 ns and therefore the rate constant for the abstraction of a hydrogen atom from the solvent $k > 10^8$ s^{-1}.[83,84]

The mechanism of the photochemical reduction of p-benzoquinone in ethanol at low temperatures has been considered[85,86]. The photochemical reduction of 1,4-naphthoquinone proceeds with the intermediate formation of the neutral naphthosemiquinone radical[87].

In certain cases the formation of semiquinone radicals on photochemical reduction of quinones is accompanied by electronic polarisation[84,87]. Immediately after the flash, an emission signal appears in the ESR spectrum, is converted into an absorption signal, and then diminishes owing to the destruction of the radicals[84,87].

The pK values of semiquinone radicals in water are fairly well known (Table 2). The assignment of the observed absorption in an organic solvent to a neutral semiquinone radical or radical-anion is usually based on an analysis of ESR spectra [87,88], but here too certain difficulties arise. The photoexcitation of chloranil in ethanol or methanol leads to the formation of the chloranil radical-anion [88], while in another study [89] it is suggested that the primary product of such photochemical reduction in isopropyl alcohol (or dioxan) is a nuetral radical.

The photochemical reduction of anthraquinone derivatives in alcoholic media has been studied in greatest detail, since this process simulates the photochemical degradation of cellulose sensitised by anthraquinone dyes and is of great practical importance [90-96].

Anthraquinone derivatives are reduced photochemically in alcoholic solutions via the reaction

$$AQ\,(T) + RCH_2OH \rightarrow AQH^{\cdot} + R\dot{C}HOH$$

and in alkaline media via the reaction

$$AQ\,(T) + OH^{-} \rightarrow AQ^{\cdot-} + OH^{\cdot}.$$

The resulting semiquinone radical-anion is fairly stable in alkaline solution in the absence of oxygen.

The quinones involved in photochemical biological processes (plastoquinones, tocoquinones, and α-tocopheryl-quinones) also give rise to the corresponding semiquinone radicals on photoexcitation. The final photochemical reduction products from certain plastoquinones and tocoquinones are o-quinone methides [76-78]. The photochemical reduction of many quinones with ring substituents proceeds via an intramolecular mechanism [97-99].

The triplet state responsible for the formation of the semiquinone radical from 1,4-benzoquinone, 1,4-naphthoquinone, and anthraquinone is probably of the $n-\pi$ type [100-103], while the triplet states of duroquinone and chloranil are of the $\pi-\pi^*$ type [82,101,104]. The precursor of the radical is probably the lowest triplet state of the corresponding quinone in all cases where semiquinones are formed [63,87].

The formation of flavosemiquinone radicals, particularly those derived from riboflavin, has been observed in the photochemical reduction of flavins or in their reduction by electrons [105-108,110-115].

It was initially suggested that dihydroriboflavin is formed via the abstraction of two hydrogen atoms from the water molecule [116-118]. Objections were raised to this mechanism [119] on the basis of the process energetics and it was postulated that the decolorisation of riboflavin proceeds via the photochemical oxidation of its own ribityl chain. There is evidence for an intramolecular decolorisation mechanism, obtained in a series of kinetic and polarographic studies by pulse photolysis and theoretical calculations [108,109,120-127]. It has been shown that the lowest long-lived triplet state is photochemically reactive in the anaerobic photochemical decolorisation of riboflavin and flavin mononucleotide [107-110,119]

It has been shown [109,127] that the singlet state of riboflavin can also be involved in photochemical reduction and that this pathway is probably the only one giving rise to the formation of the flavosemiquinone radical in air-saturated solutions.

V. SENSITISED PHOTOCHEMICAL OXIDATION OF PHENOLS AND PHOTOCHEMICAL REDUCTION OF QUINONES

In a study of the photochemical oxidation of a number of sterically hindered phenols by molecular oxygen it was observed that, on irradiation without a sensitiser, the initial phenols remain unchanged [128]. Sensitised photochemical oxidation of sterically hindered phenols proceeds via the following mechanism: a complex is formed by the excited molecule of the sensitiser and oxygen and abstracts the hydrogen atom from the hydroxy-group of the phenol with formation of the phenoxy-radical [128]. (In the photochemical oxidation of unsubstituted phenol and cresol under the influence of light with $\lambda = 253.7$ nm, it was established [73] that the presence of oxygen or other oxidants is not essential for the formation of the phenoxy-radical.)

According to another mechanism of the sensitised photochemical oxidation of phenols [129-135], the phenol is attacked by an excited sensitiser molecule, which leads to the abstraction of the hydrogen atom from the phenolic hydroxyl or to the loss of an electron by the phenoxide ion. Reactions proceeding via this mechanism have been observed [130-136] in the sensitised photochemical oxidation of phenol and its derivatives by eosin (E) and related dyes.

The photochemical oxidation reactions sensitised by eosin are of great interest for photobiology, since it has been shown that eosin causes photodynamic inactivation of proteins [136]. The experiments performed by flash photolysis (kinetic and spectrophotometric) have shown that the attack on phenol by a dye molecule in the triplet state results in the formation of a phenoxy-radical and a semiquinone radical derived from the dye [136]:

$$E\,(T) + PhOH \rightarrow EH^{\cdot} + PhO^{\cdot}.$$

It has been established that excited states of 9,10-anthraquinone-2-sulphonic, 9,10-anthraquinone-2,6-disulphonic, and 9,10-anthraquinone-2,7-disulphonic acids are quenched chemically by phenol and hydroquinone with formation of the corresponding phenoxy- (p-benzosemiquinone) and anthrasemiquinone radicals [72,90]. Various α-diketones in an excited state are also capable of oxidising phenols with formation of ketyl and phenoxy-radicals [137,138]. In the quenching of the luminescence of diacetyl by phenols there is a reversible abstraction of a hydrogen atom with formation of phenoxy-radicals [139].

Certain dyes and pigments in an excited state are capable of reducing quinones to semiquinone radicals. Thus the following reaction takes place in the photoexcitation of chlorophyll in alcohols in the presence of p-benzoquinone (duroquinone, vitamin K, and α-tocopheryl-quinone) [132,140-143]:

$$Chl^{*} + Q \rightarrow Chl^{+} + Q^{\cdot-}, \qquad (2)$$

where Chl* is the excited chlorophyll molecule (most probably in the triplet state) and $Q^{\cdot-}$ the semiquinone radical. Eosin in the excited triplet state reduces p-benzoquinone via a type (2) reaction, being oxidised itself to a radical-cation [144].

VI. ABSORPTION SPECTRA AND ACID–BASE PROPERTIES OF PHENOXY- AND SEMIQUINONE RADICALS

The absorption spectra of a number of phenoxy- and semiquinone radicals were recorded in the flash photolysis and pulse radiolysis of phenolic and quinonoid compounds.

The problem of the assignment of the observed absorption in the flash photolysis of aromatic compounds to any specific structural formula is solved individually in most cases[42,43]. Either the triplet state of the molecule or a radical are responsible for the absorption. This problem can be solved by an additional study of the kinetics of the reaction with oxygen, the application of the method of $T-T$ energy transfer, the study of the interaction of the intermediates with various additives, a comparison of the absorption spectra in the liquid and solid phases, etc. Investigation of the dependence of the absorption on the polarity of the medium, pH, ionic strength, and other parameters makes it possible to determine the charge on the transient species.

A study of substituted phenols by flash photolysis showed that, in principle, different radicals can be formed. For example, benzyl and phenoxy-radicals may be formed in the photolysis of *p*-cresol:

In such cases one has to decide to which radical the observed spectrum should be assigned. The spectra of benzyl and phenoxy-radicals differ appreciably in the shape of the bands and in the relative intensities of the long-wavelength and short-wavelength transitions. Flash photolysis of *p*-cresol yielded a spectrum almost identical in form and intensity to that of the phenoxy-radical. On this basis, it was concluded that the primary photochemical process is the formation of a *p*-methylphenoxy-radical[42].

In general the identification of the spectra of aromatic radicals has been based on the study of a series of related substituted compounds[43,145]: the method is particularly convenient and reliable for aromatic compounds, since there are many such compounds and in most cases there is a possibility of cross checks.

1. Phenoxy-radicals

The spectra of phenoxy-radicals are characterised by a system of bands in the region of 300 and 400 nm.[42] The absorption spectrum of the unsubstituted phenoxy-radical was recorded for the first time in the flash photolysis of phenol and anisole vapours in the gas phase[36]. The spectrum consists of a single diffuse band with a maximum at 292 nm. The long-wavelength band in the region of 400 nm has been observed[37,38] in the flash photolysis of phenol in various solvents. Low-temperature studies confirmed the validity of the band assignment[40,42].

The formation of phenoxy-radicals has also been established[44] in the photolysis of phenol, anisole and phenetole in a nitrogen matrix at 4.2 K. In addition to the earlier data[40], bands were found at 295 and 396.5 nm together with a broad band at 240 nm, which correspond to the absorption by the phenoxy-radical. Further photolysis by light in the wavelength range 225–345 nm led to the degradation of the phenoxy-radical itself. Subsequently, a long-wavelength band system with maxima at 395 and 382 nm was observed in the flash photolysis of phenol vapour in the presence of argon[42,46].

The absorption spectra of eighteen different alkylphenoxy-radicals were obtained by Land and Porter in the flash photolysis of the corresponding phenols[45]. They showed that aliphatic substituents have an insignificant influence on the absorption spectrum of the phenoxy-radical, leading to slight shifts of the long-wavelength band system as a function of the position of the substituent in the ring. Phenoxy-radicals are the principal short-lived species detected in the flash photolysis of proteins such as egg albumin, where they are formed from compounds of the type of tyrosine[145].

Phenoxy-radicals with large alkyl substituents have spectra in which the band distribution remains largely the same as in the spectrum of the unsubstituted phenoxy-radical, their intense colour being due to broad bands extending to the visible region. Alkylated phenoxy-radicals are blue and alkoxy- and phenyl groups cause a hypsochromic shift in the visible region, giving rise to radicals with $\lambda_{max} \simeq 530$ nm. On the other hand, electron-accepting substituents (formyl, keto-, and cyano-groups) cause a bathochromic shift and the radicals can be blue or green[12]. A weak diffuse absorption is observed in the region of 600 nm in the spectra of certain trialkylphenoxy-radicals[48]. The existence of such a broad band was also expected for the unsubstituted phenoxy-radical[42]; it was observed in the gas phase under conditions of high resolution[46]. Apart from the 380 and 395 nm bands, which correspond to $\pi-\pi^*$ absorption like the 292 nm band, a broad and weak absorption band was detected in the range 530–610 nm with $\lambda_{max} = 600$ nm; it is probably due to absorption of the $n-\pi^*$ type[43,46].

Studies on the absorption spectra of phenoxy-radicals in PMMA showed that the long-wavelength absorption limit of the radical is 850 nm.[18] However, on the basis of quantum-chemical calculations, the author[18] believes that the long-wavelength absorption in the spectrum of the phenoxy-radical in the region of 600 nm is also of the $\pi-\pi^*$ type. The theory of the absorption spectra of the simplest aromatic radical has been discussed[42].

The absorption spectra of phenoxy-radicals have been recorded in the pulse radiolysis of phenol and *p*-cresol in water[49]. The extinction coefficients of phenoxy-radicals were determined either by pulse radiolysis (when the radiation yields of the radiolysis products are known)[49] or by comparison with the absorption of hydrated electrons formed in the photolysis of phenoxide ions. When the latter method was used, unduly high extinction coefficients were apparently obtained in many instances. This is probably because the hydrated electron has a very short lifetime, comparable to the duration of the flash. A comparatively simple and reliable method for the determination of the extinction coefficient of phenoxy-radicals in experiments on the photochemical oxidation of phenols sensitised by anthraquinone-2,6-disulphonic acid has been proposed[72]. When this method is used, it is possible to obtain the extinction coefficients of halogenophenoxy-radicals[72,146]. (Halogenophenols do not give rise to hydrated electrons on photochemical excitation or effectively quench such electrons[66].) Data for the spectra of the simplest phenoxy-radicals are listed in Table 1.

The differences between the spectra of the radicals at different temperatures and in different solvents are usually small. Small changes in the absorption maxima and shapes of the bands are observed in gas–liquid–solid transitions[42].

In solutions, over the entire range of acidities (up to solutions containing 12 M H_2SO_4), phenoxy-radicals are present as uncharged species[40,43]. Protonation of the radicals usually alters greatly the absorption spectrum and such changes can be readily detected. The protonated phenoxy-radical $PhO\mathring{H}^+$ is a very powerful acid and cannot be observed with appreciable equilibrium concentrations[40,43]. The pK of certain substituted phenoxy-radicals have been obtained by flash photolysis and all the pK values are less than -1.[43]

Quantum-chemical calculations[147] showed that the existence of unsubstituted phenoxy- and semiquinone radical-cations in an aqueous medium is virtually impossible.

2. The Absorption Spectra and Dissociation Constants of Semiquinone Radicals

The absorption spectra of many short-lived *p*-semiquinone radicals have been recorded by methods of flash photolysis[79,80,147–153] and pulse radiolysis[74,154–166] in studies on hydroquinone and quinones. Pulse radiolysis proved to be a convenient method for the investigation of the properties of semiquinone radicals (the studies were performed mainly in aqueous solutions). When this method is used to generate the radicals, there is no need for the formation of an excited state (which may be readily quenched by impurities or oxygen) and it is possible to determine the extinction coefficients. The study of the dependence of the absorption intensity of the radical on the pH of the solution under otherwise constant conditions makes it possible to obtain "titration curves" of the radicals and to determine the pK values, which for the majority of *p*-semiquinone radicals are in the range 3–6 (Table 2).

The spectra of the majority of semiquinone radical-anions have maxima in the range 400–450 nm (Table 2), while the absorption maxima of the neutral radicals are displaced to the ultraviolet and are located in the range 370–425 nm.[163] This is consistent with the general postulate that the basic forms of free radicals absorb at lower energies than the acid forms[163]. In most cases semiquinone radicals and radical-anions have absorption bands in the ultraviolet and far ultraviolet[165,166] but, with one exception[167], these bands have not been investigated in detail.

The electron combined with an excited quinone molecule converts its quinonoid structure into an aromatic structure and the absorption of light involves transitions of the $\pi-\pi^*$ type in semiquinone radicals[125].

The absorption spectrum of the *p*-benzosemiquinone radical-anion has been investigated thoroughly[167]. The radical-anion was obtained by oxidising hydroquinone with manganese dioxide and its absorption and ESR spectra were recorded; the latter made it possible to determine the concentration of the radical-anions. The results are in Table 2. The absorption spectra of a number of semiquinone and flavosemiquinone radicals have also been published[70,105,106,110,164–166,170,171]. The flavosemiquinone radicals investigated differ only by the substituents in the isoalloxazine ring and have very similar absorption spectra.

Table 2. The absorption maxima, extinction coefficients, and dissociation constants of semiquinone radicals in aqueous, aqueous organic, and organic media at 20°C.

The compositions of the aqueous solutions were as follows: *a*) 1 M isopropyl alcohol and 1 M acetone; *b*) 1–2 M t-butyl alcohol; *c*) 5 M isopropyl alcohol and 2 M acetone; *d*) 3 M isopropyl alcohol; *e*) solution in cyclohexane; *f*) not absorption maximum; *g*) solution in dioxan. In the remaining cases the solvent was water.

Certain neutral semiquinone radicals are capable of combining with an H^+ ion and of being converted into an acid form:

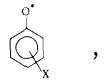
$$QH \overset{H^+}{\rightleftarrows} QH_2^+.$$

Thus, Land and Porter [148] and Land and Swallow [105] showed that the pK values for this type of equilibrium involving the durosemiquinone and flavosemiquinone radicals are respectively −1.1 and 2.3.

VII. KINETICS OF THE DESTRUCTION OF RADICALS

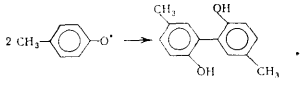
1. Phenoxy-radicals

Dimerisation is one of the most important reactions in the chemistry of phenoxy-radicals. It constitutes the basis of the oxidative coupling of phenols and leads to the formation of C−C, C−O, and O−O bonds [25]. Dimerisation involving the C−C and C−O bonds proceeds exclusively in the *ortho*- and *para*-positions with respect to the phenoxy-oxygen [26]. For example, *p*-cresol oxidised under different conditions by potassium hexacyanoferrate(III) in an alkaline solution gives rise to different final products: the *o*-dimer (2,2′-dihydroxy-5,5′-dimethylbiphenyl), the trimer, pummerer's ketone, and polymers [26]. The formation of more complex products can be account for by further interaction of the dimers with phenoxy-radicals or by the isomerisation of the dimers. The kinetics of the destruction of the *p*-methylphenoxy-radical, obtained in the pulse photolysis of *p*-cresol, have been investigated in detail [50]. It was found that the reaction obeys second-order kinetics, i.e. the radicals disappear by dimerisation. The experimental values of k/ϵ remain constant within the limits of the error over a wide range of concentrations of the initial *p*-cresol [50]. The rate constants and the values of k/ϵ are listed in Table 3, which includes data for phenoxy-radicals of the type



where X are various substituents.

The main product of the dimerisation of the *p*-methylphenoxy-radical in aqueous solution saturated with nitrogen is the *o*-dimer:



The dimerisation of two unsubstituted phenoxy-radicals results in the formation of a much greater number of products (about ten). [26] In the dimerisation of two α-naphthoxy-radicals almost all the possible products of *ortho*- and *para*-coupling are obtained and there are none containing the C−O bond; β-naphthoxy-radicals are destroyed with formation of binaphthols containing mainly the $C_{(1)}-C_{(1)}$ bond and to a much smaller extent the $O-C_{(1)}$ bond [174].

The absolute values of the rate constants for the destruction of phenoxy-radicals naturally depend markedly on the extinction coefficient adopted and are on average smaller than the k_{diff} calculated from the Debye formula [45,51,72,137]. The unduly high values of the constants frequently obtained by the Debye formula [175] can be partly accounted for by the lack of rigour in the assumptions made in its derivation.

A relation has been established [72] between the structure and the rate constant for the recombination of phenoxy-radicals.

In another study [137] the rotating sector method was employed in combination with irradiation of the α-diketone in an ESR cavity in the presence of phenol. This method makes it possible to determine the rate constants for the dimerisation of phenoxy-radicals. In benzene the rate constants vary from 1.7×10^7 litre mole^{-1} s^{-1} for the *p*-methylphenoxy-radical to 4.5×10^9 litre mole^{-1} s^{-1} for the 2-naphthoxy-radical at 30°C (Table 3). As a rule, the rate constants in benzene are an order of magnitude higher than in chlorobenzene, but are smaller than k_{diff}.

Table 3. The rate constants for the destruction of phenoxy-radicals by second-order reactions.

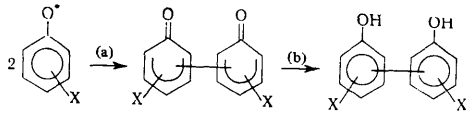
[a] E_a = 3.1 kcal mole^{-1} in toluene [11].

The activation energies for the dimerisation reactions of 14 phenoxy-radicals in benzene and chlorobenzene have been measured [176]. Comparison of these results with those obtained by the thermochemical analysis of the intermediates formed in the dimerisation reactions showed that the radicals investigated can be divided into two classes. Those for which the heat of formation of the initial intermediate (the keto-dimer) exceeds 20 kcal mole^{-1} have absolute dimerisation rate constants and activation energies which agree with the diffusion theory. For certain other radicals, for example, 4-phenyl- and 4-methoxy-phenoxy-radicals, the heat of formation of the intermediate keto-dimer is much less than 20 kcal mole^{-1} and the rate constants and activation energies differ significantly from the values predicted by the theory [176]. The final products of the destruction of PhO·, formed via the isomeric intermediate diketo-compound, are obtained as a result of the dimerisation of PhO· and subsequent enolisation with formation of the final products [137,138].



(3)

In organic solvents (benzene, chlorobenzene) stage *b* may be rate-limiting and the addition of acid sharply accelerates the process. The same mechanism of the recombination of PhO· is applicable also to an aqueous medium.

Despite the fact that the rate of process *b* should be high in an aqueous medium [176], it was found [147] that k_3 increases with decrease of pH from 8 to 1. Thus $k_3 = 1.6 \times 10^8$ litre mole^{-1} s^{-1} at pH 8 and 1.9×10^9 litre mole^{-1} s^{-1} at pH 1 for *o*-methylphenoxy-radicals. A similar conclusion can be reached by considering other experimental data [50,51].

The introduction of alkali metal salts into aqueous solutions of *o*-cresol reduces the dielectric constant of the solution and hence the rate constant for the recombination of the polar species—phenoxy-radicals [177].

The influence of atmospheric oxygen on the kinetics of the destruction of the majority of short-lived phenoxy-radicals is insignificant [72].

Disproportionation is the reaction whereby certain 4-alkyl-2,6-di-t-butylphenoxy-radicals are destroyed [13]. For example, 2,6-di-t-butyl-4-isopropylphenoxy-radicals are destroyed via second-order reactions with formation of the initial phenol and a quinone methide [48]. The deviation from second-order kinetics in the radical anihilation reaction and its occurrence in accordance with first-order kinetics, observed for 2,6-di-t-butyl-4-methylphenoxy-radicals and certain others, has been explained [45,178,179] by the isomerisation of the phenoxy-radical to the hydroxybenzyl radical with migration of the hydrogen atom of the *p*-methyl group to the phenoxy-oxygen atom. However, a more convincing explanation of the change from second-order to first-order kinetics in the radical annihilation reaction involves the formation of the intermediate 2,6-di-t-butyl-4-(2,6-di-t-butyl-4-methylphenoxy)-4-methylcyclohexa-2,6-dienone [183].

The experimental observation that there is no interconversion of the unsubstituted phenoxy- and *p*-hydroxyphenyl radicals [73] is consistent with the high activation energy for this process (more than 100 kcal mole^{-1}), calculated by the MINDO/2 method [146]. The kinetics of the reactions involving the destruction of phenoxy-radicals with comparatively complex structures have also been examined in other studies [13,180-182].

The rate of annihilation of the 2,6-di-t-butyl-4-methylphenoxy-radicals in acetonitrile in the presence of tetrabutylammonium hydroxide (TBAH) is described by a first-order kinetic equation [184]. With increase of TBAH concentration, the rate of consumption of the phenoxy-radical falls. The authors believe that TBAH forms a donor–acceptor complex with the phenoxy-radical, which may reduce the rate of consumption of the latter as a result of its stabilisation.

2. Semiquinone Radicals

The disappearance of semiquinone radicals is described by second-order kinetics. The annihilation of neutral semiquinone radicals proceeds via a disproportionation reaction:

$$QH^{\cdot} + QH^{\cdot} \rightarrow Q + QH_2, \qquad (4)$$

while the destruction of radical-anions probably involves an electron transfer reaction:

$$Q^{\cdot-} + Q^{\cdot-} \xrightarrow{+2H^+} Q + QH_2. \qquad (5)$$

The rate constants for the annihilation of neutral semiquinone radicals at room temperature in non-viscous solvents are usually about 10^9 litre mole^{-1} s^{-1} (Table 4). The diffusion constant calculated from the Debye formula is of the same order of magnitude, but, as for phenoxy-radicals, is in most cases numerically larger.

The rate constants for the destruction of radical-anions are an order of magnitude smaller than those for the destruction of the corresponding neutral radicals (Table 4). The simplest possible explanation of this finding is that, when the interaction of radical-anions is largely determined by diffusion, then the rate constant for the diffusion-controlled reaction of the charged species can be calculated from the Debye formula, which takes into account the Coulombic repulsion (or attraction):

$$k_{diff.} = \frac{8RT}{3000\,\eta} \cdot \frac{\delta}{e^{\delta} - 1},$$

where η is the viscosity of the solvent and δ a quantity which depends on the product of the charges of the reacting species. The quantity $\delta/(e^{\delta} - 1) < 1$ for species having charges of the same sign. For example, this term is 0.1 when the charges on the species are -1 and the distance of closest approach is 2 Å. [188]

Table 4. The rate constants for the destruction of semiquinone radicals via second-order reactions at about 20°C.

[a] The solutions contained 1–3 M isopropyl alcohol. [b] The ionic strength was $I \simeq 0$; a decrease of the rate constant for the radical annihilation reaction has been observed [186] with increase of ionic strength. [c] For the annihilation of the neutral radical, $E_{act} = 3.7 \pm 0.3$ and 3.9 ± 0.4 kcal mole^{-1} in isopropyl alcohol and dioxan respectively [187]. [d] For the annihilation of the neutral radical, $E_{act} = 3.3 \pm 0.3$ and 3.8 ± 0.4 kcal mole^{-1} in isopropyl alcohol and dioxan respectively [87].

The kinetics of the destruction of semiquinone radicals have been studied by pulse radiolysis [115,125-129,132], flash photolysis [79,80,82,83,88,106,111,113,147,149,153] (including detection by ESR), and by ESR in combination with the rotating sector method [87,187]; some of the results are presented in Table 4.

The data in Tables 3 and 4 show that in many cases the rate constants for the annihilation of phenoxy- and semiquinone radicals differ markedly under similar conditions (data of different workers). The causes of such differences remain obscure; possibly the main errors may be attributed to an inaccurate determination of the concentration of the radicals (extinction coefficients).

It has been found[87] that the rate constants for the destruction of a number of neutral semiquinone radicals in dioxan are approximately four times greater than is isopropyl alcohol (Table 4), owing to the difference between the viscosities of these solvents. This may be an indication that the radical-annihilation reaction is diffusion-controlled[87]. Other workers[187] also believe that the rate of destruction of many neutral semiquinone radicals in organic solvents is diffusion-controlled and that rotational diffusion of the radicals in the cage is a factor which influences the rate of reaction.

The annihilation of the anthrasemiquinone radical-anion $AQ^{\cdot-}$ in isopropyl alcohol follows second-order kinetics[87]. The authors proposed the following mechanism for the destruction of $AQ^{\cdot-}$, which is apparently general for semiquinone radical-anions in organic non-alkaline media:

$$AQ^{\cdot-} + H^+ \rightleftarrows AQH^{\cdot}, \quad (6)$$

$$2\,AQH^{\cdot} \rightarrow AQ + AQH_2. \quad (7)$$

Thus the differential equation for the rate of destruction of $AQ^{\cdot-}$ is that for second-order reactions:

$$-\frac{d[AQ^{\cdot-}]}{dt} = \frac{k_7[H^+]}{k_6}[AQ^{\cdot-}]^2$$

and $k_{obs} = k_6[H^+]/k_7$.

Semiquinone radicals differ appreciably in their ability to react with oxygen, which has been the subject of a number of investigations[149,153,157,158,164,189,190]. Thus the radical-anions derived from anthraquinone-2,6-disulphonic acid ($AQ^{\cdot-}$) and the anthraquinone-2-sulphonic acid interact effectively with oxygen:

$$AQ^{\cdot-} + O_2 \rightarrow AQ + O_2^{\cdot-}$$

($k = 5 \times 10^8$ litre mole^{-1} s^{-1}, 95% of water, 5% of isopropyl alcohol–acetone mixture, 20°C [164]), while the radical-anions derived from *p*-benzoquinone ($BQ^{\cdot-}$) do not interact[149,164]. The reverse process—the transfer of an electron from the superoxide ion to the quinone—has been studied for *p*-benzoquinone and a number of other quinones (trimethylbenzoquinone, vitamin K_3, etc.)[157,189,190]:

$$BQ + O_2^{\cdot-} \rightarrow BQ^{\cdot-} + O_2$$

($k = 9.6 \times 10^8$ litre mole^{-1} s^{-1}, aqueous solution containing 1 M t-butyl alcohol, 20°C [157]). Duroquinone (DQ) is involved in the reversible reaction

$$O_2^{\cdot-} + DQ \rightleftarrows O_2 + DQ^{\cdot-} \quad (8)$$

[$K_{C_8} = (2.3 \pm 0.2) \times 10^{-2}$, 95% of water, 5% of isopropyl alcohol–acetone mixture, 20°C].[164] The semiquinone radicals formed in the photochemical reduction of quinones do not react with the solvent radicals (radical-cations)[88]. However, the semiquinone radicals obtained as a result of the photochemical oxidation of inorganic anions by excited quinone molecules or in the photochemical reduction of quinones by excited pigment molecules interact effectively with the radical-anions and radical-cations formed[141,152,153]. For example, the radical-anion derived from anthraquinone-2,6-disulphonic acid ($AQ^{\cdot-}$) is destroyed via the reactions

$$AQ^{\cdot-} + CO_3^{\cdot-} \rightarrow AQ + CO_3^{2-}, \quad (9)$$

$$AQ^{\cdot-} + Chl^{\ddagger} \rightarrow AQ + Chl, \quad (10)$$

where $k_9 = 1.4 \times 10^9$ litre mole^{-1} s^{-1} in aqueous solution and $k_{10} = 2.3 \times 10^9$ litre mole^{-1} s^{-1} in methanol at room temperature, $Chl^{\ddagger}$ being the chlorophyll radical-cation[152].

VIII. INTERACTION WITH METAL COMPOUNDS

The study of the mechanisms of the inhibiting and catalytic effects of metal compounds in liquid-phase oxidation reactions is closely associated with the study of the joint action of these compounds with a series of important inhibitors (phenols, hydroquinone, catechol, and others). The corresponding phenoxy- and semiquinone radicals formed in the system can interact with the metal compounds. In many chemical and biochemical systems, where phenoxy- and semiquinone radicals are formed, transition metal ions and compounds are present and therefore the study of the interaction of these radicals with metal compounds is of considerable interest. Radical reactions of this type have been comparatively little investigated, although they are of fundamental importance both for the chemistry of free radicals and for the elucidation of the mechanisms of many processes in homogeneous catalysis.

It has been shwon[147] that the interaction of phenoxy- and semiquinone radicals with transition metal compounds proceeds via one of the following pathways.

$$R^{\cdot} + M^{n+}Li_m \begin{cases} \rightarrow R^{\pm} + M^{(n\mp1)+}Li_m & \text{electron transfer,} \quad (11) \\ \rightarrow RML_{m-1} + Li & \text{ligand substitution,} \quad (12) \\ \rightarrow R^{\cdot} \ldots M^{n+}Li_m & \text{formation of charge-transfer complex.} \quad (13) \end{cases}$$

If reactions (11)–(13) are not dominant, then reactions (3)–(5) as a rule occur simultaneously in the system.

A change in the absorption spectrum and in the kinetics of the destruction of *o*-methylphenoxy-radicals has been observed[177] in an acid aqueous solution containing CuCl, owing to the formation of a charge-transfer complex. Spectroscopic-kinetic evidence for the existence of complexes of *o*-methylphenoxy-radicals with Cu^{2+}, Mn^{2+}, and Fe^{2+} ions was obtained similarly. The bond in the complexes is fairly weak and their formation in a polar medium is a reversible process, since their dissociation is facilitated by solvation of the ion and radical formed. The stabilisation of phenoxy-radicals due to the formation of their complexes can be observed in media of low polarity[11].

Pulse photoexcitation of *o*-cresol in benzene, toluene, and hexane leads to the formation of the *o*-methylphenoxy-radical ($\lambda max = 405$ nm in all solvents)[11]. The introduction of cobalt acetylacetonate as an additive into the solutions alters the absorption spectra of the intermediates by causing the appearance of a new absorption band in the range 440–450 nm. Such changes in the absorption spectra of the *o*-methylphenoxy-radical are due to the formation of a complex by the fast reaction

$$PhO^{\cdot} + Co(acac)_2 \rightarrow PhO^{\cdot} \ldots Co(acac)_2. \quad (14)$$

The destruction of phenoxy-radicals and their complexes with $Co(acac)_2$ follows second-order kinetics:

$$2PhO^{\cdot} \ldots Co(acac)_2 \rightarrow \text{products.} \quad (15)$$

It was observed that $k_{15} < k_{14}$. The activation energies for the annihilation reactions of the phenoxy-radicals and their complexes in benzene were found to be 3.1 and 6.5 kcal mole^{-1} respectively. The decrease in the rate constant for the destruction of the complexes and the increase in the activation energy compared with the destruction of

the phenoxy-radicals themselves shows that $Co(acac)_2$ behaves kinetically as a spatially bulky substituent in the phenoxy-radical[11]. Changes in the absorption spectrum and in the kinetics of the destruction of the *p*-methylphenoxy-radical, indicating the formation of a new species (complex), were observed in the flash photolysis of *p*-cresol in toluene in the presence of $Fe(acac)_2$.[147]

Aromatic compounds are known to be capable of forming complexes with transition metal ions and coordination compounds. This applies particularly to aromatic free radicals. The difference is that, in the formation of a complex by an unstable (in the thermodynamic sense) radical and the metal compound, the free valence is not as a rule annihilated and complexes of this type are also unstable. The unpaired electron is then delocalised over the electron shell of the metal, which may increase the relative stability of the complex.

The existence of a complex of the stable 2,4,6-tri-t-butylphenoxy-radical and $Co(acac)_2$ has been observed by ESR.[191] An interaction was discovered between the unpaired electron and the cobalt nucleus; in addition to a triplet corresponding to the phenoxy-radical, an octet due to the presence of the complex was found.

It has been concluded[11] that $Co(acac)_2$ must nave the properties of an inhibitor of liquid-phase chain oxidation reactions of hydrocarbons. Indeed, the study of the liquid-phase oxidation of cumene and the presence of $Co(acac)_2$ showed that the latter behaves as a powerful inhibitor. The oxidation of cumene in the presence of *o*-cresol and $Co(acac)_2$ is a complex process in which the intermediate complex of the *o*-methylphenoxy-radical with a chelate plays a definite role and influences the induction period[192].

The absorption spectrum of the *p*-benzoquinone radical-anion ($Q^{\cdot-}$) has been recorded in a water–propanol solvent during the flash photolysis of hydroquinone (QH_2).[193] The disappearance of the $Q^{\cdot-}$ absorption bands and the appearance of bands due to other intermediates formed via the reactions

$$Q^{\cdot-} + Cu^{+} \rightleftarrows X_1^{\cdot} \qquad (16)$$

$$Q^{\cdot-} + Cu^{2+} \rightleftarrows X_2^{+} \qquad (17)$$

was observed in the photolysis of QH_2 in the presence of Cu^{+} and Cu^{2+}. The complexes were shown to have the 1 : 1 compositions. The equilibrium constants for reactions (16) and (17) were calculated with the aid of the relation

$$\frac{1}{[X_{1,2}^{\cdot}]} = \frac{1}{K_i[Q^{\cdot-}]_0 \cdot [Cu^{n+}]} + \frac{1}{[Q^{\cdot-}]_0}.$$

The two reactions are between ions bearing charges of different sign and therefore, other conditions being equal, K_{17} should be larger than K_{16}, which is consistent with the experimental values obtained: $K_{16} = 7.0 \times 10^3$ litre mole^{-1} and $K_{17} = 1.0 \times 10^4$ litre mole^{-1} at 20°C. The importance of the Coulombic interaction in the formation of these complexes is noteworthy. When QH_2 was introduced into an acid solution (at pH 1.0; the radical $QH^{\cdot}$ is then formed), of the salts CuCl and $CuSO_4$, the formation of complexes with $QH^{\cdot}$ was not observed; the absorption spectra of the intermediates were the same as those of $QH^{\cdot}$ and the effect on the kinetics of the annihilation of $QH^{\cdot}$ was insignificant. Calculations by the MINDO/2 method of the charges on the oxygen atoms in the water molecule, the neutral *p*-benzosemiquinone radical, and the corresponding radical-anion showed that the highest charge is that of the oxygen atom in the radical-anion, which displaces a water molecule from the coordination sphere of the copper ion, and the smallest charge is in the neutral benzosemiquinone radical, which did not form any complexes. Thus the complex-formation reaction is apparently a nucleophilic substitution process[147].

The kinetics of the destruction of radical species in the systems investigated were second-order[193]:

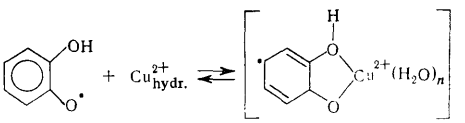
$$X_1^{\cdot} + X_1^{\cdot} \rightarrow \text{products.} \qquad (18)$$

$$X_2^{+} + X_2^{+} \rightarrow \text{products.} \qquad (19)$$

In a water–propanol medium at 20°C, $k_{18} = 1.6 \times 10^7$ and $k_{19} = 3.8 \times 10^6$ litre mole^{-1} s^{-1} at an ionic strength $I = 0$.

The above values of k_{18} and k_{19} show that the interaction of the semiquinone radical with copper ions lead to the formation of more stable radical species. The increased stability of the complexes compared with the initial radical can be caused by the partial delocalisation of the unpaired electron over the electron shell of copper and possibly by the appearance of steric hindrance in the recombination of the complexes. *o*-Benzosemiquinone and flavosemiquinone radicals can give rise to radical complexes, behaving as bidentate ligands. *o*-Benzosemiquinone radical-anions and their derivatives form complexes with many Group I–III metal ions and certain others[194–197]. These complexes, which have been investigated by ESR, consist of contact or solvent-separated ion pairs[197] or inner-sphere complexes[172,194].

The absorption spectrum of the neutral *o*-benzosemiquinone radical, obtained in a water–propanol solution in the flash photolysis of catechol has been recorded[172]. The *o*-benzosemiquinone radical forms an inner-sphere complex with the Cu^{2+} ion, where apparently $n \leq 4$:



The spectroscopic-kinetic characteristics of this complex, the complex formation constants and the rate constant for its formation and decomposition, have also been obtained. It has been established that the complex has the 1 : 1 composition. The rate constant for the destruction of the complex is two orders of magnitude larger than the rate constant for the disproportionation of *o*-benzosemiquinone radicals ($I = 0$). Thus the formation of the complex stabilises the radical as a result of the screening of the reaction centre by the oxygen atom and the delocalisation of the unpaired electron over the electron shell of the Cu^{2+} ion[172].

The study of the interaction of various flavin radical compounds with metal ions is important in the investigation of the nature of the active centres in metal-containing flavoproteins.

The complexes of flavosemiquinone radical-anions and Zn^{2+} and Cd^{2+} ions have been investigated[127,170,198,199] by electronic spectroscopy and ESR. The equilibrium

$$Fl + FlH_2 \rightleftarrows 2FeH^{\cdot}$$

shifts to the right in the presence of these metal ions:

$$Fl + FlH_2 + 2M^{2+} \rightleftarrows 2[FlM]^{+} + 2H^{+}.$$

The spin concentration then increases by a factor of 15, reaching approximately 34% of the total concentration of the flavin. It was shown that certain neutral flavosemiquinone radicals, with electron-donating substituents in the isoalloxazine ring, are capable of forming complexes with these ions[127].

The absorption spectrum of the $Fl^{\cdot-}$ radical-anion was recorded in the photoexcitation of riboflavin in dimethylformamide in the presence of a base[186]. The destruction of $Fl^{\cdot-}$ follows second-order kinetics:

$$Fl^{\cdot-} + Fl^{\cdot-} \rightarrow \text{products.} \quad (20)$$

In the presence of the salts $CdCl_2$ and $ZnSO_4$ the kinetics of the destruction of the intermediate compounds consist of two components (fast and slow). Reactions (20) and (21) correspond to the fast component:

$$Fl^{\cdot-} + M^{2+} \rightarrow \dot{F}l\,M^{+}, \quad (21)$$

and the annihilation of the complexes formed corresponds to the slow component:

$$\dot{F}lM + \dot{F}lM^{+} \rightarrow \text{products.} \quad (22)$$

$k_{22} = 2.5 \times 10^6$ and 1.0×10^6 litre mole^{-1} s^{-1} for the cadmium and zinc complexes respectively[186]. The flavosemiquinone radical-anion behaves as a bidentate ligand capable of forming complexes with metal ions having *d* electrons. On formation of the complex, the unpaired electron is delocalised over the electron shell of the metal, which stabilises the radical. The formation of a complex by the radical and the metal ion leads to a change in the redox potential. In relation to biological oxidation-reduction processes involving organometallic flavoenzymes, this implies that the system can embrace a wide range of potentials, undergoing not only $Fl \rightleftarrows FlH_2$ but also $Fl \rightleftarrows MFl^{\ddagger}$ and $MFl^{\ddagger} \rightleftarrows FlH_2$ transitions[127,186].

The complexes formed by paramagnetic ligands with diamagnetic metal ions are very rare. They are of interest for the investigation of the nature of the metal–ligand bond and also for the formation of spin labels bound to the metal in enzymes. The use of such labels is extremely promising in the study of the properties of enzymes, since it must involve the transfer of spin via the metal to the remaining parts of the ligand environment.

The absorption spectrum of the flavosemiquinone radical $FlH^{\cdot}$ has been recorded in the flash photolysis of riboflavin in water. The introduction of metal salts (including those of cadmium and zinc) into an aqueous flavin solution did not result in the formation of complexes. Some decrease of k_{20}, caused by the increase of the ionic strength, was then observed. Thus the *p*-benzosemiquinone radical can serve as a model for the elucidation of complex-formation processes involving more complicated semiquinone radicals: the $Fl^{\cdot-}$ radical-anion can form complexes with metal ions, in contrast to the neutral radical $FlH^{\cdot}$.[147]

Apart from the complex-formation reactions with transition metal ions, oxidation-reduction reactions have been observed for semiquinone radicals.

The influence of Cu^{+}, Cu^{2+}, Fe^{2+}, Fe^{3+}, Mn^{2+}, Ho^{3+}, Cd^{2+}, Co^{2+}, Mg^{2+}, Hg^{2+}, Zn^{2+}, Ni^{2+}, and K^{+} ions on the kinetics of the annihilation of the radical-anions obtained from 2-methyleneanthraquinone has been studied[149]. In certain cases the metal ions greatly reduced the lifetime of the radicals, although in others they had little or no influence on the kinetics of the destruction of the radical-anion. On average, paramagnetic ions had a greater effect than diamagnetic ions. The sharp decrease of the lifetime of the radical, observed when Cu^{2+} and Fe^{3+} ions are added, is due to the oxidation of the semiquinone by the metal ion:

$$M^{n+} + SQ^{\cdot-} \rightarrow M^{(n-1)+} + SQ.$$

p-Benzoquinone radicals are involved in oxidation-reduction reactions with iron ions. The reactions

$$Q^{\cdot-} + Fe^{2+} \xrightarrow{+2H^{+}} QH_2 + Fe^{3+}, \quad (23)$$

$$QH^{\cdot} + Fe^{2+} \xrightarrow{+H^{+}} QH_2 + Fe^{3+}, \quad (24)$$

$$QH^{\cdot} + Fe^{3+} \xrightarrow{-H^{+}} Q + Fe^{2+} \quad (25)$$

in aqueous propanol have been investigated by flash photolysis[185]. The rate constants $k_{23} = 4.3 \times 10^5$, $k_{24} = 1.5 \times 10^5$, and $k_{25} = 7.0 \times 10^5$ litre mole^{-1} s^{-1} were obtained at 20°C. It is suggested that the oxidation-reduction reactions between transition metal ions and organic radicals proceed via the formation of a complex of the radical with the metal ion, which decomposes with formation of the reduction products of the radical and oxidation of the ion[200]. Possibly reactions (23) and (24) proceed via the same mechanism and the observed rate constants refer to the rate-limiting stage of this two-stage process[185].

IX. SOME QUANTUM-CHEMICAL CALCULATIONS ON PHENOXY- AND SEMIQUINONE RADICALS

Phenoxy- and semiquinone radicals have been the subject of a number of theoretical investigations[20,201–205]. Attention was concentrated on the calculation of the distribution of spin densities. Calculations on phenoxy-radicals by the Hückel molecular orbital method lead to a poor agreement with experiment[201]. In calculations of spin densities, Porter and coworkers[202] took into account the contributions of five excited doublet states, which led to a qualitative agreement with ESR data.

Calculations of spin density in a number of phenoxy-radicals by the molecular orbital method in terms of the Hückel and McLachlan approximations and by the valence bond method led to results in agreement with experiment[203]. The distribution of spin density in benzosemiquinone radical-anions has been calculated[204] by the LCAO-SCF-MO method in terms of the McLachlan approximation with variation of the molecular orbital parameters; the results of the calculation are in good agreement with experiment.

INDO calculations have been made on the simplest phenoxy-radical[20]. The geometry of the phenoxy-radical, the π-electronic charges on its O and C atoms, the hyperfine coupling constants, and certain other parameters were evaluated. It was found that, compared with the isoelectronic benzyl and anilino-radicals, the benzene ring is least distorted in the phenoxy-radical. A similar conclusion may be reached by considering the contributions of various valence bond schemes to the radical structure. An *ab initio* calculation has been made[205] for the unsubstituted phenoxy-radical. The electronic, nuclear, and total energies of the radical, the eigenvalues of a series of operators for various wave functions, and the hyperfine coupling constants were obtained; these data are in qualitative agreement with experimental results. In general *ab initio* calculations on such systems give a less satisfactory agreement with experimental data than calculations by semiempirical methods.

The Electronic Structure and Reactivity of Cyclohexadienone Carbenes

V.V.Ershov and G.A.Nikiforov

The structure, multiplicity of the electronic states, and reactivity of cyclohexadienone carbenes are discussed. The literature on the chemical behaviour of such carbenes has not previously been surveyed. Only monocylic carbenes of the above type are considered.
The bibliography includes 70 references.

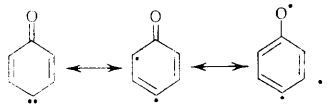
I. INTRODUCTION

Derivatives of bivalent carbon (carbenes) have continually attracted the attention of chemists in various countries. This is because of the possibility of calculating relatively easily by quantum-mechanical methods the structures of the simplest carbenes and of investigating the reactivities of these species as a function of their structure. Furthermore, a wide variety of carbenes are used extensively in preparative organic chemistry. For this reason, a series of monographs and reviews have been devoted to the chemistry of carbenes [1-9]. The chemical behaviour of cyclohexadienone carbenes differs very sharply from that of carbenes of other types. Various aspects of their structure and chemical reactions are important for theoretical organic chemistry, but have not previously been discussed in the literature.

Monocyclic carbenes of this type are used successfully in the synthesis of derivatives of sterically hindered phenols, which are inhibitors of radical processes [10]. Vigorous research is being prosecuted at the Institute of Chemical Physics of the USSR Academy of Sciences under the supervision of Academician N. M. Emanuel' on the applications of typical radical process inhibitors in various fields of experimental medicine, biology, and chemistry [11]. Sterically hindered phenols and their derivatives are employed most widely as inhibitors of the thermo-oxidative degradation of polymeric materials, oils and fuels.

II. ELECTRONIC STRUCTURE OF CYCLOHEXADIENONE CARBENES

The cyclohexadienone carbenes are a special type of cyclic carbenes whose conjugated system exhibits a very marked tendency towards the formation of an aromatic structure. Following the abstraction of the nitrogen molecule from the initial diazo-oxide†, the non-bonding electrons in the resulting cyclohexadienone carbene may be initially distributed between the σ and p_z orbitals. As in the case of cyclopentadienylidene, the electron in the p_z orbital can interact with the π-electron system of the diene. In cyclopentadienylidene this interaction leads only to the stabilisation of the triplet form without any rearrangement of the overall electronic structure of the molecule. On the other hand, in cyclohexadienone carbenes an aromatic structure is formed with an energy gain owing to conjugation (approximately 1.5 eV). The redistribution of electrons results in the formation of the carbene, which can be characterised by the following set of structures:



The distribution of non-bonding electrons is such that the σ-electron system of cyclohexadienone carbenes is to a large extent similar to that of the phenyl radical and their π-electron system is similar to that of phenoxy-radicals.

The general characteristics of the electronic structure of cyclohexadienone carbenes lead to the conclusion that their lifetime in the ground state (at any rate at low temperatures in an inert matrix) should be much longer than that of the simplest methylenes. This is confirmed by ESR data [12,13]. The ESR spectrum of unsubstituted cyclohexadienone carbene, obtained in the photolysis of benzene 1,4-diazo-oxide using filtered light in a *p*-dichlorobenzene matrix at the temperature of liquid nitrogen, consists of several signals. The most intense signal is located at zero field, while the remaining signals, with decreasing intensities, are in the region of 4550, 4770, and 6670 G. The observed signals have a very remarkable fine structure—they all exhibit distinct multiplet splitting. The observed splittings correspond to the spin–spin interaction of the unpaired p_z electron with the *ortho*- and *meta*-protons in the ring. Following the substitution of both *ortho*-positions of the carbenes by t-butyl groups or chlorine atoms, the signals become triplets.

At low temperature in an inert matrix, the signals of triplet carbene are observed virtually unchanged for a long time (1–1.5 h) in the absence of additional irradiation. This shows that the cyclohexadienone carbenes have a triplet ground state.

The reactivity of cyclic carbenes is determined by nucleophilic or electrophilic properties. Since the number of π electrons in the ring determines the net spin of the ground state of cyclic carbenes [14], appreciable differences are to be expected in their behaviour depending on the number of these electrons. In carbenes with the $(4n + 2)$

†The possibility of the generation of cyclohexadienone carbenes by the photolysis and thermolysis of arene diazo-oxides has been considered [11-13].

π-electron system the σ^2 configuration is stabilised and they have a singlet ground state with a vacant p_z orbital at the carbene centre. The vacant p_z orbital is incorporated in the overall π-electron system of the carbene molecule, which leads to the appearance of an enhanced electron density at the central carbon atom. Such carbenes are nucleophilic in the ground state. On the other hand, in carbenes with the $(4n)$ π-electron system the σ_p configuration is stabilised and they have a triplet ground state; such carbenes exhibit electrophilic properties.

In cyclohexadienone carbenes the incorporation of the p_z orbital of the central carbon atom in the overall π-electron system of the polyene part of the molecule leads to a shift of the p_z electron and the formation of an aromatic ring system. As a result, the electron density at the central carbon atom should fall. Their chemical behaviour resembles that of carbenes with the $(4n)$ π-electron ring system, i.e. they should be electrophilic. This conclusion is confirmed by ESR data [12,15-17]. The Table lists the splitting parameters of the energy levels of triplet methylenes at zero field. The D parameter characterises the spin–spin interaction of the unpaired electrons and is determined by the average value of the quantity $(1/r^3)$, [18,19] where r is the distance between the spins. This parameter may serve as a measure of the delocalisation of the p_z electron over the system of conjugated bonds and may characterise the electrophilic properties of the carbene centre. The Table shows that D is a minimum for cyclohexadienone carbene.

The splitting parameters of the energy levels of triplet methylenes at zero field.

Carbene	D, cm^{-1}	E, cm^{-1}	Valence angle, deg	References
$:CH_2$	0.6881	0.00346	136	15

	0.3284	0.00860	—	12

Since, according to its physical interpretation, the parameter D defines the probability of localising the unbound p_z electron at the bivalent carbon atom of the carbene, it follows (assuming identical distributions of π electrons in carbenes and the corresponding radicals) that the values of D for carbenes and the spin densities ρ_i for the radicals (at the same carbon atom) should be approximately the same [12,16]. Accordingly, as stated above, the π-electron system of cyclohexadienone carbenes is close to that of the corresponding phenoxy-radicals.

The parameter E characterises qualitatively the deviation of the spin–spin interaction from cylindrical symmetry and is therefore a criterion of the curvature of the methylene structure [20,21]. The E/D ratio corresponds to the contribution of the s orbital to the non-bonding sp^2 orbital of the bivalent carbon atom. For $E = 0$ $(E/D = 0)$, the contribution of the s orbital is zero, i.e. the non-bonding hybridised sp^2 orbital, located in the plane of the methylene molecule, is transformed into a pure p orbital and the methylene structure becomes linear (valence angle $\varphi = 180°$). Judging from the values of E quoted, in cyclohexadienone carbenes this angle should approach 180°. However, there is no reason to suppose that the valence angle differs appreciably from 120°. Presumably the σ bonds in the ring at the carbene centre are bent (a type of "banana bond"). In this structure for cyclohexadienone carbenes, ring strain is eliminated on the one hand and on the other there appears the possibility of a redistribution of the non-bonding σ electron among the neighbouring carbon atoms, which stabilises the carbene system as a whole.

III. THE MULTIPLICITY OF THE ELECTRONIC STATES OF REACTING CYCLOHEXADIENONE CARBENES

It was shown above that cyclohexadienone carbenes have a triplet ground state. However, the multiplicity of the ground state of the carbene frequently does not coincide with the multiplicity of its state when undergoing reaction. For synthetic use, it is essential to know the multiplicity of the electronic state of the carbene at the instant of its interaction with the substrate.

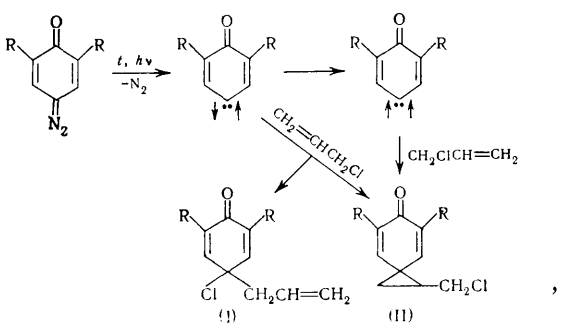
Chemical methods are nowadays widely used to determine the spin state of reacting carbenes. Thus the stereospecificity of the addition reactions of carbenes is due to the differences between the mechanisms of the interaction of the singlet and triplet forms of the carbene with the multiple bonds of *cis*- and *trans*-olefins (Skell's principle [22]). According to the majority of investigators, singlet carbenes add synchronously to the multiple bond without affecting the configuration of the initial olefin, while the triplet form reacts with formation of a trimethylene biradical, which leads to the formation of a mixture of the *cis*- and *trans*-adducts owing to the possibility of rotation about the C–C bond in the biradical (breakdown of stereospecificity). Studies on the interaction of cyclohexadienone carbenes with the multiple bonds in *cis*- and *trans*-olefins indicate a high stereospecificity of the addition (to an extent greater than 98%) in both thermal [24] and photolytic [23] formation of cyclohexadienone carbenes. This shows that the singlet form of the cyclohexadienone carbene is involved in the reaction.

Since cyclohexadienone carbenes have a triplet ground state, it follows, by analogy with gas-phase reactions, that, following the addition of an inert polyfluorinated solvent to the reacting substrate, the stereospecificity of the addition presumably breaks down in consequence of the $S \rightarrow T$ transition of the carbene when it collides with the molecules of the diluent. However, this effect (in a highly attenuated form only) was observed in the photolysis of arene diazo-oxides by filtered light at 0°C [23] and was completely absent in the thermolysis of arene diazo-oxides at 93–96°C. [24] The explanation is that at elevated temperatures the temperature conditions in the reaction, and not the effect of dilution by the polyfluorinated solvent, play a more significant role in the competition between two processes: the addition of singlet carbene to the multiple bond and the $S \rightarrow T$ transition.

The stereochemical method for the determining of the multiplicity of the electronic states of carbenes is in many cases ineffective, since, depending on the relative rates

of the intermediate stages, identical substances may be formed from both singlet and triplet carbenes [8]. For this reason, studies are now being made to discover rigorously specific reactions, which would proceed only with the triplet or singlet forms of carbenes. Research on competing reactions involving the addition of carbenes to multiple bonds and lone electron pairs of heteroatoms is extremely promising in this connection. Singlet carbenes can add both to a double bond and to lone electron pairs of a heteroatom. On the other hand, for triplet carbenes, as for other radical species, the mode of attack depends on the bond energies in the substance. Thus, in the reaction of triplet carbenes with olefins containing a halogen in the hydrocarbon chain, the double bond is most susceptible to radical attack. Consequently, the multiplicity of the electronic states of the reacting carbenes and the possibility of the $S \rightarrow T$ transition can be inferred from the change in the ratio of the yield of products resulting from the insertion of the carbene in carbon–halogen bonds to the yield of products formed as a result of the addition of the carbene to multiple bonds. This ratio decreases with increase of the fraction of the triplet form of the carbene and increases with increase of the fraction of the singlet form [25,26].

In order to investigate the multiplicity of the states of cyclohexadienone carbenes, a somewhat modified method of competition kinetics was employed [24]. The authors used allyl chloride as the substrate and, in order to increase the probability of the $S \rightarrow T$ transition, the temperature was reduced and allyl chloride was diluted with an inert solvent (hexafluorobenzene). The use of allyl chloride in the thermolysis and photolysis of 2,6-di-t-butylbenzene 1,4-diazo-oxide enabled the authors to obtain reaction mixtures consisting of a few final products suitable for spectroscopic analysis:

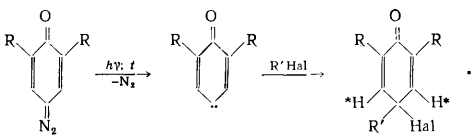


where R = $C(CH_3)_3$.

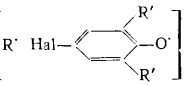
Analysis of ultraviolet spectroscopic and ^1H NMR data showed that the yields of the cyclohexadienone (I) and the spirodienone (II) and their ratio remain constant up to temperatures close to the glass point of allyl chloride. This shows that in the above temperature range the rate of reaction of the singlet carbene with allyl chloride greatly exceeds the rate of its singlet–triplet transition. With the formation of the allyl chloride matrix, the yield of I falls and that of II rises, which indicates an increasing role of the $S \rightarrow T$ transition. Evidently, on formation of the allyl chloride glass, the process becomes heterogeneous and takes place at the interface between the solid phases. The rate of reaction of the singlet carbene is now determined by its diffusion to the walls of the "cage" and may be close to the rate of the $S \rightarrow T$ transition. A further decrease of temperature tends to increase the difference between the rates of the chemical and physical processes. In contrast to the method involving a decrease of temperature, the use of the dilution technique leads to a very slight increase in the fraction of the triplet carbene. This agrees with data obtained in a study of the stereospecificity of the addition of cyclohexadienone carbenes to olefins.

In concluding this section, the possibility of employing the method of chemically induced dynamic nuclear polarisation (CIDNP) in the investigation of the multiplicity of the states of reacting carbenes must be considered. The polarisation of nuclei in the reactions of carbenes was observed for the first time by Closs and Closs [27]. Using the reactions of diphenylcarbene, they clearly formulated for the first time the idea of the selection of radicals in terms of their nuclear-spin states in the singlet–triplet transitions in radical pairs, which became the basis of the theory of the CIDNP method [28]. The method was used to investigate the thermolysis and photolysis of arene diazo-oxides [29-31].

The principal products of the thermolysis and photolysis of arene diazo-oxides in carbon tetrachloride and hexachloroacetone are the corresponding cyclohexadienone derivatives:



Their formation may be both a consequence of the rearrangement of the ylids arising in the interaction of the singlet carbene with the lone electron pairs of the halogen atom and of a radical process of the "abstraction-recombination" type. In the latter case both the singlet and triplet forms of the carbene may be responsible for the development of the reaction. Analysis of the ^1H NMR spectra of the reaction mixtures revealed a negative polarisation of the ring protons. This shows that the thermolysis and photolysis of arene diazo-oxides proceed via a radical mechanism with formation of the radical pair



as an intermediate, for which $g_{PhO\cdot} < g_{R\cdot}$ and $a_{meta} < 0$. According to the theory of CIDNP, the negative polarisation of the *meta*-protons in the recombination product of the radical pair arises when the pair was in a triplet state or when the pair was formed from the combination of independent radicals (a pair with non-correlated spins).

It was shown above that, under the usual conditions in the reaction with olefins, the carbenes are in the singlet state. Presumably cyclohexadienone carbenes also react in the singlet form with halogeno-derivatives. A singlet radical pair must then be formed initially. The radicals of this pair can recombine with the formation of cyclohexadienones or they can pass into the bulk phase, thereby producing pairs with non-correlated spins. In the former case positive polarisation of the *meta*-protons should be observed and in the latter negative polarisation. An overall polarisation has probably been observed [29-31], with the polarisation generated in the pairs with non-correlated spins predominating. This has been confirmed by experiments where radical acceptors (alkyl iodides) were added to the reaction medium [29,30]. The authors showed that, with increase of the concentration of alkyl iodides in the initial reaction mixture, the negative polarisation diminishes; at fairly high concentrations of alkyl iodides the sign of the polarisation is reversed. Evidently, following the

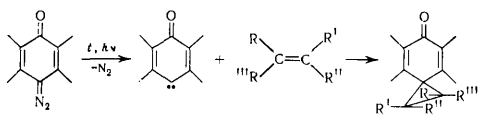
addition of alkyl iodides to the main solvent, the steady-state concentration of the radicals released into the bulk phase (particularly the $\cdot CCl_3$ and $\cdot CCl_2COCCl_3$ radicals) decreases and the contribution to the polarisation of the recombination of secondary radical pairs with non-correlated spins falls. The absorption by the *meta*-protons of cyclohexadienone compounds observed in the ^1H NMR spectra at high concentrations of alkyl iodides in the initial mixture arises because they are formed only from the primary singlet radical pairs. The polarisation of the ^{13}C nuclei[29,30] also confirms the primary formation of singlet radical pairs in the reactions of similar carbenes with hexachloroacetone.

Thus ESR and NMR data, the results of studies on the multiplicity of the states of cyclohexadienone carbenes by the method of competitive kinetics, and the high stereospecificity of their addition to the multiple bonds of olefins show that the carbenes have a triplet ground state and that under the usual conditions their reacting form is in the singlet state.

IV. REACTIONS OF CYCLOHEXADIENONE CARBENES

Addition to Multiple Bonds

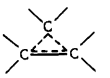
The interaction of cyclohexadienone carbenes with olefins has been most widely investigated[23,24,32-35]. The reaction with the multiple bonds of olefins of the cyclohexadienone carbenes produced by the thermolysis or photolysis of benzene 1,4-diazo-oxides results in the formation of the corresponding spirodienones containing the cyclopropane ring:



The maximum yields of the spiro-derivatives are obtained when olefins with a more nucleophilic double bond are used[32]. The introduction of functional groups into the olefin appreciably reduces the yield of the spirodienone, which is evidently associated with the ease of polymerisation of such olefins and with the difficulty of isolating the final products.

As mentioned above, cyclohexadienone carbenes add to stereoisomeric olefins with a high degree of stereospecificity[23,24,33]. Polarisation could not be observed in a CIDNP study of the thermolysis of 2,6-di-t-butylbenzene 1,4-diazo-oxide in hept-1-ene and cyclohexene [24], which confirms the conclusion that singlet carbene is involved in the reaction.

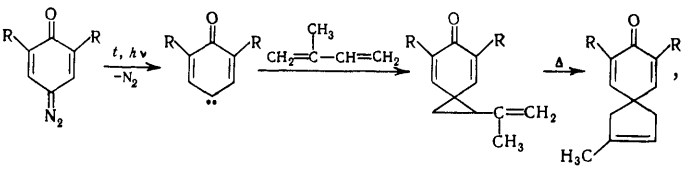
The single-stage addition characteristic of singlet carbenes is in reality more complex. The operation of dispersion forces, i.e. the interaction of the dipole moment of the carbene with the induced dipole of the olefin, leads to asymmetric addition. The non-synchronous formation of the two cyclopropane bonds is a characteristic feature of this process. Calculation shows[36] that, in the interaction of singlet methylene with ethylene, symmetrical addition is forbidden and the reaction pathway is asymmetric—it begins via an approximately π-electron mechanism and ends via an approximately σ-electron mechanism. The formation of a transition state with some sharing of the charge between the bivalent carbon of the carbene and the π bond of the olefin is then postulated:



The existence of a transition state having such a structure has been confirmed by kinetic data for dichloro- and difluoro-methylenes[37,38].

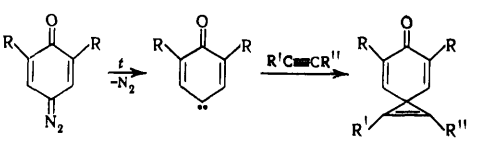
An alternative mechanism for the formation of spirodienones may involve the intermediate formation of unstable spiropyrazolones when the initial arene diazo-oxide adds to the double bond of olefins. Such adducts have been isolated in the thermolysis of 10-diazoanthrone in olefins[34]. However, this pathway is probably secondary and hardly occurs in the thermolysis and photolysis of benzene 1,4-diazo-oxides.

In the interaction of cyclohexadienone carbenes with the conjugated system of dienes, 1,2-addition to the most open double bonds might have been expected by analogy with other carbenes. However, cyclohexadiene carbenes behave in an unusual manner in this reaction—the final result is always the 1,4-addition product regardless of the presence and positions of substituents in the diene[39]. The formation of these products can be represented, on the one hand, as a result of direct 1,4-addition of the carbene to the conjugated bonds of the diene and, on the other hand, as a result of the isomerisation during the course of the reaction of the initially formed 1,2-addition product. A kinetic and spectroscopic study of the photolysis of 2,6-di-t-butylbenzene 1,4-diazo-oxide showed that in isoprene at low temperatures the second pathway is followed[39]. The authors succeeded in detecting spectroscopically and then in isolating the intermediate 1,2-addition product. Comparison of the kinetics of the isomerisation of this product and of the thermolysis of the 1,4-diazo-oxide in isoprene confirmed the proposed mechanism of the formation of the 1,4-addition product:



where $R = C(CH_3)_3$.

In contrast to double bonds, triple bonds do not exhibit a marked capacity for combination with electrophilic carbenes[40,41]. The yield of the corresponding cyclopropene derivatives in such reactions is as a rule low[40]. The reaction of cyclohexadienone carbenes with acetylenes leads to the formation of spiro[2,5]octa-1,3,6-triene-5-ones—cyclopropene derivatives of a new type in which the cyclopropene and cyclohexadienone rings are linked in a spiro-configuration[42-45]:

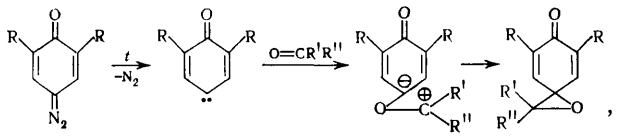


where $R = C(CH_3)_3$.

The yield of these derivatives does not exceed 40% and side products resulting from the insertion of the carbene in the C–H bond of the substituent are always present in the reaction medium.

The reactions involving the addition of carbenes to carbon–heteroatom multiple bond are less familiar because diazo-compounds can add directly to the C=X multiple bonds without the intermediate formation of carbenes. Furthermore, by no means every carbene is capable of attacking such a bond (for example, triplet carbenes). In a carbon–heteroatom multiple bond the heteroatom is usually more electronegative, i.e. behaves as the nucleophilic centre of the substrate. Consequently, depending on the electrophilic or nucleophilic nature of the bivalent carbon atom, singlet carbenes can initially attack either the heteroatom or the carbon atom in the C=X bond and identical compounds are formed in both cases.

When cyclohexadienone carbenes interact with aliphatic ketones, oxaspirodienones are formed as a result of the intramolecular stabilisation of the 1,3-dipolar ion[46,47]:



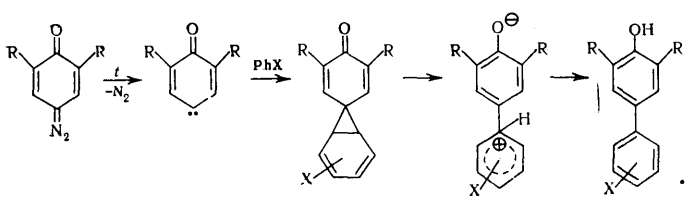
where R = $C(CH_3)_3$.

It is remarkable that oxaspirans are formed only when aliphatic ketones are used. The thermolysis of 2,6-di-t-butylbenzene 1,4-diazo-oxide in acetophenone and benzaldehyde gives rise to products resulting from insertion in the C–H bonds of the aromatic ring[47].

Interaction with Aromatic Compounds

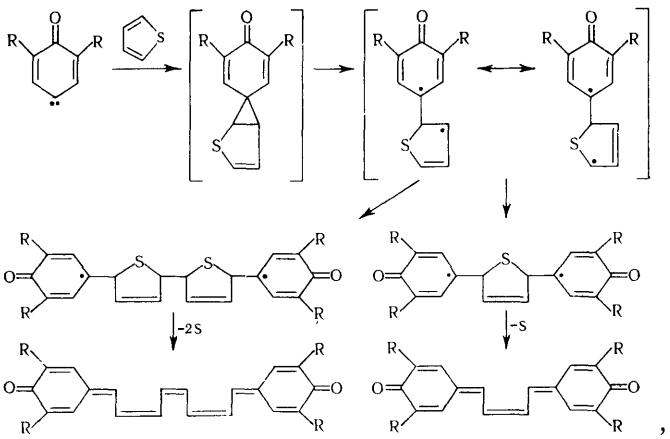
Such a reaction is characteristic of carbenes which are fairly electrophilic. It is generally accepted that it begins with attack by the carbene on the π-electron system of the aromatic compound. The further course of the reaction is determined by the stability of the intermediate norcaradiene structure. Depending on the nature of the attacking carbene, either a reversible norcaradiene–cycloheptatriene transformation is observed (the equilibrium is usually displaced towards the formation of the cycloheptatriene) or the norcaradiene structure is aromatised with formation of the formal product of insertion in the C–H bond of the aromatic ring. The latter process is more characteristic of cyclic carbenes with a π-electron system[48,49].

When cyclohexadienone carbenes interact with benzene derivatives, the main products are 4-arylphenols[50–59]. It is interesting that, when benzene derivatives are used, a mixture of isomeric 4-arylphenols is produced[55–57]. A number of investigators[51,55–58] observed the so called alcohol effect, which consists in an increased yield of 4-arylphenols when small amounts of alcohols are added to the aromatic substrate. The observed effects are explained satisfactorily by the reaction mechanism proposed by Dewar and Narayamaswami[57]:



The formation of the thermally unstable norcaradiene, which rearranges to the formal product of insertion in the C–H bond, constitutes an intermediate stage. The increase of the yield of 4-arylphenols following the addition of an alcohol is evidently associated with the increase of the lifetime of the singlet carbene owing to its stabilisation on formation of complexes with alcohol molecules. It is noteworthy that all attempts to detect the formation of the intermediate norcaradiene were unsuccessful[59]. However, the available experimental data show that the proposed reaction mechanism is the most likely.

This has been confirmed by studies on the interaction of cyclohexadienone carbenes with pyridine[51], thiophen[60,61], furan[62], and *N*-methylpyrrole[63]. In all cases the products are formed as a result of the addition of the singlet carbene to the multiple bonds of the substrate. The studies of the reactions with thiophens are the most interesting in this respect[60,61]:

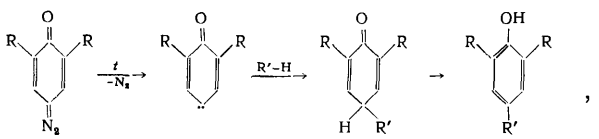


where R = $C(CH_3)_3$.

The reaction is accompanied by the formation of products not containing sulphur. Their composition can be satisfactorily accounted for by the above mechanism involving the formation of a spirodienone—the product of the addition of the carbene to a multiple bond of the thiophen.

Interaction with Hydrocarbons and Halogenohydrocarbons

The thermal decomposition of 2,6-di-t-butylbenzene 1,4-diazo-oxide in saturated cyclic hydrocarbons leads to 4-cycloalkylphenols. Their formation can be represented as a result of direct insertion of the cyclohexadiene carbene in the C–H bond of the hydrocarbon, resulting in the initial formation of an unstable quinolid compound, which readily isomerises to the phenol[54,64]:



where R = $C(CH_3)_3$. The absence of chemical polarisation in the phenol shows that the main process proceeds via a non-radical mechanism.

When alicyclic hydrocarbons are used in the reaction, a mixture of phenols is formed[64]. The low selectivity of the insertion reaction ($2^0 : 1^0 = 3.3$) is consistent with the hypothesis of the direct insertion of the singlet form of

the carbene in a C–H bond of the hydrocarbon. One should note that the reaction mixture contains stable compounds of the quinolid type, the formation of which can be accounted for by the partial transition of the carbene to the triplet state.

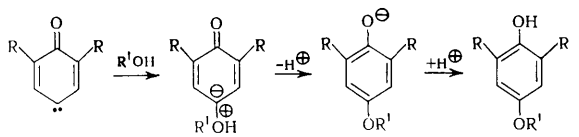
The reaction of cyclohexadienone carbenes with halogenohydrocarbons has provided wide possibilities for the synthesis of cyclohexadienone compounds, in which one of the geminal substituents is a halogen[29-31,65-67]. The interest in this reaction is due to the unusual mechanism of the insertion of carbenes in the carbon–halogen bond. In a series of studies, the reactions of cyclohexadienone carbenes with halogenohydrocarbons have been accounted for by an ylid mechanism[54,65]. The isolation of the intermediate ylid in the photolysis of 2,6-di-t-butylbenzene 1,4-diazo-oxide in 4-bromo-2,6-diazopropylphenol is quoted in support of this. The formation of side products is attributed to the $S \rightarrow T$ transition of the carbenes. However, as shown above, the $S \rightarrow T$ transition of cyclohexadienone carbenes is observed only in exceptional cases.

CIDNP data[29-31] showed that the process proceeds via a radical mechanism. The composition of the final products of the reaction of cyclohexadienone carbenes with halogenohydrocarbons is determined by their structure and the nature of the halogen. Thus, when carbon tetrachloride is used as the solvent, the main reaction product is a quinochloride. The replacement of one chlorine atom in CCl_4 by bromine or hydrogen leads to a complex composition of the reaction products[66]; nevertheless their formation is satisfactorily accounted by a radical mechanism.

Insertion in the O–H and C–O Bonds

Cyclohexadienone carbenes are electrophilic species and should therefore add to the lone electron pairs of heteroatoms with formation of intermediate ylid structures. From this standpoint, the mechanism of their insertion in the O–H and C–O bonds should be unique.

The study of the thermolysis and photolysis of benzene 1,4-diazo-oxide in aqueous[68], alcoholic[50,69], and acid media[69] showed that the main reaction products are the corresponding hydroquinones and the ethers and esters derived from them:



The main reaction is as a rule accompanied by radical side processes involving the dehydrogenation of the substrate and the formation of products derived from the phenoxy-radicals.

The composition of the products of the reaction of cyclohexadienone carbenes with the C–O bond of ethers depends on the structure of the initial arene diazo-oxide. Thus thermolysis of the unsubstituted arene diazo-oxide and of its dimethyl derivatives in tetrahydrofuran yields a mixture of high-molecular-weight products in which the arene diazo-oxide and ether fragments alternate[52,53]. On the other hand, in the thermolysis of 2,6-di-t-butylbenzene 1,4-diazo-oxide the main products are quinol spiro-ethers[70].

The characteristics of the electronic structure, the multiplicity of energy states, and the reactivity of cyclohexadienone carbenes discussed here show that carbenes of this type differ significantly from other bivalent carbon derivatives. Cyclohexadienone carbenes constitute an extremely convenient model for the investigation of the mechanisms of reactions involving the intermediate formation of methylene. The simplicity of the identification of the final products of their reaction with the substrate is of interest in connection with the development of methods for the determination of the multiplicity of the energy states of reacting carbenes. Finally, many of the reactions can be used successfully for the preparative synthesis of substituted phenols and their quinolid and spiran derivatives.

The Structure and Reactivity of 3-Hydroxypyridine Derivatives in Electrophilic Substitution

K.M.Dyumaev and L.D.Smirnov

The structure and reactivity of 3-hydroxypyridine and its derivatives in electrophilic substitution are considered and the problems concerning the mechanism and direction of electrophilic substitution in 3-hydroxypyridines are discussed as a function of the type of reaction, its conditions, and the nature of the substituent in the 3-hydroxypyridine ring. The reactivities of 3-hydroxypyridines are compared with the results of theoretical calculations by the Hückel molecular orbital and the Pariser - Parr - Pople method. Data for the biological activities of various 3-hydroxypyridine derivatives are presented.
The bibliography includes 117 references.

I. INTRODUCTION

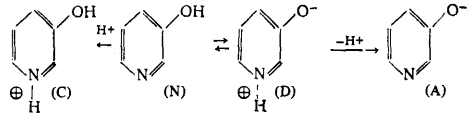
The number of studies dealing with the search for physiologically active compounds based on biogenic antioxidants has greatly increased in recent years. Academician N. M. Emanuel''s concept of the possibility of suppressing by non-toxing inhibitors undesirable free-radical reactions occurring in the organism in pathological states, in particular during malignant growth, radiation sickness, stress phenomena, and ageing, has served as a basis for the medico-biological application of these compounds[1-3]. Emanuel' suggested that phenol and polyphenol derivatives are suitable as inhibitors for this purpose. Numerous studies on the biological activity of these compounds showed that they exhibit pronounced antitumour properties and confer protection from radiation[4-6]. This stimulated further development of synthetic studies in this field. The structural difference between a number of the most effective phenolic antioxidants and the fragments of biochemical systems involved in cell metabolism, as a result of which the former are hydrophobic and possess a number of other undesirable properties, constituted an obstacle to their application in biology. In the attempts to overcome these obstacles, several ways were proposed for the synthesis of new phenolic compounds transformed as a result of the mono- and di-*ortho*-screening of the hydroxy-group. Substituted *p*-hydroxyphenylanilines, their decarboxylation products (tyramines and epinines) related to the alkaloid mescaline, *p*-hydroxybenzylamines structurally related to the precursor of the alkaloid capsaicin, and a number of arylaminobutyric acids and pyrrolidinones have been synthesised[7-10]. However, the amino-group, which ensures hydrophilic properties is as a rule also responsible for an increase in toxicity.

In order to find effective biogenic inhibitors, we undertook a study of heterocyclic hydroxy-derivatives. We chose for investigation 3-hydroxypyridine derivatives, the inhibiting properties of which might be due to the presence of the phenolic hydroxyl next to the conjugated cyclic bond system, and their structural similarity to compounds of the vitamin B_6 group (pyridoxine, pyridoxamine, and pyridoxal) ensured that the preparations synthesised were biogenic. Furthermore, the presence of the ring nitrogen atom together with the hydroxy-group made it possible to obtain water-soluble compounds as a result of salt formation. The synthesis of a large number of non-toxic and water-soluble inhibitors with biological activity was based on electrophilic reactions of 3-hydroxypyridine and its derivatives.

Attention is therefore concentrated in the present review on the characteristics of the structure and reactivity in electrophilic substitution of 3-hydroxypyridine and its derivatives.

II. ELECTRONIC STRUCTURE OF 3-HYDROXYPYRIDINE AND ITS DERIVATIVES

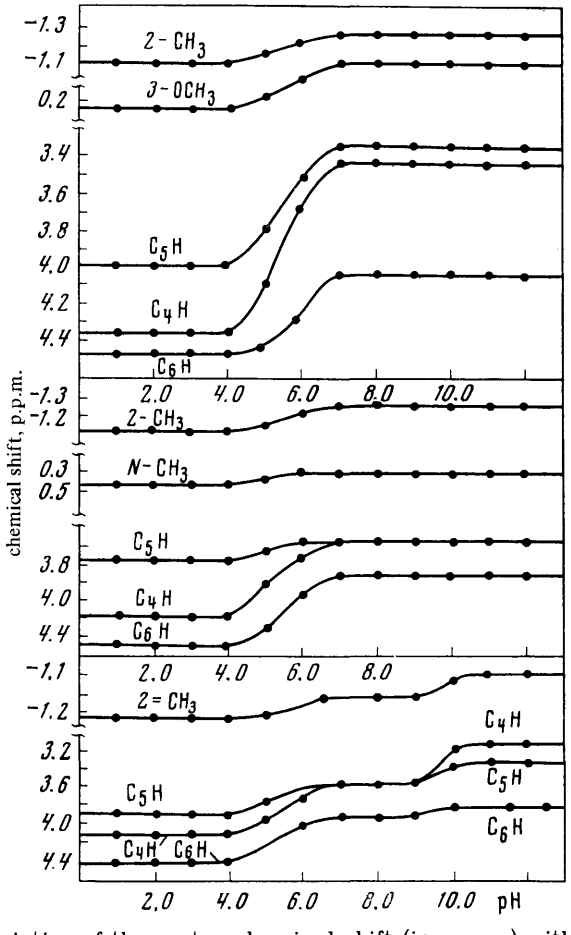
One of the characteristics of the 3-hydroxypyridine molecule, in contrast to aromatic phenols, is its ability to exist in four forms as a function of the pH of the medium: neutral (N), dipolar (D), cationic (C), and anionic (A), which is clearly reflected in the physicochemical properties and chemical behaviour of 3-hydroxypyridines in electrophilic substitution:



The presence of the dipolar form in a neutral medium was established by ultraviolet spectroscopy[11,12], potentiometric titration[13-15] as well as infrared spectroscopy and ^1H NMR.[16-18] It has been shown that in D_2O solution there is 54% of form (D) and 46% of form (N), while in pure dioxan form (D) is virtually absent[11].

The introduction of an alkyl, benzyl, or phenyl group into the 3-hydroxypyridine molecule does not decrease the possibility of the formation of all four forms. On the

contrary, the formation of the *N*-oxide of 3-hydroxypyridine has a significant influence on the acid–base equilibrium. The absence of form (D) of 3-hydroxypyridine *N*-oxide and a number of its derivatives in a neutral aqueous solution has been demonstrated by ultraviolet spectroscopy[19-20]. The limits of the existence of forms (A), (D), (N), and (C) of 3-hydroxypyridine and its derivatives were studied by ^{1}H NMR [18,21-22]—by investigating the dependence of the chemical shifts of the 3-hydroxypyridine ring protons on the pH of the medium†. The presence of three horizontal sections corresponding to the acid, neutral, and alkaline media (see Figure) has been noted and it has been shown that the ring nitrogen is fully protonated at pH < 4 and the ionisation of the OH group terminates at pH > 10.



Variation of the proton chemical shift (in p.p.m.) with the pH of the medium for different 3-hydroxypyridine derivatives: *a*) 3-hydroxy-2-methylpyridine; *b*) 3-hydroxy-2-methylpyridinium methiodide; *c*) 3-methoxy-2-methylpyridine.

† The results obtained for 3-hydroxy-2-methylpyridine are quoted as an example. The findings obtained for a large number of related compounds are similar.

The curves for aminomethyl derivatives of 3-hydroxypyridine in an acid medium have two horizontal sections due to the possibility of the protonation of two centres: the ring nitrogen and the nitrogen in the side chain.

The electronic structure of 3-hydroxypyridine has been the subject of a detailed study using quantum-chemical calculations and ^{1}H NMR data. Calculations of the electronic structure parameters of 3-hydroxypyridine [the energy of π-electron delocalisation E_π^d, the energies of the highest occupied and lowest vacant molecular orbitals (HOMO and LVMO), and the energy differences ΔE between them, the electronic charges, and bond lengths] were performed using the simple and extended molecular orbital methods[23-25] as well as the Pariser–Parr–Pople method[26]. The calculated values of E_π and E_π^d of forms (N), (A), (D), and (C) differ comparatively little from one another (Table 1). As was to be expected, the values of E_π^d for the forms containing exocyclic anionic oxygen are somewhat higher than for the hydroxy-forms.

Table 1. The energy characteristics of the electronic structure of 3-hydroxypyridine.

Form	E_π	E^d	E_{HOMO}	E_{LVMO}	ΔE
Neutral	11.975	1.917	0.564	0.894	1.458
Dipolar	10.960	2.199	0.459	0.785	1.244
Anionic	10.438	2.169	0.487	0.894	1.381
Cationic	12.482	1.988	0.630	0.786	1.416

The interaction of exocyclic oxygen with the pyridine ring is indicated by the C–O bond order, which is 0.295–0.394, and the π-electronic charge (+0.082–+0.146). The conjugation of the oxygen in the anionic form is much more marked than that of the hydroxyl oxygen: the PyC–O$^-$ bond order is 25% greater than the PC–OH bond order and the π-electronic charge on the anionic oxygen is almost twice as high as on the phenolic oxygen. The conclusion that the exocyclic oxygen interacts with the aromatic ring agrees with X-ray diffraction data, according to which the C–O bond length in phenol derivatives (1.37 Å) is smaller by approximately 0.1 Å than in saturated compounds (1.47 Å).[27] The calculated bond orders in the pyridine ring are high and similar, which may be attributed to the high degree of aromaticity of the ring and equalisation of its bonds. The interatomic distances in the four forms of 3-hydroxypyridine agree well with the available experimental lengths of the C⋯C bonds in benzene (1.397 Å), the C–N bonds in pyridine (1.34 Å), and the C–O bonds in phenols (1.37 Å) as well as the bond lengths in the ring of nicotinic acid as a model compound[28]: r_{CN} = 1.34 Å and r_{CC} = 1.39 Å.

The π-electron density distribution in the 3-hydroxypyridine ring is non-uniform largely because of the presence of the ring nitrogen atom and the exocyclic oxygen atom. In consequence of the high electronegativity of the nitrogen atom (3.0) compared with that of carbon (2.5), a considerable negative π-electronic charge (–0.192) is concentrated on the nitrogen atom of the phenolic and anionic forms. As was to be expected, protonation of the nitrogen atom leads to a marked increase of the negative π-electronic charge on the nitrogen atom (–0.394) and its corresponding decrease on the carbon atoms.

Quantum-chemical calculations by the Pariser–Parr–Pople method were also used for a quantitative interpretation of the electronic absorption spectra of 3-hydroxypyridine[29,30]. All the observed absorption bands were assigned to $\pi-\pi^*$ transitions. A satisfactory correlation has been observed between the calculated and experimental absorption bands for both neutral and anionic forms.

The influence of the substituent on the electronic structure of the 3-hydroxypyridine ring was studied by ^{1}H NMR and quantum-chemical calculations of the electronic structure of alkyl and aminomethyl derivatives of 3-hydroxypyridine[23]. The distribution of electron density in the 3-hydroxypyridine ring was found to have the following characteristics.

1. In an inert medium the electron density at the carbon atoms increases in the sequence $C_{(6)} < C_{(2)} < C_{(4)} < C_{(5)}$.
2. In an aqueous medium the sequence remains the same.
3. In an alkaline medium the electron density increases in the sequence $C_{(5)} < C_{(6)} < C_{(2)} < C_{(4)}$, while in an acid medium the sequence becomes $C_{(4)} < C_{(6)} < C_{(2)} < C_{(5)}$.
4. On passing from inert and aqueous media to an acid medium, the electron density at the carbon atoms diminishes, the decrease becoming more pronounced in the sequence $C_{(5)} < C_{(2)} \leq C_{(6)} < C_{(4)}$.
5. On passing from an inert to an alkaline medium, the electron density increases. The most marked increase is observed for $C_{(6)}$ and then for $C_{(2)}$, $C_{(4)}$, and $C_{(5)}$.

Comparison of the experimental data for an inert medium with the charges calculated by the LCAO-MO method showed that the best agreement is achieved with the results of calculations for molecules in an uncharged form, where the charge increases in the sequence $C_{(6)} \leq C_{(2)} < C_{(4)} < C_{(5)}$. The calculation for the dipolar form led to another sequence: $C_{(4)} < C_{(6)} < C_{(5)} < C_{(2)}$, which agrees well with the sequence of the chemical shifts calculated for the dipolar form in an aqueous medium. This shows that in solutions in inert solvents (dimethyl sulphoxide and dioxan) the 3-hydroxypyridine molecules exist mainly in the uncharged form. However, in concentrated solutions, association complexes of the type

may make a major contribution in view of the existence of powerful intermolecular hydrogen bonds.

Direct comparison of the chemical shifts and the calculated charges for the entire series of test compounds revealed a very approximate agreement. The reason for the observed discrepancy is, apart from the approximate nature of the Hückel method, the influence on screening by factors such as dipole moments and the anisotropy of the diamagnetic susceptibility of the C–N, C–O, C–CH_3, and other bonds. However, in calculations on the electronic structure of 3-hydroxypyridine by the extended Hückel method[25] a satisfactory agreement was obtained between the chemical shifts and the calculated charges in the above series of compounds. Since the mode of electrophilic substitution reactions of heterocyclic compounds is determined by the state of the electron cloud in the molecule, as for aromatic compounds, the application of the molecular orbital theory made it possible to predict the substitution sites in the pyridine series and its derivatives. The reactivity indices for 3-hydroxypyridine were calculated both for the isolated molecule (π-electron densities, boundary electron densities, free valence index) and the reacting molecule (localisation energy) approximations[24]. Analysis of the calculated reactivity indices of 3-hydroxypyridine in the four forms (A), (D), (N), and (C) showed that the best agreement with experiment is observed for the localisation energies L_e. According to the values of L_e, electrophilic attack on the 3-hydroxypyridine molecule in acid and alkaline media should occur in the sequence $C_{(2)} > C_{(6)} > C_{(4)}$. Comparison of the values of L_e for forms (A) and (C) indicates a greater reactivity of the former.

III. ELECTROPHILIC REACTIONS OF 3-HYDROXYPYRIDINE DERIVATIVES

1. Acid- and Base-catalysed Deuterium Exchange

The electrophilic deuteration reaction of nitrogen-containing heterocycles has been widely used to elucidate the mechanism of electrophilic substitution in these compounds and also to obtain a quantitative estimate of the influence of the ring nitrogen and of a wide variety of functional substituents on the reactivity of the heteroaromatic ring[31–37].

Acid-catalysed deuterium exchange involving 3-hydroxypyridine and its alkyl derivatives made it possible to determine the sequence and rates of substitution of various positions in the 3-hydroxypyridine ring[38]. It was found that the 2-position is the most reactive while the 4-position is the least reactive. The introduction of the *N*-oxide group greatly increases the reactivity of the 2-position. For example, it has been shown[33] that 3-hydroxypyridine *N*-oxide is deuterated in the 2-position in the uncharged form, whereas both 3-hydroxy- and 3-methoxy-pyridines are not involved in the exchange under analogous conditions. On the other hand, 3,5-dimethoxypyridine *N*-oxide enters into the exchange reaction and both the 2- and 6-positions in the neutral or protonated form are involved, depending on the acidity of the medium. The ratio of the rates of deuterium exchange involving the uncharged and protonated forms is 1000, which constitutes an excellent demonstration of the powerful deactivation of the pyridine ring on protonation of the ring nitrogen.

On passing from acid-catalysed to base-catalysed deuterium exchange involving 3-hydroxypyridine, there is an appreciable increase of the rate of exchange of the protons of the 3-hydroxypyridine ring, probably owing to the involvement of the latter in this type of substitution in the most reactive anionic form[39,40]. In contrast to acid-catalysed deuterium exchange, where the exchange of the 3-hydroxypyridine ring protons was not observed, in the base-catalysed process the $H_{(2)}$, $H_{(6)}$, and $H_{(4)}$ protons may be exchanged, depending on the conditions (Table 2). The introduction of the CH_3 group in the 2-position and particularly in the 6-position increases the reactivity of the 3-hydroxypyridine ring[39].

Comparison of the rate constants for the exchange of the ring protons of 3-hydroxypyridine and its *N*-oxide (Table 2) shows that the introduction of the *N*-oxide group also accelerates proton exchange in the sequence $H_{(2)} > H_{(6)} > H_{(4)}$. A similar behaviour was likewise observed when deuterium-exchange data were compared for 3-hydroxy-2-methylpyridine and its *N*-oxide[40]. Comparison of the results for base-catalysed deuterium exchange involving 3-hydroxypyridine and its derivatives established that the rate of exchange of the $H_{(2)}$ proton is higher by an order of magnitude than the rate of exchange of the $H_{(6)}$ proton and higher by approximately two orders of magnitude than the rate of exchange of the $H_{(4)}$ proton.

2. Nitration

The hydroxy-group facilitates substitution in the pyridine ring. In contrast to pyridine, the nitration of hydroxypyridine proceeds smoothly and in high yields. Nitration of 3-hydroxypyridine proceeds exclusively in the 2-position. 3-Hydroxypyridine reacts in the protonated form[41]. The first study of the nitration of 3-hydroxypyridine was carried out by Plazek and Rodgwald[42], who obtained 3-hydroxy-2-nitropyridine and demonstrated its structure by a series of chemical transformations. In a later investigation the 6-nitro-isomer was obtained in a negligible yield (1%) together with the 2-isomer (74%):[43]

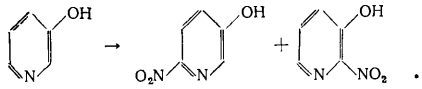


Table 2. The rate constants for the base-catalysed deuterium exchange involving 3-hydroxypyridine, its 2-methyl, 2-phenyl, 2-benzyl, and 5-benzyl derivatives, and their *N*-oxides at 160°C in 0.5*N* NaOD solution[40].

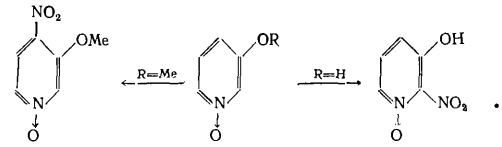
Compound	k_2, min^{-1}	k_6, min^{-1}	k_4, min^{-1}
	$1.1\cdot10^{-2}$	$1.2\cdot10^{-3}$	$5.1\cdot10^{-4}$
	$2.3\cdot10^{-2}$	$2.5\cdot10^{-3}$	$9.0\cdot10^{-4}$
	—	$3.7\cdot10^{-3}$	—
	—	$6.0\cdot10^{-3}$	$1.6\cdot10^{-3}$
	—	—	$7.8\cdot10^{-4}$
	—	$1.6\cdot10^{-3}$	$1.5\cdot10^{-3}$
	—	$4.6\cdot10^{-3}$	$1.0\cdot10^{-3}$
	$7.1\cdot10^{-3}$	$1.5\cdot10^{-3}$	$6.0\cdot10^{-4}$

Such selective substitution in the 2-position of the 3-hydroxypyridine ring is probably caused by the significant influence of the six-membered chelate complex of the hydroxy-group and the nitronium ion, formed in the transition state, on the site of substitution[44].

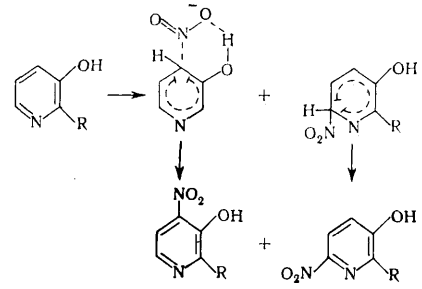
3-Hydroxypyridine *N*-oxide is nitrated similarly in the 2-position, which indicates a more powerful directing effect of the 3-hydroxy group than the *para*-directing effect of the *N*-oxide group[45]:



On the other hand 3-alkoxypyridine *N*-oxides are nitrated exclusively in the 4-position[46,47], which shows that the *para*-directing influence of the *N*-oxide group predominates.

In contrast to the base *N*-oxide, 3-methoxy-[48,49] and 3-ethoxypyridines[50] give rise to the 2-nitro- and 2,6-dinitro derivatives depending on the experimental conditions. 3,5-Diethoxypyridine *N*-oxide is also nitrated in the 2- and 6-positions instead of the expected 4-position[51,52].

Very interesting results were obtained in the nitration of 2-alkyl- and 2-chloro-3-hydroxypyridines[49,53]. It was found that in this case the 4-position as well as the 6-position is nitrated, the formation of the 4-isomer predominating[44]:



The authors suggested that the preferential nitration in the *ortho*-position relative to the hydroxyl in these compounds is due to the formation of a six-membered chelate complex in the transition state. This hypothesis is confirmed by the finding that, when the nitration is carried out at a higher temperature, which weakens the intramolecular hydrogen bond, the 6-position is preferentially substituted. On the other hand, nitration of 3-methoxy-2-methylpyridine, which cannot form a hydrogen bond with the attacking nitronium ion, proceeds exclusively in the 6-position.

The occurrence of 6-substitution only in the nitration of 3-hydroxy-2-nitropyridine can also be a consequence of the impossibility of the formation of a chelate when the nitronium ion attacks the 4-position because of the strong intramolecular hydrogen bond between the nitro- and hydroxy-groups already present in the compound. The influence of chelate formation on the direction of substitution has been confirmed also in the nitration of the *N*-oxides of 3-hydroxy-2-methyl- and 3-methoxy-2-methyl-pyridines[54,55]. The nitration of 3-hydroxy-2-methylpyridine *N*-oxide is directed exclusively to the 4-position, while 3-methoxy-2-methylpyridine is nitrated in the 6-position.

It is interesting to note that the nitration of 3-methoxy-6-methylpyridine[56] proceeds in the 2-position, in contrast to 3-methoxypyridine, while 3-hydroxy-2-methoxypyridine is nitrated exclusively in the 4-position. As expected, the nitration of 3-hydroxy-6-methyl- and 3-hydroxy-4-methyl-pyridines is directed to the 2-positions[57].

The presence of the nitro-group in the 3-hydroxypyridine ring does not preclude its further nitration. Thus nitration of 3-hydroxy-6-methyl-2-nitro- and 3-hydroxy-2-methyl-6-nitro-pyridines yielded the corresponding dinitro-derivatives[57]. Nitration of 3-hydroxy-2-nitropyridine results in the formation of 3-hydroxy-2,4,6-trinitropyridine together with the 2,6-dinitro-derivative[58]. When the 2- and 6-positions of the 3-hydroxypyridine ring were occupied by alkyl groups, the 4-position was substituted smoothly[57,59]. Thus the results presented indicate the possibility of the successive selective nitration of the 2-, 6-, and 4-positions of the 3-hydroxypyridine ring.

To elucidate the mechanism of the electrophilic substitution of the 3-hydroxypyridine ring, the kinetics of the nitration of 3-hydroxypyridine were studied[41]. Comparison of the variation of the rate of nitration with pH for 3-hydroxy- and 3-methoxy-pyridines with the results found previously for the 2,4,6-collidinium cation revealed their considerable similarity, which suggested the involvement of the 3-hydroxypyridine ring in nitration in the protonated form. The partial rate factors in the nitration of the 3-methoxypyridinium cation are 4×10^{-10} for the 2-position and 1×10^{-11} for the 6-position.

3. Halogenation

The halogenation of 3-hydroxypyridine has been studied in detail in many investigations. It has been shown that substitution proceeds primarily in the 2-position. Bromination with an equivalent amount of bromine in pyridine[60], iodination with iodine in sodium carbonate solution[61,62], and chlorination with hydrochloric acid in the presence of hydrogen peroxide[61] all lead to the formation of 2-halogeno-derivatives. The 4- and 6-halogeno-derivatives of 3-hydroxypyridine has been obtained only by an indirect procedure[60].

The iodination of 3-hydroxypyridine with an excess of iodine proceeds with formation of 2,6-diiodo- and 2,4,6-triiodo-derivatives[61]. Under these conditions, 3-hydroxy-5-methylpyridine gives rise to the 2,6-diiodo-derivative[63]. Similarly the bromination of 3-hydroxypyridine with twice the molar amount of bromine in pyridine yields the 2,6-dibromo-derivative and the reaction with an excess of bromine water results in the formation of 2,4,6-tribromo-3-hydroxypyridine[60]. The bromination of 5-bromo-3-hydroxypyridine with an excess of bromine water yielded 2,4,5,6-tetrabromo-3-hydroxypyridine[60].

The bromination of 3-hydroxypyridine *N*-oxide, like that of the non-oxidised base, leads to the 2-bromo-derivative, which can be brominated further to give the 2,6-dibromo- and 2,4,6-tribromo-3-hydroxypyridine *N*-oxides[64]. In contrast to this, the iodination of 3-hydroxypyridine *N*-oxide in a weakly alkaline solution leads to the formation of 3-hydroxy-4,6-diiodopyridine *N*-oxide as the only product[65]. The bromination of 3,5-diethoxypyridine in an acid medium results in the formation of 2,6-dibromo-3,5-diethoxypyridine, while in pyridine solution the main product isolated was 2-bromo-3,5-diethoxypyridine[66]. 2,3,4-Trihydroxypyridine gives rise to a monohalogeno-derivative of unknown structure[67].

The introduction of the electronegative nitro-group does not affect the halogenation process; the bromination of 3,5-diethoxy-2-nitropyridine yields 6-bromo-3,5-diethoxy-2-nitropyridine[66]. The iodination of 3-hydroxypicolinic acid with iodine in an alkaline medium proceeds with simultaneous decarboxylation and the formation of 3-hydroxy-2,6-diiodopyridine[68].

4. Sulphonation

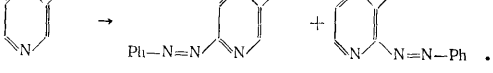
The sulphonation of 3-hydroxypyridine requires the use of extremely severe conditions and proceeds with formation (in a low yield) of 3-hydroxypyridine-2-sulphonic acid[69,70]. Similarly 3-hydroxypyridine *N*-oxide is sulphonated in the 2-position[71]. Comparison of the conditions for the sulphonation of pyridine and 3-hydroxypyridine indicates a lower reactivity of the latter in this reaction.

It has been suggested[71] that the sulphonation of pyridine and its derivatives proceeds via the initial formation of a complex of sulphur trioxide with the heterocycle, which rearranges to the corresponding sulphonic acid at a high temperature in the presence of catalysts. The rate-determining state of the reaction is the rearrangement of the complex, the ease of which is determined by the stability of the heterocycle–sulphur trioxide complex formed. The higher stability of the complex of 3-hydroxypyridine with sulphur trioxide compared with that formed by pyridine itself is probably the cause of its lower reactivity in sulphonation.

5. Azo-Coupling

The azo-coupling of 3-hydroxypyridine proceeds preferentially in the *para*-position relative to the hydroxy-group. Thus the main product formed in the interaction with benzenediazonium chloride is 3-hydroxy-6-(phenylazo)-pyridine (81%) together with a small amount (3%) of the 2-isomer[72].

On the other hand, the reaction of 3-hydroxypyridine with *p*-nitrobenzenediazonium chloride in a weakly acid solution led initially to the isolation of only the 2-azo-derivative[62]. Later studies demonstrated the formation of equal amounts of 2-azo- and 6-azo-derivatives[73]. On the other hand, when the above reaction was carried out under weakly alkaline conditions, the preferential formation of the *para*-isomer was observed; the yield of the *ortho*-isomer was 13% under these conditions:



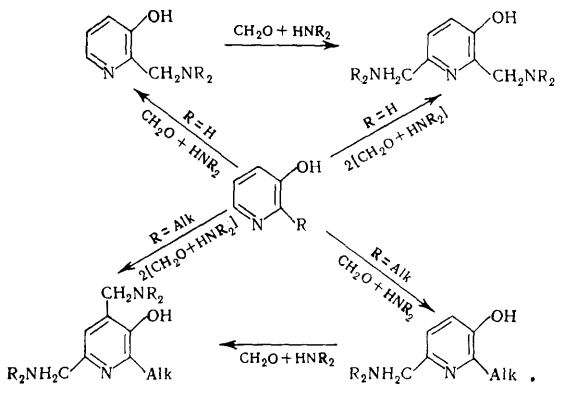
The azo-coupling of 3-hydroxypyridine *N*-oxide in a weakly alkaline solution, like that of 3-hydroxypyridine itself, involves the 6-position[74]. The azocoupling of 3-hydroxy-4-methyl-5-phenylpyridine with benzenediazonium chloride gives rise to a mixture of equal amounts of the *o*-azo- and *p*-azo-derivatives[73]. The azo-coupling of 3-hydroxy-2-methyl- and 3-hydroxy-6-methylpyridines and their *N*-oxides proceeds with formation of only the 6-azo- and 2-azo-derivatives respectively[75]. The absence of 4-substitution proved to be general in the azo-coupling of both the 2- and 6-methyl derivatives and of the 2,6-dimethyl derivatives of 3-hydroxypyridine with benzene-diazonium chloride[75]. However, the introduction of the *N*-oxide group permitted a smooth azo-coupling in the 4-position of 3-hydroxy-2,6-dimethylpyridine *N*-oxide[74].

The azo-coupling of 2,3-dihydroxypyridine, 3-hydroxy-2-methoxypyridine, and 3-hydroxy-1-methyl-2-pyridone involves the 6-position[76]. This shows that the main directing group in all the compounds is the 3-hydroxy-group. The decisive directing influence of the 3-hydroxy-group was established also in the azo-coupling of 2,5-dihydroxypyridine, which involves the 6-position[76].

6. Aminomethylation

3-Hydroxypyridine in the anionic form enters into a number of reactions with weak electrophilic agents, which are characteristic of phenolic compounds. Among these one must include the aminomethylation, hydroxymethylation, and carboxylation reactions. The aminomethylation of 3-hydroxypyridine and its derivatives has been studied both with the aim of synthesising pyridoxine (vitamin B_6),[77] its analogues[78], and antagonists[79] and with the aim of studying the comparative reactivities of the 2-, 4-, and 6-positions in the 3-hydroxypyridine ring.

The pronounced electron-accepting influence of the ring nitrogen, which greatly reduces the electron density in the aromatic ring, particularly in the 2-, 4-, and 6-positions, leads to a reduced reactivity of 3-hydroxypyridine in the Mannich condensation compared with phenols. Thus, in contrast to phenol, which readily gives rise to a trisubstituted Mannich base, 3-hydroxypyridine is aminomethylated only in the 2- and 6-positions[80]. Furthermore, the combination in a single molecule of the hydroxy-group adjoining the conjugated ring system with the ring nitrogen atom alters the sequence of substitution from *ortho-ortho-para*, as in phenols, to *ortho-para-ortho* in 3-hydroxypyridine:



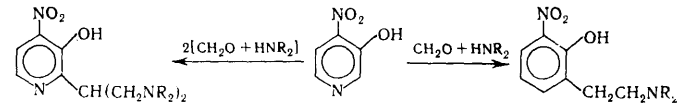
The success of the aminomethylation depends markedly on the pH of the medium[81]. Whereas phenols are readily aminomethylated in both acid and weakly alkaline media, the maximum yield of Mannich bases formed from 3-hydroxypyridines is achieved in weakly alkaline media. The different reactivities of the 2-, 6-, and 4-positions of the 3-hydroxypyridine ring in the Mannich condensation make it possible to synthesise the individual compounds. Both 2-dialkylaminomethyl- and 2,6-bis(dialkylaminomethyl)-3-hydroxypyridine can be readily obtained from 3-hydroxypyridine[80]. The mode of reaction can be controlled by an appropriate choice of reactant ratio. However, in all stages there is an initial attack on the 2-position and then on the 6-position. Under analogous conditions, 2-alkyl-3-hydroxy-[82] and 3-hydroxy-6-methylpyridines[80] are aminomethylated with formation of the corresponding 6- and 2-dialkylaminomethyl derivatives.

4-Aminomethylation is possible only for 3-hydroxypyridines containing an alkyl or alkoxy-group in the 2-position and in many instances requires the use of more severe conditions. 2,6-Dialkyl-4-dialkylaminomethyl-3-hydroxypyridine[83], 2-alkyl-3-hydroxypyridine[82,84], and 4,6-bis(dialkylaminomethyl)-3-hydroxy-2-methoxypyridine[85] were synthesised in this way. The attempt to obtain 4-substituted compounds by the aminomethylation of 6-alkyl-2-dialkylaminomethyl- and 2,6-bis(dialkylaminomethyl)-3-hydroxypyridines was unsuccessful. This led to the conclusion that the presence in the *ortho*-position with respect to the hydroxyl of a substituent forming a strong intramolecular bond with the OH group sharply reduces the reactivity of the 4-position in the Mannich condensation. It has been noted that the reduction of the acid properties of the OH group also affects the success of substitution at the $C_{(4)}$ atom[84].

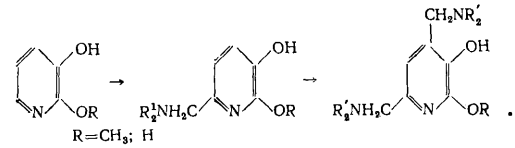
Furthermore, the course of aminomethylation is significantly influenced also by the structure of the secondary amine. Thus aminomethylation of 2,6-dialkyl-3-hydroxypyridines was unsuccessful when secondary amines such as diethylamine, diisopropylamine, and diallylamine were used, probably owing to the steric hindrance to the substitution of the 4-position[82].

The aminomethylation of 3-hydroxypyridine *N*-oxide and its 6-methoxy-2-methyl- and 2,6-dimethyl derivatives is characterised by the same sequence of the substitution of various positions of the 3-hydroxypyridine ring[86]. Comparison of the conditions for the aminomethylation of the oxidised and non-oxidised bases indicates a somewhat greater reactivity of 3-hydroxypyridine *N*-oxides[86].

Interesting results were obtained in a study of the aminomethylation of nitroderivatives of 3-hydroxypyridine. The presence of the nitro-group in the 2-position of the 3-hydroxypyridine ring does not prevent the 6-aminomethylation of 3-hydroxy-2-nitropyridine[87]. However, the aminomethylation of the 4-nitro- and 2-nitro-derivatives of 3-hydroxy-6-methylpyridine is not directed to the ring but to the side chain[88]. 2-(β-dialkylaminoethyl)-3-hydroxy-4-nitropyridines, the further aminomethylation of which leads to the formation of Mannich bis-bases via the methyl group, were synthesised in this way:



Similarly the aminomethylation of 3-hydroxy-6-methyl-2-nitropyridine yielded 6-(β-dialkylaminoethyl)-3-hydroxy-2-nitropyridines[88]. The aminomethylation of 2,3-dihydroxypyridine[89] and 3-hydroxy-2-methoxypyridine[85] leads to the initial formation of the Mannich 6-monobases and subsequently of the 4,6-bisbases, which indicates a definite role of the 3-hydroxy group in directing the substituent[85]:

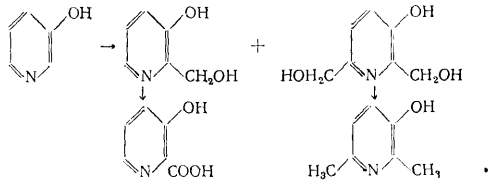


Comparison of the conditions for the aminomethylation of 2-alkyl-3-hydroxypyridines with those for 2-alkoxy- and 2-alkoxy-3-hydroxy-pyridines shows that the replacement of the alkyl group by alkoxy- and hydroxy-groups increases somewhat the reactivity of the 3-hydroxypyridine ring[85]. The aminomethylation of 3-hydroxy-1-methyl-2-pyridone proceeds, like that of 2,3-dihydroxypyridine, under mild conditions in a quantitative yield and involves the 6-position[90]. However, the attempts at 4,6-disubstitution of 3-hydroxy-1-methyl-2-pyridone were unsuccessful, which is caused, as for 3-hydroxy-2-nitropyridine and 2-dialkylaminomethyl-3-hydroxypyridine, by the presence of a strong intramolecular hydrogen bond between the 3-hydroxy-group and the *ortho*-substituent.

As in 2,3-dihydroxypyridine, the main directing group for electrophilic substitution in 2,5-dihydroxypyridine is the 3-hydroxy-group, which directs aminomethylation to the 6-position[90].

7. Hydroxymethylation

The ease of controlling the hydroxymethylation of 3-hydroxypyridine, in contrast to the rapid polymerisation of phenols under similar conditions, provide a clear example of the deactivating influence of the ring nitrogen on the chemical reactivity of the aromatic ring. 3-Hydroxypyridine can be effectively hydroxymethylated by treatment with an alkaline solution of formaldehyde[91]. This yields a mixture of mono- and di-substituted products[91,92], the formation of which cannot be avoided even when equivalent ratios of the reactants are employed[93]. The substitution of the 2-position was demonstrated by oxidising the product to 3-hydroxypicolinic acid[91] and that of the 6-position by converting the di(hydroxymethyl) compound into 3-hydroxy-2,6-dimethylpyridine[92]:



The hydroxymethylation of 3-hydroxy-2-methyl- and 3-hydroxy-6-methyl-pyridines[82,94] proceeds equally successfully with formation of the corresponding 6- and 2-isomers. 4-Substitution was not observed in either case (and also for 3-hydroxy-2,6-dimethylpyridine). The corresponding 4-hydroxymethyl derivatives of 3-hydroxy-2-methyl- and 3-hydroxy-2,6-dimethyl-pyridines were obtained indirectly from the 4-aminomethyl derivatives[82,95]. The hydroxymethylation of the 3-hydroxypyridine ring can be achieved successfully also in the presence of the electron-accepting carboxy-group in the 2-position. 5-Hydroxypicolinic acid forms the 2-hydroxymethyl derivative[96].

8. Carboxylation

Like phenol, 3-hydroxypyridine in the anionic form undergoes the Kolbe reaction with carbon dioxide under pressure. However, in contrast to phenol, the carboxylation of 3-hydroxypyridine is directed mainly to the *para*-position and not the *ortho*-position with respect to the hydroxy-group. Thus, when 3-hydroxypyridine was heated with potassium carbonate in proportions of 1 : 1.5, a quantitative yield of 5-hydroxypicolinic acid was obtained[97]. In the carboxylation of the sodium or potassium salt of 3-hydroxypyridine the formation of low yields of 3- and 5-hydroxypicolinic acids was noted, the sodium salt being substituted preferentially in the *ortho*-position and the potassium salt in the *para*-position relative to the hydroxy-group[98]. 3-Hydroxy-2-methyl-pyridine is carboxylated in the 6-position[99], while 3-hydroxy-5-methylpyridine forms an acid of unknown structure[100].

9. Other Reactions of 3-Hydroxypyridine

Other electrophilic reactions of 3-hydroxypyridine include mercuration with mercury acetate in the 2-position[101]. Vigorous attempts have been made to involve 3-hydroxypyridine in the Friedel–Krafts acylation and alkylation reactions but without success. This is probably because of the great sensitivity of these reactions to the deactivating influence of the nitrogen in the pyridine ring owing to complex formation and the corresponding change in the aromaticity of the ring. 3-Hydroxypyridine is not involved in the nitrosation reaction, which is also sensitive to the deactivating effect of electron-accepting substituents[72].

However, 2,5-dihydroxypyridine is readily nitrosated with formation of the 6-nitroso-derivative. The same position was also nitrosated in 2,5-dihydroxy-4-methyl-3-phenylpyridine[73].

IV. BIOLOGICAL PROPERTIES

3-Hydroxypyridine has been the subject of vigorous research with the aim of synthesising on its basis various biologically active compounds. Experimental studies have shown that 3-hydroxypyridine derivatives exhibit a wide spectrum of biological and pharmacological activity[102].

For example, the ethers of base-substituted 3-hydroxypyridines exhibit physostigmine-like, anticurare, and anticholinesterase activities[103]. The synthesis of a large number of 3-hydroxypyridine derivatives with bactericidal and anti-inflammatory activities has been reported[104,105]. 3-Hydroxypyridine derivatives can be used as depressants of the central nervous system[104]. Acylated 2-amino-3-hydroxypyridines have been suggested as anti-inflammatory compounds and for the treatment of cardiovascular diseases[106]. 2- and 6-Formyl-3-hydroxypyridine thiosemicarboazones exhibit a marked antileukaemic activity in both experimental and clinical tests[107]. Phosphate esters of 3-hydroxy-6-methylpyridine exhibit an insecticidal activity[108], while 3-hydroxy-2-nitropyridinium salts exhibit herbicidal activity[109]. Esters of 3-hydroxypyridines and of their nitro-derivatives have been used successfully in the synthesis of peptides and polypeptides having regular structures[110,111].

Relatively non-toxic and water-soluble radical process inhibitors with a wide spectrum of biological activity can be obtained from 3-hydroxypyridine[95]. The possibility of using inhibitors derived from 3-hydroxypyridine as agents conferring protection against radiation, discovered by Emanuel' and coworkers is of greatest interest[112,113]. 2,6-Dialkyl- and 2,4,6-trialkyl-3-hydroxypyridines exhibit the most effective anti-radiation activity. A study of the antiradiation properties of 3-hydroxypyridine derivatives and of inhibitors of other classes established a relation between the anti-radical activity of the inhibitor and its antiradiation activity[114,115]. 3-Hydroxypyridine derivatives can protect DNA molecules from radiation-induced depolymerisation[4] and also exhibit antileukaemic activity[116]. Apart from their use as prophylactic agents, alkyl-substituted 3-hydroxypyridines possess therapeutic activity against the effects of radiation and promote a more rapid recovery of the blood-forming system[116]. It has been noted that 2,6-dialkyl- and 2,4,6-trialkyl-3-hydroxypyridines possess cytogenic activity.

The mechanism of the biological action of 3-hydroxypyridine derivatives has been the subject of a detailed microbiological study on yeast cells as the biological test

object[117]. It was established that 3-hydroxypyridine inhibitors suppress the multiplication of yeast cells, which are incapable of synthesising inositol and pantothenic acid, by blocking these vitamins when the latter are introduced from outside. It has been suggested[117] that alkyl-substituted 3-hydroxypyridines function as specific inhibitors of cell division, acting primarily by arresting the division of the nuclei. It has been shown that individual alkyl-3-hydroxypyridines exhibit vitamin B_6-like activity[117].

--o0o---

Thus systematic study of the structure of 3-hydroxypyridines and of their reactivity in electrophilic substitution using quantum-chemical calculations, spectroscopic methods, and the kinetics of the acid- and base-catalysed deuterium exchange made it possible to investigate the molecular sites involved in electrophilic reactions, to develop methods for the introduction of various substituents in different specific positions in the 3-hydroxypyridine ring, and to achieve on this basis the synthesis of a large number of relatively non-toxic and water-soluble inhibitors of radical chain processes with a wide spectrum of biological activity.

Kinetic Study of the Degradation and Stabilisation of Polymers

G.E.Zaikov

The kinetics and the mechanism of the thermal, thermo-oxidative, photo-oxidative, and hydrolytic degradation of polymers are surveyed. Critical phenomena in the thermal degradation of poly(vinyl chloride) are described. Specific aspects of radical reactions in the solid phase are discussed. A list of 151 references is included.

CONTENTS

I. Introduction 833

III. Thermo-oxidative degradation 834
IV. Photo-oxidative degradation 840
V. Hydrolytic degradation 842

I. INTRODUCTION

During recent years many studies have been published on the degradation and the stabilisation of polymers. The scientific and practical value of such investigation is obvious, since lengthening the life of plastic articles is equivalent to increasing the production of such articles. The summarising papers by Emanuel',[1-5] based on the application of various kinetic methods, are especially promising in the study of the mechanism of the ageing of polymers and in the search for ways of stabilising them.

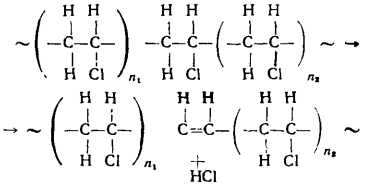
Detailed study of the kinetics and the mechanism of the degradation of polymers will permit (i) development of theoretically based accelerated methods for estimating the "lifetime" of polymers and polymeric articles under storage, processing, and service conditions, (ii) preparation of effective stabilisers for polymers and assessment of their efficiency, (iii) prolongation (or shortening†) of the useful life of polymer articles, and (iv) assessment of the effect of various additives on the stability of polymers.

Four modes of degradation of polymers—thermal, thermo-oxidative, photo-oxidative, and hydrolytic—are especially important both theoretically and practically. Overall the degradation (ageing) of polymers is a complicated radical, ionic, and molecular process involving many consecutive and simultaneous reactions.

II. THERMAL DEGRADATION

Among work on the thermal degradation of polymers a special place is occupied by studies of the degradation of poly(vinyl chloride) (p.v.c.).[6-9] This polymer is widely used in various branches of industry, but its instability when heated makes its processing and use in articles difficult.

Hydrogen chloride is evolved by the decomposition of poly(vinyl chloride):



(1)

† This is important for "one-off" uses of polymers (e.g. packaging materials) from the point of view of conservation of the environment and the regeneration of waste products.

The polymer becomes discoloured (owing to the formation of polyconjugated systems) and its physicomechanical properties change. The decomposition exhibits the principal features of a radical–chain process (rate of dehydrochlorination increased by radical initiators, and decreased by inhibitors of radical reactions)[9]. The proportionality of the rate of evolution of hydrogen chloride to the square root of the concentration of added initiators[9], indicates that destruction of the active centres involved occurs by recombination or disproportionation[7]. Degradation is initiated by the bimolecular interaction of structures P'Cl containing a labile chlorine atom with hydrogen atoms in the polymer PH to form a molecule of hydrogen chloride and two macroradicals P$^{\cdot}$ and P'$^{\cdot}$:

$$PH + P'Cl \rightarrow P^{\cdot} + P'^{\cdot} + HCl \quad . \qquad (2)$$

Molecular detachment of hydrogen chloride from the poly(vinyl chloride) molecule (reaction 1) cannot be completely excluded[7-9].

During thermal degradation in the presence of the hydrogen chloride evolved, reactions (1) and (2) are accompanied by the autocatalytic reaction

$$HCl + PH \xrightarrow{k} 2\,HCl + Pr$$

where Pr is the reaction product (macromolecules with a double bond) and k the effective rate constant. The occurrence of this reaction gives rise to critical phenomena[8,9]. The concentration of hydrogen chloride is determined in general not only by its rate of formation but also by its rate of removal from the specimen by diffusion. The variation in its concentration inside the polymer film $c(x,t)$ can therefore be described by the equation

$$\frac{dc}{dt} = D\frac{d^2c}{dx^2} + W_0 + kc,$$

where W_0 is the rate of the uncatalysed formation of hydrogen chloride, D its diffusion coefficient in the film, and k the effective autocatalysis constant. Hence the flux of hydrogen chloride through the boundary surfaces of the film ($x = 0$, $x = l$) referred to unit volume (the rate of formation of hydrogen chloride determined experimentally) can be calculated as

$$W_{HCl} = \frac{2D}{l}\frac{dc}{dx} = \sum_{n=0}^{\infty} \frac{8W_0D\left[e^{\left[k-\frac{(2n+1)^2\pi^2D}{l^2}\right]t} - 1\right]}{l^2\left[k - \frac{(2n+1)^2\pi^2D}{l^2}\right]} \qquad (3)$$

For thin films (with $\pi^2D/l^2 \gg k$ and $t > l^2/\pi^2D$) Eqn. (3) becomes

$$W_{HCl} = \frac{8W_0D}{l^2}\sum_{n=0}^{\infty}\frac{1}{\frac{(2n+1)^2\pi^2D}{l^2} - k}.$$

The rate of evolution increases as the film becomes thicker. When $\pi^2D/l^2 = k$, we have

$$W_{HCl} = \frac{8W_0Dt}{l^2},$$

i.e. W_{HCl} increases linearly with time. The presence of autocatalysis when $k > \pi^2D/l^2$ should produce an exponential increase in rate of evolution of hydrogen chloride during the process:

$$W_{HCl} = \frac{8D}{l^2}\frac{W_0e^{kt}}{k}.$$

Calculation shows [9] that at 200°C the critical film thickness (corresponding to the transition from a steady-state to an autocatalytic process) is 0.018 cm.

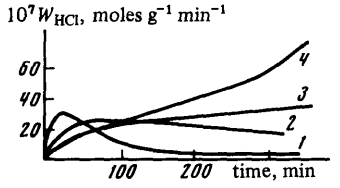


Figure 1. Rates of formation of hydrogen chloride (at 200°C) calculated by means of Eqn. (3) for poly(vinyl chloride) films of different thicknesses (mm): 1) 0.06; 2) 0.14; 3) 0.18; 4) 0.19.

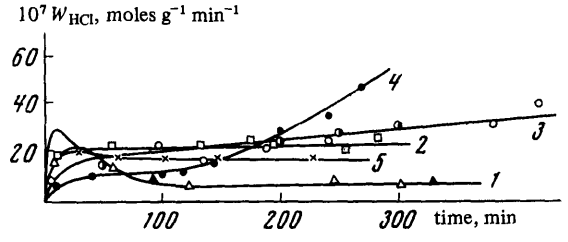

Figure 2. Rates of formation of hydrogen chloride (at 200°C) for poly(vinyl chloride) films of different thicknesses (mm): 1) 0.06; 2) 0.14; 3) 0.18; 4) 0.19; 5) finely divided powder.

Figs. 1 and 2 show good agreement between curves calculated by means of Eqn. (3), with $D = 3.3 \times 10^{-7}$ cm^2 min^{-1} and $k = 0.0103$ min^{-1}, and those obtained experimentally (at 200°C). The results demonstrate a novel type of critical phenomena in degradation processes, due to competition between catalysis by the final reaction product and its diffusion from the polymer [6-9]. It is evident from Figs. 1 and 2 that autocatalysis is absent only with very thin films and finely powdered poly(vinyl chloride). The occurrence of such critical phenomena in the thermal degradation of the polymer is the reason for the irreproducibility of the experimental results obtained by different workers.

The introduction of stabilisers to combine with hydrogen chloride (acceptors) should increase its rate of removal and hence the critical dimensions of the specimen. In the presence of an acceptor A we have

$$\frac{dc}{dt} = D\frac{d^2c}{dx^2} + W_0 + k_{eff}c,$$

where $k_{eff} = k - k_A[A]$ is the effective autocatalysis constant, k_A being the rate constant for interaction between hydrogen chloride and the acceptor, and [A] the concentration of the latter. At acceptor concentrations $[A]_{cr} \geq k/k_A$ degradation will occur under steady-state conditions whatever the size of the specimen. Taking into account the thickness of the film yields

$$[A]_{cr} = \frac{k - \frac{\pi^2}{l^2}D}{k_A},$$

i.e. the critical acceptor concentration is lower the thinner the film. This equation can be used to calculate k_A, an important quantitative parameter of hydrogen-chloride acceptors.

Thus prediction of the useful life of articles made of poly(vinyl chloride) must take into account not only the temperature and the concentration of the added stabiliser–acceptor but also the critical size of the article and the critical concentration of the stabiliser under service conditions.

III. THERMO-OXIDATIVE DEGRADATION

Significant progress in the degradation and stabilisation of polymers has recently been made particularly by kinetic investigations. The oxidation of polymers comprises in principle the same primary steps as that of simpler compounds, so that many features of their oxidation can be explained by the generally accepted scheme [10,11]. Denoting the oxidisable compound as RH (e.g. a hydrocarbon), we can write for the initial stages [10] (where R'OOR' is an initiator)

$$R'OOR' \xrightarrow{W_i} [2\,R'O'] \xrightarrow{e} R'O^{\cdot} \xrightarrow{RH} R^{\cdot};$$
$$R^{\cdot} + O_2 \xrightarrow{k_1} RO_2^{\cdot};$$
$$RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot};$$
$$ROOH \xrightarrow{k_3} RO^{\cdot} + {}^{\cdot}OH;$$
$$\left.\begin{array}{l} R^{\cdot} + R^{\cdot} \xrightarrow{k_4} \\ R^{\cdot} + RO_2^{\cdot} \xrightarrow{k_5} \\ RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_6} \end{array}\right\} \text{Inactive products};$$

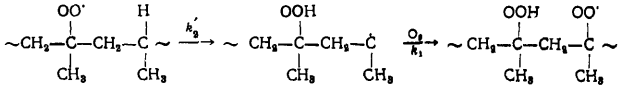
and in the presence of an inhibitor InH we have

$$RO_2^{\cdot} + InH \xrightarrow{k_7} ROOH + In^{\cdot}; \quad (4)$$
$$R^{\cdot} + InH \xrightarrow{k_7'} RH + In^{\cdot}. \quad (5)$$

However, conditions for the development of a chain reaction in a solid polymer differ markedly from those in a liquid organic compound. Recent kinetic studies of the oxidation of several (primarily carbon-chain) polymers have revealed facts that cannot be interpreted in terms of the classical scheme. Such solid-phase processes can be described quantitatively [12] by a step-by-step model of the

chain oxidation of polymers with a two-centre chain reaction and a stepwise mechanism of migration of the free valency and destruction of free radicals on collision.

According to this model the oxidation of a polymer PH involves the formation of solitary hydroperoxides POOH and adjoining peroxides $(POOH)_2$, among which the latter break down considerably more rapidly into radicals [13]. Adjacent hydroperoxy-groups are formed when a peroxy-radical attacks a β-carbon–hydrogen bond, and the resulting alkyl radical adds oxygen:



The ratio of the yields of (POOH) and $(POOH)_2$ depends on the oxygen pressure.

An important role in the mechanism of the solid-phase oxidation of polymers is played by chain-propagation reactions involving alkyl radicals‡:

$$P^{\cdot} + PH \xrightarrow{k_3''} PH + P^{\cdot},$$

which tend to move the free valency through the specimen.

As oxygen diffuses slowly and is relatively sparingly soluble in the polymer [16–20], the conversion of alkyl into peroxide macroradicals is a slow process, and the $[P^{\cdot}]/[PO_2^{\cdot}]$ ratio in the polymer is quite high, which is of great importance for solving the problem of stabilisation. Inhibitors (phenols, amines, anthracene) terminate chains in an oxidisable polymer by reacting not only with peroxide but also with alkyl radicals [21–23]. For this reason inhibitors that react mainly with alkyl radicals (iminoxyl radicals, anthracene, or quinol) inhibit the oxidation of a polymer far more efficiently than that of a hydrocarbon [23,24]. Whereas chain termination during oxidation of a polymer in solution takes place only by reaction (4), reaction (5) plays an important part in the solid polymer [25].

Thus stepwise migration of the free valency in the solid oxidisable polymer occurs by two primary processes:

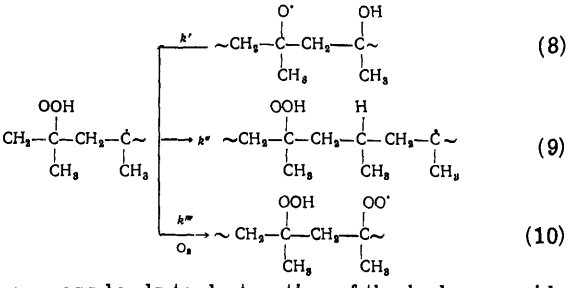
$$P^{\cdot} + PH \xrightarrow{k_3''} PH + P^{\cdot}; \qquad (6)$$

$$PO_2^{\cdot} + PH \xrightarrow{k_5} POOH + P^{\cdot}. \qquad (7)$$

During the interval between these two processes the free valency moves a distance d as a consequence of the thermal motion of the segments of the macromolecules [12]. The more mobile the segments the more rapid the migration of the active centre; the latter is determined also by the rate of the chemical reactions (6) and (7). Two such active centres are destroyed when they enter a space of $4\pi d^3/3$, where they may be brought together by the thermal mobility of the segments and interact, the rate of recombination being greater the higher the concentration of active particles, the more vigorous the movement of the segments, and the more rapid the migration of active centres through the polymer specimen [12]. The meeting of two active centres in the polymer cannot be regarded as the encounter of independent particles; k_4, k_5, and k_6 depend on the reaction conditions (pressure of oxygen, structure of polymer, solubility of oxygen, and other factors determining the composition of the radicals).

A step-by-step mechanism of migration of the free valency in the polymer predominates when the diffusion of free radicals is slow. In solution, the melt, and in the swollen polymer, where diffusion of macromolecules and their segments is facilitated, a diffusion mechanism may be a more efficient mode of migration of the free valency [26–30].

It is quite likely that, besides the "direct" step-by-step mechanism leading to formation of a block of hydroperoxy-groups on the polymer chain, $P^{\cdot}$ or $PO_2^{\cdot}$ radicals may attack hydroperoxy-groups that have just been formed [31,32]. Results obtained for the oxidation of isotactic polypropylene—a low yield of stable hydroperoxides (20–40% on the rate of absorption of oxygen at 130°C), the shortness of surviving hydroperoxide blocks, the formation of degradation products of low molecular weight even in the initial stages, and the proportionality of the rate of formation of such products to the concentration not of hydroperoxide but of free radicals—support [31] the latter mechanism (chain propagation by the breakdown of a considerable proportion of hydroperoxy-groups immediately after their formation). Furthermore [33] the rate constants for reaction of these radicals with a hydroperoxide are considerably larger than those for their interaction with P–H. Thus the free valency is located beside the newly formed hydroperoxy-group after abstraction of a hydrogen atom by a $PO_2^{\cdot}$ radical from a neighbouring unit of the macromolecule§; it may attack a hydroperoxy-group or the next unit of its own or a neighbouring macromolecule, or add oxygen to form a new $PO_2^{\cdot}$ radical [35–36]:



(8)

(9)

(10)

The first process leads to destruction of the hydroperoxide just formed, whereas the latter two processes remove the reaction centre and stabilise this group, to give a yield of stabilised hydroperoxide of [35]

$$\alpha = \frac{k'' + k'''[O_2]}{k' + k'' + k'''[O_2]},$$

$$\frac{1}{\alpha} = 1 + \frac{k'}{k'''([O_2] + k''/k''')}.$$

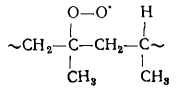
These equations show that α should depend on the oxygen pressure. The latter formula permits determination of the ratio k''/k''' of the rates of the second and third processes.

As a result of this first process hydroxyl and carboxyl groups appear within the hydroperoxide block, in both α- and β-positions with respect to tertiary and secondary hydroperoxy-groups. This process leads to rupture of the chain. The second process disturbs the regular arrangement of hydroperoxy-groups. Since the ratio of the sum of the rates of (8) and (9) to the rates of reaction (10) will depend on the concentration of molecular oxygen in the polymer, the composition of the block and the properties of the polymer hydroperoxides will depend on the oxygen pressure. Taking into account all three processes involving the $PO_2^{\cdot}$ radical, we are able to explain many experimental aspects of the oxidation of polyalkenes [31–35].

‡ The role of such reactions was shown earlier [14,15] in the co-oxidation of simpler organic compounds.

§ The $PO_2^{\cdot}$ macroradicals formed by oxidation of a polymer react mainly with a neighbouring unit in their own macromolecule [32,34].

Products of low molecular weight can be formed also by the direct decompositon of a single radical



Competition between two reactions of chain propagation—the unimolecular isomerisation and breakdown of peroxy-radicals (to form many different products with rupture of the initial carbon skeleton)

$$RO_2^{\cdot} \rightarrow R'HO + R''O^{\cdot},$$

and the bimolecular reaction

$$RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot}$$

with formation of a hydroperoxide as sole primary product—governs the composition of the oxidation products of simple organic compounds [10,11,37]. Since the corresponding activation energies are ~20 and ~10 kcal mole^{-1}, the proportion of unimolecular reactions (yielding simple degradation products) will increase with rise in temperature, and the contribution of unimolecular reactions to the oxidation of compounds of low molecular weight is usually negligible below 100°C. However, the relative proportions of the two reaction paths is determined not only by the temperature but also by the frequency of the collisions necessary for a bimolecular process. This may be responsible for the significantly larger contribution to the solid-phase oxidation of polymers made by unimolecular reactions leading to the formation of simple reaction products.

The above conditions mark the limits within which the step-by-step mechanism of migration of the free valency plays a decisive part in the oxidation of polymers. The role of this mechanism should diminish as low-molecular products accumulate, and the free valency will migrate mainly by means of reaction products possessing sufficient mobility in the polymer matrix [38]. Denoting by rH the low-molecular-degradation products, we can represent displacement of the free valency as

$$P^{\cdot} + rH \xrightarrow{k_2''} PH + r^{\cdot}.$$

The resulting low-molecular radical r$^{\cdot}$ (alkyl or, in the presence of molecular oxygen, peroxy) moves a distance

$$\lambda = \sqrt{6D_0\tau}$$

during its lifetime τ. At temperatures above 100°C the diffusion coefficient D_0 for rH and r$^{\cdot}$ lies in the range 10^{-6}–10^{-8} cm^2 s^{-1}, so that λ may reach several micrometres [38–40]. Destruction of the radical r$^{\cdot}$ by the reaction

$$r^{\cdot} + PH \xrightarrow{k_3''} rH + P \qquad (11)$$

is equivalent to the macroradical P$^{\cdot}$ "jumping" a distance $\lambda = (6D_0\tau)^{1/2}$, the frequency of such jumps being $\nu = k_2''[rH]$. [34] The coefficient for chemical diffusion of the radical P$^{\cdot}$ is

$$D_1 = D_0 k_2''[rH]\tau.$$

On the assumption that r$^{\cdot}$ is removed solely by reaction (11), we obtain $\tau = 1/k_3''[PH]$, and then $D_1 = D_0 k_2''[rH]/k_3''[PH]$. Provided that $D_0 \simeq 10^{-7}$ cm^2 s^{-1}, $[rH] \simeq 6 \times 10^{-6}$ mole cm^{-3}, and $k_2''/k_3'' \simeq 1$–100¶ we have $D_1 \simeq 10^{-8}$–10^{-10} cm^2 s^{-1}. Such a rate of migration of the free valency ensures propagation of the oxidation chain in the solid polymer, since in many cases [38] the rate provided by the step-by-step mechanism is far lower.

The recombination of radicals may also be due to the involvement of low-molecular degradation products [38–41]:

$$\left.\begin{array}{l} r^{\cdot} + P^{\cdot} \xrightarrow{k_4'} \\ r^{\cdot} + r^{\cdot} \xrightarrow{k_5'} \end{array}\right| \longrightarrow \text{Stable products.}$$

Provided that $k_4' \simeq k_5'$, we have

$$-\frac{d[P^{\cdot}]}{dt} = 2k_4' \frac{k_2''[rH]}{k_3''[PH] + k_4'[P^{\cdot}]}[P]^2.$$

When $k_4'[P^{\cdot}] \ll k_3''[PH]$, we find that

$$-\frac{d[P^{\cdot}]}{dt} = 8\pi d_1 D_0 \frac{k_2''[rH]}{k_3''[PH]}[P^{\cdot}]^2,$$

where d_1 is the sum of the radii of the colliding particles. Substituting the values $d_1 \simeq 5 \times 10^{-8}$ cm, $D_0 \simeq 10^{-7}$ cm^2 s^{-1}, $k_2''/k_3'' \simeq 200$, $[rH] = 5 \times 10^{-6}$ and $[PH] = 0.025$ mole cm^{-3}, we obtain a chain-termination rate constant of 3.5×10^9 cm^3 mole^{-1} s^{-1} (the corresponding experimental values is 9×10^9).

Another important feature of a crystalline polymer is a complicated supermolecular structure comprising alternating regions differing in degree of ordering of the polymer chain. In general we must regard a polymer specimen as consisting of various microregions of varying reactivity. The relative arrangement and dimensions of such regions, as well as the specific volumes of the various structural components, depend on many factors. The stability of a polymer is considerably influenced by the degree of ordering of the polymer chains in the solid [19,31,42–44].

The rate of interaction of a gas A with a polymer comprises the reaction velocities in the individual structural components:

$$W_a = \sum_j \rho_j W_{aj},$$

where ρ_j is the specific volume of the jth structural component and W_{aj} the rate of reaction in this component. For a second-order reaction

$$W_{aj} = k_{aj}c_j[A]_j = k_{aj}c_j\gamma_{aj}^{-1}p_a,$$

where k_{aj} is the rate constant, c_j the polymer concentration, γ_{aj} the solubility coefficient of A (all for the jth component), and $p_a = \gamma_{aj}[A]_j$ is the partial pressure of A outside the polymer. When a chain reaction occurs in an individual structural unit, the process is complicated by the migration of active centres through the boundary of this unit. Oxidation does not usually involve the crystalline regions of a polymer [43]: the solubility of oxygen is low in regions having an undistorted crystal lattice [16,18], while the reactivity of the macromolecules is diminished in these segments, since the lattice prevents formation of the optimum configuration of the activated complex [45].

It has been shown for the oxidation of polypropylene that finely spherulitic specimens are oxidised more rapidly than coarsely spherulitic specimens at different stages of the process. In the former case the reaction is probably localised mainly in the interspherulitic material. In a coarsely spherulitic polymer, where the proportion of such material is insignificant, the process occurs predominantly in the interfibre portions within the spherulite. During extensive oxidation, when radicals decay mainly by

¶ The reality of these postulates was validated in Ref. 38.

quadratic termination†, the escape of radicals from amorphous layers into the crystalline material plays a subordinate role, and the rates of oxidation of specimens having the same "crystallinity" differ insignificantly.

The observed difference between rates of oxidation of specimens differing in supermolecular structure is more strongly marked the lower the reaction temperature, and it disappears at the melting point. The presence of inhomogeneities in a polymer, as well as differences in the solubility of an inhibitor in regions of the polymer differing in degree of organisation[16-19], demands a special study of non-uniformly inhibited polymers[46-50]. Such cases are indeed found, since a non-uniform distribution of an inhibitor may result from technical defects in the preparation of the specimen.

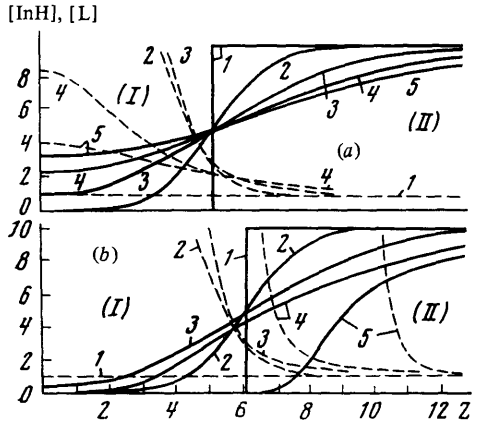


Figure 3. Distribution of relative concentrations of inhibitor [InH] (full curves) and of active centres [L] (broken curves) along a unidimensional specimen of length Z with section (I) initially uninhibited ([InH] = 0) and section (II) initially inhibited ($[InH]^{I,0}_{II,0} = 10$) for: *a*) smaller section (I); *b*) larger section (I) after different times of oxidation τ (in relative units): 1) 0; 2) 1; 3) 5; 4) 10 (12.5 in case *b*); 5) 15 (17.5).

If the inhibitor is initially absent from some part of the specimen, and neither inhibitor nor active degradation centres are able to diffuse, an autocatalytic reaction should occur in this portion independent of its size. But diffusion of inhibitor into the uninhibited region (and of active centres outwards) may result either in decay of the reaction or of gradual extension of the autocatalytic reaction throughout the specimen. Hence diffusion of inhibitor and of active centres must in general be considered when the initial distribution of inhibitor in the oxidisable specimen is non-uniform. Fig. 3 illustrates the theoretically calculated concentration distributions of inhibitor and of active centre [InH] and [L] along a unidimensional specimen after various time intervals. In both cases (*a*) and (*b*) both inhibitor and active-centre concentrations increase initially on the originally uninhibited segment. However, a difference then develops: if the size of the uninhibited portion Z is smaller than a limiting value Z_{cr}, the reaction dies out; if $Z > Z_{cr}$, a front is formed, and the reaction extends throughout the specimen. The critical value Z_{cr} depends on the concentration of inhibitor in the specimen $[InH]_{II,0}$ and on the ratio of the diffusion coefficients of inhibitor and of active centre. Both cases have been achieved in practice (Fig. 4)[47,48]. Fig. 5 shows the dependence of the induction period in the oxidation of polypropylene on the concentration of a diamine either uniformly or non-uniformly distributed in the polymer. The inflexion on curve *1* corresponds to the critical inhibitor concentration required to halt the process[50]. The inflexion on curve *2*, representing non-uniform inhibition, corresponds to the concentration at which the critical size of the uninhibited part of the polymer becomes equal to the actual size of the largest of the central segments of the powder particles devoid of inhibitor.

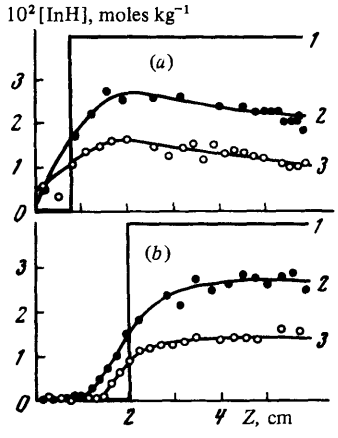

Figure 4. Distribution of actual concentrations of methylenebis-2-(4-methyl-6-t-butylphenol) [InH] in atactic polypropylene (size of specimen Z), with initially uninhibited portions of: *a*) 0.8 cm; *b*) 2 cm and initial inhibitor concentration in inhibited portion $[InH]_{II,0} = 0.04$ mole kg^{-1}, after oxidation in air at 190°C for different periods (min): 1) 0; 2) 150; 3) 300.

The investigation of oxidation processes in polymers at low temperatures is of great interest for the storage and performance of articles. Polymers are processed at high temperatures (as melts), under which conditions the specific features of low-temperature solid-phase oxidation[12,30-32,51] disappear, and new problems connected with the mechanism of high-temperature oxidation appear[51-53]. In spite of the precautions adopted in technology (e.g. processing in an atmosphere of an inert gas) the properties of the polymer change during processing, since degradation or cross-linking of the polymer chains takes place.

† In the early stages (at a low rate of initiation of radicals), when the concentration of radicals is small, decay occurs linearly, by migration of the free valency into the crystalline phase. In a finely spherulitic polymer the crystallites are too small for the radicals that have entered them to be able to react with oxygen.

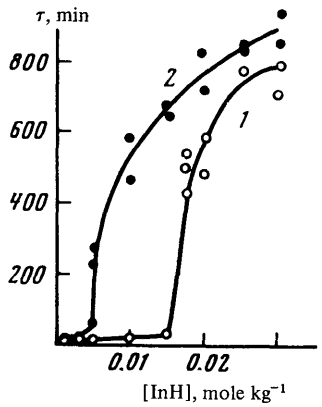

Figure 5. Dependence of induction period τ on concentration of dimethylbis-*p*-phenylaminophenoxysilane (S-1) [InH] in the oxidation of isotactic polypropylene of particle size 0.03 mm in oxygen (300 mmHg) at 200°C: 1) inhibitor applied to surface of pellets to give a non-uniform distribution; 2) pellets then heated in a vacuum at 100°C to give a uniform distribution of inhibitor.

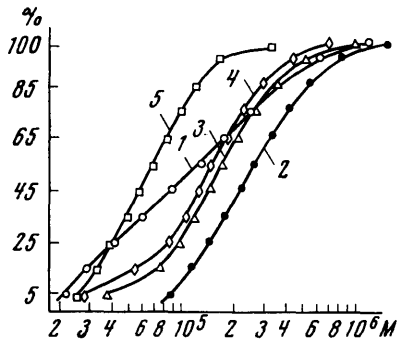

Figure 6. Dependence of molecular mass M distribution function on number of processings: 1) initial medium-pressure polyethylene; 2) polymer after first processing; 3) after second processing; 4) after third processing; 5) after thermal oxidation.

One of the most sensitive methods for recording the degradation and the cross-linking of macromolecules is analysis of the molecular-mass distribution function MMD.[29,53-56] For example, significant changes in molecular weight during multiple extrusions of (action of high temperatures and shear stresses on) high-density medium-pressure polyethylene are revealed[29] by analysis of the MMD function (Fig. 6). After the first processing the distribution curve of the initial polymer, which possesses a comparatively wide distribution (curve *1*), contracts and shifts to higher molecular weights (curve *2*). Subsequent processings produce the reverse process (curves *3* and *4*): they result in degradative processes leading to a decrease in molecular weight. In the absence of mechanical action on the polymer (subjected only to thermal oxidation) the latter undergoes only degradation (curve *5*). Degradation is probably[29] associated with thermal oxidation, whereas mechanical action is responsible for cross-linking.

Another effective method for studying ageing processes is use of a paramagnetic probe[57-67]. It consists essentially in measuring the electron spin resonance spectra of stable radicals introduced into the polymer, and calculating the appropriate parameters. The form of e.s.r. spectrum indicates structural features of the polymer matrix[57]. The following points must be borne in mind when the method is used[57].

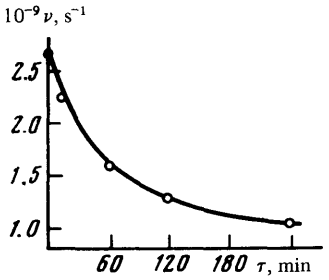

Figure 7. Dependence of rotational frequency ν of probe radical on time of oxidation of polypropylene in oxygen (400 mmHg) at 130°C.

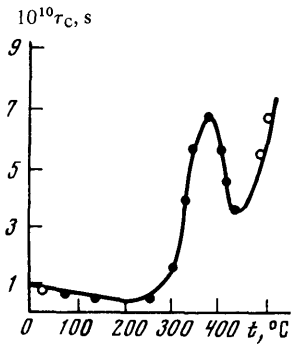

Figure 8. Dependence of correlation time of probe $\tau_c = \nu^{-1}$ on limiting temperature of initial heating of methylvinylsiloxane rubber.

Firstly, the rotational and translational mobility of stable radicals introduced into polymers indicates the intensity of molecular movements of the polymer matrix. Degradation is accompanied by a change in the molecular mobility of segments of the polymer chains, which is apparent in a change in the frequency of rotation of the probe radical. For example, a decrease in frequency during thermo-oxidative degradation (Fig. 7) corresponds to decreases in movements of segments in the amorphous phase of the polymer. In this case cross-linking occurs during oxidation. A more complicated case is illustrated by Fig. 8, where the ratio of the contributions of degradation and cross-linking changes several times with rise in temperature.

Secondly, stable radicals simulate the behaviour of simple compounds in a polymer (initiators, inhibitors, etc.), their rotational and translational mobility, and their local sites and local concentrations, which is important for calculating elementary constants for the reactions of macromolecules with simple substances.

Information obtained from study of the kinetics and the mechanism of the thermo-oxidative degradation of polymers is used [21-23] in selecting the most effective antioxidants, among which derivatives of phenols and amines are of considerable interest, as before. Among the attributes which the most efficient stabilisers should possess are (i) high rate constants of reaction with radicals (primarily peroxy and alkyl [10])

$$InH + PO_2^{\cdot}(P) \rightarrow POOH(PH) + In^{\cdot} \qquad (12)$$

(ii) a relatively inactive radical In$^{\cdot}$ formed by the action of P$^{\cdot}$ or $PO_2^{\cdot}$ on InH, [10] (iii) reaction products that are preferably effective stabilisers [21-23], and (iv) more than one functional group in the molecule [21-23,68]. Highly efficient new antioxidants have recently been prepared [for polyalkenes, polyoxymethylene, polystyrene, polychlorides, synthetic rubbers, cellulose ethers, poly(vinyl chloride), and other polymers]—the S series of stabilisers [69-72] (stabiliser S-1 is dimethylbis-*p*-phenylaminophenoxysilane).

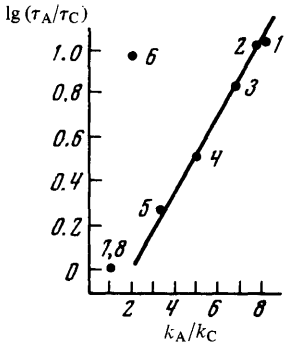

Figure 9. Dependence of $\lg(\tau_A/\tau_C)$ on k_A/k_C for: 1) *NN'*-dioctyl-*p*-phenylenediamine; 2) *NN'*-di-isopentyl-*p*-phenylenediamine; 3) *N*-isopropyl-*N'*-phenyl-*p*-phenylenediamine; 4) *NN'*-bis-α-methylbenzyl-*p*-phenylenediamine; 5) *N*-α-methylbenzylanisidine; 6) *NN'*-dibutylthiourea; 7) thiobis-2-(4-methyl-6-t-butylphenol); 8) methyl oleate.

Another important problem is to protect polymers from the action of ozone. Kinetic investigations [73] have established correlations between the rate of reaction of ozone with the test antiozonant under model conditions and the efficiency of the latter in rubbers (Fig. 9):

$$\lg\frac{\tau_A}{\tau_c} = N + M\frac{k_A}{k_c},$$

where N and M are constants, τ_A and τ_C are the induction periods for ozonisation of rubber containing the antiozonant A and of a control compound (model alkene) respectively, and k_A and k_C are the rate constants for reaction of ozone with A and with the control. The above relation not only simplifies and accelerates the testing of new potential ozonants (since little time is required to measure the rate constants for reaction with ozone) but also guides the preparation of new antiozonants.

The efficiency of the usual stabilisers (amines, phenols, and phosphorus-containing and sulphur-containing compounds) in polymers decreases with rise in temperature independently of their mechanism of action; at 270–300°C they become completely ineffective [74,75]. The reasons are that at high temperatures the In$^{\cdot}$ radicals formed by reactions (4) and (5) become reactive and capable of propagating chains, the inhibitor itself is readily oxidised, and the In–H bond is weak, so that the inhibitor becomes an initiator yielding free radicals.

Finely divided metals (M), generated by decomposition of their organic salts (e.g. oxalates) in polymer compositions during the service life of articles, are effective stabilisers against thermo-oxidative degradation at temperatures above 300°C. [76-79] The rate at which such metals react with oxygen exceeds considerably the rate at which oxygen reacts with the polymer and with the radicals formed by the degradation of polymers:

$$W_{M+O_2} \gg W_{PH+O_2}, W_{P^{\cdot}+O_2}.$$

Thus oxygen plays almost no part in chain initiation and propagation, but is entirely absorbed by reaction with the metal.

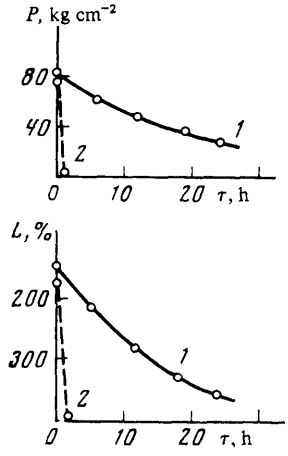

Figure 10. Variation in strength P and relative elongation L at rupture of SKTV-2 silicone rubber during ageing in air at 350°C: 1) specimen stabilised with finely divided copper; 2) control specimen stabilised with iron sesquioxide.

The lifetime of a polymer τ_p depends on the thickness of the specimen l and the solubility of oxygen in the polymer σ_x:

$$\tau_p = K\frac{l^2[M]}{D\sigma_x},$$

where K is a constant determined by the stoichiometry of the process and D is the diffusion coefficient of molecular oxygen. Figs. 10 and 11 show that specimens stabilised by finely divided metals retain their properties several

times longer. This method of stabilisation is suitable not only for polyorganosiloxanes but in principle for all polymers for which the relation $W_{M + O_2} > W_{PH + O_2}$ is satisfied (Fig. 12) under the working conditions of articles made from them.

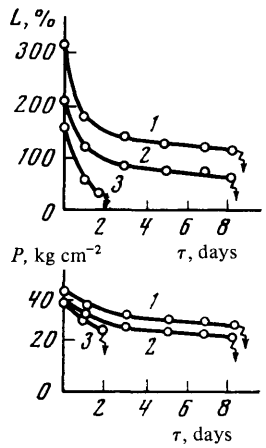

Figure 11. Variation in strength P and relative elongation L at break of siloxane rubber during ageing in air at 350°C: 1) specimen stabilised with finely divided copper; 2) specimen stabilised with finely divided iron; 3) standard specimen stabilised with titanium dioxide. The arrows show the beginning of rapid breakdown of the polymer; those on curves *1* and *2* correspond to exhaustion of the stabiliser.

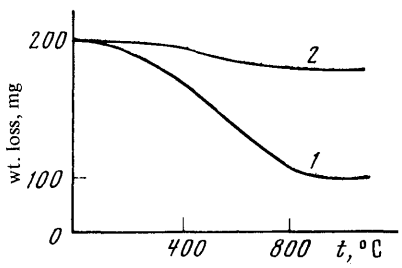

Figure 12. Thermogravimetric curves for a carbonised fibre: 1) unstabilised specimen; 2) specimen stabilised with finely divided copper.

IV. PHOTO-OXIDATIVE DEGRADATION

The photo-oxidation of a polymer comprises a complicated set of physical and chemical processes occurring under the influence of light [80-97]. It is extremely important to be able to calculate the absolute rate of photo-oxidation of a solid polymer, since this will enable the life of articles to be predicted. This was first accomplished for the photo-oxidation of polypropylene [80-82], where analysis of all possible reactions revealed a chain reaction with degenerate branching at hydroperoxides and with quadratic chain termination. Oxidation can be represented by the scheme

$$X \xrightarrow{h\nu} PO_2^{\cdot};$$

$$POOH + h\nu \xrightarrow{\varphi} PO^{\cdot} + {}^{\cdot}OH \xrightarrow{2O_2 + 2PH} 2PO_2^{\cdot} + H_2O + K;$$

$$K + h\nu \xrightarrow{2O_2} PO_2^{\cdot};$$

$$PO_2^{\cdot} + PH \xrightarrow[O_2]{k_2} POOH + PO_2^{\cdot};$$

$$PO_2^{\cdot} + PO_2^{\cdot} \xrightarrow{k_4} K + POH + O_2;$$

where **X** represents impurities in a polymer **PH** and **K** is a ketone, while φ is the quantum efficiency of the photochemical reaction. This scheme yields for the concentration of carbonyl compounds formed during photo-oxidation the formula

$$\frac{[K]}{[POOH]_\infty} = \alpha t - 2\left(3 - e^{-\frac{\alpha t}{4}}\right)\left(1 - e^{-\frac{\alpha t}{4}}\right),$$

where

$$\alpha = \int I \varepsilon d\lambda, \quad [POOH]_\infty = \frac{4k_2^2[PH]^2}{\alpha k_6}.$$

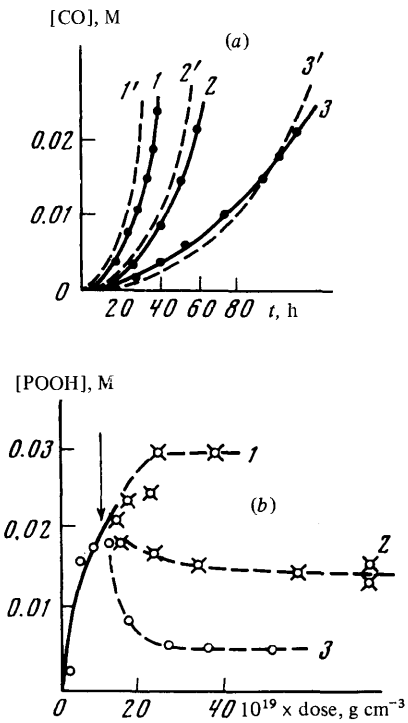

Figure 13. Comparison of experimental results (curves with points) with calculated values (broken curves, primed) for the photo-oxidation of polyalkenes. (*a*) Kinetic curves for the accumulation of carbonyl compounds under the influence of light of different wavelengths (nm): 1,1′) 280; 2,2′) 295; 3,3′) 305. (*b*) Kinetic curves for the accumulation of hydroperoxides during the photo-oxidation of polypropylene containing Methylox antioxidant (0.1 mole kg^{-1}), where the relative light intensity was changed at the time indicated by the arrow from 4 to: 1) 0.7; 2) 1.4; 3) 4 (by this time the Methylox was exhausted).

The data used in the calculation‡ included the intensity I, the absorption coefficient ϵ and the spectral distribution of the light source, and the absorption spectrum and the quantum efficiency of photodecomposition of the hydroperoxide; values of $k_2/k_6^{1/2}$ were taken from work on the dark initiated oxidation of the polymer. Fig. 13 shows good agreement between calculation and experiment, which confirms the reliability of the suggested scheme. Such agreement opens up the possibility of using polypropylene as a model polymer in investigating the mechanism of the action of photostabilisers.

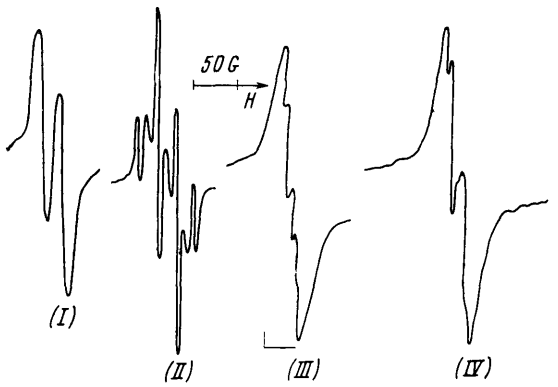

Figure 14. Electron spin resonance spectra of certain radicals obtained in the photo-oxidation of poly(methyl methacrylate):

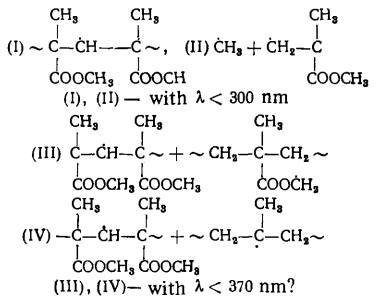
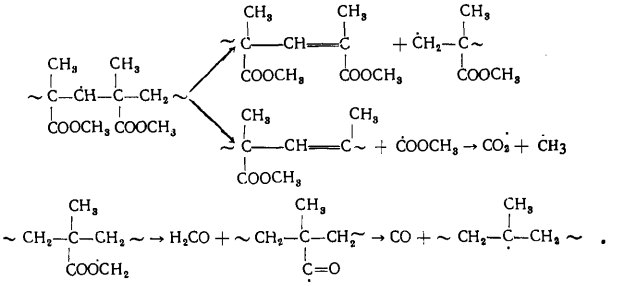


The action of light on a polymer usually gives rise at once to several chemical processes occurring at different rates. To determine the contributions made by each of these reactions it is extremely important to know the quantum efficiencies of the remaining processes [83-85,90-92]. With poly(methyl methacrylate), whose ester groups are responsible for absorption, the principal photochemical process was the rupture of ester groups with a quantum efficiency close to unity [88,91,92]; this was accompanied by the transformation of methylene groups, chain cleavage, and the accumulation of radicals in order of diminishing quantum efficiency (respectively ~0.1, 0.012, and 0.001). Many details of the mechanism of the photo-oxidation of this polymer have been elucidated from the quantum efficiencies together with the application of ultraviolet, infrared, and e.s.r. spectroscopy to its kinetic investigation [91-93]. Fig. 14 illustrates the e.s.r. spectra of intermediate free radicals recorded in the polymer, in which the main photochemical reactions are



Photoconversion in cellulose triacetate is also due to the absorption of light by ester groups. The breakdown of such groups and of ether groups and the accumulation of carbonyl compounds, hydroxy-groups, and acetic acid have respectively quantum efficiencies of 0.015, 0.01, 0.005, 0.005, and 0.005.

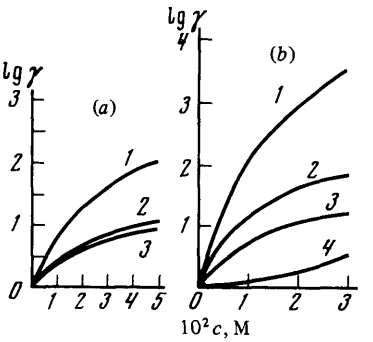


Figure 15. Coefficient of inhibition of the oxidation of diphenylmethane γ photosensitised by benzophenone (λ = 365 nm) as a function of the concentration of the photostabiliser: *a*) 2-hydroxy-4-octyloxybenzophenone; *b*) 2-(2-hydroxy-5-methylphenyl)benzotriazole: 1) total effect; and contributions made by: 2) shielding; 3) quenching; 4) inhibition.

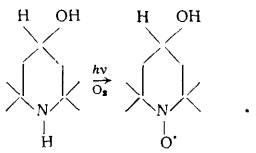
The absorption of light by polyhexanamide is most effective in causing the absorption of oxygen (φ = 0.06); [90] rupture of the chain and evolution of carbon monoxide have φ = 0.015; and the quantum efficiencies of the accumulation of carbonyl and carboxyl groups are respectively 0.009 and 0.005. Under the influence of light

radicals decompose with the formation of ~$[CH_2]_5-\dot{C}=O$ radicals, which are then converted into ~$CH_2-\dot{C}H_2$ and ~$CH_2-\dot{C}H-CH_2$~ radicals [94].

‡ The calculations were based on the usual equations of homogeneous chemical kinetics, since the photo-oxidation of polypropylene was investigated at temperatures above the glass point T_{gl}. However, processes occurring in a polymer below this temperature exhibit kinetic peculiarities—inhibition of chemical conversion during the process and kinetic arrest of the reaction [80].

Photostabilisers act by three main mechanisms: they absorb photochemically active light, quench excited states, and inhibit dark oxidation [88]. For two typical ultraviolet absorbers Fig. 15 shows the concentration dependence of the total reaction inhibition coefficient and the contributions made by shielding, quenching, and inhibition. Since the quantum efficiency is approximately unity for poly(methyl methacrylate), the photoreaction is so rapid that deactivation cannot occur, and therefore the efficiency of photostabilisers is here determined solely by their ability to absorb light. In cellulose triacetate, ester groups are decomposed with a quantum efficiency of 0.015, deactivation processes are competitive, and the photostabilisers that protect poly(methyl methacrylate) by a shielding mechanism act in cellulose triacetate by a quenching mechanism.

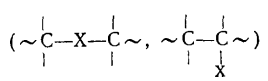
In the photo-oxidation of several polymers (e.g. polyhexanamide [88,90]) in the kinetic range in air, only a proportion of alkyl radicals are converted into peroxy-radicals. Thus such polymers can be stabilised by inhibitors that react with both types of radicals. Considerable inhibition is observed in the presence of stable nitroxyl radicals, which react only with alkyl radicals, and of chelate complexes of metals of variable valency, whose activity increases as the partial pressure of oxygen falls. In this connection great interest attaches to highly efficient new photostabilisers—secondary and tertiary aliphatic amines, derivatives of piperidine [22,87-102]—possessing neither shielding nor inhibiting effects and exerting only a weak quenching action. These compounds function [87] by photosensitised conversion of the amines into nitroxyl radicals, which are known to act as photostabilisers:



Prolonged inhibition is observed in the presence of such compounds (the stoichiometric coefficient may [63] exceed 10). The nitroxyl radical is regenerated from its reaction product with the alkyl radical by the action of a peroxy-radical:

V. HYDROLYTIC DEGRADATION

Polymers containing heteroatoms X in main and side chains



are hydrolytically unstable§. Hydrolytic degradation of a polymer involves diffusion of the active medium into the polymer and reactions involving chemically unstable bonds [103,104]. Several investigations are being undertaken in conformity with this—(i) use of simple model compounds to study the mechanisms of the conversion of hydrolytically unstable bonds of polymers in active media, (ii) determination of the main types of breakdown undergone by molecules of various polymers, (iii) establishment of the laws of the diffusion of active media into polymeric materials, and (iv) investigation of the mechanisms of the degradation of polymeric material in active media.

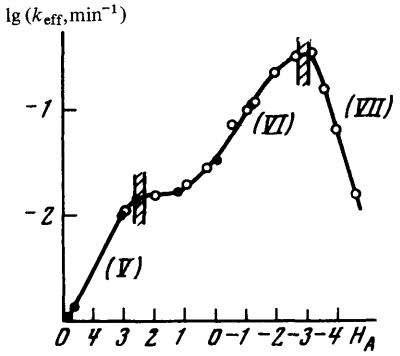


Figure 16. Dependence of effective hydrolysis rate constant k_{eff} of phthalanilic acid (at 25°C) on the acidity function H_A. The forms of the acid predominating on the various sections of the curve are

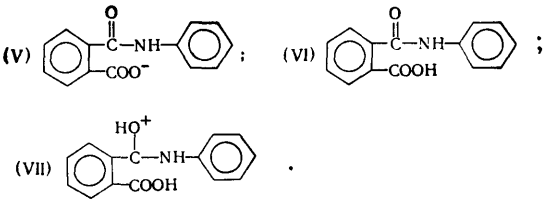

Quite detailed studies have now been made of the breakdown in acid and alkaline media of amide and imide [105-118], ether and ester [119-124], acetal [125-128], glycosidic [129-135], and siloxane [136,137] bonds. Fig. 16 illustrates the variation of $\lg k_{eff}$ with the acidity function H_A for the hydrolysis of phthalanilic acid as a model of non-cyclised units in polymers. The complexity of the dependence is explained by a mechanism in which unreactive forms are produced by protonation of the carbonyl oxygen of the amide bonds and by dissociation of the carboxy-group. The unionised form is reactive, able to react either with a carboxy-group (intramolecular catalysis along the segment H_A = 4–1) or with an oxonium ion (specific acid catalysis in more acidic solutions)¶.

Mechanisms of the hydrolytic degradation of various bonds have been surveyed [103,104]. Two types of decomposition—random and depolymerisation—can occur in polymer molecules. In the first type all hydrolytically unstable bonds are equally reactive, so that there should be no difference between a polymer and its simple analogue. In depolymerisation the effective rate constant depends on the molecular weight. In practice the two types of decomposition generally occur together [125-128].

Thus the hydrolytic degradation of polymers under homogeneous conditions can be characterised by a few true rate constants depending on the type and character of the decomposition [103,104]. In order to establish the mechanism of the degradation of polymeric materials in active media,

§ Polymers containing fluorine constitute an exception.

¶ A result of practical importance is the enhancement of the stability of amides in concentrated acids.

however, we must know how the medium diffuses in the polymer and the degree of dissociation of the electrolyte into ions [138-151]. In polymers that dissolve readily in water, e.g. poly(vinyl alcohol) (solubility 80% by mass), acids migrate with diffusion coefficients closely similar to those in aqueous solutions [144-147]. Selective sorption of electrolyte and water is observed in moderately soluble polymers, e.g. ethylcellulose (solubility 2% by mass). Fig. 17 shows the variation in the concentrations of water and hydrogen chloride during the diffusion of the vapour from 28% hydrochloric acid in ethylcellulose films at 45°C. The active medium diffuses on a single front, but the concentration ratio of water and hydrogen chloride in the polymer is approximately ten times the ratio for the gaseous phase [150].

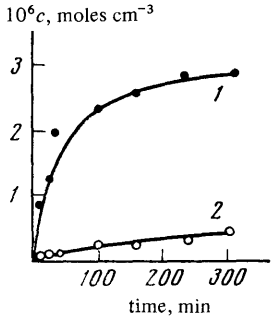

Figure 17. Variation in concentration during the diffusion of the vapour of 28% hydrochloric acid into an ethylcellulose film at 45°C: 1) H_2O; 2) HCl.

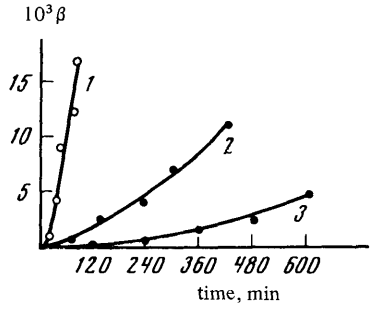

Figure 18. Time variation of degree of conversion β of ester bonds during degradation, in 53% sulphuric acid at 116°C, of poly(ethylene terephthalate) films varying in thickness (μm): 1) 5 ± 1; 2) 20 ± 2; 3) 80 ± 5.

Water and sulphuric acid diffuse at significantly different rates in sparingly water-soluble polymers, e.g. poly(ethylene terephthalate): the diffusion coefficient of water exceeds that of sulphuric acid by a factor of 10^5. [118,124] In the chemical degradation of polymers the rate of diffusion of the active medium is frequently comparable with the rate of the chemical reaction, and degradation takes place within a reaction zone whose size increases with time, ultimately reaching the size of the article. Fig. 18 illustrates the time dependence of the degree of conversion of ester bonds during the degradation of poly(ethylene terephthalate) films in 53% sulphuric acid at 116°C. [118,120,121] With a thin film (5 μm) the rate is constant after 30 min, since the acid has saturated the polymer. With films 20 and 80 μm thick the rate increases with time, as the quantity of acid in the films increases. The equations obtained kinetically permit quantitative prediction of the chemical stability of poly(ethylene terephthalate) over wide ranges of acid concentration, temperature, and time [118,120,121].

A correct interpretation of kinetic data for structurally non-uniform polymer materials requires information on the accessibility of functional groups. Hydrogen–deuterium exchange provides a convenient method for determining such accessibility in polymers having mobile hydrogen atoms [138-143]. The accessibility of amide bonds in polyhexanamide, for example, is a function of temperature (Fig. 19): at 150°C all such bonds, including those in crystalline regions, are accessible to hydrogen–deuterium exchange.

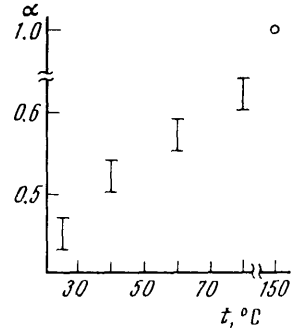

Figure 19. Temperature dependence of accessibility α of amide bonds in polyhexanamide films.

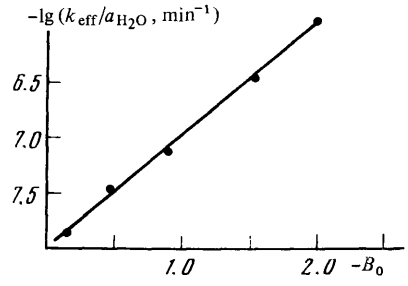

Figure 20. Dependence of $\lg(k_{eff}/a_{H_2O})$ on alkalinity function B_0 of aqueous potassium hydroxide for the degradation of poly(ethylene terephthalate) films 68 ± 2 μm thick.

In concentrated solutions the rate of chemical reaction far exceeds the rate of diffusion of molecules of the active medium into the polymer, and degradation takes place in a thin surface layer. An example is the breakdown of poly(ethylene terephthalate) film in aqueous alkalis [118,122,123].

The reaction is zero order with respect to the polymer, and the absence from the infrared multiple diffuse total internal reflection spectra of absorption bands due to decomposition products suggests that the depth of reaction approximates to a monolayer. Degradation of this type is characterised by two laws: (i) the effective rate constant is simply related to the thermodynamic parameters—the activity of water and the alkalinity function—of the aggressive medium (Fig. 20); and (ii) degree of crystallinity and orientation have hardly any effect on the kinetic parameters.

---o0o---

The results discussed above, obtained from kinetic studies of various types of polymer degradation (thermal, thermo-oxidative, photo-oxidative, and hydrolytic), apply to polymers in an unstressed state. This covers by no means all the degradation processes encountered in practice. Development of a theory of the degradation of polymeric materials in a stressed state is an urgent task of the science of polymer degradation.

Testing of Chemical Compounds as Stabilisers for Polymeric Materials

G.P.Gladyshev and V.F.Tsepalov

Test methods are briefly surveyed, a scheme of testing is examined, and experimental results obtained by means of the scheme are discussed. A list of 69 references is included.

I. INTRODUCTION

Most cases of the degradation of polymeric materials involve a free-radical chain mechanism; this enables the rate of degradation to be lowered substantially by introducing into the polymer a small quantity of a special substance to act as a stabiliser. The latter often functions either by deactivating the active radicals in the chain process or by decomposing intermediate products that provide a source of active radicals. In view of the continuous growth in the manufacture of various polymeric materials and substances for their stabilisation, the testing of chemical compounds as stabilisers has become an urgent problem.

On the basis of achievements of current research on the kinetics and the mechanism of chain processes a team including the Reviewers, headed by Academician N. M. Emanuel'[1-3] at the Institute of Chemical Physics of the USSR Academy of Sciences, has developed during recent years a set of methods for the rapid and reliable quantitative assessment of various chemical compounds as potential stabilisers for polymers whose degradation takes place by a free-radical chain mechanism. The scheme includes methods for preliminary assessment of effectiveness on model reactions (screening) and methods for the accelerated testing of compounds in polymers and polymeric materials.

II. PRELIMINARY ASSESSMENT BY MEANS OF MODEL REACTIONS

The testing of a chemical compound begins with a quantitative assessment of its chemical reactivity on model systems. Thus oxidative degradation is simulated by chain oxidation of simple compounds, whose mechanism has now been studied quite thoroughly[4-8]. The applicability of such reactions as models has a theoretical basis in the common mechanism of oxidation of organic compounds having low and high molecular weights[9-11]. In particular, peroxy-radicals function as active centres in these chain processes. The active centres in the thermal degradation of polymers are often alkyl radicals. Chain polymerisations, whose mechanism has also been thoroughly studied[12-19], are therefore used as models of thermal degradation.

The effectiveness of a chemical compound as a potential stabiliser is determined by its ability to slow down initiated chain oxidations[20,21] and polymerisations[21-23]. Various kinetic parameters, characterising such retardation, can be used as criteria of efficiency. Examples are the ratio of the rates of reaction in the absence and in the presence of the test compound, the decrease in the extent of the process (yield of polymer), etc.

Initiated oxidations and radical polymerisations can be represented by the simple scheme

(A) Chain initiation; W_i — rate of initiation , (1)

(B) Chain propagation: $R_1H + n_1 \xrightarrow{k_{p11}} n_1 +$ Product , (2)

(C) Chain termination: $2n_1 \xrightarrow{k_{t11}}$ Inactive products , (3)

where R_1H is the hydrocarbon or the monomer, n_1 is an active centre, and k_{p11} and k_{t11} are the rate constants of chain propagation and termination respectively. For sufficiently long chains the rate of the process is given by the equation

$$W = W_i^{1/2} \frac{k_{p11}}{k_{t11}^{1/2}} [R_1H]. \quad (4)$$

A more general scheme for a chain process in the presence of a substance R_2H (which may be a stabiliser) can be written

(A) Chain initiation; W_i — rate of initiation ,

(B) Chain propagation:
$R_1H + n_1 \xrightarrow{k_{p11}} n_1 +$ Product ,
$R_1H + n_2 \xrightarrow{k_{p12}} n_1 +$ Product ,
$R_2H + n_1 \xrightarrow{k_{p21}} n_2 +$ Product ,
$R_2H + n_2 \xrightarrow{k_{p22}} n_2 +$ Product ,

(C) Chain termination:
$2n_1 \xrightarrow{k_{t11}}$ (5)
$n_1 + n_2 \xrightarrow{k_{t12}}$ Inactive products . (6)
$2n_2 \xrightarrow{k_{t22}}$ (7)

The rates of the chain conversion of each substance and the overall rate of the process are described by the well known formulae for rates of co-oxidation and copolymerisation. These rates depend on the concentrations of R_1H and R_2H and the rate constants of chain propagation and termination. At low concentrations of R_2H (stabiliser

concentrations usually amount to 0.1–2%) the chain process is slowed down provided that[24]

$$\frac{k_{t12}}{k_{t11}} \cdot \frac{k_{p21}}{k_{p12}} - 2\frac{k_{p21}}{k_{p11}} > 1 .$$

Thus retardation depends on the choice of model reactions (rate constants k_{p11} and k_{t11}) and also on the three primary reactions involving R_2H and the radical formed from it. The greatest retardation is produced by substances that react rapidly with active centres (high rate constant k_{p21}) and by those from which unreactive radicals are formed (low rate constant k_{p12}).

If the additive is an inhibitor, i.e. if the radicals formed from it are inactive, we have $k_{p12} = 0$, and retardation of the chain process becomes indefinitely large. An expression for the rate of consumption of R_1H in an inhibited chain process (with $k_{p12} = 0$ and $k_{p22} = 0$) can be obtained only by making certain assumptions about the chain-terminating reactions[25]. The simplest formula is obtained by neglecting reaction (5)—quadratic termination of active centres n_1 (all active centres react with the inhibitor):

$$W_{inh} = W_i \frac{k_{p11}}{k_{p21}} \cdot \frac{(R_1H)}{(R_2H)}, \qquad (8)$$

where the inhibition coefficient $f = 1-2$ depending on the relative rates of reactions (6) and (7)†. From Eqns. (4) and (8) we find that

$$\frac{W}{W_{inh}} = \frac{f k_{p21} \cdot (R_2H)}{k_{t11}^{1/2} \cdot W_i^{1/2}} \qquad (9)$$

Thus the effect of inhibitors on the chain process is determined by the rate constant k_{p21} for reaction between inhibitor and active centre. Formula (9) can be used in many cases to assess the chemical activity of test compounds (various derivatives of amines, phenols[26], and other compounds that inhibit chain processes usually serve as stabilisers).

The rate constant k_{p21} is usually denoted by k_7 in oxidations and by k_Z in polymerisations. The nature of the oxidisable substance (the radical R·) has a slight effect on k_7.[25,27,28] A correlation may therefore be reasonably expected between this constant k_7 and the stabilising effect of the test compound. Such a correlation has indeed been established for several phenols: the more readily the peroxy-radical of tetralin abstracts the hydrogen atom from the phenol (the higher the value of k_7) the more efficient is the phenol as an antioxidant for rubber[20].

Since the reactivity of an inhibitor towards a free radical is determined by the ease of abstraction of a labile hydrogen atom, those inhibitors that are active towards alkyl radicals may be active also towards peroxy-radicals. This suggestion is supported by published results[22,23].

A most important characteristic of stabilisers against oxidative degradation is their ability to decompose hydroperoxides by a molecular mechanism. The primary product of the oxidation of an organic compound is usually a hydroperoxide, which breaks down slowly into radicals capable of initiating oxidation chains, so that oxidation proceeds autocatalytically. Decomposition of the hydroperoxide by a stabiliser prevents such autocatalysis. The efficiency of a stabiliser can conveniently be assessed on a model reaction with a simple hydroperoxide (of cumene, tetralin, etc.). A correlation was shown[22] between the half-decomposition time of cumene hydroperoxide and the induction period in the oxidation of rubbers in the presence of various antioxidants. Another important parameter is the yield of radicals per hydroperoxide molecule decomposed. Increase in the rate of breakdown should be accompanied by a decrease in this yield: otherwise the test compound will catalyse the chain degradation.

The efficiency of a chemical compound in decomposing a hydroperoxide can be assessed quantitatively by two parameters—the ratios of reaction velocities and of yields of radicals in the absence and in the presence of this compound:

$$\frac{W}{W_x} < 1; \quad \frac{e}{e_x} = \frac{W_i/W}{W_{ix}/W_x} > 1$$

where W and W_X, W_i and W_{iX}, and e and e_X are the rates of breakdown, the rates of formation of radicals, and the yields of radicals in the absence and in the presence of the test compound respectively. The rate of decomposition can be determined by measuring by iodometric titration the decrease in the concentration of hydroperoxide with time. The method of inhibitors[29] (based on the induction period) or the chemiluminescence method[25] can be used to determine the rate of formation of radicals.

The effectiveness of a stabiliser is not always determined completely by its ability to terminate chains and to decompose hydroperoxides by a molecular mechanism. Its efficiency is diminished also by reaction of an inhibitor radical with a hydroperoxide molecule

$$ROOH + \dot{In} \xrightarrow{k_{-7}} R\dot{O}_2 + InH . \qquad (10)$$

The role of this reaction will be significant if[30]

$$k_{-7} \cong \frac{2k_7k_8[InH]}{k_6[ROOH]}, \qquad (11)$$

where $k_8 = k_{t12}$ and $k_6 = k_{t11}$. In the oxidation of tetralin (at 65°C) the rate constant k_{-7} reaches 10^4 M^{-1} s^{-1} for several aromatic phenols[31]. It can be shown that Eqn. (11) is satisfied with such values of k_{-7}. The role of reaction (10) can be assessed if the model oxidation is conducted in the presence of a certain quantity of a hydroperoxide.

The relative simplicity of the procedures and the possibility of evaluating rate constants enable model reactions to be used for the rapid quantitative assessment of various classes of compounds as potential stabilisers[20-23,32]. In several cases model reactions made it possible to establish the mechanism of the action of antioxidants[28,33,34] and to elucidate the nature of synergism[33,35,36].

The above advantages of model reactions of simple compounds are accompanied by the substantial defect of not reflecting the specific character of processes occurring in macromolecular compounds. Unfortunately, the mechanism of the degradation of polymers has not yet been sufficiently studied to enable these processes to be used as models. The initiated oxidation of molten polyethylene of low molecular weight[37] and that of solid isotactic polypropylene[38] have been most thoroughly studied in this respect. Kinetic results obtained in this work can be used to assess the effectiveness of compounds as stabilisers. Radical polymerisation at high degrees of conversion can be used as macromolecular model reaction with an active centre (the radical R·) to assess the efficiency of thermostabilisers[18,39].

III. ACCELERATED TRIALS OF STABILISERS

Although model reactions and reactions in polymers have much in common, stabilisers selected on the basis of model reactions require further verification of their

† The coefficient f may vary within wider limits, e.g. with inhibitors containing several functional groups.

effectiveness in the polymers themselves or in polymeric materials. This is because the efficiency of a stabiliser in a polymer is appreciably determined by several additional physicochemical factors, the most important of which are (i) the chemical stability of the stabiliser itself (with respect to the action of heat, oxygen, certain additives, etc.), (ii) the compatibility of the stabiliser with the polymer, and (iii) the effect of the solid phase on the reactivity of the stabiliser. The best method for finally assessing the efficiency of a stabiliser is, of course, to test it in the polymer under service conditions. In many cases, however, such trials last an extremely long time (for months and even years). This period can be shortened either by raising the temperature (in the cases of thermal and oxidative degradation) or by increasing the pressure of oxygen (in the case of oxidative degradation)[20].

Since polymers and polymeric materials are complicated systems, the effectiveness of stabilisers in accelerated trials is determined by the use of general mechanical and physicochemical parameters to characterise the progress of degradation. The former include elasticity, strength, etc. Among physicochemical parameters we may note viscosity and solubility, quantity of oxygen absorbed and induction period, decrease or increase in weight, thermal effects, and change in pressure caused by the evolution of simple degradation products. Definite interrelationships should clearly exist in the variation of these parameters during degradation. In the thermo-oxidative degradation of polypropylene, for example, the rate curves for viscosity, breaking load, elongation, and oxygen absorption are of the same type[40], with the most rapid changes in these parameters occurring simultaneously.

Thus two sets of methods—preliminary assessment of effectiveness in model reactions and accelerated trials in polymers—are used to test chemical compounds as stabilisers. Both sets of methods should be quite rapid, and they should give mutually consistent results for assessing the efficiency of the stabilisers and ascertaining the mechanism of their stabilising effect.

IV. SCHEME OF TESTING

It is advisable to use the well studied polymerisation of styrene and oxidation of cumene as model reactions. The rate of initiation by azoisobutyronitrile (Aibn) is calculated by means of the formula

$$W_i = ek_d[\text{Aibn}],$$

where the rate of decomposition of the initiator

$$k_d = 1.58 \times 10^{15} \exp(-30800/RT)$$

varies slightly with the nature of the solvent[41,42]‡. The yield of radicals e is close to 1.2 for aromatic hydrocarbons[43]; its values for styrene and cumene are respectively 1.1–1.2 [44,45] and 1.1,[29] and we can adopt with sufficient accuracy $e \simeq 1.1$ for both compounds§.

‡ This value of the rate constant is identical with the average value in aromatic solvents[27].

§The yield of radicals for cumene varies[29] from 1.0 to 1.25 with rise in temperature from 40 to 80°C (the temperature range normally employed for azoisobutyronitrile as initiator), so that the average value of the yield 1.1 can be adopted for all temperatures.

The method of purification described in Ref. 46 was used for styrene, and those of Ref. 42 for cumene and azoisobutyronitrile. Cumene hydroperoxide free from inhibiting impurities can be prepared relatively simply[47]. The rates of reaction of the purified specimens should approximately satisfy Eqn. (4). The rate constants of chain propagation and termination have the values—for styrene¶

$$k_{p11} = k_p = 10^{5.7} \exp(-6000/RT)\ \text{M}^{-1}\,\text{s}^{-1};$$

$$k_t = k_0 = 10^{7.9} \exp(-2000/RT)\ \text{M}^{-1}\,\text{s}^{-1};$$

and for cumene[48]†

$$k_{p11} = k_3 = 10^{6.67 \pm 0.34} \exp[-(9800 \pm 400)/RT]\ \text{M}^{-1}\,\text{s}^{-1};$$

$$k_t = k_6 = 10^{9.2 \pm 0.3} \exp[-(6000 \pm 300)/RT]\ \text{M}^{-1}\,\text{s}^{-1};$$

The rate of polymerisation of styrene can conveniently be determined dilatometrically[18], and the rate of oxidation of cumene from the absorption of oxygen[20,49]. Previous studies[47,50] have shown that the rate of decomposition of cumene hydroperoxide (at relatively low concentrations [ROOH] < 0.1 M) into cumene and the rate of breakdown into radicals can be calculated by means of the formulae

$$W = k_d \cdot [\text{RH}][\text{ROOH}],$$

$$W_i = k_i[\text{RH}][\text{ROOH}],$$

where

$$k_d = 1.1 \times 10^8 \exp(-25400/RT)\ \text{M}^{-1}\,\text{s}^{-1},$$

$$k_i = 10^8 \exp(-26200/RT)\ \text{M}^{-1}\,\text{s}^{-1}.$$

Thus two of the four reaction velocities required to characterise the ability of a test compound to decompose the hydroperoxide can be calculated (in the absence of the test compound) from published data.

The oxidation of molten polyethylene and solid isotactic polypropylene can be used as polymeric model reactions of oxidative degradation. In molten polyethylene the cumene peroxide used as initiator decomposes into radicals over the temperature range 110–145°C with[37]

$$k_i = 10^{13.5 \pm 1.0} \exp[-(32000 \pm 2000)/RT]\ \text{s}^{-1}.$$

The rate constant determined[51] in solid polypropylene at 114°C was identical with the value[52] in solid polyethylene at this temperature. It may be postulated that the rate constants for breakdown into radicals coincide over the temperature range 114–128°C, for which it was found in polyethylene that

$$k_i = 8.5 \times 10^{15} \exp(-37500/RT)\ \text{s}^{-1}.$$

Specimens of polyethylene and polypropylene purified as in Refs. 37 and 52 had the following relations between propagation and termination rate constants—for polyethylene[37]

$$k_3/k_6^{1/2} = 10^{2.7 \pm 0.5} \exp[-(11000 \pm 1000)/RT]\ \text{M}^{-1/2}\,\text{s}^{-1/2}.$$

and for polypropylene[38]

$$k_3/k_6^{1/2} = 2.7 \times 10^6 \exp(-13500/RT)\ \text{M}^{-1/2}\,\text{s}^{-1/2}.$$

Rates of oxidation of polyethylene and polypropylene are determined from the absorption of oxygen[37,38].

The model chain reactions—the polymerisation of styrene and the oxidation of cumene, molten polyethylene,

¶ Calculated from results obtained by Bamford, Dewar, and Burnett, cited in Ref. 15.

† Rate constants for cumene taken from Ref. 48 coincide within the limits of accuracy indicated with the constants obtained by other workers[27].

and solid polypropylene—can be represented by the same general scheme (reactions 1–3), so that the same criteria are used to assess the effectiveness of test compounds. A general criterion is the ratio W/W_X of the reaction velocities in the absence and in the presence of the compound. For inhibitors this ratio is related to the kinetic parameters of the model reactions by Eqn. (9). The minimum value at which the test compound is a potential stabiliser can be taken as $fk_{p21} = 100\ M^{-1}\ s^{-1}$, which is roughly 10% of the inhibition rate constants for weak inhibitors[14,27]. Antioxidants possessing little inhibiting activity may be of interest if they decompose hydroperoxides as well as terminating chains[33].

Quantitative assessment of thermostabilisers can be based on the macromolecular polymerisation of methyl methacrylate and acrylonitrile to high degrees of conversion[39], at which the lifetimes of the radicals R· amount to tens of minutes. Thus a certain concentration of these radicals can be produced relatively simply (by photoinitiation and by thermal initiation), and then the kinetics of their decay on the test compound

$$-\frac{d[R^{\cdot}]}{dt} = k_z[R^{\cdot}][InH].$$

can be observed. Integration of this equation yields

$$\ln\frac{W_0}{W} = k_z[InH]t, \qquad (12)$$

in which W_0 is the rate of the reaction in the absence of the test compound and W the rate of reaction at time t after cessation of initiation. This shows that the inhibition rate constant k_Z can be determined directly from the measured reaction rates W and W_0. The techniques of the accelerated testing of polymers have been described in the literature[3,20,21,53–58].

V. EXPERIMENTAL RESULTS OBTAINED BY TEST SCHEME

The effectiveness of a series of stabilisers can be compared from experimental results obtained from model reactions on simple compounds and from accelerated tests on polymers[2]. Table 1 lists data on the oxidation of molten polyethylene and on the polymerisation of styrene in the presence of four stabilisers. The sequence of inhibiting effects is maintained, although the stabilisers interact with different active centres in each model reaction.

Table 1. Inhibiting effect W/W_X of stabilisers in the oxidation of molten polyethylene and the polymerisation of styrene*.

Stabiliser	Oxidation of molten polyethylene at 135°C (10^7W_i = 4.6 M s^{-1}) initiated by dicumenyl peroxide	Polymerisation of styrene in presence of oxygen at 100°C (10^7W_i = 4.4 M s^{-1}) initiated by butylphenyltriazen	Polymerisation of styrene at 100°C (10^7W_i = 4.4 M s^{-1}) initiated by butylphenyltriazen
Diphenylamine	2	1.5	1.0
Phenyl-2-naphthylamine (Neozone D)	10	4	1.2
2,6-Di-t-butyl-4-methylphenol (Ionol)	>100	>50	10
Methylenebis-2-(6-t-butyl-4-methylphenol (2246)	>100	>50	10

* When styrene undergoes polymerisation in the presence of oxygen, most of the R· radicals are converted into RO_2· radicals.

Table 2 gives data on the inhibiting effects of three stabilisers, obtained in a model reaction and in accelerated trials on rubbers. Stronger chain-reaction inhibitors produce longer induction periods in the oxidation of the rubber. It is evident also that the peak on the differential thermal analysis curve undergoes a larger displacement to higher temperatures in the presence of a stronger stabiliser (*NN'*-diphenyl-*p*-phenylenediamine). Thus results obtained on a model reaction agree well with those of accelerated trials of these stabilisers on polymers.

Table 2. Comparison of inhibiting effects of stabilisers on a model reaction and in accelerated tests on polymers.

Stabiliser	W/W_X in polymerisation of styrene in presence of oxygen at 100°C (10^7W_i = 4.4 M s^{-1}) initiated by butylphenyltriazen	Induction period in the oxidation of SKS-30ARK rubber at 130°C, min	Shift ΔT of peak on d.t.a. curve for SKD rubber
2,6-Di-t-butyl-4-methylphenol (Ionol)	>50	760	–
NN'-Diphenyl-*p*-phenylenediamine	50	390	83
Phenyl-2-naphthylamine (Neozone D)	4	200	9

Table 3. Comparison of rates of decomposition of cumene hydroperoxide for several stabilisers with their antioxidant behaviour in rubber.

Stabiliser	Ratio W_XW of rates of decompn. of cumene hydroperoxide in presence and in absence of stabiliser at 130°C	Induction period in oxidation of SKI–3 rubber at 130°C
NN'-Di-2-naphthyl-*p*-phenylenediamine (Age-Rite White)	1.0	900
NN'-Diphenyl-*p*-phenylenediamine	1.1	900
N-Isopropyl-*N'*-phenyl-*p*-phenylenediamine (4010)	1.8	780
Methylenebis-2-(6-t-butyl-4-methylphenol) (2246)	3.0	360
Trisnonylphenyl phosphite (Polyguard)	30	48

Table 3 compares data on the rates of decomposition of cumene hydroperoxide in the presence of several stabilisers with their effectiveness (based on the induction period) as antioxidants for rubber. This induction period is found to decrease with increase in the rate of decomposition of the hydroperoxide. The stabilising effects of these compounds are evidently based solely on the ability to terminate chains in the oxidation of rubber. In respect of hydroperoxide decomposition the compounds are catalysts of rubber oxidation. For this reason methylenebis-2-(6-t-butyl-4-methylphenol) is a weaker stabiliser (according to the induction period) than is *NN'*-diphenyl-*p*-phenylenediamine, in spite of having a larger inhibition parameter in the model polymerisation of styrene (Tables 1 and 2).

Thus the experimental results obtained in the above scheme of testing show good correlation between test data on model reactions and accelerated trials of chemical compounds on polymers. This permits the use of model

reactions for the rapid selection of potential stabilisers from a large number of test compounds. Furthermore, as already noted, model reactions yield information on the mechanism of the stabilising effect in terms of primary reactions.

The results indicate also a correlation between accelerated trials on stabilisers and their stabilising effects in polymers under natural conditions. Thus the test results show that derivatives of *p*-phenylenediamine should be most effective antioxidants, as is indeed observed with most rubbers[22].

VI. QUANTITATIVE RESULTS ON ANTIOXIDANT STABILISERS OBTAINED BY MEANS OF MODEL REACTIONS

Consideration has been given[3] to optimum reaction conditions for the model initiated oxidation of cumene permitting by means of Eqn. (9) the evaluation of fk_7 (fk_{p21}) in the range 10^2–10^5 M^{-1} s^{-1} at 40, 60, and 80°C. If the stabiliser is an inhibitor and is consumed only in terminating chains, the duration of its action (the induction period) is

$$\tau = \frac{f\,[\mathrm{InH}]}{W_i} \quad . \tag{13}$$

This formula can be used to find the coefficient f from the experimental induction period. For any time t we can write

$$\frac{f\{[\mathrm{InH}]_0 - [\mathrm{InH}]\}}{W_i} = t \quad . \tag{14}$$

Substituting in (8) for [InH] from (14) and integrating, we obtain for the early stages of conversion the relation[59]

$$\frac{[O_2]}{[RH]} = -\frac{k_3}{k_7}\ln\left(1 - \frac{t}{\tau}\right), \tag{15}$$

where k_3 (k_{p11}) is the rate constant of chain propagation.

* Experiments made in chlorobenzene with an equal volume of ethylbenzene.

Investigation of several known stabilisers in the model oxidation of cumene established that the rate curves for the absorption of oxygen in their presence are well linearised when plotted in the coordinates of Eqn. (15). This implies that the stabilisers inhibit the reaction in conformity with the simple scheme considered above‡. Hence the coefficients f and the inhibition rate constants can be determined by means of Eqns. (13) and (15). Table 4 lists values of k_7 and f for the stabilisers studied (rate constants were computed per inhibiting group). It includes for comparison values of k_7 obtained for various antioxidants on reaction with peroxy-radicals of ethylbenzene[61], styrene, and tetralin[27,*]. The inhibition coefficient f per independent inhibiting group is ~2 for all the stabilisers. This means that radicals formed from antioxidants react only with peroxy-radicals of cumene and do not interact.

Comparison of the rate constants for the reaction of any one inhibitor (2,6-di-t-butyl-4-methylphenol, its three derivatives in which the 4-methyl has been replaced by cyano, chloro, and methoxy; tri-t-butylphenol, *N*-phenyl-2-naphthylamine, 1-naphthol, or quinol) with various peroxy-radicals shows that k_7 is almost independent of the structure of the latter, as already noted above. The maximum difference does not exceed a factor of two, which may be largely due to experimental error, since the values of k_7 under comparison were obtained by different methods. Such independence of k_7 is of great interest in connection with testing, since it permits the choice of model reactions that have been most thoroughly studied and that are simplest to conduct.

Comparison of the rate constants k_7 for *para*-substituted 2,6-di-t-butylphenols shows a slight variation in reactivity of the inhibitor with the structure of the substituent provided that the latter contains an alkyl group directly attached to the benzene ring. The maximum deviation from the mean rate constant ($10^{4.30}$ at 60°C) does not exceed 30–70%. With the peroxy-radicals of cumene and ethylbenzene, for which rate constants have been determined most accurately, the maximum deviation from the mean ($10^{4.27}$) does not exceed 25%. Inspection of published data[27] shows that the rate constants k_7 obtained for various peroxy-radicals and derivatives of phenol having analogous *para*-substituents also have closely

‡This result is not self-evident, since inhibited oxidation has in general a complicated mechanism. A detailed survey has been made[60] of the general scheme of inhibited oxidation and published experimental results.

similar values (independently of other alkyl substituents). Only 7 of the 60 values of k_7 cited in Ref. 27 exhibit deviations from the mean exceeding a factor of 2.5, and the mean rate constant ($10^{4.35}$ at 60°C) is almost identical with the mean for 2,6-di-t-butylphenol derivatives.

Considerable variation in the rate constant k_7 is observed only in the presence of strong electron-donating or -accepting substituents[61]. Thus the σ-constants for 4-methoxyl, 4-cyano, and 4-methyl are respectively −0.776, +0.628, and −0.170. According to Table 4 the rates of reaction of the peroxy-radical of ethylbenzene with 2,6-di-t-butylphenol containing in the 4-position respectively hydroxymethyl, methyl, and cyano are in the ratios 100 : 10 : 1. Jaffe's well known review[62] gives σ-constants for many *p*-alkyl substituents and for various *para*-substituents with the alkyl directly attached to the benzene ring. The maximum difference in the σ-constants of these substituents does not exceed 0.5, which corresponds to an approximately sixfold difference in rate constants k_7 or a deviation from the mean by a factor of 2.5.

Thus the variation in the σ-constants for derivatives of phenol *para*-substituted with groups having weak donor–acceptor properties corresponds on the whole to the variation in the rate constants k_7. It is noteworthy that the pre-exponential factors in the inhibition rate constants are almost identical within the limits of experimental accuracy independently of the structure of the peroxy-radical or the nature of the antioxidant. Thus in reactions with peroxy-radicals of cumene and of ethylbenzene these factors are respectively $10^{7.21\pm0.11}$ and $10^{7.25\pm0.27}$. We can write for both series the general formula

$$k_7 = 10^{7.23\pm0.19}e^{-E/RT} \qquad (16)$$

for the inhibition rate constant, where 0.19 gives the standard deviation. We can use (16) to determine the activation energy if we know the rate constant at a single temperature; an error of a factor of two in this rate constant gives an error in the activation energy of only ±0.5 kcal mole^{-1}. Twelve inhibition rate constants are known[27] for the reaction of phenols with various peroxy-radicals. The mean pre-exponential factor in these constants is $10^{7.20}$, which coincides within the limits of experimental accuracy with the above value in Eqn. (16). This fact strongly suggests that experimental error is responsible for the compensating effect in these reactions observed between the pre-exponential factor and the activation energy[27], reaching 2 kcal mole^{-1} (more than a factor of ten in the pre-exponential factor).

Table 5. Rate constants of gas-phase radical substitutions involving relatively large radicals and molecules.

Reaction	Pre-exponential factor, lg (A, M^{-1} s^{-1})	E, kcal mole^{-1}
$NO+O_3 \rightarrow NO_2+O_2$	8.83±0.15	2.45±0.17
$C_2HCl_4+Cl_2 \rightarrow C_2HCl_5+Cl$	8.71±0.03	5.15±0.03
$C_2H_3Cl_2+Cl_2 \rightarrow C_2H_3Cl_3+Cl$	8.78±0.03	0.96±0.04
$CH_3+CH_3CHO \rightarrow CH_4+CH_3CO$	8.86±0.16	7.50±0.30

Hardly any sufficiently accurate data have yet been published on rate constants for other radical substitutions in the liquid phase. Only two rate constants of chain propagation can be cited, for the liquid-phase oxidation of cumene and ethylbenzene: the first was given[48] as $10^{6.67\pm0.26}\exp[-(9800\pm400)/RT]$; the second can be obtained from the refined value[63] of the recombination rate constant for peroxy-radicals of ethylbenzene[61] as $10^{6.64\pm0.24}\exp[-(9550\pm360)/RT]$. The two constants have the same pre-exponential factor, differing from that in formula (16) by only slightly more than the experimental error.

A considerably greater quantity of accurate data are available on rate constants for radical substitution in the gas phase[64]. Table 5 gives the most accurate values for reactions involving relatively large radicals and molecules. The pre-exponential factors evidently coincide within the limits of experimental accuracy. The rate constant can in general be written

$$k = 10^{8.80\pm0.07}e^{-E/RT}. \qquad (17)$$

If the frequency of collisions in the gas is taken to be 2×10^{11} M^{-1} s^{-1},[65] the steric factor becomes 0.003. If we write the reaction rate constant in the logarithmic form

$$E = \theta \lg A - \theta \lg k, \qquad (18)$$

where $\theta = 0.004575\,T$ kcal mole^{-1}, and compare the resulting expression with the well known Polanyi–Semenov relation

$$E = B \pm \alpha Q,$$

we obtain, with a constant pre-exponential factor, the general formula

$$k = Ae^{-\frac{B}{RT}}e^{\pm\frac{\alpha Q}{RT}}, \qquad (19)$$

for the rate constant, where $A\exp(-B/RT)$ is the exchange rate constant ($Q = 0$). The relation linking the rate constant with the heat of reaction may be satisfied for reactions in which the pre-exponential factor and the coefficient α are constant. For a series of reactions involving the same radical, with the resonance energy of the radicals neglected, Eqn. (19) can be written in the form

$$\pm(D_0 - D) + \frac{\theta}{\alpha}\lg k - \frac{\theta}{\alpha}\lg k_0 = 0, \qquad (20)$$

where D and D_0 are the bond energies for the abstractable atom in the series of reactions and for exchange ($Q = 0$) in this series, and k_0 is the exchange rate constant. It follows from (20) that a linear dependence should exist between the logarithm of the rate constant and the bond energy. This is supported by published data.

The diagram illustrates results obtained[61] for the rate constants of reactions of the peroxy-radical of ethylbenzene with sterically hindered phenols (Table 4) and the energies of the hydrogen–oxygen bond in the latter (line *1*), together with corresponding results for reactions of the sodium atom with chlorinated methanes (involving detachment of a chlorine atom and formation of sodium chloride) (line *2*), reaction rate constants for the latter series and carbon–chlorine bond energies being taken from Refs. 64 and 66. Both series comprise exothermic reactions, so that formula (20) becomes

$$D = D_0 - \frac{\theta}{\alpha}\lg k + \frac{\theta}{\alpha}\lg k_0. \qquad (21)$$

The diagram shows good agreement between experimental results and Eqn. (21). The slopes of the straight lines show that α has the values 0.40 and 0.65 for reactions of the peroxy-radical with phenols and for those of sodium with chlorinated methanes respectively. The intercepts made on the D-axis give bond energies of 94 and 96 kcal mole^{-1}: the former is close to the estimate[8] of 90 kcal

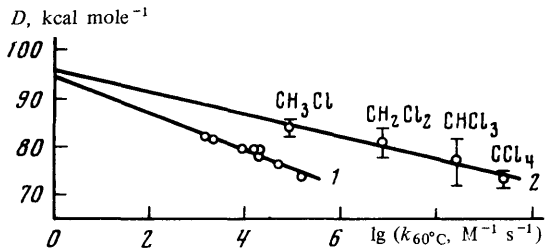
mole^{-1} for the hydrogen–oxygen bond energy in ethylbenzene hydroperoxide; the latter is almost identical with the sodium–chlorine bond energy[66] of 97.6 kcal mole^{-1}. These facts suggest that the exchange rate constants at 60°C for

$$RO^{\cdot}_2 + ROOH \rightarrow ROOH + RO^{\cdot}_2$$

and

$$Na + NaCl \rightarrow NaCl + Na$$

differ insignificantly from unity.



Linear relation between logarithm of rate constant at 60°C and bond energy of atom abstracted for series of radical substitutions of the same type: 1) liquid-phase reactions of the peroxy-radical of ethylbenzene with *para*-substituted 2,6-di-t-butylphenols; 2) gas-phase reactions of the sodium atom with chlorinated methanes.

Not all radical substitutions involving relatively large species have the above constant pre-exponential factors. In the liquid phase, for example, the rate constants for reaction of the diphenylpicrylhydrazyl radical with phenols[67] have factors of $10^{3.8-4.5}$, only one-thousandth of that in Eqn. (16). A low pre-exponential factor ($10^{3.2}$) is observed also in exchanges between sterically hindered phenoxy-radicals and phenols[67]. The low values evidently cannot be attributed to experimental error.

VII. QUANTITATIVE ASSESSMENT OF INHIBITORS IN VARIOUS COMPOSITIONS

Methods for the preliminary assessment of inhibitors on model reactions may be of general interest, since the kinetic characteristics obtained for the test compounds may be used in the investigation of chain processes occurring in hydrocarbons, foodstuffs, liquid perfumes, animal organisms, and plants. In the investigation of various compositions containing inhibiting agents it is possible to estimate the concentration of the inhibitor, establish the mechanism of its action, and determine the inhibition rate constant. Inhibitors present in lipid extracts of leaves and in petroleum have been analysed by means of the model oxidation of cumene[68,69]. Two inhibitors have been found in plants, with inhibition rate constants k_7 of 4000 and 120 000 M^{-1} s^{-1}; the second appears in the plant as winter approaches. The concentration of inhibitor—more precisely the value of $f[InH]$—in the dry extract is 0.06–0.3 mole kg^{-1}. Analysis of Western Siberian petroleum reveals four inhibitors, having inhibition rate constants of (30, 7.6, 1.4, and 0.73) $\times$ 10^4 M^{-1} s^{-1} and corresponding values of $f[InH]$ of 0.020, 0.015, 0.015, and ~0.015 mole kg^{-1}; the first three of these inhibitors are found in the asphaltenes, and the fourth occurs in the tars.

Thus both foliage and petroleum contain relatively high concentrations (0.01–0.1 mole kg^{-1}) of inhibitors. The most effective of these (with an inhibition rate constant of ~10^5 M^{-1} s^{-1}) can be assigned to the class of strongest inhibitors—antioxidants.

Phenols as Sources of Radicals in Biochemical Systems

L.S.Vartanyan

The principal radical products of the initial stages of the autoxidation of phenols in polar media are examined. Attention is concentrated on the characteristics of superoxide radicals in connection with their toxic properties and important role in certain biochemical processes. The possible contribution of the radical products of the autoxidation of phenols to the mechanism of their antitumour activity is discussed.
The bibliography includes 209 references.

I. INTRODUCTION

In 1956–1957 Emanuel' put forward for the first time the hypothesis that, in principle, inhibitors of radical reactions might be used to treat certain diseases, the occurrence and the development of which may be attributed to either the appearance of free radicals which are not characteristic of the organism under normal conditions or to the breakdown of the regulation of the radical reactions occurring in the organism under the conditions of normal metabolism[1–4]. The limitations associated with toxicity led to the isolation of relatively non-toxic alkylphenols and certain polyphenols and hydroxypyridines from the large group of compounds known in chemistry as inhibitors. Comprehensive studies have been made on the carcinolytic and antitumour activities of these substances under Emanuel''s supervision.

Considerable experience has been gained in modern biochemistry concerning studies on the metabolism and physiological activities of natural and synthetic phenols in the living organism. The results of this research have been compiled mainly in a series of collected volumes and monographs[5–8]. Among the pharmacological preparations used at present, phenolic compounds are widely represented. However, it is by no means always possible to discover any relation between the pharmacological activity of a preparation and the presence of a phenolic hydroxyl in its molecule.

A significant fraction of the radicals arising in the organism under normal conditions appears to comprise radical intermediates formed from the cofactors of oxidation-reduction enzymes in the process of their functioning. In the majority of the enzymes such radicals are firmaly bound to the active centres, as a result of which they are incapable of participating in non-specific free-radical reactions. However, the formation of superoxide radicals—the products of one-electron reduction of oxygen capable of initiating chain reactions in solution—has been demonstrated in a number of enzyme systems[9]. Such systems are apparently of interest from the standpoint of the possibility of inhibiting their action with the aid of free-radical reaction inhibitors.

The ability of phenols and other compounds to inhibit free-radical reactions is known to be associated with the presence in their molecules of a relatively weak bond (60–70 kcal mole^{-1}) which enables the inhibitor to participate readily in exchange reactions with the system radicals to form inactive radicals[10,11]. Emanuel' and coworkers[12] showed that the radicals arising in proteins under the influence of radiation can react in a similar manner directly with an inhibitor molecule, forming an inhibitor radical.

On the other hand, owing to the presence of the weak bond, the inhibitor readily undergoes autoxidation. Free radicals, which can react with cell components, damaging them, and can be involved in metabolic processes, arise in the system under these conditions. The present review deals with this aspect of the action of phenolic inhibitors of free-radical reactions.

II. RADICAL PRODUCTS OF THE AUTOXIDATION OF PHENOLS IN POLAR MEDIA

The formation of relatively stable semiquinone radical-anions is characteristic of the oxidation of phenols in polar media. As in other radical reactions of phenols, the autoxidation process involves a rearrangement of the aromatic bond systems into a quinolid system with formation of cyclohexadienones (phenol–dienone rearrangements) and conversely dienone–phenol rearrangements also take place. The intermediate molecular autoxidation products (quinones) accelerate the oxidation process, the rate of which at advanced stages is determined by the characteristics of the reduction of the quinone[13–15]. The main radicals formed in the initial stages of the autoxidation of phenol are phenoxy-radicals PhO$^{\cdot}$, superoxide radical-anions $O_2^{\cdot-}$ and semiquinones $SQ^{\cdot-}$.

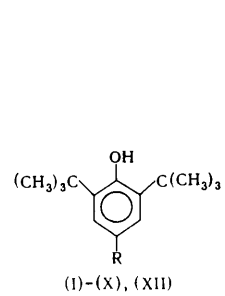
1. Phenoxy-radicals and Semiquinones in Autoxidation Processes

The autoxidation of phenols in alkaline media apparently begins with the fundamental reaction

$$PhO^- + O_2 \rightarrow Ph\dot{O} + O_2^{\cdot-} . \qquad (1)$$

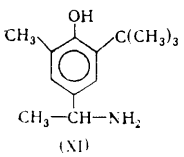
In view of the short lifetime of phenoxy-radicals in polar media[16,17], they cannot be detected by ESR under static conditions.

The kinetics of the autoxidation of sterically hindered phenols with electron-donating substituents in the *p*-position have been studied for phenols (I)–(XI).

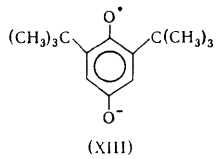


(I)–(X), (XII)

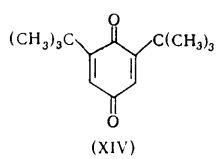
(I) R = H
(II) R = C_2H_5
(III) R = $CH_2CH(CH_3)_2$
(IV) R = CH_2Ph
(V) R = CH_3OCH_3
(VI) R = $CH_2OC_2H_5$
(VII) R = $CH_2N(CH_3)_2$
(VIII) R = $CH_2N(C_2H_4OH)_2$
(IX) R = CH_2NH_2
(X) R = CH_3CHNH_2
(XII) R = Ph



(XI)



(XIII)



(XIV)

In the oxidation of these phenols by molecular oxygen under static conditions in an aqueous alcoholic alkaline solution a radical having a triplet ESR spectrum with a splitting of 1.2–1.4 G and intensity ratios of 1 : 2 : 1 was detected. The structure of the spectrum persisted for a long time (tens of minutes) in the absence of oxygen. The kinetics of the accumulation of the radicals with the triplet spectrum were studied for phenols (VIII)–(XI).[18] The kinetic accumulation curve passes through a maximum and most of it can be described formally by the equation for first-order kinetics. Part of the curve beyond the maximum may be regarded as the kinetic curve for the consumption of the radicals. The temperature variation of the rate constant for the disappearance of the radicals was determined. For all four phenols, the activation energy obtained from this relation is 23.0 ± 0.5 kcal mole^{-1}.

The similarity of the ESR spectra and of the kinetics of the consumption of the radicals suggests that the oxidation of all the phenols investigated results in the formation of the same radical—2,6-di-t-butyl-1,4-benzosemiquinone (XIII). Its formation is characteristic of the oxidation of sterically hindered phenols with an electron-donating substituent in the *p*-position and is accompanied by the elimination of the *p*-substituent[19]. The semiquinone (XIII) is a secondary radical product formed in the initial stages of the oxidation process, probably as a result of the decomposition of an intermediate hydroperoxide with a *p*-quinolid structure—the product of the oxidation reactions of the phenoxy-radical. A detailed mechanism of the initial stages of the autoxidation of phenols has been described in a review[14].

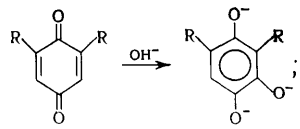
With increase of the conjugation chain and of the size of the substituent in the *p*-position, the stability of the phenoxy-radical increases. In the case of 2,6-di-t-butyl-, 4-phenyl-, and 4-naphthyl-phenols, the formation of phenoxy-radicals was observed by ESR in an aqueous alcoholic alkaline solution[20].

Direct evidence for the formation of phenoxy-radicals in the autoxidation of phenols in an aqueous alcoholic alkaline solution was obtained for phenols (VIII) and (XII)[21] by the stopped-flow method[22]. The spectra of the reaction mixture were recorded 2 s after the onset of oxidation. Absorption bands were observed for (XII) in the visible region with maxima at 428–430, 460, 480, 504, and 540 nm. Comparison of the spectrum of the reaction mixture in the oxidation of (XII) with the spectrum of (VIII) and with those of various phenoxy-radicals in polar media (results obtained by pulse photolysis and pulse radiolysis[17,23–25]) leads to the conclusion that the 428–430 nm band corresponds to the absorption of the phenoxy-radical.

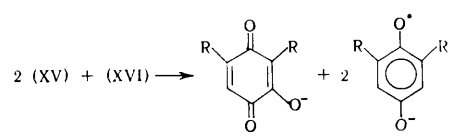
The spectrum of the reaction mixture of phenol (VIII) is more complex. In the range 430–450 nm there is a fairly broad asymmetric peak, which is probably the result of the superposition of the characteristic bands of the phenoxy-radical and the semiquinone (XIII), since it is known from the literature that different substituted semiquinones absorb mainly at 430–440 nm and less vigorously at 400 to 415 nm.[25–28] However, under certain conditions (0.005 M, 50°C) a spectrum with a narrow symmetric peak at 430 nm was also obtained for the reaction mixture of this phenol[21].

The formation of the phenoxy-radical is also supported by the detection in the reaction mixture obtained in the oxidation of phenols (V) and (VII) of disproportionation products of phenoxy-radicals—the corresponding methylenequinones [2,6-di-t-butyl-α-(*NN*-dimethylamino)-methylenequinone and 2,6-di-t-butyl-α-methoxymethyl-methylenequinone], which are stable in aqueous alcoholic alkaline solution. Under the influence of acid, these methylenequinones are converted into 3,5-di-t-butyl-4-hydroxybenzaldehyde, which has been found in the oxidation products of (VIII) following the addition of concentrated hydrochloric acid to the reaction mixture. 2,6-Di-t-butyl-1,4-benzoquinone (XIV)—the disproportionation product of the semiquinone (XIII)—was also found in the reaction mixture[19].

The study of the kinetics of the consumption of the semiquinone from phenol (VIII) by ESR showed that at advanced stages of the process an appreciable increase of the concentration of the radicals begins. When oxygen is supplied to the system after the attainment of the maximum concentration of radicals, the latter are initially almost instantaneously destroyed, after which their concentration increases sharply. This form of kinetic curve can be accounted for by the fact that the quinone (XIV), accumulating at advanced stages, is reduced and one of the reduction products is the semiquinone (XIII).[19] In the reaction of quinones with OH^- via a nucleophilic substitution mechanism the quinone is reduced to the semiquinone and *o*-hydroxyquinone should then accumulate in the system[29,30]. The principal reaction stages can be formulated as follows for alkyl-*p*-benzoquinones as an example:



(XV) (XVI)



The formation of 2,6-di-t-butyl-3-hydroxy-1,4-benzoquinone was demonstrated in the oxidation of 2,6-di-t-butyl-4-(β-hydroxyethyl)aminomethylphenol. The structure of the *o*-hydroxyquinone was demonstrated by infrared spectroscopy, ESR, and NMR. Its formation was also

demonstrated in the direct interaction of the corresponding quinone with alkali [19].

According to the ideas of Blyumenfel'd and coworkers [31,32], the primary step in the reduction of the quinone is direct electron transfer from OH^- to the quinone:

$$X + OH^- \rightleftarrows SQ^{\cdot-} + \dot{O}H, \quad (2)$$

after which the $\dot{O}H$ radicals interact with the initial quinone to form the hydroxyquinone.

The physicochemical properties and reactions of phenoxy-radicals and semiquinones have been described in detail in reviews and monographs (see Khudyakov and Kuz'min's review [25] with its bibliography).

2. Superoxide Radical-anions and an Enzymatic Method for the Investigation of Their Role in Autoxidation Processes

The formation of a phenoxy-radical as a result of the transfer of a single electron to an oxygen molecule leads to the formation of the superoxide radical-anion $O_2^{\cdot-}$, which is highly reactive. The absorption spectrum of the superoxide radical-anion, obtained by pulse radiolysis, has a maximum at 240–250 nm in aqueous solution, the extinction coefficients having widely different values according to different investigators [33,34]; $\epsilon_{O_2^{\cdot-}} = 1950 \pm 50$ litre mole^{-1} cm^{-1} appears to be the most probable value [34]. The application of the "fast freezing technique" [35] made it possible to obtain the ESR spectrum of the $O_2^{\cdot-}$ radical-anions in frozen aqueous solution; the radical-anions were formed with the aid of various chemical and enzymatic systems for the reduction of molecular oxygen; $g_\perp = 2.0$ and $g_\parallel = 2.08-2.09$. [35,36] The ESR spectrum of $O_2^{\cdot-}$ in anhydrous acetonitrile is similar to its spectrum in a frozen aqueous solution, but differs significantly from the spectrum in anhydrous dimethylformamide [37].

In aqueous solution the $O_2^{\cdot-}$ radical-anion is in equilibrium with $H\dot{O}_2$:

$$O_2^{\cdot-} + H^+ \rightleftarrows H\dot{O}_2, \quad (3)$$

whose $pK = 4.88 \pm 0.1$. [38,39] The rate constants for the recombination of $H\dot{O}_2$ and $O_2^{\cdot-}$ and for the cross-recombination are 7.6×10^5, $<10^2$, and 8.5×10^7 litre mole^{-1} s^{-1} respectively [39]:

$$H\dot{O}_2 + H\dot{O}_2 \rightarrow H_2O_2 + O_2, \quad (4)$$

$$O_2^{\cdot-} + O_2^{\cdot-} + 2H^+ \rightarrow H_2O_2 + O_2, \quad (5)$$

$$H\dot{O}_2 + O_2^{\cdot-} + H^+ \rightarrow H_2O_2 + O_2. \quad (6)$$

The $O_2^{\cdot-}$ radical-anion is an intermediate in the reduction of oxygen and can behave both as an oxidant and as a reductant depending on the composition of the reaction mixture. According to the latest data, the redox potential $E_0(O_2/O_2^{\cdot-}) = -0.33 \pm 0.01$ V, while $E_0' = 0.94 \pm 0.02$ V was obtained for the $O_2^{\cdot-}/H_2O_2$ system at pH 7. [40,41]

There are data showing that spontaneous dismutation of $O_2^{\cdot-}$ leads to the formation of $^1\Delta g$ singlet oxygen [42,43].

The formation of hydrogen peroxide is characteristic of the oxidation of phenols [44]. In the presence of H_2O_2 the reaction

$$O_2^{\cdot-} + H_2O_2 \rightarrow O_2 + OH^- + \dot{O}H \quad (7)$$

can take place [45] (by analogy with the reaction proposed for Fenton's reagent [46]). In this case hydroxy-radicals are generated together with the superoxide radical-anions in the system where phenol undergoes autoxidation.

Reaction (2) of the quinone with OH^- to form the semiquinone, discussed in Subsection 1, may be accompanied also by the reduction of quinones by the $O_2^{\cdot-}$ radical-anions with formation of the semiquinone:

$$X + O_2^{\cdot-} \rightleftarrows SQ^{\cdot-} + O_2. \quad (8)$$

The rate constants for the forward reaction (8), obtained by pulse radiolysis for a number of quinones are listed in Table 1.

Table 1. The rate constants for the reactions $X + O_2^{\cdot-} \rightarrow SQ^{\cdot-} + O_2$ involving different quinones in aqueous solution containing 5 M isopropyl alcohol and 1 M acetone [27].

Quinone	$10^{-9}k_8$, litre mole^{-1} s^{-1}
p-Benzoquinone	1.0
2-Methylbenzoquinone	0.76±0.1
2,3-Dimethylbenzoquinone	0.45±0.1
2,5-Dimethylbenzoquinone	0.36±0.1
2,6-Dimethylbenzoquinone	0.58±0.1
Duroquinone	0.005
Vitamin K	<0.0002
2,3-Dimethylnaphthoquinone	0.004
Cytochrome *c*	0.0001

The equilibrium constants K_C for duroquinone, vitamin K, and 2,3-dimethylnaphthoquinone are $(2.3 \pm 0.2) \times 10^{-2}$, $<10^{-3}$, and 2×10^{-2} respectively [27].

The use of the enzymes catalase and superoxide dismutase to investigate autoxidation in aqueous solutions established the important role of the $O_2^{\cdot-}$ radical-anions in the autoxidation of a wide variety of organic compounds: catecholamines [47–49], 6,7-dihydroxytryptamine and dialuric acid [49], pyrogallol [50], reduced flavins [51], tetrahydropteridines [52], reduced phenazine metasulphate [53], thiols [54], and inorganic sulphite [55].

Catalase catalyses the decomposition of hydrogen peroxide via the reaction

$$2H_2O_2 \rightarrow 2H_2O + O_2 \quad (9)$$

and superoxide dismutase catalyses the dismutation of the $O_2^{\cdot-}$ radical-anions via reaction (5). [56]

The conclusions reached concerning the role of H_2O_2 in the oxidation of catecholamines on the basis of the influence of catalase on this process are extremely contradictory [47–49,57]. The discrepancies between the results are probably due to the inadequate purity of the catalase preparations, which may contain an admixture of superoxide dismutase [58]. The problem of the contribution of reaction (7) and of the role of $\dot{O}H$ radicals in autoxidation process therefore remains open.

The leading role of the $O_2^{\cdot-}$ radical-anions in autoxidation processes can be demonstrated by the following examples. When superoxide dismutase is added to a system in which 6-hydroxydopamine undergoes autoxidation at pH 7.4–9.0, the rates of formation of the quinone and of absorption of oxygen decrease by 83 and 73% respectively [48]. In the oxidation of epinephrine to adrenochrome at pH 10.2, the inhibition reaches about 80% [47] and in the autoxidation of pyrogallol at pH 7.9–9.1 it ranges from 99 to 90%. [50]

The inhibition of autoxidation in the presence of superoxide dismutase can probably be accounted for by the suppression of reactions (8), (10), and (11):

$$PhO^- + O_2^{\cdot-} \xrightarrow{H^+} PhO^{\cdot} + H_2O_2 , \quad (10)$$

$$SQ^{\cdot-} + O_2^{\cdot-} \xrightarrow{H^+} X + H_2O_2 . \quad (11)$$

The dependence of the degree of inhibition on the pH of the medium, which is not related to the stability of superoxide dismutase, is noteworthy. For pyrogallol, the inhibition is more pronounced at pH < 10, while for epinephrine or tetrahydropteridines it is actually more marked at pH > 8.5, decreasing as the pH is reduced.

This apparently indicates the occurrence of two oxidation mechanisms, only one of which is associated with a significant role of the $O_2^{\cdot-}$ radical-anion. The predominance of one of these mechanisms depends on specific conditions.

After a new method is discovered, a period of its intensive application usually begins, in which the limitations of the method are not always taken into account. In view of this, some data concerning the characteristics of autoxidation in the presence of superoxide dismutase are given below.

Autoxidation reactions are extremely sensitive to traces of variable-valence metals, which have a significant influence on the rate and mechanism of the process. In the presence of Cu^{2+}, Mn^{2+}, and Fe^{2+} ions superoxide dismutase does not inhibit the oxidation of pyrogallol. The influence of metal ions is eliminated in the presence of diethylenetriaminetetraacetic acid, while ethylenediaminetetraacetic acid (0.001 M) does not suppress the action of Fe^{2+} at micromolar concentrations. The $O_2^{\cdot-}$ radical-anions probably form with metal ions intermediate complexes which do not react with superoxide dismutase[50].

The absence (under certain conditions) of inhibition by superoxide dismutase of the oxidation of low-molecular-weight thiols in the presence of heavy metals is probably associated with a similar phenomenon; on this basis, the stage involving the interaction of the thiol with the $O_2^{\cdot-}$ radical-anion has been apparently erroneously excluded[54] from the mechanism of the oxidation of thiols.

Recent data have shown[59] that phenols, particularly catechols, can combine reversibly with superoxide dismutase and can interact with the metal forming part of the active centre of the enzyme via a process of the type

$$Cu^{2+} + PhO^- \rightarrow Cu^+ + SQ^{\cdot-}. \quad (12)$$

(Superoxide dismutase contains copper, zinc, manganese, or iron depending on its biological source.)[9]

It can be shown for *p*-benzosemiquinone as an example that Cu^{2+} readily forms complexes with semiquinones and the lifetime of such complexes is significantly longer than the lifetime of the semiquinones themselves (owing to the delocalisation of the electron over the electron shell of copper and the electrostatic repulsion of the complexes from one another[28]). Apparently in consequence of the elimination of reaction (11) in the presence of superoxide dismutase and of the stabilisation of the semiquinone as a result of complex formation, the steady-state concentration of semiquinones increases and in many cases, for example in the autoxidation of 1,2-dihydroxybenzene-3,5-disulphonic acid (Tiron) can exceed by two powers of ten the steady-state concentration in the absence of superoxide dismutase. The ESR spectrum of the autoxidising Tiron–superoxide dismutase system then shows a new signal, which has been attributed to a complex formed by the copper bound in the enzyme with catechol, and the intensity of the initial copper signal falls[59]. Apart from complex formation with the metal, semiquinones can also be stabilised by their non-specific sorption on the protein molecule[60-63].

Thus not only the elimination of the $O_2^{\cdot-}$ radical-anion from the system but also the stabilisation of the semiquinones can contribute to the inhibition of the phenol autoxidation process observed in the presence of superoxide dismutase. Therefore, in elucidating the role of superoxide radical-anions in autoxidation processes with the aid of superoxide dismutase, account must be taken of both the consumption of the substance being oxidised and of the accumulation of semiquinones in the system.

The study of the influence of various organic solvents on the superoxide dismutase activity showed that the highest activity (about 90% of that in aqueous solution) is observed in *N*-methylformamide. The results obtained[64] extend the scope of the application of superoxide dismutase in the study of the mechanisms of the oxidation of organic compounds.

III. OXIDATIVE INACTIVATION OF SH-CONTAINING ENZYMES

It has been shown that propyl gallate (PG), a polyphenol inhibitor of free-radical reactions, does not inhibit the reaction catalysed by lactate dehydrogenase (LDH) (approximately 10^{-4} M) following its direct addition to the reaction system. Nor is the enzyme inactivated as a result of its prolonged preliminary incubation with PG under conditions excluding the autoxidation of phenol, nor in incubation with stable phenol autoxidation products. Enzyme activity is lost only when LDH is incubated with PG under the conditions of its autoxidation. These data led to the conclusion that the inactivation is caused by the free radicals formed from PG during its autoxidation[65,66].

This conclusion was confirmed[67] in a study of the effect of PG on other enzymes acting via various mechanisms: glyceraldehydephosphate dehydrogenase (GAPD) (also an autoxidation-reduction enzyme in glycolysis)[68], aldolase (a glycolytic lyase)[69], and RNA polymerase—the enzyme involved in the synthesis of RNA on a DNA matrix[70].

The conclusion that the radical products of the autoxidation of the inhibitor exhibit inactivating activity has been confirmed by kinetic data. The activation energy for the inactivation of LDH is 8300 ± 500 cal $mole^{-1}$ and is equal to the activation energy for the autoxidation of PG under the same conditions[71]. The agreement between the activation energies for the oxidation of PG and the inactivation of the protein shows that the rate-limiting stage in the activation of the enzyme by the inhibitor is the stage involving the formation of the semiquinone and the $O_2^{\cdot-}$ radical-anion via the overall reaction

$$PG^- + O_2 + OH^- \rightarrow SQ^{\cdot-} + O_2^{\cdot-} + H_2O,$$

where PG^- is the anion derived from propyl gallate.

SH is the most reactive group in proteins. The extensive factual data on the reactivity and role of mercapto-groups in the structure and functions of proteins are contained in Torchinskii's monograph[72].

Since all the enzymes enumerated above contain SH groups, which form part of the active centre or are important for the maintenance of the native structure, it was natural to suppose that the proteins are inactivated as a result of the interaction of their SH groups with the radicals formed in the autoxidation of the inhibitor. Indeed, direct experiments showed[68,69,73] that the radical

products of the autoxidation of PG oxidise the SH groups of the proteins with formation of S–S groups. Throughout the joint oxidation of PG and the protein, the total amount of SH and S–S groups remains constant. This implies that neither radical nor molecular intermediates in the oxidation of PG add to the protein molecule via the sulphur atoms. The inability of *o*-hydroxyquinone, formed in the oxidation of PG,[74–76] to add to the SH group is probably due to the presence of a powerful electron-donating substituent (OH group) in the ring next to the unsubstituted hydrogen[77]. One cannot rule out the possibility that the inhibitors of radical processes, whose oxidation leads to the formation quinones capable of adding to the SH-groups, inactivate the SH-containing enzymes not only as a result of the oxidation of SH groups but also by the addition of the quinone to the latter.

SH-containing compounds, including proteins are known to be capable of reducing antioxidant radicals. Their synergistic activity in relation to inhibitors is in fact associated with this factor. The enhanced rate of the consumption of SH groups in the presence of an inhibitor undergoing oxidation and the appearance of an induction period on the kinetic curve for the oxidation of the inhibitor in the presence of the protein (in the absence of the protein, PG is oxidised under these conditions at a constant rate) suggest that, during the induction period in the oxidation of PG, the following reactions take place[73]:

$$PG^- + O_2 + OH^- \rightarrow SQ^{\cdot-} + O_2^{\cdot-} + H_2O;$$
$$PG^- + O_2^{\cdot-} + H^+ \rightarrow SQ^{\cdot-} + H_2O_2;$$
$$RS^- + SQ^{\cdot-} + H^+ \rightarrow PG^- + RS^{\cdot};$$
$$RS^- + O_2^{\cdot-} + 2H^+ \rightarrow RS^{\cdot} + H_2O_2;$$
$$2\,RS^{\cdot} \rightarrow RS - SR;$$
$$2\,O_2^{\cdot-} + 2\,H^+ \rightarrow H_2O_2 + O_2.$$

It has been shown for LDH[78] that the oxidation of the SH groups alters the kinetic characteristics of the enzyme: the stability of the LDH complex with the coenzyme—reduced nicotinamide-adenine dinucleotide (NADH)—is significantly reduced (the dissociation constant increases by a factor of 4–5).

Thus the decrease of the activity of enzymes as a result of their interaction with radicals proceeds not only owing to the decrease of the number of active centres but also owing to a change in the affinity of the coenzyme for the enzyme. The latter may be caused by structural changes resulting from the oxidation of SH groups to S–S, which are not characteristic of the enzyme in the intact state.

The influence of radical autoxidation products on the structure of SH-containing proteins has been demonstrated in experiments on GAPD and aldolase by the change in specific rotation. A decrease in laevorotation and, after prolonged incubation corresponding to the decrease of the enzyme activity by about 80% and the oxidation of SH groups to the extent of 50–80%, the appearance of dextrorotation are characteristic of both enzymes (Table 2).

The inactivation of the enzyme by radicals can be prevented by allowing the inhibitor to react with the enzyme in the presence of a reducing agent: NADH for LDH[71] or β-mercaptoethanol for RNA polymerase[70]. The protection of the protein from inactivation is accompanied by the oxidation of NADH to NAD^+. It is known from the literature that NADH forms a stable complex with the SH groups of LDH. The presence of this complex stabilises the protein and protects it from thermal denaturation, denaturation by urea, and the action of various agents on the SH groups.[79–83] Since in the system with PG undergoing autoxidation the protective effect of NADH is accompanied by its oxidation, the stabilisation of LDH is temporary and its duration depends on the NADH concentration. The oxidation of LDH and NADH present together in a medium containing PG undergoing oxidation obeys the general rule governing the behaviour of a mixture of two inhibitors of different strengths in autoxidation reactions[84].

Table 2. The change in the specific rotation α_{541}^{25} (degrees) of aldolase and GAPD on oxidation[68,69].

System	Duration of oxidation, min				
	0	15	30	45	60

*In universal buffer at pH 9.7.

The conclusion that radicals formed in the autoxidation of PG oxidise the LDH–NADH complex has been confirmed by data for the oxidation of NADH in the complex by $O_2^{\cdot-}$ radical-anions obtained by pulse radiolysis[85]. It was shown that the oxidation of NADH is a chain process. The chain length is a function of the ratio [NADH]:[LDH], the concentration $[O_2]$, the dose rate, and the pH of the medium. The maximum chain length is 9.6.

The incubation with glutathione of LDH inactivated by the autoxidation radicals does not reactivate the enzyme[73]; cysteine reactivates GAPD only under certain conditions[68]. The profound changes in the structure of the protein caused by the oxidation of the SH groups can be explained by the thiol–disulphide exchange reaction[68,73]. By analogy with the reduction of simple disulphides by mercaptans, this reaction can be treated as a result of nucleophilic attack on the disulphide linkage by the mercaptide anion:

$$R'S^- + R - S - S - R \rightarrow R'-S-S-R' + RS^-.$$

According to some investigators, this reaction can proceed via a chain mechanism and can lead to the aggregation and denaturation of proteins[86,87].

The changes in the quaternary structure of proteins as a result of the oxidation of SH groups are also indicated by data showing an increase of the bond strengths between the GAPD and aldolase subunits after incubation of these enzymes in the presence of PG undergoing oxidation[88–90]. The sorption of semiquinones[60–63] and of the phenols themselves on inactive centres of the proteins can make a definite contribution to the change in the enzyme structure. This can probably explain the influence of PG on the equilibrium between the oligomer and its subunits in the case of LDH and GAPD.[90]

The reaction of the autoxidation radicals with the SH groups of proteins is fairly selective. Thus ribonuclease and trypsin, which are proteins without SH groups, are not inactivated in the presence of PG undergoing autoxidation[68]. According to Tanksley et al.[91], the inhibition of the conversion of pepsinogen into pepsin in the presence of gossypol a naturally occurring phenol, is enhanced at

alkaline pH of the medium and with increase of temperature, which should promote the oxidation of gossypol. It was shown that, under these conditions, gossypol combines with the ϵ-amino-groups of lysine via covalent linkages.

Phenols, which behave as electron donors, readily form complexes with various acceptors, charge-transfer forces making a significant contribution to the stabilisation of the complexes. In this sense interaction with molecular oxygen can be regarded as a special case—total charge transfer via reaction (1) with formation of two free radicals. The energy of the highest occupied molecular orbital E_{HOMO} is used as a criterion of the susceptibility of phenols to oxidation[14]. In the case of charge-transfer complexes (CTC) the values of E_{HOMO} for different donors should be correlated with the stability constants of the complexes formed by the donors with the same acceptor.

The biochemically important complexes of phenols, catechols, and naphthalenediols with flavins and flavoproteins are well known[92-102]. The charge-transfer complex of naphthalene-2,3-diol and lumiflavin was isolated in a crystalline state. It was shown by X-ray diffraction that the complex has a "sandwich" structure in which the flavin molecule is located between two naphthalenediol molecules[101].

Table 3. The stability constants of the PG–FMN complexes.

Flavin	K_{st}, litre mole^{-1}	
	pH 6.3	pH 8.1
Oxidised	119	70
Reduced	$\leqslant$17	—
Half-reduced	1550	$\leqslant$20

The stability constants K_{st} of the complexes formed by PG with flavin mononucleotide (FMN) reduced to different extents have been obtained[98]. Table 3 shows that at pH 6.3 (where all the components are unionised) the most stable complex is formed with the half-reduced form of the flavin. The dependence of the stability constants of the complexes on the state of ionisation of the components and on the degree of reduction of the acceptor and also the linear relation between $\lg K_{st}$ and E_{HOMO} for FMN and various donors (Table 4) indicate a significant contribution of charge-transfer forces to the stabilisation of such complexes. It has been shown for xanthine oxidase[99,104] that the formation of complexes by phenols with flavin enzymes can lead to a significant inhibition of the enzymatic reaction.

Different aspects of the mechanism of the action of phenols on enzymes have been discussed[105]. Many phenols (mainly those with electron-accepting substituents) have been tested as uncoupling agents for oxidative phosphorylation and respiration. However, it was not possible to observe correlations between any physicochemical properties of the phenols and their uncoupling capacity. For comparison with the inhibiting activity of phenols in relation to LDH and hexokinase, the authors used, for example, the hydrophobic binding constant π and the Hammett constant σ. Of the 17 phenols investigated, 10 obey the correlation equation linear in π and σ, but the inhibition effect proved to be unrelated to the activity of the phenols as uncoupling agents. It is suggested that the uncoupling agents act directly on ATPase, forming a complex at the site of addition to the enzyme of the adenine component of the substrate[106].

It has been shown that PG also inhibits respiration and uncouples oxidative phosphorylation and respiration[107]. For phenols as inhibitors of malate dehydrogenase (an SH-containing enzyme), the correlation equation takes into account the same characteristics of the phenols (π and σ), but the equations are respectively linear and quadratic in these constants[108].

Table 4. The stability of the complexes formed by FMN with various donors and the values of E_{HOMO} for the donors (phosphate buffer, pH ~ 6).[100]

Compound	K_{st}, litre mole^{-1}	E_{HOMO} (in units of β)	References
FMNH	3.352	—0.105	103
FMN	2.000 (1.778)	0.496	103 (98)
Naphthalene-2,3-diol	2.384	0.338	96
β-Naphthol	2	0.436	93
Phenol	1.494	0.515	94
n-Propyl gallate	2.076	0.255	98

The inhibiting effect of dicumarol on respiration and phosphorylation and on the uncoupling of these processes has been attributed[109] to the direct inhibition of succinate dehydrogenase. Pyrogallol, sodium gallate, and other substituted phenols inhibit catechol methyltransferase[110-113]. The inhibition of the enzyme increases as a result of its preliminary incubation with pyrogallol[112]. It is suggested[50] that the $O_2^{\cdot}$ radical-anions and possibly OH radicals, formed by reaction (7), contribute to the inhibiting effect, particularly if one remembers that catechol methyltransferase contains "essential" SH groups.

IV. BIOCHEMICAL CHANGES UNDER THE INFLUENCE OF SUPEROXIDE RADICAL-ANIONS AND THE POSSIBLE ROLE OF THE LATTER IN THE ANTITUMOUR ACTIVITY OF PHENOLS (IN ENZYME SYSTEMS AND AT THE CELLULAR LEVEL)

A few years ago the biological role of $O_2^{\cdot}$ radical-anions was considered mainly in connection with the effect of radiation. After the discovery of superoxide dismutase[56], vigorous research was begun on the role of $O_2^{\cdot}$ in the metabolism of living organisms. It was found that the products of the one-electron reduction of oxygen ($O_2^{\cdot}$ radical-anions) are invariably present as metabolites in all plant and animal organisms and microorganisms employing molecular oxygen in their metabolic processes which have been investigated hitherto. All these organisms (no exceptions have so far been found) also contain enzymes from the family of superoxide dismutases, which catalyse selectively the dismutation of $O_2^{\cdot}$ radical-anions. The hypothesis that $^1\Delta g$ singlet oxygen is also a substrate of superoxide dismutase has been frequently discussed in the literature[43,114-116]. However, the latest data[117-120] have shown that $^1\Delta g$ oxygen is formed only on spontaneous dismutation of $O_2^{\cdot}$ and in the presence of superoxide dismutase the latter precedes the formation singlet oxygen.

Superoxide dismutase is one of the "fastest" enzymes. The rate constants for the overall second-order reaction, obtained by different investigators using various methods, agree satisfactorily [121-123]. According to the latest, improved data, $k = (2.37 \pm 0.18) \times 10^9$ litre mole^{-1} s^{-1} at 25°C, [123] which is close to the rate constants for diffusion-controlled reactions.

The system for the catalytic dismutation of $H\dot{O}_2$ radicals and $O_2^{\cdot-}$ radical-anions in the presence of Cu^{2+} in acid media can serve as a chemical model of the action of superoxide dismutase. The rate constants are about 10^8 and 8×10^9 litre mole^{-1} s^{-1} respectively [124], i.e. we have here the unique case where the reaction in the model chemical system is 3–4 times faster than in the presence of the enzyme.

The rate of reactions catalysed by superoxide dismutase is independent of the pH over a wide range of the latter (5.3–9.5). [9] The enzyme is reduced and inactivated by the final reaction product (H_2O_2). [125-128] The inactivation is a second-order reaction with a rate constant of 3.1 litre mole^{-1} s^{-1} at 20–25°C and is probably associated with the decomposition by the peroxide of one histidine residue, which is essential for activity, for each of the two polypeptide chains of the enzyme [128].

Evidently, together with catalase and peroxidase, superoxide dismutase constitutes a system for the protection of organisms from the toxic effect of oxygen and its reduction products. The system of bioantioxidants can be regarded as a second line of defence operating under conditions where enzyme systems do not work [9].

Several biological sources of $O_2^{\cdot-}$ radical-anions have now been discovered. Apart from the autoxidation reactions and the reoxidation of low-molecular-weight metabolites, mentioned in Section II, the $O_2^{\cdot-}$ radical-anions arise in the autoxidation of the oxygen adducts with haem-containing proteins: haemoglobin, myoglobin, and cytochrome R-450. [120,129,130] (For the formation of the autoxidation product of haemoglobin—methaemoglobin, an alternative mechanism of electron transfer, using external donors, particularly phenols, with intermediate formation of semiquinones from the latter, has also been suggested [131].) The electron transfer chains in plant chloroplasts [123,133], in mitochondria [116,134,135], and in microsomes [136-142] in animal organisms also function as sources of $O_2^{\cdot-}$ radical-anions. Their formation in electron transfer chains is attributed primarily to the functioning of flavin dehydrogenases [143,144].

The system in which xanthine is oxidised to uric acid, catalysed by xanthine oxidase, is the most thoroughly investigated enzymatic source of $O_2^{\cdot-}$ radical-anions [35,36,145]. During this reaction, oxygen is reduced in two stages to hydrogen peroxide. Experiments on the quenching of the chemiluminescence in the xanthine oxidase system in the presence of luminol showed that inhibitors of free-radical reactions belonging to the class of sterically hindered phenols and hydroxypyridines can behave as effective quenching agents [100], probably as a result of the capture of $O_2^{\cdot-}$ radical-anions. The binding of $O_2^{\cdot-}$ can probably also make an important contribution to the mechanism of the antitumour activity of inhibitors of free-radical reactions.

The $O_2^{\cdot-}$ radical-anions formed in electron transfer chains are involved in the peroxide oxidation of lipids and the hydroxylation of extraneous substances entering the organism (including medicinal compounds) [146-148], which are called xenobiotics. The enzyme system for the hydroxylation of xenobiotics is located in microsomes.

The detoxification of xenobiotics is attributed specifically to their hydroxylation, which leads to a decrease of their solubility in the lipid phase, hinders their passage through membranes, and facilitates their elimination from the organism. The mechanism of the functioning of the hydroxylating system has been discussed in a number of reviews [149-153].

The inhibition of the metabolism of xenobiotics by PG and other antioxidants has been demonstrated [154]; the authors explain it by the combination of the inhibitors with the flavoprotein. However, one cannot rule out the possibility that the inhibition is caused by the capture of the radicals involved in the hydroxylation processes. These radical species may be both $O_2^{\cdot-}$ and $\dot{O}H$. [140,155,156] Both types of radicals are formed also in model hydroxylation reactions [157,158]. A relation has been demonstrated between the xanthine oxidase system and the xenobiotic hydroxylation system, which includes cytochrome P-450, nicotinamide adenine dinucleotide phosphate, cytochrome *c* reductase, and the lipid component of phosphatidylcholine [159]. Xanthine oxidase is exceptionally widely distributed in living organisms. It has been recently suggested that one of the important and possibly the main function of this enzyme is catalysis by the latter of the formation of H_2O_2 and $O_2^{\cdot-}$ in the cell [160].

Studies by a number of workers have shown the existence of a direct relation between enzyme systems for the peroxide oxidation of lipids and for the hydroxylation of xenobiotics. These two systems apparently use the same electron-transport chain, as a result of which the induction of peroxide oxidation leads to a decrease of the rate of hydroxylation and conversely [161-164]. There are data concerning the existence of a factor which regulates the level of activity of these enzyme systems [142].

The radicals formed in the microsomal electron transfer chain can cause the haemolysis of erythrocytes [136,137,165], which can be averted, for example, by an increase of the level of the natural antioxidant (tocopherol) in the animals from which the erythrocytes have been taken and in the presence of superoxide dismutase and catalase. Both enzymes exhibit a similar effect, protecting mitochondrial membranes from lysis associated with the peroxide oxidation of lipids [135].

The involvement of $O_2^{\cdot-}$ radical-anions in the mechanism of the action of peroxidases has been noted in a number of studies [166,167]; the bactericidal action of the enzymes, which becomes more pronounced in the presence of phenols and epinephrine, has been attributed to these radicals [168,169] (possibly in consequence of their capacity for autoxidation with formation of $O_2^{\cdot-}$ radical-anions).

In the development of the tumour process significant changes occur in the enzyme systems for the protection of the organism from the toxic effects of the products of the peroxide oxidation of lipids (with the aid of glutathione peroxidase and glutathione reductase—enzymes governing the utilisation of lipid peroxides—and superoxide dismutase). With increase of tumour growth in the organs of the tumour-carrying animal, the activities of glutathione reductase and peroxidase pass through extrema, exceeding for a time by factors of 2.5 and 6 the corresponding levels of their activity under normal conditions, while the activity of superoxide dismutase hardly changes [170]. At the same time sharp changes are observed in the activity of the enzyme system for the peroxide oxidation of lipids [171] and peroxides accumulate [172]. The results indicate a disturbance of the balance in the processes involving the formation and utilisation of lipid peroxides, which is a characteristic link in the pathogenesis of malignant growth [170]. In the tumour itself the activities of glutathione peroxidase and superoxide dismutase, cal-

culated in terms of arachidonate (one of the principal sources of peroxides) are higher by factors of 2.5 and 12 than in the livers of intact animals. Thus the rate of formation of peroxides decreases in the tumour tissue probably in consequence of the capture of $O_2^{\cdot-}$ radical-anions by superoxide dismutase and their accelerated utilisation owing to the increased activity of glutathione peroxidase. This leads to an extremely low steady-state concentration of peroxide, which cannot be determined[170]. In chemical carcinogenesis and malignant growth the activity of the system for the hydroxylation of xenobiotics varies in opposition to the activity of the system for the peroxide oxidation of lipids[173].

The problems associated with the action of inhibitors as possible regulators of the processes occurring with participation of free radicals are outside the scope of the present review and are considered elsewhere[174].

The $O_2^{\cdot-}$ radical-anions play a significant role in phagocytotic processes. It has been shown that phagocytosis is accompanied by an increase in the rate of formation of $O_2^{\cdot-}$.[175] The bacteria *E.coli*, grown on a medium deficient in iron and with a deficiency of the iron-containing superoxide dismutase, are much more sensitive to the bactericidal action of the formed elements of blood[176]. In lymphogranulomatosis (a malignant tumour of lymphoid tissue) there is no increase of the oxidative metabolism of human leucocytes in phagocytosis[175].

The $O_2^{\cdot-}$ radical-anions can cause the degradation of the synovial (interarticular) fluid and the depolymerisation of a highly polymeric acid mucopolysaccharide contained in it—hyaluronic acid[177]. The inhibition of both processes by superoxide dismutase, catalase, and substances capable of binding ȮH radicals shows that the latter are also evidently involved in the depolymerisation and degradation processes. In inflammatory processes such as arthritis there is a distinct correlation between the number of leukocytes and the degree of degradation of the synovial fluid. These data are consistent with the finding that the synovial fluid contains superoxide dismutase and catalase at concentrations smaller by 2–3 orders of magnitude than the intracellular concentrations of these enzymes.

Since the lifetime of superoxide radical-anions is relatively long (compared, for example, with ȮH radicals), they can diffuse, in principle, within the bacterial cell and can have a lethal effect on DNA. The degradation of biomacromolecules (ribonuclease and lysine:RNA ligase) has been observed[178]. The experiments on the influence of PG undergoing oxidation on DNA have shown that the decrease of the viscosity of the DNA solutions observed in the course of incubation and the appearance of single and double breaks are due to the effect of radical and molecular inhibitor oxidation products[179]. Streptonigrin, an antibiotic with a *p*-quinonoid structure, has a similar effect on DNA when it is reduced in the presence of the latter[180] and the formation of $O_2^{\cdot-}$ radical-anions was demonstrated in this process[181]. The radiation-chemical yield of the deamination products (G) in the radiolysis of aqueous DNA solutions due to $O_2^{\cdot-}$ radical-anions is close to the value of G due to ȮH radicals[182].

The possible contribution of the radical products of the autoxidation of inhibitors to the mechanism of the antitumour action of these compounds at the cellular level can be inferred from certain indirect biochemical and cytological data quoted below. *In vivo* and *in vitro* experiments showed that inhibitors of radical reactions inhibit the synthesis of protein and nucleic acids in tumour cells[183–187], possibly as a result of the interaction of the radicals, formed in the autoxidation of the inhibitors with the SH groups of the enzymes[70]. The degree of suppression of biosynthesis increases with increase of pH in the incubation medium[186] and decreases when the aeration is inadequate[67].

PG suppresses glycolysis in tumour cells[188], which is caused, according to the data of Schön and Venker[189], by the denaturing effect of the inhibitor on the proteins. A number of inhibitors (nordihydroguaiaretic acid, butoxytoluene, ascorbyl palmitate, and octyl gallate) have been shown to block the dehydrogenase processes in the liver, which the authors explain by the oxidation of the antioxidants[190].

According to Emanuel' et al.[191], inhibitors suppress the activity of the oxidation-reduction enzymes in tumour cells. Succinate oxidase [succinate dehydrogenase?] and cytochrome oxidase are suppressed in the succinate oxidase chain of the system, the latter enzyme being more sensitive to the action of inhibitors. The degree of suppression of enzyme activity falls with increase of the overall concentration of the protein in the system (including inert protein), which indicates non-specific binding of the inhibitors to the proteins. The decrease of the degree of inhibition by an order of magnitude in the presence of a deficiency of oxygen[192] shows that the species sorbed are in all probability not the inhibitors themselves but radical or molecular products formed from them in the course of autoxidation.

Treatment with inhibitors leads to the suppression of the multiplication of tumour cells under the conditions of their growth and increases greatly the number of chromosomal aberrations, giving rise to an effect analogous to that of radiomimetic substances and free radicals[193,194]. This factor suggested[193] that the observed effects are associated with the action of the radicals formed from the inhibitors in the course of their oxidation in the cell substrate.

Substituted phenols, natural phenolic compounds, and stable radicals present at certain concentrations sensitise tumour cells to irradiation[195–200].

A separate study of the influence of inhibitors on the life cycle of cells demonstrated the blocking of phases in the cycle and the consequent disturbance of the dynamics of the cell population and a change in the distribution of the population among the different phases of the life cycle[201,202]. According to Terasinia[203] and Harris[204], certain stages in the cell cycle (the second half of the phase involving the synthesis of DNA and the end of the premitotic phase) are characterised by an increased content of SH groups. The cytotoxic action of a number of catecholamines and their polyhydroxy-analogues is attributed to the ability of these compounds to generate $O_2^{\cdot-}$ and ȮH during autoxidation. As a result of treatment with PG, tumour cells lose their capacity for transplantation and explantation[205–209].

Bioantioxidants and Synthetic Inhibitors of Radical Processes

E.B.Burlakova

Data are presented for the physicochemical characteristics of bioantioxidants and the influence on their level in the lipids of organs and tissues by radical-process inhibitors introduced into animals. A wide variety of pathological states occurring against the background of changes in the amount of bioantioxidants and the possibility of treating them with the aid of synthetic inhibitors are discussed. The effectiveness of antioxidants is associated with the important role of free-radical oxidation reactions in the lipids of cell membranes.
The bibliography includes 155 references.

I. INTRODUCTION

On the hypothesis that free-radical mechanism play a major role in the development of pathological processes, Emanuel' and coworkers suggested in 1957 that relatively non-toxic inhibitors of oxidation reactions (antioxidants) be used as protectors against radiation sickness[1]. The inhibitors were regarded as potential protective agents against radiation, capable of decreasing the scale of the damage associated with the intensification of free-radical reactions in cell components under the influence of radiation[2]. In 1957 data were obtained indicating the possibility of using inhibitors as such protective agents[1]; these results were subsequently confirmed[3-7]. However, later it proved impossible to reproduce in a number of investigations the high effectiveness of inhibitors as protective agents against radiation and in some cases it was actually found that preparations of this class intensify the effect of radiation[8]. All these findings required a more profound study of the influence of synthetic inhibitors on cell metabolism. The present author believes that the fundamental questions associated with the use of inhibitors (antioxidants) in medicine are as follows:

1. Can one assume that free-radical process inhibitors manifest in the organism the same properties as in model free-radical reaction systems and is their pharmacological activity associated with their physicochemical constants?
2. Can synthetic inhibitors and the natural antioxidants present in cell components interact and be interchanged?
3. What are the molecular-biological mechanisms of the influence of inhibitors on cell metabolism?

In the present review these questions will be considered in relation to the free-radical processes in the lipid components of the cell.

II. PHYSICOCHEMICAL CHARACTERISTICS OF BIOANTIOXIDANTS

Experiments *in vitro* showed that free-radical oxidation reactions can be suppressed in the lipid fractions extracted from animal organs and tissues[9]. The overall antioxidant activity (AOA) of the lipid fraction depends on the amount, physicochemical properties, and mutual influence of the individual antioxidants present in it, and also on the presence of substances which themselves do not exhibit antioxidant properties but can intensify or weaken the action of antioxidants[10].

It has now been shown that many substances contained in the lipids of animal organs and tissues have the properties of radical-process inhibitors. These include tocopherols, ubiquinones, steroid hormones, thyroid hormones, cholesterol, phospholipids, and certain others. The mechanism of the antioxidant action of these substances has not been established in all cases.

The most thoroughly investigated antioxidants are tocopherols, which exhibit powerful antiradical properties[11-28]. The rate constant for the reaction of α-tocopherol with free radicals k_7, measured by a chemiluminescence method in the model ethylbenzene oxidation initiation reaction at 37°C, proved to be 2.6×10^6 litre mole^{-1} s^{-1}, the corresponding values for γ-tocopherol and δ-tocopherol being 1.3×10^6 and 0.5×10^6 litre mole^{-1} s^{-1} respectively[29,30]. These values exceed by 1–2 orders of magnitude the rate constants for the reactions with radicals of a number of familiar synthetic inhibitors investigated using the same model[31]. One of the interesting characteristics of tocopherols as antioxidants is a high stoichiometric coefficient of inhibition, which is 4.5 for α-tocopherol and 3.5 for γ-tocopherol[10,32]. This large number of chains terminated by one inhibitor molecule can be explained according to the authors by the inhibiting activity of the product formed from tocopherol when it interacts with free radicals. According to Tappel's mechanism, the phenoxy-radical derived from tocopherol is converted into a benzyl radical, reducing at the same time the OH group[33]. As a result of these rearrangements, one α-tocopherol molecule can react with six peroxy-radicals and one γ-tocopherol can react with four peroxy-radicals[32]. Despite their high antiradical activity, tocopherols are weak antioxidants. Thus the inhibition of the oxidation of methyl oleate and arachiden by α-tocopherol is six and three times less effective than the inhibition by the familiar inhibitor 2,6-di-t-butyl-4-methylphenol (ionol)[34,35]. It has been suggested that this is due to the high activity of the radicals formed from tocopherol, which can enter into the chain-propagation reaction and thereby weaken the effect of tocopherol as an inhibitor[36-38].

The contribution of tocopherol to the overall antioxidant activity of mouse liver lipids does not exceed 15–20% and its contribution to the antiradical activity does not exceed 40–60%.[34]

Many investigators attribute a high antiradical activity to ubiquinones, among which coenzyme Q_{10} is the most active[39,40]. The mechanism of their antiradical action is obscure. It is suggested that the ubichromenol form may be active[41]. Like tocopherols, ubiquinones are weak antioxidants[42–46]. Their relative antioxidant effectiveness is smaller by an order of magnitude than that of ionol and by a factor of 2–3 than that of tocopherol[40]. The reduced enolic forms of ubiquinones are comparable to α-tocopherol as regards their antioxidant properties[44,45]. This is because the enolic forms of ubiquinones have higher constants k_7. In our laboratory Khrapova and coworkers are making a comparative study of the antiradical effectiveness of the enolic and quinone forms of natural antioxidants. The greatest difference between the constants k_7 for these forms occurs for tocopherol, which is present in the organism mainly in the phenolic form (see Table).

The rate constants (litre mole^{-1} s^{-1}) for the interaction of the enolic and quinone forms of antioxidants with free radicals.

Antioxidant	Enolic form	Quinone form
Tocopherol	$2.6 \cdot 10^6$	$1.7\ 10^3$
Ubiquinone	$2.1 \cdot 10^5$	$5 \cdot 10^3$
Vitamin K	$3.9 \cdot 10^6$	$5 \cdot 10^3$

The ratio of the rate constants for different forms of vitamin K, which is present in lipids mainly as the quinone, is also fairly large. For ubiquinone, the difference between the rate constants is smaller, which demonstrates the ease of its transition from the oxidised to the reduced form and conversely (see Table). The contribution of ubiquinone to the antioxidant properties of liver lipids does not exceed 5–10%.[40]

Much attention has been devoted to the study of hormones as antioxidants. Thyroid hormones have been shown to exhibit antioxidant activity in the model reaction involving the oxidation of methyl oleate[46]. Amongst steroid hormones, the antiradical effectiveness of which has been studied on the basis of the quenching of chemiluminescence[47], oestrogens proved to be the most active. For example, in the model reaction involving induced oxidation of lipids in mitochondria, diethylstilboestrol has a constant k_7 of the same order of magnitude as tocopherol[47]. Adrenaline exhibits weak antiradical properties[38,48]. The antiradical action of hormones is probably associated with the presence of phenolic groups in their molecules.

There are many obscure aspects of the problem of the antioxidant action of phospholipids and its mechanism. Some studies demonstrated antiradical activity in certain phospholipids, for example in phosphatidylcholine[48], while in others it is asserted that the antioxidant activity of phospholipids can be manifested only in those cases where they are mixed with antioxidants, since phospholipids behave as synergistic agents for antioxidants[49,50]. Olcott and coworkers[51] suggested that the only phospholipids with antioxidant activity are those capable of being oxidised under the experimental conditions with formation of a nitroxy-radical, which exhibits antiradical properties.

The problem of the antioxidant activity of cholesterol is widely discussed in the literature. Cholesterol was found to have a weak influence on chemiluminescence in model systems[48,52]. However, it has not been established whether the quenching of the chemiluminescence by cholesterol is chemical or physical. The cholesterol concentrations at which an effect is observed are fairly large (0.01 M), which makes it necessary to treat with much caution conclusions concerning the antiradical properties of cholesterol. The behaviour of cholesterol in model lipid oxidation systems is fairly complex. The experimental result depends on the cholesterol concentration, the rate of oxidation of the model lipid, and the duration of oxidation. Thus it has been shown[53] that, in the oxidation of methyl oleate, cholesterol exhibits antioxidant properties in the range of moderate concentrations, while lower and higher experimental concentrations actually accelerate oxidation. The antioxidant activity increases with time. These findings can be accounted for if cholesterol is regarded as the substrate of joint oxidation with methyl oleate and when account is taken of the fact that the cholesterol oxidation products may be antioxidants. Indeed it was shown that cholesterol is oxidised via a free-radical mechanism[54] and that its oxidation can be retarded by radical-reaction inhibitors[55].

Thus the main lipid components of membranes—phospholipids and cholesterol—can play a decisive role in the changes of the overall antioxidant activity in lipids, but the mechanism of this influence is complex and at present has not been finally elucidated.

Summarising the foregoing, the following points may be noted:

1. Many substances present in the lipid phase of cells exhibit antioxidant and antiradical properties. The characteristic features of most of them are a relatively low antioxidant effectiveness.
2. The overall antioxidant activity of the lipid fraction is determined by the interaction of its components. The contributions of individual antioxidants to the antioxidant activity of lipids are comparable.
3. Although the antiradical properties of natural antioxidants vary within wide limits, this does not have a significant influence on their antioxidant properties, probably because of the high activity of the radicals derived from the inhibitor, which enter into the chain-propagation reaction and weaken the antioxidant properties of the inhibitor.

It has now been shown that endogenic antioxidants inhibit the lipid oxidation processes *in vivo* and fulfill their antioxidant function together with their other specific functions. In order to establish the role of natural antioxidants in cell metabolism, it is extremely important to elucidate the question of their interaction and capacity for interchange. It is known that many diseases entail a simultaneous decrease of the amounts of various antioxidants. For example a decrease of the concentration of not only tocopherol but also ubiquinones has been observed in vitamin E deficiency[56].

The changes in the amount of natural antioxidants in liver lipids following the introduction of tocopherol into animals have been studied[57,58]. Together with an increase of the steady-state concentration of tocopherol in lipids, there is a significant accumulation also of other natural antioxidants. According to the authors, this is a consequence of the preferential consumption of the added tocopherol in free-radical oxidation reactions, which is confirmed by an

increase of the concentration of tocopherylquinone—one of the final reaction products of tocopherols in these processes[58,59]. Similar results were obtained also in experiments where ubiquinone had been introduced[40]. These results indicate indirectly the importance of the antioxidant properties of tocopherols and ubiquinones, on the one hand, and the absence of specificity in the inhibition of the free-radical oxidation of lipid, on the other.

In certain cases the deficiency of natural antioxidants can be made good by synthetic inhibitors. Thus certain synthetic antioxidants eliminate many symptoms of vitamin E deficiency, while others are inactive[60-63]. In order to establish the principle if the selection of synthetic inhibitors to make good the deficiency of the organism's own antioxidants, it is necessary to compare their effects.

The influence of the introduction of various inhibitors on the system of natural antioxidants has been studied[64,65]. It has been established that only inhibitors with antiradical activity k_7c (c is the inhibitor concentration in lipids) comparable to that of natural antioxidants are capable of replacing them in the free-radical oxidation of lipids and of increasing the steady-state concentration of natural antioxidants. Thus the introduction of propyl gallate increases the concentration of tocopherol in mouse liver lipids by a factor of 1.5, the concentration of tocopherylquinone decreasing. This supports the hypothesis that the rate of utilisation of tocopherol decreases owing to the competitive inhibition of the free-radical oxidation of lipids by the synthetic inhibitor. The overall antioxidant activity of lipids increases following the introduction of synthetic inhibitors both due to the presence of the synthetic inhibitor in lipids and, when preparations with high values of k_7c are introduced, as a result of the increase of the concentration of natural antioxidants.

Thus the influence of synthetic inhibitors on the amount of natural antioxidants in lipids can be accounted for on the basis of the usual competitive relations for two or several inhibitors. However, in experiments with the introduction of synthetic inhibitors into animals, phenomena were also observed, which cannot be simulated experimentally. Thus it has been found that, following the introduction of large amounts of synthetic inhibitors, AOA of lipids in animal organs initially increases to a maximum and then falls significantly below the normal values[66,67]. It has been suggested that synthetic inhibitors, which have many properties in common with natural antioxidants, suppressed their synthesis or enhance the reactions in which they are consumed[66]. The dependence of the degree of reduction of the level of lipid AOA by synthetic inhibitors on their ability to inhibit oxidation reactions has been investigated[65]. It was found that the reduction is greater the higher the relative antioxidant effectiveness of the inhibitor. When 2,6-di-t-butyl-4-methylphenol is introduced into animals in a dose of 100 mg kg^{-1}, the concentration of tocopherol in lipids falls[65] and tocopherylquinone accumulates at the same time[58]. The results of these studies suggested a relation between the ability of the synthetic inhibitors present in lipids to inhibit oxidation reactions and the rate of consumption of the antioxidants.

In order to determine the cause of the change in the consumption of antioxidants, the rate of generation of free radicals in lipids was studied by a chemiluminescence method[58]. When AOA of lipids is altered by the introduction of synthetic inhibitors, a related change in the capacity of lipids for oxidation is observed. Lipids exhibit a greater ability to form radicals the higher their antioxidant activity. In other words, with increase of the amount of antioxidants, the composition of lipids changes in such a way that the rate of generation of free radicals from them increases with a corresponding increase in the rate of consumption of antioxidants[69]. Thus, after the introduction of tocopherol into animals, AOA increases by a factor of two and the capacity of their lipids for oxidation increases by a factor of about ten. Similar data were obtained after the introduction of propyl gallate and 2,6-di-t-butyl-4-methylphenol as well as in other processes associated with a change in the level of AOA of lipids. It is noteworthy that the relation between AOA of lipids and their capacity for oxidation on the one hand and the corresponding rate of consumption of antioxidants on the other is satisfactorily linear[64].

The existence of this relation ensures the maintenance of a constant level of oxidation reactions in lipids regardless of whether their AOA has changed as a result of the change in the amount and quality of the natural antioxidants or as a result of the presence of synthetic inhibitors. The product k_7c determines which antioxidants, endogenous or those introduced into the organism, will be the first to be consumed and hence whether or not AOA of lipids will fall below the normal value.

Thus synthetic inhibitors of radical processes can be used to induce specific changes in AOA of lipids and probably to influence the course of diseases where a change in AOA of lipids is a significant factor.

III. THE INFLUENCE OF SYNTHETIC INHIBITORS ON PATHOLOGICAL PROCESSES INVOLVING CHANGES IN THE LEVEL OF ANTIOXIDANTS

It has now been shown that, in the development of a wide variety of pathological states, there is a change in AOA of the lipids in the organs and tissues[10,70].

In terms of the change in AOA of lipids, all the pathological states investigated and the changes in cell metabolic processes under the influence of particular environmental factors may be divided into three groups. In the first group radiation damage caused by radiation or by the introduction of radiomimetics[66,69,71-76], the state of stress caused by low temperatures[10,77,78], hyperoxia[79], hyperthermia[80], electrostimulation[81], poisoning with benzene[78], the ageing process[77,82], ischemia[83], etc. may be included among processes occurring at a reduced AOA level. It is important to note that the higher the rate of development of the given pathological state and the greater the involvment of a particular organ, the more marked is the decrease of AOA.

The changes in AOA of the lipids in the organs of tumour-bearing animals[66,68,84-90] and reparative regeneration processes in organs and tissues[91] belong to the second group of processes occurring mainly at an increased level of AOA. As in the first case, there is a relation between the rate of development of the process, the severity of the disease, and the change in AOA[90].

Processes which lead to a change in AOA by stages, for example the induction of malignant tumours (carcinogenesis)[92-94] may be included in the third group †. In the first stage of carcinogenesis, during a period equal to one-third

† Although in the first and second groups there are various stages in the changes of AOA, they continue over a very short time interval compared with the time required for the development of the process, so that one may assume that the processes occur mainly at an increased or reduced level of AOA.

of the time required for the induction of tumours, AOA falls. It increases subsequently, but normal values are reached only after a time interval approximately equal to one-half of the induction period. Finally, the third period is characterised by a sharp increase of AOA. The changes in AOA characteristic of different types of carcinogenesis are of a general type and the curves describing them can be combined into a single general curve[92].

The most interesting and important finding is that a wide variety of pharmacological agents (vitamins, hormones, adaptogens, alkylating preparations, antimetabolites, cytostatic agents, aliphatic acid esters, alkylindolinylamines, supermutagens, etc) influence AOA in doses sufficient for a manifest pharmacological effect. There are preparations which only increase AOA (for example hydroxypyridines), those which only decrease AOA (alkylating agents), and those which can both increase and decrease AOA (adaptogens, radical reaction inhibitors, hormones, antimetabolites, derivatives of nitrosoalkylurea, etc.)[65,71,86,87,90,95-99].

The possibility of using these compounds in the treatment of particular diseases is associated with the nature of the influence of the preparations on AOA. If the pathological process takes place at a reduced AOA level, a wide variety of compounds which increase antioxidant activity have a protective effect, which is more marked the greater the increase of AOA which they induce[69]. On the other hand, preparations which diminish AOA are effective in processes occurring at an enhanced AOA level[71,89,90,95]. For example, all antitumour preparations decrease AOA and the degree of inhibition of tumour growth is greater the more marked and longer lasting is the decrease of AOA by these substances[89,90].

The relation between the influence of the preparation on AOA and on the course of a particular pathological process was demonstrated most strikingly in a study of preparations which can both increase and decrease AOA (depending on the dose) or when the same preparation is introduced at different times during the development of the process occurring with changes in AOA by stages.

As stated above, the introduction inhibitors in small doses increases the antioxidant activity of lipids with subsequent recovery to the normal value, while large doses lead to an increase of AOA and its subsequent fall below normal values. The characteristics of the action of synthetic inhibitors used in the treatment of a wide variety of pathological states of the organism are associated with these properties. Thus it has been established that the ability of the inhibitor to protect against radiation increases with its dose, reaching a maximum for the optimal dose (C_{opt}), and then decreasing. At a certain negative inhibitor dose (C_{neg}) no effect is observed and with subsequent increase of the amount of antioxidant there is a transition from protective to sensitising properties of the inhibitors[74,100-102]. A similar effect is observed when the inhibitors are introduced both before and after irradiation[103]. C_{opt} is the maximum amount of the preparation for which AOA of lipids does not decrease below the normal value[66,74].

A similar dual effect on tumour growth has been observed: small doses of the inhibitor accelerate and large doses retard the development of the tumour. The accelerating effect on tumour growth is observed in the range of doses below C_{opt},[86,89] while antitumour activity is observed for doses greater than C_{opt}.[66,68,88,89] Since the influence on tumour growth is more marked the greater the reduction of AOA by inhibitors, for each preparation there is an inverse relation between its antitumour properties and its ability to protect against radiation[104-106]. The antitumour effect of equimolar doses of preparations is greater the lower the value of C_{opt} for these inhibitors[104]. In the dose range from C_{opt} to C_{neg} inhibitors can be useful in the radiotherapy of tumours[106].

Data for the variation of AOA in tumour growth, on irradiation, and following the introduction of inhibitors led to the prediction and subsequent experimental confirmation[107-109] of the existence of four regions of different effects of the joint application of radical-process inhibitors and irradiation on the tumour and the organism of the tumour-bearing animal. In region I of inhibitor doses and irradiation the preparation protects both the animal and the tumour from the action of radiation. in region II the preparation enhances the action of radiation on both the organism and on the tumour, in region III the preparation protects the tumour but sensitises the organism to the action of radiation, and finally in region IV the preparation enhances the effect of radiation on the tumour and at the same time protects the organism[108].

The available literature data for the anticarcinogenic effect of antioxidants behaving at the same time as radical process inhibitors are extremely contradictory. It has been shown that both natural (vitamin E) and synthetic antioxidants can retard tumour growth[93,94,110-117], have no effect whatever[118-120], and can "promote" carcinogenesis[121-123].

Since in the tumour induction process there are stages involving a decrease and an increase of AOA, different effects can be expected following the introduction of inhibitors in different doses and at different stages of carcinogenesis. Indeed, the introduction of an inhibitor belonging to the class of screened phenols in a dose which only increases AOA led to the arrest of the formation of tumours in the initial period and to a decrease of the percentage of tumours formed. On the other hand, if the same amount of the preparation was introduced at the stage corresponding to the increase of AOA, the tumours appeared sooner. The reverse behaviour was observed when large doses of inhibitors, causing a decrease of AOA were introduced[124]. From these standpoints, the discrepancies in the literature data are not unexpected.

One of the important aspects of the use of inhibitors is their application to protect the organism under stress, in the course of which AOA decreases. Synthetic inhibitors applied in doses increasing AOA exhibit antistress activity and protect animals from hyperoxia[79], poisoning by benzene[78], and stress due to cold[77,78]. The introduction of inhibitors in doses decreasing AOA enhances the effect of the stress-inducing agent[78]. Numerous studies have been made on the protective properties of tocopherol in poisoning by carbon tetrachloride and in intoxication by ozone. These have been reviewed[125].

It has been shown[83] that in the experimental ischemia of kidneys lipid AOA decreases and inhibitors applied in doses increasing AOA exhibit anti-ischemic activity, significantly prolonging the life of the animal.

An important property of the inhibitors, which opens up new fields for their application (for example in tissue and organ transplants), is their ability to influence specifically the rate of cell multiplication. In small doses inhibitors accelerate cell multiplication both in reparative regeneration[91] and when introduced into intact animals, increasing the level of the proliferative activity of the cells of their organs[126]. In doses decreasing AOA inhibitors retard cell multiplication. In the light of these facts, the desirability of employing inhibitors as geroprotectors is evident[127].

Although not all the aspects of the application of radical-process inhibitors have been considered, the principal features of antioxidant therapy are already clear from the data presented:

1. Inhibitor-antioxidants can be used in the treatment of diseases involving a reduced level of AOA. The preparations are more effective the higher the level of AOA following their introduction.

2. Inhibitors can be used also to suppress processes involving an increase of AOA. The inhibiting effect is shown only for inhibitor doses which reduce AOA.

3. Depending on the dose and the method and duration of introduction, the effect of the inhibitor can be reversed. The contradictory data concerning the therapeutic effects of preparations of this class are probably associated with this fact.

4. There is a consistent relation between different aspects of the biological activity of antioxidants, and their effectiveness has been found to depend on their physicochemical constants as inhibitors. This suggests that antioxidant properties are the cause of the wide spectrum of the biological activity of radical-process inhibitors. Furthermore, this justifies an initial selection of antioxidants on the basis of physicochemical models and makes it possible to recommend the synthesis of inhibitors which are most effective in a particular application.

IV. THE ROLE OF ANTIOXIDANTS IN THE STRUCTURE AND FUNCTION OF MEMBRANES

The problem arises of the causes of the significant role of the changes in AOA in the development of the pathological process and of the basis of the therapeutic activity of preparations normalising AOA.

Lipids together with proteins are the most important components of membranes. If it is assumed that antioxidant properties are indeed important for the functioning of membranes, there should be a correlation between the changes in these properties in the membranes of various organelles and the changes in their function, depending on AOA.

Together with the study of the widely known regulatory mechanisms in the cell (such as the repression–derepression of genes, the blocking–deblocking of the genome, the inhibition and activation of enzymes by allosteric effectors, and regulation with the aid of a secondary hormone mediator–c-AMP, etc) much attention is devoted nowadays to the study of the role of membranes in the regulation of cell metabolism. Numerous instances of the experimental confirmation of the Konev–Changeux hypothesis concerning the important role of cooperative transitions in the membrane in the switching of cell metabolism occurred in recent years[128,129].

The receptor function of membranes, compartmentalisation, the contact of properties of cell surfaces, and the transport function of membranes are all aspects of their funtional activity which can be regarded as the most important regulatory mechanisms of the vital activity of the cell. The relation between the structure of membranes and their functions is well known. Structural organisation in its turn is closely related to the physicochemical properties of the main components—lipids and proteins. The presence of antioxidants in the lipid phase of the membranes has been regarded by a number of workers as an obligatory condition for the maintenance of the membrane structure, since the development of peroxide oxidation in lipids leads to its breakdown[130,131]. There exists the hypothesis that lipid antioxidants also play an intrinsic structural role in the membrane[132] The changes in AOA of the lipids in liver homogenate have been compared[133] with the changes in AOA of the lipids in various cell fractions. It was observed that both in the lipids from the nuclei and from the microsomes and mitochondria the nature of the changes in AOA is virtually the same as in the homogenate in all the instances investigated.

The fractions of AOA corresponding to lipids of particular organelles are various and change with time, which suggests a redistribution of AOA among the subcellular fractions. The instant of the attainment of AOA maximum is somewhat different for various fractions. Such data have been obtained in the normal physiological variation of AOA—the daily rhythm: after the introduction of a synthetic antioxidant, after the recovery of the weight of the liver following partial hepatectomy, under the influence of radiation, and in tumour growth. Thus the changes in AOA in the organelle lipids are of the same type, although they differ in scale and duration.

It is important to consider whether the change in the functional activity of membranes leads to a change in the antioxidant activity of their lipids. It has been established[134] that, when cells pass from stage G_1 to the stage of DNA synthesis, there is a sharp phased decrease of lipid AOA both in the nuclei and in the entire homogenate. Comparison of the change in the functional state of mitochondria and lipid AOA[133] also shows that an increase of AOA leads to an increase of respiratory control and a transition of the mitochondria to the most completely regulated state. For microsomal fractions, a change in functional activity was observed in processes involving a change in AOA[135].

Thus an increase or decrease of lipid AOA in the homogenate leads to consistent changes of the same type in lipid AOA in the organelle membranes and to corresponding polyfunctional rearrangements of their metabolism.

In discussing the mechanism of the influence of free-radical oxidation reactions in lipids on the functioning of membranes, the following versions may be considered[10]:

1. The appearance of polar peroxy-groups in lipids can lead to a change in the intensity of hydrophobic interactions and can influence lipid–protein bonds in the membrane.

2. The free valence in the lipid components of the membranes can alter the stability of the complexes of enzymes and other macromolecules, for example DNA, with the membrane. Therefore even a slight change in free-radical concentration can alter the cell metabolism.

3. The change in the rate of oxidation reactions in lipids is associated with the change in lipid composition. At the same time it is known that phospholipids are cofactors and effectors for enzymes and that a change in their relative content can have a significant influence on metabolism.

4. The functioning of the membrane leads to a change in its conformation or is accompanied by such a change. The structural transitions in membranes are in their turn induced by conformational and phase transitions in proteins or lipids. Therefore a change in the physicochemical properties of lipids can alter the physicochemical properties of the membranes and hence their functional activity.

As stated above, the present author observed that both at the cellular and membrane levels the lipid composition changes in response to an increase in AOA in such a way that the lipids are more easily oxidised. Since the oxidised forms of lipids are more popular, one could postulate that their formation is a method whereby lipids can leave the membrane and their composition can be restored[136,137]. Then an increase of AOA should retard the release of the most readily oxidisable lipids. This should result in an enrichment of the membrane lipids in these fractions, which should in turn accelerate the utilisation of antioxidants.

It has been established[53,138] that the increase of AOA induced by the introduction of synthetic antioxidants leads to an increase of the relative amount of phospholipids and to a decrease of the amount of cholesterol. Changes are also observed among the phospholipid fractions. With increase of AOA, the lipids in the liver cell membranes are enriched in phosphatidylserine, phosphatidylinositol, and phosphatidylethanolamine—the more readily oxidised fractions of phospholipids. A decrease of AOA leads also to a decrease of the relative amount of such fractions and to an enrichment of lipids in sphingomyelin and phosphatidylcholine[136,139]. Thus the changes in the rates of oxidation reactions in lipids and in their compositions are interrelated in a single system, which ensures the steady-state oxidation of lipids.

We shall consider further the results of the change in the relative composition of membrane phospholipids. As stated above, a change in the composition of membrane lipids leads to a change in their microviscosity and influences their structural rearrangements in membranes. This results in an intensification or a weakening of the metabolic activity of enzyme proteins incorporated in the membrane.

To elucidate the influence of AOA on membrane structure, a study was made of the change in the state of biomembrane components using spin probes located preferentially in the lipid or protein phases of the membrane[140]. The following iminoxy-radicals were used for the investigation: 4-capryloyloxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radicals (probe I), and 2,2,6,6-tetramethyl-4,5-benzo-1,2,3,4-tetrahydrocarbolin-3-yloxy-radicals (probe II). Probe I was located preferentially in the lipid components of the membrane and probe II in the protein components. The influence of temperature on the mobility of the spin probes in the membranes of the organelles (nuclei and mitrochondria) in the cells of organs in intact animals and following the introduction of synthetic antioxidants was investigated. At 27° and 40°C there was a general conformational transition in the membranes, revealed with the aid of both probes. An increase in lipid AOA by the introduction of the antioxidant displaces the conformational transitions towards lower temperatures. It is interesting to note that the microviscosities in the membrane lipids and proteins vary in the opposite directions: the rotational mobility of the radical increases in lipids and decreases in proteins. An extremum is reached in the lipid phase 24 h sooner than in the protein phase. Thus the introduction of the antioxidant leads to the formation of a more "liquid" lipid component and to a more viscous protein component.

The change in the antioxidant properties of membrane lipids in tumour growth and under the influence of radiation[140] also altered the microviscosities of lipids and proteins and the conditions governing the structural rearrangements in the membrane. These findings can be accounted for by a change in the composition of the lipids in these processes, since it is known that a change in the cholesterol : phospholipids ratio and in the relative content of phospholipids alters the viscosity of the membrane components and the phase transition temperatures[141,142].

The second and no less important aspect is the influence of the change in the composition of lipids on the relative rates of the enzymatic reactions for which these lipids are effectors or cofactors.

It is known that the removal of phospholipids deactivates many enzymes and leads to the loss of their sensitivity to particular regulating agents[143,144]. The addition of phospholipids and cholesterol restores the activity of these enzymes and their sensitivity, the reactivating effect being frequently related specifically to the addition of a particular phospholipid. Thus β-hydroxybutyrate dehydrogenase is reactivated by phosphatidylcholine[145,146], adenylate cyclase by phosphatidylinositol[147], and FAD-dependent malate deydrogenase by cardiolipin[148]. The addition of phosphatidylserine to adenylate cyclase restores its sensitivity to glucagon[149] and the addition of phosphatidylinositol restores its sensitivity to noradrenaline[150]. It is extremely interesting that phospholipids behave as allosteric effectors for many regulating proteins[143]. This is not suprising, since the majority of the regulatory proteins have a quaternary structure enriched in non-polar aminoacids, for which hydrophobic interactions are extremely characteristic.

In view of the foregoing, it becomes understandable why a change in AOA leading to a change in lipid composition alters the structural viscosity of lipids, the lipid–protein linkages in the membrane, and the rate of the enzymatic reactions for which phospholipids are effectors. Owing to this, a change in the rates of oxidation reactions in lipids causes a transition of the cell to a new metabolic state characterised by new relations between the rate of particular enzymatic reactions.

The influence of lipids on regulating proteins permits an explanation of the possibility of switching the cell metabolism from one pathway to another when the composition of phospholipids is altered We may quote as an example the experiment in which a synthetic antioxidant was introduced into animals with a consequent increase of the concentration of phosphatidylethanolamine in liver microsomes together with an increase of AOA. According to model experiments[151], the addition of total phospholipids or of individual components reactivates or increases the activity of glucose-6-phosphates. It was of fundamental importance to establish the possiblity of regulating the activity of enzymes by lipids *in vivo*. In our laboratory Molochkina and Dzhalyabova observed that, simultaneously with the increase of the concentration of phosphatidylethanolamine, the activity of glucose-6-phosphatase increases in liver microsomes. A similar relation obtains not only following the introduction of antioxidants, but also in other processes accompanied by a change in AOA of lipids and hence in the concentration of phosphatidylethanolamine.

From the same standpoint, it is possible to explain also the role of lipids in the regulation of the rate of cell proliferation. As stated above, an increase of AOA leads to an increase of the concentration of phosphatidylserine and phosphatidylinositol, which function as effectors for adenylate cyclase. The influence of lipids on the activity and sensitivity of adenylate cyclase—the enzyme responsible for the formation of cAMP—makes it possible to explain the role of antioxidants in the regulation of cell proliferation at the molecular-biological level. Studies have been published recently in which much attention was devoted to the change in the composition of lipids during the synthesis of DNA. It is suggested that phospholipids form complexes with a DNA molecule, altering its stability, and are essential for the initiation of the synthesis of DNA[153,154]. Furthermore, *in vivo* experiments established the influence of phospholipids on the matrix activity of the gene and a difference between the amounts of phospholipids in repressed and derepressed genes[154]. It has been shown[155] that a change in AOA and composition of nuclear lipids is associated with a change in DNA synthesis. An increase in the amount of sphingomyelin in nuclear lipids against the background of a sharp decrease of AOA at the beginning of DNA synthesis is particularly significant.

The above experimental data show that the change in the antioxidant properties of lipids, caused both by a change in the amount of intrinsic natural antioxidants and by the

introduction of non-toxic synthetic inhibitor-antioxidants, alters significantly the cell metabolism. The importance of the change in the antioxidant properties is associated with the role of membranes in the regulation of cell metabolism, the functional activity of the membranes being altered when the physicochemical characteristics and the composition of the membrane components are changed.

In view of the foregoing factors, synthetic inhibitor-antioxidants can be usefully employed to act specifically on a wide variety of processes occurring with change in AOA of lipids.

Physicochemical Mechanism of the Damage Sustained by Deoxyribonucleic Acid under the Influence of Various Agents

K.E.Kruglyakova

Data obtained in studies on the damage suffered by DNA molecules under the influence of ionising ultraviolet, or ultrasonic radiation, and chemical mutagens are reviewed. The application of chemical kinetic and other physicochemical methods (ESR, chemiluminescence, spin labels, electron microscopy, etc.) to the study of the mechanism of the damage to DNA molecules acted upon in different ways is considered and mechanisms whereby chemical and structural changes occur in DNA are analysed. The hypothesis of the free-radical mechanism of the damage sustained by DNA under the influence of radiation and of the possible use of radical-reaction inhibitors as agents offering protection from radiation is discussed and evidence for its validity is presented.
The bibliography includes 181 references.

I. INTRODUCTION

In 1957 Emanuel[9] suggested that physicochemical and chemical kinetic methods be used to investigate many pathological processes such as radiation sickness, tumour growth, ageing, and others[1-5]. These processes were studied at various levels of organisation—molecular[6,7], cellular[8-10], and at the level of the whole organism[11-14].

Studies at the molecular level included analysis of changes in important biomacromolecules such as proteins[15-17], nucleic acids[18-23], lipids[24-26], and enzymes[27-29], slight changes in the structure of which can lead to the breakdown of the normal vital processes in the cell. Much attention has been devoted to the analysis of the damage suffered by nucleic acids, particularly deoxyribonucleic acid (DNA)[30,31].

It is known that the change in the structure of DNA acted upon in different ways can easily lead to the breakdown of hereditary information, to a change in the synthesis of specific proteins, and in many instances to cell death. The use of physicochemical methods for quantitative investigation of the damage sustained by the DNA structure under the influence of various factors in model experiments yields data about the primary molecular "events" leading to damage to the macromolecule. This information is important for the solution of the general problem of nucleic acids, associated with the processes involved in their functioning in the cell (in particular for the understanding of the mechanism of the occurrence of mutations or of the death of the cell).

II. THE CHANGE IN THE PHYSICOCHEMICAL PROPERTIES OF DNA UNDER THE INFLUENCE OF IONISING RADIATION. THE MECHANISM OF THE PROTECTIVE ACTION OF RADICAL-REACTION INHIBITORS

Only the first steps have been taken so far in many attempts to elucidate the physicochemical nature of the processes occurring in the irradiated cell[32-34]. To determine the characteristics of the development of reactions leading to the death of the cell, it is important to discover which cell structures are damaged and in what sequence. Numerous radiobiological studies have shown that the nucleus is damaged by ionising radiation[35,36], cell division is affected[37], and chromosomal aberrations occur[38]. It has been shown that the replacement of thymine in DNA by its halogenated analogues intensifies the sensitivity of the cell to irradiation[39,40]. Analysis of reduction processes in the irradiated cell established a relation between the chemical changes in the DNA macromolecule and the observed radiation-induced effect[41]. These data showed that DNA is one of the principal targets for radiation.

The first studies on the radiation-induced damage to DNA following the application of high radiation doses led to the detection of both chemical changes in the macromolecule (the formation of peroxides, evolution of ammonia)[42,43] and of structural damage in DNA (a change in the viscosity of the irradiated solutions)[44]. Later investigations demonstrated that the action of ionising radiation on DNA may lead to the single and double breaks in the macromolecular chains[45-48], to a chemical modification

of the bases, and to cross-linking between the complementary DNA chains[49-51].

As new physical, biochemical, and physicochemical methods for the investigation of biomacromolecules were developed, it was possible to differentiate the action of different radiation doses on DNA, which must be taken into account in studies on the mechanism of the radiation-induced damage to the cell and the organism as a whole. Thus the employment of the method of spin labels[52] for the analysis of the damage in DNA revealed conformational changes in the macromolecules under the influence of low radiation doses (0.5–8 krad)[53]. The spin label correlation time τ_c (the average time necessary for the rotation of the stable radical by 45°) and the associated inverse variation of the radical rotation frequency ν were calculated from the ESR spectra of spin-labelled DNA. These values yield information about the kinetics of the changes in the microenvironment of the label during irradiation. The observed sharp decrease of τ_c with increasing dose indicates a change in the DNA structure near the site of addition of the label (Fig. 1).

Analysis of the lg τ_c–$1/T$ curves made it possible to determine the temperature of the structural transitions (T_{st}), which shifts on irradiation towards lower values. This indicates conformational changes in the macromolecule. It was established that the values of T_{st} for DNA isolated from various sources differ significantly. Thus T_{st} for DNA isolated from tumour cells is lower than for DNA isolated from normal cells[53,54]. The observed difference may be caused by the fact that in tumour cell DNA there are more defects in the secondary structure[55]. The validity of this hypothesis was demonstrated by analysing the defects in the secondary structure of DNA, isolated from normal and tumour cells, by the kinetic formaldehyde method[56]. The applicability of this method to the analysis of structural damage in DNA for low γ-radiation doses (up to 5 krad) has been demonstrated[57]. The authors observed a single structural defect for 2600 pairs of nucleotides.

The conformational changes in DNA at low doses were also detected by pulse polarography[58]. Some investigators point out the possibility of damage to DNA bases at low doses (2–10 krad)[59].

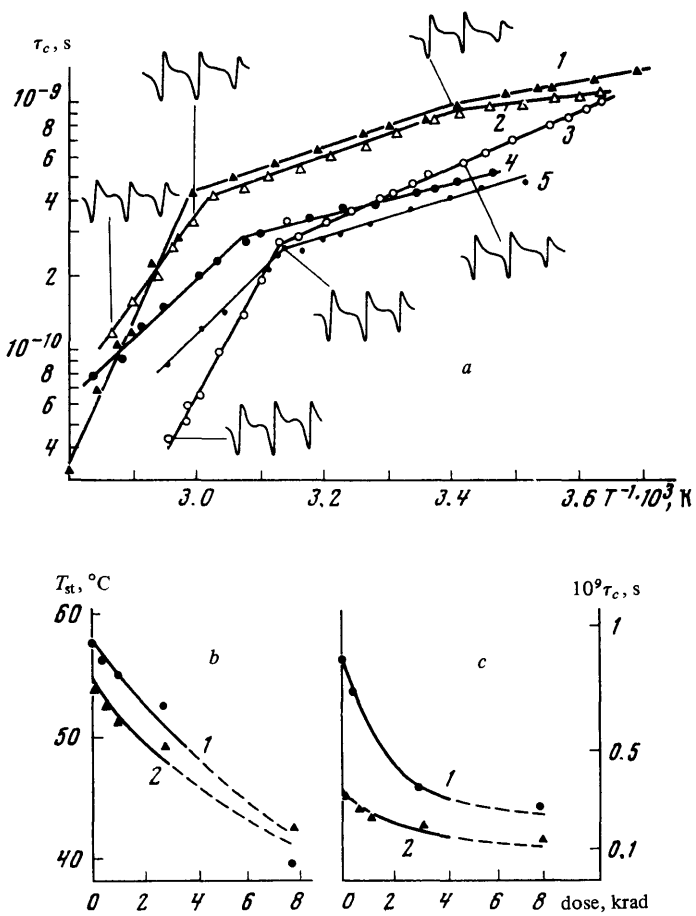

Figure 1. ESR spectra and temperature variation of the correlation time of spin-labelled DNA: *a*) [1) and 2) DNA isolated from the blood lymphocytes of two healthy cows; 3)–5) DNA isolated from the blood lymphocytes of three cows suffering from leukemia]; *b*) and *c*) variation with the dose of T_{st} and τ_c for DNA isolated from normal (curve *1*) and leukemic (curve *2*) cells.

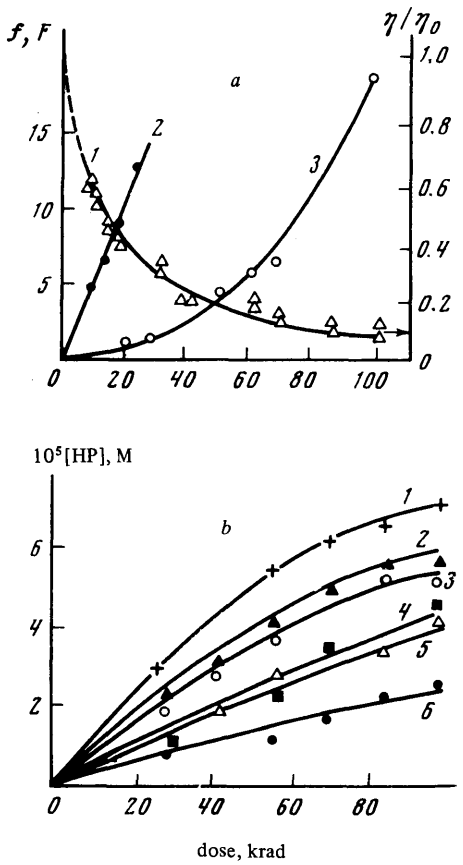

Figure 2. Variation of the physicochemical (*a*) and chemical (*b*) properties of DNA on irradiation with different doses: *a*) [1) intrinsic viscosity in relative units; 2) and 3) number of single (line *2*) and double (line *3*) breaks in DNA]; *b*) amount of DNA hydroperoxides formed on irradiation [DNA concentration (μg ml^{-1}): 1) 1000; 2) 700; 3) 500; 4) 400; 5) 100; 6) 50].

High doses (20–100 krad) lead to significant structural changes in the macromolecule (single and double breaks occur) and to chemical changes (the formation of hydroperoxides)[60–63] (Fig. 2). Infrared spectroscopy[64,65] made it possible to observe a modification of the bases at doses of 20–100 krad from the change in the intensity of the bands in the spectra of irradiated DNA solutions: deamination (3350, 3200, and 1600 cm^{-1} bands); saturation of double bonds (1580 and 1650 cm^{-1} bands); damage to the secondary DNA structure—rupture of hydrogen bonds (1700 cm^{-1} band) and of phosphate ester linkages (953 cm^{-1} band) (Fig. 3). The radiation-induced damage to DNA may be observed in electron micrographs of the macromolecule[66,67]. Long linear molecules are converted into short segments and coils after irradiation with doses in the range 60–300 krad.

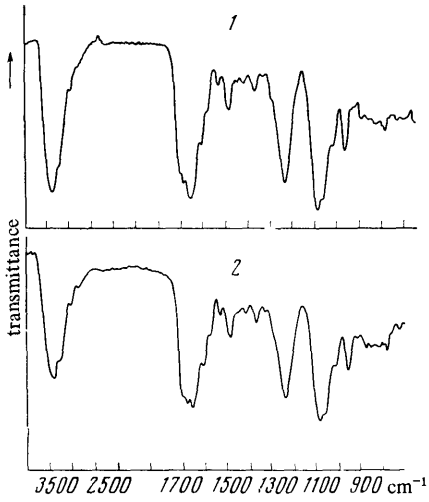

Figure 3. Infrared spectra of a calf thymus DNA film for 32% relative humidity: 1) native DNA; 2) γ-irradiated DNA (dose 55 krad).

The question arises of the causes of these significant changes in the DNA molecule and of the stages in the multistage mechanism of the damage sustained by the macromolecule where external action is necessary in order to liquidate or arrest the process. Several years ago Emanuel' put forward the following considerations on the basis of general concepts in chemical kinetics, radiation chemistry, and biochemistry[68]:

"1. The action of ionising radiation leads to the formation of free-radical states of the chemical components of the cell which may give rise to biochemical processes which are not characteristic of the living organism under normal conditions.

2. The development of free-radical reactions in the organism must lead to a decrease of the amount of inhibitors in the tissues, as happens in chemical radical processes induced by radiation in the presence of inhibitors. The decrease of the amount of tissue inhibitors impairs the ability of the organism to regulate correctly biochemical processes, which may be one of the causes of the changes characteristic of radiation sickness".

The above ideas made it necessary to investigate the free-radical states in biochemical systems, particularly in biomacromolecules—proteins, lipids, and nucleic acids. It has been shown by ESR[69,70] and chemiluminescence[71] methods that both the primary radicals formed in the course of irradiation of DNA and the secondary radicals generated as a result of the decomposition of hydroperoxy-compounds derived from DNA are important for the structural damage in the macromolecule.

The formation and reactions of DNA radicals were detected in the course of irradiation of aqueous DNA solutions at low temperatures (77 K). All the DNA radiolysis products are stable under these conditions[72]. It has been shown that the ESR spectrum of the irradiated DNA solutions contains lines due to paramagnetic species formed from water (ȮH radicals and stabilised electrons e_{st}) and DNA macroradicals. When the specimen is heated, the ȮH radicals and the electrons e_{st} vanish and the spectral lines due to the DNA radical appear. The doublet for the DNA radicals is gradually "converted" into a more complex quartet and at high temperatures (193 K) an eight-component spectrum is recorded, similar to that of the thymine radical[72,73].

With increase of DNA concentration in solution and of irradiation temperature, the yield of radicals rises. Kinetic curves for the accumulation of DNA radicals satisfy the equation $c = c_{st}(1-e^{-kD})$, where c_{st} is the steady-state concentration of radicals at high irradiation doses, k the rate constant for the destruction of radicals during irradiation, and D the radiation dose in Mrad.

To determine the nature of the radicals formed from DNA and the location of the free valence in the macromolecule, a study was made of the effect of radiation on compounds simulating individual fragments of the biopolymer—nitrogenous bases[74,75], carbohydrates[76–80], and phosphoric acid[81]. The formation of free radicals from nitrogenous bases was investigated under various conditions. The most detailed study was made of the formation and reactions of thymine radicals. It was established that thymine radicals are formed as a result of the interaction of an electron with a thymine molecule and the formation of a radical-anion, to which a hyperfine doublet structure corresponds in the ESR spectrum. On reacting with water, the radical-anion is converted into the thymine radical (of the type ṪH) (eight-component ESR spectrum). The observed hyperfine structure of the spectrum is due to the localisation of the unpaired electron at the $C_{(5)}$ atom of thymine[75].

The primary reaction in the formation of radicals in the sugar fragment of DNA is the abstraction of a hydrogen atom by ȮH radicals and free hydrogen atoms. Analysis of the ESR spectra of irradiated preparations of 2-deoxyribose and other carbohydrates[76,80,82] permitted an interpretation of the ESR spectrum of 2-deoxyribose as a result of the superposition of lines due to radicals in which the free valence is mainly located at the $C_{(1')}$, $C_{(3')}$, and $C_{(5')}$ atoms.

Irradiated frozen solutions of phosphate salts and phosphoric acid itself, DNA, and compounds simulating its sugar fragment were investigated by ESR. The ESR spectra of DNA did not contain lines characteristic of phosphoric acid radicals. This led to the conclusion that, even if the phosphate fragment in DNA is damaged, ultimately the free valence is located at the sugar fragment[81].

A comparative study of the ESR spectra of DNA, 2-deoxyribose, and nitrogenous bases led to the conclusion that at least two types of free radicals may be formed in DNA: with the free valence localised in the sugar fragment

and in the nitrogenous bases. The formation of radicals in DNA is possible as a result of both direct and indirect action of radiation.

The DNA macroradicals ($\dot{R}_{DNA}$) formed on irradiation are converted in the presence of oxygen into peroxy-radicals $R\dot{O}_2$ [72,73] and further into peroxide compounds (hydroperoxides):

$$\dot{R} + O_2 \rightarrow R\dot{O}_2 \rightarrow RO_2H.$$

Hydroperoxides are known to be radiotoxins and can in turn decompose with formation of radicals, initiating undesirable processes both in DNA solutions (a decrease of the molecular weight of the biopolymer, the occurrence of single breaks) and in the cell.

The formation of DNA hydroperoxides on irradiation has been established in a number of studies [84,85]. Kinetic analysis of the DNA hydroperoxide formation and decomposition processes showed [63,86,87] that hydroperoxides of two types are formed—relatively unstable and more stable. In a general form the rate constants for their decomposition can be represented as follows:

$$k_1 = 3.6 \cdot 10^5 \exp(-13000/RT),\ s^{-1};$$
$$k_2 = 1.3 \cdot 10^{11} \exp(-23000/RT),\ s^{-1}.$$

These expressions agree satisfactorily with the rate constants for the decomposition of hydroperoxides (HP) derived from thymine (k_t) and cytosine (k_c):

$$k_t = 4.5 \cdot 10^{11} \exp(-23000/RT),\ s^{-1};$$
$$k_u = 6.4 \cdot 10^5 \exp(-11500/RT),\ s^{-1}.$$

This suggested that, among the DNA hydroperoxides, those derived from cytosine and thymine are respectively less and more stable. The addition of inhibitors [88] demonstrated that the decomposition of cytosine hydroperoxide and hence of the less stable DNA hydroperoxide has a radical mechanism [87]. The decomposition of cytosine hydroperoxide (4.0×10^{-5} M) was retarded in the presence of α-naphthol, an effective inhibitor of free-radical reactions. The α-naphthol itself was consumed at a rate proportional to the rate of decomposition of the hydroperoxide, which indicated the possibility of the formation of radicals in the decomposition of cytosine hydroperoxide. In a study of the nature of the chemiluminescence of irradiated DNA solutions it was shown that the glow is due to the radical decomposition of DNA hydroperoxides and probably cytosine hydroperoxide [89-92]. This followed from a number of experimental findings (Fig. 4): a linear relation was observed between the chemiluminescence intensity and the concentration of hydroperoxides; the kinetic curve for the decomposition of the less stable DNA hydroperoxide had a shape closely similar to that of the kinetic luminescence curve; the activation energies for the chemiluminescence of the irradiated DNA solutions (E_{chl}) and for the decomposition of the less stable hydroperoxide (E_1) and cytosine hydroperoxide (E_c) had the following values:

$$E_{chl} = 13 \pm 1 \text{ kcal mole}^{-1};$$
$$E_1 = 13 \pm 1 \text{ kcal mole}^{-1};$$
$$E_c = 11 \pm 1 \text{ kcal mole}^{-1}.$$

The overall hydroperoxide decomposition mechanism can be represented as follows [22,71]:

$$ROOH \xrightarrow{k_0} R\dot{O} + \dot{O}H;$$
$$\dot{O}H + ROOH \xrightarrow{k_1} R\dot{O}_2 + H_2O;$$
$$R\dot{O} + R\dot{O} \xrightarrow{k_8} h\nu + \text{products};$$
$$R\dot{O} + R\dot{O}_2 \xrightarrow{k_{12}} h\nu + \text{products};$$
$$R\dot{O}_2 + R\dot{O}_2 \xrightarrow{k_{22}} h\nu + \text{products}.$$

Assuming a steady-state concentration of radicals in the system, it is possible to formulate equations for the rate of reaction of $\dot{O}H$, $R\dot{O}$ and $R\dot{O}_2$, the solution of which on the assumption that $k_8 = \sqrt{k_6 k_9}$ yields an expression for the concentration of these radicals. The destruction of $\dot{O}H$ radicals may be neglected since in the presence of ROOH the rate of their recombination is lower by several orders of magnitude than the rate of their reaction with ROOH. [93] The steady-state concentrations of the radicals are given by

$$[R\dot{O}] = \sqrt[6]{\frac{k_{22}}{k_6}}\,[R\dot{O}_2];$$
$$[R\dot{O}_2]^2 = \frac{k_0\,[ROOH]}{k_{22} + k_{12}\sqrt{k_{22}/k_6}}.$$

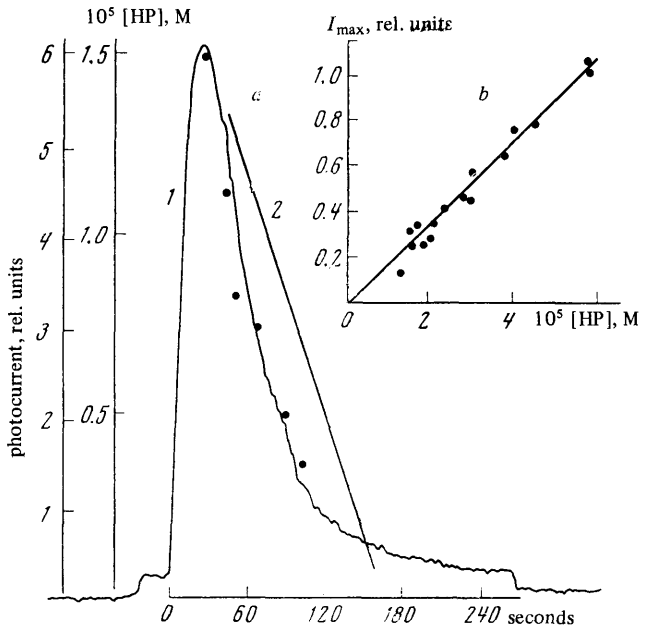

Figure 4. Chemiluminescence in the decomposition of DNA hydroperoxides: *a*) time variation of the chemiluminescence intensity (curve *1*) and of the concentration of the less stable hydroperoxide (circles on the curve) in irradiated DNA solution at 72°C; curve *2* is the semilogarithmic form of kinetic curve *1*; *b*) variation of the maximum intensity of the chemiluminescence of an irradiated DNA solution (700 μg ml^{-1}) with the initial concentration of hydroperoxides.

Since the chemiluminescence intensity I_{chl} is proportional to the rate of recombination of free radicals, one can write on the basis of the mechanism adopted

$$I_{chl} = Ak_6[R\dot{O}]^2 + Bk_{12}[R\dot{O}] \cdot [R\dot{O}_2] + Ck_{22}[R\dot{O}_2]^2.$$

Taking into account the expressions for $[R\dot{O}]$ and $[R\dot{O}_2]$, we obtain

$$I_{chl} = \alpha k_0\,[ROOH] = \alpha k_0\,[ROOH]_0 e^{-kt},$$

where

$$\alpha = \frac{Ak_{22} + Bk_{12}\sqrt{k_{22}/k_6} + Ck_{22}}{k_{22} + k_{12}\sqrt{k_{22}/k_6}}.$$

The expression obtained for I_{chl} agrees satisfactorily with experimental data [22].

Thus irradiation of aqueous DNA solutions may result in the formation of radicals both in the primary irradiation stages and as a result of the transformation of chemical products in secondary processes. Both reactions can be the primary cause of undesirable processes in the cell and can lead to breaks in the DNA chain and impairment of transcription. It was reasonable to suppose that the most effective means of preventing undesirable reactions involving free radicals might be inhibitors of free-radical processes (IRP), which have been used successfully in chemistry and have been proposed by Emanuel' [68] as agents offering protection from radiation (radioprotective agents or radioprotectors).

Studies on the radioprotective properties of IRP in model experiments with DNA [94,95] established that the most effective radioprotectors are derivatives of gallic acid, 3-hydroxypyridine, and phenylethylamine. The radioprotective effect of all the compounds under the conditions of appreciable damage to the molecule (60 krad) amounts to 80–90% when they are added before irradiation; derivatives of gallic acid and 3-hydroxypyridine exhibit a definite protective effect (20–48%) when they are used after irradiation [95]. Radical-reaction inhibitors greatly reduce the inactivation of the transforming activity of DNA under the influence of ionising radiation [96].

The observed linear relation between the protective effect and the antiradical effectiveness of the test compounds confirms the hypothesis of a significant role of free radicals in the damage to the DNA molecule and the analogous relation found in experiments on animals [97,98] shows that these compounds are promising radioprotective agents.

The protective effect of IRP added before irradiation can involve two mechanisms:

1. Via the interaction of the inhibitors with radical products of the radiolysis of water. This follows from the finding that the yield of DNA radicals on irradiation in the presence of propyl gallate (PG) is significantly reduced (G is 0.1 without PG and 0.02 with PG).

2. Via the reduction of the DNA radical by the inhibitor before the radical undergoes further reactions:

$$\dot{R}_{DNA} + InH \rightarrow RH + In\cdot.$$

This follows from experiments designed to study the changes in the DNA and propyl gallate radicals, irradiated at low temperatures, when the specimens are heated [99]. It has been shown that, when aqueous DNA solutions (5%) are irradiated in the presence of propyl gallate (0.03 M) at 77 K, $\dot{O}H$, $\dot{R}_{DNA}$, and $\dot{R}_{PG}$ radicals are formed. It has been established that, with increase of specimen temperature from 77 to 123 K, the $\dot{O}H$ radicals disappear, but the sum of the $\dot{R}_{DNA}$ and $\dot{R}_{PG}$ radicals remains unchanged. Subsequently, with increase in temperature from 173 to 193 K, the overall concentration of radicals does not alter, but $[\dot{R}_{DNA}]$ falls, while $[\dot{R}_{PG}]$ increases simultaneously. The operation of this mechanism of the protection of the macromolecule may be of interest in connection with the possible reduction reactions in the cell during irradiation.

As regards the protective action of inhibitors added after irradiation, presumably under these conditions they can interact with the radicals formed on decomposition of secondary products, for example hydroperoxides, and thus inhibit the reactions involving them. The intensity of the observed chemiluminescence of irradiated DNA solution decreased in the presence of various inhibitors (Fig. 5), the decrease being more marked the more efficient the inhibitor [90].

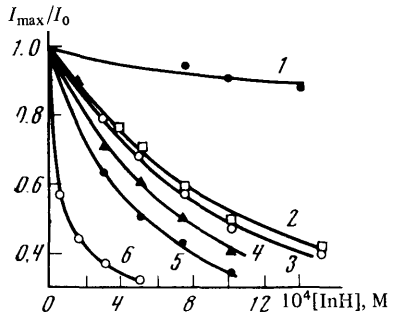

Figure 5. Variation of the intensity of the chemiluminescence of DNA solutions with the concentration of inhibitors at 72°C; inhibitor: 1) 4-ethylphenol; 2) hydroquinone; 3) catechol; 4) propyl gallate; 5) pyrogallol; 6) cysteine.

The mechanism of the possible reactions in this instance can be represented as follows [22,71]:

$$ROOH \xrightarrow{k_0} R\dot{O} + \dot{O}H;$$
$$R\dot{O} + InH \xrightarrow{k_7} ROH + In\cdot;$$
$$\dot{O}H + InH \xrightarrow{k_7} HOH + In\cdot;$$
$$R\dot{O} + R\dot{O} \xrightarrow{k_8} h\nu + \text{products};$$
$$\left.\begin{aligned} R\dot{O} + In\cdot &\xrightarrow{k_9} \\ In\cdot + In\cdot &\xrightarrow{k_9} \end{aligned}\right\} \text{without excitation of luminescence.}$$

This mechanism makes it possible to derive a relation between the intensity of the luminescence in the inhibited (I) and uninhibited (I_0) processes and the inhibitor concentration in the system:

$$\sqrt{\frac{I_0}{I}} = 1 + \frac{k_7}{\sqrt{2k_0k_8[ROOH]}}[InH].$$

A linear relation between $\sqrt{I_0/I}$ and the concentration of the inhibitor employed was indeed observed experimentally [91].

However, one should bear in mind that the reaction of the inhibitor involving the formation of free radicals may prove important in many cases as regards damage to cell components. Experiments on tumour cells by Lipchina, Pelevina, and coworkers [100] established that propyl gallate, the most effective radical-reaction inhibitor, can act in two ways depending on the experimental conditions. When PG was added to cells a short time before irradiation (15 min), a radioprotective effect was observed; on the other hand, when it was added to cells after 18 h, the latter were sensitised to radiation. The author suggested that the observed effect may be due to the possible damage of cell DNA by the PG reaction products.

To discover whether the PG reaction products can indeed react with the DNA molecule and how this affects the protective effect of PG, experiments were performed on isolated DNA where PG was added to irradiated DNA solutions at different times before irradiation and for

different degrees of oxidation of PG. [101,102] It was found that the addition of PG to the DNA solution immediately before irradiation results in a protective effect, which is enhanced with increasing PG concentration. The degree of protection falls when PG is added in an oxidised form or several hours before irradiation. The extent of the reduction of the protective effect increases with increasing contact time between PG and DNA before irradiation (Fig. 6).

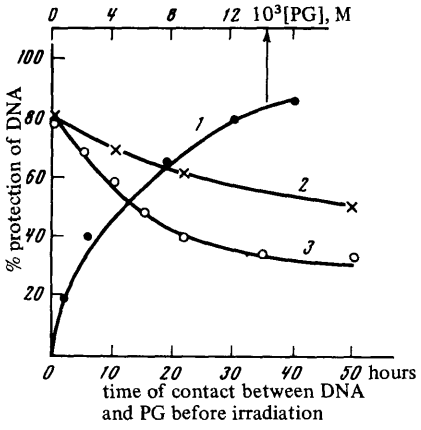

Figure 6. Effect of propyl gallate on the degradation of DNA during irradiation: 1) increase of the protective action in relation to DNA with increase of the initial propyl gallate concentration; 2) and 3) decrease of the protective action of propyl gallate in relation to DNA as a function of the duration of its contact with DNA before irradiation and of the degree of its oxidation [2) unoxidised propyl gallate; 3) propyl gallate oxidised to the extent of 30%].

One of the possible causes of the observed effect may be damage to the DNA structure by active PG oxidation products long before irradiation, which make the molecule more sensitive to subsequent irradiation.

Propyl gallate is known to be oxidised in an aqueous medium in the presence of oxygen, forming various biologically active radical and non-radical products: semiquinone radical-ions, quinones, etc. [103]. These intermediates can interact with the SH groups of proteins [104], can suppress the activity of many enzymes [105], can exhibit radiomimetic activity, and in particular can cause the rupture of chromosomes [106]. The formation of active radical intermediates is indicated by the chemiluminescence in the oxidation of PG. [102] The addition of DNA to the system both initially and at the instant corresponding to the maximum chemiluminescence intensity (Fig. 7) sharply reduces the yield of the oxidation products and the chemiluminescence. Free-radical oxidation products of the oxidation of PG were detected by ESR, their amount decreasing in the presence of DNA (Fig. 8). These findings show that the PG reaction products interact with DNA.

Experiments where PG oxidised to different extents had been added to DNA solutions showed that the longer the oxidation time of the added PG the more severe the damage to the DNA structure—single and double breaks appear in the molecule.

Thus, if one of the causes of the radiation-induced injury to cells is indeed damage of the DNA structure, then model experiments with isolated DNA will undoubtedly prove useful for the understanding of the mechanism of the damage of macromolecules and in the search for chemicals capable of causing specific changes in the sensitivity of the cells to radiation. In this sense radical reaction inhibitors are the most promising.

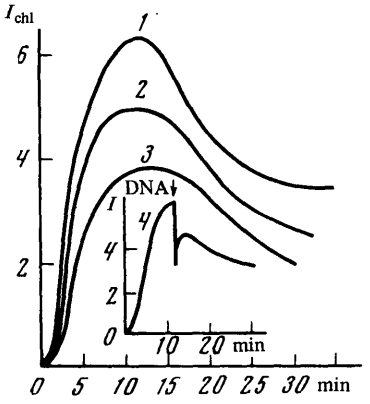

Figure 7. Variation of the intensity of chemiluminescence in the oxidation of propyl gallate: 1) at 70°C; 2) and 3) in the presence of added DNA at various concentrations [2) 80 μg ml^{-1}; 3) 160 μg ml^{-1}]; 4) variation of the chemiluminescence after the addition of DNA (80 μg ml^{-1}) at the instant corresponding to its maximum intensity.

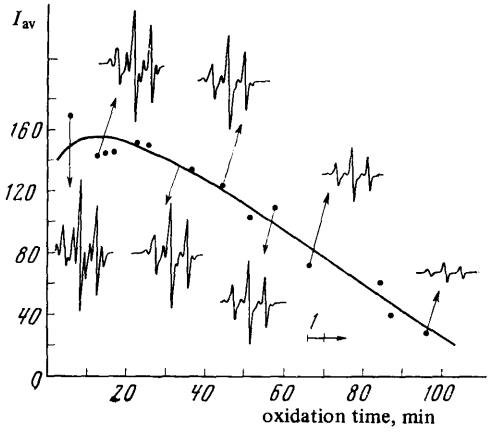

Figure 8. Variation of the intensity of the middle line in the ESR spectrum and of the shape of the propyl gallate spectra during oxidation in an aqueous alcoholic medium at 20°C and pH 11.5.

III. KINETICS OF THE DENATURATION OF DNA BY ULTRAVIOLET LIGHT

Ultraviolet light is known to be selectively absorbed by nucleic acids. DNA has been for many years the main object of studies on the effect of ultraviolet light at the

molecular level[107-109], since the nature of the observed changes in the cell[110] subjected to ultraviolet irradiation—mutations, chromosomal aberrations, and inhibition of cell respiration and DNA synthesis—indicate significant damage to the DNA.

The structural changes in DNA have been analysed by various physicochemical methods[111-116]. It has been shown that the exponential decrease of viscosity is associated with a parallel increase of optical density (hyperchromic effect), the kinetic constants for these processes having the same absolute magnitude (7.6×10^{-2} min^{-1}) [111]. Since it is well known that the hyperchromic effect is based on the impairment of the plane-parallel stacking of the bases due to hydrogen bonding and hydrophobic interaction between neighbouring bases are characteristic of native DNA, this agreement between the constants can be accounted for by the fact that the change in viscosity is due to the impairment of precisely these bonds. Thus the action of ultraviolet light reduces mainly to the denaturation of the molecule. This conclusion has been confirmed by the sedimentation analysis of DNA solutions after ultraviolet irradiation. It was shown that the sedimentation constant hardly changed in the course of the irradiation of DNA solutions (40 μg ml^{-1}) with ultraviolet light, which may indicate the absence of a sharp change in the molecular weight of the irradiated preparation[114].

The denaturation of the DNA molecule induced by ultraviolet light has been clearly illustrated by photomicrographs[112] recorded at specified time intervals. In the course of the first 5 min the photomicrographs show individual condensed sections which become clearly visible after irradiation for 20 min. On further irradiation (after 30 and 50 min) coils, the number and size of which increase, are visible in the field of view together with elongated molecules (Fig. 9). Evidently the denaturation process proceeds gradually with accumulation of denatured sections along the molecular chain.

These local conformational changes have been studied by ESR using 4-(β-aziridinopropionyloxy)-2,2,6,6-tetramethylpiperidin-1-yloxy-radicals as the spin labels[117]. It was shown that the denaturation of DNA is accompanied by an appreciable increase of the intensity of the ESR signal due to the label bound to DNA [115], which constitutes evidence that the label is joined in the first place to partly unwound or denatured sections of the DNA molecule.

The denaturation of the macromolecule can be followed by the change in the intensity of the signal of the label bound to DNA. Comparison of the changes in the ESR signal intensity I of the label and in the intrinsic viscosity of the solution η during the initial stage of irradiation showed that, as I increases η decreases. The change in the signal intensity of the label and the decrease of viscosity characterise to an equal extent the macroeffect of the ultraviolet irradiation on DNA solutions, i.e. the process in which local denaturation sites accumulate. The correlation times τ_c, which pass through an extremum (a maximum) as a function of the irradiation dose, were calculated. For low irradiation doses (up to 1.4×10^6 erg mm^{-2} for c_{DNA} = 600 μg ml^{-1}), τ_c increases, i.e. the mobility of the label diminishes; in the dose range ($1.4-3.5) \times 10^6$ erg mm^{-2} τ_c remains constant, falling sharply at still higher doses (Fig. 10).

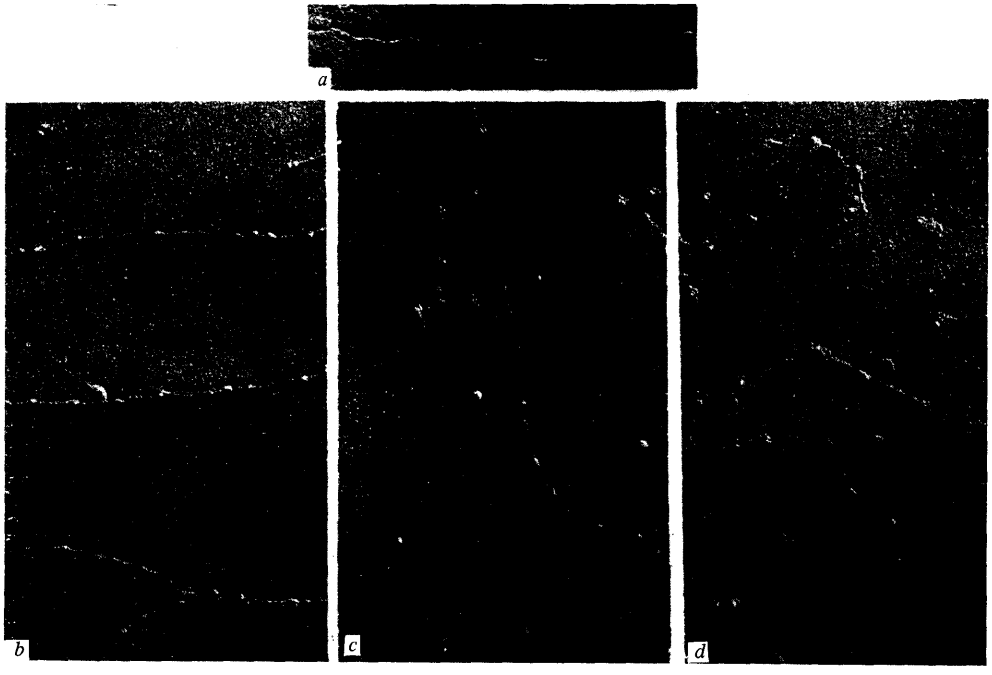

Figure 9. Photomicrographs of DNA preparations irradiated with ultraviolet light: *a*) fragment of the molecule of a native DNA; *b*) dose 3.6×10^5 erg mm^{-2}; *c*) dose 7.2×10^5 erg mm^{-2}; *d*) dose 1.2×10^6 erg mm^{-2}. The dimensions indicated in the photomicrographs correspond to 0.5 μm.

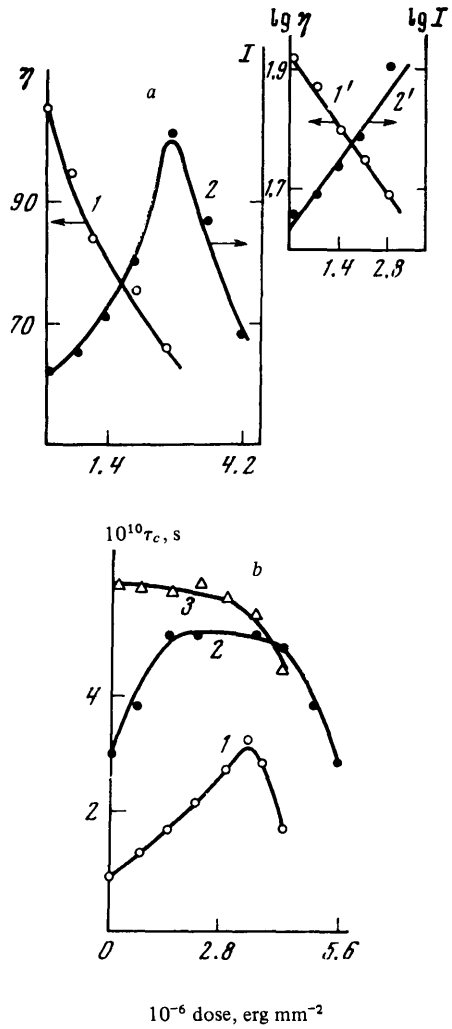

Figure 10. Variation of the viscosity and of the parameters of the ESR spectra of spin-labelled DNA as a function of the dose of ultraviolet irradiation: *a*) variation of the viscosity of DNA solutions (curve *1*) and of the intensity of the ESR signal (curve *2*) with the dose; lines *1'* and *2'* are semilogarithmic plots corresponding to curves *1* and *2*; *b*) variation with the dose of the correlation time for the spin label at different DNA concentrations [1) 400 μg ml^{-1}; 2) 600 μg ml^{-1}; 3) 900 μg ml^{-1}].

The decrease of the mobility of the radical may be caused by the increase of microviscosity within the local denaturation region. Two processes are known to occur in such regions: the accumulation of single breaks and the formation intramolecular cross-links as a result of the dimerisation of thymine bases. It has been suggested that thymine dimers accumulate in a single locally denatured region. The increase of τ_c can probably be a consequence of an increase in the yield of thymine dimers (for a single break in the polynucleotide chain). The constancy of τ_c observed in the dose range (1.4–3.5) × 10^6 erg mm^{-2} probably shows that the ratio of the thymine dimers and the breaks in the polynucleotide chain reaches a constant value. For fairly high doses (in excess of 3.5 × 10^6 erg mm^{-2}), the energy absorbed is consumed mainly in the formation of coils and globules. Under these conditions, the attached label is most probably distributed on the surface of the globule, which leads to a sharp increase of the mobility of the label and to a decrease of τ_c.

The structural changes in ultraviolet-irradiated DNA are indicated by infrared spectroscopic data. It has been observed[118] that ultraviolet irradiation of a DNA film with a 32% relative moisture content using a dose of 4.2 × 10^6 erg mm^{-2} decreases the absorption by the amino-groups of the bases by about 10%; the intensity of the C=N band at 1655 cm^{-1} falls by 10%, that of the C=C band at 1580 cm^{-1} falls by 25%, etc. The observed changes can be explained by the occurrence of photochemical reactions such as the dimerisation of thymine and the deamination of the cytosine dimer with its conversion into the uracil dimer[119]. The dimerisation reaction can be clearly followed in the infrared spectra of ultraviolet irradiated single-stranded DNA.[116]

A study of the denaturation of DNA by ultraviolet radiation led to the discovery of the phenomenon of the stepwise alteration of the rate constant for the decrease of viscosity as the concentration of the irradiated solution is altered[113]. It was suggested that the observed stepwise effect is due to the aggregation of DNA molecules in solution. The aggregation can be caused to some extent by the "cross-linking" of the macromolecules, including the dimerisation of thymine by ultraviolet light. Factors influencing aggregation (ionic strength, temperature) facilitated the manifestation of the "stepwise effect"; a decrease of ionic strength led to its complete disappearance. This is consistent with the data of Eigner and Doty[120] for the aggregation of molecules in solutions at different ionic strengths. The possibility of this behaviour follows also from the data of Doty and Glisin[121] concerning the dimerisation of the thymine in the DNA molecule in solutions at moderate ionic strengths and the decrease of the degree of dimerisation to a minimum at low ionic strengths. The stepwise effect was also shown in solutions at low ionic strengths to which metal salts (Ca^{2+} and Fe^{2+}), stabilising the DNA molecule, had been added.

Comparison of these results with data for the variation of τ_c of spin-labelled DNA solutions at different concentrations as a function of the irradiation dose shows that the minimum damage to DNA preparations occurs when the concentration is highest (900 μg ml^{-1}). This is probably a consequence of the maximum extent of aggregation of the macromolecules. Presumably the aggregation (it can also occur in a cage) "protects" the molecule from ultraviolet irradiation[115].

Since the changes in the DNA molecule observed under ultraviolet irradiation lead to a significant impairment of the vital processes in the cell, the question of seeking effective protective measures arises. Chemicals of various classes—phenols, pyrimidines, and mercapto-compounds—have been investigated[112] as protective agents. Propyl gallate, 3-pyridinol, hydroquinone, and thymine afforded 40–60% protection, while cysteine and glutathione afforded 15–17% protection. Estimation of the degree of absorption of ultraviolet light by the test compounds established that the main mechanism of the protective effect involves the screening of the DNA molecule. A similar protective mechanism was observed when glutathione, cysteine, and tryptophan were used in ultraviolet irradiation of cells[122].

The finding that the protective effect of radical-reaction inhibitors involves screening in such cases constitutes at the present time indirect evidence for the absence from

the system of appreciable concentrations of free-radical states. This is consistent with data obtained in studies[123,124], which demonstrated instantaneous recombination of the radicals formed on ultraviolet irradiation of aqueous DNA solutions at room temperature. The absence of stable radicals from ultraviolet irradiated DNA solutions was demonstrated by ESR[125]. The dominant role of the denaturation effects in DNA under the conditions of ultraviolet inactivation of bacteriophages has also been established[126].

Thus the use of physicochemical methods led to the discovery of structural and chemical changes in ultraviolet-irradiated DNA, which may be diminished by the introduction of various chemicals absorbing ultraviolet light.

IV. SPECIFIC FEATURES OF THE EFFECT OF ULTRASOUND ON DNA

Ultrasonic energy is used in making DNA preparations with various molecular weights for the investigation of the physicochemical and biological properties of DNA[127-130]. For this reason, the problem arises of the mechanisms of the depolymerisation of the DNA molecule and of the elucidation of the relative susceptibility to damage of its structural components.

It has been shown[131-133] that ultrasonic degradation of DNA, like that of other polymers, is mechanical. The existing ideas about the action of ultrasound on macromolecules indicate a dominant role of mechanical forces in the depolymerisation effect (shockwaves, hydrodynamic shear). The chemical changes in DNA are caused by the specific interactions of the molecule with activated dissociation products of water molecules (free radicals and ions) under cavitation condition[131]. Since the damage to the DNA structure by ultrasound can have consequences at the cellular level, the degradative changes in DNA were studied. The types of mechanical degradation of its strands and the initial chemical reactions of the carbohydrate–phosphate groups and the nitrogenous bases were investigated[134-136].

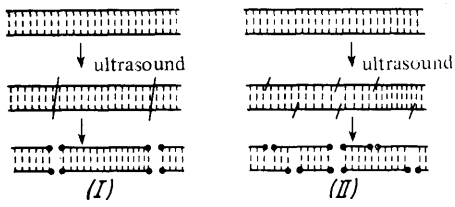

Figure 11. Schematic representation of various ways in which DNA is degraded by ultrasound.

Analysis of the physicochemical characteristics of single-stranded DNA[137,138] (sDNA) obtained from a native preparation (nDNA) subjected to ultrasound (UZG-250 generator, vibration frequency 750 kHz, intensity on the emitting surface 8–10 W cm^{-2}, duration of treatment 10–50 s) established that the DNA can be degraded either by the simultaneous rupture of both its strands (Fig. 11, scheme I) or by the independent accumulation of breaks in single strands (Fig. 9, scheme II)[131,136].

Ratios of the expected weight-average molecular weights of single-stranded DNA[139] and its intrinsic viscosities $[\eta]$ in 0.01 M Na^+ solution were calculated as a function of the postulated type of degradation of native NDA[135] from experimental values of F (the number of symmetrical breaks on depolymerisation of DNA) for s = 2 (where s is the maximum number of nucleotides between the breaks in the two DNA strands). The values of F were determined from the formula

$$F = \frac{M_0^{nDNA}}{M_t^{nDNA}} - 1 \quad .$$

The Table lists the experimental parameters of single-stranded DNA isolated from native DNA preparations exposed to ultrasound for given values of F and quantities calculated according to scheme I or scheme II. Evidently the experimental values agree with the calculated values for the degradation of DNA according to scheme I, i.e. as a result of the simultaneous rupture of both strands. There is no accumulation of random breaks in the DNA strands.

The molecular weights M and intrinsic viscosities of single-stranded DNA $\{[\eta]$ in 0.01 M $Na^+\}$ isolated from native DNA exposed to ultrasound and comparison with experiments of the values calculated in accordance with Schemes I and II.

Γ_{nDNA}	Scheme I		Scheme II		Experiment	
	$[\eta]$	$M\cdot10^{-6}$	$[\eta]$	$M\cdot10^{-6}$	$[\eta]$	$M\cdot10^{-6}$
0.28	57.3	2.29	5.6	0.22	58	2.32
0.45	53	2.12	4.46	0.18	52	2.08
0.77	46	1.85	3.48	0.14	46	1.6
2.03	31.6	1.27	2.2	0.09	23.5	0.94
3.75	22	0.88	1.6	0.06	13.7	0.55

Evidently DNA behaves as a single-stranded polymer in relation to the depolymerising action of ultrasound. The equation relating the rate of degradation of the polymer to the number of its strands is

$$\lg \frac{1-B}{B} = n \lg t + \text{const},$$

where

$$B = \frac{M_t^{nDNA}}{M_0^{nDNA}},$$

n is the number of strands in the polymer, and t the duration of action of the depolymerising factor. Fig. 12 shows that degradation by ultrasound does indeed obey the law characteristic of single-stranded polymers (with $n = 1$). Under these conditions, DNA having a molecular weight (M) of 1×10^7 is seen to decompose into fairly large molecules with M ranging from 0.3×10^6 to 1.2×10^6 (according to sedimentation analysis[129]). Ultrasound can thus be used to obtain native DNA fragments, which extends the scope of the application of ultrasound in biological experiments.

It is noteworthy that the observed depolymerisation of the macromolecules occurred under conditions of exposure to ultrasound where chemical processes associated with cavitation had not yet appeared. For longer exposures to ultrasound, leading to an increase of F, there is a slight discrepancy between the experimental data and the values calculated according to scheme I (see Table), which is probably due to the onset of chemoacoustic degradation of DNA. With increase of the duration of exposure to ultrasound from 1 to 15 min in the absence of protective substances, definite damage to individual chemical groups and bonds in the DNA molecule is observed. In particular, the intensities of a number of infrared absorption bands of DNA exposed to ultrasound change [136].

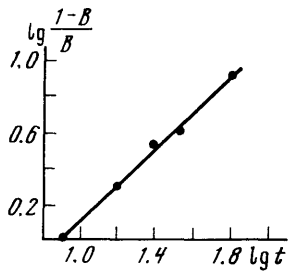

Figure 12. Kinetics of the depolymerisation of DNA by cavitation ultrasound.

In the region corresponding to the vibrations of the double bonds in the nitrogenous bases of DNA the intensity of the 1650 and 1590 cm^{-1} bands (due to the C=C and C=N bonds) diminishes, while in the region corresponding to the vibrations of the carbohydrate–phosphate chain the intensity of the 1010 cm^{-1} band [ν(COC) for deoxyribose] falls. Deoxyribose is then damaged to a greater extent than the nitrogenous bases: the decrease of the intensity of the 1010 cm^{-1} band is 17%, while that of the bands corresponding to the vibrations of the chromophoric groups of the nitrogenous bases is on average 10% (after exposure to ultrasound for 10 min). Deamination is observed only after more prolonged treatment with ultrasound.

The observed results show that the nature of the damage suffered by DNA on exposure to ultrasound differs from the effect of ionising radiation. As stated above, in the latter case the nitrogenous bases are deaminated together with the dissociation of their conjugated bonds; the bases are damaged to a greater extent. This difference is caused by the partial retention of the native DNA structure during ultrasonic degradation (caused by the simultaneous mechanical rupture of its two strands) and hence by the smaller accessibility to free radicals of the bases located within the helix. On the other hand, depolymerisation of DNA by ionising radiation entails independent accumulation of single breaks in each DNA strand [137,140], which must be accompanied by an appreciable damage to its secondary structure with a simultaneous damage to the rings of the bases.

In the literature on the infrared spectroscopy of DNA there is no unambiguous assignment of the 1060 and 960 cm^{-1} (970 cm^{-1} for a 92% relative humidity) bands to the vibrations of the individual C–O or P–O bonds of the carbohydrate–phosphate chains of DNA. A linear correlation has been observed between the relative decrease of the intensity of the 970 cm^{-1} band and the number of double breaks in DNA measured viscometrically. The correlation permits a tentative assignment of these bands to the vibrations of the C–O bond, since ultrasonic depolymerisation of DNA entails the preferential rupture of the C–O (90%) rather than P–O (10%) bonds [141]. The assignment of the 1060 cm^{-1} band to the vibrations of the C–O bonds appears to be less justified, since the intensity of this band does not decrease with increase of the duration of exposure to ultrasound.

A new band appears at 1190 cm^{-1} in the infrared spectra of DNA in the same wavenumber range. When DNA is ruptured, the number of terminal phosphate groups increases. The 1190 cm^{-1} band can be tentatively assigned to their vibrations, since absorption in the range 1190–1140 cm^{-1} is characteristic of alkyl phosphates. [64]

More far reaching changes in DNA under the influence of cavitation ultrasound led to successive decomposition of the pyrimidine and purine bases. Chromatographic analysis of the DNA hydrolysis mixtures exposed to ultrasound for periods ranging from 2 to 3.5 h demonstrated a greater resistance of the purine bases (adenine and guanine) to ultrasound compared with the pyrimidine bases (cytosine and thymine) [134]. This behaviour persists also in the susceptibility of the free bases and purine and pyrimidine derivatives to damage by ultrasound, which may have a definite biological significance.

The results obtained for the influence of ultrasound on the DNA molecule permit the employment of ultrasonic vibrations for specific and selective alterations in the DNA structure. The observed damage in DNA can have consequences at the cellular level, which has been confirmed, for example, by the formation on exposure of DNA to ultrasound of fragments with transforming activity [142] and by the results of studies on the influence of ultrasound on the chromosomal apparatus of cells and on genetic processes [143,144].

V. KINETICS AND MECHANISM OF THE REACTIONS OF AZIRIDINE DERIVATIVES AND NITROSOALKYLUREAS WITH DNA

More than 200 chemical mutagens have now been discovered. The great interest in compounds of this class is primarily due to the fact that chemical mutagens make it possible to obtain useful mutations in plants and microorganisms and have therefore found practical applications in the selection of agricultural crops and in the manufacture of antibiotics.

Since it has been shown that hereditary changes are mainly associated with nucleic acids (particularly with DNA), studies were begun to determine the possible mechanism of the action of chemical mutagens on DNA. A number of these established that mutations can arise both as a result of interaction with DNA (both in the state of replication and at rest) and as a result of reaction with its precursors. Under these conditions, alkylation of the bases and phosphate groups, replacement of one base by another, elimination of purines, etc. are possible.

The most effective mutagens proved to be substances with alkylating properties (derivatives of aziridine, *N*-nitroso-compounds, derivatives of mustard gas, epoxides, etc.). Studies *in vitro* and *in vivo* established a number of physicochemical characteristics of their action on nucleic acids. Some of the mutagens (aziridine derivatives,

mustard gas, etc.) cause changes in the macromolecule resembling the effect of radiation: a change in molecular weight, impairment of molecular shape, the formation of intramolecular and intermolecular "cross-links", etc.[145,146].

Since one of the principal problems in modern genetics concerns the possibility of achieving specific mutations, kinetic studies on the mechanism of the action of active mutagens assume particular importance. The effect of aziridine derivatives [2-aziridinylethyl methyl ketone (2-AEMK) and *N*-acetylaziridine (*N*-AA)] on DNA has been studied[147-152]. It has been shown that the effectiveness of these derivatives in terms of the intrinsic viscosity of DNA solutions increases in the sequence aziridine < 2-AEMK < *N*-AA.

The kinetics of the reaction and the physicochemical mechanism of the effect on DNA were studied in relation to *N*-AA. The kinetic curves for the variation of the viscosity of DNA solutions in the presence of *N*-AA are *S*-shaped and can be described by the equation for first-order autocatalytic reactions[151,147]:

$$\lg\frac{\eta_0-\eta_t}{\eta_t}=\lg\eta'+0.434\,\varphi t$$

$$\left(\text{when } \eta'\ll\eta_0,\ t>\frac{1}{0.434\,\varphi}\right),$$

where η_0 and η_t are the viscosities of the DNA solutions at the initial instant and at time t, lg η' characterises the size of the "seed" ensuring autocatalysis, and φ is the acceleration factor of the autocatalytic reaction. The changes in the kinetic curve show that the DNA molecule acted upon by *N*-AA undergoes not only conformational changes but also more far-reaching alterations with a change in the molecular weight.

The kinetic curve for the variation of the molecular weight of DNA can also be described in terms of the law governing first-order autocatalytic reactions, the value of φ being close to that for the variation of the intrinsic viscosity of the solution:

$\varphi = 0.31 \pm 0.02$ h^{-1} (from sedimentation data);
$\varphi = 0.28 \pm 0.02$ h^{-1} (from intrinsic viscosity data).

The changes in the DNA structure[147] discovered by electron microscopy are consistent with these observations. Only 2 h after the interaction of *N*-AA with DNA, the photomicrographs show modified DNA molecules (Fig. 13). The thickened regions formed throughout the extent of the molecule and at its ends lead to the conclusion that *N*-AA acting for a short period probably causes partial denaturation of DNA. At this instant the changes in the viscosity and molecular weight are very insignificant. After 12 h, low-molecular-weight fragments appear. By this time the molecular weight of DNA has fallen sharply. After 25 h, the photomicrographs show a large number of broken segments and coils resembling those observed after exposure to large radiation doses.

The action of 2-AEMK resembles that of *N*-AA. In this case too there is denaturation and depolymerisation of the molecules, but the reaction is slower.

The effect of aziridine (0.023 M) on DNA (1000 μg ml^{-1}) is somewhat different. After exposure to this substance for 2 min, thickened regions appear along the DNA molecule and at its ends, indicating partial denaturation. However, after 5 and 22 h the photomicrographs show, together with individual low-molecular-weight fragments, also large aggregates. A detailed study of the effect of brief exposure of DNA (50 μg ml^{-1}) to aziridine (10^{-4} M) was made using tungstophosphoric acid (TPA) as an electron-dense label which readily forms a salt-like linkage with the basic group of aziridine[150]. It was found that, after brief treatment with the mutagen (10 min), the density of the DNA filaments is uniform throughout the length of the molecule. Such uniformity of density is probably due to the fact that aziridine interacts with the phosphate groups of DNA. This is consistent with the literature data, showing that many alkylating agents can esterify the phosphate groups after acting on DNA for a short time.

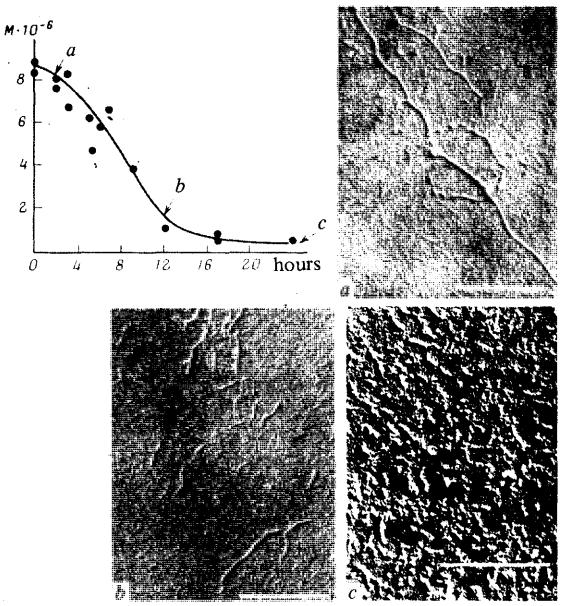

Figure 13. Photomicrographs of DNA and the kinetic curve for the variation of the molecular weight of DNA on interaction with *N*-AA; time (hours): *a*) 2.5; *b*) 12; *c*) 25.

A study of the effects of various concentrations of *N*-AA (0.012 M) on DNA[147] established that the change in the viscosity of DNA solutions remains autocatalytic in all cases. For the *N*-AA concentrations investigated, lg η' = 1.84 and $\varphi = 4.8\times10^{-2} - 2.3\times10^{-1}$ h^{-1}. The agreement of the values of lg η' for all the mutagen concentrations suggests that even at the initial instant the DNA–*N*-AA system contains the same amount of seed in all cases. Since the same DNA preparation was used in all the experiments, denatured DNA molecules, always present at the initial instant of the reaction, can evidently play the role of the seed. This is particularly likely, since denatured molecules are known to be more sensitive to various types of influences than the native molecules. The validity of this hypothesis was demonstrated in separate experiments using denatured DNA molecules[151].

DNA molecules denatured to different extents by ultraviolet light were added to the DNA-*N*-AA reaction mixture and the reaction rate was measured. It was shown that, with increase of the denaturation of DNA molecules, the induction period of the reaction fell, i.e. lg η' increased. Consequently the role of the denatured DNA molecules does indeed reduce to an increase of the amount of seed required to ensure the reaction between DNA and the mutagen.

Under the conditions of our experiments, the reaction of *N*-AA with DNA proceeds for a long time, in the course of which *N*-AA itself undergoes significant changes. It has been shown that the mutagen reaction products also play a definite role in the reaction. This is indicated by the "after effect" observed after removing the mutagen (Fig. 14). Thermochemical analysis of the transformation of *N*-AA made it possible to observe the conditions required for the formation of the maximum amount of the intermediate, the addition of which accelerated the process [149].

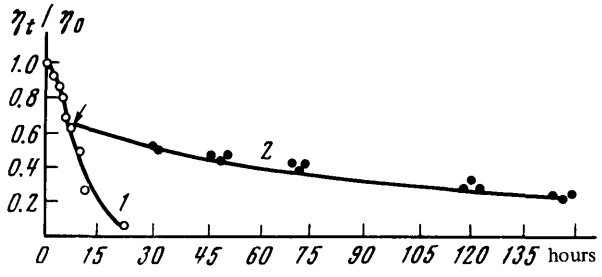

Figure 14. Variation of the intrinsic viscosity of DNA solutions acted upon by *N*-AA (curve *1*) and after the removal of *N*-AA (curve *2*) ("aftereffect"). The arrow indicates the time at which DNA was precipitated with alcohol.

The reaction of DNA with *N*-AA is accompanied by chemiluminescence [153], which appears 40 min after the start of the reaction and reaches a maximum in the course of 3 h with a subsequent slight decrease of intensity. The chemiluminescence spectrum consists of a broad band in the range 400–630 nm with a maximum at 490 nm. Kinetic chemiluminescence curves are *S*-shaped but are satisfactorily transformed into straight lines when lg $[I/(I_{max} - I)]$ is plotted. The chemiluminescence is due to oxidative processes, because its intensity falls sharply in the presence of O_2 and decreases in a stream of argon (Fig. 15). Since the change in the viscosity of DNA solutions containing the mutagen also occurs only in the presence of oxygen, the structural changes in DNA as well as chemiluminescence are probably a consequence of oxidative processes in the DNA–mutagen system.

In the reactions of the individual bases with *N*-AA there is no chemiluminescence, while in the reactions of nucleosides, nucleotides, and deoxyribose there is an appreciable chemiluminescence [154]. This shows that the reactions of 2-deoxy-D-ribose are responsible for the chemiluminescence. The latter probably arises as a result of the action of *N*-AA or its reaction products on the glycosidic carbon atom of ribose with subsequent oxidation at this atom. The stability of the glycosidic linkage is known to be influenced by the esterification of the hydroxy-groups and also by the nature of the base to which the carbon is bound: purine nucleotides are less stable than pyrimidine nucleotides and for this reason the chemiluminescence intensity in the reactions with purine nucleotides and nucleosides is higher than in the reactions with pyrimidine nucleotides. When deoxyribose is oxidised, the carbohydrate–phosphate linkages become labile and hydrolyse with rupture of the main macromolecular chain of DNA.

Radical-reaction inhibitors (propyl gallate, hydroquinone and 3-hydroxypyridine derivatives) reduce the chemiluminescence intensity to a greater extent the higher the antioxidant efficiency of the inhibitor [153].

Smotryaeva, Serebryanyi, and coworkers [155–158] investigated the mechanism of the reaction of DNA with *N*-alkyl-*N*-nitrosoureas (ANU). The interest in compounds of this class is not fortuitous, since, while behaving as supermutagens, they simultaneously exhibit both antitumour [159]

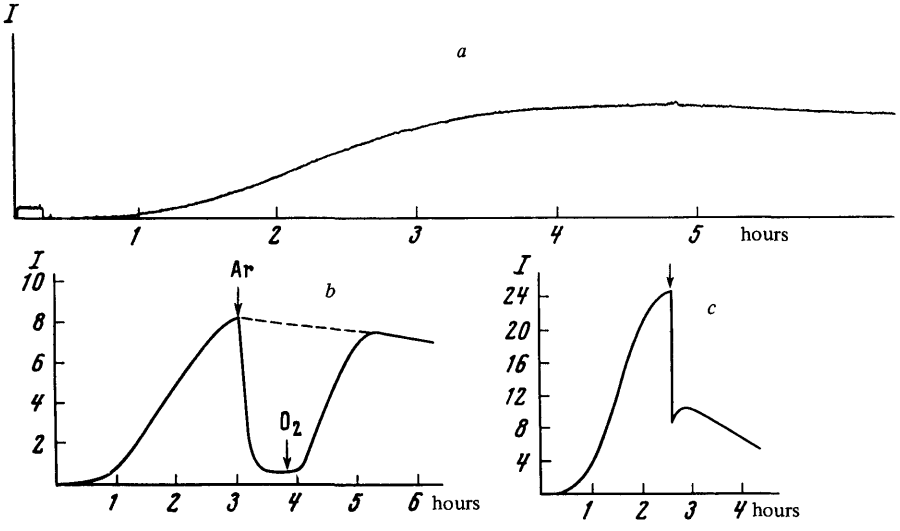

Figure 15. Chemiluminescence in the reaction of DNA with *N*-AA: *a*) kinetic chemiluminescence curve; *b*) variation of chemiluminescence intensity after the addition of argon and oxygen to the reaction mixture; *c*) variation of chemiluminescence intensity after the addition of propyl gallate at the instant corresponding to its maximum.

and carcinogenic[160] and mutagenic properties[161]. The reactions of *N*-alkyl-*N*-nitrosoureas with the genetic apparatus of the cell (in particular with the DNA molecule and the deoxynucleoprotein complex) can evidently play a significant role in such biochemical activity of the mutagens. One of the main physicochemical effects arising in the DNA structure as a result of its reaction with ANU is expressed by a sharp decrease of the viscosity of the solution and the occurrence of single and double breaks[156].

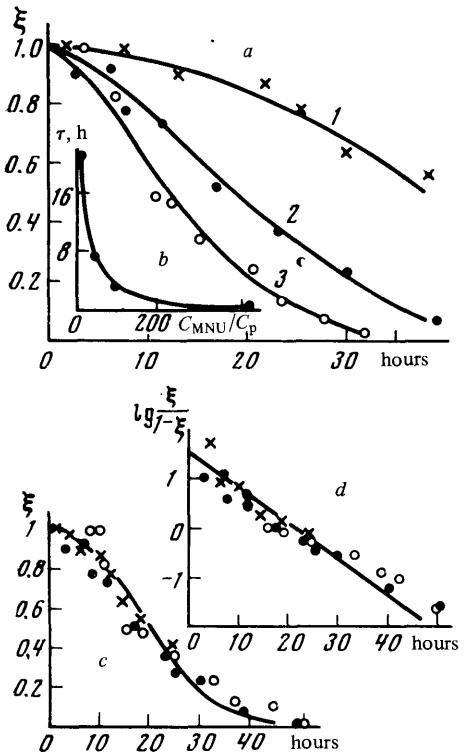

Figure 16. Kinetic curves for the variation of the intrinsic viscosities of DNA solutions (624 μg ml^{-1}) acted upon by MNU at different concentrations ($\xi = \eta_t/\eta_0$): *a*) [1) 0.02 M; 2) 0.1 M; 3) 0.2 M]; *b*) variation of the reaction induction period τ for different ratios of the amounts of MNU and DNA employed; *c*) transformation of the kinetic curves in *a* into curve *2*; *d*) semilogarithmic form of curve *c*.

The kinetic curves for the variation of the viscosity of DNA solutions in the course of reaction with *N*-methyl-*N*-nitrosourea (MNU) are *S*-shaped (Fig. 16), but give rise to straight lines when lg [$\xi/(1 - \xi)$] is plotted against time, in accordance with the equation for first-order autocatalytic reactions:

$$\lg\frac{\xi}{1-\xi} = \lg\xi' + 0.434\,kt,\quad t \neq 0,$$

where $\xi = \eta_t/\eta_0$ is a dimensionless coordinate characterising the viscosity of the DNA solution and lg ξ' and k are parameters of the kinetic curves. The kinetic curves for different concentrations can be transformed into a single curve with $k = 0.13$ h^{-1}.

The induction period of the reaction increases with decrease of the [MNU]:[DNA] ratio. In the course of the induction period chemical changes probably occur in DNA, which accumulate and are then manifested by single and double breaks in the DNA chains and by a decrease of the viscosity of the solutions (Fig. 17). This is also indicated by the experimentally observed aftereffect following the removal of the mutagen[155].

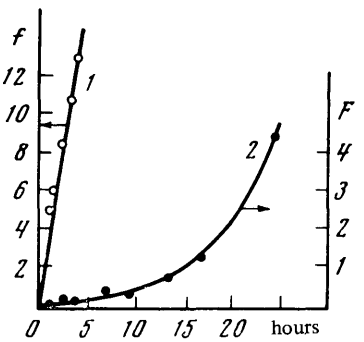

Figure 17. Damage to the DNA structure in the reaction with MNU: 1) accumulation of single breaks (*f*) in DNA molecules; 2) accumulation of double breaks (*F*).

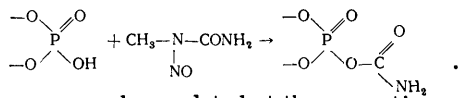
A detailed study of the inactivating effect of MNU on different phages (T7, ΦX-174) showed that the reaction with DNA, in the first place alkylation of the DNA bases with subsequent elimination of purines from the alkylated fragments of DNA and degradation, may be responsible for the inactivation. A kinetic model has been proposed for the inactivation of phages, whereby it is possible to estimate quantitatively the influence of MNU on various phages[162].

More complex effects were observed in a study of the effect of MNU on deoxynucleoprotein[156]. It was shown that the strength of the DNA–protein linkage changes in the course of the reaction together with an integral property of the deoxynucleoprotein, namely its insolubility in a medium with the physiological ionic strength. The principal cause of the observed effect is chemical modification of the DNA and protein groups involved in the DNA–protein interaction and ensuring the integrity of the deoxynucleoprotein.

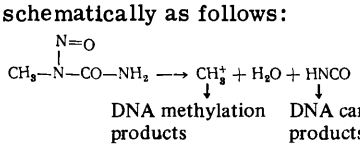
Analysis of the chemical changes in DNA and deoxynucleoprotein showed that the main chemical reaction giving rise to the degradation of DNA is again the alkylation reaction[157,163–165]. However, many biological data indicate a significant difference between the mechanism of the action of ANU and that of the action of other alkylating agents. To account for these differences, Serebryanyi[166] suggested that the ANU are agents with a complex action and their biological effect is due to the overall influence of two chemical reactions: methylation and carbamoylation. The use of MNU labelled with ^{14}CO in the reaction with DNA and deoxynucleoprotein established that there is indeed a transfer of the label from MNU to DNA and the protein, i.e. the carbamoylation reaction takes place[156,158]. The carbamoylation pathways were shown to occur in a study of the reaction of MNU with nucleotides, homopolynucleotides, and RNA.[167–169]. It was established that

mainly the phosphate groups are carbamoylated in polynucleotides:



The bases are carbamoylated at the same time, the main product of this reaction being N^4-carbamoylcytidine. Nucleotides can be arranged in the following sequence in terms of their reactivity in the carbamoylation reaction: cytidine ≫ adenosine ≃ guanosine, while in the alkylation reaction guanosine is the most reactive[168]. When MNU acts on the nucleotide complex, not only DNA but also the protein is methylated and carbamoylated[156]. The overall yields of both reactions are approximately the same; whereas both components of deoxynucleoprotein are methylated to an equal extent, mainly the protein is carbamoylated. Carbamoylation makes a significant contribution to the overall mutagenic activity of MNU, since carbamoylating agents such as isocyanic acid and its salts have been shown to possess mutagenic activity[170-172]. Later isocyanates were also found to have carcinolytic properties[173].

Thus the mechanism of action of MNU on DNA can be represented schematically as follows:



In connection with the antitumour properties of ANU, a study was made of the biochemical shifts arising after their administration *in vivo*. It was established that the synthesis of DNA, RNA, and protein is inhibited after the administration of ANU.[174-177]. The synthesis of DNA proved to be the most sensitive, that of RNA being inhibited to a lesser extent. In a study of the causes of the inhibition of RNA synthesis in a cell-free system it was shown that it involves both damage to the DNA matrix and a change in the properties of RNA polymerase due to the chemical modification of the enzyme. It is interesting that potassium cyanate, a product of the decomposition MNU, is also able to inactivate RNA polymerase[178].

The primary damage caused by MNU *in vivo* as well as *in vitro* arises as a result of methylation and carbamoylation reactions[179-181].

Chemical Geroprotectors and the Problem of Increasing the Life Span

L.K.Obukhova

The information available in the literature about the applications of geroprotectors—chemical substances used in experimental gerontology to increase the life span and to retard ageing—are described systematically and analysed. The proposed mechanisms of ageing are discussed only in connection with the characteristics of the action of the geroprotectors.
The bibliography includes 100 references.

I. Introduction 898
II. Biological activity of geroprotectors 898
III. Comparative assessment of the effectiveness of geroprotectors 900

I. INTRODUCTION

Practical steps have been taken in modern gerontology in the search for agents which retard ageing.[1–3] Experimental gerontology endeavours to develop methods for influencing the ageing process whereby one could alter the biological limit of the life span, which cannot be influenced significantly by progress in medicine and by improvements in living conditions. The increase in life span by the retardation of growth and development, of the kind achieved in the experiments of McCay et al.[4] on rats, which were fed an inadequate diet, is evidently unsuitable for humans. This stimulated the search for other ways of prolonging life. The first hopeful experimental results of the employment of chemical substances to retard ageing were obtained at the end of the 1950s, the period when the theoretical development of this problem also began[5–8]. The chemicals and their mixtures used to increase the life span have come to be called geroprotectors.

On the initiative of Academician N. M. Emanuel', a combined study of the biological activity of radical-reaction inhibitors was begun in the 1950s at the Institute of Chemical Physics at the USSR Academy of Sciences. The hypothesis that free-radical processes are important in the development of certain pathological processes (radiation disease, malignant growth), in ageing, and in damage sustained by interaction with the environment proved to be fruitful. It promoted a successful search for biologically active substances, including geroprotectors, among anti-radical preparations.

No claim is made that the present review is exhaustive. Extensive data on the application of geroprotectors for the retardation of the ageing of cell cultures, the discussion of which would require the analysis of specific mechanisms of the ageing of the cell outside the organism, have been deliberately omitted. Those interested in this problem will find in this review references to original papers.

II. BIOLOGICAL ACTIVITY OF GEROPROTECTORS

The available information about the biological activity of chemicals which increase the life span of laboratory animals is summarised in Table 1. The specific manifestations of ageing are extremely varied, but they all reflect the disorganisation of the vital functions of the organs and tissues. The ageing of the organism is frequently regarded as a consequence of the accumulation of molecular injuries in cells and primarily in the genetic material[30]. The ideas concerning the harmful effects of free radicals are consistent with several at superficially incompatible hypotheses concerning the biological manifestation of ageing.

Table 1. Biological properties of geroprotectors.

2,6-Di-t-butyl-4-methylphenol (ionol)	food antioxidant[9], antiradiation agent[10], antileukaemic and anticarcinogenic agent[11–14], inductor of microsomal liver enzymes[14,15], substance reducing the frequency of chromosomal aberrations[16]
2-Mercaptoethylamine	antiradiation agent
Vitamin E	biogenic antioxidant, substance reducing the frequency of chromosomal aberrations[16]
6-Ethoxy-2,2,4-trimethyl-1,2-dihydroquinoline	food antioxidant, inductor of microsomal liver enzymes[15], anticarcinogenic agent[13]
Nordihydroguaiaretic acid	antioxidant, inductor of microsomal liver enzymes[15]
3-Hydroxy-2-ethyl-6-methylpyridine.HCl	antiradiation agent[10], antioxidant[17]
2-(Dimethylamino)ethyl *p*-chlorophenoxyacetate (meclophenoxate)	substance preventing the accumulation of lipofuscin[18], stabiliser of biological membranes[19]
Dimethylaminoethanol	stabiliser of biological membranes[19]
Salicylates	stabilisers of biological membranes[19]
L-3,4-Dihydroxyphenylalanine	intermediate in the biosynthesis of adrenaline, used in the treatment of Parkinson's disease[20]
Sodium salt of ethylenediaminetetraacetic acid	prevents the formation of cross-links in macromolecules[21]
β-Aminopropionitrile	ditto (quoted after Comfort[2])
Corticosteroids	inductors of the biosynthesis of protein stabilisers of biological membranes[19], stimulators of the proliferation of cell cultures[22–24]
β-Diethylaminoethyl *p*-aminobenzoate (procaine)	active principle of the geriatric agent "Gerovital NZ", stimulator of the proliferation of cell cultures[27]
Ginseng and eleutherococcus extracts	substances influencing the secretory function of the adrenal cortex and the steroid hormone equilibrium[25], antioxidants, stimulators of cell division[26]
"Folcysteine U" complex	reactivates certain enzyme systems whose activity decreases wtih age, influences the SH/SS ratio[28]
"Decamevit", "Geroton", and "Amivit" polyvitamin complexes	used in geriatric practice, normalise metabolic processes, stimulate regeneration and haemopoiesis[29]

Free radicals play a significant role both in normal and in pathological vital processes. They have been detected in various tissues, subcellular structures, and in isolated

enzyme systems. It has been established that free radicals are active intermediate substrates in oxidation-reduction processes. It is suggested that about 60% of the overall concentration of free radicals in the cell, detected by ESR, is associated with electron transfer processes via the respiratory chain of mitochondria and with the formation of semiquinone radicals[31].

Free-radical states in other cell organelles have been inadequately investigated. About 20% of the overall concentration of free radicals is probably located in microsomes, where various extraneous substances are oxidised without phosphorylation and undergo detoxidation[32,33]. A correlation has been established between the amount of free radicals and the metabolic activity of the tissues[32,34]. Non-enzymatic oxidation processes involving organic molecules, mainly lipids, constitute another source of free radicals. Vitamin E, ascorbic acid, and other natural antioxidants regulate the normal level of these processes in the cell. Artificially created condition favouring non-enzymatic oxidation (irradiation, excess oxygenation) lead to pathological states[35]. Thus, following an increase in the amount and degree of unsaturation of fats in the diet, the life span of C3H mice decreased, and the incidence of mammary gland cancer rose, which may be due to the formation of toxic lipid peroxides. The introduction of α-tocopherol into the diet prevented these phenomena[36].

The possibility of intensifying free-radical reactions during ageing has been discussed in the literature, but systematic studies on these lines have not been undertaken. The concentration of free radicals in the organs of mice and rats of different ages has been investigated[37]; maximum concentrations have been recorded on the 12th and 43rd days of the animal's life, i.e. during the period of growth, after which there was a monotonic decrease. A comparative study of the organs of young (4 months old) and old (2 years old) rats of the "Vistar" strain revealed an increase with age in the concentration of free radicals in the liver and blood[38]. The free radical concentration in the brain tissue of 30 month old rats was higher than in 10 month old animals[39].

Numerous experimental data have shown that the physicochemical properties and functional characteristics of the molecules of information DNA and RNA change in the course of ageing[30,40-43]. Highly reactive free radicals of the type RO· and $RO_2^{\cdot}$ may play the role of agressive factors. The formation *in vivo* of lipid peroxides and unstable low-molecular-weight radical oxidation products, which may modify biological structures, causing, in particular, a decrease in the templet activity of DNA (quoted after Vilenchik[30]), has been demonstrated experimentally. Radical processes involving the oxidation of lipid components may be the cause of the breakdown of the integrity of membranes of subcellular particles. Lysosomes are present in the cytoplasm of almost all types of animal cells; they contain hydrolytic enzymes, which participate in the digestion of ballast substances, in the lysis of dead cells, etc. Damage to the lysosomal membrane *in vivo* can release the enzymes of the lysosomes into the cytoplasm and lead to the breakdown of its protein structures, damage to many important cell components, intensification of katabolic processes, and stimulation of the formation of connective tissue[19]. It is suggested that accumulation of the senile pigment lipofuscin is also associated with the degradation of lysosomes[44].

Inactive enzymes have been detected in the cells of old animals and in diploid cultures in the degradation phase[45-47], i.e. molecules retaining a specific structure which have lost their catalytic properties. The reason for the appearance of inactive enzymes may be structural defects in the templet, weakening of control by nuclear DNA over the synthesis of RNA[40], and postsynthetic modification of the proteins by the enzymes of lysosomes or free radicals.

The influence of antiradical preparations on the level of oxidation-reduction reactions in the tissues of the organism can be inferred from the change in the antioxidant activity (AOA) of lipids, which characterises the ability of lipid extract to counteract oxidation and is caused by the presence of natural antioxidants. Measurements of AOA of mouse liver lipids during ageing showed that it steadily decreases with age and that the rate of its variation is not the same for different strains of animals[48]. In radiation sickness, stress states (starvation, supercooling), and poisoning a decrease of AOA is observed, as in ageing. The development of these processes may be retarded and even prevented by the introduction of substances which increase the level of anti-oxidant activity. Natural and

synthetic antioxidants (tocopherol, ionol, 2-ethyl-3-hydroxy-6-methylpyridine), certain hormones (hydrocortisone, adrenaline), and preparations belonging to the class of non-specific adaptogens (eleutherococcus) are able to alter the level of AOA of tissue lipids, i.e. they can influence directly or indirectly the intensity of radical oxidation processes in the organism [49-53].

The possibility of preventing or effectively retarding a wide variety of undesirable deviations, which inevitably occur in the living organism, and also the prophylaxis and liquidation of pathological states have a bearing on the problem of the prolongation of the life span. The increase of the incidence of illness in middle age, which may be associated with the activation of latent viruses, is considered as one of the manifestations of ageing [54]. Effective geroprotectors (antioxidants—ionol and ethoxyquin) have a set of favourable properties: anticarcinogenic activity [12-14], the ability to prevent the accumulation of chromosomal aberrations [16], and antileukaemic activity [11]. Ionol is used in the treatment of bladder tumours and radiation-induced and trophic lesions of the skin [56,57].

It is well known that the toxic effect of chemical agents and medicinal preparations increases with the recipient's age. The effects of ionol, nordihydroguaiaretic acid, propyl gallate, and ethoxyquin on the activity of oxidative enzyme systems of liver microsomes, which metabolise extraneous chemical compounds, medicinal preparations, poisons, etc., have been studied [15]. The introduction of ethoxyquin into the diet of rats aged 81–440 days increased by a factor of two the enzymatic activity of the microsomal fraction; ionol and nordihydroguaiaretic acid exhibited a somewhat lower inducing capacity; propyl gallate did not exhibit the properties of an inductor and did not increase the life span of rats. Preliminary administration of ethoxyquin to rats decreases the toxic effect of carbon tetrachloride, increasing the rate of its conversion into CO_2. [58] Possibly the induction of the detoxicating enzyme system in microsomes constitutes the molecular mechanism of the mobilisation of the vital forces of the organism against the harmful effect of the chemical components in the environment.

The set of favourable properties of antiradical preparations may serve as a basis for the future development of medicinal compositions designed to reduce the rate of ageing in man.

III. COMPARATIVE ASSESSMENT OF THE EFFECTIVENESS OF GEROPROTECTORS

The wide-scale employment of laboratory rodents in the study of ageing implies the assumption of a definite similarity between the ageing processes in these species and in man. To estimate the rate of the ageing process and the effectiveness of geroprotectors, mortality indices for the population are used. The following characteristics are usually analysed: the average and maximum life span; the "median" life span, i.e. the age corresponding to 50% mortality; the law of the frequency distribution of deaths; the relative death rate linked to age by a logarithmic relation (the Gompertz index); the "expected life span". [59]

A correct study of the percentage survival of laboratory rodents is possible when not less than 800–1000 animals are used. About 3000 mice of the SAS/4 strain of both sexes have been observed from birth to death [60]. The average life spans of the males and females did not differ, amounting to 103.8 weeks. The Gompertz relation held over the range 50–100 weeks, while at more advanced ages the mortality index increased more slowly. A logistic function of the type

$$\mu = 122 \cdot 10^{-5} + \frac{3.3 \cdot 10^{-5} e^{0.0632t}}{1 + 23 \cdot 10^{-5} e^{0.0632t}},$$

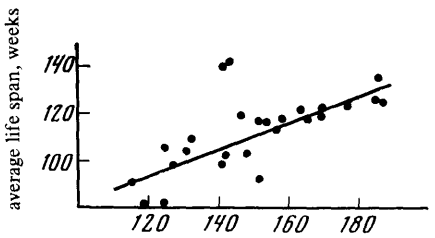
where $\mu = -(1/n)(dn/dt)$ is the relative death rate and n the number of living individuals whose age is t, is suitable for a complete description of the percentage survival curve. The distribution of life spans proved to be asymmetric.

The study of the percentage survival of laboratory Sprague-Dowley rats was continued for five years [61]; 747 animals were used in 18 experiments, 7 of which were performed in a germ-free medium and the remainder in the usual vivarium with careful maintenance of cleanliness and constant living conditions. The average life spans were virtually the same in all the experiments, the mean amounting to 692 ± 22 days. Analysis of the frequency distribution of deaths showed that, compared with the normal distribution, there is an excess of short-lived individuals. For old rats aged 800–950 days, the expected life span remains constant and the relative death rate decreases. The decrease of the Gompertz index by a factor of two at an age of 1060 days compared with an age of 450 days was observed also for CAF_1 hybrid mice [62].

In the majority of experimental studies groups of 100 and fewer animals are usually employed, which leads to appreciable differences between the percentage survival indices for animals of the same strains investigated in different laboratories and even in the same laboratory but at different times. Table 2 presents data for the life spans of mice belonging to 8 inbred strains and 8 first generation hybrid groups, one non-inbred strain of mice (CD-1), and Sprague-Dowley rats. Comparative analysis of the data in Table 2 permits the following conclusions: (1) the life span of male mice is greater by 10–12% than that of female mice, although there are exceptions [67,68]; (2) the life span of first generation hybrids is longer than for mice of the parent strains; (3) the average life span is close to the median value, i.e. the two parameters can be used to an equal extent; (4) the greatest differences between the life span are observed for the inbred strains 129 and AKR (by a factor of 2.7); (5) the average life spans obtained in different laboratories differ for strains 129, DBA/2, and the genetically similar strains C57BL/6, and C57BL/10 approximately by a factor of 20% and for strains CBA and CXH by 40%. A study of the life spans of C57BL male mice in four independent experiments in the same laboratory showed that the median and maximum life spans differ by 34 and 17%, and the source from which the animals had been obtained is significant [69].

In selecting the animals to be subjected to protracted survival tests, preference should be given to the following inbred strains with a stable genotype: 129, CBA, C57BL, C3H, C3HA, LP, BALB/c, and SWR; it has been shown that the incidence of malignant tumours in these strains or first generation hybrids is low [61,63,68,70]. The advantages of gnotobiology are not evident: a decrease of the life span of the animals under germ-free conditions is sometimes observed [66,71-73]. Since the average life span depends significantly on environmental and dietary factors, we must assume that the chemicals employed as geroprotectors really retard the ageing process only when an increase in the maximum life span is observed compared with the control group of animals of the same breed. The treatment of quantitative data for the percentage survival of mice of different inbred strains and first generation hybrid groups [63] showed that there is a linear relation

between the average and maximum life spans under optimal living conditions (see Figure). The regression equation is $y = 24.6 \pm 0.57x$, with a correlation coefficient $r = 0.85 \pm 0.055$. This relation implies that, when ageing is retarded, a decrease of mortality is to be expected for the entire population, which leads to a rightward shift of the percentage survival curve.



Regression line for the average and maximum life spans of mice according to Smith et al.[63]

The possibility, in principle, of increasing the life span of laboratory animals by means of certain chemicals as dietary additives in small amounts was demonstrated for the first time in a number of studies[5,6,8]. When inhibitors of radical reactions with the properties of antiradiation agents and antioxidants (2,6-di-t-butyl-4-methylphenol, ammonium diethyldithiocarbamate, 6-ethoxy-2,2,4-trimethyl-1,2-dihydroquinoline, and α-tocopherol) were added to the diet in amounts of 0.25–1 wt.%, the percentage survival in the test groups after 20 months amounted to 61.66, 74, and 13% compared with 9% in the control[74].

The results of subsequent investigations are combined in Table 3. The increase of the average and maximum life spans varies in the range 13–50% and 11–58%. The influence of the most effective chemicals is compared with the results obtained in studies by McCay[4], who used prolonged partial starvation of young rats as a factor retarding their growth and development and leading to an increase of their life span. In experiments carried out in 1934 the life span of test individuals exceeded by 78% the maximum life span of the control. In repeated experiments the increase of the life span varied from 22 to 32%. Nikitin and coworkers[82], who reproduced McCay's experiments, found that the average life span of test animals increased by 39% and the maximum life span by 47%.

Despite the fact that the search for chemicals retarding the ageing process has continued for about 20 years as a scientific discipline, the list of active compounds includes no more than 20 items. The principal cause of the slow development of this field is lack of knowledge of the primary causes and mechanisms of ageing. In selecting geroprotectors, the investigators were forced in most cases to employ more or less plausible hypotheses as a basis. The preferential use of laboratory rodents makes the experiments long, expensive, and laborious, and their results cannot be predicted as long as data for the mortality of a control group of animals have not been secured.

Attempts were made in a number of investigations to develop biological methods making it possible to follow the rate of ageing by procedures which are not based on mortality indices alone. Several tests have been proposed to characterise the biological age of rats. When the rate of ageing is accelerated by fractional irradiation with X-rays, comparison of the calendar and biological ages using the method proposed by the authors showed that the test group was "older" than the corresponding control group. The opposite findings were obtained when ageing was retarded by periodic feeding of Na_2-EDTA.[76,83,84] The fundamental studies[85,86] in which changes in enzyme induction associated with ageing are investigated as a biochemical expression of ageing are interesting and promising.

Table 3. Influence of chemical geroprotectors on the life span of laboratory rodents.

Compound	Dose	Strain of animals, sex, age at beginning of experiment	Difference relative to control, %		Refs.
			avergae life span	maximum life span

*At 18 months of age.

Apart from laboratory rodents, populations of the fruit fly *Drosophila melanogaster* are frequently used to investigate the ageing process and to select geroprotectors. Its use has advantages in the sense that in the tissues of the adult insect there are no dividing cells, i.e. the death of the organism coincides with the death of its cells. The life span of the adult insect depends on the conditions in the medium, the population density, and the rate of preimago development[44,87,88]. The average life spans of various strains differ significantly: it is 40 days for the short-lived mutant strains Hk^1P and Sh^5,[89] while for wild species it is almost twice as long[19]. The older the

parents the shorter the average and maximum life spans of the offspring. The life span of the second generation hybrids is somewhat shorter than that of F_1 hybrids[90]. It is possible to use F_2 hybrids in those cases where a large initial population of individuals with the same life spans is required for the experiments.

As for laboratory rodents, the retardation of ageing should lead to a decrease of the mortality of the entire population, to an increase of the maximum life span, and to a rightward shift of the entire mortality curve. Among the 38 compounds of different classes which were added to the diet in different concentrations, positive effects were found for only a few (Table 4). The majority of the compounds tested were selected on the basis of their known or postulated ability to stabilise cell or lysosome membranes towards decomposition *in vivo* and *in vitro*[91]. A reliable increase of the average life span of males was achieved under the influence of corticosteroids, salicylic acid derivatives, and meclophenoxate. The greatest increase in the maximum life span (by 42%) was attained when a mixture of salicylsalicylic acid and aspirin was used.

Table 4. The influence of chemical geroprotectors on the life span of *Drosophila melanogaster*[19,92].

Compound	Dose, mg/100 ml of medium	Strain of insect, sex	Difference relative to control, %	
			average life span	maximum life span
Hydrocortisone acetate	10	(*Canton S* × *Oregon 2S*)F_1 males	38	16
		females	21	18
Cortisone acetate	18.8	(*Canton S*) males	43	31
Deoxycorticosterone acetate	0.5	females	18	13
		males	21	21
Triamcinolone(9α-fluoro--16α-methylhydrocortisone)	4	males	18	5
		females	19	16
Aspirin	250	(*Canton S* × *Oregon RS*)F_1 males	22	27
		females	13	16
3:1 salicylsalicylic acid–aspirin mixture	490	males	24	18
Ditto	162	females	38	42
Salicylamide	650	males	17	22
		females	12	27
Meclophenoxate	120	males	7	15
		females	39	23
Ionol	0.001%	males	30	–
		females	16	–
Butylhydroxyanisole (BHA)	0.01%	males	12	–
		females	5	–

The procedure whereby biologically active substances retarding ageing are selected can be greatly shortened by employing populations of microscopic polycellular nematodes (*Caenorhabditis origgsae*) and rotifers (*Bdelloid rotifer*)[93–98], whose life span is close to 1 month and which can be grown simply and in large amounts without much expense. The presence of α-tocopherylquinone in the culture medium retarded the ageing process of nematodes whose age at the beginning of the experiment was one day, and increased by 30% the average life span. A positive effect was not observed if the age of the animals was 20 days, since irreversible changes associated with ageing had occurred[99]. The influence of inhibitors of the biosynthesis of proteins, antimetabolites, and cytostatic agents on the life span of rotifers has been studied[100]. The following inhibitors of biosynthesis were found to retard ageing: actinomycin D, streptomycin, Acridine Orange, tetracycline, and chromomycin A_3.

---o0o---

Progress in this field of experimental gerontology depends on scientific advances in the understanding of the principal mechanisms of ageing. The next urgent task is to combine the search for substances "capable of protecting the cells from senile changes in a manner similar to that occurring on restricting the diet"[87] with improved methods for recording the rate of ageing.

The Solvated Electron in Polar Organic Liquids

A.V.Vannikov

The spectroscopic characteristics and the mechanism of the motion of solvated electrons in polar organic liquids are examined. It is shown that the part of the spectrum where solvated electrons absorb is determined by the polarity of microregions in the liquid. The intensity and half-width of the absorption band depend on the region of the spectrum in which absorption occurs. The theoretical concepts concerning the nature of the solvated electron and the mechanism of its motion are considered. The bibliography includes 65 references.

I. INTRODUCTION

The study of excess electrons in liquids (solvated electrons) is of particular interest for the understanding of their behaviour as chemically reactive species giving rise to a wide variety of reactions and determining the fundamental step in electrochemical, radiation-chemical, and other processes. These processes are determined by the nature of the localised state and the diffusion characteristics of the electrons. The possibility of the dissolution of alkali metals in ammonia was first discovered by Weyl[1]. Kraus[2] suggested that the colour of the resulting solution is associated with the solvated electron formed on association of the metal atom to the cation and an electron. A brief unstable colour was also observed on dissolution of alkali metals in polar solvents, for example alcohols, at a low temperature[3]. By analogy with ammonia, it was attributed to solvated electrons. A new stage in the study of solvated electrons began after the detection of hydrated electrons by pulse radiolysis[4]. The subsequent employment of this method made it possible to obtain quantitative characteristics of solvated electrons (e_s) in various liquids where their lifetime amounts to a fraction of a second. The study of such electrons in a wide variety of organic liquids led to fundamentally new results, which are important for the understanding of the nature of the solvated state of the electron.

The principal method for detecting solvated electrons involves the measurement of absorption spectra, which characterise mainly the localised state of e_s. There have been only a limited number of investigations of the relaxation currents associated with the motion of solvated electrons. For this reason, the mechanism of their transport in polar liquids has been least thoroughly studied compared with their other characteristics. The spectroscopic characteristics of solvated electrons have now been measured in a large number of pure organic liquids, both polar and non-polar, and in mixtures of organic liquids with different proportions of the components; the experimental wavelength range in which solvated electrons absorb extends from 250 to 3000 nm. The temperature range of the measurements of the e_s spectra extends from the temperature of liquid helium[5] to temperatures in excess of critical values (in the case of water)[6]. The influence of pressure up to several kilobars on the absorption spectra of solvated electrons has been studied. The time interval corresponding to the investigation of the formation of and changes in the absorption spectra of solvated electrons is between 10^{-11} and 10^{-3} s. In some cases stable spectra of solvated electrons were recorded. Much attention has been devoted to the investigation of a large number of reactions of solvated electrons with various additives and also to the investigation of the influence of certain compounds which do not interact chemically with e_s, on the ways in which the latter are stabilised, which is reflected by a change in the characteristics of the absorption spectra. Systematic accounts of the results have been given in reviews and monographs[7-12] and reference data have been published[13,14].

II. CERTAIN THEORETICAL MODELS OF THE SOLVATED ELECTRON

Despite the abundance of experimental data, there is at present no generally accepted theoretical model which would explain all the experimental results for solvated electrons. The current aim of the main fundamental approaches to the understanding of their nature is to explain the principal parameters of the optical absorption spectra of solvated electrons, namely the half-width of the absorption band, its asymmetry, intensity, the coefficient of the temperature shift of the wavelength of the absorption maximum (λ_{max}), and the dependence of the position of λ_{max} on the macroscopic and microscopic characteristics of the medium.

The theoretical models discussed in various studies can be conventionally divided into two groups. In those of the first group an attempt is made to calculate, by considering real characteristics of the liquid, the parameters of the potential well in which the electron is localised, the distribution of the discrete energy levels in it, and the limit of the continuous spectrum of levels. In models of this group account can be taken of various types of interactions between the electron and the condensed medium. The simple polaron model considers the medium as a macroscopically continuous dielectric[15-18]. In semicontinuous or molecular-cavity models account is taken of

the molecular structure of the solvent, in contrast to the polaron model[19,20]. Consideration of the excess electron in a polar medium within the framework of the adiabatic approximation with simultaneous examination of the electronic energy and the energy of solvent rearrangement has proved to be the most successful approach[19]. In structural models it is assumed that the electron is bound to the nearest solvent molecules sufficiently strongly to neglect long-range interactions and the localisation of the electrons at several molecules[21], dimers, trimers[22], clusters[23], and structural defects[24] is considered. The principal achievement of this group of studies is agreement between the theoretically calculated and experimental λ_{max} for solvated electrons in water and ammonia. On passing to more complex organic molecules, such agreement cannot be attained. In these investigations the spectra are interpreted almost exclusively as due to a transition between two discrete levels, usually the $1s \rightarrow 2p$ transition (i.e. the electron remains bound in the excited state).

The other approach involves the selection of a form of potential whereby an agreement between the theoretically calculated absorption band of solvated electrons and the experimental band can be achieved by a suitable choice of a definite number of parameters. Thus, when the hydrogen-like potential is used and two parameters are adjusted, it is possible to reach[25] complete agreement between the calculated and experimental absorption curves for solvated electrons in various liquids over a wide range of pressures and temperatures. However, the parameters obtained in the mutual adjustment of these spectra can be in no way related to the real characteristics of the liquid and therefore the predictive value of this approach is slight. The experimental data obtained in recent years leads to the conclusion[26,27] that optical absorption is determined mainly by the transition to a continuous spectrum. On the basis of this assumption, it can be shown[28] that, by specifying the simplest form of the potential curve, namely a rectangular well, it is possible to achieve a satisfactory agreement between the theoretical and experimental absorption curves when certain parameters are chosen. Certain important characteristics of solvated electrons have been calculated[29] from the shape of their absorption line using threshold formulae and it was concluded that the lower energy side of the absorption band corresponds to photoionisation, the effective interaction in the final state being short-lived.

Evidently the development of theoretical concepts concerning the nature of the solvated electron is determined in both approaches by the possibility of a more specific allowance for the fundamental forms of interaction between the electron and the liquid medium. In its turn this entails a systematic treatment of the available experimental data and the determination of the general characteristics of the behaviour of these electrons in various liquids.

III. SPECTROSCOPIC CHARACTERISTICS IN POLAR LIQUIDS

In a number of studies, attempts were made to relate the spectroscopic characteristics of the solvated electron to the properties of the liquid in which it is solvated. A correlation has been observed[30] between the static dielectric constant (D_{st}) and λ_{max} in methanol, ethanol, propanol, and ethylene glycol. However, measurements of the absorption spectra of solvated electrons in twenty straight-chain and branched-chain alcohols[31,32] showed unambiguously that no such correlation exists. These investigations showed, for alcohols, that there is also no correlation between λ_{max} and the fundamental parameter of the polaron theory $\beta = 1/D_{opt} - 1/D_{st}$. Analysis of the absorption spectra of solvated electrons in a large number of organic liquids of different structures leads to the conclusion[31,33] that the localised state of the electron in a polar liquid is probably determined by the interaction with the polar groups of a small number of molecules of the liquid.

It is noteworthy that the question of whether or not λ_{max} is determined by the interaction of the electron with a large number of molecules of the liquid (i.e. by the dielectric characteristics of the medium) or with the first solvation layer (i.e. by short-range forces) cannot be answered by studying two-component systems[34,35], since a gradual substitution of one mixture component by another also produces a smooth change in the dielectric constant. For this reason, the spectra of solvated electrons were studied by pulsed radiolysis in monoethanolamine (MEA), a bifunctional compound, and in an equimolar ethanolamine mixture[36]. MEA and the mixture have similar chemical compositions but differ appreciably in their dielectric constants: $D_{st} = 57.7$ for MEA and $D_{st} = 10.5$ for the mixture at 20°C. The wavelength corresponding to the optical absorption maximum of solvated electrons in MEA is 910 nm [36]; it occupies an intermediate position between λ_{max} for ethanol (700 nm [30]) and ethylamine (1300 nm [37]) and is close to λ_{max} for the mixture (880 nm), although the dielectric constants of MEA and the mixture differ by a factor greater than 5. Thus the position of the absorption maximum of solvated electrons for liquids having similar chemical compositions is determined by the presence of functional groups, in the present case OH and NH_2, and is independent of the macroscopic characteristics of the liquid.

For liquids with appreciably different molecular structures, it is also impossible to observe a correlation between λ_{max} and D_{st}. The same applies to the parameter $D_{st}\rho$ (where ρ is the density), which is correlated with the changes in λ_{max} or E_{max} (the energy corresponding to λ_{max}) as a function of pressure and temperature in alcohols but not in other liquids[38]. An attempt to take into account in a more complex manner the influence of the structure of the liquid on the position of E_{max} has been made[39]. Assuming that the structure of the liquid plays a major role in determining E_{max}, the author calculated the values of the correlation parameter g_c in the Kirkwood equation for various liquids:

$$[(D_{st.} - 1)(2D_{st.} + 1)/9D_{st.}](M/\rho) = (4\pi N/3)[\alpha + (g_c\mu^2/3kT)], \quad (1)$$

where M is the molecular weight, α the molecular polarisability, and μ the dipole moment. Values of g_c greater than unity indicate a greater local polarity in microscopic regions within the liquids than might have been expected from the molecular dipole moment.

A satisfactory correlation has been observed between E_{max} and the parameter $D_{st}\rho g_c^3\alpha_p$ (α_p is the polarisability of the polar group in the molecule) for a number of amines, ethers, alcohols, water, and ammonia[39]. However, subsequent measurements of the spectra of solvated electrons in amides[40] failed to confirm the general applicability of the observed relation. For example, E_{max} for *NN*-dimethylacetamide is smaller by a factor of three than might have been expected from the relation. This is because the parameter $D_{st}\rho g_c^3\alpha_p$ is largely determined by the macroscopic characteristic D_{st}; since amides are characterised by relatively high values of D_{st} (30–40), there is a sharp

inconsistency between the similar values of E_{max} observed for amides and for example weakly polar amines, on the one hand, and the widely different values of $D_{st}\rho g_c^3 \alpha_p$ for the same liquids, on the other.

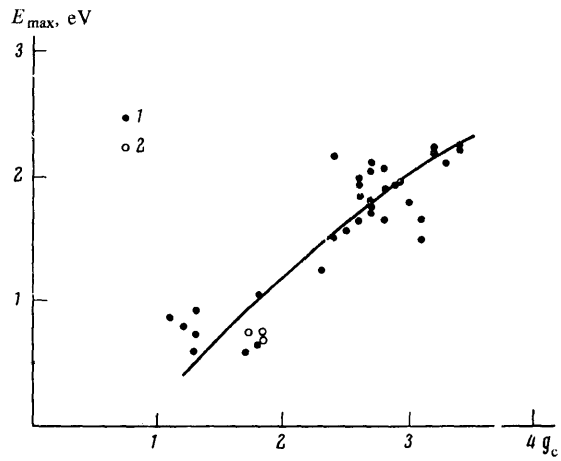

Figure 1. Variation of E_{max} (e_S) with the correlation parameter g_C of polar liquids: 1) liquids considered by Freeman[39]; 2) liquids investigated by Galvas et al.[40].

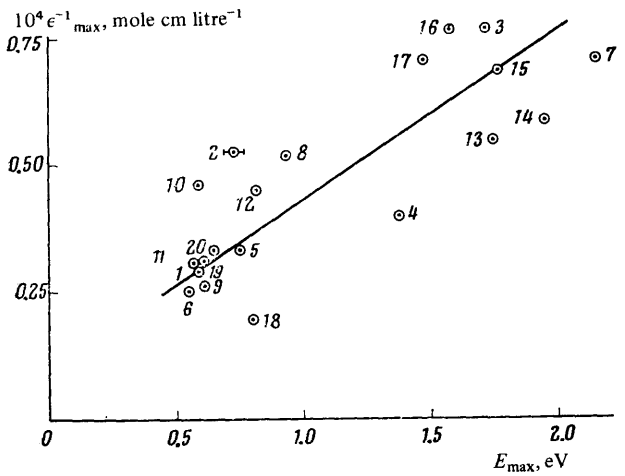

Figure 2. Variation of ϵ_{max} for the solvated electron with E_{max} in different liquids: 1) hexamethylphosphoramide[41]; 2) dimethyl sulphoxide (the upper limit of ϵ_{max} calculated from the data of Cooper et al.[63] is quoted); 3) 2-methoxyethanol[40]; 4) ethyl methyl ketone[46]; 5) squalane[64]; the remaining points were calculated from data quoted by Dorfman and Jou[42]; 6) ethyl ether; 7) ethylene glycol; 8) ethylenediamine; 9) tetrahydrofuran; 10) methyltetrahydrofuran; 11) diethylamine; 12) 1,3-propylenediamine; 13) water; 14) methanol; 15) ethanol; 16) 1-propanol; 17) isopropyl alcohol; 18) ammonia; 19) dimethoxyethane; 20) diglyme.

It was shown above that macroscopic characteristics have only a weak influence on the mechanism of the formation of the solvated electron and E_{max}. If the interaction of the electron with the nearest polar groups is regarded as the main one, a correlation may be expected between E_{max} and g_C. Indeed, Fig. 1 shows that, for all the liquids considered[39,40], including amides (open circles), the same functional relation holds between E_{max} and g_C.

There are few experimental data for the variation of the shape of the e_S absorption band on passing from one liquid to another. For ammonia[35], hexamethylphosphoramide[41], and 2-methoxyethyl ether[42], the absorption band is satisfactorily represented by a combined Lorentzian–Gaussian profile; the long-wavelength component of the absorption band is then described by the Gaussian function and the descent from the maximum in the direction of short-wavelengths obeys the Lorentzian function. In other liquids such analysis is difficult, particularly because of the inadequate accuracy of the recording of the e_S spectrum. However, it is possible to find a relation between simpler parameters characterising the spectrum and the position of the spectrum on the wavelength scale. Fig. 2 presents the variation of the reciprocal of the extinction coefficient at the maximum (ϵ_{max}) with E_{max}. Evidently, the extinction coefficient increases for all liquids with decrease of E_{max}. If one remembers that the oscillator strength of the e_S absorption band changes little (in the range 0.5–0.9), then the above finding reflects the fact that the e_S infrared absorption bands are narrower and more intense than the bands at short wavelengths.

IV. INTERACTION WITH POLAR LIQUIDS

Thus the region of the spectrum in which the solvated electron should absorb and the spectral characteristics can be predicted beforehand, albeit very approximately, for any organic liquid, subject to the condition that the electron is solvated in this liquid, i.e. does not react with the molecules of the liquid before solvation. The lifetime of the solvated electron in a particular organic liquid is usually inferred from the rate constant for the reaction of the hydrated electron with the molecules of the liquid. However, it is clear from the foregoing that in each liquid the solvated electron exhibits specific properties which do not allow the simple assumption that the properties are the same as those of the hydrated electron.

The factors governing the stabilisation of electrons in various organic liquids can be found by considering the results of a study of the interaction of low-energy (~1 eV) electrons with organic molecules in the gas phase[43,44]. This shows[46] that solvated electrons are formed in liquids whose molecules interact with electrons in the gas phase to form extremely short-lived negative ions ($10^{-15} \leq \tau \leq 10^{-12}$ s) and are characterised by a negative electron affinity. The rate constants for the e_S annihilation reactions in these liquids are $\leqslant 10^7$ litre mole^{-1} s^{-1}.

The results of the gas-phase measurements have been compared[44] with the rate constants for the interaction of hydrated electrons with the molecules of the above organic compounds in aqueous solutions. This leads to conclusions which are difficult to account for, for example when ketones are considered. Forming only extremely short-lived ions in the gas phase, they nevertheless react with hydrated electrons and the reaction is characterised by a high rate constant ($k = 6 \times 10^9$ litre mole^{-1} s^{-1}). Without considering in detail the mechanism of this reaction, the above considerations might have suggested that solvated electrons can be detected in pure liquid ketones, in view of the results of the gas-phase measurements. Indeed, a species has been detected in ethyl methyl ketone, whose

properties, such as the position of the absorption band (λ_{max} = 900 nm), its shape, its extinction coefficient ($\epsilon_{max} = 2.5 \times 10^4$ litre mole^{-1} cm^{-1}), and its half-width (0.5 eV) are quite similar to the spectroscopic characteristics of solvated electrons in other organic liquids [33,45]. Here we may note that the mobility of solvated electrons in ethyl methyl ketone (EMK) greatly exceeds the mobility of molecular ions in the same liquid [46]. Similar results were obtained in other investigations [40]. The rate constant for the reaction of electrons solvated in ethanol with dimethylformamide ($k = 1.1 \times 10^9$ litre mole^{-1} s^{-1}) suggests that in pure dimethylformamide (DMF) solvated electrons are not formed (the lifetime $\tau < 5 \times 10^{-11}$ s). In practice it was found that solvated electrons with an infrared spectrum having a lifetime of about 1 μs are formed in pure DMF. Naturally the specific features of the condensed state, particularly the association of molecules in the liquid, have an appreciable influence on the mechanism of the reaction of solvated electrons with the organic liquid molecules, as will be shown below.

Depending on the method of generation, solvated electrons can be obtained both in equilibrium with the surrounding medium (electrochemical generation, dissolution of metals) and in a non-equilibrium state (radiation-induced generation and photoionisation). In the latter case the lifetime of the solvated electron can be determined by its recombination with an ionised parent molecule or with radiolysis (photolysis) side products. However, for any method of generation, the maximum possible lifetime of the solvated electron is determined by the rate of its reaction with the molecules of the organic liquid in which it was solvated.

Despite the extensive experimental data obtained in studies of the kinetic characteristics of solvated electrons in various organic media, a comparative study of the influence of the molecular structure of liquids on the reaction of the electron with the medium has not been made. Nevertheless, the latter is one of the most important reactions [8,9]. The influence of the structure of the matrix on this reaction was studied for aliphatic monohydric alcohols with different hydrocarbon chain lengths and also for glycols and glycerols [46,47]. Using the method of pulse radiolysis, measurements were made of the rate constants for the reaction

$$ROH + e_s \xrightarrow{k} RO^- + H. \qquad (2)$$

Fig. 3 presents the values of k as a function of the number of carbon atoms n in the hydrocarbon chain in alcohols, iso-alcohols, and glycols at room temperature. The values of k for methanol and ethanol were taken from Rzad and Fendler [48] and a second, lower value for methanol from Iha and Freeman [49]. The Figure shows that k increases monotonically with increase of the hydrocarbon chain length and the constant is higher for alcohols with the iso-structure and glycols than for straight-chain alcohols. In conformity with this relation, $k = 2.4 \times 10^5$ litre mole^{-1} s^{-1} was obtained in glycerol, which agrees with the value quoted by Kajiwara and Thomas [50], but greatly exceeds the k values for propanol and propylene glycol.

Examination of the possible reaction mechanisms leads to the conclusion that the electron most probably reacts with monomeric matrix molecules which are not associated by hydrogen bonds [46]. In this case the activation energy for the reaction is related to the dipole relaxation of the liquid molecules, leading to the dissociation of the hydrogen bond, and amounts to several kcal mole^{-1}. The dependence of the rate constant on the hydrocarbon chain length of the alcohol molecules can be naturally explained, since it is known [51] that in the lower alcohols–higher alcohols series the degree of association diminishes. This also happens on passing from straight-chain to branched-chain alcohols, in agreement with the experimental results.

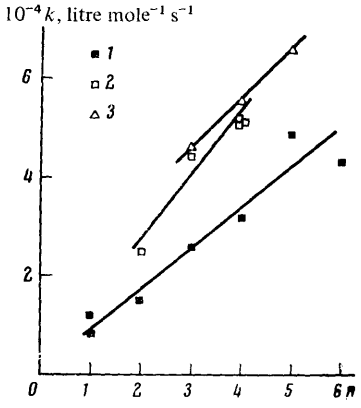

Figure 3. Variation of k with the number of carbon atoms n in the hydrocarbon chain: 1) straight-chain alcohols; 2) glycols (ethylene glycol, 1,2-propylene glycol, and 1,3-, 1,4-, and 2,3-butylene glycols); 3) iso-alcohols (isopropyl, isobutyl, and isopentyl alcohols).

The change in the rate constant on increasing the number of hydroxy-groups per molecule in the series 1-propanol, 1,2-propylene glycol, and glycerol is of interest, these being 2.6×10^4, 4.5×10^4, and 2.4×10^5 litre mole^{-1} s^{-1} respectively. When the rate constant is recalculated relative to the concentration of OH groups, it is found to increase only for glycerol: 2.6×10^4; 2.3×10^4; 8×10^4. This implies that the concentration of unassociated hydroxy-groups does not change on passing from the alcohol to the glycol and increases for glycerol, but the degree of association increases in this sequence with the corresponding variation of viscosity (2.2, 45.6, and 960 cP). Experimental confirmation of this would constitute valuable support for the hypothesis that the solvated electron reacts with the medium.

However, one cannot assume that the reaction of solvated electrons with monomeric molecules is diffusion-controlled, since, when the rate constant is calculated in terms of the concentration of monomeric molecules, which constitute only a few per cent of the total number of molecules, it is nevertheless still several orders of magnitude lower than the diffusion limit.

V. THE CHARACTERISTICS OF TRANSPORT IN POLAR LIQUIDS

Despite their importance, the reactions of solvated electrons with the molecules of liquids by which they are solvated have been studied much less than those of solvated electrons with the acceptors introduced into the liquids. Being one of the most chemically reactive species, the solvated electron reacts in many instances with organic molecules at rates controlled by the diffusion

limit. The rate constants for these reactions are determined by the mobility of the solvated electron and can be calculated using the latter. The study of solvated electron transport phenomena is important for the elucidation of the mechanism of the motion of electrons in non-ordered liquid media, for the determination of the nature of the interaction of solvated electrons with acceptors, and for the elucidation of the mechanism of oxidation-reduction reactions.

The mobilities of solvated electrons were previously measured reliably only in water[52,53] and in ammonia[54]. In water the mobility $\mu(e_S)$ of the solvated electrons generated by the ionising radiation pulse was obtained from electrical measurements, since the mechanism of the ionic process initiated by ionising radiation in water is known in detail. From this standpoint, organic liquids have been much less thoroughly investigated. Furthermore, in polar organic liquids the lifetime of the solvated electron is as a rule 10^{-4}–10^{-8} s owing to its interaction with the molecules of the liquid or the acceptor, and it is impossible to use standard methods for the determination of mobilities by measuring the time of flight of the electron between the electrodes. For this reason, a method has been developed for the measurement of the mobility of solvated electrons in which pulse measurements of their optical and electrical characteristics are combined[33].

The mobilities of solvated electrons, protons, and ions in certain polar liquids.

*The average mobilities of alkali metal and halide ions.

Spectroscopic measurements showed that in the organic liquids investigated solvated electrons generated by high-energy electron pulses disappear via a pseudofirst-order reaction. By reacting with acceptors or matrix molecules, the electron passes from the solvated state, detected by means of the optical absorption and characterised by the lifetime $\tau = k_{opt}^{-1}$, to a bound state. This entails a change in the mobility of the charged species. Numerical values of $\mu(e_S)$ were obtained by treating the current relaxation curves in terms of the equations[33]:

$$I_{max} = FG(e_s)PS[\mu(e_s) + \mu((m.i.)]/100;$$
$$\frac{I(t)}{I_{max}} = 2\left[\frac{\mu(e_s)}{\mu(m.i.)} + 1\right]^{-1} + \left\{\frac{[\mu(e_s)/\mu(m.i.)] - 1}{[\mu(e_s)/\mu(m.i.)] + 1}\right\} e^{-k_{opt}\cdot t}, \quad (3)$$

where $G(e_S)$ is the radiation-chemical yield of solvated electrons, P the dose in the pulse, $\mu(e_S)$ and μ(m.i.) are the mobilities of solvated electrons and molecular ions, F is the electric field strength, S the area of the electrodes, and I_{max} the maximum amplitude of the relaxation current. The Table lists the mobilities of solvated electrons, protons, and ions for certain polar liquids.

The data quoted by Vannikov et al.[33] first led to the conclusion that the mobility of solvated electrons in various polar media is inversely proportional to their viscosities. Recently this conclusion was confirmed in a study[55] where it was shown that the Walden rule holds for solvated electrons, and $\mu(e_S)\eta = C$. Fig. 4 presents the known mobilities of solvated electrons as a function of the viscosity of the polar liquid. The straight line corresponds to the Walden rule with $C = 2 \times 10^{-3}$ cm^2 cP V^{-1} s^{-1}. The values of $\mu(e_S)$ are quoted for room temperature, with the exception of ammonia (−60°C) and dimethoxyethane (−90°C). Since the relation $\kappa = \mu kT/e$ holds between the mobility and the diffusion coefficient κ, one can assume that a relation analogous to that illustrated in Fig. 4 holds between $\kappa(e_S)$ and η.

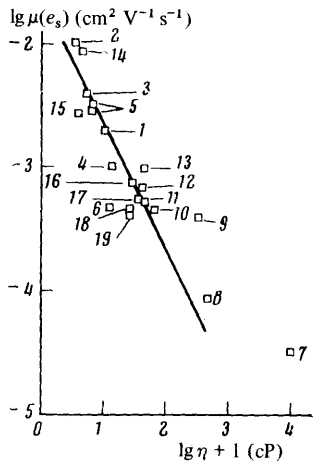

Figure 4. Variation of the mobility of the solvated electron with viscosity in polar liquids: 1) water[52]; 2) ammonia[54]; 3) n-propyl ether[55]; 4) ethanol[55]; 5) methanol[46,55]; 6) ethanol[65]; 7) glycerol[50]; the data for the remaining limits were taken from Refs. 33, 46, 47, and 57: 8) 1,2-propylene glycol; 9) dimethoxyethane; 10) hexanol; 11) 1-pentanol; 12) isobutyl alcohol; 13) isopentyl alcohol; 14) ethyl methyl ketone; 15) monobutylamine; 16) 1-butanol; 17) hexamethylphosphoramide; 18) 1-propanol; 19) isopropyl alcohol.

The results obtained for polar liquids, referring to various classes of organic compounds, show that in all cases the mobility of solvated electrons is much higher than that of molecular ions, with the exception of water, where the mobilities of electrons and hydroxide ions are the same; however, one should note that hydroxide ions exhibit anomalous mobility. Thus the mechanism of the motion of solvated electrons differs from that of the usual diffusion of ions. The activation energy for mobility measured for solvated electrons in hexamethylphosphoramide is 1.6 kcal mole^{-1} and is smaller than the activation energy for ionic mobility (4.4 kcal mole^{-1}).[59] On the other hand, the specific characteristics of the diffusion of solvated electrons distinguish it from the mechanism of the motion of protons (it has been suggested[60] that the same mechanism applies to hydrated electrons and H^+ ions), which in

certain liquids, for example in water and alcohols, leads to anomalous mobilities, since high values of $\mu(e_S)$ relative to ionic mobilities are observed also in liquids where there is no anomalous proton mobility.

In principle it is possible to postulate a mechanism for the motion of e_S based on the transition of the electron to a quasifree state with a high mobility and its subsequent solvation. Estimates based on experimental results, [19,61] have shown [46] that the minimum activation energy for the process exceeds 10 kcal mole^{-1}, which is much more than the experimental value quoted above and makes this mechanism of the motion of e_S unlikely in polar organic liquids. The jump mechanism of the motion of the electron between local regions in the liquid where orientation polarisation corresponds to a minimum in the overall electron energy appears to be more realistic [62]. The diffusional jump is accompanied by a reorientation of the liquid molecules and one may expect a correlation between the viscosity and the mobility $\mu(e_S)$, which is in fact observed, as shown above.

Thus empirical relations and gas-phase data for the interaction of electrons with organic molecules as well as macroscopic characteristics of the organic liquid and its molecular parameters make it possible to determine approximately beforehand whether solvated electrons will be formed in the given liquid and to indicate the part of the spectrum where the e_S absorption band should occur, the parameters of the spectrum, and the expected mobility and diffusion coefficient of e_S. Theoretical proof of the above characteristics will promote a significant advance in the understanding of the nature of the solvated state of electrons in polar organic liquids.

The Intermediate Chemisorbed Species in Electrocatalysis

Yu.B.Vasil'ev and V.S.Bagotskii

The fundamental data on the adsorption of various organic substances on platinum, obtained by electrochemical methods, are discussed. It is shown that electrochemical pulse methods make it possible to determine the degree of adsorption directly under the steady-state conditions of an electrocatalytic process and also to establish in many instances the nature of the adsorbed complex on the surface of the catalyst electrode.
The bibliography includes 70 references.

I. INTRODUCTION

In many electrochemical oxidation-reduction reactions the electrode behaves simultaneously as a catalyst on the surface of which purely catalytic processes can take place and individual stages of electrochemical processes can be accelerated. The catalytic processes which may precede the electron transfer stage and facilitate it, can follow this stage, or can proceed independently of and simultaneously with the main electrochemical process. The studies in recent years on a large number of electrochemical processes involving organic compounds have shown that the slow stage in such processes is frequently the purely catalytic reaction, while the electrochemical stage merely supplies one of the reactants.

The problem of the direct transformation of the chemical energy of fuel into electrical energy in fuel cells stimulated extensive research on the characteristics of the kinetics of electrode processes, of adsorption on solid electrodes, and of the influence of the nature and structure of the catalyst electrode on its electrochemical activity in relation to various reactions. To embrace the entire range of processes, the term "electrocatalysis" is widely used, showing clearly that these processes are on the border line between two fields of physical chemistry—electrochemistry and catalysis. In the study of the mechanisms of electrocatalytic processes, both the classical methods of heterogeneous catalysis and the electrochemical methods developed in recent years are used.

The considerable advances in electrocatalysis in recent years are due to two main achievements—the development of electrochemical methods for the investigation of the adsorption of reactants (and also of intermediates) and for the preparation of a reproducibly clean electrode surface and the determination of the degree of its purity.

Systematic research on adsorption phenomena by electrochemical methods was begun in 1933–1938 by Frumkin and his coworkers [1-3], who determined with the aid of the so called charging curves (curves relating the potential of a polarisable electrode to the amount of electricity passed through the system) not only qualitative but also quantitative aspects of the adsorption of hydrogen and oxygen on platinum and other platinum group metals. The most important results of these studies were the determination of the distribution of adsorbed species among adsorption sites with different bonding energies and the demonstration that the adsorption isotherm is logarithmic (Temkin's isotherm):

$$\theta = a + \frac{1}{f} \ln c,$$

where θ is the degree of surface coverage by the adsorbed species, c the concentration in solution (the partial pressure for gases), and a and f are constants (the constant f is sometimes called the surface inhomogeneity factor). These experimental observations served as a basis for the development of a theory of adsorption phenomena and of the kinetics of chemical reactions on a surface with uniformly distributed inhomogeneities [4,5], which had been widely used in heterogeneous catalysis. In the above experimental studies the charging curves were recorded very slowly (i.e. small currents were used), thereby ensuring a state close to equilibrium at almost all points.

In recent years electrochemical methods for the investigation of adsorption phenomena have been greatly developed. A number of new experimental procedures have been devised, whereby measurements can be made at a high rate, which admittedly infringes in many cases the equilibrium in the system, but on the other hand such rapid methods permit the determination not only of the overall degree of adsorption but also of its kinetics. Electrochemical methods have been used to study the adsorption of not only hydrogen and oxygen but also of a large group of other substances, particularly various organic compounds [6-8].

Electrochemical pulse methods make it possible to determine the degree of adsorption directly under the steady-state conditions of catalytic and electrocatalytic processes and to establish in many instances the nature of the complex adsorbed on the surface of the catalyst electrode.

II. THE DISSOCIATIVE NATURE OF THE CHEMISORPTION OF ORGANIC SUBSTANCES ON PLATINUM GROUP METALS AND THE NATURE OF THE CHEMISORBED SPECIES

From an analysis of the variation of the kinetics of the decrease of potential in the adsorption of methanol on a platinum electrode with the pH of the solution, Frumkin and Podlovchenko[9] put forward for the first time in 1963 the hypothesis that the adsorption (more correctly chemisorption) of methanol from solution on platinum is accompanied by the abstraction of hydrogen atoms from the adsorbed methanol molecule, i.e. its degradation. The use of various combined electrochemical methods and also the tracer atom method made it possible to show subsequently that, following its adsorption on the platinum electrode, the methanol molecules split off three hydrogen atoms. The resulting COH species is bound directly to three surface platinum atoms, liberating three electrons when it is oxidised to CO_2.[10] The results show that the adsorption of methanol can be represented as follows:

$$CH_3OH \rightarrow \underset{\times\times\times}{COH} + 3H_{ads},$$

where the crosses indicate the number of surface platinum atoms forming strong bonds with the adsorbed species.

On open external circuit, both hydrogen and the carbon-containing residues formed during dehydrogenation remain on the electrode surface. However, the hydrogen atoms completely lose their bonds with the carbon-containing species and are linked to the catalyst surface only. They behave as free adsorbed hydrogen atoms in equilibrium with the hydrogen ions in the bulk of the solution and determine the electrode potential. Hydrogen can diffuse to the opposite side of a palladium membrane, where it can be detected[11-14].

Using the large difference between the oxidation potentials of the adsorbed hydrogen and the carbon-containing residues, it is possible to remove the hydrogen atoms from the surface by applying to the electrode a potential $\varphi_r = 0.4$ V (φ_r is the potential relative to that of the reversible hydrogen electrode in the same solution), which is intermediate between the above two potentials; an additional amount of carbon-containing COH residues is then adsorbed on the liberated surface sites. This constitutes the main difference between adsorption under the usual catalytic conditions (on open external circuit) and under electrochemical conditions (when the circuit is closed). When the circuit is closed and the potential is maintained at values more positive than 0.3 V, the maximum degree of adsorption of the species can be almost a factor of two greater than that observed on open circuit.

This mechanism of the adsorption of methanol on platinised platinum was confirmed using methanol labelled with ^{14}C and tritium[15]. Thus in the adsorption of $^{14}CT_3OH$ on a platinised platinum electrode at a potential such that hydrogen should be removed from the electrode surface, only species containing ^{14}C are adsorbed, but the adsorbed species does not contain tritium.

Experiments showed that the nature of the chemisorbed species does not change when the electrode potential, the concentration of methanol, the pH of the solution, and temperature are altered. There is no doubt that the dehydrogenation process does not proceed immediately via the elimination of three hydrogen atoms but involves separate stages:

$$\underset{\times}{CH_3OH} \xrightarrow{k_1} \underset{\times\times}{CHOH} + H_{ads};$$

$$\underset{\times\times}{CHOH} \xrightarrow{k_2} \underset{\times\times\times}{COH} + H_{ads},$$

where $k_1 < k_2 < k_3$, so that the elimination of the first hydrogen atom is slowest, the second and third atoms being removed more rapidly.

Similar methods have been used to establish the nature of the chemisorbed species on platinum group metals in the adsorption of various organic substances (hydrocarbons ranging from methane to hexane, alcohols from methanol to octanol, formic acid, formaldehyde, carbon dioxide, ethylene glycol, glycolaldehyde, nitromethane, nitroethane, maleic acid, etc.). It has been shown that the chemisorbed species formed initially in the adsorption of organic molecules can be transformed on the surface as a result of secondary reactions into other species, more stable under the given conditions. For example, formic acid adsorbed on a platinum electrode gives rise to the primary species COOH,[16-18] i.e.

$$HCOOH \rightarrow H_{ads} + \underset{\times}{COOH},$$

which reacts at $\varphi_r < 0.4$ V with adsorbed hydrogen:

$$\underset{\times}{COOH} + 2H \rightarrow \underset{\times\times\times}{COH} + H_2O,$$

yielding the same species as in methanol solutions. Chemisorbed species resulting from the partial oxidation of the initial species can also be present on the surface. For example, in a study of the adsorption of methane on the surface of a platinum electrode it was shown that the chemisorbed species is similar to that derived from methanol, having the composition COH.[19,20]

At room temperature carbon dioxide is not usually adsorbed on the surface of a platinum electrode free from adsorbed gases, but is readily adsorbed on the surfaces of the electrode on which hydrogen has been adsorbed (i.e. as a result of reaction with hydrogen). This leads to the formation of chemisorbed species similar to that obtained in methanol solutions[21-25].

The processes occurring in the adsorption of compounds containing two and more carbon atoms in the molecule are much more complex, so that it is now difficult to determine their nature, particularly when the adsorption proceeds on open circuit and the adsorbed hydrogen remains on the surface. Cracking, hydrogenation, and polymerisation can then occur[26,27]. The mechanism of cracking, i.e. of the dissociation of the C–C bond, has been studied in detail[29-32] in the adsorption and oxidation of ethylene, ethane, and other hydrocarbons on a platinum electrode. In the adsorption of ethylene and ethane two types of chemisorbed carbon-containing species are formed—species which are oxidised readily and with difficulty. The species which are difficult to oxidise contain two carbon atoms and are readily removed from the surface by hydrogenation, forming ethane. The readily oxidised species contain one carbon atom and are hardly hydrogenated.

The mechanism of the adsorption of ethylene and ethane on platinum can be represented as follows:

$$\begin{array}{l} CH_2{=}CH_2 \\ \quad\downarrow k_{ads} \\ CH_3{-}CH_3 \underset{+2H_{ads}}{\overset{-2H_{ads}}{\rightleftharpoons}} \underset{\times\quad\times}{CH_2{-}CH_2} \xrightarrow{k_{decomp}} \end{array}$$

[species (II)]

$$\begin{array}{l} \quad\quad CO_2 \\ \quad\quad\uparrow \\ \rightarrow \underset{\times\times}{CH_2} \rightarrow \underset{\times\times\times\times\times\times}{CH} \rightarrow \underset{\times\times\times\times\times\times}{COH} \end{array}$$

[species (I)]

The principal constants for the adsorption of various organic substances on a platinum electrode.

*Electrode: A—smooth platinum; B—platinised platinum; solution: alk—alkaline (1 *N* KOH); no symbol acid (0.5–1 *N* H_2SO_4).

The relative amounts of species (II) and (I) depend on the ratio of the rate constants for adsorption and decomposition.

The experimental data available at present show that, in the adsorption of organic compounds on platinum, triple and double bonds are dissociated most readily, dehydrogenation at the α-carbon atom is more difficult, and the hydrocarbon group is dehydrogenated and C–C bonds are ruptured only under more severe conditions. With increase of temperature, the degrees of dehydrogenation and degradation of the initial molecule also increase.

The Table presents the main constants characterising the adsorption processes of certain organic substances on smooth and platinised platinum electrodes.

III. THE FUNDAMENTAL CHARACTERISTICS OF THE ADSORPTION OF ORGANIC SUBSTANCES ON PLATINUM

It has been shown in numerous investigations [8,16,27,38,56,57] that the dependence of the surface coverage of the platinum electrode θ'_R on the bulk-phase concentration of the organic substance at different potentials, temperatures, and pH values is described by Temkin's logarithmic isotherm at moderate coverages (Figs. 1 and 2):

$$\theta'_R = a + \frac{1}{f'} \ln c$$

(the degree of coverage θ'_R is defined as the ratio of the occupied sites to the number of surface sites available for

the adsorption of hydrogen; since f depends on the definition of θ, it is designated in this case by f'). The quantity a (characterising adsorbability) depends on the electrode potential, the pH of the solution, and the nature of the organic substance, while the values of f' are almost the same ($f' = 14 \pm 2$) for the adsorption of a wide variety of organic substances on platinum electrodes. The dimensions of the adsorbed species have a marked influence on the limiting surface coverage $\theta_R'^{max}$ and on the fraction of the surface blocked owing to steric hindrance.

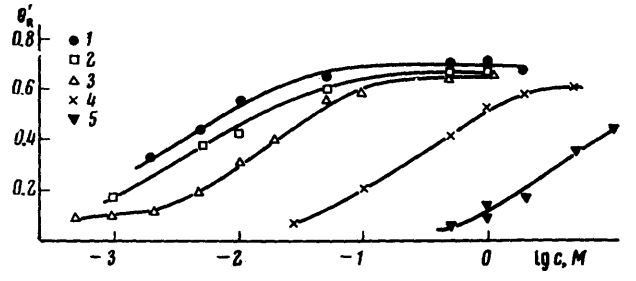

Figure 1. Steady-state methanol adsorption isotherms on a platinised platinum electrode in 1 N H_2SO_4 at various potentials φ_r (V): 1) 0.5; 2) 0.55; 3) 0.6; 4) 0.7; 5) 0.8.

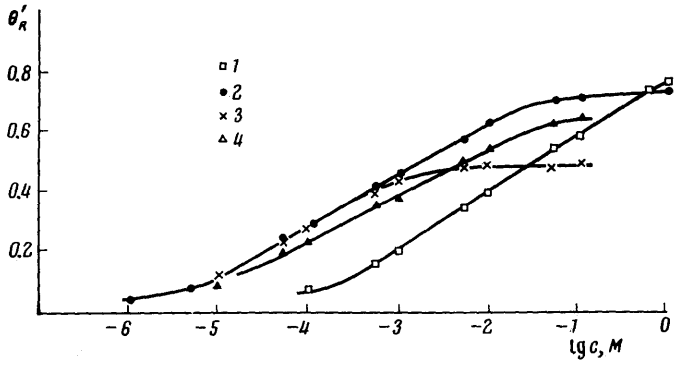

Figure 2. Steady-state isotherms for the adsorption of various aliphatic alcohols on a smooth platinum electrode in 1 N H_2SO_4 at an adsorption potential $\varphi_r = 0.4$ V: 1) CH_3OH; 2) C_2H_5OH; 3) n-$C_5H_{11}OH$; 4) t-$C_5H_{11}OH$.

The rates of adsorption on platinum of all the organic substances investigated are described under different conditions by the Roginskii–Zel'dovich equation (Figs. 3 and 4): [8,16,27,38,56-59]

$$v_{ads} = k_{ads} c \exp(-\alpha f' \theta_R'),$$

where α is the transfer coefficient (usually $\alpha \simeq 0.5$). On passing from one organic substance to another, the adsorption rate constants vary approximately in the same sequence as the adsorbabilities. The results of studies of the variation of k_{ads} with potential have shown that it is influenced mainly by the adsorption of hydrogen and oxygen which is related to the potential, and not by the electrode potential itself [8,16,26,27]. Therefore the equation for the rate of adsorption of an organic substance can be written as follows:

$$v_{ads} = (1 - \Sigma\theta_i) k_{ads} c \exp(-\alpha f' \Sigma\theta_i'),$$

where the summation is carried out over all the chemisorbed species: organic species, oxygen, hydrogen, etc.

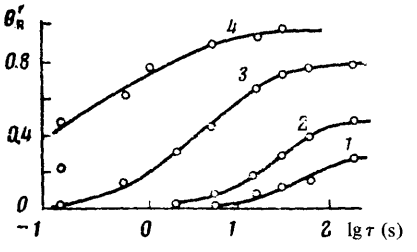

Figure 3. Kinetics of the adsorption of methanol on a smooth platinum electrode in 1 N H_2SO_4 at an adsorption potential $\varphi_r = 0.4$ V and various methanol concentrations (M): 1) 0.001; 2) 0.01; 3) 0.1; 4) 1.

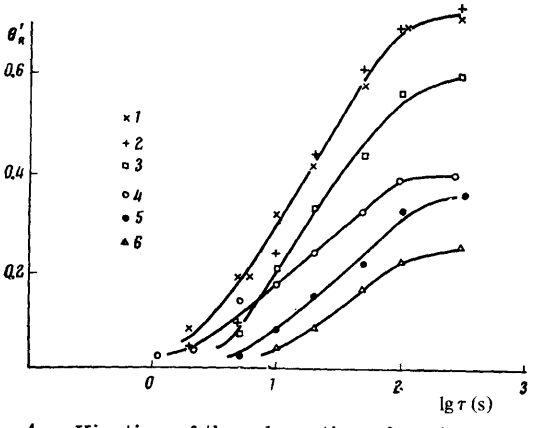

Figure 4. Kinetics of the adsorption of various organic substances on a platinum electrode at a potential $\varphi_r = 0.4$ V: 1) saturated ethylene solution in 1 N KOH; 2) saturated ethylene solution; 3) 10^{-4} M allyl alcohol; 4) 10^{-4} M maleic acid; 5) saturated styrene solution diluted 100 times; 6) 10^{-4} M furmaric acid; 2) 1 N H_2SO_4.

The activation energies E_a for the adsorption of various organic substances on platinum increase linearly with surface coverage (Fig. 5): [16,27,50,57]

$$E_a = E_a^0 + \alpha f' R T \theta_R'.$$

The observed kinetic and adsorption characteristics permitted a quantitative interpretation of the nature of the curves describing the decrease of the electrode potential on open circuit when an organic substance is introduced into the solution [60,61].

The kinetics of the elimination of chemisorbed species from the surface of platinum (Fig. 6) are described by the equation

$$v_{sp.} = k_{sp.} \exp(\beta f' \theta'_R),$$

where β is the transfer coefficient (usually $\beta \simeq 0.5$). Chemisorbed nitromethane, nitrobenzene, acetic acid, and maleic acid species are removed as a result of their hydrogenation [47,51] and methanol species are removed as a result of oxidation.

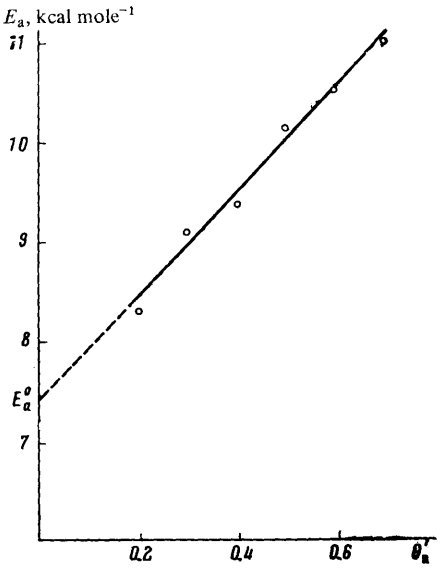

Figure 5. Variation of the activation energy E_a with θ'_R in the adsorption of CO_2 in 1 N H_2SO_4 at a potential φ_r = 0.1 V and p_{CO_2} = 1 atm.

Determination of the variation of the heat of adsorption of methanol on a platinum electrode with surface coverage showed that the applicability of Temkin's logarithmic isotherm to adsorption is a result of a linear relation between the heat of adsorption Q_{ads} of methanol and surface coverage [57]:

$$Q_{ads} = Q^0_{ads} - f' R T \theta'_R.$$

IV. DEPENDENCE OF THE ADSORPTION OF ORGANIC SUBSTANCES ON THE POTENTIAL

The dependence of the adsorption of neutral organic substances on the potential for mercury and many other metallic electrodes is determined primarily by the position of the zero-charge point and the electrostatic effect of the charges of the electrical double layer [62,63]. Frumkin showed by a thermodynamic procedure [64,65] that a different situation should obtain for platinum and certain other electrodes capable of adsorbing large amounts of hydrogen and oxygen. When the adsorption process is reversible, the degree of adsorption of the organic substance should decrease even for low degrees of surface coverage by hydrogen or oxygen; the maximum degree of adsorption of the organic substance may be expected in the range of potentials between the regions corresponding to the adsorption of hydrogen and oxygen.

Experiment has shown that the variation of the degrees of adsorption of many organic substances on platinum with the potential is normally described by a dome-shaped curve with a broad maximum in the potential range 0.3 to 0.6 V, where the degree of adsorption of hydrogen and oxygen are minimal (Figs. 7 and 8). [5,8,17,38,66] The constancy of surface coverage in this range of potentials shows that the potential itself on the charge of the double layer hardly affects the adsorption of methanol, since the specific adsorption forces are much greater than the electrostatic influence of the surface charge.

When the potential shifts towards more negative ($\varphi_r <$ 0.3 V) or more positive ($\varphi_r \geq$ 0.5–0.6 V) values, the

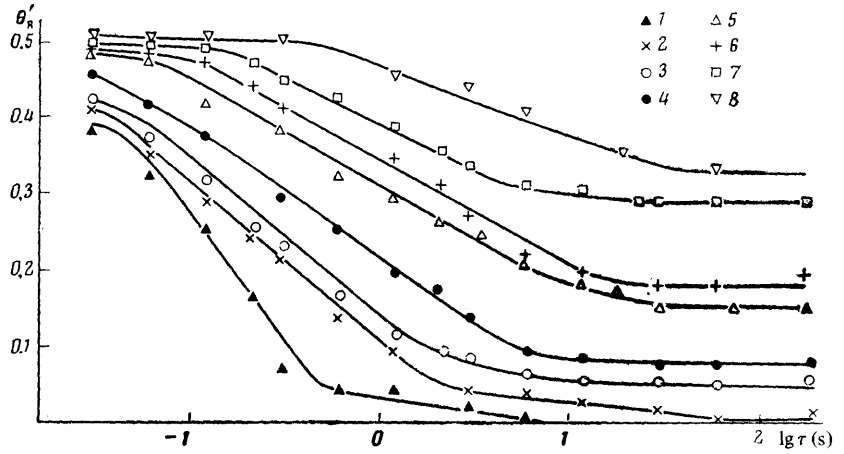

Figure 6. Kinetics of the hydrogenation of species chemisorbed at φ_r = 0.2 V from 10^{-4} M $C_4H_4O_4$ + 1 M H_2SO_4 solutions at various hydrogenation potentials (V): 1) −0.025; 2) 0.0; 3) 0.0125; 4) 0.025; 5) 0.05; 6) 0.075; 7) 0.1; 8) 0.125.

degree of adsorption falls (to a first approximation linearly as the potential is altered). The decrease of the degree of adsorption at negative potentials is due to the influence of the adsorption of hydrogen on the adsorption of the organic residue or to the hydrogenation of the species.

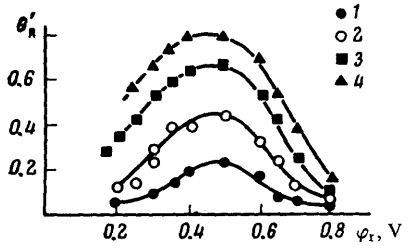

Figure 7. Variation of θ'_R with the potential φ_r in the adsorption of methanol on a smooth platinum electrode in 1 *N* H_2SO_4 solutions for different methanol concentrations (M): 1) 0.001; 2) 0.01; 3) 0.1; 4) 1.

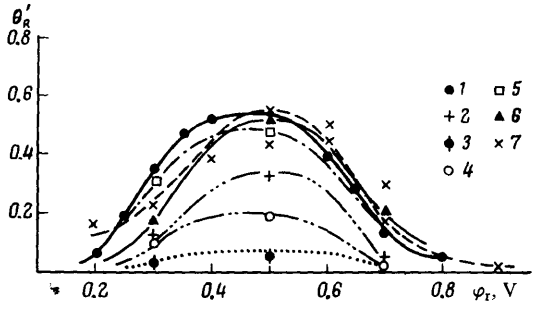

Figure 8. Variation of θ'_R with the potential φ_r on a smooth platinum electrode for 0.01 M methanol in 1 M phosphate buffer solutions at different pH: 1) 0.32; 2) 1.4; 3) 2.8; 4) 6.2; 5) 10.1; 6) 12.2; 7) 13.1.

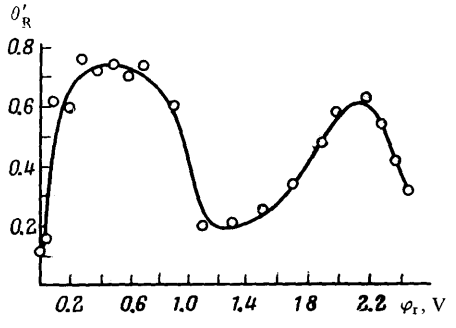

Figure 9. Variation of θ'_R with the potential φ_r in 1 *N* H_2SO_4 + 10^{-3} M C_4H_6 solution.

The decrease of surface coverage at positive potentials is associated with the oxidation of the chemisorbed species, since the rates of adsorption and electrochemical oxidation become comparable. The width and position of the dome-shaped curve for different organic substances may vary somewhat owing to the changes in the relative rates of individual processes (adsorption, oxidation, hydrogenation, etc.).

Experiment shows that, to a first approximation, the curve relating the degree of adsorption of the organic substance to the potential shifts with pH in the same way as the hydrogen and oxygen adsorption regions [8,47,51]. The shift of the adsorption regions of the organic substances as the pH of the solution is varied constitutes a characteristic property of the platinum electrode and of other electrodes adsorbing considerable amounts of hydrogen.

It has been shown for the adsorption of butadiene [54] and urea [55] on platinum that at high anodic potentials the organic substance can be adsorbed on an oxide layer, which leads to the appearance of a second adsorption maximum at $\varphi_r = 2.2$ V (Fig. 9).

V. THE INTERMEDIATE CHEMISORBED SPECIES AND THE MECHANISMS OF ELECTROCATALYTIC PROCESSES

The influence of pH and electrode potential on the rates of electrochemical oxidation [67-70] and electrochemical reduction [46-51] of various organic substances on platinum group metals shows that, apart from the adsorbed organic species, another species, formed in the preceding rapid electrochemical stage is involved in the slow stage. In an oxidation reaction the adsorbed species is OH_{ads}, formed as a result of the electrochemical oxidation of water:

$$H_2O \rightleftarrows OH_{ads} + H^+ + e.$$

The slow stage in the oxidation of methanol is the non-electrochemical interaction of carbon-containing chemisorbed species with OH_{ads} radicals. In acid solutions the slow stage is

$$\underset{\times\times\times}{C} - OH + OH_{ads} \rightarrow \underset{\times\times}{C}{=}O + H_2O;$$

the subsequent oxidation stages being faster. Similarly the slow stages in the oxidation of formaldehyde and formic acid are the reactions

$$\underset{\times\times}{C}{=}O + OH_{ads} \rightarrow \underset{\times}{C}\begin{matrix}{=}O\\ \diagdown OH\end{matrix};$$

$$\underset{\times}{C}\begin{matrix}{=}O\\ \diagdown OH\end{matrix} + OH_{ads} \rightarrow CO_2 + H_2O.$$

Under steady-state electrochemical oxidation conditions, methanol is dehydrogenated and OH_{ads} radicals are formed simultaneously. Bearing in mind that the dehydrogenation of methanol does not proceed in a single stage via the abstraction of three hydrogen atoms but involves a series of stages, presumably the OH radicals formed react with methanol at any stage in its dehydrogenation, giving rise to various oxidation products. Therefore the entire oxidation process can be represented schematically as shown in Fig. 10.

Detailed studies of the mechanism of the adsorption and electrochemical oxidation of simple organic substances ranging from methane to carbon dioxide on platinum group metals have shown that, despite the great complexity and wide variety of these reactions, they can be described by a single multistage mechanism. The nature of the chemisorbed species on the surface is determined by the relative

rates of the individual stages in the processes, illustrated in the scheme, and also by the simultaneous electrochemical formation of the chemisorbed species OH_{ads} or H_{ads}. In its turn it determines the nature of the oxidation products under steady-state conditions. For example, at low pressures, where the conversion of species (II) into species (I) is fairly rapid, ethane and ethylene are oxidised fairly rapidly and completely to CO_2. On the other hand, at fairly high ethylene pressures, where the main chemisorbed species is H_2C-CH_2, ethylene undergoes mild oxidation to ethylene glycol.

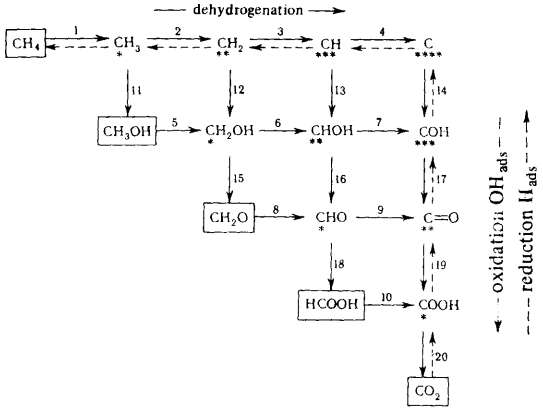

Figure 10. General scheme for the adsorption, electrochemical oxidation, and electrochemical reduction of simple organic substances.

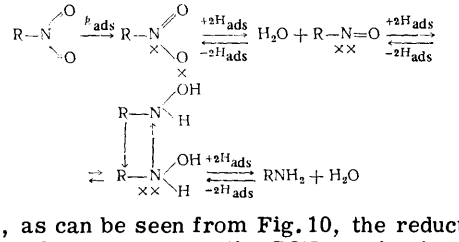
The mechanism of the reduction of compounds with a C=C double bond has been studied in the electrochemical hydrogenation of maleic acid on a platinum catalyst electrode[51]. It has been shown that the slow stage in this process involves the interaction of the chemisorbed organic species with the adsorbed hydrogen formed in the preceding rapid electrochemical stage:

$$HOOCCH{\underset{\times}{-}}CHCOOH+2H_{ads} \rightarrow HOOCCH_2-CH_2COOH.$$

In contrast to this, in the electrochemical reduction of aliphatic nitro-compounds on platinum group metal catalyst electrodes the addition of the first hydrogen atoms is fast and the slow stage involves the addition of subsequent hydrogen atoms, which leads to the desorption of the chemisorbed organic species from the electrode surface[47]. Under these conditions, in the electrochemical reduction of nitro-compounds the surface is covered by partly reduced chemisorbed species. The overall process mechanism can be represented as follows:



Similarly, as can be seen from Fig. 10, the reduction of CO_2 by adsorbed hydrogen to the COH species is rapid and the slow stage is the subsequent interaction of this species with adsorbed hydrogen to form methane.

Thus chemisorbed species play a very important role in electrocatalytic processes, determining the direction of the process, its rate, and the yields of various products.

The Estance Method

A.Ya.Gokhshtein

A method based on the measurements of estance—the derivative of the surface tension of a conducting solid with respect to an electrical variable—is proposed for the investigation of surface phenomena. The basis of the method involves two mutually opposed effects—the change in the surface tension of the solid when its potential relative to a flowing medium is altered and the change in the potential on elastic deformation of the solid. The experimental technique, certain problems of the theory of the method, and examples of its employment are described.

I. INTRODUCTION

The dependence of the interfacial tension between two liquids on the potential jump at the interface is known as the phenomenon of electrocapillarity[1]. As a result of research by Frumkin and his school[2-4], this phenomenon has become one of the principal sources of information about the structure of the electrode–electrolyte boundary. The large volume of information obtained by measuring the surface tensions of liquid electrodes stimulated the search for a method which would permit the measurement of the influence of the potential on the surface tensions of solid electrodes too.

II. THE SURFACE TENSIONS OF SOLID ELECTRODES

1. Principle of the Method

The variation of the surface tensions of solid electrodes with potential could not be measured previously because of the extremely slight deformation of the solid electrode and the appreciable side effects. An increase of the surface tension by 1 dyn cm^{-1} shortens a silver plate 1 cm long and 0.1 cm thick only by 0.001 Å. Appreciable internal stresses within the material of the electrode arise owing to the diffusion of extraneous species into the bulk of the electrode. Under the conditions of the example quoted, the result of the measurements may be distorted when the temperature of the electrode changes by only 10^{-6} K. In the method proposed these difficulties have been eliminated.

The essence of the method can be described briefly as follows[5-11]. If the surface tension of the solid electrode γ depends in some way on the electrode potential φ relative to the solution, then the oscillations in φ with an amplitude $\Delta\varphi$ should lead to oscillations in the surface tension with an amplitude $\Delta\gamma$. The variation of $\Delta\gamma$ with φ is recorded, the following procedure being used. The solid electrode, for example an L-shaped electrode, is clamped in a specified manner to a piezoelectric element (Fig. 1) and forms with the latter a mechanical system possessing a series of resonance frequencies. These frequencies are used in the measurements. The length of the working section of the L-shaped electrode is about 1 cm. The lower surface of the electrode is wetted by the electrolyte. It is raised somewhat above the level of the electrolyte, which makes it possible to refer to it as a suprameniscus electrode. An alternating current at a specified frequency is passed through the electrode and the potential oscillations received from the piezoelectric element are amplified at the same frequency. After rectification, this signal is applied to the vertically deflecting plates of a cathode ray tube. The horizontal scan of the beam is proportional to the average electrode potential.

Measurements can be made under two sets of conditions depending on whether one keeps constant the amplitude of the electrode charge density q (by specifying the alternating current amplitude) or the amplitude of the electrode potential φ. Under the first set of conditions, $\Delta\gamma$ is proportional to the derivative $\partial\gamma/\partial q$ and under the second set to $\partial\gamma/\partial\varphi$, which we call respectively the q-estance and the φ-estance or simply the estance (when there is no possibility of a misunderstanding). The term "estance" is modelled on the term "impedance" using as a basis the word "elastic" in connection with the study of elastic materials. The variables $\partial\gamma/\partial q$ and φ have definite advantages over others, since both these quantities have the same dimensions. They are used in the oscillograms in Figs. 2–5, where the modulus of estance $|\partial\gamma/\partial q|$, abbreviated to $|\gamma_q|$ is plotted against φ, expressed relative to the potential of the normal hydrogen electrode.

The introduction of the quantity $\partial\gamma/\partial q$ also follows naturally from a number of observed phenomena. One of these is the independence of the estance $\partial\gamma/\partial q$ of frequency in slow localised adsorption of charged species (Fig. 2*a*, on the right). This striking feature cannot be obtained by plotting $\partial\gamma/\partial\varphi$ or γ against φ.

The loss of information due to the differentiation of the $\gamma-\varphi$ relation in the process described is small. Static measurements, where there is no differentiation, nevertheless cannot yield the absolute value of γ. It is measured to within an arbitrary constant, which disappears on differentiation.

Yet another problem is important. In principle, static measurements can yield the variation of γ not only with φ

but also with the chemical potential μ of the adsorbed substance. The derivative $\partial\gamma/\partial\mu$ contains information about the concentration of this substance on the surface. However, $\partial\gamma/\partial\varphi$ can also be measured at different values of μ.

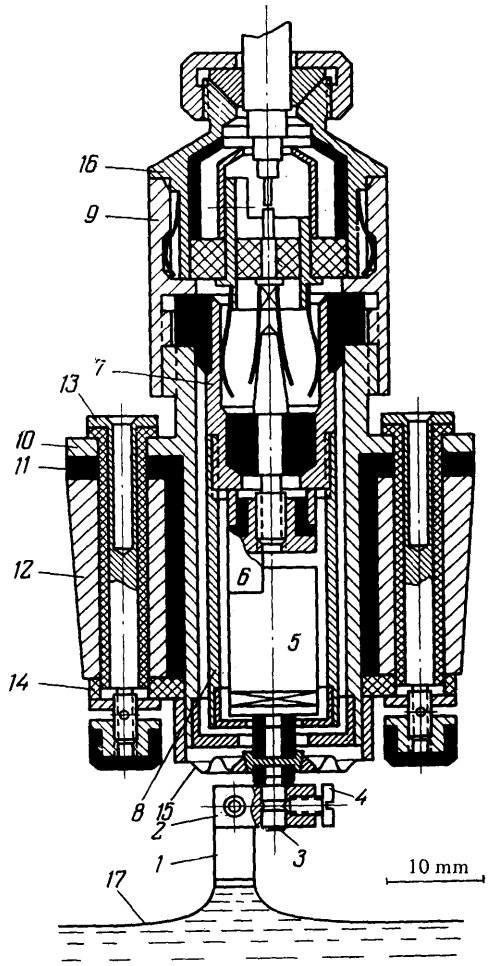

Figure 1. Unit for the transformation of surface tension: 1) L-shaped supramenisscus electrode; 2) holder; 3) shaft; 4) focussing screw; 5) piezoelectric element; 6) bush; 7) cartridge; 8) inner screen; 9) lock nut; 10) outer screen; 11) insulating beaker; 12) ground collar; 13) terminals; 14) insulating ring; 15) protective membrane; 16) coaxial plug; 17) electrolyte.

By integrating the derivative $\partial^2\gamma/\partial\mu\partial\varphi$ obtained in this way with respect to φ and starting with the desorption region (the potential φ_d at which there is no adsorbate on the electrode surface), we arrive at the following expression for $\partial\gamma/\partial\mu$:

$$\frac{\partial\gamma}{\partial\mu} = \int_{\varphi_d}^{\varphi} \frac{\partial}{\partial\mu}\left(\frac{\partial\gamma}{\partial\varphi}\right) d\varphi. \qquad (1)$$

Vanishingly small deformations of the solid electrode as a whole, occurring in measurements of the surface tension, have the same physical significance as the appreciable deformations caused by large forces. However, our aim was not to observe such vanishingly small deformations but to measure the forces under conditions where the deformations due to these forces are virtually absent.

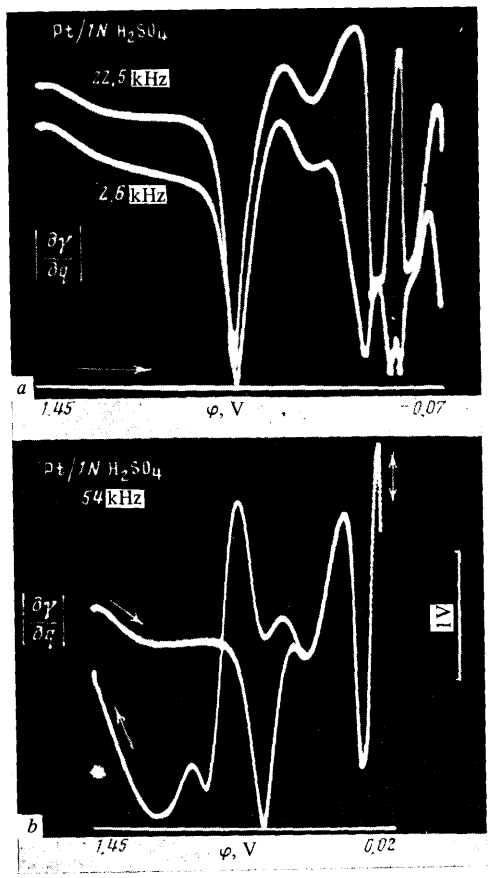

Figure 2. Estance–potential oscillograms for platinum in sulphuric acid: *a*) curves obtained by a single scan at two frequencies simultaneously; *b*) the merging of the forward and reverse curves in the hydrogen potential range

The measurements were made by comparing the surface tension with an independent standard tension, which is applied to the same surface and therefore simulates exactly the required quantity. The deformation does not have to be measured. As a result of this, the estance method is not restricted to any special shape of the electrode or to any specific mode of vibration of the electrode at different frequencies. The abandonment of deformation as the object of measurement is also natural because, when appreciable inertial forces act on the electrode, the deformation cannot serve as a unique measure of the surface tension forces.

The requirement of a small deformation is significant in the measurement of oscillating surface tensions of solids under equilibrium conditions and even more so under non-equilibrium conditions. This is because of the

influence of elastic deformation on the state of the solid and of its surface. The process of measurement can distort the surface tension if the latter is able to execute a large amount of work in altering the surface.

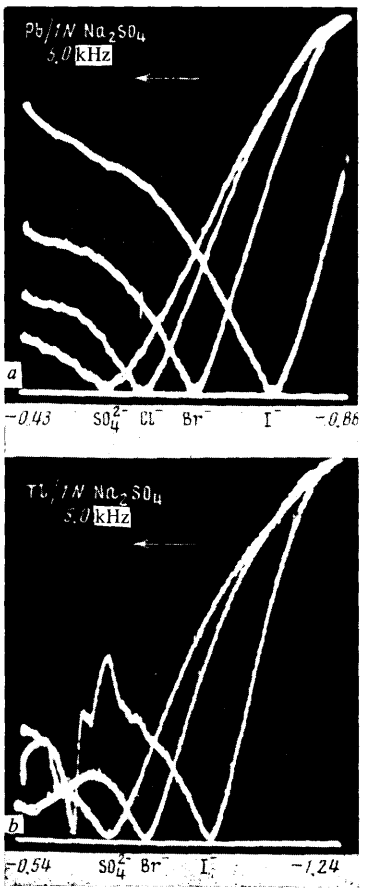

Figure 3. The influence of surface-active anions on the position of the zero estance point; electrodes: *a*) lead; *b*) thallium.

The estance method ensures a sensitivity to within not more than 0.01 dyn cm^{-1} with respect to the oscillating surface tension. It is more than enough to record exactly all the details of the dependence of the surface tension of the solid electrode on the potential. At the same time there is a capacity for a further improvement of sensitivity.

2. Experimental Technique

The results of estance measurements do not depend on the shape of the electrode. In the first experiments the electrode employed consisted of a strip of foil, which had been stretched beforehand, immersed vertically in a liquid electrolyte[5,6]. The lower end of the strip was attached to the bottom of the vessel and the upper end to a piezoelectric element built into the shell of the apparatus. With increase of the surface tension of the strip, the force applied to the piezoelectric element changes. The greater the rigidity of the piezoelectric element the smaller the shortening of the strip and the more complete the transmission of the increment in surface tension to the piezoelectric element. Thus, in measuring the force it is necessary to reduce the deformation. This constitutes the fundamental difference between the measurements of the force and deformation. The former can be achieved in general without altering the dimensions of the specimen; for this purpose, it is sufficient to balance the measured force by another force. Thermodynamically this is the most correct method of measurement. Under the given conditions, the balancing force is provided by the response of the piezoelectric element (if its rigidity is much greater than that of the foil). This device is suitable for measurements both under oscillatory and quasistatic conditions when the curve relating γ to φ is recorded directly for a linear variation of the electrode potential[5].

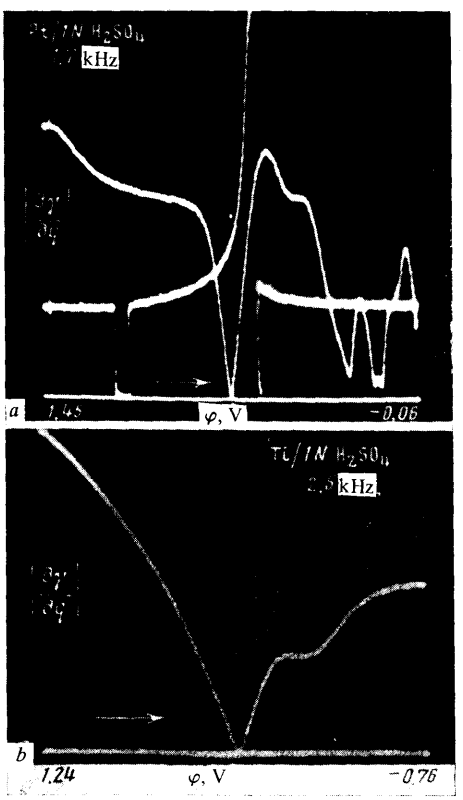

Figure 4. Estance–potential oscillograms: *a*) platinum, scale determined by thermal simulation; *b*) titanium, stepwise variation of estance in the hydrogen potential range.

Subsequently it was found that short (1 cm) and relatively thick (about 1 mm) plates can be used as the electrodes. One end of such an electrode is attached to the piezoelectric element and the other is free and immersed

in the electrolyte[8]. The piezoelectric element records the inertial force of the plate oscillating under the influence of the variable surface tension. The response of the thick (and therefore rigid) plate to the shrinking tendency of its surface layer constitutes the balancing force under these conditions. With increase of the thickness of the plate, its deformation diminishes. However, as in the previous case, the residual capacity for the improvement of sensitivity is great. Furthermore, the mass of the plate increases with its thickness, which partly compensates the loss of inertial force caused by the decrease of deformation.

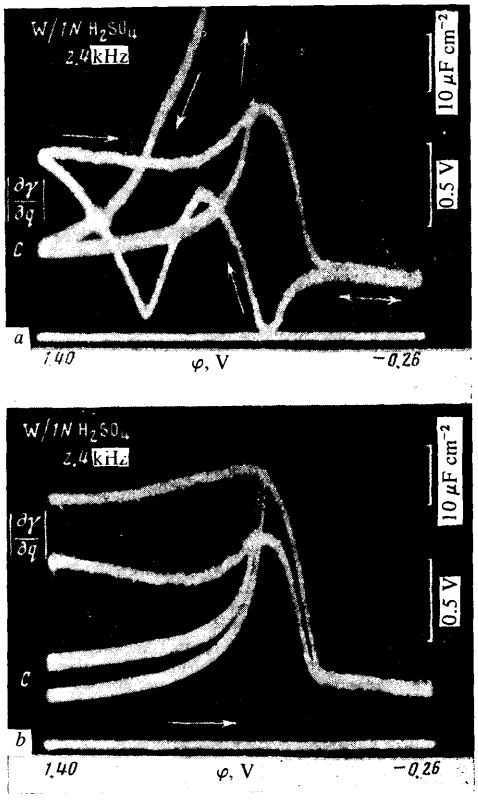

Figure 5. The variation of the estance $|\partial\gamma/\partial q|$ and the capacitance C recorded simultaneously as a function of the potential for tungsten in sulphuric acid: *a*) forward and reverse curves; *b*) different degrees of oxidation of tungsten.

A fully immersed electrode (foil strip), with both its sides operative to the same extent, was used in the first experiments because of the necessity to prevent possible distortions caused by pressure at right angles to the electrode during the passage of the alternating current[5-7]. The magnitude of this pressure was not known previously. In the course of the investigation it was found that, under the conditions of estance measurements, the above pressure is negligibly small (we shall return to its estimation at the end of this review). This made it possible to employ also electrodes with only one side operative. An example is provided by the supramenisscus electrode.

Other types of electrodes were also proposed for studies of this kind[9], for example a dipolar electrode consisting of parallel plates with the electrolyte in the gap between them and an electrode with a vertical meniscus and a non-wettable frame.

3. The Influence of Side Effects

An interesting feature of the method described is virtually complete absence of an influence by side effects, as a result of which the oscillograms recorded are identical with the estance–potential curves and do not require a preliminary treatment. The internal stresses within the bulk of the electrode are isolated because diffusion in the solid is unable to follow the oscillations of the potential jump on its surface. The Joule heating of the electrolyte is quadratic in terms of the current and varies at twice the alternating current frequency, so that it is not recorded at the frequency of the estance measurement.

The shift of the electrolyte meniscus relative to the solid electrode, caused by the effect of the potential on the wetting angle[12], is slow at frequencies in excess of 10 Hz. Insulation of the electrode at the level of the meniscus (coating of the lateral faces of the supramenisscus electrode with glass, insulation of straight plates and foil strips at the sites where they emerge from the solution) does not influence the results of estance measurements in the above frequency range. Consequently such insulation is not necessary in the experiments under consideration.

4. The Standard Tension

For polarisable electrodes, which are the main object of study in the investigation of the structure of the interfacial layer, the alternating current is consumed in charging the sides of this layer, which leads to a change in surface tension. The evolution of heat on the surface of the electrode is then negligibly small.

On the other hand, in a concentrated oxidation-reduction system at moderate frequencies the alternating current is almost wholly consumed in the electrochemical reaction which is accompanied by the evolution of an appreciable amount of Peltier heat (of the order of 0.1 cal C^{-1}). On the other hand, the interfacial layer and the surface tension hardly change under these conditions. Depending on the direction of the current, the heat of reaction is evolved or absorbed at the electrode–solution boundary. Variable thermal and mechanical stresses, which induce oscillations in the electrode plate of exactly the same type as in the oscillating surface tension at the same frequency, develop in the electrode near this boundary. It is therefore sufficient to record the readings of the apparatus in the experiment with the oxidation-reduction system to be able to assess its sensitivity to surface tension[9].

The estance–potential curve for platinum in sulphuric acid is superimposed in Fig. 4*a* on the curve for the thermal vibrations of the same platinum electrode after the replacement of sulphuric acid by a solution of the 0.2 M $K_3Fe(CN)_6$–0.2 M $K_4Fe(CN)_6$ oxidation-reduction system with a Peltier coefficient $\Pi = 0.43$ V at 20°C. Exact formulae for thermal calibration, taking into account thermal waves in the bulk of the electrode, have been published[11]. It is interesting that for platinum the coefficient in these formulae is found to be close to unity, so that the level of the horizontal section of the calibration

curve on the left-hand side of Fig. 4*a* approximately corresponds to $\Pi = 0.43$ V (we may note that the estance $\partial\gamma/\partial q$, plotted along the ordinate axis, is also measured in volts).

In order to calibrate in this way electrodes made of other metals, after the main experiments they were coated with a thin layer of gold (0.5 μm) in an electroplating bath, which protects them from disintegration in the above oxidation-reduction medium.

The heat evolved in the reversible electrochemical dissolution of the electrode itself in a specially selected medium can be employed similarly. In another method of thermal simulation of surface tension, use is made of the Peltier heat evolved at the boundary between two metals. The end of a narrow strip of platinum foil is lightly welded to the rear side of the suprameniscus electrode. For calibration, an alternating current is passed through this junction. The simulation effect is the same as for evolution of heat on the working electrode surface. This method permits calibration in the course of the main experiment. A simplification is introduced by replacing the welded foil by a drop of liquid metal (gallium or mercury). The drop is placed on the rear surface of the electrode and is connected to the current generator via a rigid conductor. If the junction between the two metals occupies an insignificant proportion of the rear electrode surface, the nature of the distribution of current in this junction is immaterial.

Another procedure for the thermal simulation of surface tension involves the passage of a high-frequency amplitude-modulated current. The surface of the electrode is periodically heated by the Joule heat evolved in the electrolyte. This operation is performed during the main experiment without changing the solution. However, it is necessary to take precautions in order to eliminate the influence of the thermal expansion of the electrolyte; in dilute aqueous solutions this can be achieved, for example, by making measurements near 4 °C (when a surface source of heat such as the heat of reaction, is employed, the bulk of the electrolyte is not heated and this precaution is of course unnecessary).

For rectangular high-frequency sinusoidal current pulses with a tracking frequency $\omega/2\pi$ and the reciprocal of the Q-factor π/α, the amplitude of the standard thermal tension at the frequency $\omega/2\pi$ is

$$\Delta\gamma_r = \frac{\sin\alpha}{\pi}\Delta j^2 r D_T^{1/2}\omega^{-3/2}\cdot\frac{1}{1-\nu}\cdot\frac{\varkappa Y}{\zeta\rho}|M|, \qquad (2)$$

where Δj is the amplitude of the current density; parameters of the electrolyte: r is the resistivity and D_T the thermal diffusivity; parameters of the electrode: ν is the Poisson coefficient, Y the modulus of elasticity, κ the coefficient of linear thermal expansion, ζ the specific heat, and ρ the density; the quantity M takes into account the loss of heat from the electrode surface; in the upper part of the audiofrequency range $|M|$ is usually close to unity; the formula for M has been published[11].

5. Thermal Tension in Adsorption on the Electrode

Apart from its main purpose, the estance method can be used also to estimate the heat evolved on the electrode during adsorption, which was apparently difficult to achieve by other methods in earlier investigations. In those rare cases where the thermal and surface tensions act simultaneously, they can be readily separated by virtue of the phase difference caused by the loss of heat to the bulk of the electrode[11]. Measurements have shown that the heat evolved in adsorption is usually negligibly small against the background of the estance values. Thus, according to an estimate made by the estance method, the evolution of heat in the adsorption reaction $H^+ + e \rightleftharpoons H_{ads}$ on platinum does not exceed 1 kcal faraday^{-1} or 0.05 V.

6. Examples of the Interpretation of the Oscillograms

Fig. 6 illustrates the estance–potential curves for platinum in sulphuric acid obtained simultaneously at frequencies of 2.6 and 22.5 kHz (they correspond to the oscillograms in Fig. 1*a* adjusted to the same vertical scale). A study was made of the range of potentials in which hydrogen is adsorbed on platinum. Therefore all the details of these curves are associated with the characteristics of the adsorption of hydrogen.

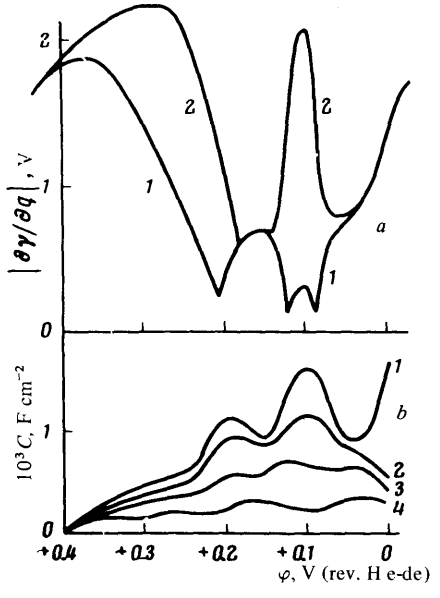

Figure 6. The influence of frequency on the variation of the estance (*a*) and the capacitance (*b*) with potential for platinum in sulphuric acid; frequency (kHz): *a*) [1) 2.6; 2) 22.5]; *b*) [1) 0.03; 2) 1.7; 3) 4; 4) 10].

The influence of frequency on estance is unexpected; sections corresponding to a strong dependence of estance on frequency alternate along the potential axis with sections where estance is almost independent of frequency and two such sections are located within the region corresponding to the adsorption of hydrogen. As the potential shifts in the cathodic direction, the sections alternate as follows: (1) from +0.50 to +0.30 V—the section where the potential is independent of frequency due to the absence of hydrogen from the platinum surface (the adsorption of hydrogen begins near +0.30 A); (2) from +0.30 to +0.18 V—the section of a strong dependence on frequency; (3) from +0.18 to +0.14 V—the section with potentials independent of frequency; (4) from +0.14 to +0.04 V—the

section of a strong dependence on frequency (there is a dip in the curve at 2.6 kHz and a peak at 22.5 kHz); (5) below +0.04 V—the section where the potential is independent of frequency [13].

For comparison, Fig. 6*b* presents the known capacitance curves for the same system at different frequencies [14]. In contrast to estance, the capacitance decreases monotonically with frequency at all the potentials in the hydrogen adsorption region. Under these conditions, the capacitance is almost wholly due to the discharge of hydrogen ions from the electrolyte before their adsorption on platinum in the form of atoms. The discharge stage is slow [3] regardless of the final state of the adsorbed atom. At high frequencies the discharge lags behind the change in periodic component of the potential, which leads to a decrease of the capacitance with frequency.

In contrast to this, the variation of estance with frequency is directly related to the *final* state of the adsorbed hydrogen atoms. It has no bearing on the discharge stage and its rate, since in the estance method the current amplitude and hence the number of hydrogen atoms which reached the surface *after* the discharge are specified beforehand. Thus the sections where estance is and is not independent of frequency separate along the potential axis adsorption regions with different final states of the hydrogen atoms.

This quite definite result follows immediately from the estance–potential oscillograms without any need for their quantitative interpretation. Another problem, i.e. the problem of the adsorption mechanisms along each of the differentiated sections, requires special study, which has been carried out [13]. Here we shall enumerate some of the results obtained here. It had been known previously that hydrogen can exist on platinum in two states (which shall be designated conventionally by H_e and H_m), but the limits of the regions corresponding to adsorption in these states had not been known. It was assumed that H_e is adsorbed initially and then H_m. It follows from the estance data that along the sections where estance is independent of frequency H_e is adsorbed (the third and fifth sections), while in the intermediate region with a strong dependence of estance on frequency H_m is adsorbed (the fourth section). Along this section, the dip in the estance curve at 2.6 kHz is due to an interruption in the adsorption of H_e and the estance peak at 22.5 kHz is caused by the internal transition $H_e \rightleftharpoons H_m$ when the potential is altered. The fact that the internal transition influences the estance markedly and is not manifested in the capacitance measurement is due to the difference between force (estance method) and energy (capacitance method). A large change in the force can be caused by an arbitrarily small energy. In this case an appreciable alteration of the surface tension is caused by a small expenditure of energy in changing the state of the interfacial layer. This is the reason for the enhanced sensitivity of the estance method to a number of processes which cannot be detected by "energy" methods.

Some of the effects detected by the estance method in the adsorption of hydrogen on platinum are illustrated in Fig. 7, which represents schematically the surface layer of platinum.

Effect of the interruption of adsorption. As the potential varies in the cathodic direction, the adsorption of external hydrogen (H_e) is interrupted by the adsorption of internal hydrogen (H_m), but begins anew after vacancies in the internal hydrogen have been largely filled.

Effect of the internal transition. There is a discrete change in the state of adsorbed hydrogen when the potential is altered. In a pure form the effect is observed at high frequencies when the supply of hydrogen from the electrolyte ceases and the overall amount of adsorbed hydrogen does not vary with potential. The transition is possible at potentials where the vacancies in both external and internal hydrogen are far from being completely filled.

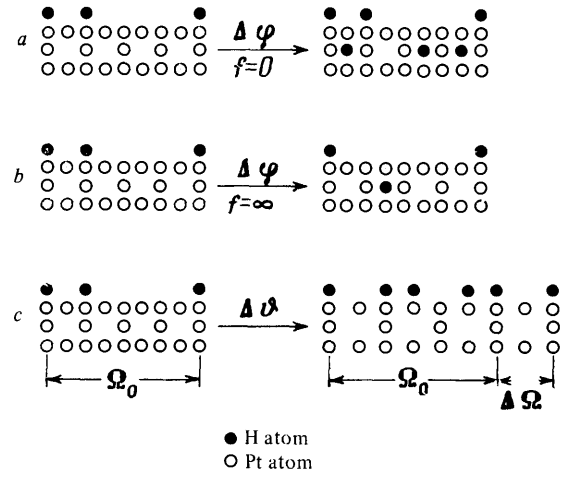

Figure 7. Schematic illustration of the effects observed by the estance method in the adsorption of hydrogen on platinum: *a*) the interrupted adsorption effect; *b*) the internal transition effect; *c*) the effect involving an increase of the surface density of adsorbed hydrogen on elastic extension of platinum; Ω_0 = initial area of the electrode; f = frequency.

Effect of the increase of adsorbed hydrogen density during elastic extension of platinum. The number of surface platinum atoms and the number of adsorbed atoms per unit surface area vary in opposite directions. With increase of the distance between the surface platinum atoms, the average distance between the hydrogen atoms diminishes. This shows that, as the platinum atoms move apart, their affinity for external atomic hydrogen rises.

The first two effects are caused by the change in electrode potential and the third is due only to the elastic deformation at a constant potential. Thus information about the events on the electrode when the potential is varied under conditions without deformation can also be obtained with equal success from the same estance–potential oscillogram.

The dual nature of estance–potential oscillograms will be considered further.

III. ELASTIC CHARGING OF THE INTERFACIAL LAYER

1. The Change in the Potential of the Polarisable Electrode on Elastic Deformation

An electrode in the form of a stretched foil strip immersed in the electrolyte undergoes periodic elastic extension and contraction with an elongation amplitude of the order of 10^{-6} at a definite frequency to which the measuring apparatus is tuned. Under the conditions of a constant charge, the potential of this electrode oscillates with an amplitude of the order of 1 μV. For a specified relative deformation amplitude, the potential oscillations are independent of the dimensions of the electrode. The results are recorded oscillographically in terms of a plot of $|\partial\varphi/\partial\theta|$ against φ, where $\theta = \Delta\Omega/\Omega$ is the relative change in the area of the electrode Ω on elastic deformation.

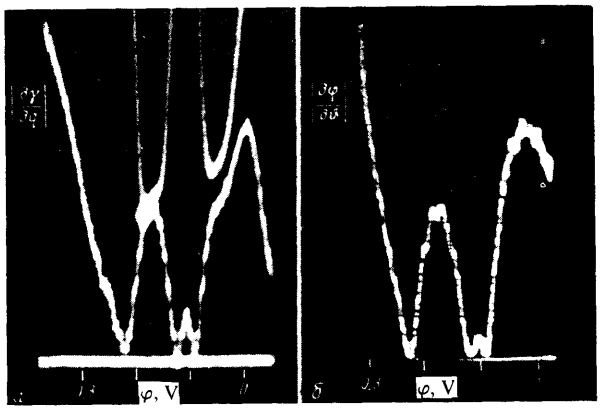

Figure 8. Comparison of oscillograms for estance (*a*) and the elastic charging of the interfacial layer (*b*); the potential is given relative to that of the reversible hydrogen electrode.

2. Mutually Opposed Effects

The $|\partial\varphi/\partial\theta|-\varphi$ oscillogram obtained in a reversible system (for example for platinum in 1 N sulphuric acid solution in the hydrogen potential range) is of exactly the same form as the $|\partial\gamma/\partial q|-\varphi$ oscillogram (Fig. 8). The significance of this agreement, which appeared unexpected in the very first experiment on elastic charging, is that the surface tension varies with the charge in the same way as the potential varies with the surface area [15,16]

$$\frac{\partial\gamma}{\partial q} = \frac{\partial\varphi}{\partial\theta}, \qquad (3)$$

(the derivative $\partial\varphi/\partial\theta$ is obtained for a constant overall electrode charge). Hence follows also the equation

$$\frac{\partial\gamma}{\partial\varphi} = -q - \frac{\partial q}{\partial\theta}. \qquad (4)$$

After Eqn. (3) had been suggested by experiment, it became clear that it should follow from thermodynamics. However, until the elastic charging effect had been observed there was no reason to compare the two derivatives. Furthermore, in the thermodynamics of surface phenomena it is simpler to formulate the equation than to elucidate the significance of the quantities involved in it. An example is provided by Young's simple equation for the angle of wetting of a solid by a liquid, which was proposed in 1805.[17] However, controversy concerning the physical significance of its variables is still continuing, namely whether these are forces acting along three interfaces or whether they represent the work of formation of these interfaces [18,19].

In the absence of experiments on elastic charging the significance of the quantity θ in Eqn. (3) would have remained obscure, i.e. it would not have been known whether it represents elastic or plastic deformation. On the other hand, if one could imagine an effect opposite to that of the potential on the wetting angle, the significance of the quantities in Young's equation would become clearer.

3. The Equation for the Wetting of Solid Electrodes

Frumkin and coworkers [20-22] have made systematic studies on the influence of the potential on the wetting of liquid electrodes. At the boundary between the electrode and a gas bubble a conducting electrolyte film was observed [21]. The publication of studies specially devoted to the wetting of solid electrodes began recently. A series of detailed studies by Morcos, in which measurements were made of the wetting angle for a planar solid electrode as a function of potential [23-26], and the investigation of Bonnemay et al. [27] are noteworthy.

Below we shall describe an approach to the problem based on the relation between the forward and reverse effects. Consider a solid electrode of arbitrary shape partly immersed in a liquid electrolyte solution (for example a half-immersed rectangular plate). Suppose that z is the vertical coordinate of the electrode (the depth of immersion is reckoned from the horizontal level of the liquid solution), $\mathcal{P}$ the weight of the partly immersed electrode for a fixed z (the force experienced by the object from which the electrode is suspended), Q the overall charge of the electrode, and φ the potential of the electrode relative to a reference electrode immersed in the same electrolyte. If the remaining parameters of the system are kept constant, the total differential of its free energy is

$$dF = -\mathcal{P}dz + \varphi dQ \quad . \qquad (5)$$

Hence we obtain the fundamental equations

$$\frac{\partial\mathcal{P}}{\partial Q} = -\frac{\partial\varphi}{\partial z}, \qquad (6)$$

$$\frac{\partial\mathcal{P}}{\partial\varphi} = \frac{\partial Q}{\partial z} \qquad (7)$$

representing the change in the weight of the partly immersed electrode when the change in potential corresponds to the change in the charge of the electrode on immersion.

Suppose further that the electrode has a cylindrical surface with a vertical generatrix and directrix of arbitrary form (for example, a vertical plate). The contour of the horizontal section through the electrode at the level of the solution at a point remote from the meniscus will be called the water line of the electrode. The wetting boundary does not coincide with this line and is not in the general case a two-dimensional curve. For example, at

the edges of the plate the meniscus is below its position in the central part of the plate. We introduce the following notation: s is the length of the water line and, what amounts to the same thing, the perimeter of the electrode cross-section and q_i and q_n are the charge densities on the immersed and unimmersed parts of the electrode respectively. If the electrode is not smooth, then q_i and q_n must be replaced in the corresponding formulae by αq_i and αq_n, where α is the roughness factor. The overall charge of the electrode is $Q = s[zq_i + (H - z)q_n]$, where H is the height of the electrode. Since the densities q_i and q_n are independent of z, it follows that $(\partial Q/\partial z)/s = q_i - q_n$. On substituting this in Eqn.(7), we obtain the equation for the wetting of solid electrodes:

$$\frac{1}{s}\frac{\partial \mathcal{P}}{\partial \varphi} = q_i - q_n. \qquad (8)$$

This is the fundamental equation. It makes it possible to determine $q_i - q_n$ directly from the dependence of the weight of the electrode on the potential. No restrictions are then imposed on the form of the electrode cross-section and the shape of the meniscus. The non-uniformity of the wetting line is permissible, for example the fall of the meniscus at the edges of the plate.

The following formula was obtained similarly:

$$\frac{1}{s}\frac{\partial \mathcal{P}}{\partial \mu} = \Gamma_i - \Gamma_n, \qquad (9)$$

where μ is the chemical potential of the adsorbable substance and Γ_i and Γ_n are the relative surface amounts of this substance on the immersed and unimmersed parts of the electrode respectively (relative to the simultaneous adsorption of the solvent).

Under conditions where q_n is independent of φ, the differential equation (8) yields

$$\frac{1}{s}\frac{\partial^2 \mathcal{P}}{\partial \varphi^2} = C, \qquad (10)$$

where $C = \partial q_i/\partial \varphi$ is the differential capacitance of the electrode. The minimum weight $\mathcal{P}$ is reached when $q_i = q_n$.

A force equal to the weight of the meniscus is applied to the electrode along the wetting line. We project a small section of this line on to the water line. The ratio of the corresponding fraction of the weight of the meniscus to the length of the projection will be called the weight tension $\mathscr{C}$. The weight tension is the same at all points on the water line for any shape of the latter. Thus the weight of the meniscus is $s\mathscr{C}$. For this reason Eqn.(8) can be rewritten as follows:

$$\frac{\partial \mathscr{C}}{\partial \varphi} = q_i - q_n. \qquad (11)$$

Formulae referring to special types of electrodes follow from Eqn.(8). Suppose, for example, that the electrode consists of a thin layer of metal deposited on the inner surface of a capillary with radius a and that the capillary contains a column of electrolyte with a height h and density ρ. Then $s = 2\pi a$ and $\mathcal{P} = \pi a^2 h\rho$ (the weight of the liquid in the capillary) to within constant terms. Eqn.(10) immediately yields the following result:

$$\frac{\rho a}{2}\frac{\partial^2 h}{\partial \varphi^2} = C, \qquad (12)$$

which agrees with the formula obtained previously by Bonnemay by differentiating Young's equation and by examining the geometry of the meniscus in the capillary [27]. Measurement of the height of the rise of the liquid by an optical method (involving the passage of X-rays through the liquid [27]) is associated with errors comparable to the radius of the capillary.

However, it follows from the general equation (8) that there is no need to consider the geometry of the meniscus, to make separate calculations for each shape of the electrode, and to measure a specific parameter characteristic of each given electrode. It is sufficient to measure the influence of the potential on a parameter common to all electrodes, namely their weight. This greatly simplifies the experiment, increasing its accuracy and sensitivity.

The weight tension $\mathscr{C}$ is related to the wetting angle θ and the surface tension of the liquid by the expression

$$\mathscr{C} = \sigma_0 \cos\theta. \qquad (13)$$

Hence we obtain from Eqn.(11)

$$q_i - q_n = -\sigma_0 \sin\theta \frac{\partial \theta}{\partial \varphi}. \qquad (14)$$

Eqns.(8) and (11) are applicable to isotropic and anisotropic surfaces. The charge densities on the right-hand side of Eqn.(11) are independent of the orientation of the anisotropic surface following immersion. Consequently $\mathscr{C}$ is a scalar quantity. It characterises the work of wetting and has no bearing on the surface tension of the solid, which is a tensor. The quantities entering into Young's equation are also scalar and cannot be identified with forces. On the other hand, owing to the term $\partial q/\partial \theta$, which depends on the direction of deformation, Eqn.(4) defines a tensor—the surface tension γ.

4. The Surface Tension and the Work of Formation of the Surface of a Solid Electrode

The difference between the surface tension of a solid γ and the reversible work of formation of its unit surface σ, noted 100 years ago by Gibbs [28], has not so far been confirmed experimentally owing to the lack of data for the surface tensions of solids. The results of the present study permit such a comparison at the level of derivatives of these quantities with respect to the potential.

Fig. 9 illustrates the variation of $\partial\gamma/\partial\varphi$ and $\partial\sigma/\partial\varphi$ with potential φ for platinum in 1 N H_2SO_4; $\partial\gamma/\partial\varphi$ was measured by the estance method and $\partial\sigma/\partial\varphi$ is equal, according to Lippman's equation, to the total charge density q of the platinum electrode, the dependence of which on the potential was measured for the first time by Frumkin and coworkers [3]. The difference between the two quantities is large: like the charge, $\partial\sigma/\partial\varphi$ varies monotonically with potential, while $\partial\gamma/\partial\varphi$ passes through zero three times in the hydrogen potential range. Accordingly the integrated relation between the surface tension of the platinum electrode and the potential has three extrema—two maxima at +0.1 and +0.2 V (relative to the potential of the reversible hydrogen electrode) with an intervening minimum.

After substracting q from the φ-estance in accordance with Eqn.(4), we obtain $\partial q/\partial\theta$—the change in charge density as a result of elastic deformation at a constant potential. The variation of $\partial q/\partial\theta$ with φ is indicated by a dashed line; hence it is clear that, in the system under consideration, the term $\partial q/\partial\theta$ in Eqn.(4) predominates over the term q and largely determines the variation of γ with φ.

Thus the experimental data obtained by the estance method demonstrate a difference between the surface tension of a solid and the reversible work of formation of its

unit surface and also that this difference obtains in the region of electrocapillary phenomena. The latter had been overlooked until the present investigation.

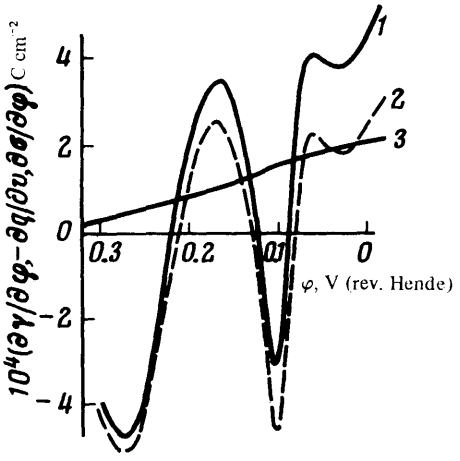

Figure 9. The difference between the surface tension γ and the work of formation of unit surface area σ of a solid electrode at the level of derivatives of these quantities with respect to the potential φ for platinum in 1 N H_2SO_4: 1) $\partial\gamma/\partial\varphi$; 2) $-\partial q/\partial\theta$; 3) $\partial\sigma/\partial\varphi$.

5. The Surface Tension of a Rough Surface

Suppose that the rough interface coincides with one of the sides of the plate and that α is the roughness factor: the ratio of the area of the rough surface Ω to the area of its average plane Ω_0 is $\alpha = \Omega/\Omega_0$. The surface tension γ directed along rugosities deforms the plate as a whole in a specific manner. It is necessary to find γ_0, acting uniformly, which when directed along the plane would give rise to the same deformation. For each specific electrode, the results of the surface tension and elastic charging methods should coincide regardless of whether the electrode surface is smooth or rough. Hence, and also on the basis of the principle of the reciprocity of the displacements, it was found that the increments in the tensions γ_0 and γ refer to the increments of the areas Ω and Ω_0 on elastic deformation. We call the ratio

$$\beta = \Delta\Omega/\Delta\Omega_0 = \Delta\gamma_0/\Delta\gamma \qquad (15)$$

the differential roughness factor. In many cases the model of a rough surface with rugosities in the form of parallel ridges with a symmetrical triangular cross-section is applicable. For an isotropic surface, consisting of sections with ridges running in random directions[13], we have

$$\beta = \frac{1}{2}[(1-\nu)\alpha + (1+\nu)\alpha^{-1}]. \qquad (16)$$

For example, for lead ($\nu = 0.44$) the deviation of β from unity on such a surface does not exceed 11% in the range $1 \leq \alpha \leq 3$.

The knowledge of β permits the determination of the true estance from its planar equivalent (subscript 0) measured experimentally. For φ- and q-estance, we have

$$\frac{\partial\gamma_0}{\partial\varphi} = \beta\frac{\partial\gamma}{\partial\varphi}; \quad \frac{\partial\gamma_0}{\partial q_0} = \frac{\beta}{\alpha}\frac{\partial\gamma}{\partial q}. \qquad (17)$$

6. Discrepancies Between the Forward and Reverse Effects

Among the irreversible processes which disturb the correspondence between the results of surface tension and elastic charging measurements, the Faraday diffusion current, caused by the presence of traces of electrochemically active substances in solution, is encountered most frequently. Stirring is known to increase this current. A strip undergoing longitudinal deformation stirs the solution much less than a transversely vibrating suprameniscus electrode. This in fact dictated the choice of a strip for recording elastic charging.

It is interesting that the diffusion current does not influence at all the result of measurements of oscillating surface tension (it is smaller by several orders of magnitude than the specified charging current amplitude). This is the reason for the discrepancies and demonstrates at the same time the advantages of the surface tension method. Hence it is also seen that the agreement between the surface tension and elastic charging data is not predetermined beforehand and that even the discrepancies between these data can lead to useful conclusions about the test object.

Noting the similarity between the data derived by the two methods, we began with the first harmonics of the quantities recorded by them—the surface tension and the potential. At the level of the highest harmonics the two methods yield different information even in reversible systems.

IV. SOME PROBLEMS OF THE THEORY OF ESTANCE

1. The Surface Tension Increment

Consider a solid electrode in a solution containing, together with a solvent, m components which are electrically neutral overall. The electrode potential φ is specified relative to a reference electrode, which is reversible with respect to one of the ions forming part of the electrolyte. In the general case the change in the surface tension of the solid electrode γ is described by the equation[15]:

$$d\gamma = -\left[q + \left(\frac{\partial q}{\partial\theta}\right)_{\varphi,\mu_k}\right]d\varphi - \sum_{s=1}^{m}\left[\Gamma_s + \left(\frac{\partial\Gamma_s}{\partial\theta}\right)_{\varphi,\mu_k}\right]d\mu_s, \qquad (18)$$

where q is the electrode charge density, Γ_s and μ_s are the excess amounts on the surface relative to the solvent and the chemical potentials of the solution components, θ is the relative change in the area of the electrode during its elastic deformation, and $k, s = 1, \ldots, m$.

2. Indication of Localised Adsorption

The slope of the estance–potential curve is characterised by the derivative $\gamma_{q\varphi} = \partial(\partial\gamma/\partial q)/\partial\varphi$. The amplitude of the second harmonic of the potential at a specified

sinusoidal current is proportional to the derivative $\varphi_{qq} = \partial^2\varphi/\partial q^2$. On metallic electrodes in the absence of localised adsorption, $\gamma_{q\varphi} = -1$ both at the zero-charge point and at the zero points of the second harmonic:

$$\gamma_{q\varphi} = -1 \text{ when } q = 0 \text{ or } \varphi_{qq} = 0. \quad (19)$$

Under the same conditions, $\gamma_{q\varphi}$ at zero estance is

$$\gamma_{q\varphi} = -1 + \frac{\partial\varphi_0}{\partial\vartheta}\frac{1}{C}\frac{\partial C}{\partial\varphi} \text{ when } \gamma_q = 0, \quad (20)$$

where C is the differential capacitance of the electrode and

$$\frac{\partial\varphi_0}{\partial\vartheta} = \frac{\partial\gamma}{\partial q}\Big|_{\varphi=\varphi_0} \quad (21)$$

is the shift of the zero-charge potential φ_0 on elastic deformation of the electrode. For non-localised adsorption, this quantity does not exceed 0.03 V [29] and the property $\gamma_{q\varphi} = -1$ therefore persists to within at least 10% also at zero estance.

The deviation of the slope $\gamma_{q\varphi}$ from unity at the above points is a sufficient indication of localised adsorption. For cadmium in 0.01 M NaF, the slope of the estance–potential curve at zero estance (and at the point where $q = 0$) is close to -3. Hence we conclude that water is locally adsorbed on cadmium [29].

3. The Estance of the Diffuse Double Layer

If the fluidity of the liquid electrolyte persists up to its boundary with the dense part of the double layer, elastic deformation does not alter the parameters of the diffuse layer. Under these conditions, at the zero-charge point and a low electrolyte concentration a, the following relation holds:

$$\gamma_{q\varphi} = -1 - B\sqrt{a} \text{ when } \varphi = \varphi_0, \quad (22)$$

where B is a constant independent of a. On dilution and therefore on increase of the thickness of the diffuse part of the double layer, the slope $\gamma_{q\varphi}$ tends to unity regardless of the structure of the dense part of the double layer.

The fluidity condition probably does not hold in all systems. On dilution, an appreciable decrease of the slope should occur for cadmium in aqueous NaF solutions. However, up to a concentration of 0.001 M, this effect is not observed, which suggests that on cadmium there is a locally adsorbed polymolecular film of water in which the diffuse part of the double layer adjoining the electrode is accommodated; this film has an ordered structure but retains the defects characteristic of the liquid in the form of migrating vacancies, which permits the motion of ions at the electrode and preserves nearly normal capacitance values.

4. The Estance of a Solid *in Vacuo*

Consider a planar condenser consisting of identical plates *in vacuo*, whose electron work function is φ_{0V}. When an alternating current is passed through the condenser and the average stress applied to its plates is zero (for example the plates are connected to the secondary winding of a transformer), the oscillations of the surface tension γ of each plate at the current frequency can be measured. Then [30]

$$\frac{\partial\gamma}{\partial q} = \frac{\partial\varphi_{0v}}{\partial\vartheta}, \quad (23)$$

i.e. the estance is equal to the change in the electron work function on elastic deformation of the specimen.

5. The Introduction of Elastic Deformation into the Adsorption Isotherm

When electrically neutral species are adsorbed from the solution, their chemical potential in solution μ is independent of the electrode potential φ. At a constant value of φ the surface concentration of these species Γ is a function of μ and of the relative change in the area of the electrode on elastic deformation θ: $\Gamma = \Gamma(\mu, \theta)$. In its usual sense [4], the adsorption isotherm defines the variation of Γ with μ in the absence of deformation (when $\theta = 0$):

$$\Gamma = \Gamma(\mu, 0) = f(\mu). \quad (24)$$

Suppose that

$$\xi(\mu, \vartheta) = \frac{\partial\gamma}{\partial\Gamma}(\mu, \vartheta) \quad (25)$$

is the contribution of the adsorbed species to the surface tension known on the basis of experimental data to be a function of both μ and θ. Then expansion of Γ in powers of θ is

$$\Gamma(\mu, \vartheta) = f - \vartheta(f + f'\xi) + \frac{1}{2}\vartheta^2[f + f'(2\xi + \xi\xi_\mu - \xi_\vartheta) + f''\xi^2], \quad (26)$$

where

$$f' = df/d\mu,\ f'' = d^2f/d\mu^2,\ \xi_\mu = \partial\xi/\partial\mu,\ \xi_\vartheta = \partial\xi/\partial\vartheta.$$

6. The Increase of Estance with the Thickness of the Polarised Layer

In many systems, for example on platinum and tungsten, in aqueous solutions at fairly anodic potentials the estance increases with the degree of oxidation of the surface (the capacitance curves corresponding to different degrees of oxidation are superimposed in Fig. 5*b* on the estance curves; a decrease of the capacitance curve is accompanied by a rise of the estance curve). The increase of estance with the thickness of the coating, in the given instance an oxide coating, is a sign of the existence of an intrinsic dipole moment of the coating and is described by the expression [31]

$$\frac{\partial\gamma}{\partial q} = \left(-1 + \frac{\partial\delta}{\partial\vartheta} - \frac{\partial w}{\partial\vartheta}\right)(\varphi - \varphi_n) + \left(\frac{\partial\delta_0}{\partial\vartheta} - \frac{\partial\delta}{\partial\vartheta}\right)\frac{P}{\varepsilon}\mathfrak{h} + \frac{\partial\varphi_n}{\partial\vartheta}, \quad (27)$$

where P is the intrinsic polarisation of the coating (the dipole moment per unit volume), ϵ the effective dielectric constant of the coating, θ the relative change in the area of the electrode on elastic deformation, w, δ, and δ_0 are the relative values of the dielectric constant, the thickness of the coating, and the length of one arm of the dipole respectively, φ_n is the zero-charge potential of the oxidised electrode extrapolated to zero thickness of the oxide film, and $\mathfrak{h}$ the effective thickness of the coating, whose significance is retained at coverages less than the monolayer value, equal to the ratio of the volume occupied by the coating to the area of the electrode.

V. THE INFLUENCE OF BULK-PHASE FORCES ON THE ELECTRODE

1. Inertial Oscillation of the Electrolyte on Passage of an Alternating Current

Suppose that an electrolyte solution is in a long open channel and that a current at a density $j = \Delta j \sin\omega t$, where t is the time and $\omega/2\pi$ the frequency, passes along the

channel. Then at points remote from the walls of the channel the solvent coordination system is displaced relative to the laboratory coordinate system at the rate [7,32]

$$v_0 = (\Delta j/F\rho)\,\mathbf{M}\sin\omega t, \tag{28}$$

where F is the Faraday, ρ the density of the solution,

$$\mathbf{M} = \tau_a(m_a - \rho_0\psi_a) - \tau_c(m_c - \rho_0\psi_c) \tag{29}$$

the reduced mass, τ, m, and Ψ are respectively the transport number, the gram-ionic weight, and the apparent ionic volume of the anion (subscript a) and the cation (subscript c), ρ_0 is the solvent density, and Ψ_a and Ψ_c are the fractions of anions and cations in the volume displaced from the pure solvent on dissolution of one equivalent of the electrolyte; these values have been determined recently by several methods and are quoted in the literature [33,34].

2. The Viscous Force of the Electrolyte

The wall of the channel through which the sinusoidal current is flowing within the electrolyte is acted upon by a viscous force [32]

$$g = \sqrt{\omega\chi}\,(\mathbf{M}\Delta j/F)\cos\left(\omega t + \frac{3}{4}\pi\right), \tag{30}$$

where χ is the kinematic viscosity of the solution; the force g is referred to unit area of the wall. It is manifested independently of the electrophoretic force.

Under the conditions of estance measurements, the alternating current flows only at right angles to the surface of the electrode, which does not therefore experience a tangential force. However, it is possible to devise a special experiment where conditions are created such that the alternating current in the electrolyte flows only parallel to the electrode surface. Then the surface is acted upon by the force g.

3. Generation of Ultrasound at the Electrode

Suppose that the electrode is absolutely rigid and consists of a plane bounding half the space of the electrolyte (this condition holds, for example, for a metallic membrane both sides of which are active to an equal extent). Then the pressure on the electrode caused by the displacement of the centre of gravity [7] in the volume of electrolyte adjoining the electrode on passage of the alternating current is $p_0 = -\Delta p_0 \sin\omega t$ with the amplitude

$$\Delta p_0 = u\mathbf{M}\Delta j/F, \tag{31}$$

where u is the velocity of sound in the solution.

The electrode processes also contribute to the pressure. For example, the passage of one equivalent of cations from the bulk of the electrolyte to the surface of the electrode leads to an increase of the overall volume of the layer near the electrode by $V_{ce} - V_{cs}$, where V_{ce} and V_{cs} are the partial equivalent volumes of the cation in the double layer and in the electrolyte respectively. The heat evolved at the electrode on passage of one equivalent of electricity, which increases the volume near the electrode by a certain amount (by $V_\Pi = \Pi F\beta/\zeta\rho$ for a thin membrane, where β is the coefficient of cubic expansion of the solution, ζ the specific heat of the solution, and Π the effective Peltier coefficient). Thus the overall pressure amplitude in the given case is

$$\Delta p = u(\Delta j/F)\,[\mathbf{M} + \rho(V_{ce} - V_{cs} + V_\Pi)]. \tag{32}$$

On electrodeposition, V_{ce} is replaced by the equivalent volume of the metal. The quantity ρV_Π is of the order of 0.1 g equiv.$^{-1}$ for non-polarisable electrodes and is virtually zero for polarisable electrodes.

4. Diffusion Waves at the Electrode

Suppose that an electrically neutral substance present in the bulk of the electrolyte and supplied to the electrode via diffusion undergoes periodic adsorption and desorption at the electrode–electrolyte interface. If m is the molecular weight of the test substance, V_{ns} its partial molar volume in the solution, D its diffusion coefficient, and $c(x,t)$ its concentration at a distance x from the electrode at time t, then mass transport as a result of the diffusion of the substance in the layer near the electrode leads to a variable pressure:

$$p_v = D(m - \rho V_{ns})\,\partial c/\partial t\,(0,t)\ . \tag{33}$$

It is remarkable that the pressure p is completely independent of the distribution of the substance in the electrolyte and is determined solely by the rate of change of its concentration at the surface of the electrode.

Another component of the pressure, due to the change in the volume of the layer near the electrode caused by adsorption, is taken into account in the same way as in the electroadsorption of cations discussed above.

5. The Mass Attached to the Electrode

For an electrode with identical current densities on both sides (a vertically immersed plate, a foil strip), the pressures experienced by these two sides fully cancel out and have no influence on the results of estance measurements. The pressure applied to a narrow supramениscus electrode, only one side of which is operative, differs from that which was defined above relative to an absolutely rigid electrode infinite in extent.

Like the deformation of a solid electrode occurring when the surface tension changes, the linear velocity of the electrode vibrations is so small that viscous forces may be neglected and the electrode may be assumed to move in a non-viscous liquid. Since the supramениscus electrode can be in contact with its electrolyte, the electrolyte oscillating at a frequency v_0 acts on the electrode with a force $G_0 = -m_0(dv_0/dt)$, where m_0 is the mass attached to the electrode. On the other hand, the inertial force due to the transverse vibrations of the electrode itself when the surface tension is altered amounts to $G_e = -m_e(dv_e/dt)$, where v_e is the velocity of the electrode and m_e its mass. The acceleration dv_0/dt is smaller by two orders of magnitude than dv_e/dt. Furthermore, usually $m_0 \ll m_e$. As a result of this, the pressure hardly distorts the estance measurements with the aid of the supramениscus electrode. Electrodes of special shape, for which the influence of the transverse surface tension is compensated, are used to record the pressure.

6. Diffusion of the Electrolyte and Thermal Vibrations of the Electrode

Heating of the electrolyte by the sinusoidal current leads to thermal vibrations of the electrode at twice the current frequency. The electrode is acted upon at the same frequency by the second harmonic of the surface

tension [35]. For each of these two effects, there is a special form of the alternating current (other than sinusoidal) for which the influence of the second effect is fully ruled out. In particular, thermal vibrations of the electrode can be distinguished.

Only a thin layer of electrolyte is involved in the transfer of heat from the electrolyte to the electrode. Its thickness $b = \sqrt{2D_T/\omega}$ decreases at a frequency $\omega/2\pi$; D_T is the thermal diffusivity of the liquid electrolyte. Suppose that the electrolyte consists of two components at concentrations c_1 and c_2 (in equivalents) and with the equivalent conductances Λ_1 and Λ_2, which are independent of concentration in dilute solutions. The steady-state values of c_1 and c_2, which are equal to those in the bulk of the solution, are designated by c_{10} and c_{20}. We introduce the parameter $v = c_{20}c_2/c_{10}c_1$. When the concentration near the electrode c_1 changes abruptly from c_{10} to 0, the thickness of the diffusion layer is defined by the expression $d = \sqrt{\pi D_C t}$, where t is the time elapsed from the instant of the concentration jump and D_C the effective diffusion coefficient taking into account the migration in the electric field. We introduce the notation

$$\lambda = \frac{d}{b} = \sqrt{\frac{\pi}{2}\frac{D_c}{D_\tau}\omega t}; \qquad (34)$$

$\mathfrak{P}$ is the ratio of the amplitudes of the thermal vibrations of the electrode before and after the concentration jump for the same alternating heating current.

Suppose that $\lambda \gg 1$ and $\lambda v \ll 1$; the thickness of the diffusion layer is then large compared with that of the thermal layer, but the c_1 concentration drop in the thermal layer continues to be greater than the background concentration c_{20}. Then

$$\mathfrak{P} = \sqrt{2}\lambda(1+v)e^{\lambda v}\sqrt{[\mathfrak{C} + \ln(\sqrt{2}\lambda v) - \lambda v]^2 + \left(\frac{\pi}{4} - \lambda v\right)^2}, \qquad (35)$$

where $\mathfrak{C} = 0.5772$ is the Euler constant.

Electrochemical Processes in an Alternating Current

B.M.Grafov and E.A.Ukshe

The theory of electrochemical impedance is reviewed. Alternating current circuits equivalent to an electrochemical reaction proceeding via an adsorption state are examined for reversible and irreversible systems. The dynamic adsorption equation for a non-equilibrium electrode is discussed. The theoretical circuits are compared with experimental data for the iodine-iodide system.
The bibliography includes 59 references.

I. INTRODUCTION

The use of alternating current in electrochemistry has a long history. The first studies of these lines were begun as early as the 19th century and were associated with the measurement of the conductivities of electrolytes[1]. However, at that time it was already noted that the overall resistance of the electrochemical cell to the alternating current includes the resistance of the electrode–electrolyte boundary. Warburg[2] and Kruger[3] obtained equations for electrode impedance in the special case of diffusion-controlled electrode processes and attempted to measure it. However, the lack of a sufficiently deep understanding of the mechanism of electrochemical reactions and of a reliable experimental technique resulted in comparatively little development in this field — the alternating current was used for a long time exclusively for conductimetric studies.

A decisive breakthrough occurred only after studies by Frumkin and coworkers[4,5], in which the capacitance of the electrical double layer of an ideally polarised mercury electrode was determined for the first time by direct measurements in an alternating current and a capacitance minimum was observed in dilute aqueous solutions at the zero-charge potential, which constituted experimental confirmation of the diffuse double layer theory. Somewhat later Dolin, Ershler, and Frumkin[6–8] used alternating current to investigate the kinetics of the evolution of hydrogen on a platinum electrode. These studies began the wide-scale employment of alternating current in electrochemical kinetics[9–21]. Quantitative measurements of the impedance of readily polarisable electrodes have recently undergone a fresh development and have been discussed in detail in a number of reviews[22–27].

II. IMPEDANCE OF SLOW ELECTROCHEMICAL REACTIONS

The main property of cells with ideally polarisable electrodes is that their impedance corresponds to the simplest a.c. circuit comprising the series-connected electrolyte resistance R_e and the double-layer capacitance C_d (Fig. 1*a*):

$$Z = R_e + (j\omega C_d)^{-1}. \quad (1)$$

The rate of relaxation of the double layer in solutions is fairly high, so that, even at frequencies of the order of several Megahert, C_d (as well as R_e) is independent of the a.c. frequency[28,29]. For comparatively slow electrode processes, it is possible to isolate three classical mechanisms under these conditions.

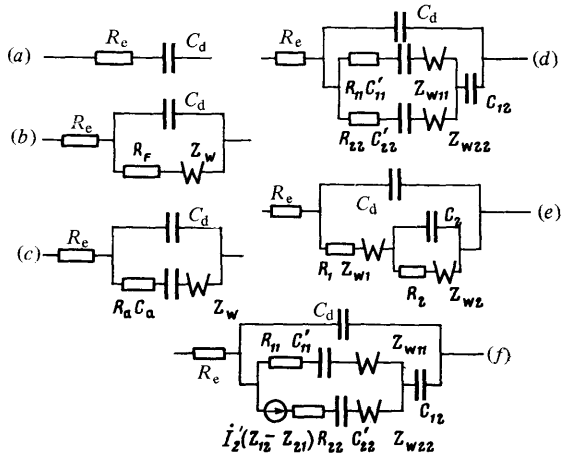

Figure 1. Equivalent a.c. circuits.

1. An electrochemical reaction not accompanied by the adsorption of the reactants: the Ershler–Randles impedance[30–32]. The process is illustrated graphically in Fig. 2*a* and the equivalent a.c. circuit is shown in Fig. 1*b*. The corresponding analytical expression for the impedance is

$$Z = R_e + \{j\omega C_d + [R_F + \tilde{W}/\sqrt{j\omega}]^{-1}\}^{-1}, \quad (2)$$

where

$$R_F = RT/(nF)^2 V_0 \quad (3)$$

is the resistance to charge transfer,

$$\tilde{W} = RT/(nF)^2 c_0 \sqrt{D} \quad (4)$$

the Warburg constant, i_0 the exchange flux for the charge-transfer reaction, c_0 the concentration of electrochemically active species in the bulk of the electrolyte, D their diffusion coefficient, F the Faraday, and n the number of charges transported in an electrochemical reaction of the type

$$Ox + ne \rightleftharpoons Red. \tag{5}$$

The expression in square brackets in Eqn. (2) is called the Faraday impedance (Z_F).

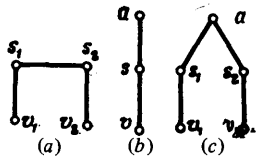

Figure 2. Schematic graphical representation of electrode processes.

2. An adsorption process without electrochemical reaction: the Frumkin–Melik–Gaikazyan impedance[33,34]. The process is illustrated by a graphical scheme in Fig. 2 and the equivalent a.c. circuit is shown in Fig. 1*c*:

$$Z = R_\Omega + \{j\omega C_d + [R_a + \tilde{W}_a/\sqrt{j\omega} + (j\omega C_a)^{-1}]^{-1}\}^{-1}, \tag{6}$$

where

$$\left.\begin{aligned} R_a &= RT/q_A^2 V_0;\ C_a = q_A^2/\tilde{\mu}_A, \\ \tilde{W}_a &= RT/q_A^2 c_0 \sqrt{D}, \end{aligned}\right\} \tag{7}$$

q is the electrode charge, A the amount of substance in the adsorbed state, $\tilde{\mu}$ the electrochemical potential of the adsorbed substance, $q_A = (\partial q/\partial A)\varphi$, and $\tilde{\mu}_A = (\partial\tilde{\mu}/\partial A)\varphi$. Here both C_d and C_a make up the double layer capacitance; although the charging of the C_d capacitance is rapid, the C_a capacitance charges slowly and the kinetics of its charging process are determined by the rates of adsorption (R_a) and diffusion ($\tilde{W}_a$) of the species undergoing adsorption, for example dipolar organic molecules.

3. An electrochemical reaction complicated by a chemical reaction: the Gerischer impedance[35–37]. In contrast to the Ershler–Randels impedance, in this case the electrochemically active species appear near the electrode both as a result of diffusion and as a result of a chemical reaction, for example the decomposition of a complex. For this reason the Warburg impedance in the usual circuit (Fig. 1*b*) is replaced by a complex resistance, which depends on the frequency in a more complicated manner (see, for example, Vetter[13]).

III. IMPEDANCE OF ELECTROCHEMICAL REACTIONS COMPLICATED BY ADSORPTION

The theory of the impedance of electrochemical reactions complicated by adsorption has been developed since 1961.[21,38–47] Fig. 2*c* illustrates a schematic graphical representation of a reaction proceeding via an adsorbed state. A characteristic feature of such processes is that charge transfer from the reacting species to the metal can in general take place in two stages. In the first stage (line s_1a) the oxidised form passes from the state near the surface of the electrode (point s_1) to the adsorbed state (point a). This entails the transfer of a charge n_1. In the second stage (line as_2) the substance passes from the adsorbed state in the reduced form to the state near the electrode surface (point s_2). This entails the transfer of a charge n_2. The overall number of electrons supplied to the electrode via the external circuit on transition of the reactant from point s_1 to point s_2 is n under the conditions of a constant potential, so that

$$n_1 + n_2 = n; \tag{8}$$

here n_1 and n_2 need not be integral numbers. Only their sum n is an integar. The quantities n_1 and n_2 are macroscopic characteristics— they define the amount of electricity which is supplied on average to the electrode via the external circuit when an ion or molecule of the surface-active substance passed from one state to another.

Following Lorenz and Salie[39], we put

$$n_1 = ln;\ n_2 = (1-l)n\ . \tag{9}$$

The coefficients l and $1-l$ characterise the fraction of the charge transferred in each of the two adsorption stages. The charge transfer in the individual stages of the electrochemical reaction can be related to the adsorption characteristics of the system[21,48]:

$$l = \frac{\Gamma_{1\mu_1} + \Gamma_{1\mu_2}}{\Gamma_{1\mu_1} + \Gamma_{2\mu_2} + \Gamma_{1\mu_2} + \Gamma_{2\mu_1}}, \tag{10}$$

where Γ_1 and Γ_2 are respectively the Gibbs adsorptions of the oxidised and reduced forms μ_1 and μ_2 are their chemical potentials, and $\Gamma_{1\mu_2} = \Gamma_{2\mu_1}$. This relation makes it possible to calculate the charge transferred from thermodynamic data for the overall charges of the reversible electrode. Such calculations have been made, for example, for charge transfer in the adsorption of H^+ ions and hydrogen atoms on a platinum electrode[48]. It was found that in this system the parameter l varies markedly with the potential and also depends on the composition and pH of the solution. In many cases l is greater than unity. In other words, in the adsorption of H^+ ions, excess negative charge can be transferred to them.

The impedance of an electrochemical reaction proceeding via two adsorption stages can be calculated using the method of equivalent multiterminal networks and Onsager's reciprocal relations[21,43,44]. Although from the standpoint of the theory of electric circuits the electrochemical cell always consists of a two-terminal network (diode), in the presence of a two-stage process an individual current corresponds to each stage (I_1 and I_2). However, since adsorption processes do not tkae place independently because we are dealing with reactions of the same substance, the currents I_1 and I_2 are related. This can be expressed with the aid of relations between the current and polarisation analogous to the equations for a four-terminal network:

$$\left.\begin{aligned} \Delta\varphi &= Z_{11}I_1 + Z_{12}I_2, \\ \Delta\varphi &= Z_{21}I_1 + Z_{22}I_2, \end{aligned}\right\} \tag{11}$$

where Z_{11} and Z_{22} are the input impedances for two adsorption processes (s_1a and s_2a) and Z_{12} and Z_{21} describe the interaction of these processes.

Eqns. (11) characterise a four-terminal network, which is the electrical equivalent of the given process. A characteristic feature of such a four-terminal network is that the potentials at the two pairs of its terminals are the same

and equal to $\Delta\varphi$. Eqns. (11) express in essence the phenomenological law of non-equilibrium thermodynamics as applied to electrochemical reactions. Since in the absence of an alternating current the system is at equilibrium, the Onsager relation $Z_{12} = Z_{21}$ (the equality of the kinetic cross-coefficients) should hold. Direct calculations for this process, illustrated schematically in Fig. 2*c*, show that the frequency dependences of the coefficients Z_{12} and Z_{21} are in fact the same and their equality can be confirmed independently by analysing the Gibbs adsorption equation (or more precisely the equality of the cross-derivatives of the Gibbs adsorptions of the two forms with respect to the chemical potentials $\Gamma_1\mu_2 = \Gamma_2\mu_1$).[21,46]

The Faraday impedance, calculated by Eqns. (11), can be formulated as follows:

$$Z_F = \frac{Z_{11}Z_{22} - Z_{12}^2}{Z_{11} + Z_{22} - 2Z_{12}}, \qquad (12)$$

where

$$Z_{11} = R_{11} + \widetilde{W}_{11}/\sqrt{j\omega} + (j\omega C_{11})^{-1}, \qquad (13)$$

$$Z_{22} = R_{22} + \widetilde{W}_{22}/\sqrt{j\omega} + (j\omega C_{22})^{-1}, \qquad (14)$$

$$Z_{12} = -(j\omega C_{12})^{-1}, \qquad (15)$$

and the coefficients R_{11}, C_{11}, $\widetilde{W}_{11}$, etc. are expressed in terms of parameters characterising the electrochemical reaction:

$$R_{ii} = RT/(n_iF)^2V_{i0};\ \widetilde{W}_{ii} = RT/(n_iF)^2c_{i0}\sqrt{D_i};\ C_{ik} = n_in_kF^2/\widetilde{\mu}_A, \qquad (16)$$

where $i, k = 1$ or 2. The equivalent a.c. circuit for the given process can be constructed, for example, in the way shown in Fig. 1*d*. In this case we have

$$(C_{ii}')^{-1} = C_{ii}^{-1} + C_{ik}^{-1}\ (i \neq k). \qquad (17)$$

In order to represent the Faraday impedance in a fairly compact analytical form, we introduce the following notation:

$$l/(1-l) = \xi, \qquad (18)$$

$$c_{10}\sqrt{D_1}/c_{20}\sqrt{D_2} = r;\ V_{10}/V_{20} = p\ . \qquad (19)$$

Then Eqn. (12) can be reduced to the form

$$Z_F = \frac{\widetilde{W}_{11}C_{11}^{-1}(1+r)\xi^2x^3 + [R_{11}C_{11}^{-1}(1+p) + \widetilde{W}_{11}^2r]\xi^2x^2 + R_{11}\widetilde{W}_{11}(p+r)\xi^2x + pR_{11}\xi^2}{C_{11}^{-1}(1+\xi)^2x^2 + \widetilde{W}_{11}(1+r\xi^2)x + R_{11}(1+p\xi^2)}, \qquad (20)$$

where $x = (j\omega)^{-1/2}$.

The case where the effective charge transfer in one of the stages is insignificant is of considerable interest. When the adsorption of the oxidised form is not accompanied by an appreciable charge transfer, i.e. when

$$\xi \ll 1;\ n_2 \simeq n\ , \qquad (21)$$

we have

$$Z_F = R_{22} + \frac{\widetilde{W}_{22}}{\sqrt{j\omega}} + \frac{1}{j\omega C_{22} + [R_{11}\xi^2 + \widetilde{W}_{11}\xi^2/\sqrt{j\omega}]^{-1}}\ , \qquad (22)$$

where $R_{11}\xi^2 = RT/(nF)^2V_{10}$ and $\widetilde{W}_{11}\xi^2 = RT/(nF)^2c_{10}\sqrt{D_1}$. Similarly, when charge transfer occurs predominantly in the stage involving the adsorption of the oxidised form, then

$$\xi \gg 1;\ n_1 \simeq n, \qquad (23)$$

and

$$Z_F = R_{11} + \frac{\widetilde{W}_{11}}{\sqrt{j\omega}} + \frac{1}{j\omega C_{11} + [pR_{11} + r\widetilde{W}_{11}/\sqrt{j\omega}]^{-1}}\ , \qquad (24)$$

where $pR_{11} = RT/(nF)^2V_{20}$ and $r\widetilde{W}_{11} = RT/(nF)^2c_{20}\sqrt{D_2}$. Eqns. (22) and (24) both correspond to the same equivalent circuit (Fig. 1*e*).

The results can be used to analyse the electrode reaction on platinum in the iodine–iodide system. The impedance of this system has been investigated[49–52]. Vetter[49] and Tyagai et al.[52] concluded that the electrode reaction proceeds via the discharge–recombination mechanism, the discharge stage being slow. Llopis et al.[50] showed that the experimental data correspond to the equivalent circuit in Fig. 1*e*. The hodograph of the input impedance of the cell is of the form shown in Fig. 3. Dane et al.[51] found the exchange current of the electrochemical reaction from the impedance data assuming that the resistance R_D is equal to the diameter of the half-circle shown in Fig. 3 by a dashed line and that $i_0 = RT/FR_D$. The study of the variation of i_0 with the concentration of I^- ions and of dissolved iodine led the authors[51] to the conclusion that the reaction proceeds via the discharge–electrochemical desorption mechanism. This view was confirmed by other methods and it was shown that the exchange currents are comparable for both stages[53].

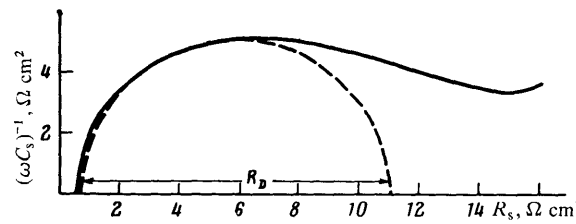

Figure 3. The hodograph of the impedance of the Pt/(1 *N* H_2SO_4 + 3.5 × 10^{-5} mole cm^{-3} KI + 0.46 × 10^{-6} mole cm^{-3} I_2) boundary at 25 °C (data of Llopis et al.[50]); impedance parameters: $R_e = 0.7\ \Omega\,cm^2$, $R_1 = 9.8\ \Omega\,cm^2$, $R_2 = 3.5\ \Omega\,cm^2$, $W_1 = 0$, $W_2 = 95.5\ \Omega\,cm^2s^{-1/2}$, $C_d = 3\ \mu F$ cm^{-2}, $C_2 = 31\ \mu F\ cm^{-2}$. The diameter of the dashed half-circle is approximately 10.2 Ω cm^2.

Parameters of the electrode impedance of the I_2/AgI system[54].

t, °C	C_d, μF cm^{-2}	C_2, μF cm^{-2}	R_1, Ω cm^2	R_2, Ω cm^2	W_1, Ω $cm^2s^{-1/2}$	W_2, Ω $cm^2s^{-1/2}$
197	46.3	15.9	0.10	0	98	2160
363	58.0	17.6	0.19	0	210	1180
498	64.5	20.8	0.20	0	130	590
549	79.6	21.5	0.20	0	92	325
618 (melt)	102	—	0.045	0	63	—

As shown previously[21], the discharge–recombination and discharge–electrochemical desorption mechanisms lead to the same a.c. current (Fig. 1*d*). If the diffusion of I^- ions does not make an appreciable contribution to the impedance (a fairly concentrated solution) and the discharge is transferred preferentially in the first stage so that $n_2 \simeq 0$ and $n_1 \simeq 2$, then the circuit in Fig. 1*d* transforms into that in Fig. 1*e*, for which $ZW_1 = 0$. The rates of the two adsorption stages, characterised by the resistance R_1 and R_2, are comparable (Fig. 3), which agrees with the results

of Povarov et al.[53]. Thus the experimental data of different workers for the impedance of the Pt/I_2, KI, H_2SO_4 boundary can be explained from the same standpoint using Eqn. (24). The C, I_2/α-AgI boundary with a solid electrolyte behaves similarly[54]. The equivalent circuit of the Faraday process in such a system is the same as in Fig. 1*d*. The impedance parameters are listed in the Table. In this case both the diffusion of I^- ions proceeding via the lattice defects and the diffusion of molecular iodine are significant. The impedance ZW_2 corresponds to the former and ZW_1 corresponds to the latter. This follows from the fact that, when the crystal melts, the impedance ZW_2 falls to zero, since all the I^- ions begin to participate in the transport.

IV. IMPEDANCE OF NON-EQUILIBRIUM ELECTROCHEMICAL SYSTEMS

The study of the properties of the electrochemical impedance of complex systems showed that it is necessary to use the principles of non-equilibrium thermodynamics and particularly the Onsager reciprocal relations. It was found that the dynamic adsorption equation for an irreversible electrode can be obtained from the Onsager relations and the adsorption equation for a reversible electrode[53]. In fact, for an ideally reversible electrode one can write the Gibbs adsorption equation:

$$-d\gamma = \Gamma_1 d\mu_1 + \Gamma_2 d\mu_2. \qquad (25)$$

The chemical potentials of the oxidised and reduced forms can be expressed in terms of the electrochemical ($\tilde{\mu}$) and the electrical (φ) potentials, i.e.

$$-d\gamma = \Gamma_1 d(\tilde{\mu}_1 + z_1 F\varphi) + \Gamma_2 d(\tilde{\mu}_2 + z_2 F\varphi). \qquad (26)$$

If the adsorbed species are in equilibrium with the adsorption layer, then we have for the reaction mechanism corresponding to Fig. 2*e*

$$-d\gamma = \Gamma_1 d(\tilde{\mu}_a + z_1 F\varphi) + \Gamma_2 d(\tilde{\mu}_a + z_2 F\varphi), \qquad (27)$$

$\tilde{\mu}_a$ being the electrochemical potential of the adsorbed species and z_1 and z_2 their charges. It follows directly from Eqn. (27) that[21]

$$-d\gamma = \Gamma_1 d\mu_1 + \Gamma_2 d\mu_2 + Q' d\eta_1 + Q' d\eta_2, \qquad (28)$$

where Q' and Q'' are the total thermodynamic charges on the electrode[56] and η_1 and η_2 are the overvoltages in the first and second adsorption stages.

The equation was obtained in relation to equilibrium conditions, but it is valid also for non-equilibrium electrodes (i.e. when a direct current is imposed), provided that the following two conditions are fulfilled: (a) when a direct current flows, the mechanism of the electrode process does not change; (b) the processes in the surface layer are fairly rapid, so that the thermodynamic properties of this layer are determined unambiguously by the electrode potential and the electrochemical potentials of the adsorbed species. In other words it is assumed that, regardless of whether there is an equilibrium between the surface and bulk-phase states, the state of the surface layer remains the same function of its surface variables.

If the electrochemical system in the absence of an alternating current does not correspond to equilibrium, for example when a direct current is imposed, the Onsager relations cease to hold although the Faraday process can still be represented by the equivalent multiterminal network. The overall impedance of the electrochemical reaction proceeding via the adsorbed state is in this case given by

$$Z_F = \frac{Z_{11}Z_{22} - Z_{12}Z_{21}}{(Z_{11} + Z_{22}) - (Z_{12} + Z_{21})}, \qquad (29)$$

where $Z_{12} \neq Z_{21}$. Formally the impedance Z_F can also be represented by a rational-fractional function of $(j\omega)^{-1/2}$ in which the numerator is a third-degree polynominal and the denominator is a second-degree polynomial. Thus the frequency variation of the impedance does not depend on the degree of reversibility of the system in terms of a direct current, but is determined exclusively by the mechanism of the electrochemical process. The coefficients of the rational-fractional function can vary with the degree of polarisation under a direct current. This relation can be determined on the basis of a specific reaction model.

In view of the inequality of Z_{12} and Z_{21}, the equivalent a.c. circuit of the type shown in Fig. 1*d* should include a dependent current source (see, for example, Atabekov[57]). Thus aperiodic equivalent circuits, analogous to those proposed by Barker[58,59] for reversible systems, can be constructed for irreversible systems.

The development of the theory of electrochemical impedance leads to great possibilities for the application of alternating currents in electrochemical kinetics to the study of complex reactions accompanied by adsorption both near equilibrium and following the imposition of a direct current.

The Fundamental Step in Electrode Reactions

R.R.Dogonadze and L.I.Krishtalik

The modern quantum-mechanical theory of the fundamental step in electrode reactions, which takes into account the necessity for the reorganisation of the polar medium and the qualitative difference between the behaviour of classical and quantum-mechanical degrees of freedom, is briefly reviewed. The experimental studies on the influence of various factors on the pre-exponential factor, the kinetic isotope effect, and the activation energy for the evolution of hydrogen have demonstrated a satisfactory agreement with the predictions of the quantum theory and a qualitative contradiction with the Horiuti-Polanyi model, which postulates the extension of the O-H bond in the activation process.
The bibliography includes 50 references.

I. INTRODUCTION

Reviews dealing with the theory of the fundamental step in electrode reactions[1] and certain experimental studies in this field[2] were published ten years ago in the issue of this journal devoted to the 70th birthday of Academician A. N. Frumkin. Since then the problem as a whole has developed very significantly, new ideas have been put forward, justified theoretically, and proved experimentally. In principle, these have permitted a theoretical analysis of any complex reaction involving charge transfer becoming possible.

II. THE QUANTUM THEORY OF THE FUNDAMENTAL STEP IN ELECTRODE REACTIONS

At the beginning of the 1960s only the simplest electron transfer reactions, unaccompanied by the dissociation, formation, or rearrangement of covalent bonds, could be treated theoretically. These studies revealed the decisive role of the reorganisation of the polar medium, i.e. the reorientation of the solvent dipoles in the course of such reactions. Electron transfer takes place after the molecules of the medium have attained a configuration (intermediate between the equilibrium initial and final configurations) as a result of thermal fluctuations for which the energies of the initial and final states are equal. These ideas were then extended to any charge-transfer reaction in the course of which not only the medium but also the reactants undergo rearrangement.

The principal ideas in the quantum chemistry of the fundamental step of electrochemical reactions will be described using as an example the discharge of hydrogen ions. This reaction was chosen, firstly, because it is apparently one of the electrochemical processes which have been investigated in greatest detail and, secondly, this reaction constitutes the simplest instance where the fundamental step involves the dissociation of a single covalent bond and the formation of another covalent bond. Finally, as will be seen below, the difference between the quantum theory and the theory of absolute reaction rates in relation to the mechanism of the fundamental step is manifested most clearly in proton transfer processes.

One of the first microscopic models used to describe the fundamental step in the electrochemical proton transfer process was proposed by Horiuti and Polanyi[3]. This study played a major role in the development of the theory of the kinetics of the fundamental step in chemical reactions, since it explained correctly for the first time a number of phenomenological relations. According to this theory, the proton is transferred from the AH^+ species to the electrode via a gradual extension of the $A-H^+$ bond, which corresponds to the excitation of the high vibrational levels in the AH^+ molecule. Subsequently, in order to account for the isotope effect, it was suggested that some tunnelling can occur near the top of the barrier (see, for example, Bell's review[4]). It is important to emphasise that, both in the initial study by Horiuti and Polanyi and in subsequent investigations based on the ideas of the theory of absolute reaction rates, the dynamic role of the polar medium in the fundamental step was completely ignored.

Dogonadze and coworkers[5,6] made the first attempt to consider proton transfer, within the framework of an extremely simplified model, on the basis of a fully quantum-mechanical calculation without any *a priori* hypothesis concerning the reaction pathway on the potential energy surface. Subsequently it was possible to improve significantly, on the one hand, the quantitative model used to describe the polar medium[7-9] and, on the other hand, to examine a more realistic model of the ion undergoing discharge, taking into account the possible changes in the intramolecular configurations of the reactants[10]. The method for calculating the rate of the fundamental step developed in these studies was in principle applicable not only to proton transfer reactions but to reactions of virtually any type. The modern quantum theory of chemical and electrochemical reactions in a condensed phase has been reviewed[11-15]. In the present survey we shall describe only some results of this theory and shall discuss qualitatively the overall features of the fundamental step.

In chemical kinetics the mechanism of the fundamental reaction step is usually treated with the aid of the potential energy surfaces of the initial state $U_i(Q)$ and the final state $U_f(\zeta)$. Here we denote by the symbol Q the entire set of coordinates of the degrees of freedom which are altered in the course of the reaction, and exert a dynamic influence on the fundamental step. Thus Q includes the set of coordinates R defining the configuration of the molecule (dipoles) of the medium and the set of coordinates r defining the intramolecular configuration of the reactants.

Quantum-mechanical calculation has shown (see, for example, Dogonadze and Kuznetsov[14]) that the probability of the transition per unit time from the initial potential energy surface $U_i(Q)$ to the potential energy surface of the final state $U_f(Q)$ can be formulated as follows†:

$$w_{if} = \text{const} \cdot L_{if}(Q^*) \cdot \Phi_i(Q^*, 1-\Theta^*) \cdot \Phi_f(Q^*, \Theta^*), \quad (1)$$

where $\Phi_i(Q, 1-\Theta)$ is the quantum-statistical distribution function for the coordinates in the initial state calculated for an effective temperature $T/(1-\Theta)$, $\Phi_f(Q,\Theta)$ is similarly the distribution function for the coordinates in the final state calculated for a temperature T/Θ, Θ is an auxiliary variable the physical significance of which will be explained below, $2L_{if}$ is the resonance splitting of the U_i and U_f surfaces in the vicinity of their intersection and is determined by the electronic exchange integral, Q^* are the coordinates of the "transition" configuration, and Θ^* is the value of Θ in the transition state; it is identical with α—the transfer coefficient or the symmetry factor in the Brønsted relation.

The transition configuration Q^* and the transfer coefficient Θ^* are determined in the following way according to the quantum theory[10,11]. For a fixed arbitrary value of Θ, we initially seek a maximum in the function $L_{if}(Q)\cdot\Phi_i(Q, 1-\Theta)\cdot\Phi_f(Q,\Theta)$ with respect to Q; then, having found $Q^*(\Theta)$, we determine Θ^* from the condition for the maximum in the function $L_{if}[Q^*(\Theta)]\cdot\Phi_i[Q^*(\Theta), 1-\Theta]\cdot\Phi_f[Q^*(\Theta), \Theta]$ with respect to Θ. Having found Θ^*, we find the transition configuration $Q^* = Q^*(\Theta^*)$.

The formula of the theory of absolute reaction rates can be easily found from Eqn. (1). For this purpose, it is sufficient to suppose that motion is classical for all degrees of freedom. Then the classical Boltzmann distribution function[19,20] should be used as the distribution function with respect to coordinates:

$$w_{if}^{cl} = \text{const} \cdot L_{if}(Q^*) \cdot \exp\left[-(1-\Theta^*)\frac{U_i(Q^*)}{kT} - \Theta^*\frac{U_f(Q^*)}{kT}\right]. \quad (2)$$

The system of equations for Q^* and Θ becomes under these conditions

$$(1-\Theta)\frac{\partial U_i(Q)}{\partial Q_k} + \Theta\frac{\partial U_f(Q)}{\partial Q_k} = kT\frac{\partial \ln L_{if}(Q)}{\partial Q_k}, \quad (3)$$

$$U_i[Q^*(\Theta)] = U_f[Q^*(\Theta)]. \quad (3')$$

Condition (3′) implies that the transition from the surface U_i to U_f proceeds via the intersection surface, where U_i is equal to U_f. This condition corresponds fully to the classical features of the transition adopted in the theory of absolute reaction rates.

In analysing Eqn. (3), one should bear in mind that the exchange integral L_{if} depends virtually only on the intermolecular coordinates R of the reactants. For this reason, in determining the transition configuration with respect to the intramolecular coordinates r^* and the coordinates of the molecules of the medium q^*, the right-hand side of Eqn. (3) can be replaced by zero. In other words, for fixed intermolecular coordinates R of the transition configuration, a saddle point on the surface of intersection of U_i and U_f corresponds to r^* and q^*. Eqn. (3) for the coordinates R^* makes it possible to find the optimum distance between the reactants and their optimum mutual orientation. The existence of this optimum is a consequence of the fact that L_{if} decreases sharply with increase of the distance between the reactants, while for short distances the probability of the mutual approach of the reactants $e^{-U_i/kT}$ diminishes sharply.

Taking into account condition (3′), formula (2) can be rewritten as follows:

$$w_{if} = \text{const}\, L_{if}(Q^*)\exp\left[-\frac{U_i(Q^*)}{kT}\right]. \quad (4)$$

Here $U_i(Q^*)$ plays the role of activation energy and const. contains a number of factors which determine the transmission coefficient and the frequencies of the fluctuations leading to the formation of the transition state (the entropy term).

Together with the classical limit, which formally occurs when sufficiently high temperatures ($T \to \infty$) are considered, it is of interest to examine the opposite limiting case of low temperatures ($T \to 0$). Here the behaviour of the system is determined by purely quantum-mechanical factors and the distribution function for the coordinates is equal to the square of the modulus of the wave function for the system in the ground state Ψ_0.[19,20] Above we pointed out the formal criterion for the classical ($T \to \infty$) and quantum-mechanical ($T \to 0$) behaviour of the system. In order to obtain the real quantitative criterion in terms of temperature, we shall consider the case, which is of practical interest, where the system is described by a set of harmonically vibrating oscillators. Denoting by $Q_k^{(i)}$ and $\omega_k^{(i)}$ the normal coordinates and frequencies in the initial state and by $Q_k^{(f)}$ and $\omega_k^{(j)}$ the normal coordinates and frequencies in the final state, Eqn. (1) can be rewritten as follows[19]:

$$w_{if} = \text{const}\, L_{if}(Q^*)\prod^{k}\exp\left[-(Q_k^{*(i)})^2\tanh\frac{\hbar\omega_k^{(i)}(1-\Theta^*)}{2kT} - (Q_k^{*(f)})^2\tanh\frac{\hbar\omega_k^{(f)}\Theta^*}{2kT}\right]. \quad (5)$$

Eqn. (5) becomes identical with Eqn. (2), corresponding to the classical limit, when all the hyperbolic tangents are replaced by their arguments, which is possible for arguments much smaller than unity. Thus we arrive at the following criterion of classical behaviour of the system‡:

$$\hbar\omega_k^{(i)}(1-\Theta^*) \ll 2kT, \qquad \hbar\omega_k^{(f)}\Theta^* \ll 2kT. \quad (6)$$

Since the transfer coefficient $\alpha = \Theta^*$ lies in the range zero to unity[2,11,13], it is sufficient for classical behaviour of the system that the energy of the vibrational quantum $\hbar\omega$ should be small compared with the energy of thermal motion $2kT$.

We shall use criterion (6) to elucidate the problem of the quantum-mechanical or classical behaviour of the proton in chemical and electrochemical reactions. We shall assume initially that the reaction proceeds in the normal region of thermal excitation where $\alpha \simeq 0.5$. According to condition (6), the parameter $\gamma \simeq \hbar\omega/4kT$ should be estimated in this case. If $\omega \simeq 6\times10^{14}$ s^{-1} is adopted as the vibrational frequency, then we obtain $\gamma \simeq 3.75$ at room temperature. Since $\tanh 3.7 \simeq 0.999 \simeq 1$, we obtain the

† Eqn. (1) is valid for non-adiabatic processes when the transmission coefficient κ is less than unity. Adiabatic processes have been examined in a number of studies[16-18]. Since $\kappa \ll 1$ for proton transfer reactions, as shown by studies on the isotope effect, in the present review we shall consider only non-adiabatic reactions.

‡ Together with condition (6), another condition, namely the requirement that the subsequent terms of the expansion of the tangent be small, follows from Eqn. (5). It has been shown[10] that this condition does not usually alter significantly Eqn. (6).

following distribution function for the coordinates of the proton:

$$\Phi(Q) = \frac{1}{\sqrt{\pi}} e^{-Q^2} \equiv |\Psi_0(Q)|^2, \quad (7)$$

where $\Psi(Q)$ is the wave function of the ground vibrational state of the proton. Thus the distribution function of the proton coordinates at room temperature is determined by purely quantum-mechanical laws. In particular, the coordinates $Q > 1$, which are located in the inaccessible region according to the classical theory, can be realised only by virtue of the tunnel effect. Finally, we may note that, according to Eqn. (7), the distribution function for the proton coordinates is independent of temperature, like that for any quantum-mechanical particle.

We shall now consider the region of barrierless reactions, i.e. highly endothermic processes [2,11-15]. In this case the transfer coefficient Θ^* is close to unity and, according to condition (6), when $\hbar\omega(1-\Theta^*) \ll 2kT$, the behaviour of the proton in the initial state is classical. The physical significance of this result is that in highly endothermic processes a preliminary excitation of the proton to a high vibrational level, where its behaviour becomes virtually classical, is necessary. In particular, one may say that, in the formation of the transition state, the chemical bond involving the proton undergoes classical "extension". Evidently [this also follows from formula (6) according to which $\hbar\omega\mathfrak{G}^* \gg 2kT$ for the proton in the barrierless region], after the rearrangement of the electronic state in the transition region, the proton is in the vibrational ground state. In this sense, one may say that the classical degree of freedom of the proton is converted into the quantum-mechanical degree of freedom in the course of the reaction. A completely analogous treatment has shown that, in reactions without activation energy, i.e. in highly exothermic processes, where Θ^* is close to zero, the proton passes from its ground vibrational state to a highly excited vibrational state.

One must emphasise that the conclusion concerning the virtually classical behaviour of the proton in a barrierless discharge is valid only for very high activation energies, i.e. far from the region of transition from normal discharge to barrierless discharge. The existing theory, which provides a qualitatively correct explanation of the variation of α from 1/2 to 1, does not describe the transition region quantitatively. In particular, it is not yet been possible to account for the expérimental observation of a sharp variation of α over a very narrow range of potentials [2]. Certain estimates, carried out using Morse potentials, have shown that in the transition region the lowest excited levels of the proton make an appreciable contribution together with its ground vibrational level, but the behaviour of protons still remains significantly of the quantum-mechanical type [11].

The scheme described above leads to the following physical picture of the transition from the initial to the final state. On the potential energy surface for the initial state, a classical fluctuation takes place initially in accordance with the Boltzmann Law along the degrees of freedom for which the first condition (6) holds. The extension of the length of these classical degrees of freedom depends significantly on the behaviour of the given degree of freedom after the reaction: if it remains classical also after the reaction, the transition configuration is determined by Eqn. (3), but, when there is a change from a classical to a quantum-mechanical (quantised) degree of freedom as a result of the reaction, the extension is virtually a maximum, since in the final state the system must be at the zero-point level, i.e. must be localised near the equilibrium configuration of the final state.

As a result of the classical fluctuation, all the zero-point (ground) energy levels of the quantum-mechanical subsystem, satisfying conditions which are the opposite of conditions (6) in both the initial and final states, are equalised in the initial stage. In fact we are dealing here with the general Franck–Condon principle, according to which the rearrangement of the state of the fast subsystem (in our case the quantum-mechanical subsystem) can occur only when the energies of the initial and final states are equal, since the slow subsystem (in our case the classical subsystem) cannot change (because of the considerable inertia) its coordinates and momenta, in order to compensate the difference between the energies of the fast subsystem.

In the second stage quantum fluctuation, i.e. tunnelling of the quantised degrees of freedom, begins for fixed coordinates of the classical subsystem. For a certain configuration of the quantised degrees of freedom, corresponding to the inaccessible region according to the classical theory, the energies of the initial and final states of the electronic subsystem are equalised. Thus at this stage the condition of the usual Franck–Condon principle is fulfilled; according to this principle, the change of state of the electronic (fast) system takes place for fixed coordinates and momenta of the nuclear (slow) subsystem. After the Franck–Condon barrier to the electronic subsystem is removed in the second stage, in the third stage there is electron tunnelling from the initial to the final state, after which there is an initial relaxation of the quantised and then the classical degrees of freedom of the system.

Cases are in principle possible (and probably extremely common) where the electronic subsystem follows adiabatically the motion of the remaining quantised subsystems, for example protons. In this case the second and third stages described above in fact merge into one and the only transition under the barrier is the one executed by the quantised subsystem of the nuclei. For such processes, which are adiabatic with respect to electrons and non-adiabatic with respect to other quantised degrees of freedom, L_{if} in Eqn. (1) can be understood as, for example, the proton exchange integral and no longer the electron exchange integral.

It is interesting to consider one of the characteristics of the reactions in the course of which a classical degree of freedom is converted into a quantised degree of freedom. If the conditions

$$\frac{2kT}{\hbar\omega^{(f)}} \ll \Theta^* \ll 1, \quad (8)$$

hold in the system, then the right-hand side of the inequality ensures that the reaction proceeds virtually without activation energy, while the left-hand side of the inequality implies that the given degree of freedom can be treated as virtually of the quantum-mechanical type in the final state (see Dogonadze et al.[6]). This implies that, although the process as a whole occurs almost without activation energy (in the sense that Θ^* is close to zero), it follows from the picture of the transition described above that there will be preliminary activation along the given degree of freedom from the initial equilibrium configuration to the final equilibrium configuration. Processes in which $\Theta^* \simeq 0$ but the activation energy is non-zero and constant (independent of the heat change) have come to be called quasi-non-activated processes. Quasi-barrierless processes, where $\mathfrak{G}^* \simeq 1$ but the activation energy differs from the heat change by a constant amount, can be treated similarly [21,22].

On passing from simple potential energy surfaces, having the form of multi-dimensional paraboloids, to more complex surfaces, the qualitative picture of the transition naturally does not change. Only the form of the criterion of the quantum-mechanical or classical behaviour of the given degree of freedom is altered: instead of condition (6), we have a more complex condition. The new feature introduced into the qualitative picture by the anharmonicity of the potential energy curves is that, along different sections of the potential energy curve, there can be a change from the classical to the quantum-mechanical (tunnel) motion of the particle or conversely. For example, when the vibrational frequency near the minimum satisfies the condition of classical behaviour ($h\omega \ll 2kT$), the behaviour of the system far from the minimum can be nevertheless of the quantum-mechanical type if the potential energy curve rises very steeply in consequence of the marked repulsion from another particle. The opposite situation can also arise when the vibrational frequency near the minimum satisfies the condition for quantum-mechanical behaviour ($h\omega \gg 2kT$) and yet the motion of the particle is classical at a sufficient remove from the minimum where the potential energy curve acquires a low slope.

However, one should remember that the motion of the particle becomes classical in a state very close to dissociation. For example, numerical calculation of the quantum-statistical distribution function for the proton coordinates using the Morse potential curve with the parameters D (dissociation energy) = 172.5 kcal mole^{-1} and ω (frequency near the minimum) = 4×10^{14} s^{-1} has shown that the motion of the proton becomes classical when it departs from the minimum by a distance of about 4 Å. Such extension of the bond requires an energy consumption of the order of 100 kcal mole^{-1}, i.e. much greater than the experimental activation energies (< 20 kcal mole^{-1}). Therefore under real experimental conditions the classical behaviour of the proton in the highest state is unlikely.

III. EXPERIMENTAL STUDY OF THE FUNDAMENTAL STEP IN ELECTRODE REACTIONS

We shall consider the possibility of an experimental comparison of two fundamentally different models of the fundamental step in the discharge of a proton donor—the model involving a gradual extension of the O–H bond and the model postulating a rearrangement of the solvent structure with a subsequent quantum jump of the proton from the initial to the final state. Both give virtually the same explanations of the majority of the known experimental facts. This is not surprising, since, for a semi-quantitative treatment of the majority of observations, it is sufficient that certain simple phenomenological relations, associated with the existence of an energy barrier, are maintained regardless of the causes responsible for the barrier. Therefore, in order to choose between the two models, it is necessary to seek relations for which they would give rise to qualitatively different predictions.

The first group of phenomena for which significant differences between the conclusions reached on the basis of the two theories may be expected is associated with the pre-exponential factor, namely with the influence on the latter of the probability of a tunnel transition of the proton through the barrier. The correction for tunnelling within the framework of the bond extension model has been estimated in a number of studies. Without going into their analysis, we may note the common and most significant feature of all these investigations—in this model tunnelling is determined by the same barrier as the activation energy—the barrier along the proton coordinate. On the other hand, within the framework of the quantum-mechanical theory, the activation energy is determined by the barrier on the classical coordinate, describing the orientation of the solvent dipoles, and the probability of the transition under the barrier is determined by the energy profile along the proton coordinate. Thus in the first model the activation energy and the pre-exponential factor are linked by a definite relation, while in the second model they can in principle vary independently.

The existence of barrierless electrode processes, in particular the barrierless discharge of the hydrogen ion, for which the activation energy is equal to the heat of the fundamental step (see Krishtalik's review [2]), was demonstrated previously. In the bond extension model the barrierless process involves the absence of a barrier on the path followed in the motion of the proton and hence the absence of a tunnell effect. The implication is that in this model κ for the barrierless discharge should be unity, while in the usual discharge $\kappa < 1$. In the quantum-mechanical model the energy profile along the solvent coordinate is barrierless, while the barrier along the proton coordinate is retained. Thus this theory leads to the conclusion that values of $\kappa < 1$ are of similar order of magnitude for both the barrierless and the usual discharges§.

Theoretical calculation of the pre-exponential factor, particularly for electrode processes, by the method of the theory of absolute reaction rates involves certain difficulties concerning the estimation of the entropy of the activated state [24,25]. However, for a barrierless discharge all these difficulties disappear, because here the activated state is identical with the final state. This permits a fairly rigorous calculation of the theoretical value of the pre-exponential factor for the barrierless discharge [26]. The theoretical value $\lg k = 5.7$ (the pre-exponential factor k is expressed in A cm^{-2}) is much higher than the experimental value $\lg k = 3.0$. This discrepancy indicates a significantly non-adiabatic process ($\kappa = 10^{-2.7}$), i.e. a fairly low probability of proton transfer below the barrier. As shown above, $\kappa \ll 1$ for a barrierless discharge can be hardly explained by assuming that the extension of the O–H bond determines the activation process, but it can be naturally accounted for within the framework of the quantum-mechanical theory.

A similar conclusion can be reached also by comparing the pre-exponential factors for the barrierless and the usual discharges. In order to compare the tunnelling probabilities, it is necessary to compare ideal rather than real pre-exponential factors, i.e. a correction must be introduced for the change in the entropy of the electrode process and account must be taken of the concentration dependence of the pre-exponential factor. Such a calculation has been made [27] and showed that the tunnelling probabilities for the barrierless and the usual discharges are similar (the difference between them is within the

§ Since the experiments are performed at potentials close to the transition region, the possibility of a change from the quantum-mechanical to the classical motion of the proton discussed above need not as yet be taken into account here. The involvement of the first excited vibrational levels in the barrierless process together with the ground level can lead to an increase of κ.

limits of experimental error). This result also agrees with the quantum-mechanical theory, but is difficult to explain on the basis of the bond extension model.

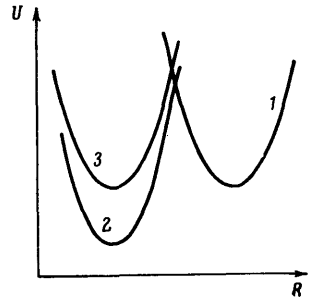

Figure 1. Schematic potential energy curves: 1) component describing the O–H bond; 2) and 3) components describing the M–H bond ($E_{M_2} > E_{M_3}$).

We shall consider the influence of the nature of the metal on the probability of proton tunnelling[28]. From the standpoint of the bond extension model (Fig. 1), the higher the energy of the M–H bond ($E_{M\text{-}H}$) the lower the height of the barrier for tunnelling and the narrower the barrier (the potential curve rises more steeply for a more rigid bond). Consequently Fig. 1 leads to the conclusion that tunnelling by the proton is facilitated by higher values of $E_{M\text{-}H}$. In the quantum-mechanical model the probability of the transition below the barrier increases with increased overlap of the wave functions of the proton in the initial and final states. The more rigid the bond the more highly localised the proton and the less effective the overlapping of the wave functions (Fig. 2). Therefore, within the framework of the given model, one may expect a decrease of tunnelling probability with increase of $E_{M\text{-}H}$. Fig. 3 shows that experiment agrees with this conclusion.

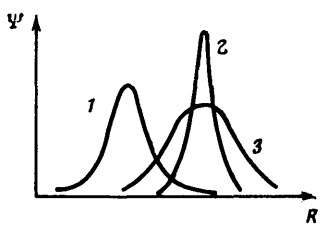

Figure 2. Wave functions of the proton in OH (curve *1*) and MH (curves *2* and *3*) ($E_{M_2} > E_{M_3}$).

The probability of tunnelling by the proton influences significantly another quantity susceptible to measurement—the isotope separation factor S. The experimental value is determined by kinetic isotope effects for two irreversible stages—discharge (S_d) and electrochemical desorption (S_{ed})[35,36]:

$$S = \frac{2S_dS_{ed}}{S_d + S_{ed}}. \qquad (9)$$

Electrochemical desorption on mercury and similar cathodes is highly exothermic, so that its activation energy should become zero[2,22,37].¶ If the activation process consists of the extension of the bond, then the non-activated electrochemical desorption should proceed at the same rate for all hydrogen isotopes, since there is no barrier to tunnelling by the proton and since, by virtue of the zero activation energy, the effect of the difference between the zero-point energies disappears. In other words, in this model $S_{ed} = 1$. But this implies that $S = 2S_d/(S_d + 1) \leqslant 2$. This conclusion is completely inconsistent with experimental data—as will be shown below, fairly large effects can be observed on mercury and similar metals ($S_{H/T}$ varies from 3 to 17). On the other hand, in the new quantum-mechanical theory this difficulty does not arise, because the non-activated process is associated solely with the absence of a barrier on the coordinate for the solvent dipoles, while the barrier persists along the proton coordinate[28].

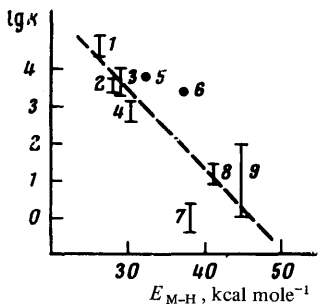

Figure 3. Variation of the pre-exponential factor for the hydrogen evolution reaction in acid solutions with the M–H bond energy: 1) 40.6 at.% thallium amalgam[29]; 2) lead[30]; 3) mercury[25,26,31]; 4) 60.3 at.% indium amalgam[32]; 5) gallium–16.4 at.% indium[31]; 6) gallium[31]; 7) silver (0.1 *N* HCl)[33]; 8) silver (0.1 *N* H_2SO_4);[33] 9) indium[34].

Within the framework of the bond extension model, the metal of the cathode influences S mainly because of its influence on the isotope effect at the discharge stage, since it affects S_{ed} much less (and in non-activated desorption not at all). If one considers the nature of the overlap of the proton wave functions in the initial and final states, it is seen that the change in the M–H bond energy acts in the same direction on tunnelling probability both in the discharge and in electrochemical desorption, i.e. both on S_d and on S_{ed}. The influence of the nature of the metal on tunnelling probability was considered above from the standpoint of both the models discussed. In agreement with the quantum-mechanical model and the experimental pre-exponential factors for the reaction, it was found[28] that an increase of the M–H bond energy, which hinders proton transfer under the barrier, increases the kinetic isotope effect.

¶ The conclusion that the electrochemical desorption of hydrogen from metals of the same type as mercury proceeds without activation energy is confirmed by the results of Rotenberg, Pleskov, and coworkers[38] (see below).

Experimental data indicate a significant lowering of the isotope separation factor with increase of the potential[28,39]. Within the framework of the bond extension model, this type of relation can be explained by a decrease of the activation barrier with increase of the potential and, accordingly, by the facilitation of tunnelling by the proton[40]. The new theory leads to the conclusion that there is no direct relation between the activation energy (barrier on the coordinate of the solvent dipoles) and the probability of proton tunnelling. The decrease of S with increase of the potential can be explained from this standpoint by the larger overlap of the wave functions for the initial and final states because of the approach of the hydronium ion to the electrode under the influence of the electric field. The validity of this explanation is evident from a comparison of the isotope effects in acid and alkaline solutions. In the latter the uncharged water molecule, which is naturally attracted to the electrode much less strongly than the H_3O^+ ion, serves as the proton donor. Its distance from the electrode hardly changes with potential and therefore there is no dependence of the isotope effect on the potential (Fig. 4).[28,41]

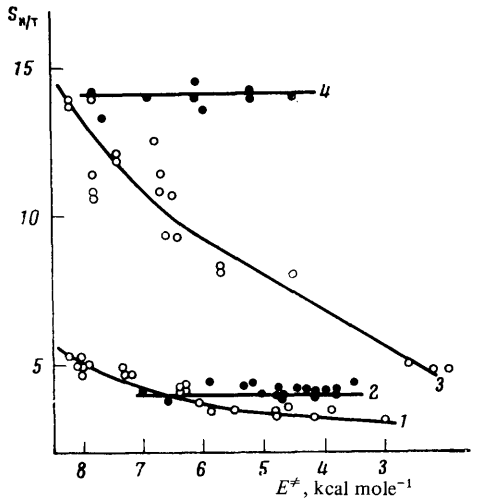

Figure 4. Variation of the separation factor for protium (H) and tritium (T) with activation energy: 1) mercury, acid[28,42]; 2) mercury, alkali[28,42]; 3) gallium, acid[28,41]; 4) gallium, alkali[41].

From the standpoint of the O–H bond extension model, there is no fundamental difference between the discharge of H_3O^+ and H_2O—in both cases the potential barrier is lowered with increase of the overvoltage and facilitation of tunnelling is to be expected. Fig. 4 shows that, for the same activation energies in acid and alkaline solutions, there is a significant difference between the variation of S with potential. This shows that, in full agreement with the new quantum-mechanical theory, there is no direct relation between the activation energy and the probability of tunnelling by the proton†.

The above explanation of the variation of S with potential presupposes that, with increase of the electric field, the pre-exponential factor for the discharge of the hydrogen ion should increase. In the study of the temperature dependence of the rate of this reaction over the usual, fairly narrow range of potentials this effect lies at the limit of experimental error (a weak tendency to change has been observed[31]), but it has been shown[44] that, on a silver cathode for potentials in the region of 1 V, the pre-exponential factor increases at least by two orders of magnitude.

The much weaker attraction of water molecules to the electrode compared with the H_3O^+ ion must result in a greater distance between the initial and final positions of the proton and hence in a smaller tunnelling probability. This conclusion has been fully confirmed experimentally—the ratio of the tunnelling probabilities for H_3O^+ and H_2O, found from the pre-exponential factors, is $10^{5.6}$ for gallium and $10^{4.8}$ for the indium–gallium alloy[31].

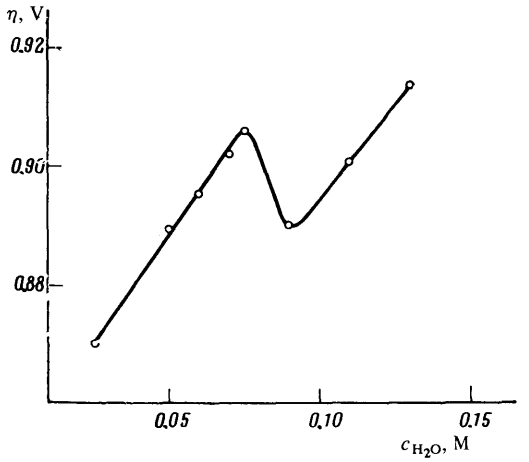

Figure 5. Variation of the hydrogen overvoltage (for $\log i = -4.0$) in 0.01 N $HClO_4$ solution in acetonitrile with the concentration of water.

Another approach to the study of the mechanism of the fundamental step in hydrogen evolution consists of employing a medium with properties significantly different from those of water. We chose the aprotic weakly basic solvent

† Christov[43] drew attention to the fact that, for certain parameters of the barrier on the proton coordinate, the optimum region for tunnelling is located at some distance from the top of the barrier, so that the tunnelling probability is independent of activation energy. This factor might explain, within the framework of the bond extension model, the constancy of S in alkaline solutions, but, on the one hand, there is no evidence that the real parameters of the barrier correspond to conditions necessary for this and, on the other hand, even with the aid of these additional hypotheses it is still impossible to account for the above data concerning the barrierless and non-activated processes and the influence of the nature of the cathode metal.

acetonitrile as a medium of this kind[45]. In anhydrous acetonitrile the hydrogen overvoltage of the mercury cathode in an acid solution is lower by about 150 mV than in water. After the addition of small amounts of water, which is a much stronger base than acetonitrile, hydronium ions are formed and the concentration of acetonitrilonium ions, which are the main proton donors, decreases. This leads to a corresponding increase of the overvoltage (Fig. 5). At a fairly high concentration of water the fraction of H^+ ions bound to the solvent becomes vanishingly small and hydronium ions become the main source of protons. From this instant, further addition of water decreases the overvoltage because the concentration of H^+ ions bound to water becomes virtually constant, while the concentration of the electrode reaction product (free water) increases. This results in a maximum on the curve in Fig. 5.

The hydronium ion can exist in acetonitrile both in the H_3O^+ form and as its association complex with one, two, or three water molecules (the last form predominates in aqueous solutions). Calculation based on Kolthoff and Chantooni's data[46] showed that, near the maximum on the curve in Fig. 5, the dominant species are $H_3O^+.H_2O$ and H_3O^+. This implies that the ion undergoing discharge is surrounded mainly by acetonitrile molecules. On the other hand, at a higher water concentration the fraction of $H_3O^+.2H_2O$ and $H_3O^+.3H_2O$ ions increases, i.e. the immediate coordination sphere of the H_3O^+ ion becomes increasingly similar to that in aqueous solution, which gives rise to a new increase of overvoltage. Although the mole fraction of water under these conditions is only 0.007 and the macroscopic properties of the medium have still not been able to change significantly, the micromedium near the hydronium ion becomes more "water-like" by virtue of the selective formation of hydrates and this has a significant influence on the kinetics of the discharge of the hydronium ion. Thus the influence of the change in the properties of the medium under the conditions of a virtually unchanged type of bond dissociation process are clearly manifested in these experiments.

Pre-exponential factors and activation energies.

Ion undergoing discharge	Medium	A_0, kcal mole^{-1}	lg k (A litre mole^{-1} cm^{-2})
CH_3CNH^+	CH_3CN	18.2	2.1
H_3O^+	CH_3CN	18.2	3.2
H_3O^+	H_2O	21.9	3.4

The influence of the medium and of the nature of the bond being ruptured is shown even more clearl y when the pre-exponential factors and the activation energies for the discharge of acetonitrilonium and hydronium ions are compared in acetonitrile and in water. All the pre-exponential factors in the Table have been recalculated for the same concentration of H^+ ions and for the same mole fraction of the conjugate base, which is unity (this correction, which is necessary to compare the data, was introduced for H_2O in the discharge of H_3O^+ in acetonitrile).

The Table shows that the discharge of the CH_3CNH^+ and H_3O^+ ions in acetonitrile solutions is characterised by significantly different pre-exponential factors and virtually the same activation energies, while the discharge of H_3O^+ in the two different media (water and acetonitrile) is characterised by virtually identical pre-exponential factors but different activation energies. Thus it has been found that the pre-exponential factor is determined mainly by the nature of the bond dissociated (N–H or O–H), while the activation energy depends on the solvent (acetonitrile or water). This conclusion is fully consistent with the predictions of the theory, according to which the activation energy is determined by the rearrangement of the structure of the medium and the pre-exponential factor is determined by the probability of tunnelling by the proton. On the other hand, from the standpoint of the bond-extension model, both the pre-exponential factor and the activation energy are determined by the bond undergoing dissociation, so that different relations are to be expected—similarity of the activation energies for the discharge of H_3O^+ ions in acetonitrile and water and different values of A_0 for the discharge of CH_3CNH^+ and H_3O^+ in acetonitrile. Thus different experimental data support a mechanism of proton transfer which relates the activation process only to a rearrangement of the structure of the medium without a significant extension of the bond between the proton and the proton donor.

Another aspect of the problem of the fundamental step in hydrogen evolution, which has been studied in the very last few years, is the nature of the rapid stage—the removal of adsorbed hydrogen. In their studies by the photoemission method Rotenberg, Pleskov, and coworkers[38] succeeded in determining the sum of the transfer coefficients for two reactions involving the removal of adsorbed hydrogen—electrochemical desorption and ionisation. For the mercury cathode in the range of potentials susceptible to investigation, it was found to be 0.5, which supported the hypothesis that one of the stages has no activation energy (most probably electrochemical desorption). On the other hand, for the bismuth cathode it was possible to attain potentials at which the above sum became zero, i.e. the possibility that both reactions can occur without activation energy was demonstrated.

Non-activated electrochemical desorption of hydrogen from metals of the same type as mercury was found to be fully irreversible (at least at overvoltages susceptible to measurement). This follows unambiguously from the isotope separation factor, which exceeds significantly the equilibrium constant for the isotope exchange between hydrogen and water[47].

The irreversibility of electrochemical desorption leads to the appearance of a new interesting phenomenon- a non-equilibrium ratio of the ortho- and para-modifications of hydrogen in the gas evolved on electrolysis at reduced temperatures[48,49]. A theory of this phenomenon was developed recently within the framework of the general quantum-mechanical theory of proton transfer[49].

In the hydrogen evolution reaction the species transferred (the proton) behaves significantly in accordance with the quantum-mechanical mechanism. Another situation arises in the transfer of heavy ions, linked by weaker bonds, i.e. their motion takes place in accordance with both the classical and quantum-mechanical mechanisms. As shown above, this feature of systems with heavy atoms leads to the occurrence of quasi-barrierless and quasi-non-activated processes characterised by $\alpha = 1$ and $\alpha = 0$ respectively. In this case the barrier disappears only for motion along the solvent coordinate, but remains on the heavy atom coordinate. However, the latter barrier does not change with the potential, so that α is determined only by the motion along the solvent coordinate.

The existence of quasi-barrierless processes was postulated previously for the chlorine evolution reaction on graphite and for the oxidation of azide on platinum [2]. The occurrence of quasi-barrierless and the reverse quasi-non-activated processes was recently demonstrated unambiguously for the evolution and ionisation of chlorine on ruthenium–titanium oxide anodes (RuO_2–TiO_2 solid solution). This process proceeds in stages:

$$Cl^- \overset{-e}{\rightleftarrows} Cl_{ad} \overset{-e}{\rightleftarrows} Cl^{+I} + Cl^- \rightleftarrows Cl_2.$$

The slow stage, involving the abstraction of the second electron, can be both of the usual type ($\alpha_a = 1/2$) and of the quasi-barrierless type ($\alpha_a = 1$), while in the opposite direction it is a quasi-non-activated process ($\alpha_c = 0$). If the slow stage were not of the quasi-barrierless type but simply of the barrierless type, i.e. if the abstraction of the second electron were not followed by the relaxation process involving a change in the heavy particle coordinate, then the second and third stages would have occurred as a single step and the reaction would have been of second order with respect to chloride ions. The experimental first order of the reaction demonstrates the quasi-barrierless nature of the electrode process [50].

The Electrical Double Layer Capacitance and the Zero-charge Potentials of Metals in a Solid Electrolyte

S.V.Karpachev, I.D.Remez, V.V.Sal'nikov, and A.T.Filyaev

Studies of the properties of the electrical double layer and of the zero-charge points for certain metals in a solid electrolyte consisting of stabilised zirconium dioxide are reviewed. The influence of the electrode potential, temperature, and composition of the gas phase on the double layer capacitance and the zero-charge point is examined. A correspondence is established on the basis of experimental data between the potential of the minimum on the "capacitance-potential" curve and the zero-charge points for tin and silver.
The bibliography includes 16 references.

I. INTRODUCTION

As a result of research by Frumkin and his school, the importance of studies of the structure of the electrical double layer and zero-charge potentials for electrochemical kinetics has now been demonstrated. In a study of the cathodic evolution of hydrogen from acid aqueous solutions Frumkin et al.[1] discovered the dependence of the overvoltage on the concentration of an extraneous electrolyte at a constant current density and acid concentration. They showed that this is due to the influence of the added neutral electrolyte on the double layer structure (on the ψ_1 potential). Furthermore, Frumkin showed[2] that in the cathodic reduction of complex anions the current decreases sharply until the attainment of the zero-charge potential owing to the increasing diffuseness of the double layer. This effect was established for several metals, the zero-charge potentials of which are appreciably different.

Electrochemical cells with an electrolyte consisting of stabilised zirconium dioxide have now acquired great practical importance and for this reason a more profound study of the electrochemical kinetics in solid electrolytes has become necessary; the investigation of the properties of the electrical double layer and of the zero-charge potentials of metals in the stabilised zirconium dioxide solid electrolyte has begun. The experimental data obtained for this new type of electrolyte are extremely interesting in the light of the theoretical ideas developed by Frumkin and his school.

II. EXPERIMENTAL DATA FOR THE STRUCTURE OF THE ELECTRICAL DOUBLE LAYER IN SOLID ELECTROLYTES

The first measurements of the double layer capacitance in the stabilised zirconium dioxide electrolyte were made by ourselves on a platinum wire electrode[3]. The dependence of the electrical double layer capacitance on potential is presented in Fig. 1. The capacitance–potential curves have a distinct minimum at a specific potential. The measurements were made at 1020°C in an electrolyte having the composition 85 mole % ZrO_2 + 15 mole % CaO in an atmosphere of argon freed from oxygen by being passed over metallic calcium at 650°C. All the measurements were performed at 10 kHz with the capacitance and resistance connected in series in one of the arms of an a.c. bridge. It was subsequently established that at 10 kHz there is still some dispersion of the capacitance and therefore the measured capacitance values involve an error; however, the type of the variation of the capacitance with potential is probably correct.

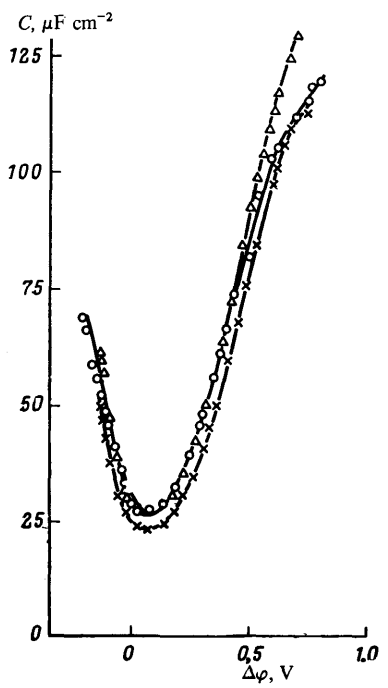

Figure 1. Variation of the differential electrical double layer capacitance with potential on a platinum electrode. The reproducibility of the results for three specimens is indicated.

We assumed that the dispersion of the capacitance at such comparatively high frequencies is due to the low value of the Faraday impedance caused by the high temperature. Hence it was necessary to carry out experiments at higher frequencies. Furthermore, it was desirable to employ as the test electrode a drop of fused metal rather than the solid metal. Evidently in this case the surface area of the junction between the electrode and the electrolyte, determined from geometrical dimensions, is closer to the true value.

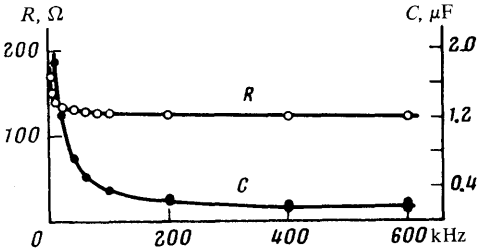

Figure 2. Variation of the capacitance and resistance with frequency.

The double layer capacitance was measured for liquid silver and tin drops at the equilibrium potential in the same electrolyte at 970°C in an atmosphere of purified argon[4]. The electrode potentials were determined with the aid of an electrochemical gas-analyser, which consisted[5] of a ceramic test-tube made of stabilised zirconium dioxide with platinum electrodes attached to its inner and outer surfaces. The test-tube was positioned so that the outer electrode was in the gas space of the electrochemical cell and the inner space of the test-tube communicated with the atmosphere. The potential difference arising in the electrochemical concentration cell between the platinum electrodes made it possible to determine the oxygen pressure in the gas space of the cell; it amounted to 10^{-12}–10^{-14} atm. The impedance of the second platinum electrode (which was deposited on the surface of the solid electrolyte plate on the side opposite to that containing the drop) was neglected because of its large area. Separate experiments established that the auxiliary electrode was virtually unpolarised under the experimental conditions.

Fig. 2 presents curves characterising the dispersion of the resistance R and the capacitance C. The values of R and C were recalculated for a series-connected circuit. Evidently at a frequency of about 500 kHz a constant capacitance is reached and the measurements were made at this frequency. Having estimated the surface area of the junction between the metal drop at the electrolyte, the specific capacitance of the double layer was determined approximately. For silver and tin, it was found to be the same (20 μF cm^{-2}).

Somewhat later we made a detailed study at 970°C of the dispersion of the capacitance and resistance[6] using zirconium dioxide stabilised by yttrium oxide as the electrolyte. The oxygen pressure in the cell was maintained in the range 10^{-12}–10^{-14} atm, as before. The dispersion of the capacitance was investigated as a function of the yttrium oxide content in the solid electrolyte and the electrode potential. It was established that the capacitance in the series-connected circuit becomes constant at a frequency of 600 kHz. In the range of frequencies from 400 to 600 kHz the capacitance changed insignificantly—by up to 10%; therefore all subsequent experiments were performed at a frequency of 400 kHz, since the error in the measurement of the impedance components increased with a.c. frequency. This suggests that, with the series-connected resistance and capacitance, whose impedance is equal to that of the cell, the resistance refers to that of the electrolyte and the capacitance is that of the electrical double layer.

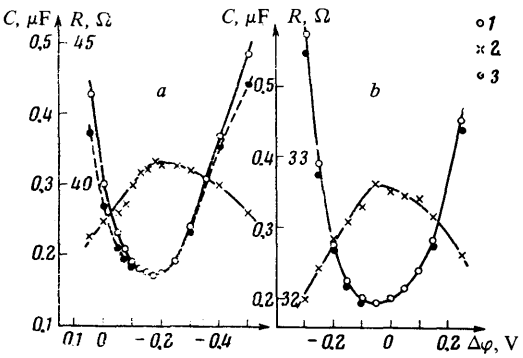

Figure 3. Variation of the differential electrical double layer capacitance (*1*) and of the resistance of the electrolyte (*2*) with polarisation for liquid silver and tin drops: *a*) tin; *b*) silver; points *3* represent the variation of the capacitance with allowance for the change in the area of the electrode/electrolyte junction as a result of the spreading of the drop.

We regarded the method described as satisfactory and used it to investigate the double layer capacitance on liquid silver and tin drops. The electrolyte disc had a diameter of 17 mm and was 1.8 mm thick; the diameter of the metallic drops was 0.7–1.0 mm. The decrease of the potential in the electrolyte may be neglected in view of the low polarising currents and the high conductivity of the electrolyte. Since the surface area of the platinum electrode was large, its contribution to the measured capacitance was neglected. The potential of the test electrode was reckoned relative to an air reference electrode.

Fig. 3 presents curves relating to the capacitance of the liquid silver and tin electrodes to polarisation. They have a deep minimum at specified potentials. The potentials of the minima on the capacitance curves for silver and tin are respectively −1.08 and −1.29 V. Curves relating the capacitance to the potential at different oxygen pressures in the gas phase were also obtained and it was found that a change in oxygen pressure does not affect the shape of the curves and the positions of the potential minima. One may conclude that the test electrodes are reversible with respect to oxygen. For this reason, regulation of the potential by altering the oxygen pressure in the gas phase or by polarisation with a direct current leads to the same result.

Fig. 3 also presents curves for the variation of the resistance of the electrolyte with electrode polarisation,

which has a distinct maximum. This can be explained by the fact that the surface tension at the boundary between the liquid drop and the solid electrolyte varies with polarisation, and hence the area of the junction between the drop and the electrolyte also varies. There is reason to believe that the resistance maximum corresponds to the interfacial tension maximum, i.e. to the zero-charge potential of the metal. Since the minimum on the capacitance curve and the maximum on the resistance curve occur at virtually the same potential, one may say that the potential of minimum capacitance coincides with the zero-charge potential. It might have been supposed that, owing to the variation of the area of the junction mentioned above, there is a change in the dependence of the capacitance on the potential and in the potential of minimum capacitance. However, the electrolyte resistances at different potentials show that this effect is very small and does not alter either the potential of minimum capacitance or the variation of the capacitance with potential (Fig. 3, dashed curve).

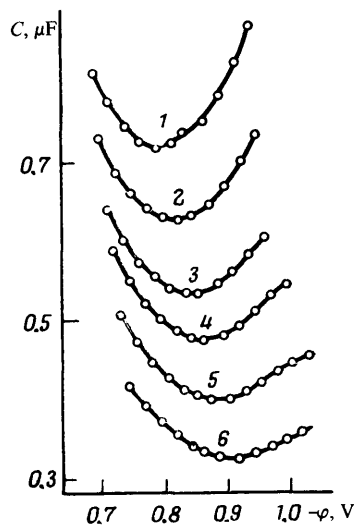

Figure 4. Variation of the electrical double layer capacitance with potential for a liquid silver electrode at different temperatures (°C): 1) 1123; 2) 1093; 3) 1060; 4) 1032; 5) 1001; 6) 969.

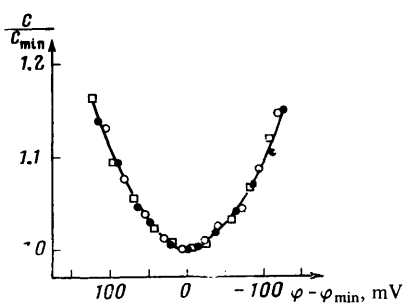

Figure 5. Variation of C/C_{min} with $\varphi - \varphi_{min}$ for three temperatures (1123°, 1060°, and 969°C); C is the electrical double layer capacitance at a potential φ and C_{min} and φ_{min} are the capacitance and potential corresponding to the minimum on the curve (see Fig. 4).

The temperature variation of the double layer capacitance was studied in the temperature range 970–720°C in an atmosphere of helium at a frequency of 400 kHz for a silver electrode in an electrolyte to which 8 mole % of yttrium oxide had been added[7]. The results (Fig. 4) show that the minimum capacitance increases with temperature and the minimum itself becomes somewhat sharper on the corresponding curves. However, when the capacitance is referred to its minimum value at a given temperature, then the points for all six temperatures fit on the same curve (Fig. 5). Hence one may conclude that the variation of the capacitance with potential is of the same type over the entire experimental temperature range. Indeed, if the shape of the curves were partly determined by the Faraday process, it would be difficult to expect such an agreement. Since the points on the $\lg C - 1/T$ curve fit satisfactorily on a straight line, one may conclude that the double layer capacitance increases exponentially with temperature over the entire experimental range of potentials. Similar capacitance–potential curves were obtained also in fused electrolytes[8].

III. ZERO-CHARGE POTENTIALS OF METALS

The capacitance–potential curves for dilute aqueous solutions also have a minimum coinciding with the zero-charge potential in the case of a symmetrical electrolyte. For aqueous solutions, a theory of this phenomenon was devised by Frumkin. However, there is as yet no corresponding theory for solid and fused electrolytes. Therefore further studies on the double layer capacitance at the boundary between liquid metals and a solid electrolyte are necessary, measurements of this kind in electrolytes with different defective structures and for a wider range of metals being particularly needed.

The zero-charge potentials of liquid silver, tin, gold, and copper were determined in the electrolyte 0.887 ZrO_2 + 0.08 Y_2O_3 + 0.04 Al_2O_3.[9] The solid electrolyte consisted of a disc 17 mm in diameter and 2–3 mm thick. The metal drop diameter was 2–3 mm. The electrolyte discs were prepared by the method already described. The measurements on silver and tin were made at 1085°C, on gold at 1190°, and on copper at 1174°C in an atmosphere of purified helium. The pressure of oxygen in helium was 10^{-12}–10^{-14} atm. The helium was freed from oxygen and the residual oxygen pressure was determined as in the measurements of the electrical double layer capacitance.

The zero-charge potential was determined by measuring the variation of the wetting angle θ with the potential. The wetting angle was determined from photographs of the drop profile, and $\cos\theta$ was plotted against φ. Under the conditions of a constant composition of the gas atmosphere, at the potential corresponding to zero charge the angle θ has the minimum value and the $\cos\theta - \varphi$ curves passed through a maximum. The platinum electrode, deposited on the lower side of the disc, was used to polarise the drop with a direct current. The test electrode potential was measured relative to an air reference electrode.

The curves obtained for silver and tin are presented in Fig. 6. Relative to the air reference electrode, the zero-charge potentials of silver and tin are respectively −0.97 and −1.23 V.[9] The high experimental temperature and the test metals were chosen so that the equilibrium oxygen pressure over the metal oxides was greater than the residual oxygen pressure in the cell at a given temperature. The following factor is striking. The difference between the zero-charge potentials of silver and tin

is $\varphi_0^{Ag} - \varphi_0^{Sn} = 0.26$ V. On the other hand, the difference between the potentials corresponding to the minimum double layer capacitances on the same metals is $\varphi_C^{Ag} - \varphi_C^{Sn} = 0.21$ V. These results show that the difference between the potentials of minimum capacitance for silver and tin is approximately the same as the difference between their zero-charge potentials. The agreement may be regarded as satisfactory bearing in mind that the accuracy of the determination of the zero-charge potentials is to within 25 mV.

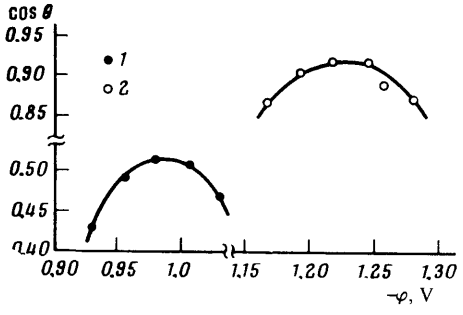

Figure 6. Variation of the cosine of the wetting angle with potential: 1) silver; 2) tin.

In a study of the correspondence between the potential of minimum double layer capacitance and the zero-charge potential in solid electrolytes[10] it was shown that such agreement can be accounted for when certain assumptions are made concerning the structure of the surface solid electrolyte. It is quite possible that such correspondence does not always obtain in solid and fused electrolytes.

The results of the measurements of the zero-charge potentials were adjusted to the same temperature (1085°C) by the procedure of Remez et al.[11] and are given in the Table.

The zero-charge potentials φ_0^M (M = metal).

Metal	Solid electrolyte		Aqueous electrolyte
	φ_0^M relative to air electrode, V	φ_0^M relative to φ_0^{Sn}, V	φ_0^M relative to φ_0^{Sn}, V
Silver	−0.97	+0.26	−0.32
Gold	−0.99	+0.24	+0.56
Copper	−0.85	+0.38	+0.47
Tin	−1.23	0.00	0.00

The values recommended by Leikis et al.[12] were used as the zero-charge potentials in aqueous solutions. The greatest difference relative to aqueous solutions is observed for silver. The zero-charge potentials of gold are of the same sign, but differ by 0.32 V. The difference for copper is a minimum (0.09 V). The experimental data obtained are insufficiently extensive to reach general conclusions on their basis. However, one may say a few words about the tabulated data.

Frumkin[1] demonstrated convincingly the role of the adsorption of not only ions but also neutral molecules both with and without intrinsic dipole moments. Furthermore, Frumkin[13] put forward the idea that, under certain conditions, the difference between the zero-charge potentials of two metals may be equal to the difference between their electrode work functions. Later Frumkin and coworkers[14] devised a detailed theory of this effect in which account is taken of the different degrees of adsorption of solvent molecules, particularly water molecules, on different metals. However, it is hardly useful to make such a comparison under the conditions of our experiments, since the electrode work functions of the metals investigated were determined at room temperature and our experimental temperature was in excess of 1000°C; it is necessary to determine the electrode work functions of the metals at high temperatures. Nor can one rule out the possibility that in our case adsorption, which may be different for different metals, plays a role in the zero-charge potential jump. For example, one may postulate the adsorption of oxygen ions or their vacancies.

The results of a study of the effect of carbon monoxide at the zero-charge potentials of silver and tin must be considered[15]. The experimental technique was as described above. When the gas phase contained 50 mole % of carbon monoxide, the zero-charge potential of silver was found to be −1.16 V relative to the air reference electrode. As stated above, in an atmosphere of helium this potential is −0.97 V. Thus the zero-charge potential of silver was displaced in the negative direction by 0.19 V as a result of the presence of carbon monoxide in the gas phase. The zero-charge potential of tin in the presence of 50 mole % of carbon monoxide was found to be −1.21 V, the corresponding value in helium being −1.23 V. The difference of 0.02 V is within the limits of the error of the measurements and one may assume that the change in the gas phase did not affect the position of the zero-charge point for tin.

The above shift of the zero-charge potential of silver can be tentatively explained by the adsorption of carbon monoxide molecules at the interface. Possibly chemisorption takes place in the present instance. The carbon monoxide molecule has a comparatively small dipole moment (0.12×10^{-18} absolute electrostatic units), but one cannot rule out the possibility that, as a result of adsorption, it acquires a larger dipole moment. It is appropriate to mention here our studies of the differential double layer capacitance on silver in an atmosphere of CO_2 and CO at 970°C.[16] The dependence of the capacitance on the potential was investigated and, as in an atmosphere of helium, curves with a deep minimum were obtained. The minimum capacitance increases with the CO content in the gas phase and the potential corresponding to the minimum on the curves also shifts in the negative direction.

Electrochemical Methods of Studying Transfer Processes in Liquids

R.Sh.Nigmatullin, B.A.Kader, V.S.Krylov, and L.A.Sokolov

The theoretical basis of the electrochemical method of studying mass and momentum transfer in solid-liquid systems is outlined. Published work on the most important practical applications of the method is reviewed, including electrochemical modelling of heat and mass transfer processes, measurement of averaged and spectral hydrodynamic characteristics of the interaction between a flow of liquid and a solid surface, and the study of the fine structure of turbulent boundary layers. Theoretical and practical problems arising in electrochemical transducers are discussed. 135 references.

I. INTRODUCTION

Modern scientific research relies increasingly on new instrumental means of obtaining information without using transducers liable to distort (to a greater or lesser extent) the phenomenon under study. Notable new techniques in the field of hydrodynamics and convective heat and mass transfer, which includes processes of outstanding importance in chemical and electrochemical technology, are laser anemometry, the radioactive indicator method, shadow photography, flow visualisation, etc. A special place among these methods belongs to the electrochemical method, in which an electric current is used as a measure of the rate of mass transfer from a flow of electrolyte solution to a conducting solid surface (the electrode).

The first attempts at electrochemical modelling of mass transfer processes in systems with a given configuration of hydrodynamic flows took place in the late 1940's and early 1950's [1,2]. More recently numerous groups of workers have demonstrated and examined in detail the possibilities of the method, and established its power in studies of transfer and exchange processes in liquid–solid and gas–liquid systems. The electrochemical method allows us to probe the structure of laminar and turbulent boundary layers (where the main resistance to heat and mass exchange resides), to obtain information on the fine structure of the turbulent flow in the viscous sub-layer of the boundary layer, to measure local values of the electrokinetic potential and of the rate of mass transfer, to investigate spatial and time correlations between local properties of hydrodynamic, concentration, and thermal fields, and to model the dynamic characteristics of many types of heterogeneous process of practical interest. As well as being very accurate and reproducible, electrochemical measurements are free from heat losses, they do not alter the area of the interfacial surface, and they are simple and convenient.

In recent years the electrochemical method of measuring viscous friction and of modelling heat and mass transfer processes in turbulent and in laminar flows has attracted the attention of researchers in many countries, including the USSR, USA, Germany, France, Japan, and others. The aim of this paper is to review the most important developments in the use of the electrochemical measurement method and of electrochemical modelling, to present the most interesting and useful results, and to discuss some problems in the theory of electrochemical transducers and some practical difficulties encountered in the application of this very valuable method of investigation.

II. PRINCIPLES OF THE MEASUREMENT OF THE RATE OF ELECTROCHEMICAL MASS TRANSFER UNDER STABILISED FLOW CONDITIONS

The electrochemical method of studying mass transfer relies on measuring the current density of an oxidation–reduction reaction at the surface of an electrode mounted in the wall of the vessel or exposed to the flow in some other way: under the chosen conditions the magnitude of the reaction current is determined by the hydrodynamic conditions of the process by which the reacting ions are supplied to the working electrode (concentration polarisation regime). In this case all the processes occurring at the working electrode (and therefore also the current flowing in the electrochemical cell consisting of a current source, anode, cathode, and flowing electrolyte) are described with sufficient precision by a system of hydrodynamic equations combined with the equations of convective mass transfer. The reaction rate is usually much greater than the rate of arrival of ions at the electrode surface by convective diffusion and migration, and therefore we can assume to a very good approximation that the concentration of reacting ions at the surface of the transducer is zero ($c_w = 0$). Hence the driving force of the ionic mass transfer ($c_0 - c_w$) is equal to the concentration of the ions at a point far removed from the electrode (c_0). Purely diffusional mass transfer is achieved by adding to the working solution an excess of an indifferent electrolyte which does not react electrochemically at the electrode

but minimises the contribution of electromigration to the transport of reacting ions. A typical current–voltage characteristic for a reaction showing concentration polarisation is reproduced in Fig. 1 together with a diagram of the circuit arrangement. In most cases the momentum associated with the substances taking part in the electrochemical reaction is small compared to the momentum of the solvent. Hence the properties of the hydrodynamic flow surrounding the electrode are practically unaffected by the electrochemical reaction.

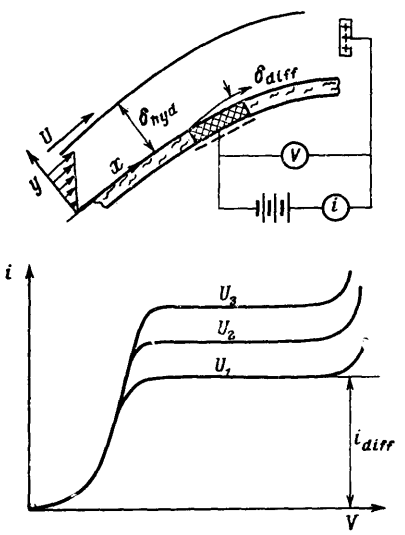

Figure 1. Schematic of the electrochemical measurement method and current–voltage characteristics for different flow rates of the solution ($U_1 < U_2 < U_3$): x is the spatial co-ordinate in the flow direction, y is the co-ordinate at right angles to the flow, δ_{hyd} is the effective thickness of the hydrodynamic boundary layer, δ_{diff} is the effective thickness of the diffusion boundary layer, i is the measured current, V is the voltage applied to the measuring cell, i_{diff} is the limiting diffusion current.

Often the size of the electrode in the flow direction (along the x axis) can be made much smaller than the characteristic hydrodynamic dimension, e.g. the cross-sectional diameter of a streamlined body or the distance from the electrode to the point of entry of the hydrodynamic flow. Hence, and with very few exceptions (for example, when very high pressure gradients are present in the system), the potential due to viscous fraction remains practically constant over the electrode surface. Constant tangential stress at the wall is a characteristic condition of systems consisting of a body immersed in a flow of liquid. A system of this type has been used[3] to study, by the electrochemical method, the detachment of a transverse flow surrounding a circular cylinder.

In any practical application of the electrochemical method it is important to bear in mind the following limitations, which apply to the chosen electrochemical reaction and electrolyte.

1. The reaction should not generate any products capable of disturbing the hydrodynamic conditions near the electrode.
2. The concentration polarisation at the measuring electrode should not be large enough to give rise to side reactions, which would alter the limiting diffusion current.
3. The reaction rate should be high enough to ensure that the effect of activation polarisation is negligible.
4. The reaction at the anode should be the inverse of the reaction at the cathode, to ensure that the concentration of the ions reacting at the working electrode remains constant during the experiment.
5. The composition of the electrolyte should be chosen so as to minimise the contribution of migration to the ionic mass transfer.
6. The electrolyte should be readily available in a pure form, adequately stable in solution, and it should offer a wide range of physical properties (viscosity, molecular diffusion coefficient, etc.).
7. The physical properties of the electrolyte (density, viscosity, diffusion coefficient, etc.) as well as their temperature and concentration dependence should be known with sufficient precision.
8. The electrolyte composition and the electrode reaction should be chosen so as to ensure reliable measurement of the limiting diffusion current in the concentration polarisation regime.

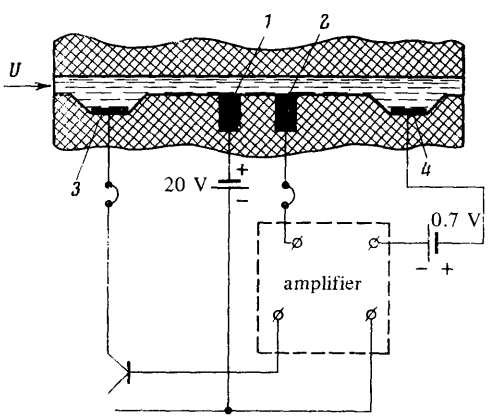

Figure 2. Electrochemical method employing two measuring electrodes: *1*) electrode for injecting electrically active material into the solution, *2*) electrode for monitoring the rate of transport of electrically active material by the flow, *3*) and *4*) auxiliary electrodes.

Two modifications of the electrochemical method have been described. The first relies on a single measuring electrode (transducer), which forms a reversible redox system with the electrolyte (see Fig. 1). The output signal of this transducer is the limiting diffusion current. Most of the published work on hydrodynamics and mass transfer was done by this method. However, the one-electrode transducer has a number of shortcomings, including excessive sensitivity of the calibration to the concentration of the species responsible for charge transfer at the interface, and also to the blocking of surface sites during the experiment.

The second modification of the electrochemical measuring system comprises two electrodes located at different points in the flow (Fig. 2). The first two-electrode flow-through cell (in the "disk and ring" configuration) was proposed by Frumkin and Nekrasov[4] for electro-analytical measurements. The electrically active products are generated by an electrochemical reaction in the central area of a rotating disk electrode, and detected by a peripheral, annular electrode mounted on the same disk. Many alternative forms of this system were subsequently developed for investigating the transport properties of liquids and gases and the special features of homogeneous and heterogeneous processes complicated by ionic mass transfer in solutions[5].

A cell consisting of a plane-parallel channel with two parallel strip electrodes separated by a narrow gap and mounted in one wall at right angles to the flow[6] offers a number of advantages over the "disk and ring" configuration. It is easier to construct, and it gives a theoretical description of the velocity and concentration profiles in a convenient analytic form. If the inter-electrode gap is small enough to allow the boundary diffusion layers to overlap, the measured current densities can give information on the hydrodynamic structure of the boundary layers under both the laminar and the turbulent flow regime. If the relationship between the measured limiting diffusion current and the parameters of the boundary layer velocity profiles is known in an analytic form we can determine the local hydrodynamic parameters of the flow with high precision (for example, the distribution of the average tangential stress at the wall, the spectral characteristics of the velocity and surface friction pulsations, etc.). Analytic solutions of the convective mass transfer problem, applicable in correlation measurements under laminar flow conditions, have been obtained for both the above forms of the two-electrode measuring cell[7-12].

III. CAPABILITIES AND ADVANTAGES OF THE ELECTROCHEMICAL METHOD

Electrochemical transducers are most effectively employed in modelling convective heat and mass transfer processes in liquids[1-12], and also in measurements of viscous flow stresses at the boundary between a turbulent liquid and a solid wall[13-18]. Electrochemical measurements are free from many of the difficulties associated with the methods traditionally used in experimental hydrodynamics, thermo-physics, and chemical technology. Thus even the first attempts at modelling mass exchange[1-3] were successful in demonstrating and exploiting the advantages of the electrochemical method. From a practical standpoint the most important of these advantages are the following.

1. Absence of thermal gradients, which introduce variations in the physical properties of the liquid across the thickness of the boundary layer.
2. The experimental analysis can be extended to the region of relatively high Prandtl numbers, where the temperature dependence of the properties of the liquid becomes most important.
3. In contrast to methods based on dissolution of the wall followed by measurement of weight loss, the electrode surface remains unchanged throughout the experiment.
4. Local measurements of the rate of mass transfer can be attempted because the electrode is only a few microns long in the direction of the flow.

Recent work on the measurement of boundary layer friction[19-23] has convincingly demonstrated the power of the electrochemical method and highlighted its advantages over the more traditional thermo-anemometric method. Firstly, electrochemical friction transducers are practically free from thermal losses, which are very difficult to estimate in thermo-anemometric transducers (especially the thin-film variety). Secondly, the liquid flowing round the solid body can be used as the working electrolyte in the electrochemical method, whereas the thermo-anemometric method requires a different, often very reactive, liquid. Thirdly, and this is very important, the diffusion coefficient of solutes is often several orders of magnitude smaller than the thermal diffusivity coefficient, and therefore (other conditions being equal) the information on the hydrodynamic flow reaches the electrochemical transducer from liquid layers closer to the solid surface than in the thermo-anemometric method. This is the reason why the electrochemical method was chosen to solve a number of fundamental problems concerning the fine structure of the viscous sub-layer. On of these problems was to establish in a functional form the law governing the change in the effective turbulent transport coefficients near a solid wall.

Some entirely new methods of studying boundary layer transport processes in gas–liquid flows have been developed[24] on the principle of electrochemical measurements. The problem of modelling tubular heat exchangers in chemical reactors has been largely resolved by an electrochemical study[25] of the interaction between the surface diffusion layers of closely spaced horizontal cylinders with their axes parallel and in the same vertical plane. The electrochemical method has been used with success also in measurements of large-scale velocity and pressure pulsations in the volume of a turbulent flow[26] and in the boundary layer detachment region[27].

IV. GENERAL THEORETICAL PROBLEMS

A large number of papers have been written on the theory of the electrochemical method of measuring rates of mass and momentum transfer[2,3,9-18,28-33]. Since the greatest theoretical and practical interest resides in the turbulent flow case we shall confine the discussion which follows to the present status of the theory of electrochemical transducers operated in the turbulent flow regime of the electrolyte solution.

1. Description of the Operation of Electrochemical Transducers in Terms of the Diffusional Boundary Layer Theory

The transducers best suited to the measurement of local characteristics of boundary layers have small dimensions in the direction of the mean flow. It becomes even more important to minimise the size of the transducer when we wish to measure the pulsation characteristics of the boundary layer, because in these measurements the sensitivity of the transducer decreases as its size increases (owing to the random changes in the magnitude of boundary layer friction along the transducer surface). An alternative explanation of the decrease in sensitivity with increase in size of the transducer is the averaging (over the transducer surface) of the current oscillations produced by various perturbations over distances smaller than the characteristic dimension (length) of the mass transfer region. For this reason the diffusion transducer is insensitive, in this region of geometrical dimensions,

to the fine structure of the spectrum of turbulent pulsations. We shall therefore discuss, in the first instance, only those transducers having sufficiently small dimensions in the direction of flow.

Consider an electrode of width h and length l, integral with the surface exposed to the flow, and located in the region of uniform tangential stresses. We shall impose the condition $l \ll h$, so that end effects at right angles to the flow direction can be ignored. This condition is satisfied, for example, by a ring electrode mounted flush with the tube wall in the region of hydrodynamically stabilised flow. We shall assume that the liquid flowing past the transducer contains a uniformly distributed passive additive at concentration c_0 (i.e. an additive which does not affect the flow dynamics). Let the origin of the spatial co-ordinates be at the front edge of the transducer, with the x axis along the direction of flow and the y axis at right angles to the planar wall. The stationary diffusion equation for planar turbulent two-dimensional flow, which applies in the regions where the passive additive is neither being generated nor consumed, can be written

$$\bar{u}_x \frac{\partial \bar{c}}{\partial x} = \frac{\partial}{\partial x}\left(D\frac{\partial \bar{c}}{\partial x} - \overline{u_x'c'}\right) + \frac{\partial}{\partial y}\left(D\frac{\partial \bar{c}}{\partial y} - \overline{u_y'c'}\right), \quad (1)$$

where the primes denote the pulsations of the instantaneous values with respect to their mean values. This equation can be solved by a number of procedures, the simplest of which (proposed by Boussinesq [34]) assumes a linear relation between the turbulent flows $\overline{u_x'c'}$, $\overline{u_y'c'}$ and the gradient of the mean concentration of additive. In the general case of an anisotropic velocity field Boussinesq's hypothesis can be formulated as

$$\overline{u_x'c'} = -K_{xx}\frac{\partial \bar{c}}{\partial x} - K_{xy}\frac{\partial \bar{c}}{\partial y}, \quad \overline{u_y'c'} = -K_{yx}\frac{\partial \bar{c}}{\partial x} - K_{yy}\frac{\partial \bar{c}}{\partial y}, \quad (2)$$

where the coefficients of the turbulent diffusion tensor (K_{ij}) are functions of the x and y co-ordinates. Most of the published theoretical work based on the hypothesis (2) assumes, often without justification, that the x and y axes are the main axes of the K_{ij} tensor, i.e. that $K_{xy} = K_{yx} = 0$. Other supplementary conditions have also been postulated, for example $K_{xx} = 0$ or $K_{xx} = K_{yy}$. Some workers assume diagonality of the K_{ij} tensor on the grounds that the directions of the x and y axes are defined by the same conditions as the hydrodynamically stabilised flow. None of these arguments is really strict [35]. We can only state that under stabilised flow conditions and near the walls, when the viscous flow stress τ_w does not vary in the direction of the flow, the components of the K_{ij} tensor are independent of the longitudinal co-ordinate x, i.e. that $K_{ij} = K_{ij}(y)$.

At very large values of the Prandtl diffusion number (the usual condition for mass transfer in liquid drops) the main resistance to mass transfer is concentrated in a thin boundary layer within which the velocity distribution can be assumed to be linear in the transverse co-ordinate y:

$$\bar{u}_x(y) = \frac{u_*^2}{\nu} y. \quad (3)$$

Here u_* is the characteristic turbulent pulsation velocity, related to the frictional stress τ_w at the wall by the expression $u_* = (\tau_w/\rho)^{1/2}$ where ρ is the density of the liquid and ν is the molecular kinematic viscosity. The components of the turbulent diffusion coefficient tensor in the boundary layer are given with sufficient precision by the first term of a Taylor series expansion in powers of y:

$$K_{ij} = \nu b_{ij}\left(\frac{yu_*}{\nu}\right)^{n_{ij}} = \nu b_{ij} y_+^{n_{ij}}.$$

An analysis of Eqn. (1) with the hypothesis (2) has shown [36] that at Prandtl numbers greatly in excess of unity the structure of the diffusion layer near the surface of the transducer is such that K_{yy} is the only components of the K_{ij} tensor making a significant contribution to the rate of mass transfer. Hence Eqn. (1) can be simplified, retaining only the component

$$K_{yy} = \nu b y_+^n, \quad (4)$$

where the exponent n is some effective value averaged over the thickness of the diffusion boundary layer, and in principle could be a function of the Prandtl number (note that for finite Prandtl numbers the expression of the K_{yy} coefficient in a Taylor series will contain, in general, more than one power of the dimensionless distance y_+). The experimental determination of the numerical value of the parameter n has been discussed several times in the literature [35-40], but there are still differences of opinion. The majority view is that the most probable range of n values is $3 \leqslant n \leqslant 4$. Thus an electrochemical investigation aiming to determine [41-45] "the limiting damping law of the turbulence" gave $n \simeq 3$. Other workers [46,47] find that $n \simeq 4$.

The general boundary conditions needed to ensure a unique solution of Eqn. (1) assume a constant concentration of the passive additive in the region far removed from the transducer surface

$$\bar{c}(x, \infty) = c_0; \quad \bar{c}(-\infty, y) = c_0$$

and they also assume a balance between the rate of the electrochemical reaction k and the mass flow of ions j_w to the surface of the planar diffusion transducer, determined by the rate of diffusion under conditions such that ionic migration under the influence of an electric field can be ignored:

$$D\frac{\partial \bar{c}}{\partial y}\Big|_w = \begin{cases} 0 & \text{for } x < 0 \text{ and } x > l; \\ kF(c_w) & \text{for } 0 \leqslant x \leqslant l. \end{cases}$$

The form of the function $F(c_w)$ is determined by the kinetics of the surface reaction. We shall assume in what follows that this reaction is of the first order, i.e. that $F(c_w) = c_w$, where the subscript w denotes conditions at the wall (i.e. for $y = 0$).

In the dimensionless variables of boundary layer theory

$$\vartheta = \frac{c_0 - \bar{c}}{c_0}, \quad X = \frac{x}{l}, \quad Y = \frac{y}{l}\left(\frac{u_*^2 l}{9Dvx}\right)^{1/3} = \frac{1}{\alpha}\frac{y}{l}$$

and introducing the above approximations Eqn. (1) becomes, for $\alpha \ll 1$,

$$(1 + \chi X^{n/3}Y^n)\frac{\partial^2\vartheta}{\partial Y^2} + 3Y^2\left(1 + \frac{\chi n}{3}X^{n/3}Y^{n-3}\right)\frac{\partial\vartheta}{\partial Y} - 9XY\frac{\partial\vartheta}{\partial X} = 0, \quad (5)$$

where $\chi = b\mathrm{Pr}^{(3-n)/n}(9lu_*/\nu)^{1/3}$ is the dimensionless parameter of the problem. The boundary conditions in dimensionless variables are

$$\vartheta(-\infty, Y) = 0; \quad \vartheta(X, \infty) = 0;$$
$$\frac{\partial\vartheta}{\partial Y}(X, 0) = \begin{cases} 0 & \text{for } X < 0 \text{ and } X > 1; \\ KX^{1/3}[\vartheta(X, 0) - 1] & \text{for } 0 \leqslant X \leqslant 1. \end{cases} \quad (6)$$

Here the symbol $K = k(9l\nu/u_*^2 D)^{1/3}$ denotes the dimensionless rate constant of the electrochemical reaction. If this constant is formally allowed to approach infinity the last of the boundary conditions (6) becomes

$$\vartheta(0 \leqslant X \leqslant 1, 0) = 1, \quad (7)$$

which corresponds to the limiting case of a fully polarised transducer. Kader and Dil'man [36] have obtained an analytic solution of Eqn. (5) for this case.

2. The Problem of Describing Small Transducers

Analysis of Eqn. (5) shows that the turbulent diffusion mechanism plays a negligibly small role if the longitudinal co-ordinate x is small enough. This conclusion has a simple physical significance: the pulsations of the hydrodynamic and of the concentration field are quickly damped near the wall, and have no effect on the rate of mass transfer at the wall itself (i.e. within the thickness of the diffusional boundary layer). It is important in practice to estimate the length of the electrode for which the contribution of turbulent mass transfer in the viscous layer can be ignored (allowing, however, for the real velocity profile, which can be quite different from the purely laminar profile). An exact solution of this problem for arbitrary values of n and b has been obtained[36]. The critical transducer length l_1, up to which the effect of turbulent transfer can be ignored, is given by the expression

$$l_1 = \left[\frac{3r_*(2n+3)\,\Gamma(1/3)\,\Gamma(2n/3)}{bn\,\Gamma^2(n/3)\,\Gamma\left(\frac{n+1}{3}\right)}\right]^{n/3} \frac{\nu}{9u_*}\,\mathrm{Pr}^{\frac{n-3}{3}}, \qquad (8)$$

where $\Gamma(x)$ is a gamma-function, and the quantity r_* denotes the precision (expressed as a percentage) of the experimental determination of the tangential stress at the wall.

Formula (8) becomes much simpler for $n = 3$, enabling the parameter b to be evaluated from experimental results (a value of approximately 10^{-3} was obtained by Kader and Dil'man[36]):

$$l_1 = 30\frac{\nu r_*}{u_*}. \qquad (8a)$$

In order to arrive at an estimate of the order of magnitude of the critical length l_1 under practical conditions we shall consider a transducer mounted in the wall of a tube of diameter $d = 1$ cm. Assuming that the transducer can measure the tangential stress with a precision $r_* = 10\%$, the critical length l_1 calculated by formula (8a) will vary with the Reynolds number Re for the flow in the tube (Re = Ud/ν, where U is the mean velocity of the flow) over the following range

$\mathrm{Re}\cdot 10^{-3}$	5	10	50	100	500	1000
l_1, cm	8.82	4.84	1.18	0.632	0.149	0.079

If the length of the electrode is less than l_1 there is a difficulty arising from the leading and the trailing edge of the transducer. In most of the papers quoted above the theory of diffusion transducers is developed in the boundary layer approximation, involving the assumption that the transducer is polarised over its entire length. It is well known, however, that the boundary layer approximation does not adequately describe the real distribution of the concentration near the edges of the transducer, i.e. in the regions of steeply changing wall conditions, where calculations based on this approximation can be seriously in error as a result of molecular diffusion in directions parallel to the wall. Thus the error becomes more significant with smaller transducers. Furthermore, since every point on the electrode surface is not equally accessible, and the reaction rate is finite, the concentration of reacting ions at the surface in the region of the leading edge must vary from its initial value to zero, i.e. some parts of the electrode are not polarised. Since the influence of the finite reaction rate is strong near both edges of the diffusion transducer, the two effects must be considered together.

However, all the work published so far deals with the two effects separately. Ling[48] has made a numerical analysis of the influence of edge effects in small, fully polarised transducers, while other workers[9,32] studied the concentration distribution along the surface of the transducer in the boundary layer approximation. The only fairly comprehensive numerical analysis of edge effects in systems designed for the measurement of stationary mass transfer and friction was published only recently[33]. On the other hand the effects are completely ignored in papers dealing with the sensitivity of electrochemical transducers to pulsations in the viscous sub-layer of the turbulent boundary layer[15,16,31,49].

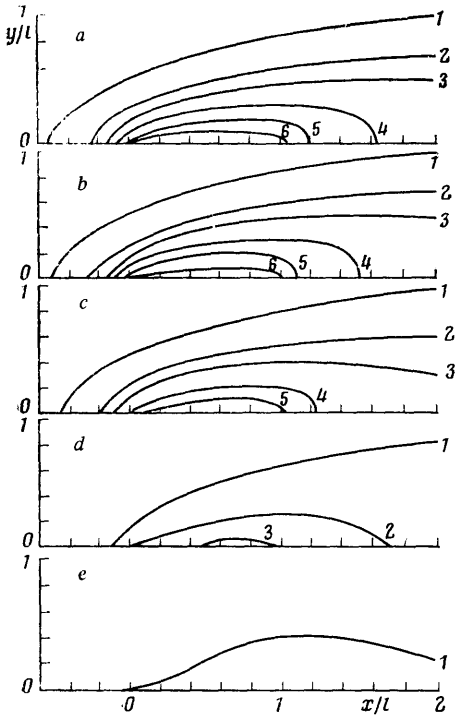

Figure 3. Concentration field above a thin-film diffusion transducer of dimensionless length $L = u_* l\sqrt{\mathrm{Pr}}/\nu = \sqrt{50}$ for different values of the dimensionless rate of electrochemical reaction K_0: *a*) $K_0 = \infty$, *b*) $K_0 = 10$, *c*) $K_0 = 1$, *d*) $K_0 = 0.1$, *e*) $K_0 = 0.01$; curves *1–6* correspond to θ values of 0.01, 0.1, 0.2, 0.4, 0.6, and 0.8 respectively.

Kader and Gukhman[33] solved the problem of mass transfer to the surface of an electrochemical transducer having a short length in the direction of the flow by using the average velocity profile of formula (3) and ignoring the influence of turbulent pulsations, but allowing for molecular diffusion in the longitudinal direction. Fig. 3, taken from that paper, shows the lines of equal concentration near the surface of diffusion transducers of equal length $l = (\nu/u_*)\,(50/\mathrm{Pr})^{1/2}$ for different values of the dimensionless complex parameter $K_0 = k\sqrt{\mathrm{Pr}}/u_*$ ($0.01 \leq K_0 < \infty$). The arbitrary edge of the diffusional boundary layer, corresponding to $\theta = 0.01$, is discussed in the same paper.

Longitudinal molecular diffusion results in a change in the concentration of reacting ions upstream from the

transducer. It is evident from the Figure that the diffusional boundary layer has a finite thickness at the leading edge of the electrode. However the influence of longitudinal molecular diffusion in this region becomes less marked as the parameter K_0 decreases. This effect stems from the peculiarities of the polarisation of thin-film diffusion transducers: the polarisation decreases as K_0 decreases, and for $K_0 = 0.01$ the arbitrary edge of the diffusional boundary layer ($\theta = 0.01$) coincides with the surface of the transducer. The surface concentration gradient is almost constant along the transducer under these conditions [33]. Calculation shows that even in small transducers operating under activation control the effect of longitudinal molecular diffusion is negligibly small.

An important characteristic of the efficiency of a thin-film diffusion transducer is the magnitude of the local diffusional flow at the leading edge ($x = 0$, $y = 0$). It can be shown [33] that this flow (j_{wf}) is given by the expression

$$j_{wf} = A\frac{u_* c_0}{\nu}\mathrm{Pr}^{-1/3}, \qquad (9)$$

where the coefficient A is finite for all values of the transducer length†, and depends on the value of K_0. Numerical values of the A coefficient for different characteristic values of K_0 are set out below:

K_0	0.01	0.1	1.0	10	∞
A	0.0099	0.091	0.575	1.65	2.40

3. Relative Role of Kinetic and Diffusion Effects for Transducers of Different Size

It follows from the above results that even for $K_0 = 10$ the transducer is not fully polarised ($\theta_w \neq 1$) over its entire length. The situation is illustrated in Fig. 4, which shows the distribution of the dimensionless surface concentration of diffusion transducers of different size ($5 \leq (u_* l\sqrt{\mathrm{Pr}}/\nu) \leq \sqrt{5000}$) for different reaction rates ($0.01 \leq K_0 < \infty$). It can be seen from the curves that the polarisation of the transducer increases with the length of the transducer and with K_0, in keeping with the expected decrease in the role of end effects with increase in the length of the transducer. The results of the analytic solution in the boundary layer approximation are also plotted in the Figure (broken lines). As expected, this solution gives a poor description of the real concentration field in the immediate vicinity of the leading and the trailing edge of the transducer, but it agrees very well with the numerical calculation over the central region. It follows from the general propositions of the boundary layer theory that the width of this region must increase with the dimensionless transducer length $L = u_* l\sqrt{\mathrm{Pr}}/\nu$. It is interesting to note that the direction of the difference between the analytic and the numerical solution (theoretical values of θ_w lower at the leading edge and higher at the trailing edge) suggests that the $\langle\theta_w\rangle$ values obtained by computer averaging over the length of the transducer for the boundary layer approximation should be fairly constant even for relatively short transducers. The present section is devoted to a discussion of these effects.

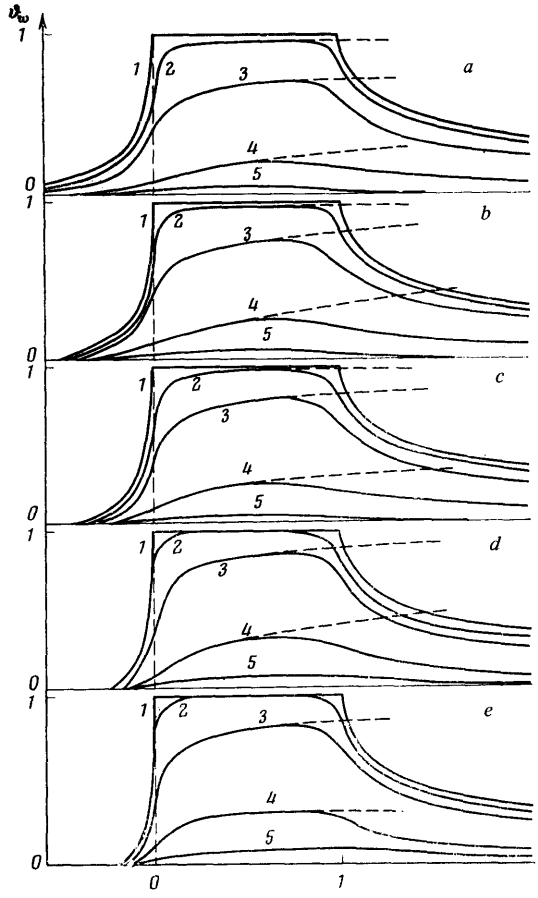

Figure 4. Concentration distribution on the surface of a thin-film diffusion transducer. The solid lines are given by the numerical solution, the broken lines by the analytic calculation in the boundary layer approximation: *a*) $L = 5$, *b*) $L = \sqrt{50}$, *c*) $L = 10$, *d*) $L = \sqrt{500}$, *e*) $L = \sqrt{5000}$; curves *1–5* correspond to values of the dimensionless rate K_0 of ∞, 10, 1, 0.1, and 0.01 respectively.

It follows from Eqn. (5) that the role of the edge effects may vary with L. Of course, for any value of L there will always be values of x so small that the product $\alpha^2\partial^2\theta/\partial x^2$ cannot be assumed to be small. Under these conditions the term $\partial^2\bar{c}/\partial x^2$ in Eqn. (1) cannot be ignored near the leading edge of the transducer, and the boundary layer approximation ($\partial^2\bar{c}/\partial x^2 = 0$) cannot be applied in this case. However, the fraction of the transducer surface for which this effect is appreciable decreases with increase of L.

†The conclusion from the exact solution of the diffusion problem (with allowance for longitudinal diffusion) that the diffusion flow is finite at the leading edge of the transducer is inconsistent with the results of later approximate calculations [134,135]. The contradiction probably arises from the assumption of a modified velocity profile in the latter work, corresponding to slipping of the liquid on the solid wall. However, even in the limit of a vanishingly small slip velocity the final analytic formula for the diffusional flow at the leading edge is incorrect, because at sufficiently small distances from the transducer surface the convective mass transfer due to slip dominates over the mass transfer associated with laminar flow in the viscous sub-layer.

Hence we may assume that for

$$\langle \alpha^2 \rangle = \int_0^1 \alpha^2(X)\,\mathrm{d}X = \left(\frac{9}{L^2}\right)^{2/3} \int_0^1 X^{2/3} dX \ll 1$$

the influence of edge effects on the general mass flow in a thin-film diffusion transducer is negligible. Thus we can say that in a transducer of length

$$l \gg l_2 = 12\,\frac{\sqrt{\nu D}}{u_*} \qquad (10)$$

the analysis based on the boundary layer approximation is quite correct. We note that the exact result obtained by Ling[48] for the case of $k \to \infty$ agrees fairly well with the estimate of Eqn. (10).

In a similar way we can estimate the length l_3 for which the rate of the electrochemical reaction plays a significant role. We use the last of the boundary conditions given in Eqn. (6). The electrochemical transducer can be said to be fully polarised when

$$\langle KX^{1/3} \rangle = \frac{k}{u_*}(9\,L\,\mathrm{Pr}^{2/3})^{1/3} \int_0^1 X^{1/3}\,\mathrm{d}X \gg 1,$$

i.e.

$$l_3 = 260\,\frac{u_*^2 D^2}{k^3 \nu}. \qquad (11)$$

The following interesting conclusions can be made from this estimate. As the frictional velocity increases, i.e. as the mean velocity of the flow passing the transducer increases, the length l_3 will vary if all other conditions remain the same. Depending on the value of the complex parameter K_0, this variation can be quite steep. If the constant k for the electrochemical reaction is small, even relatively long transducers may not be polarised over their entire length for typical working values of the overvoltage.

V. ELECTROCHEMICAL MODELLING OF MASS TRANSFER PROCESSES

Because of its many advantages, already mentioned, the electrochemical method has proved very successful in studies of mass transfer and phase exchange in solid–liquid systems. Initially the work was aimed at identifying improved solution compositions and the corresponding electrode reactions. It was usually carried out in measuring cells having well known hydrodynamic characteristics (rotating disk[50,51], rotating cylinder[52], flat plate[53], circular tube[54], and others). More latterly a very large number of publications on the electrochemical modelling of mass-transfer processes of practical interest has appeared in the literature (in particular, processes used in the chemical and petrochemicals industries). In many instances the experimental results have led to a broader and deeper physical understanding of the mass transfer mechanism, and have stimulated a great deal of theoretical work.

Both stationary and non-stationary methods have been used in electrochemical investigations of mass transfer. Since the two types of method have a number of individual features, we shall discuss them separately.

1. Stationary Methods

Electrochemical modelling has been used to study, with a precision unmatched by other methods, the mass recoil coefficients at the inlet of a circular tube as a function of length and of the Prandtl diffusion number[54–56]. By using thin annular electrodes these coefficients were measured at very small distances from the head of the mass transfer vessel (approximately one-thousandth of the radius of the tube). No previously known method could approach this level of precision.

Mass transfer in the gap between two rotating cylinders has been examined in detail[57–59]. The authors varied (over wide limits) the cell geometry and the rate of rotation of the cylinders, and they studied the influence of surface roughness on the rate of mass exchange between the phases. They were able to obtain quantitative empirical expressions describing not only the kinetics of stationary mass transfer, but also the conditions governing the hydrodynamic stability of the flow.

Interesting and unexpected results were obtained when electrochemical modelling was applied to rough surfaces. It was shown[60] that not only does the rate of mass transfer (relative to that in a smooth-walled system) not increase with flow velocity but it actually decreases, and may fall below unity[61]. These results, which were contrary to all expectations, were subsequently confirmed in more accurate experiments[45]. A theoretical explanation has recently been put forward, and generalised to a full quantitative theory of the phenomenon[62,63].

Very many electrochemical investigations using a rotating disk have been reported[42,64–72]. Some of them[64–67], confined to the purely laminar flow regime at the surface of the disk, were aimed primarily at measuring the diffusion coefficients of ions in electrolyte solutions. On the other hand, studies relying on turbulent mixing have dealt with the damping law of the turbulence in the immediate vicinity of the wall[42,68], with the influence of surface roughness on the rate of mass transfer[69,70], and with the local rates of mass transfer from small regions of various shapes on the surface of the disk[71,72].

Interesting results have been reported also on free convection near vertical and inclined plates with a smooth or a rough surface[73,74], near cylindrical objects under conditions when the curvature of the surface can influence the rate of mass transfer in the turbulent regime of free convection[75], and also on ionic mass transfer under free convection accompanied by heat transfer[76].

The stationary method has been used with success in system involving transverse flows over cylinders[3,77,78], in measurements of instantaneous local rates of mass transfer between an oscillating liquid film and a solid wall with a direct flow or a counter-flow of gas[79], and in studies of mass transfer in the turbulent flow beyond the point of greatest discontinuity in an annular tube[80]. Lastly, the stationary electrochemical method has been applied in studies of mass transfer in liquids have unusual properties[81].

2. Non-stationary Methods

It has been shown theoretically[82] that the stabilisation time of the concentration boundary layer formed at the surface of a flat plate with zero angle of attack by a sudden change in surface concentration is given approximately by

$$t_c \simeq \mathrm{Pr}^{1/3} x/U$$

and under normal conditions is measured in milliseconds. On the other hand the duration of the transient electrical process corresponds to the time constant t_{el} of the circuit

consisting of the double layer capacitance C_d and the ohmic resistance of the electrolyte R_{el} [83]:

$$t_{el} \simeq R_{el} C_d.$$

In most cases of practical interest the time t_{el} is of the order of a microsecond [84]. Hence we may assume that the diffusion-controlled reaction regime is established almost instantaneously. These considerations provide the basic concepts underlying the electrochemical modelling of non-stationary mass transfer processes: the non-stationary situation is modelled either by a sharp change in electrode potential or by a sharp change in hydrodynamic conditions.

The theoretical foundations of modelling non-stationary processes were laid by Lighthill [85], who studied the effect of small periodic perturbations in the main hydrodynamic flow on the surface friction and heat exchange coefficients at the liquid–solid interface. Others [86-89] developed theoretical analyses of heat and mass transfer processes from simple geometrical bodies (sphere and cylinder) oscillating in a liquid with an amplitude small in comparison with the characteristic dimensions of the system. The result of this work was a series of quantitative relationships defining the sensitivity of the electrode to mechanical oscillations in the measuring system. Mitchell and Hanratty [15] carried out numerical calculations of non-stationary models of mass and momentum transfer processes near walls exposed to turbulent flows, and obtained a solution of the convective diffusion equation at the wall of an annular tube in the presence of periodic perturbations of the pressure gradient. A theoretical discussion [90,91] of the convective diffusion of a passive additive in an arbitrary velocity field opens the possibility of measuring large-scale velocity pulsations by a correlation method. Lopatin and coworkers [92] have looked for an analytic form of the function describing the response of the surface of a rotating disk electrode to periodic perturbations of the concentration of reacting ions in the bulk of the solution.

Among the experimental studies of non-stationary mass transfer we should mention, first of all, a systematic investigation of the development of a diffusion boundary layer at a metal plate exposed to a stationary flow of electrolyte solution at different angles of attack [93-95], and also some work on mass transfer to a transversely located cylinder [96,97] and to the wall of an annular tube [98]. Mass transfer in non-stationary flows was studied experimentally near the surface of a vibrating disk [99], and also in the case of pulsating flow in a tube [100,101]. Much of this work was stimulated by the needs of a new and rapidly expanding branch of technology: chemotronic instrumentation, i.e. the construction of apparatus for the translation of non-electrical quantities into electrochemical signals [102-105]. Another important application of non-stationary methods is in the development of electro-diffusion anemometers, whose operating principle has been discussed in detail [28-32,49].

VI. ELECTROCHEMICAL METHODS OF STUDYING HYDRODYNAMIC PROBLEMS

Accurate methods of determining experimentally the hydrodynamic structure of various flow configurations (mean velocity and tangential stress profiles, fluctuation parameters associated with turbulence, etc.) are needed to provide objective information on the mechanism of turbulent transfer near a solid surface, and thus to test the many hypotheses to be found in the literature on the fine structure of boundary layers. They are also needed for reliable engineering calculations of the hydraulic parameters of turbulent flows in industrial mass exchange apparatus, chemical reactors, thermophysical plant, and other systems.

As pointed out above, the electrochemical method offers very attractive possibilities in all these areas. Its ability to measure with great precision both the averaged and the spectral characteristics of flow near the walls of channels and of submerged bodies has been repeatedly demonstrated. With gas–liquid flows within channels the electrochemical principle offers the only possibility of measuring the true tangential stress at the wall [32,106]: all other known methods (such as the pressure drop method, the floating element method, the Stanton tube methods, etc.) are either totally inapplicable or insufficiently accurate. Electro-diffusion transducers have been used for direct measurements of surface friction and its pulsations for different flow regimes of two-phase media in vertical and horizontal tubes, for accurately establishing "regime charts" of the parameters governing the various flow regimes of two-phase mixtures, and in studies of the hydrodynamic analogy between bubbling and ebullition under forced flow conditions [24,32].

The spherical electrochemical transducer [107,108] has been found very effective for the measurement of velocity profiles in laminar flows. It consists of a spherical platinum electrode 0.5 to 1.0 mm in diameter, located in the flow region of interest and operated under conditions of concentration polarisation. Concentration and temperature errors are avoided by inserting into the flow an auxiliary micro-electrode whose output is independent of the flow rate and is determined by the concentration of the depolariser (oxygen) and by temperature. This transducer can measure local flow rates with a spatial resolution limited by the width of the disturbed hydrodynamic region. For $Re < 1$ this region extends over approximately six electrode radii on either side of the transducer. At higher Reynolds numbers the width of the disturbed region decreases.

Significant advances have been made in the design and practical application of electrochemical surface friction transducers. Some theoretical aspects of the operation of these transducers are discussed in detail in the following sections.

1. Measurement of Mean Tangential Stresses

For a fully polarised transducer operating under laminar diffusion layer conditions (when the ionic mass transfer is unaffected by turbulent pulsations in velocity and pressure) Eqn. (5) with the boundary conditions (6) takes the form of the well-known Leveque problem [109]

$$\frac{d^2\vartheta}{dY^2} + 3Y^2 \frac{d\vartheta}{dY} = 0; \quad \vartheta(\infty) = 0; \quad \vartheta(0) = 1. \tag{12}$$

The solution of this problem, in the form

$$\vartheta(Y) = 1 - \frac{3}{\Gamma(1/3)} \int_0^Y \exp(-x^3)\, dx, \tag{13}$$

allows us to establish the relationship between the ionic mass flow j_w to the electrode, proportional to the electric current in the measuring cell, and the tangential stress τ_w at the wall:

$$j_w = 0.807\, c_0 \left(\frac{D^2 \tau_w}{\rho \nu l}\right)^{1/3}. \tag{14}$$

We should remember that the length l of the transducer must be less than the quantity l_1 defined by Eqn. (8). (This equation imposes a limit on the range of dimensions for which the contribution of the turbulent mass transfer mechanism can be ignored.) At the same time, the length of the transducer should be large enough to justify neglecting edge effects, with the assumption that the transducer surface is fully polarised. According to the estimates made above, the condition is $l \geqslant \max(l_2, l_3)$, where l_2 and l_3 are the characteristic lengths defined by Eqns. (10) and (11).

The experimental conditions for the measurement of the mean wall friction, and the constructional details of the measuring cells, have been discussed by several workers [13-15,30,110-115]. These papers describe measurements of the tangential stress at the wall of a cylindrical tube, of a plane-parallel channel, and of a two-dimensional cavity in liquid and gas–liquid flows, and they deal with the interaction between a liquid (laminar, or turbulent) and a solid wall under thin-layer flow conditions. The electrochemical method has been used to study in detail the stabilisation of local friction in the initial portion of a plane-parallel channel [116], in flows under a longitudinal pressure gradient [117], and in flows involving complex vortex structures [30].

The correlation method of measuring the averaged characteristics of turbulent flows in boundary layers [30] has great conceptual and practical interest. One variant of this method involves monitoring the correlation between the random pulsations of the flows on two planar electrodes mounted on the experimental plate, mutually parallel and with their edges at right angles to the flow direction. The measured correlation function R is related to the pulsations of the currents at the two electrodes (i_1 and i_2) by the expression

$$R(|x_1 - x_2|, \tau) = \frac{1}{T}\int_0^T i_1(x_1, t)\, i_2(x_2, t - \tau)\, \mathrm{d}t, \qquad (15)$$

where τ is the variable time-lag of the current i_2 with respect to i_1, T is the measurement time ($T \gg \tau$), and x_1 and x_2 are the co-ordinates of the electrodes (the linear dimensions of the electrodes are assumed small in comparison with the distance $l = x_1 - x_2$). The function R goes through a maximum at $\tau = \tau_m$, given by $\tau_m = l/V$ where V is the mean velocity of the turbulent vortices in the disturbed region of the diffusion boundary layers at the electrodes. In this way we can measure the characteristic velocity V of the turbulent vortices near the wall by noting the time τ_m.

The correlation method can be used also to measure the tangential stresses in a laminar flow by introducing concentration markers from a third, auxiliary electrode a short distance in front of the first electrode.

The most characteristic feature of the correlation method is the lack of dependence of the measurement error on the diffuseness of the concentration wave in the region of the two electrodes, and on the presence of obstructions.

2. Measurement of the Spectral Characteristics of Wall Friction

The turbulent pulsations of the surface friction can be quantitatively characterised by the mean-square fluctuation of the friction $\overline{(\Delta\tau_w)^2}$, which is related to the distribution function of the spectral density $\epsilon_\tau(\omega)$ by the expression [118]

$$\overline{(\Delta\tau_w)^2} = \int_0^\infty \varepsilon_\tau(\omega)\, \mathrm{d}\omega, \qquad (16)$$

where the integration is carried out over the whole range of pulsation frequencies ω. The spectral density function describing the pulsations of electric current $\epsilon_i(\omega)$ can be determined by analogy with the function $\epsilon_\tau(\omega)$. The functions $\epsilon_\tau(\omega)$ and $\epsilon_i(\omega)$ are interrelated by the expression

$$\varepsilon_i(\omega) = |\xi(i\omega)|^2 \varepsilon_\tau(\omega), \qquad (17)$$

where $\xi(i\omega)$ is termed the response function of the diffusion layer to harmonic pulsations of the velocity of the liquid with frequency ω (the symbol i denoting an imaginary quantity). If the time-average frictional stress at the wall is termed $\overline{\tau_w}$, we can obtain the following relationship between the mean square frictional stress fluctuation $\overline{(\Delta\tau_w)^2}$ and the mean square total current $\overline{(\Delta I)^2}$ by using expressions (16) and (17):

$$\frac{\sqrt{\overline{(\Delta\tau_w)^2}}}{\overline{\tau_w}} = \frac{\sqrt{\overline{(\Delta I)^2}}}{\overline{I}} \left(\int_0^\infty \frac{\varepsilon_i(\omega)\, \mathrm{d}\omega}{|\xi(i\omega)|^2}\right)^{1/2}, \qquad (18)$$

where $\overline{I}$ is the time-average current. In the case of a rectangular electrode of area S and length l the mean current can be expressed in terms of the mass flow of ions, given by formula (14), by introducing the simple relationship $\overline{I} = mFSj_w$ where m is the number of electrons transferred across the metal–solution interface by the elementary electrochemical reaction and F is the Faraday.

It follows from Eqns. (17) and (18) that the spectral and the averaged characteristics of the pulsation field of the tangential stresses can be determined simply from a knowledge of the response function of the diffusion layer $\xi(i\omega)$. The latter can be evaluated, in principle, by solving the equation for a non-stationary boundary diffusion layer with a velocity profile given by the first non-vanishing term of the expansion in powers of the distance from the wall:

$$u_x = \frac{\overline{\tau_w} y}{\rho\nu}(1 + \lambda f(t)), \quad u_y = 0, \qquad (19)$$

where $f(t)$ is a harmonic function of time and λ is the dimensionless amplitude of the pulsating velocity field.

An analysis of the solution of the non-stationary convective diffusion equation in the velocity field given by formula (19) with $f(t) = \exp(i\omega t)$ has shown [85] that the response function $\xi(i\omega)$ can be expressed as follows to a second-order approximation in the terms of the dimensionless amplitude λ:

$$\xi(i\omega) = 1 + \lambda\xi_{1,1}e^{i\omega t} + \frac{\lambda^2}{2}(\xi_{2,0} + \xi_{2,2}e^{2i\omega t}) + 0(\lambda^3), \qquad (20)$$

where $\xi_{1,1}$, $\xi_{2,0}$, and $\xi_{2,2}$ are functions of the longitudinal co-ordinate x.

Several workers [15,30,119,120] have tried to calculate the functions $\xi_{1,1}$, $\xi_{2,0}$, and $\xi_{2,2}$ by introducing various simplifying assumptions. Analytic expressions were obtained for the function $\xi_{1,1}(x)$ with small or large values of the parameter $\epsilon = (\rho\nu l\,\omega^{3/2}/\tau_w D^{1/2})^{2/3}$. In physical terms, this parameter denotes the ratio of the squares of the thickness of the stationary diffusion boundary layer (in the absence of velocity pulsations) and the periodic diffusion boundary layer [30,120]. The contribution from second-order amplitude terms has also been estimated, and it was shown that both high-frequency and low-frequency pulsations can lower the time-averaged and the area-averaged mass transfer coefficient [119,120].

Methods of determining experimentally the pulsation characteristics of the turbulent velocity field in boundary layers close to the wall have been developed from the published analytic expressions for the response function [30].

An experimentally simple but effective method of measuring surface friction is based on non-stationary pulse measurements [121]. The method does not differ in principle from the method shown in Fig. 2. A pulse of electrically active material is injected into the hydrodynamic flow by an electrochemical reaction at the upstream "marker" electrode *1* (see Fig. 2). This pulse is carried by the flow to the measuring electrode *2* (arbitrarily called the "counting" or indicator electrode). A definite time elapses between the application of the pulse at the marker electrode and its arrival at the counting electrode. This time (called the time-lag t_l) depends on the hydrodynamic regime and can be used as a measure of its intensity.

The time-lag can be evaluated from the following considerations. The total transfer time includes a term for the diffusion of the electrically active material to some distance y at right angles to the flow, and a term for the hydrodynamic transport to the indicator electrode. The diffusion time includes diffusion from the marker electrode and diffusion to the counting electrode. To the accuracy of the numerical factor of the diffusion time we can write

$$t_{diff} \simeq \frac{y^2}{D}. \tag{21}$$

The hydrodynamic time is given by the expression

$$t_{hyd} \simeq \frac{\rho \nu x}{\tau_w y}, \tag{22}$$

where x is the distance between the marker and the counting electrode. Thus the total transfer time is

$$t_{tot} \simeq \frac{y^2}{D} + \frac{\rho \nu x}{\tau_w y}. \tag{23}$$

It follows from Eqn. (23) that we can define a distance y_{min} corresponding to the minimum transfer time. Evidently, the smallest transfer time is equal to the time-lag. Hence we conclude that the thickness of the diffusion layer within which the electrically active material is transported from one electrode to the other is given (to the nearest order of magnitude) by the expression

$$y_{min} \simeq \left(\frac{\rho \nu x D}{\tau_w}\right)^{1/3}, \tag{24}$$

i.e. it is equal to the thickness of the stationary diffusion layer. Hence the time-lag is of the same order of magnitude as the relaxation time of the diffusion layer:

$$t_l \simeq \left(\frac{\rho \nu x}{D^{1/2}\tau_w}\right)^{2/3}. \tag{25}$$

It follows that the time-lag is inversely proportional to the tangential frictional stress to the power 2/3. This analysis (which ignores the finite size of the electrodes themselves) provides a numerical value of the multiplier needed in Eqn. (25): a recent calculation [120] gives

$$t_l = 2\left(\frac{\rho \nu x}{D^{1/2}\tau_w}\right)^{2/3}. \tag{26}$$

The frequency method [121] is closely related to the pulse-time method. If the electrodes *1* and *2* are included in the negative feedback circuit of an amplifier, undamped oscillations will occur at some frequency. The oscillation condition is a phase shift of 180° between the signals at the marker and the counting electrode. Using Eqn. (26), the frequency of the resulting oscillations can be expressed as

$$f = \frac{1}{2t_l} = \frac{1}{4}\left(\frac{D^{1/2}\tau_w}{\rho \nu x}\right)^{2/3}. \tag{27}$$

Thus the frequency of the oscillations is directly proportional to the tangential stress arising from viscous friction to the power 2/3.

The analysis applies also to a turbulent boundary layer if the diffusional transport in the normal direction takes place within the thickness of the laminar diffusion layer. Since the thickness of the diffusion layer increases only as far as the edge of the indicator electrode, the permissible size x of the electrode system [see formula (8)] should include the length of the marker electrode and the length of the inter-electrode gap. The length of the indicator electrode should have only a second-order effect on the sensitivity of the electrochemical measuring system.

Since the frequency of the electrical oscillations is linearly related to the tangential frictional stress to the power 2/3, the sensitivity η of the electrochemical transducer can be conveniently defined as

$$\eta_{2/3} = f\bar{\tau}_w^{-2/3} = \frac{D^{1/3}}{4}(\rho \nu x)^{-2/3}, \tag{28}$$

where the subscript 2/3 indicates non-linearity of the transformation.

A very interesting situation arises for large values of the tangential stress, when the thickness of the turbulent diffusion layer becomes less than the thickness of the laminar diffusion layer. Whereas in the case of a laminar diffusion layer the time-lag of the pulse includes the diffusion time of the electrically active material in the normal direction and the time for hydrodynamic transport in the tangential direction, under the conditions of a turbulent diffusion layer the only slow transfer step is the transport through the turbulent diffusion layer. The electrically active material which has passed through the turbulent diffusion layer is rapidly carried through the required distance in the tangential direction. Leaving aside the problem of the sensitivity which the indicator electrode must have in order to detect the concentration pulse, we can state that undamped oscillations will be generated in a turbulent diffusion layer and that their frequency will be of the same order as the relaxation frequency of the turbulent diffusion layer.

Assuming an effective exponent (n) of 4 for the damping law of the turbulent pulsations near the solid wall, given by Eqn. (4), we can apply the expression $f \simeq D\delta_{hyd}^{-2}$ and estimate the frequency of the resulting oscillations as

$$f \simeq \frac{\bar{\tau}_w}{\rho \nu} \mathrm{Pr}^{-1/2}. \tag{29}$$

The frequency of the oscillations for a predominantly turbulent diffusion layer is proportional to the first power of the tangential frictional stress and is independent of the inter-electrode distance over a wide range.

According to Eqn. (29) we can conveniently define the sensitivity of the transducer as

$$\eta_1 = f/\bar{\tau}_w = D^{1/2}/\rho \nu^{1/2}, \tag{30}$$

The subscript 1 denotes linearity of the transformation.

The electrochemical frequency method of measuring friction was tested experimentally using a model of the electrochemical tangential stress transducer [121] made of electrically insulating material. The electrode system was mounted flush with the surface exposed to the liquid flow, and consisted of three parallel linear electrodes made of platinum and oriented at right angles to the flow direction. The electrodes were connected in the following sequence along the flow: marker electrode, counting electrode, and common electrode. Sea-water was used as the electrolyte. The application of a positive potential to the

marker electrode induced an electrochemical reaction at the electrode surface, causing oxidation of chloride ions to chlorine atoms. The counting electrode was connected to a constant negative polarity of sufficient magnitude to draw the limiting current of the chlorine–chloride redox system. The amplifier input was connected to the counting circuit, and the output to the marker circuit. Self-oscillations were produced at some definite ratios of the current in the marker circuit and in the counting circuit. The phase-shift angle between the marker current and the counting current, and hence the self-oscillation frequency, is a function of the tangential frictional stress.

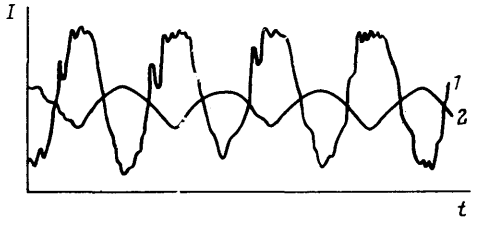

Figure 5. Oscillographic determination of the frequency of the electrical signals generated in experiments on the electrochemical measurement of tangential stress: *1*) marker current , *2*) counting current.

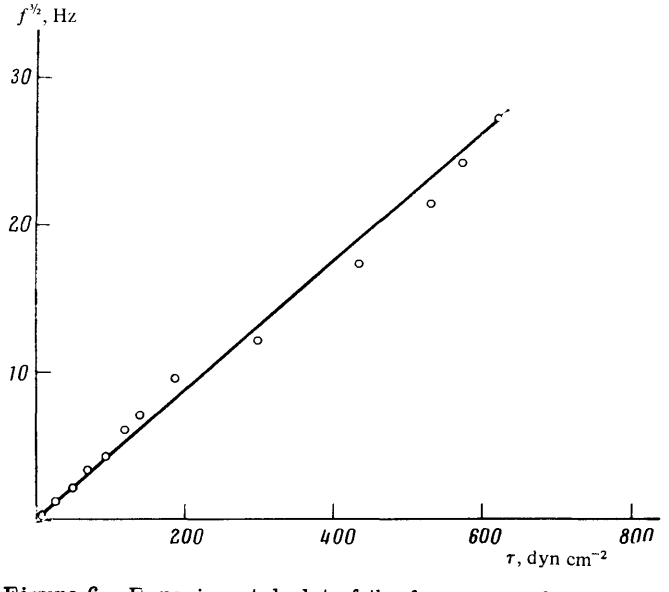

Figure 6. Experimental plot of the frequency of generated oscillations against the tangential stress at the solid wall ($f^{3/2}$ against τ).

The experimental results are summarised in Figs. 5 and 6. The generation frequency was measured oscillographically (a typical trace is shown in Fig. 5). Fig. 6 shows an experimental plot of the generation frequency against the tangential frictional stress for a laminar flow regime. It can be seen that the power law of the experimental plot is close to the theoretical value.

Electrochemical transducers for the measurement of local velocity distributions in a flow have been widely used in recent years. These devices (wedge-shaped, spherical, or circular) are positioned in the flow of electrolyte at right angles to the flow, and they do not differ in principle from the wall-mounted electrodes described above.

VII. STUDY OF THE STRUCTURE OF TURBULENT FLOW

The electrochemical method can be used to investigate the mechanism of momentum and mass transfer in liquid layers a few tens of microns thick. Hence it offers a unique and most effective means of probing the fine structure of the turbulence in the viscous sub-layer of a turbulent boundary layer. We have already referred to the work[41-44] on the limiting damping law of the turbulence at a solid wall. The structure of the turbulence has been investigated also by other workers[13-18,38,122-124], who studied vortex configurations, the rate of propagation of vortices by convection in the flow, and the microscopic and macroscopic features of turbulence.

Improved modifications of the electrochemical method are currently being developed for studying the structure of hydrodynamic flows and for measuring average and local rates of mass transfer[125]. One of these modifications relies on electrochemiluminescence, whose intensity is proportional to the local rate of mass transfer. Interesting results can be obtained by exploiting the colour change of some electrolytes under the influence of local changes of pH. A procedure for visually observing and studying velocity fields is based on this phenomenon.

VIII. SOME PRACTICAL PROBLEMS

In our opinion, the most important scientific and engineering problems still to be solved in order to ensure wider practical exploitation of electrochemical modelling are the following: 1) the choice of electrochemical systems with the required physical and transport properties; 2) the theoretical understanding and practical control of blocking effects at the transducer surface during operation, and of transducer activation; 3) a more detailed study of correlation and other measurements using transducers of very small dimensions (in particular, for the measurement of transverse velocity pulsations); 4) an appreciation of the role of turbulence on the response of physically large transducers. Some of these problems have been discussed repeatedly in the literature, and have been the object of special investigations. For example, Eisenberg and coworkers[52] have discussed the choice of the best electrolytes and electrode reactions for modelling mass transfer. No less important is the problem of transducer blocking, which we shall briefly review in the following paragraphs.

A common problem in electrochemical measurements extending over long periods of time is the possible contamination of the electrode surface (e.g. by adsorbed surface-active materials, insoluble products of the electrode reaction, oxide films, evolved gas bubbles, etc.). These contaminants can inhibit the access of the reacting species to the transducer surface, and thus lower the rate constant of the electrochemical indicator reaction. The parasitic resistance experienced by the ionic mass transport as a result of the presence of contaminating surface layers adds

to the difficulty of interpreting the electrochemical mass transport data and introduces a need for empirical correction factors. Partial surface blocking is the most likely explanation of the substantial differences (20–30%) between measurements of stabilised electrochemical mass transfer obtained by different methods under identical hydrodynamic conditions (see, for example, Refs. 54 and 55).

Since it is impossible in practice to achieve complete control over the surface conditions of the transducer, especially in large-scale apparatus containing large volumes of electrolyte, we must continue to search for theoretical methods of assessing (within the limits imposed by the unavoidable assumptions) the effect of surface blocking on the results of electrochemical measurements.

The methods used to describe convective heat and mass transfer processes in systems with non-uniform surface activity are highly relevant to our problem. One of the simplest yet fairly typical models of a heterogeneous surface consists of a rotating disk with one or more annular active regions isolated from the other regions by the disk[126,127]. Another typical model consists of a flat plate with alternating active and "lacquered" parallel bands at right angles to the direction of the flow[6,128]. The effect of surface contamination on the efficiency of electrochemical diffusion transducers can also be described in terms of a model assuming a continuous variation in activity along the phase boundary[33,129-131]. Kader and Gukhman[33] allowed for partial blocking of the transducer surface by assuming a thin, uniform layer offering a constant resistance to the ionic mass transfer. The mass flow of reacting ions through this layer was assumed proportional to the difference in concentration of the ions on the two sides of the layer. In this way the blocking effect could be allowed for by replacing (in the boundary condition) the true rate of the electrochemical reaction by some arbitrary quantity linearly related to the surface concentration of reactant.

The parameters of the model can often be optimised by comparing the results of model calculations with experimental data. However it is far preferable (though not always possible in practice) to seek information on the distribution of the blocking impurities on the electrode surface. If this information can be obtained the apparent rate of the electrochemical mass transfer process can be calculated, in principle, either analytically or by numerical methods. Approximate methods of calculating the rate of mass transport to isolated active regions of arbitrary shape on the surface of a rotating disk have very recently been proposed, assuming a laminar flow regime[132,133].

o0o

We have attempted a general review of the theoretical foundations, practical applications, prospects, and outstanding problems of the electrochemical method of studying and modelling transport processes in liquids. The method is relatively new, but its effectiveness and generality have already been amply demonstrated in practice. The large effort currently being devoted by various research teams to further developments and improvements of the electrochemical method justifies the belief that many fundamental problems in the theory and practice of mass transfer and inter-phase exchange will be solved with the help of this method.

The Influence of the Nature of the Metallic Phase on the Structure of the Electrical Double Layer and the Kinetics of the Evolution of Hydrogen

U.Palm and V.Past

The influence of the crystallographic structure of the surface of a solid electrode and of the specific interaction between the solvent and the metal on the properties of the electrical double layer and the adsorption of ions and dipolar molecules on metals which do not adsorb hydrogen is examined. The problem of the influence of the structure of the electrical double layer on the kinetics of the evolution of hydrogen on bismuth, tin, lead, and cadmium, in acid and alkaline solutions is discussed.
The bibliography includes 80 references.

I. INTRODUCTION

Significant progress has been achieved in the last decade in quantitative studies of the structure of the electrical double layer, adsorption phenomena, and the laws governing the occurrence of electrochemical reactions on electrodes made of a wide variety of different metals. Metals on which conditions of ideal polarisability can be achieved to a satisfactory degree of approximation over a wide range of potentials φ are the most suitable for a quantitative test of the theoretical concepts concerning the structure of the electrode/solution interface[1-4]. In contrast to mercury, on solid electrodes a fundamentally new problem involves the study of the influence of the crystallographic characteristics of the surface of the metal on the structure of the electrical double layer, particularly its dense component (together with the problem of the influence of the chemical nature of the metal). The investigation of the structure of the interface on different faces of a single crystal is most promising in this sense.

Frumkin and coworkers[5,6] showed that one of the most exact methods for the study of the structure of the electrical double layer involves the measurement of the variation of the differential capacitance C with φ. However, in the measurement of the capacitance of solid metals it is necessary to eliminate the sources of the false frequency dispersion of the capacitance (roughness of the surface, the phenomenon of saturation, etc.)[3,4,7,8]. A number of methods for smoothing the surfaces of test electrodes have now been developed and successfully applied.

Frumkin and coworkers[9] showed that surface fusion of the metal constitutes a promising method for the preparation of solid electrodes with the roughness coefficient of the surface close to unity. A special procedure for the preparation of drop-shaped surface-fused electrodes with a smooth surface has been developed in the Electrochemical Laboratory at the Tartu State University[10,11]. Subsequently the procedure was used to prepare drop-shaped antimony[12], tin[13], and cadmium[14] electrodes. Fig. 1 shows that the variation of $1/C$ with the reciprocal of the diffuse layer capacitance $1/C_d$ of bismuth can be represented over a wide range of KF concentrations (0.001–2 M) and for different surface charges ϵ by straight lines with an average reciprocal of the slope of 1.01–1.02.[15] It has been shown[16] that the slope of the linear plot of $1/C$ against $1/C_d$ for $\epsilon = 0$ differs from unity by less than 10% in the case of antimony. These results show that surface-fused electrodes have a perfectly smooth surface.

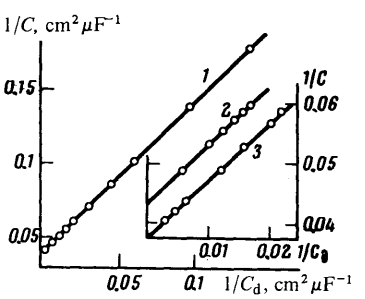

Figure 1. Variation of the reciprocal of the differential capacitance $1/C$ with the reciprocal of the capacitance of the diffuse layer $1/C_d$ in the range of KF concentrations from 0.001 to 2.0 M for different values of ϵ (C cm^{-2}): 1) 0; 2) −3; 3) +2.

Among solid electrodes, bismuth is the metal which exhibits the widest (after mercury) range of ideal polarisability potentials in both aqueous[10,15] and non-aqueous[17-19] media. On the other hand, many of the physical and chemical properties of bismuth differ significantly from those of mercury and metals resembling it, and lead to its classification as a semimetal. Bismuth is therefore an

interesting object of study for the elucidation of the influence of the nature of the metallic phase and also of the crystallographic structure of the surface on the double layer parameters and adsorption. In this review attention is concentrated on the following problems in relation to bismuth together with the relevant data for other electrodes:

(1) the influence of the crystallographic structure of the electrode surface on the characteristics of the double layer and on the adsorption of molecules and ions;

(2) the influence of the nature of the metal and of the chemisorption of solvent molecules (particularly water) on the structure of the interface and on adsorption;

(3) the dependence of the characteristics of the cathodic evolution of hydrogen on the nature of the metal and the structure of the double layer.

II. THE INFLUENCE OF THE CRYSTALLOGRAPHIC STRUCTURE OF THE ELECTRODE SURFACE ON THE PROPERTIES OF THE ELECTRICAL DOUBLE LAYER AND ON ADSORPTION

The vast majority of the literature data concerning the structure of the electrical double layer and adsorption on solid metals refer to electrodes with a polycrystalline surface. Measurements on individual faces of a single crystal are associated mainly with the determination of the zero-charge potential $\varphi_{\epsilon=0}$ of the face. The characteristics of the adsorption of ions and molecules on single crystal faces have been studied quantitatively on zinc[20,21], bismuth[22], gold[23], and silver[24]. Nevertheless the experimental data which have accumulated indicate an appreciable influence of the crystallographic characteristics on the double layer parameters. It has been established in studies on zinc[20,21,25] and bismuth[26-30] that the role of the nature of the polycrystallinity of the surface is manifested particularly clearly in the adsorption of organic compounds with a powerful attraction interaction in the adsorption layer.

In the study of the adsorption of pyridine[26], certain aliphatic ketones[27], esters[28], and camphor[29] on a surface-fused bismuth electrode the phenomenon of the splitting of adsorption–desorption maxima has been observed (Fig. 2). Such phenomena, which have been noted in many instances also on the polycrystalline surface of zinc[20,21,25], are absent from the homogeneous mercury surface and the (111) face of a bismuth single crystal. According to data for bismuth, the adsorption of pyridine and the majority of the ketones and esters investigated is accompanied by the splitting of the cathodic maxima into two, which is more pronounced the higher the concentration of the organic substance in solution. There are actually three peaks on the C–φ curves for propyl acetate solutions. The anodic maxima, which are obtained only for bismuth among solid metals, exhibit a smaller tendency towards splitting; the splitting of the anodic peaks into two components has been observed only for the adsorption of propyl acetate[28] and camphor[29] on bismuth.

As for the zinc electrode, the splitting of the adsorption maxima on bismuth is due to the polycrystallinity of the electrode, the surface of which comprises faces with different crystallographic indices. The individual narrow peaks in the region of the adsorption–desorption maxima (Fig. 2) describe the desorption of organic molecules from different single crystal faces, one of which is the (111) face. Presumably the difference between the values of $\varphi_{\epsilon=0}$ on different single crystal faces is the main factor among several responsible for the splitting of the maxima. The value of $\varphi_{\epsilon=0}$ for the basal (111) face of the bismuth single crystal in potassium sulphate solution is −0.68 V relative to the saturated calomel electrode[31], i.e. it is more negative by 30 mV than $\varphi_{\epsilon=0}$ for a surface-fused electrode[10,32]. On the basis of the value of $\varphi_{\epsilon=0}$ for the (111) face, the values of $\varphi_{\epsilon=0}$ for the remaining two faces involved in adsorption measurements can be estimated approximately from the peak potentials. $\varphi_{\epsilon=0}$ for the face corresponding to the first, i.e. least cathodic, peak of the split propyl acetate maximum is between −0.62 V and $\varphi_{\epsilon=0}$ for the face corresponding to the middle peak is in the range between −0.63 and −0.65 V.[30] However, it must be emphasised that the values quoted are merely approximate and do not permit the identification of the face.

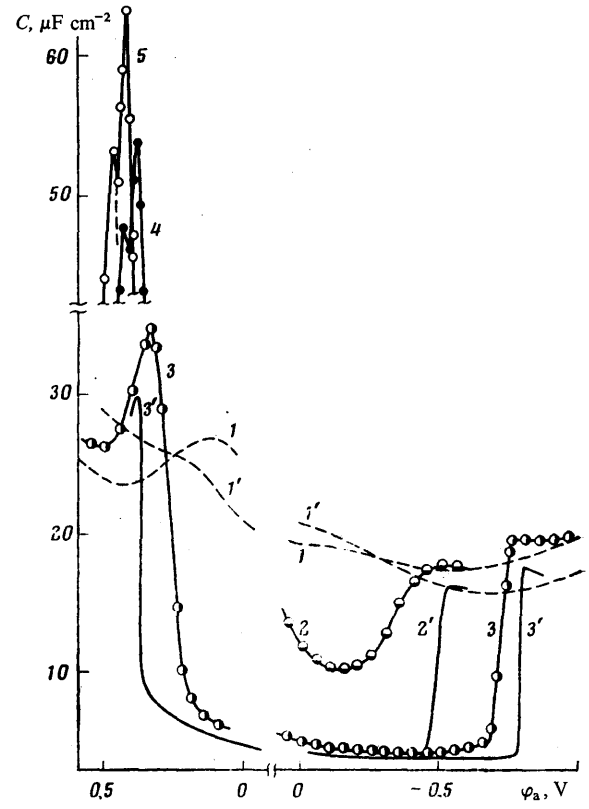

Figure 2. Differential capacitance curves for bismuth (curves *1* and *5*) and mercury (curves *1′* and *3′*) in 0.1 M NaF (bismuth and mercury) and $HClO_4$ (bismuth) solutions with added camphor; camphor concentration (M): 1) and 1′) 0; 2) and 2′) 2×10^{-4}; 3) and 3′) 1.5×10^{-3}; 4) 5×10^{-3}; 5) 7×10^{-3} (the potentials are given relative to the zero-charge point).

Electron-diffraction analysis has established that the splitting of the adsorption maxima is favoured by the macroscopic nature of the crystallographic heterogeneity of the surface of the bismuth electrode, characterised by

the presence on the surface of relatively large single-crystal sections[28-30]. The highly developed polycrystallinity and the associated appreciable energy inhomogeneity promote the manifestation of a broad spectrum of interactions in the adsorption layer, which leads to the spreading of the maxima and not to their splitting[25,30]. Mathematical analysis of electron diffraction patterns showed that, on a completely smooth bismuth surface produced by surface fusion (characterised by greatly extended reflections), there are relatively large single-crystal regions with the Miller indices (100), (101), (111), and (211).[30] Together with macroscopic single-crystal planes, one sometimes encounters aggregates of single crystals comprising between two and four crystallites with the indices (100), (111), (101), (552), (321), etc. Statistical treatment of the electron-diffraction data showed that the surface of the surface-fused bismuth drop comprises mainly two–three distinct single-crystal faces (the fraction of the total drop surface corresponding to them is about 80–90%). The crystallographic structure of the surface produced by partial fusion is statistically reproducible in different experiments owing to the stability of the conditions employed in the preparation of bismuth electrodes[10,11].

III. THE INFLUENCE OF THE NATURE OF THE METAL AND THE CHEMISORPTION OF SOLVENT MOLECULES ON THE STRUCTURE OF THE INTERFACE

Frumkin and coworkers[33,34] showed for the first time that the influence of the nature of the metal on the structure of the double layer and adsorption can be shown very clearly in terms of its hydrophilic properties. In particular, it has been established that, owing to the strong chemisorption of water molecules, the classical theory of the double layer is inapplicable to the double layer on gallium[35].

According to the literature data, in the region where $\epsilon \geq 0$ the adsorption parameters of organic compounds and ions depend markedly on the nature of the metal, owing to both their different hydrophilic properties and to the specific interaction of the functional group in the adsorbate molecule with the electrode surface. Table 1 presents the standard free energies of adsorption ΔG°_{A} of aliphatic alcohols, acids, and ketones, on mercury[36-38] and bismuth[27,39,40]. It is seen that the values of $-\Delta G^{\circ}_{A}$ for the higher members of the homologous series of the above compounds on bismuth are somewhat lower than on mercury. Since the functional group in the molecules of the higher homologues is so remote from the electrode surface that its specific interaction with the electrode may be neglected, the above difference is a result of the difference between the water adsorption energies on bismuth and mercury. Comparison of the values of $-\Delta G^{\circ}_{A}$ for different compounds shows that the energy of adsorption of water molecules on bismuth is on average 0.3–0.4 kcal mole^{-1} higher than on mercury. On the other hand, comparison of data for the adsorption of alcohols on bismuth and cadmium[41] shows that the energy of adsorption of water on bismuth is lower by 0.35–0.45 kcal mole^{-1} than on cadmium.

The relatively higher free energies of adsorption of the first members of the homologous series on bismuth compared with mercury are due to the appreciable specific interaction of the oxygen atoms in the functional group with the bismuth surface. The difference between the specific interactions of the functional groups with bismuth and mercury can be characterised by the quantity

$$[(-\Delta G^{0}_{A})_{n=6} - (-\Delta G^{0}_{A})_{n=2}]_{Hg} - [(-\Delta G^{0}_{A})_{n=6} - (-\Delta G^{0}_{A})_{n=2}]_{Bi} = (\Delta\Delta G^{0}_{A}).$$

Table 1 shows that the energy of interaction of the OH group with bismuth is 0.31 kcal mole^{-1} higher and that of the COOH group 0.60 kcal mole^{-1} higher than with mercury. It is interesting to note that the oxygen atoms in water and alcohol molecules interact with the bismuth surface approximately to the same extent. The stronger interaction of the COOH group with the electrode surface compared with the OH group is due to the face that the carboxy-group contains two oxygen atoms. The behaviour indicated by Table 1 has been confirmed also by comparing the adsorption activities of aliphatic compounds on bismuth and on the free surfaces of the solution[27,42,43].

Table 1. Standard free energies of adsorption of aliphatic compounds.

Compound	$(-\Delta G^{0}_{A})_{Hg}$, kcal mole^{-1}	$(-\Delta G^{0}_{A})_{Bi}$, kcal mole^{-1}	$(-\Delta G^{0}_{A})_{Hg} - (-\Delta G^{0}_{A})_{Bi}$, kcal mole^{-1}

Butyl methyl ketone	5.35	5.00	0.35

*n is the number of carbon atoms in the hydrocarbon group.

The adsorption data obtained make it possible to establish a series of surface activities of aliphatic compounds reflecting the interaction of the functional group with the electrode surface. Judging from the values of ΔG°_{A}, the interaction of the functional group with the bismuth surface becomes stronger in the sequence OH < C=O < COOH.[29,44] This sequence reflects the enhancement of the specific interaction between the oxygen atoms and the bismuth surface.

The π-electron interaction between the aromatic ring and the positive surface charges, which should depend in principle on the nature of the metal, is known to play a significant role in the adsorption of aromatic compounds on electrodes. Table 2 presents the values of the adsorption energy gain $-\Delta G_{A}$ on passing from the solution/air interface to the interface with bismuth or mercury for $\Delta\sigma = 0.5$ μJ cm^{-2}.[45] The data in Table 2 show that the adsorption of all aromatic compounds on the bismuth surface is energetically more favourable than on the free surface of the solution. According to the Table, the values of $-\Delta G_{A}$ for mercury are 0.3–1.3 kcal mole^{-1} higher than for bismuth.

As shown above, one of the causes of the increased surface activity of organic compounds on bismuth is a

stronger adsorption of water molecules than on mercury. Together with this, it is necessary to take into account also the semimetallic nature of bismuth, which leads to a weakening of the π-electron interaction between adsorbate molecules and the surface. The energy of the π-electron interaction between the adsorbed molecules of benzene derivatives and an uncharged bismuth surface can be estimated approximately by comparing the values of $-\Delta G_A$ for phenol and cyclohexanol. According to the data in Table 2, the difference between the values of $-\Delta G_A$ for phenol and cyclohexanol (0.7 kcal mole^{-1}) characterises the energy of the π-electron interaction of benzene derivatives; however, depending on the nature and structure as well as the orientation of the adsorbed molecules, this value can vary somewhat. The energy of the additional π-electron interaction when the molecule includes a second benzene ring (naphthalene derivatives) appreciably exceeds the energy of the interaction of the functional group (OH, NH_2, etc.) with the bismuth surface.

Table 2.

Compound	$-\Delta G_A$, kcal mole^{-1}		Compound	$-\Delta G_A$, kcal mole^{-1}	
	Bi	Hg		Bi	Hg
Phenol	1.0	1.8	o-Toluidine	1.5	2.2
Cyclohexanol	0.3	—	Pyridine	0.6	0.9
Catechol	1.8	2.7	Benzene	0	0.5
Hydroquinone	2.8	3.7	Toluene	0.4	0.7
o-Cresol	1.3	—	Naphthalene	2.2	—
Benzyl alcohol	1.3	—	α-Naphthol	3.9	—
Benzoic acid	1.3	1.74	α-Naphthylamine	3.6	—
Aniline	1.2	2.5	α-Naphthoic acid	3.6	—

The difference between the adsorption behaviour of organic compounds on mercury and bismuth becomes appreciably enhanced for high positive surface charges. Experimental data have shown that anodic adsorption–desorption maxima for aliphatic compounds on bismuth are displaced by 0.1–0.15 V towards less positive values of φ than on mercury[27–29,39–45]. The main cause of this effect is the appreciable intensification of the chemisorption of water molecules with increase of ϵ on bismuth[46].

An important result of the different hydrophilic properties of metals and of different interactions of the functional group with the electrode surface in the adsorption of organic compounds is appreciable differences in the orientation of the adsorbate molecules in the adsorption layer[27–29,39–45]. On a bismuth electrode, organic compounds are oriented more vertically in the adsorption layer than on the mercury surface. The differences between the orientations of the adsorbed molecules are clearly shown in the adsorption of coumarin on bismuth and mercury. Coumarin molecules are adsorbed on mercury[47] and bismuth[48] in two different positions: in the vertical position at $\epsilon < 0$ and in an inclined position near $\varphi_{\epsilon=0}$. Fig. 3 shows that the regions corresponding to the adsorption of coumarin on mercury in the two positions are separated by narrow reorientation peaks; on the other hand, there is virtually no reorientation maximum on bismuth. Theoretical analysis of experimental C–φ curves for the adsorption of coumarin, based on the model of three parallel condensers, showed that the orientation of coumarin molecules in the adsorption layer on bismuth is appreciably more vertical than on mercury, as a result of which the attraction interaction between the horizontally and vertically oriented molecules on bismuth is much stronger than on mercury[48].

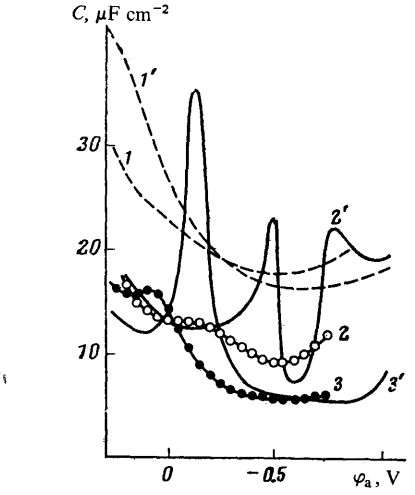

Figure 3. Differential capacitance curves for bismuth (curves *1–3*) and mercury (curves *1′–3′*) in 1 *N* potassium sulphate (bismuth) and sodium sulphate (mercury) solutions with added coumarin; coumarin concentration (M): 1) and 1′) 0; 2) and 2′) 7×10^{-4}; 3) and 3′) 5×10^{-3} (the electrode potentials were measured relative to the zero-charge point.

Although there are few literature data on the structure of the electrical double layer in non-aqueous solvents, nevertheless one might assert that the specific interaction of solvent molecules with the metal surface in the dense layer is manifested also in non-aqueous solvents.

Table 3.

Solvent	$\Delta\varphi^{Bi-Hg}_{\epsilon<0}$, V	$\Delta\varphi^{Bi-Hg}_{\epsilon=0}$, V	$\Delta\varphi^{Bi-Hg}_{\epsilon<0} - \Delta\varphi^{Bi-Hg}_{\epsilon=0}$, V	Electrolyte
Water	−0.145	−0.190	−0.045	0.1 *N* Na_2SO_4
Methanol	−0.14	−0.18	−0.04	0.1 *M* NH_4F
Acetonitrile	−0.13	−0.16	−0.03	0.1 *M* $NaClO_4$
Dimethyl-formamide	−0.14	−0.25	−0.11	0.1 *M* $NaClO_4$
Dimethyl sulphoxide	−0.09	−0.15	−0.06	0.1 *M* $LiClO_4$

Table 3 presents the differences between the zero-charge potentials on mercury and bismuth ($\Delta\varphi^{Bi-Hg}_{\epsilon=0}$) and the potential differences at a constant high negative charge ($\Delta\varphi^{Bi-Hg}_{\epsilon=0}$) for various non-aqueous solvents[19]. The latter differences should depend relatively little on the nature of the solvent[34,49].

The data in Table 3 show that the values of $\Delta\varphi^{Bi\text{-}Hg}_{\epsilon \ll 0}$ (for $\epsilon = -10 - -17 \mu C\ cm^{-2}$) depend comparatively little on the nature of the solvent, while the dependence of $\Delta\varphi^{Bi\text{-}Hg}_{\epsilon = 0}$ is appreciably greater. Evidently in all the solvents investigated the preferential orientation of the dipoles with the negative ends towards the metal surface at $\epsilon = 0$ is somewhat more pronounced on bismuth than on mercury. Particularly notable effects are observed in dimethylformamide (DMF) and dimethyl sulphoxide (DMSO). Comparison of the $\epsilon - \varphi$ curves for mercury and gallium or an indium–gallium alloy showed that near $\varphi_{\epsilon = 0}$ for gallium or an indium–gallium alloy DMSO molecules are clearly oriented with the negative end of the dipole towards the electrode surface[49]. On the other hand, in acetonitrile the specific interaction between the acetonitrile dipoles and gallium or an indium-gallium alloy is extremely weak.

The nature of the solvent has an appreciable influence on the adsorption of ions on electrodes. The most systematic data for the adsorption of ions from non-aqueous solvents are available for the bismuth electrode[17,19,50–56]. Table 4 presents the adsorption equilibrium constants ($\ln\beta_{\epsilon = 0}$), referring to the virial isotherm, for various ions on bismuth.

Evidently the free energy of adsorption depends very strongly on the nature of the surface-active ion, and increases greatly on passing from cations to anions. Among alkali metal cations, Cs^+ and Rb^+ exhibit the highest surface activity, while the remaining cations are adsorbed much more weakly.

The significant difference between the free energies of adsorption of cations and anions shows that different types of forces are responsible for the specific adsorption of the two types of species. For a given ion, the free energy of adsorption depends significantly on the nature of the solvent. In the adsorption of cations from protic solvents (water and alcohols) the values of $\ln\beta_{\epsilon = 0}$ are higher by several orders of magnitude than for adsorption from aprotic solvents (DMF). The main cause of this effect is the appreciable enhancement of the solvation of cations on passing to aprotic solvents[57]; the different energies of interaction of the corresponding solvent molecules with the electrode surface also play a definite role. The opposite phenomenon occurs in anion-active systems—the free energy of adsorption increases appreciably (with the exception of the SCN^- anion) on passing from protic to aprotic solvents, which is mainly associated with the weakening of the solvation of anions in aprotic solvents[57]. As a result of the weakening of the solvation of halides, in the series $I^- > Br^- > Cl^-$, aprotic solvents lead to the equalisation of the free energies of adsorption.

Judging from the available literature data[53], the free energy of adsorption of cations depends little on the nature of the electrode. On the other hand, the free energy of adsorption of anions on bismuth in aqueous and alcoholic solutions is appreciably lower than on mercury. In DMF (there are no data for mercury in acetonitrile) the energy of adsorption of anions on bismuth[56] is virtually the same as on mercury[58].

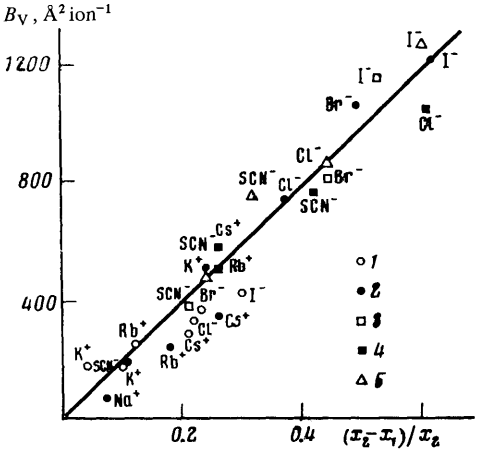

Figure 4. Variation of the second virial coefficient with the ratio $(x_2 - x_1)/x_2$ for different ions in different solvents: 1) water; 2) methanol; 3) acetonitrile; 4) dimethylformamide; 5) ethanol.

The nature of the solvent has a significant influence on the repulsion interaction between specifically adsorbed ions. It has been established for the bismuth electrode that the repulsion interaction is enhanced for a given ϵ = const., both with increase of the radius of the ions and with increase of the dimensions of the molecules of the solvent. Fig. 4 compares the second virial coefficients B with the ratios $(x_2 - x_1)/x_2$†.[17,51] To a first approximation, the relation illustrated in Fig. 4 may be regarded as linear; it suggests that the repulsion interaction of the adsorbed ions increases almost in proportion to the distance of the plane containing the charge centres of the specifically adsorbed ions from the outer Helmholtz plane. This relation can be accounted for qualitatively by the weakening of the screening effect of the diffuse layer on the repulsion between the specifically adsorbed ions with increase of the distance $x_2 - x_1$.[17,51,58,59]

IV. THE INFLUENCE OF THE STRUCTURE OF THE ELECTRICAL DOUBLE LAYER ON THE KINETICS OF THE CATHODIC EVOLUTION OF HYDROGEN

Kinetic studies have shown that surface-fused solid electrodes are the most suitable objects for the quantitative study of electrode reactions, particularly the cathodic

† x_1 and x_2 are the distances of the inner and outer Helmholtz planes from the electrode surface respectively.

evolution of hydrogen. When the surface of the metal is fused in an inert atmosphere, a stable state of the surface layer of metal is achieved and the occurrence of certain side reactions (the incorporation of cations from an alkaline solution), which greatly hinder the study of the true kinetics of hydrogen evolution, is strongly inhibited on electrodes of this kind[60].

Owing to the relatively high hydrogen overvoltage and the negative potential $\varphi_\epsilon = 0$, metals such as bismuth, tin, lead, and cadmium are suitable for the investigation of the influence of the structure of the electrical double layer on the rate of evolution of hydrogen in the region of polarisations close to $\varphi_\epsilon = 0$, where double layer effects should be manifested most clearly. According to the equation proposed by Frumkin on the basis of the theory of the slow discharge of H_3O^+,

$$\eta = a + \frac{1-\alpha}{\alpha}\psi_1 - \frac{1-\alpha}{\alpha}\frac{RT}{F}\ln c_{H_3O^+} + \frac{RT}{\alpha F}\ln i, \qquad (1)$$

the overvoltage η for a constant composition of the solution is influenced not only by the change in current density i, but also by the change in the ψ_1 potential. In Eqn. (1) a is a constant, α the transfer coefficient, and F the Faraday.

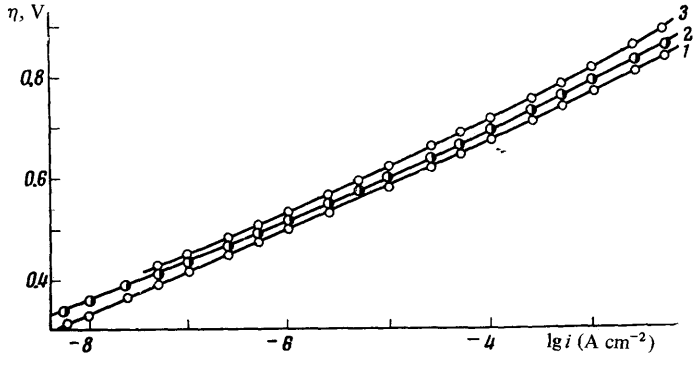

Figure 5. Polarisation curves for the evolution of hydrogen on bismuth in different solutions: 1) 1 N $HClO_4$; 2) 0.1 N $HClO_4$; 3) 0.1 N $HClO_4$ + 0.9 N $LiClO_4$.

Measurements on bismuth have shown that, in highly purified solutions (complete elimination of oxygen and of traces of other depolarisers), the variation of η with $\lg i$ in solutions of surface-inactive electrolytes is described by smooth curves without any sharp jumps in both aqueous[61,62] and methanol[63] media (Fig. 5). The low slopes of these curves, which depend on the acid concentration $c_{H_3O^+}$ and on η, are caused both by the change in the diffuseness of the double layer with electrode potential and electrolyte concentration and by the fact that the coefficient α for the hydrogen evolution reaction on bismuth exceeds 0.5.[61,62]

Using the values of ψ_0 instead of ψ_1 (this is justified to a first approximation for surface-inactive electrolytes), corrected Tafel relations (c.t.r.) were plotted for the hydrogen evolution reaction on bismuth. Such relations in 0.1 and 1.0 M $HClO_4$ solutions are linear over a wide range of potentials (Fig. 6). The results show that α is independent of acid concentration and amount to 0.61 ± 0.01. The higher value of the coefficient α was confirmed in a study of the dependence of η on $c_{H_3O^+}$ at a constant overall electrolyte concentration with the coefficient $(\partial\eta/\partial \ln c_{H_3O^+})_c = -36$ mV and also in the determination of the change in η caused by the increase of the overall electrolyte concentration $c_{H_3O^+}$ = const.

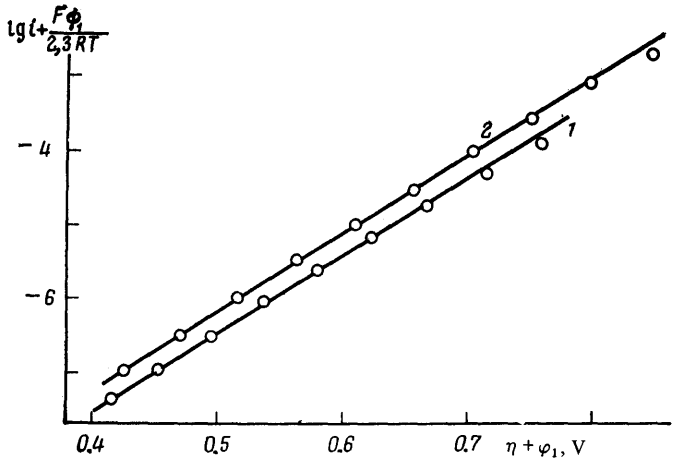

Figure 6. Corrected Tafel relations for the cathodic evolution of hydrogen on bismuth in $HClO_4$ solutions (N): 1) 1.0; 2) 0.1.

It has been shown[64] that, when the fundamental postulates of the diffuse layer theory and the double layer model proposed by Gram in the absence of specific adsorption are used, the slope of the η–$\lg i$ curve can be calculated from the formula

$$b_{theor} = \left[\frac{\alpha F}{RT} + \frac{2(1-\alpha)C_G}{\sqrt{4A^2c + \epsilon^2} + \frac{2RT}{F}C_G}\right]^{-1}, \qquad (2)$$

where C_G is the capacitance of the dense layer and $A = \sqrt{DRT/2\pi}$ (D is the dielectric constant). Comparison of the experimental coefficients b with b_{theor} in 0.1 M $HClO_4$ solutions corresponding to different values of η for bismuth shows that, when $\eta < 0.8$ V, the agreement between experiment and calculation is extremely satisfactory. The significant discrepancies between the values of b for $\eta \geq 0.8$ V are probably caused by the specific properties of bismuth (metallisation) and are not related to the inaccuracy of Eqn. (2).[64]

Quantitative analysis of kinetic and capacitance data in terms of the model ideas developed by Krishtalik[65] showed that in the case of bismuth a fraction of the overall potential jump at the interface corresponds to the metallic phase[66]. It has been suggested that the decrease of α for $\eta \geq 0.8$ V ($\epsilon \gg 0$) is due to the metallisation of bismuth[29]. This hypothesis has been confirmed in a study of the chemisorption of water on bismuth[67].

Data similar to those quoted above were also obtained in a study of the kinetics of the evolution of hydrogen in the region of $\varphi_\epsilon = 0$ on gallium, indium, and their amalgams at elevated temperatures[68-71]. On the other hand, at room temperature the slope of the η – $\lg i$ curves for gallium[72], tin[73], and cadmium[14] proved to be virtually

independent of η, although the values of $\varphi_{\epsilon=0}$ for these metals are in the range of i accessible to measurement. The causes of such phenomena on cadmium and tin have not been established; they are probably associated with the enhanced hydrophilic properties of these metals[14,72].

Direct study of the kinetics of the cathodic evolution of hydrogen in an alkaline medium is possible on electrodes smoothed by surface fusion, because there is virtually no incorporation of alkali and alkaline earth metals into such electrodes owing to the comparatively overvoltage for such incorporation[60]. It has been found that the evolution of hydrogen on antimony[12,74], tin[75], and cadmium[14] electrodes takes place in alkaline solutions of different compositions via the mechanism involving the slow discharge of protons derived from water molecules. This mechanism was proposed for the first time by Frumkin and coworkers[76] for the nickel electrode as early as 1939.

Alkali and alkaline earth metal cations in solution exhibit an accelerating effect on the rate of evolution of hydrogen, which in the case of tin increases in the series from Li^+ to Cs^+ and from Ca^{2+} to Ba^{2+}.[75] In interpreting this effect, use was made of the hypotheses of both the specific adsorption of cations and of the involvement in the discharge process of the water molecules in the hydration shells of the cations[75,77]. As regards the influence of cations on η in an alkaline medium, there is a similarity between tin on the one hand and antimony[12,74] and cadmium[14] and partly liquid gallium[78] and saturated indium amalgam[77,79] on the other. The evolution of hydrogen on pure mercury in alkaline solutions is known to proceed via a mechanism different from that described above[79,80].

Adsorption Phenomena on Platinum Group Metal Electrodes

O.A.Petrii

Certain fundamental concepts and definitions in the thermodynamic theory of the platinum electrode are examined and the concepts of the zero total charge and zero free charge potentials and methods for determination of these quantities are discussed. Data indicating charge transfer in chemisorption processes are analysed and a thermodynamic approach to the analysis of this phenomenon is considered. The influence of the pH of the solution on the structure of the platinum metal-electrolyte solution interface is examined.
The bibliography includes 186 references.

I. INTRODUCTION

The study of the structure of the platinum metal–electrolyte solution interface was begun by Frumkin and coworkers at the end of the 1920s and the beginning of the 1930s.[1-8] They developed methods for the measurement of charging and adsorption curves, laid the foundations of the thermodynamic theory of surface phenomena on platinum metals, and formulated the fundamental idea of a close relation between the adsorption of ions in solution and the adsorption of hydrogen and oxygen atoms. Subsequently the Soviet electrochemical school made a significant contribution to the study of the above interface, which has been reflected in a number of reviews[9-13]. Some of the main results obtained in the last 10–15 years are discussed in the present review. The considerable attention devoted to the adsorption properties of platinum metals during this period is due to attempts at devising fuel cells and the extensive development of research on liquid-phase catalytic hydrogenation and oxidation reactions and electrosynthetic processes.

One of the characteristic features of the development of such studies in recent years is the increased number of systems investigated. Together with a further deepening of the investigation of the adsorption properties of the platinum electrode, measurements have also been made on other platinum metals and their alloys (on smooth polycrystalline and single-crystal electrodes, on electrolytic deposits of platinum metals, on metal blacks, and on deposited catalysts).

A second noteworthy characteristic feature is the wide range of experimental techniques which have been used in the investigation of adsorption phenomena on platinum group metals. Thus the method of radioactive tracers[14-16] has been significantly improved, which made it possible to increase the accuracy and reliability of the results obtained by this method and extended its scope, particularly in the study of the kinetics of adsorption and of the exchange of adsorbed ions with ions in the solution. The potentiodynamic method and potentiostatic pulse methods for the investigation of adsorption have been appreciably expanded and developed[17-23]. A series of adsorption studies has been carried out by the two-electrode thin-layer method[24-48]. New information about the state of the surface layer on platinum metals has been provided by the method involving the measurement of estance[49-66]. The method of the rotating disc electrode with a ring has been used to investigate the adsorption and anodic elimination of adsorbed species[67-78]. Attempts have been made at a detailed study of the surface properties of platinum metals with the aid of optical methods (ellipsometry, electroreflectance)[79-86] and by measuring the electrical resistance of thin metallic films sputtered *in vacuo* on to a non-conducting base[87-95].

II. SOME CONCEPTS AND RELATIONS OF THE THERMODYNAMIC THEORY OF THE PLATINUM ELECTRODE

The third characteristic feature of the period under consideration is the application of the thermodynamic theory of the reversible electrode in the interpretation of the behaviour of platinum metals in electrolyte solutions. This theory was outlined by Frumkin and coworkers[7-9], was applied by them for the first time in a later study[96], and was subsequently developed further[97-124]. The last series of studies was stimulated directly by the derivation[97] of an equation which made it possible to carry out a comparatively simple experiment test of the applicability of the Gibbs adsorption equation to platinum metals. Such a test for 30 different systems comprising platinum[98,99,101,105,109,110,112,125], palladium[126], rhodium[100,101,104,111], iridium[108,111,115], ruthenium, and platinum–ruthenium[101,103] electrodes showed that the thermodynamic theory is applicable not only at potentials in the hydrogen and "double layer" regions, but also in the initial section of the region corresponding to the adsorption of oxygen on the electrodes. The pronounced phenomena associated with the chemisorption of ions from solution result in a narrowing of the region of practical applicability of the theory.

The thermodynamic theory led to the development of the method of isoelectric potential shifts[98,99] (the first measurements of the shifts of the potential of an isolated

electrode following the alteration of the pH of the solution were undertaken in early investigations[7,8]). A potentiometric titration procedure for a constant total surface charge, which made it possible to investigate the adsorption properties of platinum and rhodium in the range of intermediate pH value which had been previously inaccessible to experimental study[128-131], was developed recently[127].

In the experimental test of the thermodynamic theory in solutions of acids HA with an excess of the neutral salt CA $\{[HA] \ll [CA]\}$ the following relation was used:

$$(\partial\varphi_r/\partial\mu_{H^+})_{\Gamma_H,\mu_{CA}} = (\partial\Gamma_{H^+}/\partial\varphi_r)_{\mu_{H^+},\mu_{CA}}/(\partial\Gamma_H/\partial\varphi_r)_{\mu_{H^+},\mu_{CA}}, \quad (1)$$

where φ_r is the potential relative to the reversible hydrogen electrode in the same solution, μ_{H^+} and μ_{CA} are the chemical potentials of hydrogen ions and the salt, and Γ_H and Γ_{H^+} are the Gibbs adsorptions of hydrogen atoms and ions respectively. All the quantities in Eqn. (1) are expressed in electrical units. This equation is valid also for solutions of neutral salts which have been made alkaline. The term "isoelectric potential shift" (introduced for the first time by Ponomarenko et al.[132]) was proposed for the quantity $(\partial\varphi_r/\partial\mu_{H^+})_{\Gamma_H,\Gamma_{CA}}$. The Gibbs adsorptions Γ_H and Γ_{H^+} represent the amounts of the corresponding components which must be introduced into the system for their chemical potentials to remain unchanged without the supply of electricity from the outside when the surface area of the electrode is increased by 1 cm^2. Evidently the electrode potential also remains constant under these conditions. The Gibbs adsorptions must be distinguished from the excess surface amounts, which are designated by A_H and A_{H^+} respectively. The relations between Γ_H and A_H and between Γ_{H^+} and A_{H^+} are

$$\Gamma_H = A_H - \varepsilon, \quad (2)$$

and

$$\Gamma_{H^+} = \varepsilon + A_{H^+}, \quad (3)$$

where ϵ is the charge of the metallic component of the electrical double layer.

Whereas both Γ_H and Γ_{H^+} are thermodynamic quantities susceptible in principle to direct experimental determination, the introduction of the quantities A_H, A_{H^+}, and ϵ is associated with definite model assumptions. In particular, in the determination of A and ϵ no account is taken of the partial charge transfer via the Lorenz mechanism[133] for all the ions in the double layer. For strongly chemisorbed ions, it is almost impossible to determine ϵ unambiguously. In the presence of an excess of the salt in solution, hydrogen ions are displaced from the diffuse part of the double layer by the salt cation[113,134,135], so that $A_{H^+} = 0$ and $\Gamma_{H^+} = \epsilon$.

It has been shown[117-119] that $\Gamma = -Q'$ and $\Gamma_{H^+} = Q''$, where Q' and Q'' are the total surface charges, i.e. the amounts of electricity which must be introduced at μ_{H^+} = const. or μ_H = const. respectively in order to prevent a change in the composition of the bulk phase following an increase of the surface area of the electrode by 1 cm^2 when the loss of material is compensated by the introduction of an amount of substance $\Gamma_H + \Gamma_{H^+} = A_H + A_{H^+}$ (H in the former case and H^+ in the latter case). Henceforth the symbol Q will be used for Q' and this quantity will be called the total charge (the condition μ_{H^+} = const. is omitted for brevity). Instead of Q'', the symbol Γ_{H^+} will be empoyed; in order to distinguish this total charge from Q, we shall adopt the term free charge for Γ_{H^+}.

III. CHARGING CURVES OF THE FIRST AND SECOND KINDS

According to the general concept of the electrode charge, there should exist two types of charging curve for platinum metals. The usual charging curve, characterising the relation between the total charge Q and the potential φ at a constant chemical potential of hydrogen ions (μ_{H^+} = const.) may be called the charging curves of the first kind. Since according to the literature[117,119]

$$(\partial\sigma/\partial\varphi_A)_{\mu_{HA},\mu_{CA}} = \Gamma_H = -Q, \quad (4)$$

where σ is the amount of reversible surface work and φ_A the potential referred to an electrode reversible with respect to the anion, integration of charging curves of the first kind makes it possible to determine the electrocapillary curves of the first kind (to within an integration constant). Accordingly, the derivative $(\partial Q/\partial\varphi)_{\mu_{H^+},\mu_{CA}} = -(\partial\Gamma_H/\partial\varphi)_{\mu_{H^+},\mu_{CA}} = C$ may be called the differential capacitance of the first kind. In the literature this quantity is usually referred to as the polarisation capacitance or the total capacitance of the electrode.

Charging curves of the second kind represent the relation between the total charge Γ_{H^+} and the electrical potential corresponding to a constant chemical potential of hydrogen μ_H = const. (φ_r = const.). Since

$$(\partial\sigma/\partial\varphi_A)_{\mu_H,\mu_{CA}} = -\Gamma_{H^+}, \quad (5)$$

integration of charging curves of the second kind leads to electrocapillary curves of the second kind. The quantity $(\partial\Gamma_{H^+}/\partial\varphi)_{\mu_H,\mu_{CA}}$ may be called the differential capacitance of the second kind. In a solution containing an excess of an extraneous inactive electrolyte, it can be set equal to the equilibrium capacitance of the electrical double layer.

The methods for the measurement of the usual charging curves are generally known[9]. In order to find the charging curves of the second kind corresponding to φ_r = 0, a potentiometric titration method with a large indicator electrode has been employed[7,8,136,137]. Charging curves of the second kind for anodic values of φ_r have been obtained by intersecting a family of Γ_{H^+}–φ_r curves, obtained by potentiometric titration under isoelectric conditions, by vertical φ_r = const. lines[130,138]. These curves have a simpler shape than the usual charging curves corresponding to the condition μ_{H^+} = const., since the changes in the amounts of adsorbed hydrogen and oxygen at φ_r = const. are relatively small. The decrease of the slope of the curves with increasing φ_r is due to the transition from the region of adsorption of the cations to that of the anions.

IV. THE ZERO TOTAL CHARGE AND ZERO FREE CHARGE POTENTIALS

It follows from the general concept of electrode charge that there should exist zero total charge and zero free charge potentials for platinum metals. The potential at which the quantity $-\Gamma_H = Q = \epsilon - A_H$ becomes zero is called the zero total charge potential $\varphi_{Q=0}$ (z.t.c.p.). The potential at which the total charge Γ_{H^+} becomes zero in a solution with an excess of a neutral salt is called the zero free charge potential $\varphi_{\Gamma_{H^+}=0}$ (z.f.c.p.).

A method for determination of z.t.c.p. on the basis of the non-thermodynamic equation $Q = \epsilon - A_H$ has been

described[7,8,116] and the results of the determination of $\varphi_{Q=0}$ for platinum metals by this procedure are presented in Table 1. The highest anodic values of $\varphi_{Q=0}$ correspond to palladium and platinum. The $\varphi_{Q=0}$ shift in the negative direction with increase of the adsorbability of the anions of the solution and in the positive direction with increase of the adsorbability of the cations. It has been shown[115,124] that the method in which the surface of the electrode is scraped off in solution[139-142] should lead in principle to $\varphi_{Q=0}$ if an equilibrium is established during the scraping process between the electrode and the solution and the pH of the latter remains constant.

The most reliable values of z.f.c.p. were obtained from direct measurements of the relation between Γ_{H^+} and φ_r or from measurements of the dependence of the adsorption of anions Γ_{A^-} and cations Γ_{C^+} on φ_r in solutions with an excess of the salt. In the second method, employed for the first time by Balashova and Merkulova[143], z.f.c.p. represents the potential at which $\Gamma_{A^-} = \Gamma_{C^+}$, since, by virtue of the electroneutrality condition, $\Gamma_{H^+} = \Gamma_{A^-} - \Gamma_{C^+}$. The values of z.f.c.p. found by the above method are listed in Table 2. The z.f.c.p. shift in the negative direction along the series Pt > Pd > Rh > Ir > Ru and are less positive than the z.t.c.p. Both z.t.c.p. and z.f.c.p. shift in the negative direction in the presence of specifically adsorbably anions and in the positive direction in the presence of specifically adsorbable cations.

In solutions of a surface-inactive electrolyte, z.f.c.p. is the zero-charge potential of the double layer (z.c.p.) and is analogous to z.c.p. of metals which do not adsorb hydrogen and oxygen. The Li^+ and Na^+ cations and F^- anions are least adsorbable on platinum metals[144-149]. In the presence of these ions z.f.c.p. may be regarded as z.c.p. In other cases chemisorption bonds arise between the surface of the metal and the adsorbed ions, whose strength depends on the nature of the ion and the electrode and also on the potential and pH of the solution. As a result, there is a possibility of partial or even total transfer of the charge of the ion being adsorbed to the surface of the metal. The transition of ions undergoing adsorption to the atomic adsorbed state under the conditions of an "insufficient potential", i.e. up to potentials corresponding to equilibrium values, for example in metal–metal ion systems, has been recently investigated by a wide variety of methods[24-48,67-78,83,95,150,151]. Measurements of the superequivalent adsorption of anions on platinum (Fig. 1) and rhodium are instructive in this respect[152]. These measurements indicate an increase of the superequivalent adsorption of anions on platinum in the series $SO_4^{2-} < I^- < Cl^- < Br^-$ and on rhodium in the series $SO_4^{2-} < Br^- < Cl^-$. The anomalous positions of I^- and Br^- in these series and also the nature of the variation of the degree of adsorption of cations with potential for positive surface charges (Fig. 1) can be interpreted, provided it is assumed that the degree of charge transfer from the anions to the surface of the metal increases with increasing adsorbability of the anions and when the potential shifts towards anodic values.

Owing to charge transfer, the definition of ϵ and the assumption that $\varphi\Gamma_{H^+}=0$ is equal to z.c.p. become arbitrary. For this reason, the quantity $\varphi\Gamma_{H^+}=0$, the physical significance of which is independent of the nature of the solution, may be regarded as equal to z.c.p. merely as a matter of convention in systems containing specifically adsorbable ions. The conventional nature of the concept of z.c.p. in the presence of strong specific adsorption can be clearly demonstrated[153] for a platinum electrode coated by adsorbed iodide and thallium ions. It has been shown that the position of z.c.p. depends on whether the adsorbed iodide and thallium ions become attached to the metallic or ionic components of the double layer.

V. FORMAL CHARGE TRANSFER COEFFICIENTS IN CHEMISORPTION PROCESSES

The problem of charge transfer in chemisorption processes has been recently discussed in detail[154-165]. It is noteworthy that the thermodynamic approach to charge transfer in the adsorption of hydrogen atoms on the surface of platinum was outlined in early investigations[7,8] in terms of the contributions of the hydrogen atom (X) and the double layer ion (Y), with the corresponding charge on the metal, to the potential jump at the electrode/solution interface. It has been shown[158,163] that chemisorption processes can be usefully characterised by formal charge transfer coefficients, which are referred to as such because they reflect not only the fraction of the charge transferred from the adsorbed species to the electrode but also the change in the parameters of the double layer caused by the adsorption process. In the adsorption of hydrogen atoms on the electrode surface the formal charge transfer coefficient n_2 may be calculated from the equation

$$n_2=(\partial\Gamma_{H^+}/\partial\Gamma_\Sigma)=-X/Y, \tag{6}$$

where $\Gamma_\Sigma=\Gamma_H+\Gamma_{H^+}$. The results of the calculation of n_2 indicate an appreciable polarity of the bonds between platinum and rhodium on the one hand, and oxygen on the other[138,158,163]. The chemisorption of an ion j on a platinum electrode is characterised by two formal charge-transfer coefficients:

$$n_j'=(\partial\Gamma_H/\partial\Gamma_j)_{\Gamma_{\Sigma,\varphi}} \tag{7a}$$

and

$$n_j''=(\partial\Gamma_{H^+}/\partial\Gamma_j)_{\Gamma_{\Sigma,\varphi}}, \tag{7b}$$

where Γ_j is the Gibbs adsorption of the ion.

VI. THE INFLUENCE OF THE pH OF THE SOLUTION ON THE STRUCTURE OF THE ELECTRODE/SOLUTION INTERFACE

The thermodynamic theory yielded relations between z.t.c.p. and z.f.c.p. on the one hand and the concentration of the neutral salt at a constant pH (and also at a constant concentration of the acid or alkali in solution) on the other[101,123]:

$$(\partial\varphi_r/\partial\mu^{\pm}_{CA})_{Q,\mu_{H^+}}=-(\partial\Gamma_{C^+}/\partial Q)_{\mu^{\pm}_{CA},\mu_{H^+}}-(\partial\Gamma_{A^-}/\partial Q)_{\mu^{+}_{CA},\mu_{H^+}}; \tag{8}$$

$$(\partial\varphi_r/\partial\mu^{\pm}_{CA})_{\Gamma_{H^+},\mu_{H^+}}=-2(\partial\Gamma_{C^+}/\partial\Gamma_{H^+})_{\mu^{\pm}_{CA},\mu_{H^+}}-$$
$$-2(\partial A_H/\partial\mu_{CA})_{\varphi_r,\mu_{H^+}}/(\partial\Gamma_{H^+}/\partial\varphi_r)_{\mu_{H^+},\mu^{\pm}_{CA}}, \tag{9}$$

where $\mu^{\pm}_{CA}$ is the average chemical potential of the salt ions. These expressions can be referred to as the relations for the Esin–Markov coefficient in the case of platinum metals. Owing to the presence of two total charges (Q and Γ_{H^+}), there exist two Esin–Markov coefficients for platinum metals, in contrast to mercury. When a comparison is to be made with a mercury electrode, one should evidently use the quantity $(\partial\varphi_r/\partial\mu^{\pm}_{CA})_{\Gamma_{H^+}\mu_{H^+}}$.

Eqns. (8) and (9) become identical and the same as the relation for mercury when the electrode surface is free from adsorbed hydrogen and oxygen atoms (the double-layer potential range). Direct determinations of the Esin–Markov coefficients in the double-layer region[101] led to the conclusion that they are equal to −1, i.e. that there is no discreteness effect in the adsorption of anions on platinum metals. This phenomenon has been explained by pronounced charge transfer from the anions to the surface of the metal.

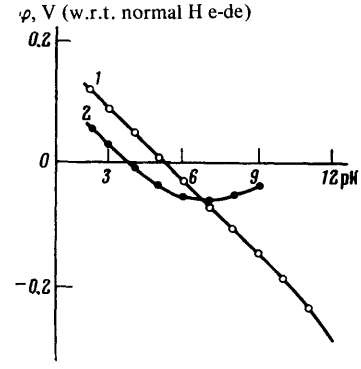

Figure 2. Variation of z.t.c.p. (curve *1*) and z.f.c.p. (curve *2*) with solution pH for a platinised platinum electrode in 0.1 *N* KCl (according to the data of Frumkin et al.[130]).

The variation of z.t.c.p., z.f.c.p., and Γ_{H^+} with solution pH is of special interest, The variation of z.t.c.p. for platinum and rhodium with pH over the entire range of the latter was found directly by the method of potentiometric titration under isoelectric conditions[127-131] (Fig. 2). It was found that at lower pH values, the potential $\varphi_{Q=0}$ shifts in a negative direction by 35–50 mV (depending on the composition of the solution and the nature of the metal) when pH is increased by unity. This relation becomes somewhat more marked at higher pH values and, for example in the case of the rhodium electrode in 0.1 *N* Na_2SO_4 at pH 7–12, the shift of $\varphi_{Q=0}$ amounts to about 58 mV per pH unit. According to the thermodynamic theory, we have for solutions with an excess of the salt[120]

$$(\partial\varphi/\partial\mu_{H^+})_{Q=0}=[1-(\partial\epsilon/\partial A_H)_{\mu_{H^+}}]^{-1}. \tag{10}$$

The observed relations between $\varphi_{Q=0}$ and pH imply that at lower pH values $(\partial\epsilon/\partial A)_{\mu_{H^+}}<0$, i.e. the free charge becomes more positive when φ_r shifts. At pH values in the alkaline region $(\partial\epsilon/\partial A_H)_{\mu_{H^+}}\simeq 0$, which corresponds to the relatively weak dependence of Γ_{H^+} on φ_r in alkaline solutions.

The variation of z.f.c.p. and Γ_{H^+} with pH was first observed by Shlygin et al.[6] Subsequently interest in this problem was aroused by the study of Kheifets and Krasikov[167]. The influence of pH on the z.f.c.p. values for platinum metals has been investigated[109,115,116,168,169]. The most complete data have been obtained by the method of potentiometric titration under isoelectric conditions[130,131]. Fig. 2 illustrates the variation of z.f.c.p. with pH for a platinised platinum electrode in 0.1 M KCl solution. A similar variation of z.f.c.p with pH was also found for platinised platinum and rhodium electrodes in 0.1 N Na_2SO_4. It follows from Fig. 2 that in the pH range 2.3–5 z. f. c. p. shifts with increasing pH towards cathodic values by about 35 mV when the pH is altered by unity. In the pH range 5–9 the shift of z. f. c. p. is small, and at pH > 7 z. f. c. p. begins to shift in the positive direction as the pH is increased. The complex variation of $\varphi_{\Gamma_{H^+}=0}$ with pH is due to the fact that $\varphi_{\Gamma_{H^+}=0}$ shifts from the hydrogen to the double layer region and then to the region where adsorbed oxygen is deposited. The following relation holds for the variation of z.f.c.p. with pH:[106,107,109]

$$(\partial\varphi/\partial\mu_{H^+})_{\Gamma_{H^+}=0} = [1 - (\partial\epsilon/\partial A_H)_{\varphi_r}]^{-1}, \qquad (11)$$

which shows that the shift of z.f.c.p. in the negative direction with increasing pH corresponds to $(\partial\epsilon/\partial A_H)_{\varphi_r} < 0$. When $A_H = 0$, we obtain $(\partial\varphi/\partial\mu_{H^+})_{\Gamma_{H^+}=0}$, and when $(\partial\epsilon/\partial A_H)_{\varphi_r} > 1$, the shift of z.f.c.p. may be in the positive direction. Then pH ~7, $\varphi_{Q=0} = \varphi_{\Gamma_{H^+}=0}$ (Fig. 2). In this case $\varphi_{Q=0}$ and $\varphi_{\Gamma_{H^+}=0}$ correspond to the double layer region of the platinum electrode, i.e. to the region of its ideal polarisability where $Q = \Gamma_{H^+}$.

The results made it possible to plot the variation of z.f.c.p. with A_H and to find its value for $A_H = 0$, i.e. for the platinum surface free from hydrogen and oxygen. It proved to be −0.06 V (relative to the normal hydrogen electrode). Thus z.f.c.p. for the platinum surface free from hydrogen and oxygen is more positive by only 0.2–0.3 V than z.c.p. for mercury. The difference $\varphi^{Pt}_{\epsilon=0} - \varphi^{Hg}_{\epsilon=0}$ is inconsistent with the familiar relation between the electron work function and z.c.p.,[170–172] since the difference between the electron work functions of platinum and mercury is 0.9–1.0 V according to ultrasonic measurements[173]. The problem of the causes of the discrepancy requires further study. Possibly it is associated with the different structures of the adsorbed layers of water on platinum and mercury and with the difference between the structure of platinum crystallites grown in contact with water or platinum subjected to anodic-cathodic activation on the one hand and platinum treated with ultrasound at a high temperature on the other.

Fig. 3 presents the variation of the free surface charge of a platinised platinum electrode with potential in 0.1 M KCl solution at different pH values obtained by the method of potentiometric titration under isoelectric conditions[130]. These data make it possible to put forward the hypothesis of a gradual transition with increasing pH to an electrode surface negatively charged throughout the entire range of φ_r. Such a phenomenon is typical for all platinum metals. Its interpretation is based on allowance for the simultaneous influence of two factors: the shift of the range of potentials in which measurements are made in the negative direction and a more pronounced overlapping of the regions corresponding to the adsorption of hydrogen and oxygen as the pH is increased. Hydrated surface oxide groups are probably weakly acidic and split off hydrogen ions in alkaline media, adsorbing cations. Thus in alkaline solutions there is a transition from the adsorption of cations, caused by the ionisation of the adsorbed hydrogen and decreasing over a range of φ_r values, to the adsorption of cations on the surface of oxide groups, which becomes more marked also over a range of φ_r values.

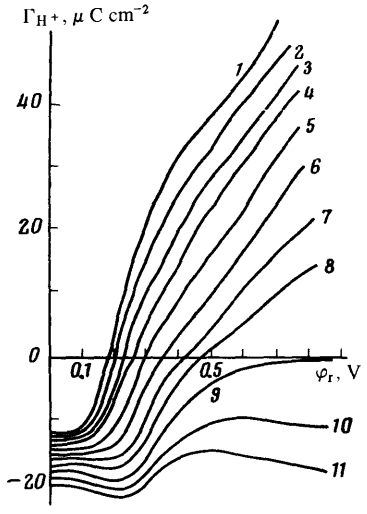

Figure 3. Variation of the free surface charge of a platinised platinum electrode with φ_r in 0.1 N KCl at different pH: 1) 2.3; 2) 3; 3) 4; 4) 5; 5) 6; 6) 7; 7) 8; 8) 9; 9) 10; 10) 11; 11) 12 (according to the data of Frumkin et al.[130]).

The relation between the degrees of adsorption of hydrogen and oxygen ions and atoms leads to the possibility of observing under certain conditions at a constant pH two values of z.f.c.p. corresponding to the reduced and oxidised electrodes. The existence of z.f.c.p. for oxidised platinum followed from the measurements of Balashova and Frumkin[174]. Two values of z.f.c.p., at 0.13 ± 0.02 V and 0.47 V (relative to the normal hydrogen electrode), were found[168] by the radioactive tracer method in a 0.04N Na_2SO_4 solution at pH 6. A similar phenomenon occurs in 0.004N Cs_2SO_4 solution. Two values of z.f.c.p. were observed for iridium in a 1N KI + 0.01N KOH solution[115] (Table 2). Only one value of z.f.c.p. was found for ruthenium[103], in the region corresponding to the adsorption of oxygen, since the z.f.c.p. for the reduced electrode is in the region corresponding to the evolution of molecular hydrogen. Owing to the overlapping of the regions corresponding to the adsorption of hydrogen and oxygen and their involvement in the potential jump at platinum metals, conditions can arise, in principle, over a relatively wide range of potentials where the surface carries almost no free charge (see, for example, curve *9* in Fig. 3).

The rhodium electrode–0.1 M KCl system proved to be particularly convenient for the observation of two values of z.f.c.p. and for the investigation of their characteristics. The results of the determination of the variation of Γ_{H^+} with φ_r for this system by the method of potentiometric titration under isoelectric conditions are

illustrated in Fig. 4. The z.f.c.p. corresponding to oxidised rhodium shifts in the negative direction by 80–140 mV when the pH increases by unity.

At high anodic potentials oxide ions are probably formed with participation of oxygen and the cations and anions of the supporting electrolyte[175–180]. Experiments by the tracer atom method indicate a non-monotonic change with potential in the charge of the metallic component of the ion double layer in this range of polarisations[179,180].

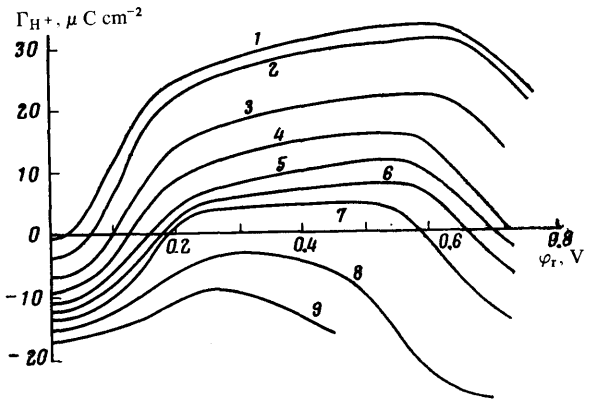

Figure 4. Variation of the free surface charge of a rhodium electrode with φ_r in 0.1 *N* KCl at different pH: 1) 3; 2) 4; 3) 5; 4) 6; 5) 7; 6) 8; 7) 9; 8) 10; 9) 11 (according to the data of R. Notoya's data).

The adsorption of ions is greatly influenced by the inhomogeneity of the surfaces of platinum metals, which has been specially emphasised in a number of publications[20–23]. The inhomogeneity leads to a logarithmic Temkin isotherm for the relation between the adsorption of ions and their concentration in solution and to the Roginskii–Zel'dovich equation for the kinetics of the adsorption of ions[20–23,181–184]. The intrinsic inhomogeneity of the surface of platinum has been demonstrated[185] by differential isotopic methods. Among the interesting conclusions reached in the study of the exchange of ions adsorbed on platinum metals for ions from the solution, the conclusion that a transition state involving both an adsorbed ion and an ion from the solution must be formed in the exchange process[186] is noteworthy.

Some Problems of Electrochemical Kinetics in the Light of Photoemission Studies

Z.A.Rotenberg and Yu.V.Pleskov

It is shown on the basis of photoemission data that the electronic work function of a metal in solution is independent of the nature of the metal. The photoemission method for the measurement of the Ψ' potential yields results which agree with calculations based on the Gouy-Chapman theory. Measurements of photocurrents in acid solutions permit the experimental observation and investigation of non-activated electrochemical reactions of atomic hydrogen on various metals.

INTRODUCTION

The specific features of photoelectron emission at the interface between metals and electrolyte solutions[1], whereby a distinction can be drawn between such emission and photoemission from metals into a vacuum, are associated primarily with the presence of the electrical double layer at the metal–solution interface, and also with the occurrence of homogeneous and heterogeneous reactions in the vicinity of the electrode. These are manifested in a series of general relations typical for the usual electrode processes. Therefore the study of the photoemission of electrons may be regarded as a new approach to the investigation of the fundamental problems of the electrical double layer structure and electrode kinetics. In this connection it is significant that photoemission constitutes the simplest form of electron transition at the interface which is not associated with adsorption and dissociation or formation of chemical bonds and it is therefore particularly convenient for investigations of this kind. Certain results of photoemission studies are discussed below, these are closely related to the fundamental problems of modern theoretical electrochemistry in the formulation and solution of which Frumkin's studies have been of decisive importance.

II. THE ELECTRONIC WORK FUNCTION OF THE METAL IN SOLUTION AND THE NATURE OF THE METAL

The photoemission of electrons from a metal into an electrolyte solution is a threshold phenomenon, like photoemission into a vacuum, the quantitative description of which is based on the concept of the electronic work function of the metal in the given medium. Owing to the presence of the electrical double layer, in which virtually the entire potential jump between the metal and the solution is concentrated, the electronic work function of the metal in solution w_{ms} depends on the electrode potential:

$$w_{ms} = w^0_{ms} + e\varphi, \qquad (1)$$

where w^0_{ms} is the work function of zero potential and e the absolute electronic charge. In photoemission Eqn. (1) is valid provided that the electrical double layer is completely transparent to the emitted electrons[2]. In contrast to emission into an electrolyte, for emission into a vacuum the electronic work function is almost independent of the potential difference applied from the outside (with the exception of special cases in autoelectron emission), since the resulting barrier due to the internal potential difference between the photocathode and anode extends throughout the space between the electrodes and is therefore impermeable to photoelectrons.

For this reason, the concepts of the electronic work function of the metal *in vacuo* and in an electrolyte are not physically equivalent. In the first system the electron work function is understood as the work of transferring the electron from the bulk of the metal into a vacuum to a distance where the Volta potential is constant (this distance is of the order of 10^{-5}–10^{-4} cm).[3] In the general case this work differs from the work of transferring the electron from the metal to infinity *in vacuo* (the electrochemical potential). In the second system the electronic work function is the work of transferring the electron from the metal to the bulk of the solution where there is no double layer field.

Metals at the same electrode potential are characterised by identical electronic work functions in solution, since in this case electron transfer from one metal to another does not require an expenditure of energy. Therefore Eqn. (1) is universal and independent of the nature of the metal.

The quantitative relation between the photocurrent j, on the one hand, and the energy of the light quantum $\hbar\omega$ and the electrode potential, on the other, is described by a 5/2 law[1]:

$$j = A(\hbar\omega - \hbar\omega_0 - e\varphi)^{5/2}, \qquad (2)$$

where $\hbar\omega_0 = w^0_{ms}$ and A is a constant which depends on the nature of the metal. Extrapolation of the experimental $j^{0,4}$–φ photocurrent curve on the basis of Eqn. (2) makes it possible to find the threshold potential φ_0 and hence the electron work function at $\varphi = 0$:

$$w^0_{ms} = \hbar\omega - e\varphi_0.$$

Experimental data obtained for different metals are presented in Fig. 1.[4] The zero-charge potentials of the test metals and hence their electronic work functions *in vacuo*

differ significantly (by up to 0.5 V). On the other hand, the threshold photoemission potentials are the same within the limits of experimental error.

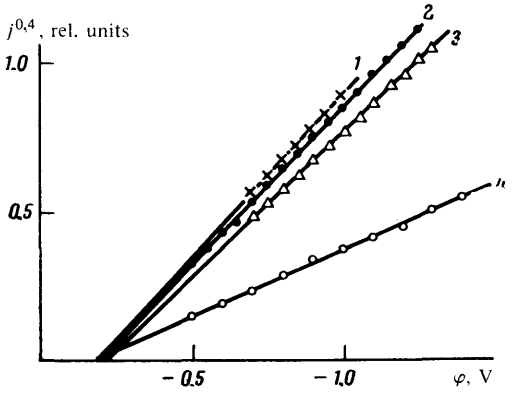

Figure 1. The constancy of the photoemission threshold: 1) indium (0.1 *N* KF); 2) bismuth (0.5 *N* KCl); 3) lead (0.5 *N* Na_2SO_4); 4) mercury (0.5 *N* KF); electron acceptor—O_2; light wavelength —365 nm; the potentials are quoted relative to the saturated calomel electrode throughout.

There exists a universal empirical relation (for aqueous solutions, potential measured relative to saturated calomel electrode) for the electronic work function w_{ms}, which is independent of the nature of the metal which determines φ_0:

$$w_{ms}(\varphi) = 3.45 + e\varphi. \qquad (3)$$

The conclusion that the electronic work function is independent of the nature of the metal agrees with the concepts developed for the first time by Frumkin[5,6], according to which the electronic work function *in vacuo* does not enter in an explicit form into the kinetic slow discharge equation when the potential is referred to a fixed reference electrode.

The constancy of the threshold potential is maintained also when the structure of the electrical double layer is altered (for example, on specific adsorption of various substances, which alter the zero-charge potential), since the double layer remains fairly thin and therefore transparent to the emitted electrons[7].

III. THE "ψ' CORRECTION" IN PHOTOEMISSION AND THE POSSIBILITY OF A DIRECT EXPERIMENTAL DETERMINATION OF THE ψ' POTENTIAL

The kinetics of electrode reactions were considered for the first time in Frumkin's studies[8] in relation to the electrical double layer structure. In the simplest but fairly general case the influence of the double layer on the rate of the electrode reaction is taken into account quantitatively by introducing the ψ' potential into the equation for the slow discharge current. In photoemission the role of the double layer is in many ways similar to its role in electrochemical kinetics. Whereas in concentrated electrolyte solutions the double layer is almost transparent to photoelectrons, in dilute solutions its diffuse component is no longer transparent to such electrons, since its thickness may exceed (for electrolyte concentrations smaller than 0.1 *N*) the de Broglie wavelength of the emitted electrons. In this case the electronic work function changes (relative to the value for the concentrated solution) by an amount $e\psi'$ and the photoemission equation (2) becomes[1]:

$$j = A[\hbar\omega - \hbar\omega_0 - e(\varphi - \Psi')]^{3/2}. \qquad (4)$$

It follows from Eqn. (4) that the rate of photoemission is not influenced by the total φ potential jump, but only by its component $\varphi - \psi'$. The complete analogy with the influence of the ψ' potential on the activation energy for the discharge of the species in the outer Helmholtz plane of the electrical double layer is striking.

The possibility, in principle, of an experimental determination of the ψ' potential follows from a comparison of the emission photocurrents in dilute [Eqn. (4)] and concentrated [Eqn. (2)] solutions. †

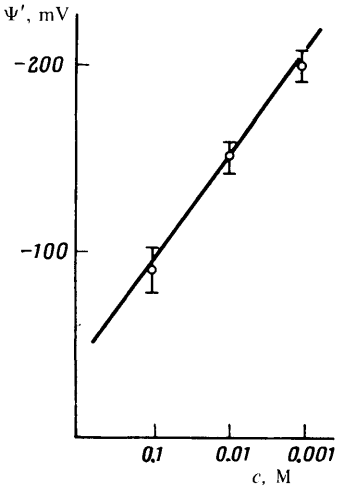

Figure 2. Variation of the ψ' potential with the concentration of the electrolyte (HCl); mercury electrode, -1.1 V; continuous straight line —calculation based on the Gouy–Chapman theory.

The photocurrents for mercury and lead electrodes have been measured[9] in HCl solutions at different concentrations (from 0.001 to 1 *N*) and negative potentials where $\psi' < 0$. The ψ' potentials found from the shift of the $j^{0,4} - \varphi$ curves in dilute acid solutions along the potential axis relative to the curve in 1 M HCl are presented in Fig. 2 as a function

† In general, difficulties arise in such measurements; these are associated with the influence of the structure of the double layer not only on the emission step itself, which is described by Eqns. (2) and (4), but also on the processes accompanying emission. These processes are mainly migration of hydrated electrons in the field of the diffuse layer. To eliminate undesirable effects of this kind, which complicate the determination of the ψ' potential, it is necessary to create conditions where hydrated electrons hardly return to the electrode and therefore the influence of the structure of the double layer reduces merely to a change in the emission current itself. In the measurements described below this condition was fulfilled.

of the logarithm of the concentration of the electrolyte. The continuous straight line was calculated on the basis of the Gouy–Chapman theory. The quantitative agreement between the experimental and theoretical data is of fundamental importance, since the photoemission method for the determination of the ψ' potential and the traditional differential capacitance method are based on completely different physical approaches. It must be emphasised that in the Gouy–Chapman theory one considers the ψ' potential averaged over a plane parallel to the electrode surface and not the local ψ' potential which can be determined, in principle, from kinetic measurements. By virtue of the delocalisation of the emitted electron in this plane, the averaged ψ' potential is also measured by the photoemission method. Therefore the above comparison of the theory with experiment is physically justified.

IV. THE OBSERVATION AND INVESTIGATION OF ELECTRODE REACTIONS WITHOUT ACTIVATION ENERGY

Electrode reactions differ from the usual chemical reactions specifically by the fact that their activation energies increase linearly with electrode potential. On the basis of the Brønsted relation, Frumkin et al.[10] concluded that at high overvoltages the activation energy for the electrode process can become zero and the rate of reaction can cease to depend on the potential. Such non-activated electrode reactions could not be detected until recently by the usual electrochemical methods because the direct measurement of the limiting currents for non-activated discharge was precluded by diffusion-dependent restrictions, which inevitably arose. Only recently was a system discovered[11] in which the supply of the reactant to the surface did not constitute the rate-determining step and the measured limiting current could be treated as the current of a process without activation energy ‡.

Electrode reactions without activation energy were observed for the first time (although not by direct measurement of the limiting current) in a study of the photoemission of electrons from mercury in acid solutions[13]. As a result of the capture of hydrated electrons by the hydronium ions in the layer of solution adjoining the electrode, hydrogen atoms are formed and then removed from the electrode surface via two electrochemical reactions:

$$H + H_2O\,(H_3O^+) + e^- \rightarrow H_2 + OH^-\,(H_2O); \quad (5)$$

$$H + H_2O \rightarrow H_3O^+ + e^-. \quad (6)$$

The measurement of the photocurrent in such systems and in systems where there is no oxidation of atomic oxygen makes it possible to determine the ratio of the currents consumed in the oxidation and reduction of hydrogen atoms. Analysis of the kinetic scheme showed that this ratio is $(2j_0 - j)j$, where $2j_0$ is the photocurrent in the absence of the oxidation of hydrogen and j is the measured photocurrent. The variation of $(2j_0 - j)/j$ with φ is described by the equation[13]

$$\varphi = \frac{2.3\,RT}{(\alpha + \beta)\,F}\left(\lg\frac{2j_0 - j}{j} + \text{const}\right), \quad (7)$$

‡ Krishtalik's observation[12] of barrier-free hydrogen ion discharge processes served as direct evidence for the occurrence of non-activated ionisation of hydrogen on mercury.

from which it is possible to determine the sum of the transfer coefficients $(\alpha + \beta)$ for the two coupled reactions (5) and (6).

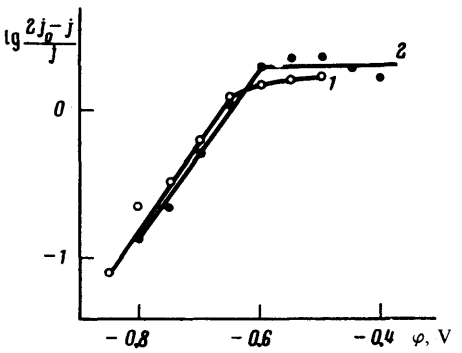

Figure 3. Determination of the transfer coefficients for the reactions of atomic hydrogen on bismuth by Eqn. (7): *1*) 0.5 *N* KBr + 0.003 *N* HCl; *2*) 0.5 *N* KCl + 0.06 *N* HCl.

As an example, Fig. 3 illustrates the graphical treatment in terms of Eqn. (7) of experimental data obtained for a bismuth electrode[4]. At potentials more positive than -0.6 V the ratio of the atomic hydrogen oxidation and reduction currents is independent of φ and, when $\varphi < -0.6$ V, the ratio decreases with the potential. Accordingly, $\alpha + \beta = 0$ in the region of positive potentials and $\alpha + \beta = 0.4$ in the region of negative potentials. The sum of the transfer coefficients being equal to zero is equivalent to each being zero. Thus reactions (5) and (6) both proceed without activation energy when $\varphi > -0.6$ V. The electrochemical desorption reaction (5), being a cathodic reaction, remains without activation energy (i.e. $\alpha = 0$) also at negative potentials when $\alpha + \beta = 0.4$. Hence it follows immediately that the transfer coefficient for the hydrogen ionisation reaction $\beta = 0.4$. This value agrees with the results of direct measurements of the rate of discharge of the H_3O^+ ion on bismuth[14], for which the transfer coefficient $1-\beta = 0.6$; this also demonstrates the overall self-consistency of the process mechanism described. The electrochemical desorption reaction (5) on bismuth proceeds mainly with participation of water molecules, in agreement with the hypothesis that the process mechanism involves zero activation energy[15].

Reactions with zero activation energy involving atomic hydrogen have also been observed on mercury[13] and antimony[16]. The kinetics of these processes are sensitive to the adsorption on the electrode of various substances which alter the structure of the double layer and may be formally interpreted[4] on the basis of Frumkin's theory of the ψ' effect.

Electrochemical Oxidation of Organic Compounds on Anodes Consisting of Certain Transition Metal Oxides

M.Ya.Fioshin and I.A.Avrutskaya

The mechanism and kinetics of the electrochemical oxidation of organic compounds on nickel, cobalt, copper, and silver anodes at potentials corresponding to the formation of the higher oxides of these metals are discussed. The problems of the practical use of the electrodes in the electrosynthesis of organic compounds are examined. The feasibility of different versions of electrosynthetic processes with participation of the higher oxides, regenerated electrochemically, is demonstrated for the nickel oxide electrode.
The bibliography includes 44 references.

I. INTRODUCTION

Electrochemical oxidation reactions of organic compounds on certain transition metal electrodes coated by oxides have been attracting attention in recent years. The studies using these electrodes have been carried out both from the theoretical standpoint in order to investigate the kinetics and mechanism of the oxidation and from the practical standpoint for the assessment of the possibility of using oxide electrodes in the electrosynthesis of organic compounds. Alcohols[1-3], among which di-*O*-isopropylidene-L-sorbose may also be included[4-7], and amines[3] have been oxidised on a nickel oxide electrode, alcohols and amines[8] on a cobalt oxide electrode, amines[9,10] on silver(II) oxides, and alcohols and amines[11] on copper(III) oxides.

II. KINETICS AND MECHANISM OF THE PROCESSES ON ANODES CONSISTING OF TRANSITION METAL OXIDES

The nature of the phenomena occurring on the surface of anodes consisting of a number of transition metal oxides has not yet been completely elucidated. This is why certain views put forward in the literature are contradictory and serve as a basis for further discussion.

The determination of the complete picture of the processes occurring on these electrodes is apparently precluded by the virtual lack of data on the sorption of organic compounds involved in the oxidation reactions, while adsorption phenomena must be taken into account in seeking new procedures for organic electrosynthesis[12].

It has been shown[11] that the mechanisms of the oxidation of alcohols and amines on nickel, cobalt, copper, and silver anodes coated by the oxides are similar and do not involve simple electron transfer, as happens, for example, in the oxidation of amines on graphite.

Potentiodynamic measurements established that the first oxidation stage involves the electrochemical formation of the higher metal oxide and that the entire mechanism can be represented schematically as follows:

$$OH^- + \text{lower oxide} \overset{\text{fast}}{\rightleftharpoons} \text{higher oxide} + H_2O + e; \quad (1)$$

$$(\text{organic substrate})_{soln} \overset{\text{on higher oxide}}{\rightleftharpoons} (\text{organic substrate})_{ads}; \quad (2)$$

$$\text{higher oxide} + (\text{organic substrate})_{ads} \rightarrow \text{lower oxide} + \text{intermediate radical (rate-determining stage)}; \quad (3)$$

$$\text{intermediate radical} - (n-1)e \rightarrow \text{product} \quad \text{or} \quad (4)$$

$$\text{intermediate radical} + (n-1)\,\text{higher oxide} - (n-1)\,\text{lower oxide} + \text{product} \quad (5)$$

here n is the number of electrons involved in the reaction.

For thin oxide layers (particularly on nickel), the equilibrium corresponding to reaction (1) is established rapidly[13], while for thicker layers the diffusion of electroactive species in the film becomes rate-determining[14]. However, according to other data[15] the existence in the oxidation of organic compounds of an equilibrium between the lower and higher nickel oxides, involving nickel hydroxide in the case of thin layers, appears to be doubtful.

Many experimental data[11] support the idea that the organic compounds are oxidised in the adsorbed state on the higher oxide in accordance with reaction (2), although adsorption has not been the subject of a special study and the weak adsorbability of organic substances on iron-group and silver-group metals under analogous conditions has been merely mentioned[16].

The next stage [stage (3)], involving the interaction of the adsorbed organic compound with the higher oxide, was studied in greatest detail, particularly for the nickel oxide electrode. The oxidation of various substances on each electrode proceeds at the same potentials, corresponding to the formation of the higher oxides of the given metal[11]. The mechanism involving a chemical interaction of the organic substance with the higher oxide is indicated by the absence of a dependence of the oxidation current on the potential at low currents and by the dependence of the limiting rate of the electrochemical reaction on the rate of rotation of the disc electrode. Furthermore, a cathodic current is not revealed by the cyclic voltage–current curves for the oxidation process on transition metal oxide anodes in the presence of organic compounds at low rates of application of the potential, and high activation energies for the electrode process have been noted.

To confirm the hypothesis that a chemical reaction mechanism is possible, one can employ data for the chemical oxidation of certain organic compounds by the higher oxides of the same metals. Thus in the oxidation

of alcohols[17] and amines[18] by higher nickel oxides the same products are formed as in the anodic oxidation.

The chemical interaction with the higher oxide probably proceeds in the solid phase and is not associated with the transfer of the metal to the solution, since corrosion of the anode is not observed in the oxidation process. To estimate the rate of chemical interaction of the organic substance with the higher oxide, a study has been made (particularly for nickel) of the time variation of the potential of a non-polarised nickel oxide electrode in the course of its joint reduction by the cathodic current and the compound being oxidised[19]. These results established that the rate of reaction is proportional to the concentration of the organic compound and the amount of the higher oxide on the electrode surface. The calculated chemical oxidation rate constants for certain alcohols are listed in Table 1.

Table 1. The rate constants k for the oxidation of various alcohols on a nickel oxide electrode.

Alcohol	k, mole^{-1} s^{-1}	Alcohol	k, mole^{-1} s^{-1}
Methyl	0.04	Benzyl	0.4
Ethyl	0.06	Furyl	0.8

However, data obtained later by the same authors using the potentiodynamic method[15] conflict, in their view, with the earlier conclusion that the rate of oxidation is proportional to the amount of higher oxide on the electrode surface. According to these data[15], the rate of reaction depends to a considerable degree on the previous history of the electrode. In particular, the rate is greatly reduced on the surface of a nickel oxide electrode which had been subjected to a preliminary oxidation. An increase of the amount of higher oxide of the type NiOOH on the electrode surface has an inhibiting effect on the oxidation reaction. The authors to not rule out the possibility of a direct interaction between the higher nickel oxide and the organic compound but the rate of the reaction must be lower than the rate of oxidation on the fully oxidised surface at potentials which are insufficient for the electrochemical reduction of the oxide layer.

On the other hand, according to other results[11] direct electron transfer in the rate-determining stage is unlikely, since secondary amines are oxidised more slowly than primary amines and tertiary amines are not oxidised at an appreciable rate. This is also confirmed by the occurrence of a kinetic isotope effect in the oxidation of normal and deuterated methanol ($k_{CH_3OH}/k_{CD_3OH} = 7.0$). A similar kinetic isotope effect was observed also in the chemical oxidation of diphenylmethanol by higher nickel oxides ($k_{(C_6H_5)_2CHOH}/k_{(C_6H_5)_2CDOH} = 7.4$).[20]

These results suggest that the rate-determining stage is the abstraction of a hydrogen atom from the molecule of the compound being oxidised with formation of free-radical species [reaction (3)], occurring in the interaction with higher metal oxides. In the chemical oxidation of a series of substances by higher nickel oxides the formation of radicals was confirmed by ESR.[20] A study of the electrochemical oxidation of alcohols to acids on a nickel oxide electrode also established that the rate-limiting stage is the oxidation of the alcohol to the aldehyde[21].

The mechanism of the oxidation of certain organic compounds on a nickel electrode may change depending on the potential, this being related to the degree of oxidation of the electrode surface. At negative potentials the reaction proceeds as a result of direct electron transfer to the smooth nickel electrode or via a dissociative adsorption mechanism[22], while at more positive potentials the oxidation mechanism includes a chemical reaction between the higher nickel oxide and hydrazine[23].

All the above remarks concerning the mechanism of the oxidation of organic compounds on oxide electrodes make it possible to classify the higher oxides of these metals as heterogeneous catalytic transferring agents.

III. ELECTROSYNTHESIS OF ORGANIC COMPOUNDS ON CERTAIN TRANSITION METAL OXIDE ELECTRODES

The data concerning the use of certain transition metal oxide electrodes in the electrosynthesis of organic compounds are few. Table 2 presents comparative results for the oxidation of alcohols and amines on electrodes coated by oxides[11].

Table 2. Current yields of the products of the oxidation of alcohols and amines on anodes coated by oxides.

Starting material	Reaction products	Current yield, %		
		nickel (0.55 V)	silver (0.75 V)	copper (0.7 V)
n-Propylamine	Propionitrile	84	83	85
	Propionaldehyde	11	2	2
n-Butylamine	Butyronitrile	85	85	–
	Butyraldehyde	6	2	–
Isopropylamine	Acetone	80	70	85
Diethylamine	Acetonitrile	46	27	30
	Acetyldehyde	3	3	5
	Acetic acid	36	29	40
Ethanol	Acetic acid	98	–	96
1-Propanol	Propionic acid	95	–	–
2-Propanol	Acetone	90	–	9

The oxidation of alcohols to the corresponding acids in an alkaline medium proceeds on these electrodes with a higher selectivity than in electrolysis in acid solutions on platinum and lead dioxide anodes and makes it possible to avoid esterification reactions, which complicate the process in an acid medium.

Among the electrodes considered, the nickel oxide electrode has been most widely used in the electrosynthesis of organic compounds. It is noteworthy that the specificity of the oxidation on oxide electrodes has also been reflected in the practical application of processes involving higher nickel oxides. There is a fairly wide variety of different ways in which electrosynthetic processes involving higher nickel oxides, regenerated electrochemically in the course of the oxidation, can be carried out. The electrochemical oxidation is performed at an electrode obtained by depositing nickel(II) hydroxide on an inert current-conducting base with subsequent formation of the higher oxide on anodic polarisation[1]. The positive plates of iron–nickel and cadmium–nickel accumulators have also been used as the anodes[5,24–27]. The nickel

oxides may be present in solution as a suspension. Solutions of an alkali[24,25,28,29] or an alkali metal halide[30-39] are used as the electrolyte. In electrolysis in a solution of alkali the higher oxide is regenerated during the transient contact between the solid particle and the current lead. During electrolysis, the current lead is coated by nickel oxides and, as shown below, acquires the properties of a nickel oxide electrode. When the electrolyte is a halide solution, the higher oxide is regenerated both electrochemically and, as in chemical oxidation[17,40], by the interaction with the hypohalite. The oxidation of di-*O*-isopropylidene-L-sorbose (DAS) to di-*O*-isopropylidene-2-oxo-L-gulonic acid (DOGA)—the intermediate in the synthesis of ascorbic acid—has been investigated in detail in the presence of bromides. Under these conditions, the oxidation mechanism can be represented schematically as follows[35]:

$$2\,Br^- - 2e \rightarrow Br_2 \text{ (on the anode)};$$
$$Ni(OH)_2 - e \rightarrow NiOOH + H^+ \text{ (on the anode)};$$
$$Br_2 + 2\,OH^- \rightarrow BrO^- + Br^- + H_2O;$$
$$2\,Ni(OH)_2 + NaBrO \rightarrow 2\,NiOOH + NaBr + H_2O;$$
$$C_{11}H_{17}O_5CH_2OH + 4\,NiOOH + H_2O \rightarrow C_{11}H_{17}O_5COOH + 4Ni(OH)_2.$$

* Obtained by a single impregnation of porous nickel initially in nickel chloride solution and then in alkali with subsequent anodic polarisation.
** Factory-made foil electrode.
*** c_{DAS} = 0.58 M.

Higher nickel oxides can be used as chemical oxidants with subsequent electrochemical regeneration in a separate apparatus[41]. Isopentyl alcohol was oxidised in this way to isovaleric acid in 80% yield. The nickel oxide electrode has been most widely used in the electrochemical oxidation of alcohols to the corresponding acids in an alkaline medium, the results obtained in the electrochemical oxidation of DAS being of greatest practical importance.

The electrochemical oxidation of DAS in an alkaline medium has many advantages compared with halide solutions from the standpoint of the yield of the product, the efficiency of the process, and also its cost. Therefore the fundamental characteristics of the electrochemical oxidation of DAS with participation of nickel oxides will be examined only for alkaline solutions. The influence of the electrode material on the electrochemical oxidation of DAS in an alkaline medium has been investigated[25]. The results are presented in Table 3 and in Fig. 1.

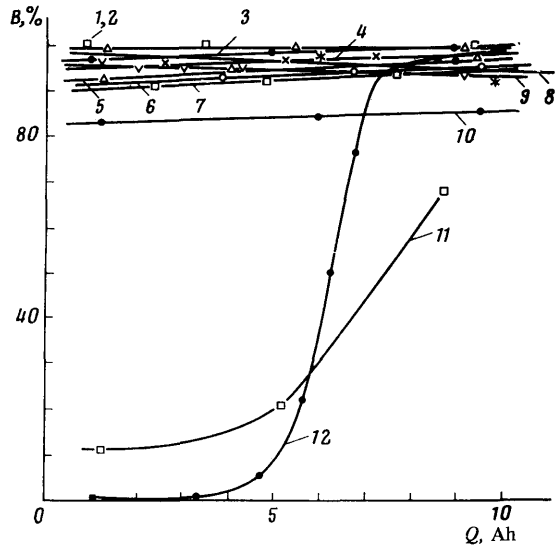

Figure 1. Variation of the current yield of oxygen (B) with the amount of electricity passed through the system in the electrochemical oxidation of DAS on different electrodes: 1) cobalt oxide (electrolytic); 2) ruthenium oxide; 3) nickel; 4) platinum (purified DAS); 5) platinum (technical DAS); 6) cobalt oxide (thermal); 7) stainless steel; 8) lead dioxide; 9) manganese dioxide; 10) porous nickel; 11) nickel oxide (obtained under laboratory conditions); 12) nickel oxide (factory made foil electrode); c_{DAS} = 0.29 M; c_{NaOH} = 3%; t = 60°C; Q = 1 Ah/g DAS.

The current yield of oxygen on nickel, manganese dioxide, lead dioxide, platinum, and stainless steel anodes and also on cobalt oxide and ruthenium oxide electrodes is constant and close to 100%. Accordingly, the consumption of DAS on these electrodes is low (Table 3) and DOGA is not formed.

The electrode potentials at which DAS is oxidised with a low efficiency vary in the range 0.95–1.15 V and there is no definite relation between the electrode potential, the consumption of DAS, and the fraction of the current consumed in its oxidation.

The current yield of oxygen on a porous nickel electrode is 83–84%. DAS is then consumed to an appreciable extent and a small amount of DOGA is formed. A different behaviour has been observed on two nickel oxide electrodes. A considerable proportion of the current was initially consumed in the oxidation of DAS and then, with decrease of its concentration, the current yield of oxygen

rose and reached 100% on an industrial specimen containing a large amount of active mass per unit surface of the electrode. On the second specimen, the fraction of the current consumed in the evolution of oxygen was somewhat higher throughout the experiment and, for the same amount of electricity consumed, the reaction did not reach completion and DAS which failed to react remained. The main oxidation product on nickel oxide electrodes is DOGA, formed in a material yield exceeding 90%. The lower yield of DOGA and the larger amount of DAS which did not react on the lamellar nickel oxide electrode can probably be explained by the poor contact between the solution and the active mass and the consequent decrease of the rate of the chemical interaction.

Comparison of the data for the oxidation of DAS on a smooth nickel electrode, a porous nickel electrode, and three specimens of nickel oxide electrodes makes it evident that the rate of oxidation of DAS increases with increase of the amount of the active mass of the oxides per unit surface of the electrode.

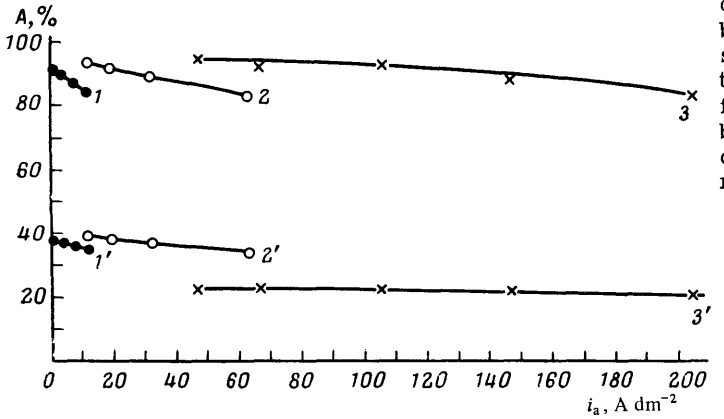

Figure 2. Variation of the yield of DOGA (A) with current density; 0.22 M DAS; 2% NaOH; t = 55°C; Q = 1 Ah/g DAS: 1) and 1′) the material and current yields for coaxially arranged electrodes separated by a distance of 5 mm; 2) and 2′) the material and current yields for horizontally arranged electrodes separated by a distance of 32 mm. 0.4 M DAS; 2.4% NaOH; t = 59°C; Q = 1.72 Ah/g DAS: 3) and 3′) the material and current yields for a vertical arrangement of the electrodes separated by a distance of 25 mm.

The addition of variable-valence metal salts [such as iron(III), cobalt(II), and manganese(II) salts] does not affect the electrochemical oxidation of DAS. The introduction of nickel salts into the solution promotes the formation of DOGA on electrode materials such as smooth nickel, stainless steel, and graphite, on which DOGA could not be obtained in the absence of an additive. The addition of nickel salts increases the yield of DOGA also on nickel oxide electrodes and their effect is more marked on an electrode with a small amount of active mass per unit surface. During electrolysis in the presence of nickel salts, porous electrodes made of different materials become coated by nickel oxides. The presence of nickel compounds on the surface of graphite and in its pores is confirmed by the fact that DOGA is formed even in the absence of an additive on an electrode which had been used beforehand in the presence of nickel salts. In contrast to graphite, the steel electrode remains inactive in subsequent experiments.

The electrosynthesis of DOGA in an alkaline medium on graphite anodes at a current density of 2.4 A dm^{-2} in the presence of dispersed nickel oxides is carried out on an industrial scale using a continuous process[29]. It can be greatly intensified by increasing the current density to 12–15 A dm^{-2}.

It is noteworthy that one of the advantages of the use of nickel oxide electrodes in the electrosynthesis of DOGA is the high rate of the process. Fig. 2 illustrates the influence of current density on the yield of DOGA for different relative positions of the electrodes[5]. When the distance between the electrodes is small, the yield of the product decreases sharply with increase of current density. For a horizontal arrangement of the electrodes and a large distance between them, it is possible to extend greatly the range of current densities without a significant reduction of the material yield of DOGA. At a constant current density the yield depends appreciably on the distance between the electrodes, which can probably be explained by the influence of factors such as the stirring of the electrolyte in the space between the electrodes, the access of the electrolyte to this space, and the filling of the system with gas. For small distances between the electrodes and high current densities, the decisive factor is the filling of the system with gas, which reduces the volume of the reacting solution.

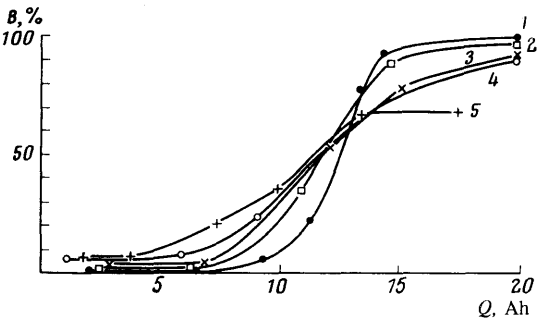

Figure 3. Variation of the current yield of oxygen (B) with the amount of electricity passed through the system at different current densities (Ah dm^{-2}): 1) 5; 2) 10; 3) 21; 4) 29; 5) 50; c_{DAS} = 0.58 M; c_{NaOH} = 3%; t = 60°C.

The optimal conditions for the electrosynthesis of DOGA were established by the simplex design method at a constant current density of 50 A dm^{-2}; then the possibility of carrying out the process at higher current densities was studied under the same conditions. An increase of current density to 100 A dm^{-2} in solutions with high DAS concentrations does not affect appreciably the yield of DOGA (Fig. 2). At higher current densities and a given concentration of alkali the yield falls and the electrode breaks up. The latter is probably associated with the

high rate of the process as a result of which the layer of electrolyte adjoining the anode surface is acidified by the DOGA formed. The change in current density leads to a redistribution of the relative amounts of the current consumed in the electrochemical oxidation of DAS and in the evolution of oxygen (Fig. 3).[24] With decrease of current density, the fraction of the current consumed in the evolution of oxygen falls and the duration of electrolysis increases, which should evidently favour the chemical interaction between DAS and the higher oxides.

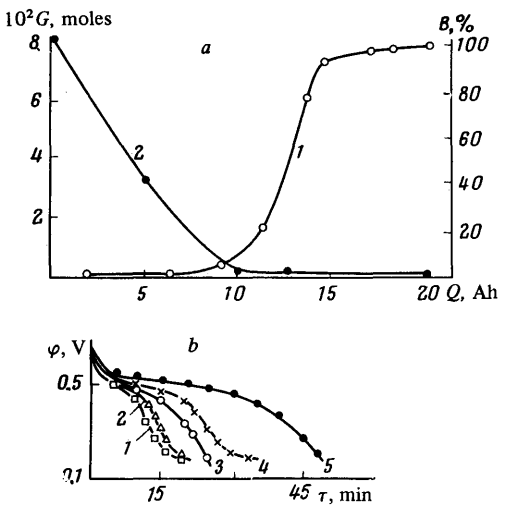

Figure 4. *a*) Variation of the current yield of oxygen (*B*) (curve *1*) and of the amount (*G*) of DAS which failed to react (curve *2*) with the amount of electricity passed through the system; c_{DAS} = 0.58 M; c_{NaOH} = 3%; t = 60°C; i_a = 5 A dm^{-2}; *b*) variation of the potential of a non-polarised nickel oxide electrode with time in 3% NaOH solution at 60°C and different DAS concentrations (M); 1) 0.58; 2) 0.46; 3) 0.35; 4) 0.23; 5) 0.12.

Table 4. The influence of Fe^{3+} ions on the yield of DOGA (c_{DAS} = 0.58 M, c_{NaOH} = 2%, t = 59°C, Q = 1 Ah/g DAS, D_a = 32 A dm^{-2}, $c_{Fe^{3+}}$ = 0.007 M).

Current yield of DOGA, %	35.8	35.6	32.2	31.6

It is noteworthy that, in the study of the influence of factors such as the concentration of DAS (Fig. 4) and temperature (Fig. 5) on the rate of the process, a correspondence was noted between the changes in the rates of anodic oxidation and chemical interaction. As in an earlier investigation[20], the latter was estimated from the time variation of the potential of a non-polarised nickel oxide electrode discharged in the presence of DAS. Thus the rate of the anodic oxidation of DAS increases with increase of its concentration, the amount of oxides per unit electrode surface, and temperature, and there is a parallel variation of the rate of the chemical interaction of the organic substance with nickel oxides, which may serve as indirect confirmation of their involvement in the oxidation of DAS in the electrolysis, in conformity with the mechanism proposed by Fleischmann et al.[11]

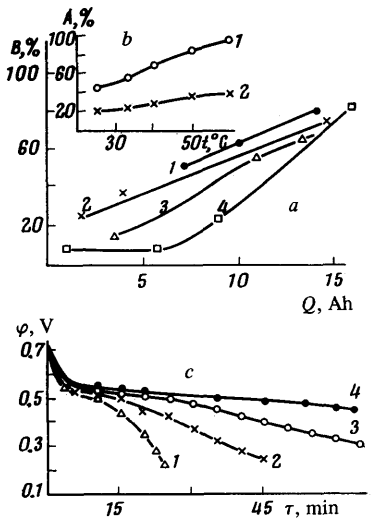

Figure 5. *a*) Variation of the current yield of oxygen (*B*) with the amount of electricity passed through the system at different temperatures (°C): 1) 20; 2) 30; 3) 40; 4) 60; *b*) temperature variation of the material yield of DOGA (*A*) with respect to the DAS introduced (curve *1*) and of the current yield (curve *2*); c_{DAS} = 0.58 M; c_{NaOH} = 3%; i_a = 29 A dm^{-2}; *c*) time variation of the potential of a non-polarised nickel oxide electrode in 3% sodium hydroxide solution at a DAS concentration of 0.35 M and different temperatures (°C): 1) 60; 2) 50; 3) 40; 4) 20.

The extensive experience gained in the use of nickel oxide electrodes in alkaline accumulators has shown that their discharge characteristics are fairly sensitive to inorganic admixtures[42]. The problem of the stability of the active properties of the nickel oxide electrode has also been studied in the electrosynthesis of organic compounds[43]. When the nickel oxide electrode had been used for a comparatively long time, no change in its activity was observed in solutions of purified DAS. Since purification of DAS complicates the technological process and involves loss of product, a study was made of the behaviour of foil and metalloceramic electrodes in the electrochemical oxidation of technical DAS. In contrast to the series of experiments with the purified product, the material yield of DOGA relative to the DAS introduced gradually fell, amounting to 64% on the metalloceramic electrode after the consumption of 2.12×10^3 Ah dm^{-2}, while at the beginning of the series it was 98%. There was a corresponding decrease also of the current yield.

The foil electrode, which contains a smaller amount of active mass per unit geometrical surface of the electrode, loses its activity more rapidly than the metalloceramic electrode. The loss of electrode activity consists in a decrease of the fraction of the current consumed in the electrochemical oxidation of DAS and in an increase of the current yield of oxygen. It has been established that the active properties of the electrode are influenced by inorganic admixtures. Table 4 shows how the yield of DOGA falls gradually under the influence of Fe^{3+} ions.

A similar effect is produced by Ca^{2+} ions. The latter also retard the chemical interaction of DAS and aliphatic alcohols with nickel oxides, which indicates a correspon dence between the rates of the chemical and anodic processes.

The causes of the change in the activity of the nickel oxide electrode are probably analogous to those noted when similar electrodes are used in current sources, their behaviour being determined by the kinetics of the electrochemical oxidation and of the reduction of solid oxides[44], but at much lower current densities.

Different ways of activating nickel oxide electrodes have been investigated. A partial and brief increase of electrode activity occurs after alternate preliminary cathodic and anodic polarisation in a solution of alkali. It is possible to maintain the active properties of the nickel oxide electrode during the electrochemical oxidation of technical DAS by the periodic introduction into the solution of nickel ions (0.01 M), which renews the electrode surface. However, as the electrode continues to be used, the maximum yields are 90–92% after the consumption of $(5.9–6.5) \times 10^3$ Ah dm^{-2} even in the presence of nickel ions, which is somewhat less compared with the results obtained in the absence of additives in the first experiments.

When the electrochemical oxidation of technical DAS on a nickel oxide electrode was carried out with continuous injection of nickel ions (0.004 M), the yield of DOGA remained stable throughout the tests (5.9×10^3 Ah dm^{-2}).

The Mechanism of the Excitability of Biological Membranes

Yu.A.Chizmadzhev, V.F.Pastushenko, and V.S.Markin

The phenomenology of the excitation of a cell membrane is described. It is shown that, in the adsorption inhibition of a mobile transferring agent, the descending branch of the voltage-current characteristic can be obtained. The Hodgkin-Huxley model is interpreted in terms of ionic channels and the statistical properties of such a system are examined. In particular, the spectrum of the electrical fluctuations of potassium channels is analysed. Experiments in which "gating currents" were measured are briefly described and interpreted in terms of the cooperative dipole model.
The bibliography includes 16 references.

I. INTRODUCTION

The phenomenology of the electrical phenomena occurring on excitable cell membranes can be described in detail by the Hodgkin–Huxley empirical equations[1]. Until recently the attempts to create physically consistent models outside the framework of a formal description have been speculative, since a suitable experimental basis was lacking. Nevertheless the endeavour to achieve some kind of physical model is quite justified. Strictly speaking, Hodgkin and Huxley themselves indicated, although not without reservations, one of the simplest possible interpretations of the formal scheme. Studies in recent years on the selectivity and permeability of ionic channels[2,3], experimental and theoretical investigations of the electrical noise spectra of membranes[4-7], and finally brilliant experiments in which measurements were made of the so called "gating currents"[8-11] altered the situation radically. On the one hand, a need arose for certain modifications to the formal Hodgkin–Huxley scheme and on the other a basis appeared for the development of a physical model of excitability. This paper is devoted to a brief analysis of the present state of the problem of excitability.

II. PHENOMENOLOGY OF THE EXCITATION PROCESS

Here we shall describe only briefly the well known model of the squid axon and shall note certain details which we believe to be important. According to the Hodgkin–Huxley model, the membrane potential satisfies the following equation in the process of three-dimensional homogeneous excitation:

$$C\frac{d\varphi}{dt} = -I. \tag{1}$$

The significance of this equation is that the membrane is regarded as a condenser with a capacitance $C \simeq 1\ \mu F\ cm^{-2}$. The ionic current I is formulated as the sum of three currents—the sodium, potassium, and leakage currents:

$$I = I_{Na^+} + I_{K^+} + I_L. \tag{2}$$

In its turn each current is regarded as the current generated by a battery with a constant e.m.f. and a variable resistance (apart from the leakage resistance):

$$I_{Na^+} = g_{Na^+}(\varphi - \varphi_{Na^+}); \tag{3}$$

$$I_{K^+} = g_{K^+}(\varphi - \varphi_{K^+}); \tag{4}$$

$$I_L = g_L(\varphi - \varphi_L);\ g_L \approx 3 \cdot 10^{-4}\ \Omega^{-1}\ cm^{-2}. \tag{5}$$

Each of the three e.m.f.'s (φ_{Na^+}, φ_{K^+}, and φ_L) is assumed to be known and determined by the differences between the concentrations of the corresponding ions in accordance with the Nernst formula. Under physiological conditions, these quantities are $\varphi_{Na^+} = +115$ mV, $\varphi_{K^+} = -12$ mV, and $\varphi_L = +10$ mV. On the other hand, the conductivities of the membrane with respect to potassium and sodium, g_{Na^+} and g_{K^+}, can vary with time; their dynamics is defined as follows: for conductivity with respect to sodium, two dynamic variables, denoted by m and h, are introduced and the following relation is postulated:

$$g_{Na^+} = \bar{g}_{Na^+} \cdot m^3 h;\ \bar{g}_{Na^+} = 0.12\ \Omega^{-1}\ cm^2, \tag{6}$$

where $\bar{g}_{Na^+}$ is the maximum possible conductivity. On the other hand, m and h satisfy the relaxation equation in which the coefficients (which are different for m and h) depend on the potential:

$$\frac{dm}{dt} = \alpha_m(1-m) - \beta_m m, \tag{7}$$

$$\frac{dh}{dt} = \alpha_h(1-h) - \beta_h h. \tag{8}$$

The dynamics of the conductivity of the membrane with respect to potassium is formulated in an exactly similar way:

$$g_{K^+} = \bar{g}_{K^+} n^4,\ \bar{g}_{K^+} = 3.6 \cdot 10^{-2}\ \Omega^{-1}\ cm^{-2}, \tag{9}$$

and the dynamic variable n satisfies an equation analogous to Eqns. (7) and (8):

$$\frac{dn}{dt} = \alpha_n(1-n) - \beta_n n. \tag{10}$$

By fixing the potential on the membrane and by separating the sodium and potassium currents, Hodgkin and Huxley

found the required form of the relation between the coefficients α_i and β_i ($i = m$, n, or h) on the one hand and the potential on the other:

$$\alpha_m = 0.1\,(\varphi - 25)\,[1 - \exp(2.5 - 0.1\,\varphi)]^{-1}, \quad (11)$$

$$\beta_m = 4\exp(-\varphi/18); \quad (12)$$

$$\alpha_h = 0.07\exp(-0.05\,\varphi); \quad (13)$$

$$\beta_h = [1 + \exp(3 - 0.1\,\varphi)]^{-1}; \quad (14)$$

$$\alpha_n = 0.01\,(\varphi - 10)\,[1 - \exp(1 - 0.1\,\varphi)]^{-1}; \quad (15)$$

$$\beta_n = 0.125\exp(-\varphi/80). \quad (16)$$

In Eqns. (11)–(16) the coefficients α and β have the dimensions of the reciprocals of milliseconds and the potential is expressed in millivolts and is reckoned from the so called rest potential, defined as the difference between the internal and external potentials of the fibre at rest and equal to −60 mV.

The main attempts, of which we are aware, at a physical interpretation of the system described by the Hodgkin–Huxley equations are set out below.

III. INTERPRETATION OF THE HODGKIN–HUXLEY MODEL

In fact the problem is to discover the physical significance of the dynamic variables m, n, and h. In the first studies by Hodgkin and Huxley an attempt was already made to treat these variables as the concentrations of transferring species. Subsequent experiments showed that ion transport across biological membranes is not achieved with the aid of transferring species but takes place via ionic channels. However, an action potential was recently obtained on two-layer lipids membranes under conditions where the mechanism involving mobile transferring agents is extremely probable[12]. It is therefore useful to consider briefly the nature of excitability in a simple example[13].

Adsorption Inhibition of a Transferring Agent

Suppose that the ions A and B can cross the membrane with the aid of different transferring agents T and M. We shall assume that the solution contains a substance X which can bind the transferring agent T on the surface of the membrane. Then the partial voltage–current characteristic of the ion A is

$$I_A = (1 - \Gamma)\,I_A^*(\varphi), \quad (17)$$

where I_A^* is the voltage-current characteristic in the absence of the inhibitor and Γ the fraction of bound transferring agents.

The equation for the membrane potential is

$$C\frac{d\varphi}{dt} = -(I_A + I_B) + I, \quad (18)$$

where I is the external current. The fraction of bound transferring agents is described by the equation of adsorption kinetics:

$$\frac{d\Gamma}{dt} = \alpha(1 - \Gamma) - \beta\Gamma; \qquad \alpha = k_1 e^{z\varphi/s}, \quad \beta = k_2 e^{-z\varphi/s}. \quad (19)$$

We shall examine the special case where the partial voltage–current characteristics are arranged as shown in Fig. 1. The isoclinic lines for this system of equations are presented in Fig. 2*a*. In this case the point of intersection represents the unique stable stationary state. However, the system possesses threshold properties and is capable of generating single pulses. If the system is deflected sufficiently from the state of equilibrium, its subsequent motion will be described by the dashed line in Fig. 2*a*.

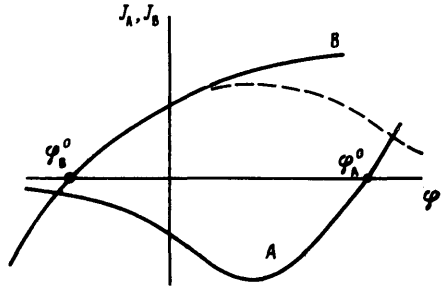

Figure 1. Partial characteristics of the ions A and B. The intercepts made by the curves on the abscissa axis define the equilibrium potentials φ_A^0 and φ_B^0. The dashed line represents the possible variation of I_B.

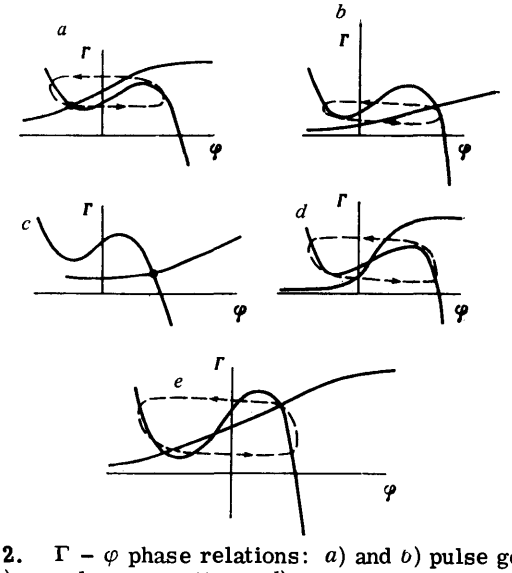

Figure 2. $\Gamma - \varphi$ phase relations: *a*) and *b*) pulse generation; *c*) no pulse generation; *d*) auto-oscillations; *e*) transitions from one stable state to another. The dashed line illustrates the phase trajectories.

In case *b* (Fig. 2) the situation is analogous except that the "action potential" has a different sign. In case *c* the stationary state is stable but the generation of a pulse is impossible, since whatever the deviation from the state of rest the system returns to the latter. In case *d* the only stationary state is unstable, since an auto-oscillatory process takes place in the system. In case *e* there are three stationary states, of which the extreme ones are stable and the intermediate one is not. By a stimulus

exceeding the threshold value, the system can be transferred from one stable state to another, where it can remain indefinitely.

We have analysed the behaviour of the membrane potential in the presence of an inhibitor, the surface concentration of which played the role of a dynamic variable. Another model of an excitable membrane, in which there are no inhibitors but significant diffusion-dependent restrictions are imposed on one of the ions in the layer of solution near the membrane, has been investigated in an analogous manner[13].

Ionic Channels

We shall consider, for example, the potassium channel which "opens" on simultaneous "activation" of four species which do not interact. The rate constants for "activation" α_n and "inactivation" β_n depend on the potential. When these rate constants are interpreted by Eyring's procedure, we have for the constant α_n in the range of negative potentials

$$\alpha_n = e^{2.5\, e\frac{\varphi}{kT}}.$$

Hence it follows that the potassium channel is "activated" when a certain hypothetical species overcomes an activation barrier with a height of $2.5e\varphi$. If the activation is achieved with migration of the charged species in the direction of the force driving the current, then such activation may be attained by transferring a species with a charge of $2.5e$ through the entire thickness of the membrane. On the other hand, when the activation occurs with partial charge transfer, say over a distance $\epsilon\delta$, where δ is the thickness of the membrane, then the field could execute the required work by transferring the $2.5e/\epsilon$ charge between points corresponding to the potential difference $\epsilon\varphi$ (in terms of the constant field approximation). If the elementary displacement amounts to, for example, 5 Å, then $\epsilon = 1/20$ and the charge transferred will be equal to 50 electronic charges or 25 electronic charges when $\epsilon = 1/10$. Both versions are relatively unsuitable from the physical standpoint. The large charge might be accounted for by attributing its displacement to many species and not to a single species. However, in this case the problem would then arise of the explanation of the rigid linkage between these species, because the required potential relation $\alpha_n(\varphi)$ would arise only if the possibility of an asynchronous migration of the species were ruled out.

Below we shall consider in detail one of the cooperative models, but now we shall formulate a convenient method for describing excitable ionic channels in terms of transitions between different conformational states[6]. For brevity, we shall confine ourselves to the potassium channel, since there is no difficulty in extending the treatment to the sodium channel. We postulate that the potassium channel contains x identical independent subunits, each of which can exist in one or two states—0 ("passive" state) and 1 ("active" state). The channel conducts only when all x subunits are in state 1.

Consider an assembly of N identical channels. It is possible to introduce a concentration of channels in which the number of subunits in state 0 is i. It will be designated by c_i. Evidently we have c_0, c_1, ..., c_x, in all $x + 1$ concentrations, corresponding to $x + 1$ different states of the channel. Denoting the rate constant for the transition from 0 to 1 by α and that for the transition from 1 to 0 by β, we obtain a system of equations describing the kinetics of the changes in the concentrations:

$$\left.\begin{aligned}
&\frac{dc_0}{dt} = \alpha c_1 - \beta x c_0;\\
&\frac{dc_1}{dt} = 2\alpha c_2 + \beta x c_0 - \alpha c_1 - \beta(x-1)c_1;\\
&\cdots\cdots\cdots\cdots\cdots\\
&\frac{dc_j}{dt} = -j\alpha c_j + (x-j+1)\beta c_{j-1} - (x-j)\beta c_j + \alpha(j+1)c_{j+1},\\
&\cdots\cdots\cdots\\
&\frac{dc_x}{dt} = -x\alpha c_x + \beta c_{x-1}.
\end{aligned}\right\} \quad (20)$$

By considering the coefficients α and β as functions of the potential, it is possible to describe by Eqns. (20) experiments in which the potential is fixed, because, within the framework of our scheme, the conductivity varies in proportion to the concentration c_0: $g_K = Ng_0c_0$.

We shall now define the steady-state distribution of channels between the states. Putting $d/dt = 0$ in Eqns. (20), we have

$$\left.\begin{aligned}
&\bar{c}_1 = x\frac{\beta}{\alpha}\bar{c}_0 \equiv x\zeta\bar{c}_0;\\
&\bar{c}_2 = \frac{x-1}{2}\zeta\bar{c}_1 = \frac{x(x-1)}{2}\zeta^2\bar{c}_0;\\
&\cdots\cdots\cdots\cdots\cdots\\
&\bar{c}_j = \frac{x!}{(x-j)!\,j!}\zeta^j\bar{c}_0 = c_x^j\zeta^j\bar{c}_0\ ,
\end{aligned}\right\} \quad (21)$$

where a bar over symbol denotes a steady-state value of the given quantity. From the condition

$$\sum_{i=0}^{x} c_i = 1\ , \quad (22)$$

we find

$$\sum c_x^j\zeta^j\bar{c}_0 = 1; \quad (23)$$

hence we have

$$\bar{c}_0 = \frac{1}{(1+\zeta)^x}\ . \quad (24)$$

Thus, after introducing the definition

$$n = \frac{\alpha}{\alpha+\beta} = \frac{1}{1+\zeta}\ , \quad (25)$$

it is immediately seen from Eqn. (24) that, when $x = 4$, the expression for $\bar{c}_0$ is the same as the Hodgkin–Huxley equation for conductivity. Therefore one can write

$$c_0 = n^x.$$

When an experiment with a fixed potential is considered, we have the following solution of Eqn. (10):

$$n = n_\infty - (n_\infty - n_0)e^{-\lambda t}, \quad (26)$$

where $\lambda = \alpha + \beta$. Therefore the conductivity under the conditions of a fixed potential is given by

$$g_K = Ng_0[n_\infty - (n_\infty - n_0)e^{-\lambda t}]^x. \quad (27)$$

When $x = 4$, this expression is exactly the same as the Hodgkin–Huxley equation, provided that we put $\alpha = \alpha_n$ and $\beta = \beta_n$.

Eqns. (24) and (27) confirm that the kinetic scheme described can be regarded as a physical interpretation of the Hodgkin–Huxley model. However, until recently it was impossible to test this scheme directly. The spectra of current fluctuations, which should in principle throw light on the validity of the kinetic scheme, were measured

a comparatively long time ago[14,15]. However, the spectrum usually measured varied with the reciprocal of the frequency $1/f$. This type of variation could not be obtained not only in the Hodgkin–Huxley scheme but also in any other. Therefore it was not certain that the measured quantities are associated with the fluctuations in the conductivity of ionic channels. In 1973 Fishman[7] measured the spectrum of the conductivity fluctuations of the potassium channel, having defined it as the difference between the fluctuation spectra of a normal membrane and a membrane with blocked potassium channels. His spectrum had a density defined by

$$G(\omega) = \frac{f_1(\varphi)}{\lambda^2 + \omega^2}; \quad \omega = 2\pi f,$$

where $\lambda = \alpha_n + \beta_n$ and $f_1(\varphi)$ is a function. These experiments enabled Chen and Hill[6] to compare Hodgkin's kinetic scheme with Fishman's experiments, which led to the observation of a discrepancy between the theory and experiment: the theoretical variation of the critical frequency λ with potential was described by a line lying appreciably above the experimental points (the critical frequency was determined from the point of intersection of the zero and infinite asymptotes in the plot of G against $\ln\omega$). This discrepancy was appreciably reduced by Chen and Hill[6], who assumed the possibility that the current may be conducted by the potassium channel not only in state 0 but also in others. The comparison of Hodgkin's scheme with the results of fluctuation analysis has so far been merely in the nature of a preliminary step. However, it is already clear that fluctuation analysis will be one of the most important instruments for the investigation of the nature of excitability.

IV. GATING CURRENTS

There have been considerable advances in recent years in the elucidation of the physical nature of the excitation process. The brilliant experiments of Armstrong, Bezanilla, Keynes, Rojas, Meves, and others[8-11], led to the observation of asymmetric currents, all the characteristics of which show them to be migration currents of the charged species within the membrane. There is reason to believe that these currents are directly related to the migration of charged groups controlling the conductivity of the sodium channel.

In view of the importance of the problem, it is necessary to define briefly the so called gating current. In the method with fixation of the potential, a membrane incapable of transmitting ions is maintained at a certain potential. Next a potential pulse with a specified amplitude (about 150 mV) and of sufficient duration is applied, the resulting current is recorded, and, after the cessation of the potential pulse, the system is again maintained at the initial potential. Next, a potential pulse of the opposite sign is applied; this leads to a new record of the current as a function of the time elapsed from the beginning of the pulse. The so called gating current is obtained by subtracting the currents corresponding to the same time from one another. The sign of equality then naturally depends on the initial potential and for a certain value of the latter the amplitude of the gating current is zero[9]. It is remarkable that an approximate agreement between the characteristic time of the change in the gating current and the time of the change in the variable m has been observed experimentally over the entire range of potentials. On the other hand, no indication has been obtained of any correlation between the gating current and the variables h and n. Apparently this cannot be accounted for by the inadequate accuracy of the measurements—it is better to change the hypothesis concerning the kinetics of the activation of the sodium current and to seek an appropriate kinetic scheme.

V. THE COOPERATIVE DIPOLE MODEL

The interpretation of gating currents in the Hodgkin–Huxley scheme is based on the hypothesis that several charged groups, which are a constituent part of the channel, migrate through the entire thickness of the membrane. From the physical standpoint, this assumption is unlikely. It is more reasonable to postulate that there is a reorientation of dipoles surrounding the channel, which is equivalent to the transport of a charge across the entire membrane. Then the gating current reflects the rearrangement of the system of dipoles. It differs from the usual displacement current by the asymmetry of the sign of the field. The system of dipoles must be cooperative, since otherwise it would be impossible to explain the marked dependence of the electrical characteristics on the potential.

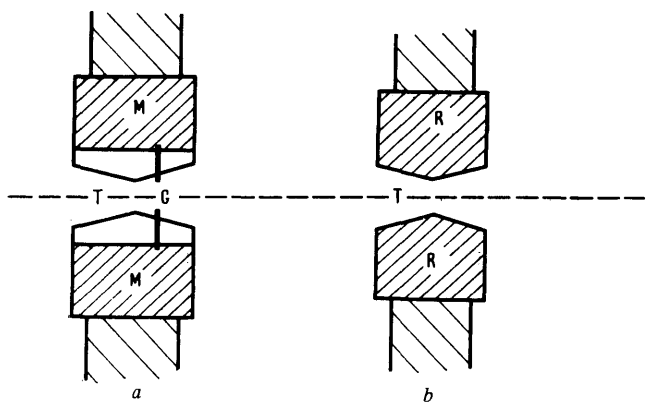

Figure 3. Model of the excited ion channel: *a*) regulation by the alteration of the molecular geometry of the transport system T (M—measuring device; G—gate); *b*) electrostatic scheme for the regulation of conductivity; rigid geometry of transport system; R—regulation system.

The change in the permeability to ions in the course of the reorientation of dipoles may be due to various causes. If the reorientation is coupled with appreciable conformational changes in the system, then the "opening" or "closing" of the channel can have the significance of a change in its molecular geometry. Another case is also possible, where the dipole reorientation influences the electrostatic component of the energy of the ions in the channel, without altering its geometry, and hence influences the concentration of the ions in the membrane and their effective mobility[16].

Models of the channel constructed taking into account the above possibilities are illustrated in Fig. 3. The ion channel probably consists of the transport system proper

(T) and the system regulating the permeability (R). The R unit can include a device measuring the field on the membrane (M), which is linked via certain degrees of freedom with the "gate" (G), i.e. with mobile molecular groups which alter the geometry of the transport system (Fig. 3*a*). There are so far no data which would provide an answer to the question whether the gate is localised or whether the rearrangement involves a considerable proportion of the transport system. Fig. 3*b* represents the electrostatic version of the regulation. There is no point in separating the measuring system from the gate proper, since the geometry of the transport system is assumed to be rigid and the R unit measures the field and regulates the permeability simultaneously. In any of these models the so called gating current is associated with the dipole reorientation in the R or M system. The problem of the calculation of the gating current is entirely independent and requires no hypotheses concerning the mechanism of the regulation of permeability.

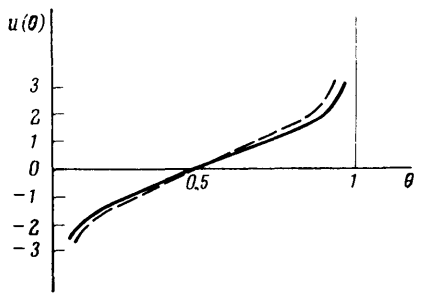

Figure 4. Variation of the cooperative energy of the subunit with θ. The continuous curve corresponds to $\epsilon = 0.2$ and the cooperativity parameter $w = 3.5$. Dashed line—$\epsilon = 0.05$ and $\omega = 3.88$; the phase transition takes place when $w = 4$.

We shall assume that the R (or M) system of the ion channel consists of a large number of subunits, each of which has a dipole moment. Suppose that each subunit can be in one of three states (0, 1, or 2), which differ in the magnitude of the projection of the dipole moment on the axis of the channel and correspond to the transition of the latter from the state of rest to activation and inactivation. In the quasichemical approximation the energy of the subunit in the ith state $V_i(\theta_1, \theta_2, \varphi)$ can be formulated as follows:

$$V_i = w_i(\theta_1, \theta_2) + \varepsilon_i(\theta_1, \theta_2)\,\psi, \tag{28}$$

where $\psi = e\varphi/kT$ is the membrane potential, ϵ_i the effective displacement of the charges in units of the thickness of the membrane, θ_i the degree of filling of the ith state, and w_i the cooperative component of the energy. The rate constants for the transitions are expressed as usual in terms of the differences between the energies of the states, for example:

$$k_{01} = Ae^{\alpha(u_1+\varepsilon_1\psi)};\ u_1 + \varepsilon_1\psi = V_0 - V_1. \tag{29}$$

It is easy to formulate kinetic equations within the framework of the linear scheme:

$$\dot{\theta}_i = -(k_{i1} + k_{i0})\,\theta_i - k_{ij}\theta_j + k_{ij};\ i, j = 0, 2;\quad i + j = 2. \tag{30}$$

We shall confine ourselves to the case of two states, which corresponds to the activation of the ion channel. Assuming that $\theta_2 = 0$, we obtain from Eqn. (30) the equation

$$\dot{\theta}_0 = -(k_{01} + k_{10})\,\theta_0 + k_{10}, \tag{31}$$

the steady-state solution of which has the form analogous to the familiar Frumkin isotherm:

$$\frac{\theta_1}{1-\theta_1}\,e^{-u(\theta_1)} = \frac{A}{B}\,e^{\varepsilon\psi};\ \theta_0 = 1 - \theta_1. \tag{32}$$

According to the experimental data[9], the charge displacement on activation of the sodium channel is described satisfactorily by the formula

$$\theta(\psi) = \frac{1}{1 + e^{-z\psi}};\quad z = 1, 3. \tag{33}$$

Fig. 4 illustrates the $u(\theta)$ relations for different values of ϵ found from the condition that Eqns. (32) and (33) become identical. It follows from Fig. 4 that, in the region of moderate degrees of saturation, $u(\theta)$ is represented satisfactorily by a linear function with cooperativity constants of 3.88 ($\epsilon = 0.05$) and 3.5 ($\epsilon = 0.2$). For low and high degrees of saturation, the cooperativity is still greater.

Fig. 5 illustrates the steady-state $\theta - \psi$ curve obtained for the linear approximation $u(\theta) = 3.5\ (\theta - 0.5)$. Thus, even a slight reorientation of small dipoles yields the required slope of the $\theta - \psi$ curve as a result of the marked cooperativity.

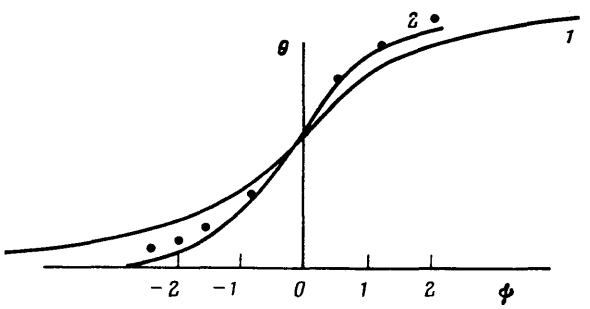

Figure 5. The fraction of transferred charge as a function of potential. Curve *1* was plotted on the basis of Eqn. (32) with a linear fit to the function $u(\theta)$. Curve *2* was calculated by Eqn. (33); circles—experimental data[9].

In order to calculate the gating current, it is necessary to determine the time variation of θ. This relation is illustrated in Fig. 6 for $\alpha = 1$. In this case the $\theta - t$ relation is quasiexponential at a fixed potential. The gating current is found by differentiating the expression for the $\theta(t)$ function.

The method for the determination of conductivity depends on the version of the model of the channel considered—that in Fig. 3*a* or 3*b*. In the former case it is possible to find the conductivity by fitting the function $\varphi(\theta)$ on the basis of experimental data. This procedure is analogous to the selection of the power function ($g_{K^+} \propto n^4$ and $g_{Na^+} \propto m^3h$) in the Hodgkin-Huxley model. In the

second case it is possible to find the form of the $g(\theta)$ function from physical considerations by calculating the concentration of carriers in the channel and the conductivity from the formulae:

$$c \simeq \bar{c} \cdot e^{F}; \; g \simeq c, \tag{34}$$

where F is the change in the energy of the ion in the channel on reorientation of the dipoles, which can be readily estimated:

$$F \simeq \frac{eQ\delta\xi}{4\pi kTSN}(1-\theta). \tag{35}$$

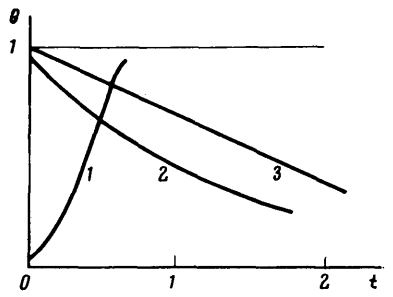

Figure 6. Variation of θ with t: 1) "direct clamp" from $\theta = 0.05$ to $\theta = 0.95$; 2) "reverse clamp" from $\theta = 0.95$ to $\theta = 0.05$; 3) variation of $\lg\theta$ with t corresponding to curve 2.

Here $Q\delta$ is the total change in the dipole moment ($Q \propto 2 \times 10^3 e/\mu^2$), S is the area of the lateral surface of the channel, N the density of the channels, and ξ the structure factor. When $\xi \simeq 10^3$, the energy $F \simeq 10\theta$. Calculations show that there is a great similarity between the variation of θ^4 and $e^{6(\theta-1)}$ in the region of moderate values of θ. The exponential relation between conductivity and θ has the advantage that it makes it possible to explain readily, by the additivity of the energy, the formula $g_{Na^+} \simeq m^3h$ and also the shift of the conductivity current maximum relative to the gating current maximum.

Anodic Dimerisation, Addition and Substitution Reactions of Organic Compounds

L.A.Mirkind

The review deals with certain general characteristics of the behaviour of organic substances at high positive potentials, which determine the mechanism and kinetics of anodic dimerisation (condensation), addition, and substitution reactions. A systematic account is given of the most significant results of studies in recent years on organic electrosynthesis based on the above classes of reactions.
The bibliography includes 303 references.

I. INTRODUCTION

There has been a considerable growth in recent years of research on anodic dimerisation (condensation), addition, and substitution reactions dealing with the study of the kinetics and mechanism of anodic processes and with the development on the basis of the above classes of reactions of effective methods for the electrochemical synthesis of various monofunctional and polyfunctional compounds which are valuable intermediates in many branches of polymer chemistry and organic synthesis. Since a systematic account has been given of the data accumulated in 1970–1971 in a number of special reviews dealing with the problem as a whole [1-3] or with individual classes of reactions [4-8], we shall confine ourselves to the consideration of the results in later publications, concentrating attention on general characteristics and also on certain problems concerning which there is still controversy in the literature.

The enhanced interest in the study of reactions of the above classes has been aroused primarily by the fact that the electrochemical methods for carrying them out have many advantages over chemical methods [9,10].

1. The anodes used for the oxidation (platinum, graphite, lead dioxide, etc.) are inert, in contrast to chemical oxidising agents which give rise to undesirable side reactions. There is also no need for the subsequent separation of the oxidant reduction products.

2. The possibility of a smooth variation of the potential within wide limits makes it possible to achieve selective reactions in the presence of several oxidisable groups or of degrees of oxidation and also to carry out oxidations in the same apparatus under conditions ranging from very mild to very severe.

3. It is easy to control the changes in the nature and rate of formation of the intermediate species by regulating the potential and anodic current density and by modifying the electrical double layer, which makes it possible to generate under mild conditions high local concentrations of such species in the vicinity of the electrode and this frequently facilitates a selective or specific course of the reaction.

4. Since the electron transfer is determined by the changes in the anodic potential, the temperature can be in many instances freely selected, which is also an important preparative advantage†.

The above characteristics are responsible for the specific features of the reaction pathways and the products formed in anodic reactions and in many cases make it possible to achieve processes which either have no chemical analogues or lead to the same products in a simpler way. As an example one may quote the reactions of organic-inorganic synthesis in the electrolysis of mixtures of organic (acetic, propionic) and inorganic (sulphuric, perchloric, nitric) acids [11-14]. At low temperatures (−20°C) and high potentials ($\varphi \geqslant 3.0$ V) peroxy-compounds having the general formula $RCOOOR_1$ are formed at a platinum anode in concentrated acid solutions:

$$RCOO^- + R_1O^- \xrightarrow{-2e} RCOOOR_1;$$
$$R=CH_3,\ C_2H_5;\ R_1=SO_3H,\ ClO_3,\ NO_2\ .$$

The chemical procedures for the preparation of such substances are fairly complex.

There are also no chemical analogues of addition reactions such as the carboxydimerisation of conjugated dienes resulting in the formation of higher unsaturated dicarboxylic acids [15]:

$$2\,(HOOC)_2 + 2\,C_nH_{2n-2} \xrightarrow{-2e,-2H^+,-2CO_2} HOOC\,(C_nH_{2n-2})_2\,COOH;$$

the synthesis of dicarbonyl compounds in the oxidation of sodium dimethylmalonate and sodium acetylacetonate in the presence of styrene or ethyl vinyl ether [10,16] ($k = 1$ or 2):

$$2\,(RCO_k)_2CH^- + \rangle\!=\!\langle^{Y} \xrightarrow{-2e} (RCO_k)_2CH\left(\begin{array}{c}Y\\|\\|\end{array}\right)_k CH\,(CO_kR)_2;$$

and the anodic aroyloxylation of 1,3-dienes [17,18]:

$$2\ XArCOO^- + C_nH_{2n-2} \xrightarrow{-2e} XArCOOC_nH_{2n-2}OOCArX;$$
$$X=C_nH_{2n+1},\ C_nH_{2n+1}OOC,\ OH\ .$$

† Reactions involving unstable radicals, for example $RCOO^{\cdot}$, the occurrence of which is promoted by low temperatures, constitute an exception [14].

The unusual features of the reaction pathways in anodic processes of the above classes are determined in many respects also by the fact that at least the individual stages of these processes are electrocatalytic, since they occur at an interface and depend significantly on the state of the electrode surface.

II. CERTAIN CHARACTERISTICS OF ANODIC PROCESSES AT HIGH POSITIVE POTENTIALS

The majority of anodic dimerisation, addition, and substitution reactions require comparatively high positive potentials (1.5–3.5 V) and, in order to understand their mechanism, it is necessary to take into account many common features of electrode processes under these conditions.

At high anodic potentials the oxidation of the substrate is in most cases accompanied by the oxidation of the solvent usually employed (water, lower aliphatic alcohols, acetone, etc.). Under these conditions, there is a change in the state of the electrode surface and in the composition and bonding energies of the adsorbed components of the electrolyte and the oxidation intermediates, which is inevitably reflected in the direction or relative rates of secondary chemical reactions.

The water in the electrolyte, which is almost always present as an impurity even in dried organic solvents, leads to the liberation of oxygen, accompanying the oxidation of the organic substance. On platinum metals (which are most frequently used), certain oxides are formed, which alter sharply the adsorption and catalytic properties of the surface and lead to a decrease of the effective potential in the zone corresponding to the formation of the transition state of the species undergoing oxidation.

It is therefore reasonable that, in the study of the mechanisms of such reactions, it is necessary to take into account in the first place the influence of heterogeneous factors on the rate and direction of electrode processes. It is also necessary to discover whether chemical reactions preceding electron transfer (including those accompanied by the adsorption of the neutral substrate or oxidation intermediates) occur and also the requirements for the orientation of the molecule on the electrode surface and the preferred orientation. It is essential to determine the nature of the oxidant (the electrode itself, oxygen, or the intermediates in the oxidation of water and OH^- ions), the species being oxidised, and the intermediates formed initially (radicals, radical-ions, or ions), and the sequence of stages in their reactions.

In certain cases it is possible to determine the nature of the primary product formed on the electrode by direct measurements. For example, the formation of phenylacetoxy-radicals in the oxidation of phenylacetic acids in acetonitrile has been demonstrated[19,20] by ESR; the influence of the solvent on the hyperfine structure of the spectrum indicates the stabilisation of the radicals by solvation effects. The formation of adsorbed phenoxy-radicals in the oxidation of sterically hindered phenols (SHP) on a graphite electrode over a wide pH range has been demonstrated by ESR.[21] This finding shows that, in both alkaline and in acid and neutral solutions, the primary step in the electrochemical oxidation of SHP is a one-electron transition. Analysis of the ESR spectra in the oxidation of substituted phenols on platinum and of stable phenoxy-radicals on graphite leads to a similar conclusion[23].

However, the above problems have not been fully elucidated for any reaction of the classes under consideration, largely because of experimental difficulties associated with the study of electrode processes and potentials in excess of the reversible oxygen potential (φ_0). In most cases the methods used as low potentials for the unoxidised metal are insufficiently effective under these conditions and the adsorption and kinetic characteristics discovered for dilute aqueous solutions of simple organic substances at $\varphi < \varphi_0$ [22] cannot be reliably extrapolated to this region[2,3,24,25]. When non-aqueous solvents are used, addition complications arise.

Nevertheless vigorous studies in recent years of new methodological approaches to the investigation of electrode processes under these conditions and the combined application of various electrochemical[26-41], optical-spectroscopic[42-48], radiochemical[49-56], mass-spectrometric[57], electron diffraction[58-60], and conductimetric[61] methods together with methods based on the identification of the products of potentiostatic electrolysis[2,3,62-64] have already made possible certain qualitative or semiquantitative generalisations. This applies in the first place to problems concerning the state of the electrode surface (mainly the platinum electrode) over a wide range of potentials and its influence on the direction and rate of electrochemical reactions. However, most of the studies have dealt with inorganic systems. Among these mention should be made in the first place of the series of investigations by Veselovskii, Kasatkin, Yakovleva, and coworkers on the synthesis of oxidants at high positive potentials[63,64] and also by Tyurin and coworkers on the oxygen evolution reaction on platinum metals[26-29,65-68]. Among reactions involving organic substances, only the electrochemical oxidation of carboxylates has been studied in this way[69].

Numerous experimental data confirming the thesis of the decisive influence of the compositions and properties of surface compounds of the electrode with the components of the solution and the intermediates in the electrochemical oxidation on the direction and rate of electrode reactions at $\varphi > \varphi_0$ have now accumulated. Unfortunately in most of the studies devoted to preparative organic electrochemical synthesis at high anodic potentials this factor has so far been ignored and the conclusions concerning the mechanism are reached mainly on the basis of a comparison of the composition of the products of the electrolysis and the corresponding chemical reactions. The necessity to take into account the characteristics of the surface phenomena, in particular the adsorption processes at the electrode/solution boundary, has been acknowledge in only a few studies carried out in recent years[70-78].

The $i-\varphi$ curves and the variation of the double layer capacitance, the adsorption pseudocapacitance, and the polarisation resistance with the potential, measured in solutions of different compositions at platinum metals, gold, and graphite, exhibit sharp breaks, maxima, and minima. As an illustration, Fig. 1 presents $\lg i-\varphi$ curves for a solution of monomethyl glutarate in methanol using gold (curve *1*), iridium (curve *2*), rhodium (curve *3*), platinum (curve *4*), pyrographite (curve *5*), and vitreous carbon (curve *6*)[77] electrodes, while Fig. 2 illustrates the variation of the double layer capacitance with potential at smooth platinum in 1 *N* H_2SO_4 solutions with added $n\text{-}C_5H_{11}COOH$ obtained by an a.c. bridge method[28].

In many cases the reaction is inhibited by the electrolyte component which begins to be oxidised vigorously at a value of φ more positive than that corresponding to the potential jump or current (capacitance) drop. Fig. 3 presents plots of polarograms, in terms of semilogarith-

mic coordinates, recorded at a rotating platinum anode in alkaline solutions of pelargonic acid[78]. Evidently, with increase of the concentration of the carboxylate anion, the oxidation of which with formation of hexadecane takes place mainly at potentials corresponding to section V, there is a decrease of both the potential and the maximum current of the discharge of the OH^- ion—the dominant oxidation process along the lower sections.

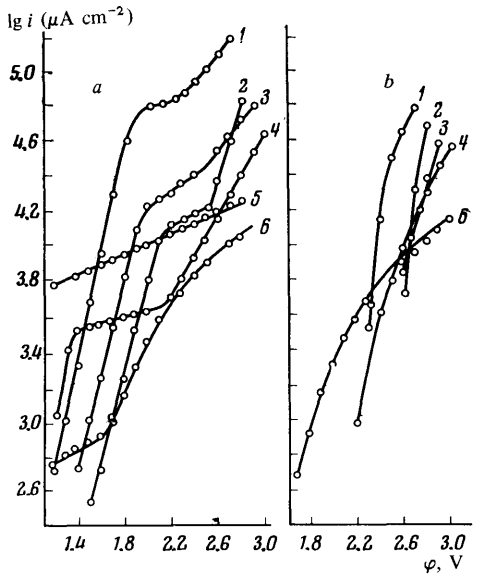

Figure 1. Anodic polarisation curves (*a*) and partial polarisation curves (*b*) for the oxidation of monomethyl glutarate in a methanol solution of 0.3 M $CH_3OOC(CH_2)_3$. .$COONa$ + 1 M $CH_3OOC(CH_2)_3COOH$ on electrodes made of different materials.

The adsorption of stable final or intermediate products[79,80] and the electrolyte anions[81,82], the change in the rate-determining stage[83-86], and the formation of surface oxides[26-29,38,64,88] have been considered in the literature as the probable causes of the inhibition of electrochemical oxidation and of the change in the properties of the interface in various systems. In many instances the relation between the surface coverage, the composition and properties of the chemisorbed products of the dissociation of water (OH^-), and the kinetic properties of the oxidation reactions were characterised quantitatively[28,29,38,67,88,90].

A wide variety of surface oxygen compounds of platinum metals and gold are known to exist[91-95]. The number of studies dealing with the nature and stoichiometry of surface oxides, their relative stabilities, the conditions governing their formation and interconversions, and their involvement in oxygen evolution reactions and in oxidation of organic substances greatly increased in recent years. The greatest number of studies have dealt with platinum[24-32,36,38,40,43,48,96-102], much less attention being devoted in this respect to graphite[39,101,104,106], gold[33,37,42,43], palladium[33,52,107], iridium[102,103], ruthenium[102], and rhodium[102,108-110].

Potentiodynamic measurements in solutions of inorganic acids and alkalies[26,27,56,83,85,111,112] have shown that the overall degree of coverage of the surface of smooth platinum by chemisorbed oxygen increases monotonically up to potentials φ_r‡ ≃ 2.1 V and reaches a limiting value (2.3–2.7 monolayers), which no longer changes as the potential is increased further (Fig. 4).[56]§

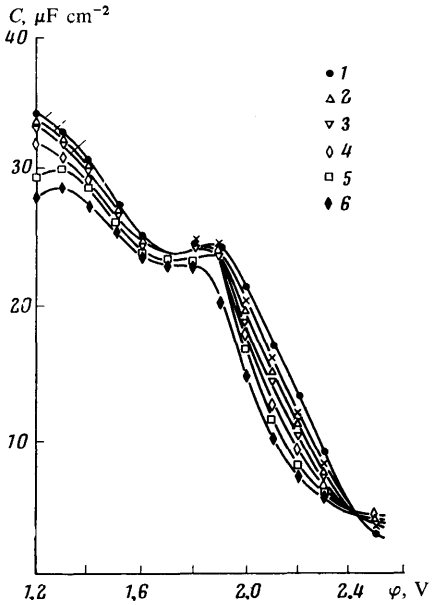

Figure 2. Variation of the double layer capacitance with potential on smooth platinum in 1 *N* H_2SO_4 with added $n\text{-}C_5H_{11}COOH$ at different molar concentrations: 1) 0; 2) 3×10^{-5}; 3) 10^{-4}; 4) 3×10^{-4}; 5) 10^{-3}; 6) 3×10^{-3}.

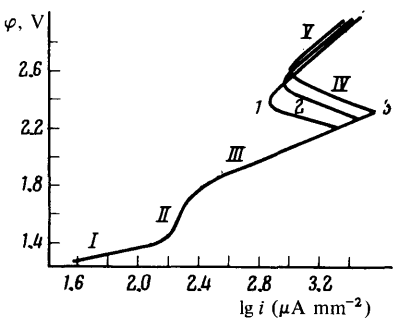

Figure 3. Anodic polarograms obtained on platinum in 0.5 *N* $NaOH + xN$ $CH_3(CH_2)_7COONa$ solutions for different *x*: 1) 1; 2) 0.5; 3) 0.1; the rate of application of potential was 10 mV s^{-1}.

‡ φ_r is the potential relative to the hydrogen electrode in the same solution.

§ Q_O and Q_H are the amounts of electricity consumed in the reduction of oxygen and the "deposition" of hydrogen respectively.

At $\varphi_r = 1.4-1.6$ V monolayer coverage by the oxide is attained, the oxide being reduced at $\varphi_r \simeq 0.6$ V (the so called first form of the oxide); at higher potentials the second form of the oxide is formed, being reduced at hydrogen adsorption potentials ($\varphi_r \simeq 0.2$ V). Multilayer bulk-phase deposits are formed in the range $\varphi_r = 2.1$ to 2.3 V,[26,27,59,113-115], mainly in dilute solutions at an elevated temperature, evidently only after the saturation of the surface by chemisorbed oxide layers and at a small number of active centres on the metal[27]. For both platinum and gold electrodes, a significant change in the properties of the surface oxide with time has been noted, in consequence of the increase of bonding energy or the incorporation of oxygen atoms in the crystal lattice of the subsurface layers of the metal.

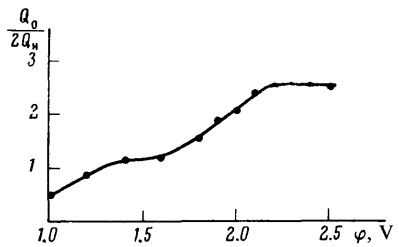

Figure 4. Variation of the degree of surface coverage of smooth platinum by chemisorbed oxygen with potential.

The oxides on platinum belonging to the second form are chemically inert with respect to many organic (and inorganic) substances; an increase of the degree of surface coverage by an oxide of the second form θ_{OII} in the range 1.6–2.3 V results in the inhibition of the electrochemical oxidation of the majority of the compounds investigated, which is reflected in a decrease of the current or an increase of the Tafel slope. The influence of the surface coverage of the platinum electrode by chemisorbed oxygen on the inhibition of the electrochemical oxidation of organic substances has been characterised quantitatively in some investigations[24-29,62,90].

The adsorption of oxygen on platinum at high positive potentials has a competitive mechanism: depending on the concentration and nature of the substance, the fraction of the surface atoms O_{ads} [or other intermediates in the oxygen evolution reaction (OEV)] displaced by the specifically adsorbed inorganic anions, neutral atoms (for example Cl°), or organic compounds changes[24-29,34,35,38,46,65-68,88].

The behaviour of organic substances has been so far inadequately investigated along these lines. In contrast to the range of low potentials, it is much more difficult to determine the structure of the adsorbed species on an oxidised electrode and the nature of their interaction with the surface (associative or dissociative); there are very few data concerning the surface phenomena on electrodes in non-aqueous solvents. The quantitative study of the adsorption of neutral molecules of high potentials involves significant methodological difficulties. These processes are in fact of great importance for the classes reactions under consideration, since it has been shown in recent years[1-3] that the adsorption of a neutral substrate predetermines the efficiency and mode of addition and substitution processes involving short-lived radicals and radical-ions generated on the electrode surface as a result of charge transfer.

III. CHARACTERISTICS OF THE ADSORPTION OF NEUTRAL ORGANIC SUBSTANCES ON OXIDISED PLATINUM

The possibility of the chemisorption of organic molecules on platinum at potentials exceeding significantly that of the reversible oxygen electrode (up to $\varphi_r = 3.0$ V) has been established[116,117] for conjugated dienes and then for other systems[24,25,35,55,118,129]. In recent years this phenomenon has been investigated vigorously by Tyurin and coworkers, who demonstrated the general nature of the adsorption characteristics at high potentials discovered previously[26-29,67,68,133]. It is useful to consider this problem in greater detail, since the existence of this effect is, on the one hand, of fundamental importance for the understanding of the mechanisms of the majority of reactions of the classes being considered and, on the other hand, in many studies it has hitherto been either denied or simply ignored in the discussion of the possible reaction pathways. In the majority of investigations the impossibility of appreciable adsorption of neutral molecules in the range of potentials corresponding to vigorous evolution of oxygen and coverage of the surface by oxides is postulated *a priori*.

On the basis of earlier data[116-119], Kuhn and Sunderland[120] recently investigated the possibility of the adsorption of certain olefins by analysing their oxidation products in aqueous solutions and concluded that the nature of the substances formed (their amount is extremely small owing to the negligible solubility of the olefin) may be interpreted from the standpoint of homogeneous reactions. Therefore, according to the authors[120] the effects observed previously[116-119] may be identified as a result of physical adsorption. It must be emphasised that a one-sided study of the nature of the oxidation products only is hardly a fruitful procedure for obtaining evidence for adsorption and even less so for the determination of its energy characteristics or steric effects. This must be mentioned because such an approach has been widely used recently—for example in studies of anodic substitution reactions with participation of indane[73-76] and stilbene[70] and of the postanodic condensation of carboxylates[71,72], in which unusual directing effects of the substituents and relative amounts of isomeric products were observed. Without casting doubt on the possibility of the adsorption of the substrate in the reactions considered, one must emphasise that such results can be associated also with other features of electrochemical oxidation reactions, for example with a structure which is not characteristic of chemical analogues or with a high local concentration of intermediate species[121,123].

In order to investigate the adsorption of organic substances at high positive potentials, indirect electrochemical methods were mainly used previously, namely coulometric adsorption displacement methods, methods involving a diminution of the capacitance or pseudocapacitance, and the method based on the inhibition of oxidation reactions[2,3]. However, it has been emphasised[2,24,56] that they all suffer from significant limitations and probably yield reliable information only when several are combined. In certaininstances there is a quantitative

correspondence between all the criteria of surface coverage by an organic adsorbate, characteristic of each of these methods, as has been observed, for example, in the adsorption of pentyl alcohol and valeric acid on platinum (Fig. 5).[28] However, all the methods enumerated are based on a number of assumptions. As shown for the adsorption of ethylene[124], aliphatic alcohols[125], and dienes in methanol solutions of oxalic acid[15], cycloalkanes[25,35], and chloride ions[126], they do not always permit an unambiguous interpretation of experimental data, leading to results such as negative adsorption, negative slopes of kinetic isotherms, etc. When the potentiodynamic rapid cathodic pulse method, which has been widely used for adsorption measurements at $\varphi > \varphi_0$, is applied, the conditions governing the correct determination of θ by the integration of $i-\varphi$ curves are not always ensured (and may not hold) since no account is taken of the possible change in the stoichiometry of the displacement[127] and of the influence of the adsorbate on the maximum surface coverage by electrochemically active species and on the kinetics of their reduction under pulsed conditions. The separation of the effects due to the blocking of the active centres of the metal and the inhibition of the reduction of the chemisorbed oxygen is usually difficult[68].

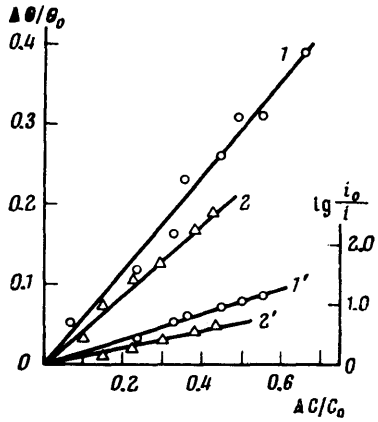

Figure 5. Variation of the inhibition coefficients for the oxygen evolution reaction $\lg(i_0/i)$ (lines *1'* and *2'*) and for the displacement of oxides $\Delta Q/Q_0$ (lines *1* and *2*) with the depression of the capacitance $\Delta C/C_0$ for 1 *N* H_2SO_4 + n-$C_5H_{11}OH$ (lines *1* and *1'*) and 1 *N* H_2SO_4 + n-$C_5H_{11}COOH$ (lines *2* and *2'*) at $\varphi = 2.2$ V; the circles on the straight lines correspond to different concentrations of additives.

It is therefore useful to compare the results obtained by electrochemical methods with data derived from direct adsorption measurements. The fruitfulness of this approach has been emphasised[124]. The study of the adsorption of a number of organic substances has been undertaken[55,56,128-133]: aromatic hydrocarbons[35,55,56], alcohols[128,129], carboxylic acids[53,54,129], and thiourea[130,133] on smooth platinum in 1 *N* H_2SO_4 solutions up to $\varphi_r \simeq 2.5$ V using a combination of electrochemical methods and the ratioactive tracer method. Direct adsorption measurements with the aid of compounds labelled by radioactive isotopes fully confirmed both the very fact of an appreciable adsorption of organic molecules at high positive potentials and the principal quantitative characteristics found previously. Fig. 6[56] illustrates the variation of the surface coverage θ and the degree of adsorption Γ with potential obtained by the potentiodynamic method (lower curves) and with the aid of labelled compounds (upper curves) for benzene and naphthalene. The nature of the curves is basically similar; the differences between them are associated with the fact that the values of θ actually characterise the degree of displacement of chemisorbed oxygen and those of Γ characterise the overall surface excess of the organic substances both within the oxide and on the oxide. Comparison of the measurements by electrochemical and isotopic methods permits conclusions to be made about the stoichiometry of the displacement, the relative distribution of the adsorbed substances in the surface layers, and many other features.

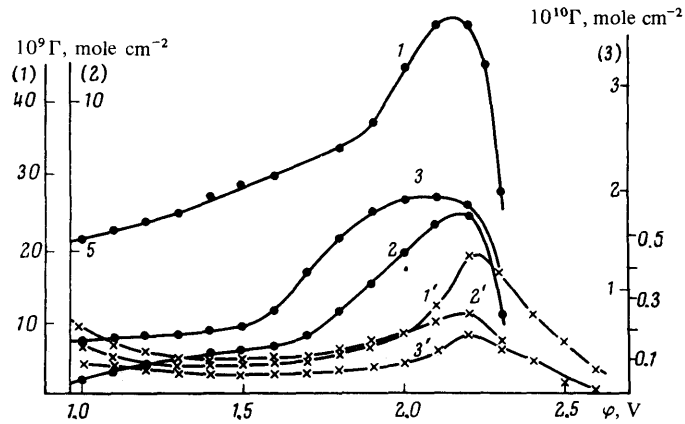

Figure 6. Variation of the degree of adsorption Γ (curves *1–3*) and of the degree of surface coverage θ (curves *1'–3'*) of platinum with potential: 1) and 1') 0.089 M benzene; 2) and 2') 2×10^{-4} M naphthalene; 3) and 3') 0.01 M benzene.

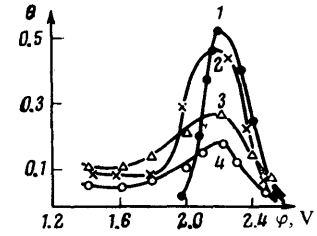

Figure 7. Variation of the degree of surface coverage of platinum by different substances with potential: 1) 5×10^{-4} M cyclohexane; 2) 5×10^{-4} M cyclohexene; 3) 10^{-4} M naphthalene; 4) 10^{-3} M benzene.

Figs. 7 and 8 illustrate the $\theta-\varphi$ and $\Gamma-\varphi$ relations obtained by the potentiodynamic method for hydrocarbons (butadiene, cyclohexene, and cyclohexane)[35] and by the radioactive tracer method for C_{1-6} aliphatic alcohols[128].

The data presented confirm the general nature of the effect of the adsorption of organic substances at $\varphi > \varphi_0$ and show that, apart from the familiar maximum in the double layer region, the $\Gamma-\varphi$ curves have yet another maximum at potentials of 2.1–2.3 V, where the limiting coverage of the platinum anode by chemisorbed oxygen is reached. A similar phenomenon has been observed for oxidised rhodium [108]. The presence of a number of adsorption maxima for smooth platinum has also been confirmed by other data [132-136], according to which there exists yet another region of enhanced adsorption activity of platinum at high positive potentials.

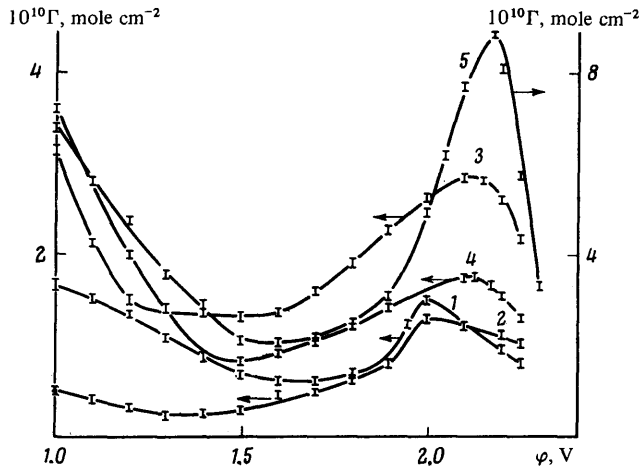

Figure 8. Variation of the degree of adsorption Γ of different substances on platinum with potential: 1) 0.15 M CH_3OH; 2) 0.0532 M C_2H_5OH; 3) 0.1 M i-C_3H_7OH; 4) 0.090 M t-C_4H_9OH; 5) 0.048 M n-$C_6H_{11}OH$.

Analysis of the experimental data accumulated in recent years permits certain generalisations of the characteristics of the adsorption of organic substances on oxidised platinum.

1. The adsorption of organic compounds (at least of the major proportion of the adsorbate) is as a rule irreversible and is accompanied by the displacement of chemisorbed oxygen. The introduction of molecules into the oxide layer stabilises them on the surface. There is a broad overall spectrum of energy states, including weakly bound species [128].

2. In the series of compounds of the same type and having similar molecular weights, those with multiple bonds exhibit a greater adsorbability.

3. In contrast to unoxidised smooth and platinised platinum, on which far-reaching degradation of molecules takes place, the adsorption of organic compounds on the oxidised metal may be manifested as an associative process [2,3,62,137].

4. In contrast to the range of low potentials, for which a logarithmic adsorption isotherm with similar values of the inhomogeneity factor f (Damaskin et al. [22]) is typical, at $\varphi > \varphi_0$ the variation of surface coverage with concentration c is not of a single type. In some cases it is described satisfactorily by the Temkin equation with f depending on the potential and the nature of the substance [62,131]:

$$\theta = \frac{1}{f}\ln(Bc);\ B = \text{const.},$$

while in others (for example, for alcohols [128,135] or acids [129]) the agreement with the Freundlich equation is better (Fig. 9):

$$\theta = Bc^n;\ n < 1.$$

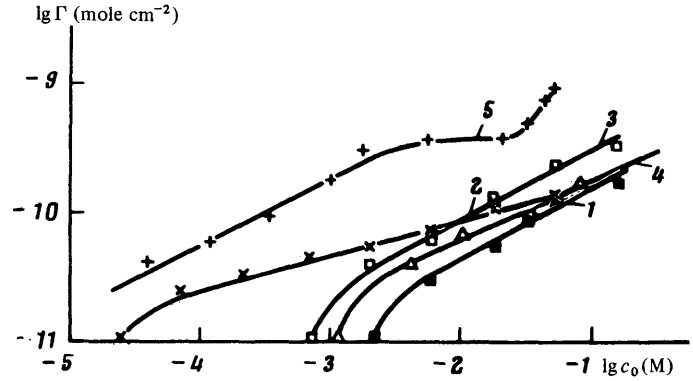

Figure 9. Variation of the degree of adsorption of different substances on platinum at the maximum potentials with the concentration of alcohols in terms of logarithmic coordinates: 1) CH_3OH; 2) C_2H_5OH; 3) i-C_3H_7OH; 4) t-C_4H_9OH; 5) n-$C_6H_{11}OH$.

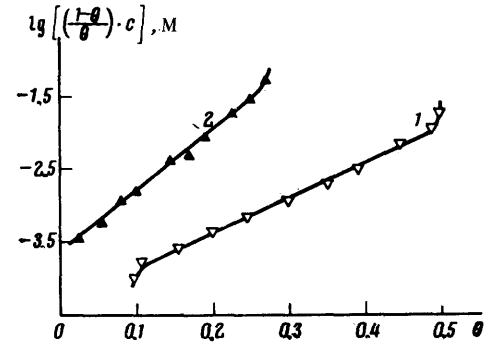

Figure 10. Variation of the degree of surface coverage of platinum with the concentration of buta-1,3-diene at different potentials (V): 1) 2.1; 2) 2.8.

The adsorption of dienes from sulphuric acid solutions obeys the Frumkin equation (Fig. 10): [134]

$$Bc = \frac{\theta}{1-\theta}\exp(f_1\theta);\ f_1 = \text{const}.$$

5. The adsorption kinetics are described by power equations of the Banham–Barth (Kwan) type [128]:

$$\theta = k\cdot\tau^n;\ \tau - \text{time},\ k = \text{const.};$$

or the Zel'dovich–Roginskii type [35,130]:

$$\theta = A + \frac{1}{\alpha f}\ln\tau;\ \alpha \leqslant 1;\ A = \text{const.}$$

6. The formation of multilayer coatings at concentrations differing by not more than an order of magnitude from saturation has been observed for certain substances [55,56]. Fig. 11 [56] presents curves relating Γ and θ to c for benzene and naphthalene; the ascending branches of the curves correspond to the appearance of multilayer deposits. Weber and Loučka also concluded recently that multilayer adsorption is possible (for sulphur on smooth platinum) [138].

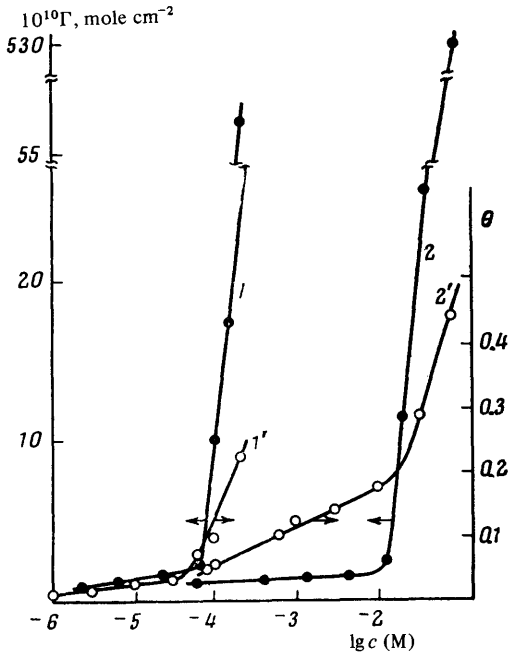

Figure 11. Variation of the degree of adsorption Γ (curves *1* and *2*) and of the degree of surface coverage θ (curves *1′* and *2′*) by different substances with concentration: 1) and 1′) naphthalene; 2) and 2′) benzene.

7. The substance adsorbed on energetically inhomogeneous surfaces of platinum metals and graphite can not only block the active centres but can also have a significant influence on the kinetics of the oxidation and the energy of adsorption on the unoccupied sections. In conformity with the model of the "surface electron gas" [139,140], one can predict both an inhibiting and a promoting influence of the initially adsorbed substance on the rate of discharge and also a change in the metal–adsorbate bond strength on the free sections of the surface.

The sign of the effect will be determined by the nature of the adsorbate and of the oxidation process. Indeed Gileadi and coworkers [141–143] observed the selective inhibition of oxidation reactions by certain compounds, particularly by phenols. The inhibition of the electrochemical oxidation of benzaldehyde and acetophenone (compounds which are readily oxidised by atmospheric oxygen but are resistant to anodic oxidation), reported by Solomin and Kryuchkova [144], probably belongs to phenomena of this type. The authors [144] begin with the following process mechanism (postulating the intermediate formation of benzoyl hydroperoxide, the decomposition of which results in the appearance in solution of a process inhibitor—phenol):

$$C_6H_5CHO \rightarrow C_6H_5COOOH \rightarrow C_6H_5OH + CO_2.$$

Kazarinov and Dolidze observed an appreciable increase in bonding strength and a decrease of the rate of oxidation of methanol adsorbed on platinum together with hexyl alcohol [145].

Effects with a different sign, namely selective promotion of the oxidation of oxalic acid at low coverages of the platinum anode by dienes in alcoholic solutions [15,146] and the stimulating effect of the adsorbate on coverage by oxygen [24,35], have been observed. Similar phenomena were recently noted in the adsorption of submonolayer amounts of noble metals [147] as well as arsenic, sulphur [148,149], mercury, and acetonitrile [150] on platinum. It was shown that, depending on θ and the nature of the substance being oxidised, the reaction is either accelerated or inhibited.

Since the thermodynamic method developed by Frumkin [151–152] and experimentally validated [22] for degassed platinum metals is inapplicable to the analysis of irreversible adsorption processes on oxidised metals, in certain investigations attempts were made to interpret the nature and characteristics of adsorption at high values of φ on the basis of other concepts.

In the first studies carried out in this field [116–119] it was assumed that the high bonding energy between the adsorbate and the metal, which stabilises the latter with respect to oxidation by the oxygen evolved, is due to the presence in the adsorbate molecule of valence-unsaturated groups, the interaction of π electrons of which with the positively charged surface of the anode leads to the formation of stable chemisorbed compounds (of the type of π complexes). The interpretation of the nature of the adsorption effects at high potentials was developed further in studies by Tyurin and coworkers [66,67]. In particular, the authors postulate that the second form of the surface oxide formed on the platinum electrode above 1.5 V is a coordination compound of the metal and the intermediate products of the oxygen evolution reaction and other components of the electrolyte: ions and neutral molecules. All the species enumerated behave as ligands, which compete with one another in the half-sphere of the complex in which the electron-accepting species is Pt^{4+}. Within the framework of this mechanism, the increase of the degree of adsorption in the range 1.5–2.2 V is caused by the increase of the degree of surface coverage $\theta_{O_{II}}$ and its decrease at higher potentials is associated with the increase of the rate of oxidation of the adsorbate. However, it has been noted [3] that both treatments suffer from a number of disadvantages. The complex-adsorption model was improved further in recent investigations [153].

We shall consider next the characteristics of each of the reaction classes discussed taking into account the above considerations.

IV. ANODIC DIMERISATION REACTIONS

The most important of the anodic dimerisation processes is the Kolbe electrochemical condensation of carboxylic acids and its modification—the condensation of dicarboxylic

acid monoesters (the Brown–Walker reaction):

$$2\,RCOO^- - 2e \rightarrow RR + CO_2 .$$

These reactions are of preparative interest for the synthesis of many valuable bifunctional compounds and in many cases there are favourable prospects for their industrial application. This involves the synthesis of sebacic acid diesters by the electrolysis of monoalkyl adipates [154] and also the synthesis of suberic acid by the condensation of monomethyl glutarate [77,159]. A number of reviews have been devoted to the synthetic and kinetic aspects of Kolbe type reactions [3,4,69,154,156,157]. Here we shall note the principal process conditions and also certain trends in the recent research in this field.

The yield of the dimeric product is determined by a number of experimental and structural factors. The dimer is formed mainly at high potentials ($\varphi > 2.1$ V), using smooth platinum, iridium, and graphite anodes in an aqueous medium. The use of non-aqueous solvents promotes condensation; in organic media (alcohols, acetonitrile, dimethylformamide, etc.) the choice of the anodic material is less limited—anodes made of gold, palladium, lead dioxide, and certain other materials are suitable in addition to platinum metals. An increase of temperature and the addition of extraneous electrolytes lead to a decrease of the yield of the dimer. The influence of structural factors is discussed below. The investigation of the influence of a series of experimental conditions on the kinetics of the electrochemical oxidation of monomethyl glutarate on platinum in methanol has been reported [77,155]. In particular, it has been shown that the nature of the anode material does not have a decisive influence on the electrochemical oxidation process. The observed fractional order of the reaction of the monoester shows, according to the authors, that the rate-determining stage is the discharge of the monoester anions (on a uniformly inhomogeneous surface).

A similar conclusion concerning the nature of the rate-limiting stage was reached also in studies on the electrochemical oxidation of propionate in an aqueous medium [160] and of acetate in anhydrous acetic acid [158]. Very low reaction orders $n \ll 1$ were also observed in the oxidation of alkylboronic acids, the electrochemical oxidation reactions of which have much in common with the Kolbe reaction [161]. The influence of the nature of the monoester on the oxidation kinetics in methanol solutions on platinum has been discussed [155]. The principal kinetic features are identical with those observed earlier for monomethyl adipate and acetate [116,117,119], which permits the fully justified conclusion that there is a profound analogy between the kinetics of electrode processes in the Brown–Walker and Kolbe reactions in aqueous and alcoholic solutions of many monocarboxylic acids and dicarboxylic acid monoesters. With increase of the length of the hydrocarbon chain, the adsorbability of the carboxylate anion increases also, as has been observed in aqueous solutions [119]; as a result, the maximum solvent oxidation current falls and there is a linear relation between the logarithm of current density and the number of methylene groups in the molecule. The necessity for the adsorption of the carboxylates on the anode prior to their discharge also follows from the results of a study of a Kolbe cross-reaction (mixed reaction) [71].

The problem of the use of carbon electrodes in the oxidation of carboxylates in various solvents (water, methanol, ethanol, and dimethylformamide) has been thoroughly investigated [162]. Experiments have been performed on the electrolysis of oenanthic acid solutions and pure oenanthic acid, solutions of phenylacetic and phenoxyacetic acids, and also methyl and ethyl succinates on soft and hard graphite, vitreous carbon, and baked carbon electrodes. The Kolbe reaction proceeds in protic solvents on vitreous and baked carbon, while side reactions mainly occur on soft graphite (alkyl oenanthates are the main products in oenanthic acid solutions). Considerable differences were observed when pyrolytic graphite anodes with the surface parallel and at right angles to the plane of the lattice unit cells were used; in the former case the yield of products was appreciably lower. The above experiments appear to confirm the necessity to take into account the role of the adsorption stages also in anodic reactions on graphite materials.

This view is supported by the results of studies of other oxidation reactions on carbon anodes [163]. The authors postulate that, in accordance with Balandin's multiplet theory, the efficiency of the electrochemical oxidation is determined by the structural and energy correspondence between the substrate molecule and the electrode surface.

Despite the fact that Kolbe type anodic condensation reactions have already been studied for a long time and particularly vigorously in the last five–eight years, many problems involving their mechanism have still not been unambiguously solved and have been the subject of a lively discussion in papers by Conway, Eberson, Fioshin, and many other workers [1–3,69,154,156]. Since the kinetic aspects of the reaction based on an analysis of the literature up to 1967 have been summarised in an extensive review [69], we shall not consider here these problems in detail. We shall only note that analysis of numerous experimental data obtained in recent years using a number of electrochemical, radiochemical, and optical methods for the indentification of products of potentiostatic electrolysis and also the interpretation of these results in original studies lead (with rare exceptions [165,166]) to the following mechanisms of the processes corresponding to different sections of the polarisation curve (Fig. 3) in carboxylate solutions on platinum: section I—evolution of oxygen on a surface partly coated by the first form of the oxide and by adsorbed carboxylate ions; section II—ditto on a surface coated by a monolayer of the first form of the oxide and onset of the formation of the second form. Along section III, the discharge of anions begins, with formation of acyloxy- and alkyl-radicals adsorbed on platinum and displacing oxygen (mainly the second form). The high adsorption energy prevents their surface mobility and recombination. The transition region IV corresponds to the reorganisation of the surface oxide with the coadsorbed radicals, resembling the surface "two-dimensional crystallisation", which has been observed in solutions of inorganic acids [168]. Section V corresponds to the discharge of carboxylate ions on this modified surface with formation of condensation products via an electrochemical desorption mechanism.

Other views on the mechanisms of anodic processes in the oxidation of carboxylic acids have been developed in a study by Fioshin and Vasil'ev [82], where it was assumed that the discharge of carboxylate anions begins only at potentials corresponding to section V, i.e. when $\varphi \geqslant \varphi_{cr}$¶, while the inhibition of the oxidation in the transition region is caused by the specific features of the adsorption of these anions. This view, which has been supported by other workers [77,155], has been criticised in a review by Vijh and Conway [69].

¶ φ_{cr} is the initial potential on section V.

The results published in a number of communications[78,167,169,170] can serve as an additional argument in support of the above scheme, postulating the discharge of $RCOO^-$ under the conditions corresponding to the lower sections of the $i-\varphi$ curves. At potentials corresponding to section III the formation of alcohols and of a small amount of dimers was observed in the oxidation of pelargonic acid at a platinum anode in an alkaline medium[78,167], while in the electrolysis of ω-chloroacids in the presence of 1,3-dienes the formation of additive dimers was also noted[170]. The study of the electrochemical oxidation of propionate in an aqueous medium by the pulse and voltage-current methods also indicates the adsorption of the carboxylate up to φ_{cr}.[172] According to the authors, the rate-limiting stage is in the oxidation of $C_2H_5COO^-$; the adsorbed propionyloxy-radical formed decomposes into CO_2 and $C_2H_5^{\cdot}$, the latter reacting with $C_2H_5COO^{\cdot}$ to form ethylene and propionic acid. According to Takeda et al.[160] the charge transfer in the rate-limiting stage in glacial acetic acid on platinum, palladium, gold, lead dioxide, and graphite electrodes takes place via a layer of adsorbed $CH_3^{\cdot}$ or $CH_3COO^{\cdot}$ radicals.

Among the unsolved problems concerning the mechanism of the Kolbe reaction, that of the so called "anomalous" carboxylates occupies an important place. They include aromatic, substituted, and unsaturated carboxylic acids with multiple bonds and substituents X (X = halogen, OH, NH_2, Ph, or RCH=CH) in the α- and β-positions with respect to the carboxy-group. These compounds either do not undergo the dimerisation reaction at all or a dimer is formed in an insignificant yield,which appreciably limits the preparative scope of the Kolbe electrochemical synthesis. For example, in the anodic oxidation of acids of the adamantane series in an alcoholic medium[171] the main electrolysis product is the corresponding alkoxy-derivatives and not the dimers.

On the other hand, when the carboxy-group is linked to the bridgehead carbon atom via a methylene group, then electrochemical oxidation leads to ring expansion. The latter reaction can serve as a new method for the preparation of cyclic compounds with large rings.

The formation of a methoxy-derivative together with the dimer was observed by Coleman and Eberson[173] in the anodic oxidation of caesium 9-methylanthracene-10-acetate in a mixture of methanol and tetrahydrofuran. In a reaction involving the anodic decarboxylation of sodium epoxy-β-phenyl propionate at a platinum anode Japanese investigators[160] failed to detect the corresponding dimer; the main reaction products were benzaldehyde, acetophenone, benzyl acetate, and methyl benzoate. The desired product of the Kolbe electrochemical synthesis was not found (or was obtained in a negligible yield) also in the electrolysis of 2,2-dichloro-3-phenylcyclopropanecarboxylic acid on platinum in hydroxylated solvents[174], in the oxidation of cyclohexene-3-carboxylic acid and norborn-5-ene-2-carboxylic acid in acetonitrile[175], of 2-methoxy-1-cyclopentene-1-carboxylic acids in methanol[169], and of α-chloro- and α-fluoro-acids (valeric, caproic, and isobutyric)[176].

It has been shown[177,178] that, under the usual conditions of the Kolbe reaction, the electrolysis of aqueous solutions of perfluoro-acids also does not yield the dimeric product. In the electrochemical oxidation of trifluoroacetate at an oxidised platinum anode in the presence of added water, Na_2HPO_4, and H_2SO_4 in the electrolyte Knunyants and coworkers[179] obtained CF_3OOCF_3 and CF_3OCF_3 instead of hexafluoroethane. The results of Korchinskii and Andreev[180] confirm the fact that dicarboxylic acids also do not give rise to the corresponding dimers. In the oxidation of maleic and fumaric acids in the potential range corresponding to the upper section of the polarisation curve they observed the formation of acetylene. In a study[185] of the products of the preparative electrolysis of tri-t-butylcyclobutenedicarboxylic acid it was shown that, depending on the composition of the solution, various substances are obtained (2,3,5-tri-t-butylfuran, etc.), but the Kolbe dimer was not identified.

According to the majority of the investigators of these reactions (Eberson, Woolford, Fleischmann, etc.[1-3]), the anomalous behaviour of substituted carboxylates is associated with a lower ionisation potential of the radicals formed and their subsequent oxidation to the corresponding carbonium ions which then react with the nucleophilic components of the solution Z^- [reaction (1b)]:

$$RCOO^- \xrightarrow{-e,-CO_2} R^{\cdot} \begin{cases} \longrightarrow RR & (1a) \\ \xrightarrow{-e} R^+ \xrightarrow{Z^-} RZ\,. & (1b) \end{cases}$$

This view is shared also by the authors of the communication[171] concerning the adamantane acids. The results of the preparative electrolysis of phenylacetic acids[181] and also the study of the "pseudo-Kolbe reaction" mentioned above[173] lead to the same conclusion; in the latter case the authors concluded on the basis of voltage–current measurements that the electron is removed from the aromatic ring and not from the carboxy-group.

The occurrence of the substitution reaction with formation of the products RZ is favoured by the following conditions: low current densities, the use of graphite materials for the anode and of water as the solvent, pH > 10, and the addition of extraneous anions (HCO_3^-, HSO_4^-, $H_3PO_4^-$, Hal^-) and cations (Fe^{2+}, Mn^{2+}, Pb^{2+}, etc.). RZ can be formed either via a carbonium ion [reaction (1b)] or via the homolytic addition of R$^{\cdot}$ and Z$^{\cdot}$. It is usually difficult to differentiate the two reaction pathways. The so called "method of detecting radicals by an acceptor" is extremely effective in many cases for this purpose; its characteristics and examples of its practical application have been described[3,62].

Berenblit, Sokolov, and coworkers, who made a thorough study of the main products and by-products of the direct anodic condensation and cross-condensation of β-perfluoromethoxypropionic acid and certain monoesters of perfluorodicarboxylic acids in non-aqueous media, also concluded that the nature of the by-products cannot be accounted for solely by the homolytic interaction of the intermediate perfluoroalkyl radicals and requires the assumption of their simultaneous oxidation to the corresponding perfluorocarbonium ions[182,183].

On the basis of the mechanism described above for anodic processes in the oxidation of carboxylates, the ratio of the rates of reactions (1a) and (1b) will presumably depend, other conditions being equal, on the strength of the bond between the surface and the adsorbed RCOO$^{\cdot}$ (R$^{\cdot}$) radicals. In view of these considerations, a study was undertaken[17,18,184] of the electrochemical oxidation of carboxylates which are known not to from dimers (monoesters of $\alpha\beta$-unsaturated aliphatic dicarboxylic, aromatic, and alicyclic acids) in the presence of small amounts of vigorously adsorbed additives (for example unsaturated hydrocarbons, conjugated dienes, etc.). Indeed, under these conditions the heterogeneous-catalytic influence of such compounds on the dimerisation process was observed and the Kolbe reaction was achieved with an acceptable yield. In particular, in the oxidation of monomethyl maleate the product is the dimethyl ester of muconic

acid—the starting material for the synthesis of high-quality polymeric materials; the chemical methods developed for the synthesis of muconic acid are still insufficiently effective. Dimeric products were obtained also for other classes of anomalous carboxylates. There is a close relation between the adsorbability of the catalytic additive and its influence on the mode of the process—there is a direct correlation between the adsorption criteria and the yield of the dimer.

A similar effect is apparently encountered also in the case of perfluorocarboxylic acids, which are oxidised with formation of Kolbe products only in non-aqueous media, particularly those containing acetonitrile. The modification of the surface layer occurring in the adsorption of acetonitrile molecules in carboxylate solutions [186] probably leads to a weakening of the metal–adsorbate bond and to a change in the relative rates of reactions (1a) and (1b) in favour of the former, which increases. These considerations are supported by results [177,182,187], which confirm the influence of the solvent on the effectiveness of the dimerisation, including "cross dimerisation". In the latter case 1,1,1-trideuterotrifluoroethane and 1,1,1-trideuteropentafluoropropane were synthesised [187] in the electrolysis of mixtures of deuterated acetate with trifluoroacetic and pentafluoropropionic acids respectively by regulating the composition of the solution.

Anodic dimerisation reactions of the non-condensation type occur in the electrochemical oxidation of certain aromatic hydrocarbons, amines, phenols, and olefins. According to the ideas developed previously [188], the reactions can proceed via two mechanisms: ECC_N [reaction (2a)] and ECC_B [reaction (2b)], where the subscripts N and B denote respectively nucleophilic and electrophilic reaction stages:

$$2\,RH \xrightarrow{-2e} 2\,RH^{+} \rightarrow {}^{+}HRRH^{+} \begin{cases} \xrightarrow[X_N]{2Z^-} ZHRRHZ & (2a) \\ \xrightarrow{-2H^+} RR\,. & (2b) \end{cases}$$

(E) (C) (C_B)

Either dehydropolymers [reaction (2b)] or (in the presence of a suitable nucleophilic agent Z^-) disubstituted dimers [reaction (2a)] are formed under these conditions. The first pathway reduces in fact to an addition reaction, permits a different interpretation of the mechanism (via a homolytic addition stage), and will be discussed in the next Section. Some examples of reactions of this kind were described previously [189–191], but only the studies in recent years have shown that dimerisation of this type can serve as an effective method for preparative synthesis. In many instances nearly quantitative yields of the desired products were obtained.

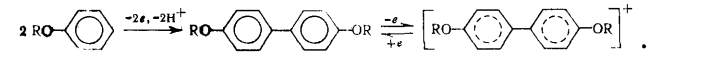
The electrolysis of benzene leads to a mixture of oligomers [192,193] with a yield reaching $A = 90\%$ in a solution containing $AlCl_3$ and HCl; [193] the electrochemical oxidation of 1,2,4-trimethoxybenzene and tetraphenylethylene resulted in the formation of 2,4,5,2′,4′,5′-hexamethoxybiphenyl ($A = 85\%$) [191] and 8,10-diphenylphenanthrene ($A = 100\%$) [194] respectively. The anodic dimerisation of many substituted anilines and phenols and also the mixed dimerisation of certain compounds have been achieved similarly.

The most important examples of these reactions have been compiled [1]. In recent years a series of studies on these lines was undertaken by Nyberg [195–197], who put forward an interesting concept to account for the mechanisms of the direct and mixed dimerisation of aromatic hydrocarbons. According to this concept, the higher the spin density or the positive charge density in the radical-cation formed, the greater the ease of its formation. It is thus possible to explain the preferential formation of biphenyls compared with diphenylmethanes and also the dependence of the yield of products on the concentration of the initial hydrocarbons in the anodic oxidation of polymethylbenzenes in non-nucleophilic media (CH_3NO_2 and CH_2Cl_2). [196] If the spin density (and the positive charge density) is higher in the ring of the radical-cation, biphenyls are mainly formed. On the other hand, if the spin density is higher in the substituent, then the benzylmethyl radical-cation with the charge located in the methyl group is formed preferentially; this radical-cation loses a proton and is converted into a benzyl radical, which is rapidly oxidised to a benzyl cation. The latter reacts with the initial hydrocarbon, giving rise to a diphenylmethane derivative:

$$ArCH_3 \xrightarrow{-e} ArCH_3^{+} \xrightarrow{-H^+} ArCH_2^{\cdot} \xrightarrow{-e} ArCH_2^{+} \xrightarrow{ArCH_3,\,-H^+} ArCH_2ArCH_3\,.$$

This view makes it possible to explain, for example, the formation of 1-mesitylnaphthalene in the absence of bimesityl in the mixed anodic dimerisation of naphthalene and mesitylene on platinum [196]. According to the above considerations, the more readily formed naphthyl radical-cation either dimerises in accordance with Eqn. (2b) to binaphthyl or interacts with mesitylene to form a mixed dimer; the absence of bimesityl confirms the fact that the corresponding mesityl radical-cation is not formed under these conditions.

The anodic dimerisation of a number of aryl esters derived from anisole, *o*-bromoanisole, and *o*-methylanisole has been achieved in high yields [198,199] by using trifluoroacetic acid or its mixtures with methylene chloride as solvents. Under these conditions, the dimeric radical-cation is stabilised and can be detected by the voltage–current procedure. According to the authors [198], the reaction proceeds as follows:



The dimerisation takes place only in the *p*-position and if the latter is blocked the radical-cation cannot be detected.

An interesting example of an effective combination of anodic and cathodic dimerisation in the same electrolyser has been described [200]. By electrolysing a solution of diethyl malonate and methyl acrylate in acetonitrile in the presence of potassium iodide under conditions favouring anodic dimerisation (high dilution, low current densities), the authors obtained high yields of the ester $(C_2H_5OOC)_2$–CH–$HC(COOC_2H_5)_2$ on the anode and dimethyl adipate on the cathode. The use of $LiClO_4$ instead of KI almost completely suppresses the formation of tetraethoxycarbonylethane but does not effect the yield of dimethyl adipate. The dimerisation of acetoacetic ester also does not occur in the presence of ClO_4^-—the product is 2-ethoxycarbonyl-4-methoxycarbonyl-1-methylfuran.

In other cases the anodic dimerisation of anionic dicarbonyl compounds such as sodium dialkylmalonate and sodium acetylacetonate was achieved successfully with satisfactory yields [201–203]. A large number of examples of the anodic dimerisation of the anions of polar organic compounds have been described:

$$2\,R^{-\delta}\!-\!X^{+\delta} \xrightarrow{-2e;\,-nX^+} 2R^{\cdot} \rightarrow RR,$$

in particular phenols, oximes, aliphatic nitrocompounds, organometallic compounds, alkynes (see Eberson and

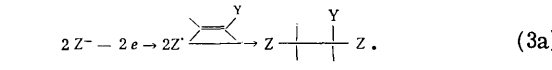
Schäfer[1], Table 12), and also enolic ethers[204]. In certain cases a mixed dimerisation can be achieved with a high degree of efficiency[205].

V. ANODIC ADDITION REACTIONS

This class of reactions, which has been vigorously investigated in the last decade, probably involves the greatest concentration of the advantages of electrochemical methods formulated above. Processes of this type are in many cases distinguished by a high efficiency, selectivity, and ease of the synthesis of relatively high-molecular-weight compounds from simple monomers.

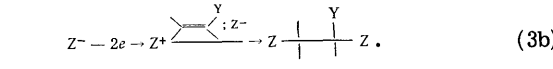
According to modern ideas, it is possible to achieve three versions of the anodic addition of a nucleophilic agent to the double bonds of the acceptor.

(a) Via a radical generated on the anode:



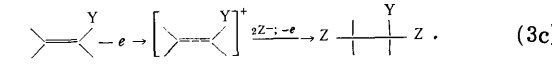
(3a)

(b) Via the electrophilic agent formed initially:



(3b)

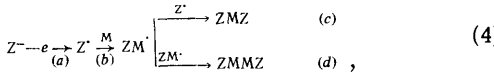
(c) Via the radical-cation formation stage:



(3c)

These reaction pathways can be by no means always distinguished; the criteria proposed are as a rule insufficiently reliable[1-3].

The radical pathway is assumed by the majority of investigators for the electrochemical additive dimerisation of olefins initiated by the electrochemical oxidation of carboxylic acids, alcohols, water, and nitric acid[206-238]:



(4)

where M is the olefin molecule and Z = RCOO, $H_2C_2O_4$,[15, 206,211-216,223,224,227] RO,[217-221] halogen[226], (CH_3CO_n).$CH_{n=1,2}$,[10,230-232] $O_2NC_nH_{2n-2}$,[234,235] N_3,[237] etc.[197,236] Among unsaturated compounds, mainly conjugated dienes[15,52,206-227], styrene[229,234-236], and ethyl vinyl ether[230,234,235] as well as other activated olefins, are involved in this reaction. The dimerisation reactions of Z as well as the homolytic abstraction of hydrogen from the electrolyte components ($Z^{\cdot} + RH \rightarrow HZ + R^{\cdot}$) take place simultaneously with reaction (4). When $Z^- = AlkCOO^-$, stage (4a) is followed by the spontaneous decarboxylation stage, but, when $Z^- = ArCOO^-$, this does not occur, because of the much greater stability of the aroyloxy-radicals compared with acyloxy-radicals. Certain substituted boronic acids behave similarly to aliphatic carboxylates[232].

The interpretation of the mechanism of the anodic additive dimerisation in accordance with Scheme (4) has not been altogether generally accepted. For variants of the reaction in which $Z^- = AlkO^-$, $ArCOO^-$, and certain other species, heterolytic pathways are assumed in a number of investigations, postulating a preliminary oxidation of the substrate on the anode followed by the interaction of the resulting carbonium ions by Z^-. A number of reports are devoted to the mechanism of reactions of this type[1-3].

The accumulated experimental data for this field were recently analysed and the possible reaction pathways were discussed in relation to the additive dimerisation initiated by the oxidation of carboxylates[3] and alcohols[7]. The study of the influence of various factors on the mode and efficiency of additive dimerisation has shown that, regardless of the nature of Z^- ($HC_2O_4^-$, $C_nH_{2n-2}COO^-$, $AlkOOCArCOO^-$, ω-ClC_nH_{2n-2}.COO^-, and $AlkO^-$[62,206-215]), the fundamental kinetic characteristics are similar. This apparently indicates a common mechanism for such processes. The homolytic mechanism of the addition reaction is unambiguously indicated by the nature of the products obtained in certain variants of the additive dimerisation, for example that initiated by alkyl radicals formed in the electrochemical oxidation of carboxylates[206-209,223,224]. In some investigations experiments on potentiostatic electrolysis showed that the additive dimers are formed at potentials lower than those required for the oxidation of substrate molecules[170].

Analysis of the results of studies of the additive dimerisation reactions has shown that the necessary condition for their occurrence is the adsorption of acceptor molecules on the electrodes.

High yields of adducts were obtained using as acceptors compounds for which an appreciable adsorption activity has either been found or postulated (on the grounds of structural considerations) at the high positive potentials required for the formation of $RCOO^{\cdot}_{ads}$. This is also indicated by the following considerations. Whereas the formation of $R^{\cdot}$ in the bulk of the solution[165,166] is in principle possible for unsubstituted straight-chain carboxylates (this is particularly likely for phenylacetic acids[19]), such a reaction is probably ruled out in the oxidation of "anomalous" carboxylic acids, which are not dimerised. The products formed indicate the oxidation of $R^{\cdot}$ to the corresponding carbonium ion. Such radicals can therefore be formed only in the adsorbed state and the formation of additive dimers in these instances constitutes convincing evidence for the involvement of the substrate also in the adsorbed form. In the studies quoted previously[17,18,184,225] the above phenomenon was confirmed for non-dimerising carboxylates of various classes in the presence of an adsorbable acceptor (adsorption has been demonstrated by independent methods[35,55,56,116,134]). As a result of the reaction, appreciable amounts of polymeric products were obtained only under special conditions (at extremely low current densities); chain termination at stages where $m \leq 2$ (m is degree of polymerisation) also indicates a heterogeneous process. The transfer of $R^{\cdot}$ to the bulk of the solution (which usually contains high acceptor concentrations) would inevitably lead to the appearance of at least oligomers in consequence of the "cage effect".

It follows from the foregoing considerations that similar reactions involving suitable acceptors, for example 1,3-dienes, can serve as an effective method for the detection of the intermediates formed during electrolysis.

Elementary kinetic analysis of the reaction mechanisms involving adsorbed acceptor molecules on the electrode demonstrates a satisfactory agreement between the variations of the yields of individual adducts with a number of process parameters[238]. It follows from Eqns.(4a), (4b), (4c), and (4d) that the relative rates of formation of the reaction products must be extremely sensitive to changes in the effective concentrations of $R^{\cdot}$, which is determined, other conditions being equal, by the anodic current density, and to the degree of surface coverage by the olefin. Indeed, it has been frequently shown that, by altering the anodic current density, the nature of the electrode

material, and the acceptor concentration, it is possible to vary within wide limits the ratios of the products formed and to carry out the process under conditions favouring the synthesis of each separately [208-221]. This factor converts the reaction into a unique method of synthesising many valuable polyfunctional compounds.

The mechanism of addition via an anodically generated electrophilic agent is apparently assumed only for oxidative halogenation at double bonds and also for the electrochemical analogue of the Ritter reaction, achieved by Foita et al. for cyclohexene [239] and then by Weinberg and Hoffmann [240] for other compounds on chlorination in acetonitrile. In the former case chlorination of cyclohexene yielded 2-acetamido-1-chlorocyclohexane, while in the latter electrochemical halogenation of 1-phenylbut-2-ene and cyclopentene also led to 2-acetamido-1-halogeno-adducts. The introduction of acetamido-groups likewise takes place in the electrochemical oxidation of α-substituted and aromatic carboxylic acids [241,242], adamantane, 1-halogenoadamantanes and esters [243,244] in nitriles. According to the ideas of Eberson and Nyberg [241], the electrochemical introduction of acetamido-groups into carboxylates proceeds via the intermediate formation, as a result of two-electron oxidation of a carbonium ion, which reacts further with acetonitrile in the following way:

$$R_3CCOO^- \xrightarrow{-2e,-CO_2} R_3C^+ \xrightarrow{CH_3CN} R_3CN{=}\overset{+}{C}CH_3 \xrightarrow{H_2O,-H^+} R_3CNHCOCH_3 \quad (5a)$$

Similar views on the reaction mechanism have been expressed by other workers [243,244]. However, Japanese investigators, who studied the oxidation of benzoic acid in acetonitrile and propionitrile [242], suggest that the addition products (*N*-acetylanthranilic and *N*-propionylanthranilic acids) are formed via the oxidation of the benzoate ion to the benzoyloxy-radical, which is deprotonated and reacts further with the nitrile.

A number of studies on the anodic chlorination of ethylene [245], vinyl chloride, and butadiene [246] in an aqueous medium and in aliphatic alcohols have been published in recent years. In the case of ethylene dichloroethane was obtained under optimal conditions in an aqueous medium in yields up to 80%, while in the oxidation of olefins in a hydrochloric acid solution in methanol mixed chloro-methoxy-adducts were formed together with chloro-derivatives. Comparison of the electrochemical and chemical chlorination of ethylene (the influence of the nature of the anode, of admixtures in HCl, and other factors) demonstrated definite differences between the mechanisms of the two processes and led the authors [245] to the conclusion that adsorption processes play a significant role in the electrochemical reaction.

The third variant of the anodic addition reaction presupposes a two-electron transition in stages, initiated by the oxidation of the substrate molecule itself (an olefin or an aromatic compound). The addition products are formed in accordance with an EC_BEC_B mechanism:

$$\underset{(E)}{M} \xrightarrow{-e} \underset{(C_B)}{M^+} \xrightarrow{Z^-} \underset{(E)}{ZM^\cdot} \xrightarrow{-e} \underset{(C_B)}{ZM^+} \xrightarrow{Z^-} ZMZ \quad . \quad (5b)$$

This pathway has been postulated by some investigators for the alkoxylation and acetoxylation of furan derivatives, quinones, and substituted pyridines [7]. The anodic depolarisation effect, observed in many instances when the substrate is introduced into the electrolyte, has been frequently used as a criterion of the occurrence of the process via this mechanism. Critical comments have often been made concerning this approach [2,3,62].

VI. SUBSTITUTION REACTIONS

The study of anodic substitution reactions has also attracted much attention in recent years, since processes of this type give rise to a wide variety of synthetic possibilities. Studies in this field have been reviewed [1,247,248]. Here we shall deal only with certain general considerations concerning reactions of this kind.

Processes in which a group X (usually a hydrogen atom) in the substrate molecule RX is replaced on electrochemical oxidation by a substituent Z (Z = OR, OCOR, halogen, CN, etc.) belong to this class. The reactions can be divided into three groups in accordance with their mechanism [1].

(a) Homolytic substitution of hydrogen by a radical generated on the electrode:

$$Z^- \xrightarrow{-e} Z^\cdot \xrightarrow{RX,-XZ} R^\cdot \xrightarrow{Z^\cdot} RZ \quad . \quad (6a)$$

(b) Substitution of the condensation type in the electrolysis of carboxylates:

$$RCOO^- + Z^- \xrightarrow{-2e,-CO_2} RZ \quad . \quad (6b)$$

(c) Nucleophilic substitution via a radical-cation:

$$RX \xrightarrow{-e} RX^+ \xrightarrow{Z^-} RXZ^\cdot \xrightarrow{-e,-X} RZ \quad . \quad (6c)$$

As for anodic addition reactions, it is frequently difficult to distinguish the substitution processes involving different mechanisms.

The most striking examples of the first type are apparently those involving electrochemical halogenation. Among these, anodic fluorination is of the greatest practical importance. It constitutes a convenient method for the synthesis of perfluoro-compounds and has a number of advantages over the analogous chemical reactions, obviating the necessity for working with elemental fluorine [5,6,249-252].

The radical mechanism of the electrochemical fluorination proposed by Simons [250] is not, however, generally accepted at present. This reaction exhibits a high electrocatalytic specificity and proceeds in liquid hydrogen fluoride, mainly on nickel anodes. In an early study by Gramstad and Haszeldine [251] it was suggested that the active principle in this reaction is higher nickel fluorides. Subsequently a similar view was developed in another investigation [252]; the authors believe that many kinetic features of the reaction (for example the induction period) agree well with the hypothesis of the intermediate formation of complexes by the organic substance and nickel fluorides, such as $(RH_2)_2NiF_6$ and $(RH)_3NiF_6$.

The influence of the preliminary treatment of the electrodes on the electrochemical fluorination process has been established [253]. In particular, the induction period is shortened for nickel anodes coated chemically by NiF_2. The authors base their treatment on the mechanism of the anodic fluorination of organic compounds involving the initial formation of their complexes with nickel fluoride followed by electrochemical oxidation at the C–H bond with formation of radicals, which recombine with F$^\cdot$. In a study of the fluorination of aliphatic amines by Japanese workers [256], a mechanism was proposed for the electrode processes involving the discharge of F^-, the homolytic substitution of H by F, and oxidative cleavage of the C–C and C–N bonds followed by polymerisation.

On the basis of the results of the anodic fluorination of fluorobenzenes on platinum in acetonitrile [255], Knunyants and coworkers concluded that in this case the first stage of the process is one-electron oxidation of the substrate followed by the interaction of the radical-cation with a fluoride anion; the second stage is accompanied by the simultaneous transfer of a second electron with abstraction of a proton.

Thus the mechanism of the anodic fluorination is still controversial. Various hydrocarbons, including halogenohydrocarbons, carboxylic acids, ethers, amines, nitriles, and other classes of organic compounds have been used as the substrates in this reaction. Apart from the investigations the results of which are discussed in earlier reviews [1,5,6,247], mention should also be made of a number of recently published communications dealing with the fluorination of carbon monoxide, phosgene, substituted benzene and pyridine [259,260], methane, propane, ethylene [254], fluorobenzene and trifluoromethylbenzene [255], amines [256,257], tetrahydrofuran [261], ethylene chlorohydrin [262], dithiols and cyclic sulphides [263], *NN*-dialkylanilines and *NN*-dimethyltoluidines [264], ethylene glycol ethers [265], chloroethers [266], and other compounds [258].

In all cases a complex mixture of fluoro- and perfluoroderivatives, including degradation products and polymers (their amount is particularly large in the fluorination of alcohols and amines), is usually formed. The highest selectivity has apparently been achieved in a study [265] of the fluorination of triphenylmethane; under the conditions discovered in that investigation, fluorotriphenylmethane is formed in 80% yield.

Under the conditions of electrochemical fluorination, carboxylic acids do not undergo anodic condensation, but give rise to a mixture of substitution products with different fluorine contents in the molecule of the initial acid; the yields of the fluoro-derivatives increase with the molecular weight of the homologues. It has been shown [267,268] that the presence of alkoxy-groups in the carboxylic acid greatly facilitates the fluorination reaction compared with the unsubstituted analogues. The yields of perfluoromethoxyacyl fluorides are significantly higher than in the fluorination of the corresponding acids (14–41%); with increase of the chain length of the alkoxy-group, its stability in the electrochemical fluorination processes falls appreciably. The organic solvents usually employed in anodic reactions are not inert under the fluorination conditions, in particular acetonitrile gives rise to monofluoroacetonitrile and to succinodinitrile.

The homolytic mechanism has been adopted in most investigations for other halogenation reactions. However, these problems have been studied in much less detail than fluorination because they can be achieved without significant difficulties by the usual chemical methods. Several communications dealing with the behaviour of various electrodes (platinum, iridium, and ruthenium) in chloride solutions and also with the electrochemical chlorination of simple aliphatic hydrocarbons on graphite, platinum, and iridium anodes were published recently [269-271]. It has been shown [269] by the potentiodynamic method that the adsorption of Cl^- on platinum begins at hydrogen desorption potentials; it is postulated that Cl˙ atoms are adsorbed on a $Cl\bar{a}ds$ layer. Cl^- ions are not adsorbed on iridium anodes at Cl_2 and O_2 evolution potentials. Experiments on the electrochemical chlorination of methane, ethane, and ethyiene in the dark and under illumination led Kuhn and coworkers [270] to the conclusion that the substituion process has no specific heterogeneous features and is the result of a photochemically or thermally initiated reaction of the organic substance with molecular chlorine. This mechanism makes it possible to explain the observed higher rate of reaction compared with the value calculated on the basis of diffusion kinetics. According to the authors, the depolarising influence of the test gases is caused by the decrease of the concentration of Cl_2 evolved at the anode.

On the other hand, the results of the anodic chlorination of ethane on a graphite electrode, where a mixture of dichloroethane (75%) and ethyl chloride (20%) is formed, differ significantly from those obtained in chemical chlorination with molecular chlorine, which apparently indicates a heterogeneous mechanism of the reaction under these conditions [272]. Mastrogostino et al. [273], who carried out the electrochemical chlorination of aromatic hydrocarbons (benzene, toluene, and xylene) in anhydrous acetic acid at chlorine oxidation potentials, concluded that in this case the chlorinating agent is Cl_2^- and not Cl˙.

The radical substitution pathway has been adopted for the alkoxylation and acetoxylation of organosilicon compounds [274,275] and substituted amides [276]. However, Eberson and Nyberg [277] assume for this reaction the pathway corresponding to the third case, which is discussed in detail below. Substitution reactions accompanying the electrolysis of carboxylates have already been mentioned in the appropriate Section. Conditions favouring this reaction and hindering dimerisation are low current densities, high temperatures, water as the solvent, the addition of extraneous inorganic anions and cations, pH > 10, and graphite and non-platinum metal anodes. The preferential formation of substituted products is observed in the electrochemical oxidation of "anomalous" carboxylates (Section IV). Alcohols are formed in an alkaline medium (the Hofer–Moest reaction; $Z = OH^-$).

It is extremely difficult to decide unambiguously whether there is substitution via a carbonium ion R^+ or whether mixed radical recombination of R˙ with Z˙ takes place. In many instances the products RZ formed in electrolysis (ethers, esters, and alcohols) have a structure typical for heterolytic substitution involving a carbonium ion [278]. Sometimes the nature of the substances formed in the electrolysis can be more readily accounted for by postulating the formation of an intermediate alkoxonium ion $RCOO^+$, which then either combines with Z^- or undergoes solvolysis [279-281].

The substitution reactions occurring in the electrolysis of carboxylates have been used successfully to synthesise alcohols, acetamides, nitro- and alkoxy-derivatives, and many other classes of organic compounds [1,248]. The necessity for the preliminary substrate oxidation stage has been assumed by the majority of the investigators of the substitution reactions of aromatic compounds. This conclusion is frequently justified by the depolarising influence of the substrate on the anode under galvanostatic conditions, although, as stated previously [2,3], such arguments are not always sufficiently convincing. This also applies to the interpretation of certain results of potentiostatic electrolysis. For example, the acetoxylation of aromatic substances at $\varphi < \varphi_{cr}$, which has been regarded [282-284] as an important confirmation of mechanism (6c), can be readily interpreted also as a result of homolytic interaction with a substrate molecule of the radical AcO adsorbed on the electrode below φ_{cr}.

A detailed comparison of the composition of the anodic substitution products of many aromatic compounds with the results of the analogous chemical reactions has shown, however, that in many instances pathway (6c) is preferable to the homolytic mechanism. In particular an $EC_N\bar{E}C_B$ mechanism has been adopted for the introduction of

acyloxy-, cyano-, and bromo-groups into the benzene ring or at the α-carbon atom in alkylamines:

$$\underset{(E)}{HArR} \xrightarrow{-e} \underset{(C_N)}{\overset{+}{H}ArR} \xrightarrow{Z^-} \underset{(E)}{ZHArR} \xrightarrow{-e} \underset{(C_B)}{ZH\overset{+}{A}rR} \xrightarrow{-H^+} ZArR \,. \qquad (7a)$$

The substitution in the side chain is best explained by an EC_BEC_N mechanism [285-288]:

$$\underset{(E)}{ArCH_2R} \xrightarrow{-e} \underset{(C_B)}{Ar\overset{+}{C}H_2R} \xrightarrow{-H^+} \underset{(E)}{ArCHR} \xrightarrow{-e} \underset{(C_N)}{Ar\overset{+}{C}HR} \xrightarrow{Z^-} ArCHZR \,. \qquad (7b)$$

The anodic substitution reactions constitute in many cases convenient and effective methods for the synthesis of a wide variety of compounds and are frequently a useful alternative to purely chemical methods. In addition to earlier studies in this field, discussed previously [1-3,248], mention should also be made of certain investigations in recent years. In particular, Japanese workers [289] achieved the electrolytic benzoyloxylation of a number of *NN*-dimethylamides in the oxidation of benzoic acid in organic solvents and demonstrated a significant influence of the nature of the solvent and of the supporting electrolyte on the yield of products. The maximum yields were achieved in acetonitrile in the presence of $(Et_4N)ClO_4$. An appreciable role of solution composition has also been noted for reactions involving the introduction of hydroxy- and acetamido-groups [290] and also in the methoxylation of alkylbenzenes [291] and in the acetoxylation of propene [301]. In a study [292] of the anodic introduction of bromo- and cyano-groups into *p*-dimethoxybenzene and 9-phenylanthracene in acetonitrile by the volt-amperometric method and the method based on a rotating electrode with a ring it was possible, according to the authors, to refine the mechanism of the anodic substitution of aromatic compounds. It was concluded that the interaction with the nucleophilic agent proceeds at the stage involving the formation of an aromatic radical-cation and not after the formation of a carbonium ion. In another report the results of the introduction of cyano-groups into substituted diphenylamines are considered [293]. The reaction with *o*- and *m*-derivatives takes place only at the *p*-position and the yield is high (44–61%). It is suggested that the oxidation is accompanied by the formation of a radical-cation, which then interacts with CN^-. Comparison of the results obtained for the introduction of cyano- and acetoxy-groups into a number of aromatic hydrocarbons and their derivatives (biphenyl, toluene, chlorobenzene, anisole, naphthalene, and mesitylene) has shown that substitution by CN groups takes place almost exclusively in the *p*-position, in contrast to the acetyl group, which the authors explained by the more marked nucleophilic properties of the cyano-group [302]. Eberson and coworkers support a heterolytic mechanism for this reaction [302,303].

The formation of products of anodic substitution (Z^- = CH_3O^- or AcO^-) in the allyl position was established in a study of the oxidation of olefins in acetic acid, methanol, acetonitrile, and in an acetonitrile–water mixture at a carbon electrode [294]. To account for the results, the authors base their treatment on an ECEC mechanism. Nyberg and coworkers [295] succeeded in achieving the acetoxylation of a number of methylbenzenes in the side chain with a high yield and selectivity. The results were interpreted from the standpoint of the above concept of positive charge and spin densities. In another study [296] aromatic hydrocarbons (mesitylene, naphthalene, and butylbenzene) were oxidised anodically in the presence of NO_3^-. It was established that in this case three types of substitution processes take place: hydroxylation, nitration, and nitrohydroxylation, the ratios of the products of these reactions depending on the concentration of the substrate, the potential, and the nature of the anode. Other variants of the anodic substitution reactions were also investigated: the introduction of the pyridyl group into substituted anthracenes [297] and hydroxylation of phenols [298-300]. It has been shown [274,275] that the electrochemical pathway is also extremely effective for the synthesis of methoxy- and acetoxy-derivatives of a number of organosilicon compounds.

In most of the earlier studies in this field the results were treated from the standpoint of homogeneous chemistry. However, many data obtained recently conflict with this approach.

Thus in a study of the electrolytic acetoxylation of indane by Eberson and coworkers [73,74] it was not possible to detect indene —the elimination product from the 1-indanyl cation, the formation of which was to be expected when an ECEC mechanism was postulated for reactions of this type. The nature of the products indicates further oxidation of indene, which is formed in the adsorbed state according to the authors. In another study [76], dealing with the anodic acetoxylation of 2-t-butylindan on platinum and PbO oxides, the authors obtained an anomalous ratio of the *cis*- and *trans*-isomers, compared with homogeneous reactions, and suggested that the adsorption partly controls the stereochemistry of this reaction. From the authors point of view, the influence of the addition of extraneous aromatic compounds (naphthalene and pentamethylbenzene) on the relative amounts of the *o*- and *p*-substituted derivatives obtained in the anodic acetoxylation of anisole is consistent with the conclusion that the substrate is adsorbed on the anode [75]. The effect is observed even at a very low concentration of the additive, tending to a limit with its increase. Certain compounds (biphenyl and t-butylbenzene) do not affect the relative amounts of the isomers, which is explained by their weak adsorbability under these conditions.

Regardless of the reliability of this type of procedure for the estimation of the degrees of adsorption of the electrolyte components on electrodes, the above results confirm the fruitfulness of the combined approach to the study of chemical reactions and surface phenomena for a more correct understanding of the mechanisms of reactions of the classes considered.

The Low-temperature Quantum-mechanical Limit for the Rates of Chemical Reactions

V.I.Gol'danskii

The influence of quantum-mechanical effects on one of the fundamental laws of chemical kinetics—the Arrhenius law—is considered. Criteria characterising the limits of the low-temperature region where the extent of quantum-mechanical tunnelling transitions exceeds exponentially the transitions over the barrier are quoted. Studies of the low-temperature tunnelling of electrons and hydrogen atoms are briefly mentioned and the history of research on low-temperature radiation-induced solid-phase polymerisation, the development of which led to the discovery of the phenomenon of the low-temperature quantum-mechanical limit for the rates of chemical reactions in relation to the formaldehyde polymerisation reaction, is briefly considered.

The results of experiments using low-inertia calorimeters, whereby it is possible to determine directly the average time (τ_0) required to add one new link to the polymer chain of formaldehyde during its polymerisation by radiation and during postpolymerisation and to establish that below 80 K the increase of τ_0 slows down and that at $T \approx 10$-4 K the time τ_0 reaches a plateau ($\tau_0 \approx 0.01$ s), are described. Possible explanations of the observed low-temperature limit for the rate of a chemical reaction are critically examined and a semiquantitative explanation is given for this phenomenon, which may be particularly common in combined electronic-confirmational transitions in complex biological molecules and may play a definite role in chemical and biological evolution (cold prehistory of life?).

The bibliography includes 56 references.

I. INTRODUCTION

Little more than 100 years have elapsed since the discovery (1869) of the first quantitative law of chemical kinetics—Guldberg and Waage's law of mass action. The second fundamental kinetic law is 20 years more recent, having been discovered in 1889. Svante Arrhenius explained the marked temperature dependence of the rates of chemical reactions and derived his famous exponential formula, according to which the reaction rate constant k is proportional to e^{E/k_BT}, where E has since been called the activation energy (k_B is the Boltzmann constant).

It is of interest to recall certain aspects of the discovery of the Arrhenius law. The Swedish scientist investigated the inversion of cane sugar by acids in aqueous solution and suggested that sugar exists in two equilibrium forms, active and inactive, and that the equilibrium between these forms obeys the law of mass action. The rate of inversion is proportional to the concentration of the active form. Furthermore, Arrhenius believed that the rate of inversion is much lower than the rate of interconversion of the active and inactive forms of sugar, i.e. that the chemical reaction does not decrease the concentration of the active form relative to its equilibrium value, which is low in any case, and does not disturb the equilibrium between the active and inactive forms: $C_a/C = K$ (C_a is the concentration of active molecules and C that of inactive molecules). Then the rate of inversion of active sugar molecules is

$$-\frac{dC_a}{dt} \simeq -\frac{dC}{dt} = k_a C_a = k_a K C = kC, \quad (1)$$

where k_a is the actual rate constant and k the observed rate constant.

Arrhenius suggested that the rate constant for the inversion of active sugar molecules k_a is independent of temperature and that the increase of the observed rate of inversion with increasing temperature is wholly determined by the van't Hoff reaction isochore (derived from thermodynamic considerations five years earlier—in 1884):

$$\frac{d\ln k}{dT} = \frac{d\ln K}{dT} = \frac{Q}{k_B T^2}, \quad (2)$$

where Q is the energy required to convert an inactive sugar molecule into an active molecule.

Arrhenius's main idea has remained unchanged until our time. Admittedly Arrhenius assumed that the active form of the initial reactant consists of a chemical modification, whereas now we regard the active form as differing from the inactive form in having a higher energy content. However, the two approaches are by no means completely incompatible. On the contrary, the initial formulation of Arrhenius's idea was actually revived to some extent by the activated complex theory, which treats the rate of reaction on the basis of the equilibrium between the initial reactants and a transition state.

In one way or another we now define the activation energy as the difference between the average energy of the molecules entering into the chemical reaction and the average energy of all the initial molecules. In other words, the activation energy E can be defined as the height of the potential barrier which prevents the mutual approach of the reacting atoms and molecules.

Since the rate constant for a chemical reaction k is proportional to the fraction of reacting molecules with energy exceeding the activation energy E, the distribution of molecules in terms of the kinetic energy W, described by the Boltzmann equation (1868)

$$\frac{1}{N}\cdot\frac{dN}{dW} = \frac{2\pi}{(\pi k_B T)^{3/2}}\sqrt{W}\cdot e^{-\frac{W}{k_B T}}, \quad (3)$$

naturally leads to a temperature variation of the rate of reaction in accordance with the exponential Arrhenius law:

$$k = Ae^{-\frac{E}{k_B T}}. \quad (4)$$

The Arrhenius law has been confirmed by many thousands of examples over a wide range of temperatures and the activation energy has become one of the most important parameters subsequently employed in chemical kinetics.

Clearly, when many chemical reactions occur in a system, the observed temperature variation of the rate of the overall process may be more complex and may not be described by the Arrhenius law. This is illustrated by two examples in Fig. 1. Suppose that two reactions take place in the system: (1) A → B and (2) A → C with activation energies E_1 and E_2 and $E_2 > E_1$. If the formation of C in reaction *2* must be preceded by reaction *1* (for example, reaction *2* proceeds as follows: A + B → C + B), then an apparent increase of the activation energy for the formation of C will be observed as the temperature is reduced with a gradual transition from $E = E_1$ to $E = E_2$. The observed rate of appearance of C is in this case determined by the slower of the two reactions. On the other hand, if the reactions occur simultaneously, then a decrease of temperature entails an apparent decrease of the activation energy for the disappearance of A with a gradual transition from $E = E_2$ to $E = E_1$—the observed rate of decrease of the amount of A is determined by the faster of the two reactions and a decrease of temperature results in an "automatic" selection of the pathway leading to the transformation of A with the smallest activation energy. Looking ahead, we may note that the overall form of the temperature variation of k then resembles the variation obtained for a unique pathway with allowance for quantum-mechanical tunnel effects.

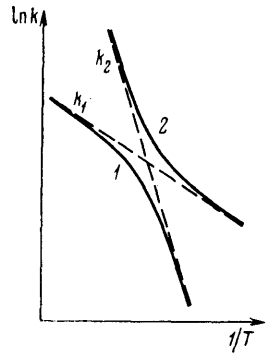

Figure 1. Characteristic temperature variation of the observed rate constant k for the disappearance of the initial reactants or for the appearance of the reaction products in two consecutive (curve *1*) and simultaneous (curve *2*) reactions with different activation energies ($E_2 > E_1$).

The introduction of quantum mechanics led to three most important consequences for chemical kinetics. Firstly, quantum mechanics explained the very presence of a potential barrier in chemical reactions. This barrier arises because electrons obey Fermi-Dirac statistics, i.e. the Pauli principle extends to them—the number of sites in each energy state is limited and for this reason exchange repulsion between electrons takes place. Secondly, when the problem of the excess energy of the reacting atoms and molecules is considered, one must consider in the general case the quantisation of the rotational, vibrational, and electronic forms of this

energy. Thirdly, and this is now the most important factor for our purposes, quantum mechanics led to the discovery of the possibility of various transitions not only over potential barriers but also through these barriers—the so called tunnelling transitions.

II. THE TUNNEL EFFECT IN CHEMICAL KINETICS (GENERAL POSTULATES)

The problem of the possible role of the tunnel effect in chemical kinetics was first formulated by Borgin[1] as early as 1929 and important contributions were made to the theoretical analysis of this problem by Roginskii and Rozenkevich's studies (1930)[2] and by the large series of studies by Bell, starting from 1933–1937.[3]

However, the attempts to observe experimentally the contribution of the tunnel effect at relatively high temperatures did not yield unambiguous results, while the region of low temperatures, where the tunnel effect should be manifested more clearly, remained uninvestigated for a long time. It was not until the 1950's that interest was aroused in the occurrence of all possible chemical reactions at low temperatures and the experimental observation of even very slow reactions of this type became possible (for example by microwave spectroscopy, by tracer atom techniques, etc.). In this connection the present author formulated in 1959 criteria characterising the limits of the low-temperature region where the tunnel effect exceeds Arrhenius transitions over the barriers and the kinetics of tunnelling transitions through symmetrical potential barriers were examined in general terms[4,5].

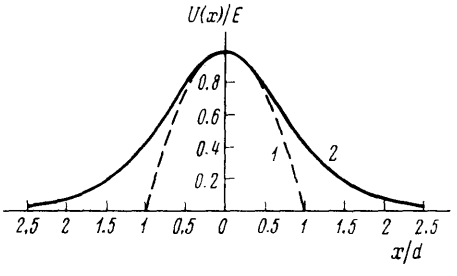

Figure 2. Typical examples of one-dimensional potential barriers: 1) parabolic; 2) Eckart.

Qualitative analysis of the temperature criteria is very simple. For a strong tunnel effect, one requires the "quantisation" of the system, i.e. its "quantum-mechanical size" λ must be greater than its classical size d. On the other hand, a low value of the ratio k_BT/E is needed in order that the transitions over the barrier should be slow. Therefore the following inequality must hold in order that the tunnel effect should predominate: $\lambda/d > k_BT/E$, or, in other words, $\hbar/d\sqrt{2mE} > k_BT/E$ or $T < (\hbar/k_Bd\sqrt{2})\sqrt{E/m}$, where E is the height of the barrier, d its half-width, and m the mass of the tunnelling species. An exact treatment yields an additional multiplier π, so that the temperature T_t below which tunnel effects predominate exponentially over Arrhenius effects is given by the following formula for any barrier described by a parabola at its apex:

$$T_t = \frac{\hbar}{k_B\pi d\sqrt{2}}\sqrt{\frac{E}{m}}. \qquad (5)$$

when $E \simeq 1$ eV and $d \simeq 3$ Å, $T_t \simeq 50$ K for protons and $T_t \simeq 1600$ K for electrons.

In the formulae describing the permeability of potential barriers, it is convenient to consider the characteristic energy of the system $\epsilon = \hbar^2/md^2$ and to compare two dimensionless parameters: E/ϵ and E/k_BT.

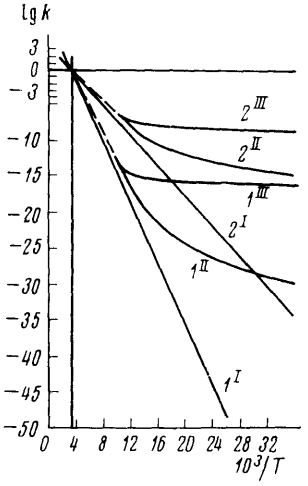

Figure 3. Temperature variation of the rates of reactions involving transitions over barriers (curves *1*II and *2*I) and with allowance for tunnelling through Eckart (curves *1*III and *2*II) or parabolic (curves *1*III and *2*III) barriers; barrier parameters: $a = 50$ (curves *1*) or $a = 25$ (curves *2*).

The typical forms of potential barriers are the parabolic barrier $U(x) = (1-x^2/d^2)E$ and the so called Eckart barrier $U(x) = ECh^{-2}x/d$ (Fig. 2). The dependence of lg k on $1/T$ with and without allowance for the tunnel effect is illustrated for both barriers in Fig. 3 with $a = \pi\sqrt{2}\sqrt{E/\epsilon} = 25$ and 50. At low temperatures ($T < T_t$) we have instead of the usual Arrhenius relation a unimolecular reaction rate constant which decreases as $T^{3/2}$ for the Eckart barrier tending towards zero, because the "bottom" of a barrier of this form is infinitely wide. On the other hand, in the case of the parabolic barrier the rate constant for a unimolecular chemical reaction reaches a plateau at low temperatures, tending to a definite limit.

A change from the continuous (Boltzmann) energy distribution to a discrete quantum-mechanical distribution of the tunnelling mass in a typical case of a symmetrical transition between systems, described by Morse potential curves (Fig. 4), does not alter the above criterion for the boundary temperature T_t of the "tunnelling region". For a quantum-mechanical distribution with respect to energy levels, the rate constant reaches a plateau at low temperatures, whatever the form of the barrier, which corresponds to a tunnelling transition from the zero-point vibrational level.

The picture described above is extremely simple but unfortunately has been used very rarely in this form. In the general case the states of the system on either side of the potential barrier are different and this alters the situation radically. Only when the tunnelling species is in a free state on either side of the barrier and is described by a planar wave is its passage through the barrier a non-resonance process and its probability varies monotonically with energy. However, a chemical reaction in no way constitutes a transition of a planar wave through the barrier, but is associated with the transition of a species or a group of species from one potential well to another—above the barrier separating these wells or through it.

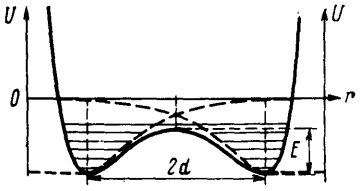

Figure 4. Schematic illustration of the barrier formed by the superposition of two "opposed" Morse potential curves.

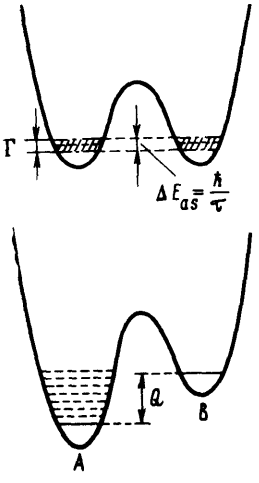

Figure 5. Schematic illustration of the distribution of energy levels in two identical and different potential wells.

The energy states of the system in each potential well are quantised; they are characterised by a set of discrete levels and tunnelling is possible only under resonance conditions, i.e. when the levels are the same in both wells. This can be illustrated by Fig. 5. If two identical "traps" which may contain an electron, for example two protons, are brought closer together, we obtain a system of two equivalent potential wells. In each of these traps taken separately the electron would exist at a certain stationary level (infinitely narrow in the ground state). In the presence of a system of two completely identical wells, the electron is delocalised—it tunnels continuously from one well to the other, and the characteristic time of such subbarrier transition τ_0 is shorter the narrower and lower the barrier separating the wells. Neither the residence of the electron in the left-hand well nor its presence in the right-hand well constitute any longer stationary states of the system and the levels of the electron in each well now have a finite width $\Gamma = \hbar/\tau_0$. In other words, neither the wave function Ψ_l (electron in the left-hand well) nor the function Ψ_r (electron in the right-hand well) are any longer eigenfunctions of the system; such functions are now their combinations—symmetrical: $\Psi_s = (1/\sqrt{2})[\Psi_l + \Psi_r]$, and antisymmetric: $\Psi_a = (1/\sqrt{2})[\Psi_l - \Psi_r]$. This implies that the system can exist in two states differing in energy by $\Delta E_{as} = \hbar/\tau$ (Fig. 5) and the two states Ψ_s and Ψ_a are the same and coincide with Ψ_l and Ψ_r only when $\tau \to \infty$ (when the two wells move apart to an infinite distance).

However, the absolute identity of the two wells is exceptionally rare or altogether impossible†. On the other hand, in the general case when the two wells differ, the levels in them become non-stationary and tunnelling transitions between the wells are possible only when the levels coincide to within $\Delta E = \hbar/\tau$, where $\tau \geqslant \tau_0$; τ_0 is the tunnelling time in the idealised case of identical wells, i.e. for an absolutely symmetrical barrier.

We shall now consider the general case of two different wells for an exothermic transfer of a certain species m between molecules A and B : $A + Bm \to Am + B$. To make the treatment specific, we shall assume that m is an electron, A an oxidant, and Bm a reductant. Since we are interested in the region of low temperatures, we shall further assume that in the initial state all the molecules Bm are in the lowest energy level—the level of zero-point vibrations.

If the level nearest (from below) to the initial level in potential well A is separated from the latter by a distance $\Delta E \gg \Delta E_0$, where $\Delta E_0 = \hbar/\tau_0$, then under adiabatic conditions, i.e. in the absence of interactions between electrons, the nuclei of the molecules A and B, and the surrounding medium, a tunnelling transition is impossible and the state of the electron in well B is stationary (to within a negligibly low rate of the radiation-induced transition: $A + Bm \to Am + B + h\nu$). In fact, under such conditions, there is simply no place to which the energy of the transition ΔE could be transferred.

For the transition to become possible, it is necessary to find a "sink" for this energy or to modify the form of the potential wells (and hence the positions of the levels in them) in such a way that the levels coincide in the two wells, i.e. the condition $\Delta E \leqslant \Delta E_0$ holds. The transfer of the energy ΔE both to an individual molecule and to the crystal lattice can serve as a "sink". In the region of low energies (when $\Delta E \leqslant 0.02$ eV) the dissipation of the energy ΔE is associated with the excitation of the vibrational lattice quanta—phonons. In the present instance we are considering the "softest" region of the vibrational lattice spectrum—its acoustic branches, and there is a

† For example, even the transfer of an electron ($H + H^+ \to H^+ + H$) or an H atom ($H + H_2 \to H_2 + H$) might be regarded as a transition between two absolutely identical wells only in terms of the approximation of a complete absence or a complete equality of the interactions [interaction energies?] of H and H^+ on the one hand and H and H_2 on the other with the surrounding medium, which is not as a rule the case.

possibility not only of single-phonon but also of multiphonon transitions, in particular two-phonon transitions with absorption of the energy ΔE. For large energies (up to 0.2–1 eV), the energy ΔE is consumed in the excitation of normal vibrations in molecules or of high-frequency, optical branches of the vibrational spectra of the molecular crystal lattices.

The interaction of electrons and nuclei, responsible for the dissipation of the electronic excitation energy via vibrational degrees of freedom, permits non-adiabatic electronic transitions in which the Franck–Condon principle does not hold and the internuclear distance changes. At the same time the interaction of electrons and nuclei broadens the levels approximately by the factor $\sqrt{M/m}$, where M is the mass of the nucleus and m the mass of the electron, and this also promotes tunnelling, decreasing ΔE as a result of the possibility of the mutual approach and overlapping of the edges of the broadened levels. The broadening of the levels occurs also due to the interaction of the molecules with their environment (which is characteristic of a condensed phase), when the system comprising two potential wells is no longer adiabatic. Such interaction in fact leads to the appearance of a band in the optical branches of vibrational lattice spectrum instead of the vibrational spectral lines due to individual molecules.

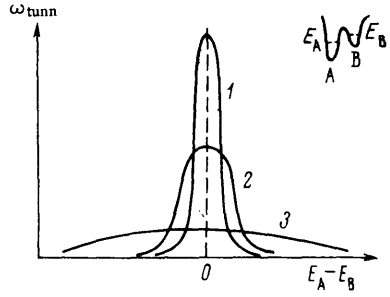

Figure 6. Illustration of the broadening of the levels and of the corresponding decrease of the maximum probability of resonance transitions ω_{tunn}; $(\Gamma A)_1 < (\Gamma A)_2 < (\Gamma A)_3$.

As happens in any type of level broadening, the probability integral for the transition to each given level remains unchanged and consequently the maximum resonance probability of the transition characteristic of narrow levels decreases sharply (Fig. 6). The situation with an extremely high probability of tunnelling transitions within narrow resonances, associated with a complete absence of such transitions between resonances, is replaced by a much weaker (i.e. slow) tunnelling transition over a wide range of energies, which, however, depends little on the excitation energy. The exponential decrease of reaction rate with decreasing temperature should therefore be gradually retarded, reaching a plateau, as in the case of two identical wells; however, even at $T \to 0$ there remains a finite and sometimes measureable probability of a tunnelling transition from the zero-point vibrational level in the initial potential well to the virtually continuous spectrum of vibrations in the final potential well.

Another variant of tunnelling transitions—as a result of the equalisation of the levels in the two wells ($\Delta E \lesssim \Delta E_0$)—is associated with the fluctuations in time of the magnitude of the polarisation interaction of Am and Bm with the surrounding medium, for example the interaction of charged molecules with the dipoles moving around them[6,7]. Such fluctuations correspond to a time dependence of the configurations (depths and shapes) of both potential wells shown in Fig. 5. The levels in the two wells are then displaced (over a period of time) upwards and downwards and in the course of such displacement the positions of the levels in A and B may coincide for a brief period, which implies the occurrence of the resonance condition necessary for tunnelling. However, in this variant the fluctuations are frozen at very low temperatures and, when the levels in the "frozen" wells do not overlap and interaction with the surrounding medium (discussed above) is not included, the rate of reaction tends to zero or more precisely to an extremely low value characteristic of radiation-induced transitions.

Thus, although the quantum-mechanical properties of the substance, namely the presence of the zero-point vibrational level, and the tunnel effect involving transitions through potential barriers lead in principle to the possibility of chemical reactions even at the very lowest temperatures, one can in no way assert *a priori* that chemical reactions can occur at measureable rates in the vicinity of the absolute zero. Only experiments can provide an answer to this question.

III. EXAMPLES OF THE TUNNELLING OF HYDROGEN ATOMS AND ELECTRONS AT LOW AND VERY LOW TEMPERATURES‡

All experimental studies on the problem of tunnelling transitions carried out until recently can be divided into two groups depending on whether processes involving the transfer of hydrogen atoms or electrons were observed.

The available data (quantitative or semiquantitative) for hydrogen-atom transfer reactions, which may indicate an appreciable contribution of tunnelling transitions, are listed in the Table. Among these data, the most complete results were obtained in a study of the displacement of the free-radical state in the radical pairs of γ-irradiated dimethylglyoxime (Yakimchenko and Lebedev[8]). It was shown that the temperature variation of the rate of reaction becomes much less pronounced at low temperatures—the observed activation energy falls from 7.3 kcal mole^{-1} at 190–220 K to 1.4 kcal mole^{-1} at 77–110 K and in addition a marked retardation (by 3–5 orders of magnitude) of the substitution of hydrogen by deuterium is observed. Thus the presence of the tunnel effect was clearly demonstrated. Comparison of the experimental data with the present authors' 1959 calculations[4] (Fig. 7) made it possible to determine the parameters of the activation barrier: $E = 15 \pm 1$ kcal mole^{-1} and $d = 0.6 \pm 0.1$ Å.

‡ The concept of "low temperatures" is fairly arbitrary and in addition is different in physics and chemistry. In physics low temperatures are usually understood as temperatures below 4 K (liquid helium). In chemistry the temperature range from 195 K (dry ice) to 77 K (liquid nitrogen) is referred to as low temperatures, while temperatures below 77 K are regarded as ultralow.

However, all the experimental data on tunnelling by hydrogen atoms so far refer to relatively high temperatures (in excess of 77 K) and the attainment of a plateau by the rate of such reactions has not been observed in any investigation—the observed activation energy has not been less than about 0.05 eV. The attainment of a limiting rate at low temperatures (down to 4.2 K, with a direct determination of the rate) has until very recently been observed only in electron transfer processes. Thus De Vault and Chance[9,10] and Grigorov[11] demonstrated that the rate of electron transfer from cytochrome *c* to chlorophyll is independent of temperature in the range 4.2–77 K (Fig. 8). The present author investigated[12] the trapping of electrons by O^- ions in irradiated alkaline ice and showed that the rate of such trapping $e^-_{tr} + O^- \rightarrow O^{2-}$ does not change between 4.2 and 120 K.

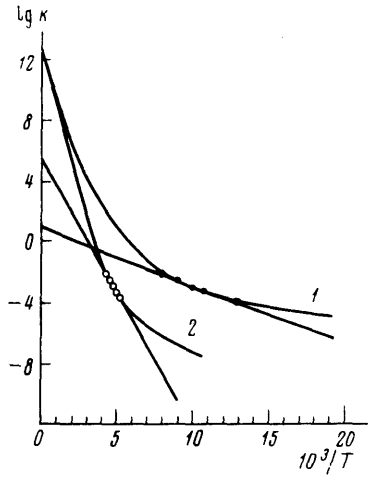

Figure 7. Calculated and experimental temperature variation (in terms of the Arrhenius coordinates) of the rates of reactions involving the transfer of hydrogen atoms (curve *1*) or deuterium atoms (curve *2*) in γ-irradiated dimethylglyoxime crystals.

In all similar cases one is dealing with the tunnelling transfer of electrons over large distances, amounting to several tens of angstroms (for $d \simeq 30$ Å and $E \simeq 1$ eV, we have $T_t \simeq 160$ K). The occurrence of such transfer explains the large radii corresponding to the trapping of electrons by acceptors[13] and the low concentrations of the ionic species stabilised on radiolysis[14] and holds out great promise that a whole series of new kinetic phenomena may be discovered. For example, in the low-temperature radiolysis of solid organic substances a decrease of the probability of electron stabilisation should be observed with increase in the concentration of traps in excess of limiting concentrations of ions, $[T] > [I]_{lim}$, since, under conditions where the distance between traps is less than the distance of effective tunnelling transfer, an electron tunnelling from one trap to another will roll down towards the cation B^+. Another, more "chemical" effect is associated with the fact that the displacement of the reactants in solid-phase reactions usually takes place at very low frequencies ($\nu_m \simeq 1\ s^{-1}$) and therefore species with charges of different signs (A^- and B^+) will neutralise one another in consequence of electron transfer by tunnelling before they meet in the reaction cage, i.e. while there are still several layers of neutral matrix molecules M between them.

$$A^- + M + B^+ \rightarrow A + M + B\ .$$

The subsequent reaction, if it occurs at all, would now involve a homolytic mechanism.

Thus, by ensuring the occurrence of reactions between spatially separated species in the solid phase, the tunnel effect can alter the reaction mechanism and even the final radiolysis products formed. Estimates have demonstrated the possibility of this type of electron trapping and of the separation in time of charge recombination processes and the subsequent chemical reaction even in viscous liquids. In general, in the liquid phase the tunnel effect weakens significantly the influence of the electrostatic interaction between reactants bearing charges of the same sign.

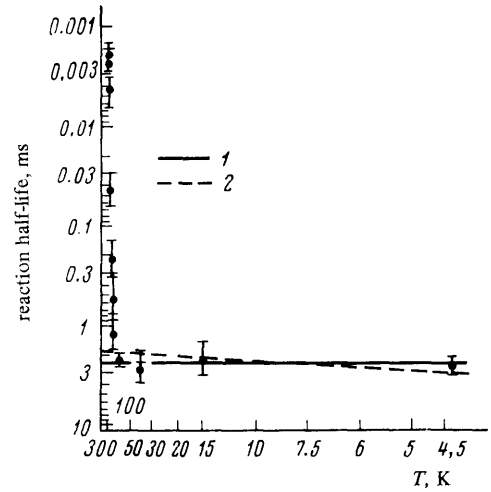

Figure 8. Experimental data of De Vault and Chance[9,10] for the rate of oxidation of cytochrome *c* by chlorophyll at different temperatures: 1) $E = 0$; 2) $E = 4$ cal mole^{-1}.

In polymer chemistry and in biochemistry the tunnel effect can ensure electron transfer between macromolecular fragments which cannot collide, for example because of steric hindrance. A theoretical interpretation of electron transfer by tunnelling over large distances between complex biological molecules with allowance for the possibility of simultaneous conformational changes in these molecules has been recently developed by Chernavskii, Blyumenfel'd, and other Soviet workers (see, for example, Refs. 15 and 16) and we shall return to this topic.

However, it must be emphasised that so far electron transfer from one species to another can hardly be called a genuine chemical reaction. Such a reaction necessarily involves a rearrangement of atoms or at least a change in valence bond lengths and in the corresponding angles, i.e. a displacement of atoms in space.

Reactions with transfer of hydrogen atoms by tunnelling.

IV. RADIATION-INDUCED SOLID-PHASE POLYMERISATION AT LOW AND VERY LOW TEMPERATURES

Typical examples of chemical reactions in the full sense of this word include polymerisation reactions. These are chain reactions: after the appearance under the influence of light, radiation, or other factors of the primary active centre, i.e. after the endothermic chain initiation step, the subsequent exothermic chain propagation process, ending in chain termination, takes place spontaneously.

It is not surprising that low-temperature solid-phase polymerisation (particularly radiation-induced polymerisation, i.e. initiated by penetrating radiation) has long attracted the attention of investigators. The first example of such polymerisation was the observation of the radiation-induced polymerisation of solid acrylamide by Mesrobian et al. in 1954[17]. Subsequently a number of fundamental studies on solid-phase radiation-induced polymerisation at low temperatures were carried out by Magat, Shapiro, and others in France, by Okamura, Tabata, and others in Japan, and by Bamford and others in England.

The history of the early studies on this problem has been discussed in a number of monographs and reviews (see, for example, Refs. 18–25) and there is therefore no point in considering it in detail here. A common feature of these early investigations was that the yield of the polymer from a particular radiation dose on the frozen monomer at a specific low temperature was not determined at the experimental temperature but only after heating and fusion of the irradiated monomer. As a result, it remained uncertain, even in those cases where the slope of the curves relating the yield of the polymer to the irradiation dose [characterising the radiation yield of the polymerisation (i.e. the number of polymerising molecules G per 100 eV of the radiation energy)] was independent of temperature, whether this was not caused, for example, simply by the fact that during the low-temperature irradiation only the initial active polymerisation centres are generated, while the polymeric chains grow after irradiation or even during the warming process, for example, always at the same temperature (at the melting point).

The next stage was the investigation of the solid-phase polymerisation of a number of monomers at the Institute of Chemical Physics of the USSR Academy of Sciences, where the usual gravimetric determination of the yield of polymers after warming the irradiated monomers was supplemented by monitoring the warming process calorimetrically[25–28]. Since it was impossible to observe under these conditions the additional heat evolution due to polymerisation, it was concluded that the solid monomers were polymerised directly in the course of irradiation. The results of such experiments are presented in Fig. 9. Seemingly they lead to the conclusion that there is no activation energy for the polymerisation of many solid monomers even at relatively high temperatures—from the melting point down to liquid nitrogen temperature. Subsequently it was, however, shown that at that time such a conclusion would have been premature and unjustified.

In many cases the temperature variation of the yield of the radiation-induced solid-phase polymerisation was found to differ significantly from a simple plateau and depended markedly on the phase state of the irradiated monomers (the example of acrylonitrile proved to be particularly complex[29,30]). It became clear that the sensitivity of the calorimeters used in the investigations[25–28] was far too low to ensure the observation of postpolymerisation during the warming process.

Finally, it must be specially emphasised that the temperature independence of the polymerisation radiation yield (it was in fact this quantity and not the true rate of propagation of polymer chains that was determined in all the investigations where the polymer yield–radiation dose curves were measured) does not by itself demonstrate that the low-temperatures solid-phase polymerisation is a non-activated process, because the radiation yield G depends (this will be discussed further below) on two kinetic constants—the rate constants for the propagation and termination of polymer chains—and the temperature variation of G is accordingly determined by at least two fundamental activation energies. Even the most accurate measurements of the slopes of the polymer yield–dose curves (i.e. the determination of the radiation yields of polymerisation) cannot alone provide information about the rate of polymerisation, but they do give information about the rate constants for the fundamental polymer chain propagation and termination processes and about the presence or absence of activation energy in these fundamental processes as long as the time resolution of the measuring method does not become shorter than the characteristic time of the polymer chain propagation process. It became clear that it is necessary not only to improve sharply the accuracy of the calorimetric method

but also to decrease at the same time its inertia, so that one must learn to observe the magnitude and rate of heat evolution during irradiation itself rather than during the postpolymerisation and heating of the irradiated monomers. Since the retardation of any activated processes must be manifested more clearly the lower the temperature of the medium, the extension of research on radiation-induced solid-phase polymerisation to lower temperatures—to liquid helium temperature (4.2 K)—became extremely urgent.

In 1965 Abkin and coworkers at the Karpov Physicochemical Institute observed the formation of polymers in tetrafluoroethylene and acrylonitrile irradiated at liquid helium temperature[31]. Almost simultaneously a group of investigators at the Institute of Chemical Physics submitted for publication reports of the formation of polymers in acrylonitrile and hexamethylcyclotrisiloxane irradiated at 4 K.[32] Both publications appeared at the beginning of 1966. However, in the light of what has been said about the apparent absence of an activation energy in radiation-induced solid-phase polymerisation above 77 K (Fig. 9), it is clear that these data[31,32] could not provide an answer to the question whether the polymers were really formed during irradiation at liquid helium temperature (they were even less likely to yield the rate of propagation of the polymer chain under these conditions) or in the subsequent process during heating. Thus the problem of the possible direct polymerisation in the vicinity of 4 K continued to remain controversial.

A number of interesting studies designed to solve this problem were carried out in subsequent years by Abkin and coworkers. They investigated the polymerisation of four monomers: tetrafluoroethylene (TFE), acrolein, vinyl acetate, and acrylonitrile; the study of the first two substances was particularly detailed. Experiments involving the addition of inhibitors to TFE irradiated at low temperatures or its "bleaching" (irradiation with visible or ultraviolet light leading to the destruction of active polymerisation centres) made it possible to separate the polymerisation effects during irradiation and postpolymerisation. After the application of corrections for postpolymerisation, the polymerisation yield at 77 K was found to be close to 2% (for an irradiation dose of about 50 Mrad).[33] As regards irradiation in liquid helium, "additional data indicating the formation of small amounts of polymer in the TFE crystal irradiated at 4.2 K were obtained with the aid of the radiothermoluminescence method".[33] This conclusion was supported also by the formation of fluoroalkyl macroradicals of the type $\sim CF_2-\dot{C}F-CF_2\sim$ detected by ESR in the irradiation of TFE near 4 K.[34]

Acrolein was a second object of detailed study by Abkin and coworkers[35,36]. Using the variation of the relative contributions of the isotactic and syndiotactic addition of new units to the growing polymer chain with the irradiation temperature of the solid monomer, which they observed by infrared spectroscopy, the authors[35-38] showed that part of the polymer is formed directly during irradiation even at the temperature of liquid helium. The initial macroscopic rate of polymerisation, defined as $dP/dt = (k_i k_p/k_t) I[M_0]$ {where k_i, k_p, and k_t are the rate constants for polymer chain initiation, propagation, and termination respectively, I is the intensity of ionising radiation (dose rate), and $[M_0]$ is the initial monomer concentration} was about 0.1% h^{-1} at I = 1800 rad s^{-1}.[37]

In their interpretation of the results of these experiments, the authors[37] concluded that the formation of polyacrolein at very low temperatures indicates an appreciable

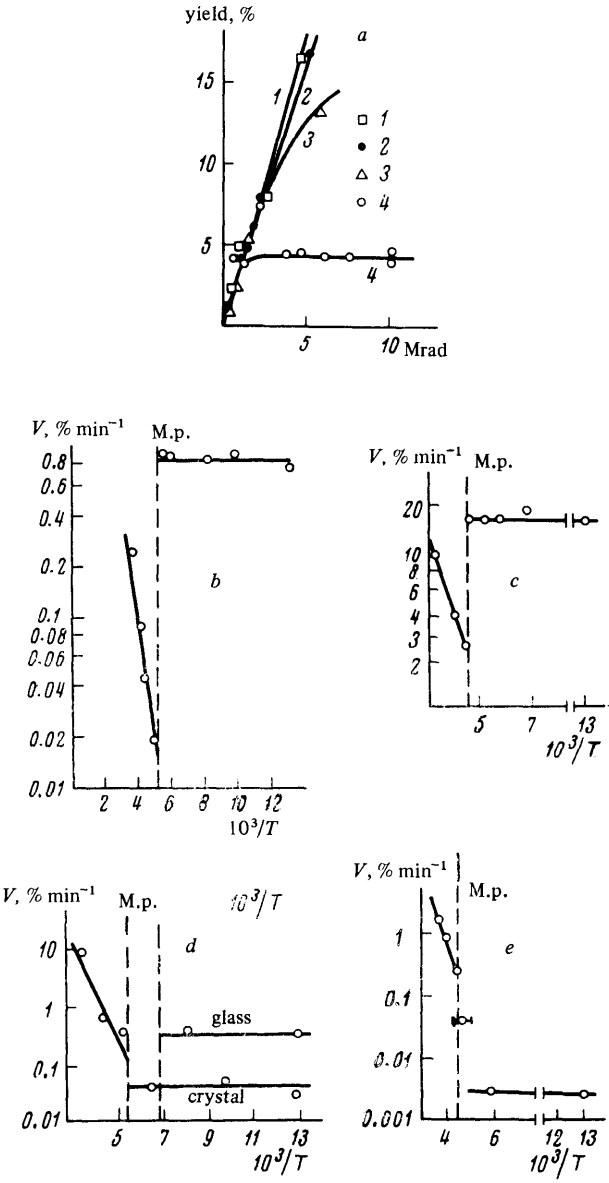

Figure 9. *a*) Variation of the polymer yield with radiation dose for acrylonitrile (AN) in the solid state at different temperatures [temperature (K): 1) 166; 2) 153; 3) 133; 4) 77]; *b*)–*e*) variation of the initial slope (V) of the polymer yield–radiation dose curves with the reciprocal of temperature for four monomers according to data obtained in studies[26-28] in which the gravimetric determination of the yield of polymer in warmed irradiated monomers was supplemented by the calorimetric monitoring of the warming process [*b*) AN, $I \simeq 0.3$ Mrad min^{-1}; *c*) formaldehyde (FA), $I \simeq 10$ Mrad min^{-1}; *d*) vinyl acetate (VA), $I \simeq 10$ Mrad min^{-1}; *e*) methyl methacrylate (MMA), $I \simeq 0.75$ Mrad min^{-1}]. The plateau at low temperatures (apparent absence of activation energy) corresponds to the following radiation yields of the polymerisation reaction: $G \simeq 400$ (AN), $G \simeq 10$ (VA—glass) and $G \simeq 1$ (VA—crystal), $G \simeq 5 \times 10^8$ (FA), and $G \simeq 3$ (MMA). The data in this figure were taken from studies carried out at the Institute of Chemical Physics of the USSR Academy of Sciences at the beginning of the 1960's.[25-28]

mobility of the monomer molecules in the irradiated crystal, and the attainment of a "limiting" yield of the polymer (i.e. the appearance of a plateau on the yield–dose curves) at very low percentage conversions suggests that only a small fraction of monomer molecules exhibit this type of high mobility. Abkin and his coworkers expressed the view that mobile molecules of this kind are distributed in the regions of dislocations and extended defects at the monomer grain boundaries and that in such regions diffusion is considerably facilitated and may proceed virtually without activation energy.

Analysing the role of ionising radiation in low-temperature polymerisation processes, Abkin and coworkers concluded that, "in solid-phase polymerisation the effect of radiation is manifested not only in initiation steps but also in chain propagation reactions as a result of the transformation of the radiation energy into the kinetic energy of the molecules localised near dislocations"[30]. They believe that, together with radiation, the energy of polymerisation itself is a factor which may ensure chain propagation: "radiation-induced polymerisation in the crystal is possible only as a result of the conversion of the radiation energy into the energy of intermolecular motion. This conversion is probably only the initial step in the growth of the polymer chain; subsequently chain propagation takes place owing to the energy evolved on polymerisation".[40]

Calculation (from the numerical characteristics of the relations between the yield and dose indicated above) of the so called radiation yields of polymerisation G, i.e. the number of molecules polymerising per 100 eV of the radiation energy, gives the following values: $G \simeq 4$ for TFE at 77 K and $G \simeq 2.5$ for acrolein at 4 K. Much higher radiation yields are usually characteristic of chain reactions. However, on the hypothesis that polymer chains cannot grow throughout the crystal but only at dislocations and extended defects, the yield of the polymer must be attributed only to the part of the energy absorbed in regions capable of polymerisation and not to the entire radiation energy absorbed by the solid monomer, which may significantly increase the values of G compared with those quoted above.

The development of the present author's research, in which the observation of the formation of a polymer in monomers irradiated at liquid helium temperature was continued[32], followed different paths. The author assumed the necessity for a direct determination of the rate constants for the propagation (k_p) and termination (k_t) of polymer chains.

The length of kinetic chains ν is determined by the ratio of the probabilities of the propagation and termination of these chains: $\nu = k_p/k_t$. The macroscopic rate constant for the accumulation of the polymer in the irradiated monomer, determined from the yield–dose curves, is a complex quantity, which, as stated above, is defined by the expression $k = k_i k_p/k_t = k_i \nu$. Therefore the absence of a temperature variation of this effective constant (or in other words the independence of the radiation yield of the polymer G of temperature) by itself implies merely a small difference between the activation energies for chain propagation and termination, but not that each of these quantities is itself small.

Another variant of solid-state polymerisation involving an apparent absence of activation energy is possible. It was pointed out by the present author as early as 1963–1965[26–28] to explain the apparent absence of activation energy in the solid-phase polymerisation of a number of monomers illustrated in Fig. 9—from the melting point down to 77 K: "We are dealing with a polymerisation mechanism in which the chain length is not determined by the competition between chain termination and propagation at each unit but by some kind of steric conditions, i.e. when the chain length is predetermined by the properties of the material. All temperature dependence then disappears from the expression for the rate of radiation-induced polymerisation $\{k_i I[M_0]\nu\}$, where the only temperature-dependent term is usually the chain length. However, in this case the chain propagation time is determined by the presence of activation energy in each unit of the chain ..."[26,28].

In the light of these considerations, the present author's aim was to determine directly the propagation time of the polymer chain $\tau = 1/k_t = \nu/k_p$ and its temperature variation in order to establish how temperature influences the duration of the fundamental polymer chain propagation steps $\tau_0 = \tau/\nu = 1/k_p$, whether or not the rates of these fundamental steps tend to a limit or become vanishingly small as the temperature is reduced.

V. LOW-TEMPERATURE RADIATION-INDUCED POLYMERISATION OF FORMALDEHYDE. THE OBSERVATION OF THE LOW-TEMPERATURE LIMIT TO THE RATE OF CHAIN PROPAGATION

In a series of studies in 1971–1972 by a group of workers at the Institute of Chemical Physics and the Branch of the Institute at Chernogolovka, including Barkolov, Kaplan, Kiryukhin, and the author of the review, it was possible to observe for the first time the phenomenon of the low-temperature limit to the rate of the chemical reaction in the radiation-initiated polymerisation of formaldehyde (FA). Here the fundamental chemical polymer chain propagation step may be, as shown in Fig. 10, the tunnelling transfer of either an electron or a hydrogen atom. However, in both cases the polymerisation should be accompanied by the approach of the formaldehyde molecule as a whole to the polymer chain, since the density of polyformaldehyde is higher than that of the initial monomer. Consequently the fundamental polymer chain propagation step involves a decrease in the effective distance between neighbouring CH_2O groups by an amount $\Delta\bar{a} = \bar{a}_0 - \bar{a}_f$, where $\bar{a}_0$ is the corresponding distance in the monomer crystal and $\bar{a}_f$ in the polymer chain. At the same time the valence angles of the CH and CO bonds are also altered. Thus in this case the fundamental chemical reaction step takes place in the full sense of the word.

In a series of the present author's experiments on the low-temperature radiation-induced polymerisation of formaldehyde in the solid phase[41–44] by a calorimetric method, the polymer chain propagation time was determined directly. At temperatures exceeding 80 K this time was found with the aid of an adiabatic low-inertia film calorimeter[42]. The design of the calorimeter is illustrated in Fig. 11. It consisted of an aluminium disc *1* 20 mm in diameter and 0.05 mm thick. A resistance thermometer *2* and a calibration heater *3* were glued to the lower side of the disc. The disc was suspended on thin conducting leads within a copper heat shield *4*. The entire assembly was placed in a glass vacuum jacket provided with a carbon adsorption pump *5*. The complete calorimeter was placed in a Dewar vessel containing liquid nitrogen.

Gaseous formaldehyde was frozen onto the calorimeter disc via a heated Kovar capillary *6*. The weight of the test substance in the experiments using this calorimeter

was varied from 15 to 75 mg, which corresponded to a layer thickness on the calorimeter disc of 0.1–0.5 mm. In order to record the calorimeter signal, a multichannel moving coil oscillograph was used. In the determination of the inertia of the calorimeter the calibration current pulse and the calorimeter response were recorded simultaneously on the same apparatus. The calibration was achieved in two ways—with the aid of the calibration heater and by heating the calorimeter by γ-radiation (this leads to uniform heating of the calorimeter disc with the monomer). Fig. 12 shows that the inertia of the calorimeter was 0.3–0.5 s.

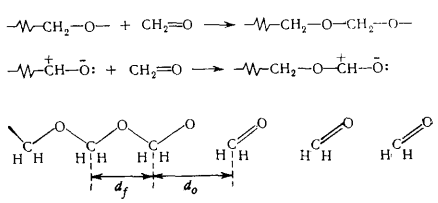

Figure 10. Fundamental processes and a simplified schematic geometrical illustration of the polymerisation of formaldehyde.

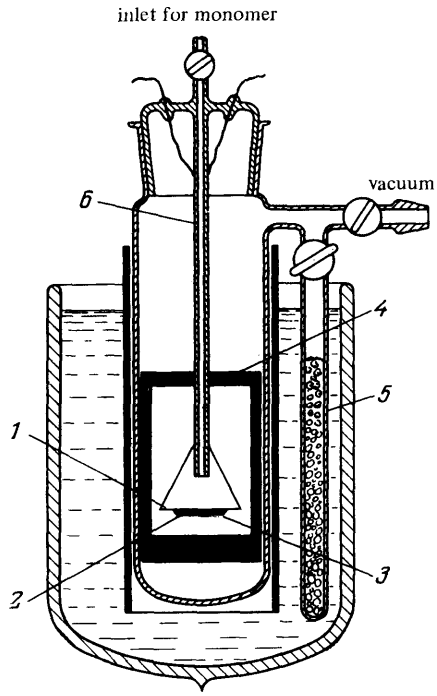

Figure 11. Schematic illustration of the low-inertia adiabatic film calorimeter.

Most of the present author's experiments on radiation-induced polymerisation were carried out using the γ-radiation from ^{60}Co apparatus. However, since the radiation sources in this apparatus were raised mechanically to the working position so that the dose rate reached a maximum in 60–70 s, the kinetics of the initial polymerisation stage might have been distorted by the change in the intensity of the initiating radiation with time. To avoid this, the bremsstrahlung from an electron accelerator with an energy of 5 MeV was used to initiate the polymerisation in the above experiments. This radiation source could be switched on and off in only a few microseconds.

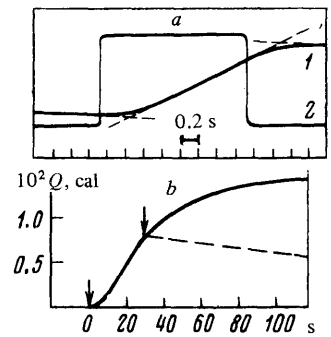

Figure 12. *a*) Calibration oscillogram for the film calorimeter [1) time variation of the calorimeter signal; 2) current flowing through the calibration heater of the calorimeter]; *b*) kinetics of heat evolution in the polymerisation of formaldehyde in the field of γ-bremsstrahlung [temperature 80 K; weight of formaldehyde 0.03 g (thickness of layer approximately 0.2 mm); dose rate 7 rad s^{-1}]. The arrows indicate the instants when the electron beam was switched on and off. Dashed line—calorimeter signal in the calibration experiment.

Initially the dose rates of the bremsstrahlung were measured with the aid of a film calorimeter—they varied linearly in the range from 3 to 40 rad s^{-1} with increase of the electron current on the stopping target from 1 to 12 μA. Fig. 12 presents the results of experiments on the polymerisation of solid formaldehyde in the bremsstrahlung field. The rate of polymerisation reached a constant value (the attainment of a linear increase of heat evolution with time) in 2–3 s; this is also the polymer chain propagation time, after which the rate of chain termination is equal to the rate of the radiation-induced initiation, i.e. the number of chains growing simultaneously in the system becomes constant.

In the temperature range 4–80 K a diathermal calorimeter, the design of which is illustrated in Fig. 13, was used to measure the polymer chain propagation time in solid formaldehyde. The calorimeter shell consisted of a thin-walled Kovar capillary *1* (2 mm in diameter), which was evacuated after the introduction of the monomer, filled with the helium heat exchanger, and sealed off. A calibration heater *2* was wound on the outer surface of the Kovar capillary and a copper–gold–iron thermocouple *3* was attached. The thermocouple recorded to within 0.5 K the temperature drop across the diathermal shell, i.e. between the calorimeter shell *1* and the copper shield *6*, which was in thermal contact with liquid helium, i.e. was at a temperature of 4.2 K. Thus the absolute measurement of experimental temperature was achieved with the aid of this capillary at the All-Union Institute of

Physicotechnical and Radiotechnical Measurements (VNIIFTRI) in accordance with a USSR State Standard. The calorimeter was suspended in a glass vacuum jacket *4* surrounded by the copper shield. The entire assembly was placed in a helium bath within a glass cryostat *5*, so that the temperature could be varied by raising the capillary with the formaldehyde to a particular height above the level of liquid helium in the bath and also by balancing the evaporator heater and the calorimeter heater. The calorimeter was calibrated both with the aid of the calibration heater and by heating the calorimeter by the γ-radiation itself, a special low-inertia device with a dropping lead diaphragm for rapid (about 0.05 s) application of the radiation field being used in these experiments.

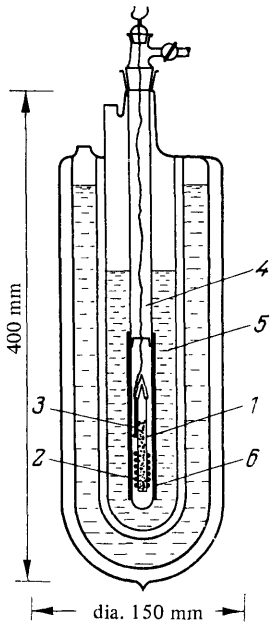

Figure 13. Schematic illustration of the diathermal calorimeter used in low-temperature experiments.

By fitting the $W = W_0(1 - e^{-t/\tau})$ curve to the plot in Fig. 14 (curve *1*) of the increasing rate of polymerisation after switching on the initiating radiation, it was possible to determine the characteristic process time τ, i.e. the average polymer chain propagation time in formaldehyde. Below 10 K, this time approached 10 s. Analogous experiments with polyformaldehyde, which was heated entirely by the absorption of γ-radiation, made it possible to measure the characteristic calorimeter time τ_c at different temperatures ($\tau_c \simeq 1$–4 s at 4–20 K)—see curve *2* in Fig. 14.

For a correct interpretation of the experiments carried out near the helium temperature (5–20 K), the problem of the possible increase of temperature within the irradiated monomer block as a result of the radiation energy and heat of polymerisation is extremely significant. The heat capacity of a substance near the absolute zero decreases sharply as the temperature is reduced. An idea about the maximum possible temperature rise within the monomer block can be obtained by estimating the adiabatic temperature rise in the system during 2–3 s, i.e. the period during which thermal equilibrium was established in the system. There are no literature data for the heat capacities of solid formaldehyde. Using the same calorimeter, the present author estimated the specific heat of formaldehyde at 6–7 K, approximately 2×10^{-3} cal g^{-1} K^{-1} being obtained (the accuracy of these determinations did not exceed 50%). We may note that the result was of the same order of magnitude as the low-temperature specific heats of other organic substances, for example acrylonitrile (6×10^{-3} cal g^{-1} K^{-1} at 10 K) and benzene (0.8×10^{-3} cal g^{-1} K^{-1} at 6 K). It also proved to be close to the estimates based on the Debye approximation, if one assumes that the Debye temperature $\theta \simeq 100$ K, the value determined for a number of molecular crystals.

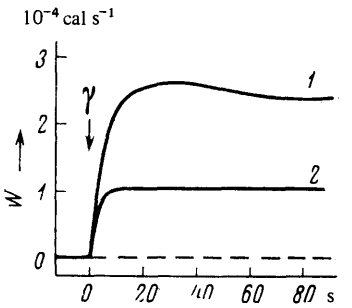

Figure 14. Variation of the rate of heat evolution in the initial period of the irradiation of specimens in the diathermal calorimeter: 1) irradiated tubes with the monomer (0.25 g); 2) irradiated tubes with polyformaldehyde (polymer sample 0.25 g, about 1 g together with tube); dose rate $I = 45$ rad s^{-1}.

Curve *2* in Fig. 14 shows that the heat evolution due to the absorbed radiation (45 rad s^{-1}) in the 0.25 g specimen (about 1 g together with the support) did not exceed 10^{-4} cal s^{-1}. In view of the specific heat of formaldehyde stated above, this corresponds to an adiabatic heating rate of about 0.1 K in 2–3 s. The heat evolution due to the polymerisation of formaldehyde at the above dose rate amounted to about 1.5×10^{-4} cal s^{-1} in a 0.25 g specimen (Fig. 14, curve *1*). This heat evolution was capable of giving rise to a heating rate somewhat higher than that due to irradiation but not exceeding 0.5 K in 2–3 s.

In separate experiments with an adiabatic calorimeter at 80–140 K, the present author determined the heat of polymerisation of formaldehyde, which proved to be 8.5 ± 1 kcal $mole^{-1}$. Having adopted the same value also at lower temperatures and having determined experimentally the rate of heat evolution due to polymerisation at different specified dose rates, the author was able to determine directly the radiation yield G of the low-temperature solid-phase polymerisation. This yield is of the order of 10^7 at 140 K, 10^5 at 80 K, and 10^3 at 4 K. Such high radiation yields, which had never been observed previously at low temperatures, are themselves of considerable interest, demonstrating the possibility of the spontaneous propagation of long chains even in the vicinity of the absolute zero.

However, the values of G combined with experimental chain propagation times are of even greater interest.

In fact, having determined experimentally on low-inertia calorimeters the polymer chain propagation time τ at different temperatures (the variation of $\lg\tau$ with $1/T$ is represented by curve *1* in Fig. 15), the author was able to reach fairly definite conclusions about the average time τ_0 required for the fundamental step involving the addition of a single new link to the growing polymer chain. If the radiation yield of chain initiation, i.e. the yield of the reaction involving the creation of the initial active centres, is g, then in the absence of chain transfer the length of the polymeric molecule is $\nu = G/g$ monomer units and the average time required for the addition of a new link to the chain is $\tau_0 \simeq \tau/\nu$. The efficiency of chain initiation by ionising radiation may be regarded as independent of temperature: $g \simeq$ const. Having put $g \simeq 1$ (the value characteristic of the formation ions or radicals) to make the treatment concrete, we adopted $\tau_0 \simeq \tau/G$ as a fairly accurate estimate. Curve *2* in Fig. 15 represents the variation[45] of $\lg\tau_0$ with $1/T$.

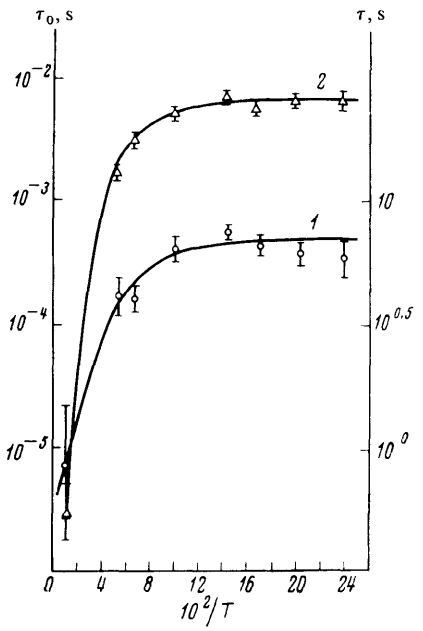

Figure 15. Temperature variation (in terms of the Arrhenius coordinates) of the total polymer chain propagation time τ (curve *1*) and of the average time required for the increment by one new unit of the polyformaldehyde chain $\tau_0 = \tau/G$ (curve *2*).

In the range 80–150 K, τ_0 increases with decrease of temperature in accordance with the Arrhenius law with an activation energy $E \simeq$ 2000–2500 cal mole^{-1} and reaches $\tau_0 \simeq 10^{-5}$ s at 80 K. At lower temperatures there is a marked deviation from the Arrhenius law—the average time required for the addition of a single chain unit tends to the constant value $\tau_0 \simeq 10^{-2}$ s, while extrapolation in accordance with the Arrhenius equation would yield unreasonably large values (about 10^{30} years at 10 K and 10^{100} years at 4.2 K).

The question naturally arises whether or not macroscopic heating of the formaldehyde specimens occurred in the present author's experiments owing to the ^{60}Co radiation energy and the heat of polymerisation. However, the above estimates make it possible to give a quite definite negative answer to this question. In principle, one can imagine the possibility of more marked local heating in regions adjoining the new polymer chain unit just formed, owing to the heat of the fundamental chain propagation step. However, during a period of the order of 10^{-2} s, such heating under the conditions of isotropic heat conduction would have to include a region with a linear dimension of the order of tens of micrometers and is therefore quite negligible.

VI. INTERPRETATION OF THE LOW-TEMPERATURE LIMIT TO THE RATES OF CHEMICAL REACTIONS

Thus a kind of limit has been observed experimentally for the rate of chain propagation in radiation-initiated solid-phase polymerisation of formaldehyde at low temperatures. After this the general problem of the interpretation of the low-temperature limit of the rates of chemical reactions became crucial, because it can be treated in different specific ways.

According to the ideas of Abkin and his coworkers[35-40] quoted above, the growth of polymer chains at low temperatures is not a spontaneous process but is due to the influence of external radiations, which, as it were, "prod" the growing chains. The necessity for such "prodding" leads to a decrease of the radiation yield of the chain reactions from $G = g\nu$ to g. The ambient temperature should then naturally play a markedly secondary role in determining the rate of polymer formation. In the case of the formaldehyde polymerisation reaction investigated by the author, the enormous radiation yields of polymerisation mentioned above constitute evidence against this explanation. However, the decisive objection to the idea that the low-temperature growth of formaldehyde polymer chains occurs as a result of the additional energy supplied by radiation is provided by an experiment carried out very recently at the Institute of Chemical Physics[46] in which postpolymerisation of formaldehyde was observed directly at liquid helium temperature at which the monomer was also irradiated. The diathermal calorimetric technique described above (Figs. 13 and 14) was used in this experiment, but with the difference that, owing to the special magnetic seal employed, it was possible not only to switch on but also to switch off the ^{60}Co radiation field very rapidly, in several hundredths of a second. The positions of the plateaux in the initial parts of curves *1* and *2* in Fig. 16 (curve *1*—for a 0.25 g formaldehyde sample; curve *2*—for the analogous polyformaldehyde sample; the total weight of the irradiated calorimeter cell was about 1.5 g and the dose rate $I \simeq$ 60 rad s^{-1}) show that, in the radiation field at $T \simeq$ 4–5 K, the calorimeter records the polymerisation of formaldehyde with a radiation yield $G \simeq 2 \times 10^3$. After the rapid switching off of γ-irradiation, polymerisation does not cease instantaneously (like heat evolution due to the irradiation of polyformaldehyde, where the characteristic time for the decay of heat evolution is determined by the relaxation of the calorimeter and amounts to approximately 2–3 s for curve *2*), but its rate decreases with a characteristic time (curve *1*) $\tau \simeq$ 10–20 s, i.e. virtually the same as the time needed for the growth in the rate of

polymerisation at liquid helium temperature in the radiation field. Thus the propagation of formaldehyde polymer chains at 4–5 K was demonstrated experimentally also in the absence of irradiation and its rate was determined and found to be virtually the same as in the radiation zone.

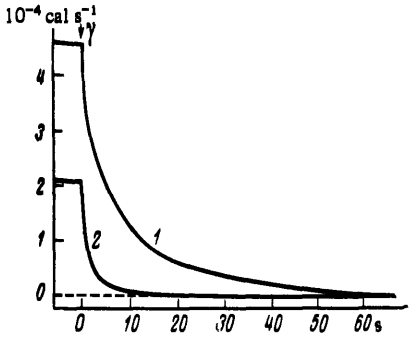

Figure 16. Variation of the rate of heat evolution during the irradiation of specimens in the diathermal calorimeter and after the cessation of irradiation (this instant is indicated by an arrow). Overall weight of the cells with the substance about 1.5 g; weight of formaldehyde (curve *1*) and polyformaldehyde (curve *2*) specimens about 0.25 g; ^{60}Co irradiation dose rate $I \simeq 60$ rad s^{-1}; experimental temperature $T \simeq 4$–5 K.

Semenov suggested that non-activated solid-phase polymerisation processes may develop via the energy chain mechanism involving the migration of an exciton (an excitation quantum) along the growing chain[25,47]. However, under these conditions the linear rate of chain propagation would be expected to be of the same order of magnitude as the velocity of sound in the solid (about 10^5 cm s^{-1}), the time required to add a new link to the growing polymer chain would be $\tau_0 \simeq 10^{-13}$ s, and the total chain propagation time for the above values of G would be in the range $\tau \simeq 10^{-10}$–10^{-6} s. The experimental values of τ are higher by many orders of magnitude.

According to the results of Benderskii et al.,[48] optical phonons traversing relatively large distances arise in molecular crystals under illumination; the time of their conversion into acoustic phonons, i.e. into heat, is fairly long (about 10^{-6} s). Since the end of the growing polymer chain may be regarded as a trap for optical phonons, there is a possibility of an additional supply of energy to the polymer chain from another chain growing at the same time. In this case $\tau_0 \simeq 10^{-2}$ s would no longer represent the time required for the spontaneous increase of chain length by a single unit, but would represent the time required for the addition at the end of the chain of a phonon from some other, "foreign" chain. However, τ_0 would then be inversely proportional to the total number of chains growing simultaneously in the system or, in other words, to the dose rate of the radiation (I) initiating the polymerisation. However, the present authors experiments demonstrated the independence of τ_0 of I.

Ovchinnikov's calculations[48,50] indicate the possibility of the existence in molecular crystals of localised long-lived vibrational states with lifetimes up to several seconds (the results of the calculation for nitrogen N_2 at $T = 30$ K). The slowness of the "de-excitation" of such state is in fact due to the factor already discussed above, namely the non-resonance mechanism of the single-quantum energy transfer from the excited to the non-excited oscillator: owing to the anharmonicity of the intramolecular vibrations, the energy difference between two high levels $\Delta E_n = E_n - E_{n-1}$ is smaller than $\Delta E_1 = E_1 - E_0$ and the transfer of the energy E_n to a non-excited neighbouring molecule is possible only with simultaneous absorption of phonons, i.e. when the lattice energy is employed. In the complete absence of coupling between the two oscillators, the rate of this process would become vanishingly low near the absolute zero, and the lifetime of the molecule at the E_n level would be determined by very slow radiation-induced transitions $E_n \rightarrow E_0$ or by the multiquantum resonance transfer of the entire energy E_n.

The involvement of long-lived vibrational states in low-temperature polymerisation as active terminal groups would require a constant additional energy supply to the growing chain due to its intrinsic heat of polymerisation and its probability would be almost unity [more precisely $(\nu - 1)/\nu$ or $(G-1)/G$]. Furthermore, the available experimental data support the view that the active centres for the growing polymer chain of solid formaldehyde at low temperatures are stabilised long-lived ions rather than any excited states.

When irradiated formaldehyde is warmed outside the radiation zone, the calorimeter detects a fairly rapid postpolymerisation—at lower temperatures the lower the irradiation temperature, the higher the dose, and the more sensitive the calorimeter (as mentioned above, after irradiation at 4 K the present author was able to observe recently postpolymerisation even at the irradiation temperature[46]). However, on optical bleaching of the irradiated specimen, its solid-phase postpolymerisation (before fusion) is completely suppressed. The bleaching effect is in fact characteristic of ions and can be accounted for by their ejection from traps and neutralisation. Hence one may conclude that the active centres in low-temperature formaldehyde polymerisation are ionic.

A characteristic feature of ionic active centres is known to be their involvement in ion–molecule reactions which do not require activation energy and frequently proceed with geometrical or larger cross-sections. The study of such gas-phase reactions was begun by Tal'roze[51,52] and their possible role in the condensed phase has been frequently mentioned in the literature. However, the time required for the addition of a new link to the growing chain of solid polyformaldehyde at low temperatures ($\tau_0 \simeq 10^{-2}$ s at $T \rightarrow 0$), which is too short for a transition over the barrier, is at the same time found to be too long for a barrier-free non-activated transition and makes it necessary to return to the idea of quantum-mechanical transitions through activation barriers with which this review was begun.

Having compared all the experimental data, we shall now consider the explanation of the quantum-mechanical low-temperature limit to the rate of polymerisation of formaldehyde on the basis of tunnelling transitions from the zero-point vibrational level, which are naturally impossible for any endothermic reaction[45]. An attempt will be made below to describe quantitatively this explanation without going into its mathematical details and almost without formulae.

As stated above, polymerisation may involve electron or hydrogen atom transfer, but it is in any case associated with a displacement of the monomer molecule as a whole. The tunnelling displacement of the formaldehyde

molecule over a distance $\Delta d = d_0 - d_f$, is undoubtedly a slower process than the tunnelling by an electron, since $M/m = 5.5 \times 10^4$ (M is the mass of formaldehyde and m that of the electron). As regards the tunnelling by a proton over a distance close to d_0, one cannot claim *a priori* that this process is faster than the tunnelling by formaldehyde over a distance $\Delta d \ll d_0$. However, the present author's direct experiments demonstrated the absence of a significant difference between the rates of polymerisation of normal and deuteriated formaldehyde at low temperatures (about 4 K).[53] On this basis, one may assume that, regardless of the polymerisation mechanism, tunnelling by the formaldehyde molecule as a whole in fact constitutes the rate limiting step for the process at low temperatures.

We shall consider the addition of formaldehyde molecules to a growing polymer chain on the basis of the quantum-mechanical theory of relaxation processes[54-56]. This theory arose mainly in connection with the problem of the radiationless relaxation of excited electronic states in molecules. It is based on the adiabatic Born–Oppenheimer theory and is applicable over an extremely wide range of conditions.

The different states of formaldehyde molecules are represented in terms of the adiabatic approximation by the potential curves in Fig. 17. The adiabatic potential curve a describes the state of the formaldehyde molecule joined to the growing polymer chain, curve b_1 represents the state of the initial monomer molecule, and curve b_2 represents the state of the next, neighbouring molecule (the zero on the abscissa axis is displaced to the right for this curve by an amount $\Delta d = d_0 - d_f$). Curves a and b_1 and b_1 and b_2 do not intersect. According to the rules of quantum mechanics, such intersection is prevented owing to the occurrence of particular interactions in the system described by the curves and instead of their intersection a gap arises between them.

At the initial instant the two monomer molecules are in states b_1 and b_2 and well a is vacant. Within the framework of the adiabatic approximation, this situation corresponds to a stable stationary state§, since none of the levels in well b_1 (at ultralow temperatures only the zero-point vibrational level is populated in this well) overlaps with any of the levels in the deeper well a.

In other words, not only are the monomer molecule and the growing polymeric active centre themselves stable in isolation, but also, in the absence of both a "free" transition over the barrier (i.e. at fairly low temperatures) between the two wells and under the conditions of the overlapping of their levels, even the monomer molecule adjoining the terminal group would be fully stable. However, owing to the interaction of the reacting molecules with the surrounding medium, i.e. owing to energy exchange with the lattice, the situation changes and there arises the possibility of an exothermic chemical reaction, in our example the polymerisation of formaldehyde, even at the absolute zero.

States a and b_1 can be regarded as two different electronic states of the polyformaldehyde active centre (poly-FA*)–formaldehyde system. State a, in which formaldehyde is displaced to the growing chain and there is a rightward "jump" of the terminal free valance, corresponds to the ground electronic state of the system in Fig. 18. State b_1, in which the formaldehyde molecule is separated from the growing polymer chain, corresponds to the electronically excited state. Owing to the interaction of the electrons and nuclei in the poly-FA*–formaldehyde system, the adiabatic approximation breaks down and the $b_1 \rightarrow a$ transition becomes possible, i.e. the system may relax via the chemical chain propagation step. Mathematically such relaxation is related to the presence in the Hamiltonian of a higher-order term involving the small Born–Oppenheimer parameter $\kappa = (m/M)^{1/4}$, called the non-adiabatic operator.

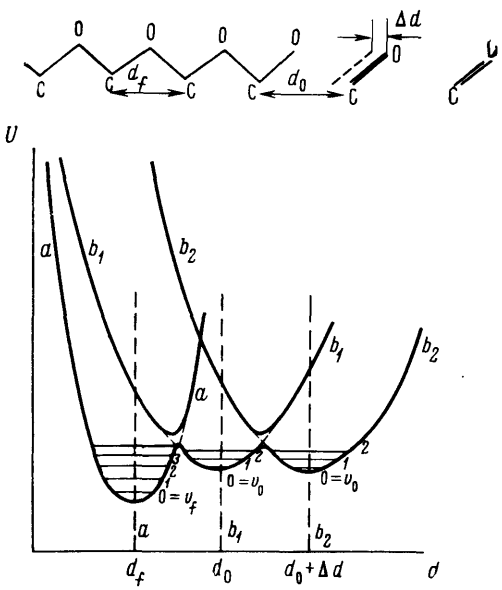

Figure 17. Upper part—simplified schematic illustration of the disposition of the solid FA monomer molecules and of the polymer chain. Lower part—schematic illustration of the tunnelling transitions of the CH_2O groups in polymerisation ($b_1 \rightarrow a$) and in filling the "cavities" arising during polymerisation in the vicinity of the terminal group of the polymer chain ($b_2 \rightarrow b_1$): a) diabatic potential curve for the formaldehyde molecule attached to the growing polymer chain; b_1) analogous curve for the initial monomer molecule; b_2) analogous curve for the next monomer molecule (the zero on the abscissa axis for this curve has been displaced to the right by an amount Δd).

The next formaldehyde molecule can undergo resonance migration from state b_2 to the vacated well b_1 with subsequent addition to the polymer chain ($b_1 \rightarrow a$), etc.

In the initial state (subscript 0) the system is at the level of zero-point vibrations: $\upsilon_0 = 0$, and the vibrational frequency of the monomeric formaldehyde molecule is ω_0, which is much less than the vibrational frequency of the monomeric CH_2–O unit in the final state (subscript f), i.e. in the polymer chain, which is ω_f. Owing to the interaction between the electronic states 0 and f, due to the non-adiabatic operator $\hat{L}$, there is a possibility of the radiationless transition $0 \rightarrow f$ to the level of the final state which is nearest as regards vibrational energy. The

§ To within extremely slow transitions $\upsilon_1 \rightarrow a$ with emission of a photon.

probability of such a transition is defined by the expression (see, for example, Henry and Kasha[54])

$$W_{0f} = \frac{2\pi}{\hbar} L_e^2 F_{0,v_f} \rho_f, \qquad (6)$$

where $L_e = \int \Psi_0 \hat{L} \Psi_f d\tau_e$, Ψ_0 and Ψ_f are adiabatic (without taking into account the interaction with the medium) electronic wave functions of the initial and final states, and F_{0,v_f} is the so called Franck–Condon factor (the square of the overlap integral of the vibrational wave functions of the initial and final states¶).

The multiplier ρ_f is defined as the density of the vibrational levels in the final state. In the absence of the inhomogeneous broadening of the levels, ρ_f differs from zero only within the limits of the level Γ (the Breit-Wigner formula) and the transition $0 \rightarrow f$ can occur only when the levels in wells b_1 and a coincide, i.e. in the presence of resonance. In the case of pronounced broadening it is possible to estimate ρ_f simply as $\rho_f \simeq 1/\hbar\omega_f$. The multiplier ρ_f is then $\hbar\omega_f/\Gamma$ times smaller than at the maximum of the non-broadened resonance line (with a width Γ).

It follows from the properties of the non-adiabatic operator that $\left|\frac{L_e}{\hbar\omega_e}\right| \propto \kappa^3$ where ω_e is the characteristic frequency of the electronic transitions. The Franck–Condon factor depends very markedly (exponentially) on the tunnelling distance $\Delta\vec{d}$ and the mass of the tunnelling group M:

$$F_{0,v_f} \propto f(v_f, \beta) \cdot \exp\left[-\frac{1}{1+\beta^2} \cdot \frac{M\omega_f}{\hbar} \cdot (\Delta d)^2\right], \qquad (7)$$

where $v_f = Q/\hbar\omega_f$, Q is the heat of polymerisation, $\beta = \sqrt{\omega_f/\omega_0}$, and the function f contains Hermitian polynomials.

For estimates, it was assumed that $\omega_e/2\pi \simeq 10^{15}$ s^{-1}, $\omega_f/2\pi c \simeq 1000$ cm^{-1}, and $\omega_0/2\pi c \simeq 100$ cm^{-1}, and $Q \simeq 0.37$ eV (so that $v_f = 3$) was determined experimentally. However, the quantity Δd, which is extremely important for the calculations, remained unknown, because it was impossible to find in the literature data on the geometry of the formaldehyde monomer crystals and even the density of solid formaldehyde at low temperatures is unavailable. However, it is clear that the density of the monomer must be lower than the density of the polymer, because the distance between the neighbouring formaldehyde monomer molecules (planar triangles) $\begin{matrix} H \\ \diagdown \\ C{=}O \\ \diagup \\ H \end{matrix}$ is determined by the relatively large van der Waals radii of the carbon and oxygen atoms and the distance between neighbouring CH_2O groups in the polymer chain is determined by the smaller lengths of the valence bonds; (for example, in polyoxymethylene the C–O bond length is 1.43 Å, which corresponds, for nearly tetrahedral valence angles, to a distance between two neighbouring carbon or oxygen atoms in the polymer chain $d_f \simeq 2.4$ Å).

Extrapolation of the densities of liquid formaldehyde at higher temperatures to the melting point yields $\rho_0 \simeq 1$ g cm^{-3} and the density of polyoxymethylene is $\rho_f \simeq 1.43$ g cm^{-3}. Assuming that $\Delta d \simeq d_f[(\rho_f/\rho_0)^n - 1]$, where $n = 1/3-1$, we obtain a very wide range of values of $\Delta d \simeq 0.3-1$ Å.

The author therefore decided to proceed as follows: the experimental value $W_{0f} \simeq 1/\tau_0 \simeq 10^2$ s^{-1} was adopted and a test was made to discover whether this corresponds to a reasonable value of Δd on the assumption of the tunnelling of the CH_2O group as a whole. Such "reverse" calculation gave $\Delta d \simeq 0.4-0.5$ Å, which is consistent with the above estimates.

The filling of the "vacancy" formed on polymerisation by neighbouring formaldehyde molecules proceeds via a tunnelling resonance transition between zero-point vibrational levels of two neighbouring equivalent wells, $b_{n+1} \rightarrow b_n$ (Fig. 17), i.e. as if by diffusion in the monomer lattice of the cavity formed on polymerisation.

The observed rate of polymerisation is limited either by the fundamental step involving the addition of a new unit to the polymer chain ($0 \rightarrow f$) or by the transport of monomer molecules to the terminal unit ($0 \rightarrow 0$)†. However, it is significant that at very low temperatures both processes have quantum-mechanical mechanisms and are due to tunnelling transitions from the zero-point vibrational level. With increase of temperature, as higher vibrational levels in the initial and final states are filled, the transitions over the barrier begin to play an increasing role and the rate of reaction begins to obey the Arrhenius law (for $M = 30$, $E \simeq 0.1$ eV, and $\Delta d \simeq 0.5$ Å, the boundary between the tunnel and Arrhenius regions is at $T_t \simeq 25$ K).

Thus, although the necessary data are not as yet available for an accurate calculation of the probability of the occurrence at the absolute zero of the chemical reaction involved in the polymerisation of formaldehyde studied by the present author, the estimates obtained are in reasonable agreement with experimental results. Nevertheless, it would also of course be desirable to analyse at least semiquantitatively other possible models and examples of the occurrence of the low-temperature limit to the rates of this and other chemical reactions. At the same time one should bear in mind that, other conditions being equal, the parameter which determines the contribution of the tunnel effect to the observed rate of the process is the product md^2 [or $\sqrt{m}d$—see Eqn. (5) for the characteristic "tunnel temperature"], where m is the mass of the tunnelling species and d the tunnelling distance.

Whereas tunnelling over a distance of tens of angstroms may be typical for an electron at low temperatures, while for a proton the distance is 1–2 Å, for groups with a molecular weight M tunnelling through a barrier with a width $d \simeq 1/\sqrt{M}$ (Å) becomes immeasurably slow and the barrier cannot be overcome in this way. It is therefore possible that the author was lucky to "encounter" formaldehyde, which proved to be one of the extremely rare successful systems for which it is possible to observe and investigate quantitatively the tunnelling of whole molecules or molecular groups.

¶ Eqn. (6) takes into account only one of the complications (mentioned above), which hinder exothermic tunnelling transitions between non-identical potential wells–the necessity for the breakdown of the Franck–Condon principle, i.e. the occurrence of an electron–nucleus interaction. The rate of transfer of the transition energy to the surroundings is not taken into account here, it being assumed that it is much higher than the rate of the transition itself.

† The transport of monomer molecules to the terminal unit (the transition of formaldehyde from well b_{n+1} to well b_n, diffusion of the cavity) can occur, in contrast to chain propagation ($b_1 \rightarrow a$), as a resonance tunnelling transition. Nevertheless, the rate of this transition need not necessarily exceed the rate of intrinsic chain propagation, because, as can be seen from Fig. 17, owing to the exothermic heat of the chemical reaction, the width of the barrier in the $b_1 \rightarrow a$ transition is much smaller than in the $b_{n+1} \rightarrow b_n$ transitions.

It is significant that the present author's findings for the low-temperature polymerisation of formaldehyde constitute to a certain extent models for tunnelling electron transfer between complex biological molecules, already mentioned above, when such transfer requires a conformational change in the biological molecules as an obligatory concomitant process. Although the occurrence of such complex electron transfer has not so far been observed experimentally, it has been postulated[15,16] as an intermediate stage in a process where only the location of the electron is altered but not the geometry of the valence bonds of the oxidant and reductant. Interaction under conditions where the possibility of a non-resonance tunnelling transition of an electron is ensured because it is accompanied by conformational changes in biological macromolecules is illustrated in Fig. 18.[15,16]

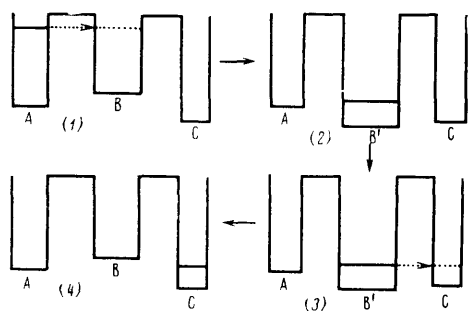

Figure 18. Schematic illustration of electron transfer from the reductant (A) to the oxidant (C) accompanied by conformational transitions of the transferring agent ($B \rightleftharpoons B'$).

Electron transfer from a reductant (potential well A) to an oxidant (well C), occurring with the evolution of energy Q, proceeds only with participation of an intermediate transferring agent. The state of equilibrium of the oxidised form of the transferring molecule is described by the potential well B, while the state of equilibrium of its reduced form is different, owing to the polarisation of the medium, and is described by the potential well B′. When the electron enters well B at the level in resonance with the initial well A, the medium is polarised and the conformational transition $B \rightarrow B'$ takes place, and, when the new electronic level in well B′ is in resonance with a level in well C as a result of this transition, there is a possibility of electron transfer to C and of the reverse conformational transition $B' \rightarrow B$.

Thus the non-resonance electron transition (1) → (4) (Fig. 18) is regarded as the sum of two resonance tunnelling electron transitions: (1) A → B and (3) B → C and two conformational transformations $B_1 \rightarrow B_2'$ and $B_3' \rightarrow B_4$. The main evolution of energy in a set of transitions of this kind occurs in the stage (3) → (4) owing to the conformational transformation of the transferring molecule, which has given up the electron, to the equilibrium configuration for the oxidised form: $B_3' \rightarrow B_4$.

In accordance with the foregoing, the evolved energy Q may be dissipated by the excitation of either phonons or the normal vibrations in the transferring molecules which are fairly strongly linked to the electronic state of the system.

The rate of the combined electronic-conformational transitions should probably tend to a limit on reducing the temperature, as described above for the polymerisation of formaldehyde. Since the processes of the type described should depend on the energy difference between the occupied electronic level of the reductant and the vacant level of the oxidant, it is believed[15,16] that they may be regulated by membrane potentials.

However, the fundamental importance of the above results, the role of the low-temperature tunnelling of not only electrons and protons but also of whole segments of biological molecules or molecular groups, is by no means restricted to this important problem of molecular biology, which is concerned with electronic and conformational transitions.

The detailed study of the low-temperature limit to the rates of chemical reactions and the extension of the reactions investigated towards temperatures still lower than 4 K may be of even wider fundamental significance. For example, the occurrence of chemical reactions at ultralow temperatures makes it necessary to consider seriously whether it would be possible to revive an organism subjected to prolonged freezing under conditions where the influence of external chemical reaction initiators (for example, various types of radiation) is not excluded.

However, another consideration is even more important—near the absolute zero the entropy factors, which are very important in the thermodynamics of chemical reactions, cease to play a role and therefore the equilibria of all reactions are displaced towards exothermic processes, including even those which lead to the formation of highly ordered systems. Furthermore, one should bear in mind the possibility of a kind of autoregulation of the direction of such spontaneous reactions—processes with a relatively small heat evolution (closer to resonance processes) should proceed with greater probability and, as the complexity of the molecules formed increases, the probability of the dissipation of the evolved energy via intramolecular degrees of freedom becomes more pronounced. Admittedly, the rates of reactions near the absolute zero are greatly reduced but, in relation to natural evolutionary processes, one can boldly recall Mayakovskii's words: "eternity awaits both you and me and it would cost us little to waste an hour or two".

It is quite possible that, at the low temperatures in space under the conditions of initiation by cosmic rays, even the most complex molecules, up to proteins, can be reliably formed, although the rate of their formation is extremely slow, and that slow chemical reactions at low and ultralow temperatures, which are, however, clearly directed towards the maximum heat evolution, may play a definite role in the processes involved in chemical and biological evolution. There is a possibility of what one might call a "cold prehistory of life".

Hyprophosphorous Acid and Its Salts

N.V.Romanova and N.V.Demidenko

The review deals with the analysis of the literature on the synthesis, properties, and applications of hypophosphorous acid and its salts in pharmaceutical practice, for the surface treatment of metals, in analytical chemistry, etc.
The bibliography includes 168 references.

I. INTRODUCTION

Of the three main acids containing one phosphorous atom in the molecule—phosphoric, phosphorous, and hypophosphorous—the last has been least investigated and is most difficult to synthesise in a high yield; there have also been few studies on its salts (hypophosphites).

Hypophosphites have been attracting attention not only because of their extensive applications as reducing reagents, but also in connection with their possible use for the preparation of various polymeric materials.

Information about the synthesis of hypophosphorous acid and various alkali metal hypophosphites, their structures, and properties, and the conditions governing the formation of their complexes in aqueous and non-aqueous media is presented below.

II. HYPOPHOSPHOROUS ACID: PREPARATION AND PROPERTIES

Pure hypophosphorous acid $H(O_2PH_2)$ consists of white crystals melting at 26.5°C and decomposing above 50°C. Its heat of fusion is 2.4 kcal mole^{-1} [1-4] and the heat of solution of the crystalline acid in water is about −0.18 kcal mole^{-1}.

An interesting laboratory method for the preparation of $H(O_2PH_2)$ involves the oxidation of phosphine (PH_3) in an aqueous suspension of iodine[5]. Phosphine, obtained by the reaction of potassium phosphide with dilute hydrochloric acid, is passed into a flask containing a stirred suspension of iodine until the solution is decolorised. At a reduced pressure (40 mmHg) it is possible to remove hydrogen iodide and water, leaving behind pure $H(O_2PH_2)$. The latter is also formed on slow oxidation of white phosphorus in the presence of water, but its yield is insignificant. When white phosphorus is oxidised by passing moist air over its surface, only 10–12% of the initial amount of phosphorus is converted into $H(O_2PH_2)$.[6]

Hypophosphorous acid is obtained by the decomposition of alkaline earth metal phosphides with water. It is possible to synthesise the acid by treating an aqueous solution of calcium hypophosphite with an equivalent amount of H_2SO_4. A method for the purification of hypophosphorous acid by the recrystallisation of commercial 50% $H(O_2PH_2)$ has been described[7]. The pure acid can be obtained by converting technical sodium hypophosphite into hypophosphorous acid by ion exchange[8].

Hypophosphorous acid is a powerful monobasic acid. According to Kolthoff's data[9-13], its dissociation constant is 8.0×10^{-2}. The fact that hypophosphorous acid is monobasic shows that in this structure the phosphorus has a coordination number of four.

In studies of the kinetics of the oxidation of hypophosphorous acid by halogens by bromine and chlorine (Griffith and McKeown) and by iodine (Griffith et al.)[14-19] it was found that the rate-determining stage of the oxidation is the conversion of the inactive form of hypophosphorous acid $(H_3PO_2)_I$ into the active form $(H_3PO_2)_{II}$. It has been suggested that the $(H_3PO_2)_I$ form is a tautomer with two hydrogen atoms attached to phosphorus, while $(H_3PO_2)_{II}$ contains two hydroxy-groups attached to phosphorus. It is noteworthy that under identical conditions the reaction with chlorine is faster than that with bromine, while the reaction with iodine is slowest.

Fig. 1 presents titration curves for hypophosphorous acid and certain other lower acids of phosphorus. The dissociation constant of $H(O_2PH_2)$ has been compared with the K_{diss} for other acids and it has been shown that these values are consistent with calculated data[20,21].

Table 1 lists the dissociation constants of a number of phosphorus acids.

III. THE STRUCTURE AND PROPERTIES OF THE HYPOPHOSPHITE ION

The structure of the hypophosphite ion has been investigated by X-ray diffraction using ammonium hypophosphite[23,24]. This anion has the form of a distorted tetrahedron two corners of which are occupied by oxygen atoms and the other two by hydrogen atoms, with the phosphorus located in the centre of the tetrahedron. It has been shown that the P–O distance is 1.51 Å, the P–H distance about 1.5 Å, and the O–P–O and H–P–H angles are respectively 120° and 92°.

The structures of magnesium, nickel, and cobalt hypophosphite hexahydrates have been investigated similarly by X-ray diffraction[25,26]. It has been established that in the magnesium salt the $H_2PO_2^-$ anion has a nearly tetrahedral structure with a P–O distance of 1.52 Å and an O–P–O angle of 109°. The observed P–O distances correspond approximately to 0.6 of a π bond per σ bond, which is equivalent to 1.2π bonds per phosphorus atom.

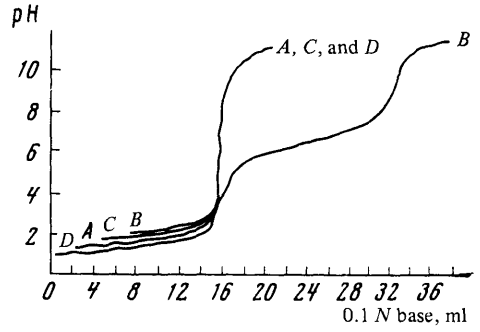

Figure 1. pH titration curves: *A*) for hypophosphorous acid; *B*) for phosphorous acid; *C*) for pyrophosphorous acid; *D*) for hydrochloric acid. The pH values were established relative to standard buffer solutions.

Table 1. Dissociation constants of various phosphorus acids at 20–25°C[22].

Acid	Formula	pK_1	pK_2	pK_3	pK_4
Hypophosphorous	$H^+ + H_2PO_2^-$	1.1	—	—	—
Phosphorous	$2H^+ + HPO_3^{2-}$	1.3	6.7	—	—
Monoethyl phosphite	$H^+ + (RO)HPO_2^-$	0.8	—	—	—
Methylphosphonic	$2H^+ + RPO_3^{2-}$	2.3	7.9	—	—
Propylphosphonic	$2H^+ + RPO_3^{2-}$	2.4	8.2	—	—
Phosphoric	$3H^+ + PO_4^{3-}$	2.1	7.1	12.3	—
Hypophosphoric	$4H^+ + {}^{-2}O_3PPO_3^{2-}$	(2.0)	(2.6)	7.2	10.0
Pyrophosphoric	$4H^+ + {}^{-2}O_3POPO_3^{2-}$	1.0	2.0	6.6	9.6

The ^{31}P NMR spectra[27–30] of hypophosphite solutions reveal 1 : 2 : 1 spin–spin splitting with a between-peak separation of 0.33 G (Fig. 2). Similarly the ^1H NMR spectrum has two peaks corresponding to 1 : 1 spin–spin splitting. This implies that two hydrogen atoms (nuclear spin 1/2) are bound covalently to the phosphorus atom (nuclear spin 1/2) so that, even if their mutual exchange or their exchange with water does occur, these processes are fairly slow (the half-exchange period is of the order of several minutes). According to published data, approximately 95% or more of the free acid or its salts exists in a form where four atoms are linked directly to phosphorus.

The hypophosphite ion has a $[^{31}P]$ spectrum with three peaks of relative intensities 1 : 2 : 1. The phosphite anion contains two peaks of equal intensities in its spectrum and trimethyl phosphite gives rise to nine peaks with the theoretical intensity ratios 1 : 9 : 36 : 84 : 126 : 84 : 36 : 9 : 1. The multiplet structure of the NMR spectra is due to the indirect spin–spin splitting by covalently bound hydrogen atoms.

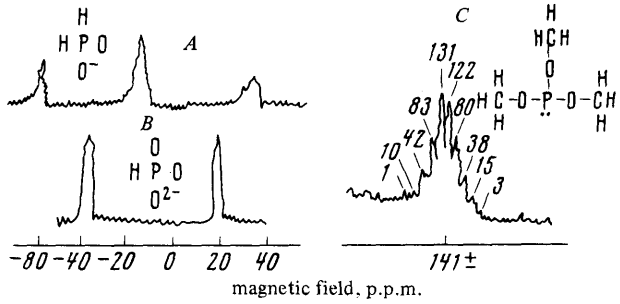

Figure 2. The NMR spectrum of phosphorus in hypophosphite and phosphite anions and in trimethyl phosphite: *A*) hypophosphorous acid; *B*) phosphorous acid; *C*) trimethyl phosphite.

In addition, the Raman spectra of hypophosphorous acid and some of its salts have been investigated[31–37] and it has been shown that the hypophosphite ion has C_{2v} symmetry, attributable to the tetrahedral species $H_2PO_2^-$.

Despite the fact that the acid and its alkali metal and alkaline earth metal salts contain tetracoordinate phosphorus, owing to the equilibrium between tautomeric forms it is possible to displace the equilibrium towards the form with tricoordinate phosphorus. This can be achieved under conditions where an electron acceptor (but not a hydrogen ion) can participate in utilising the free electron pair of the tricoordinate phosphorus atom. Possibly such conditions obtain in addition products or double salts of tin(II) hypophosphite with tin(II) bromide or iodide[38].

The kinetics of the isotope exchange between hypophosphites and water and between hypophosphites and other salts of phosphorus oxyacids have been thoroughly investigated. In earlier studies[39,40] it was stated that the two hydrogen atoms linked directly to the phosphorus atom of the hypophosphite anion are incapable of exchange with the hydrogen atoms of water. However, the latest investigations[41,42] established that this process does occur slowly but at a measurable rate. The rate of substitution of one hydrogen atom of the hypophosphite anion (linked directly to phosphorus) is given by the following equation in which the numerical constants refer to 30.0°C:

$$R = 3.33\,[H^+]\,[H_2PO_2^-] + 2.9\,[H_3PO_2]^2,$$

where R is expressed in litre mole^{-1}h^{-1}. This exchange is believed to be determined by the conversion, mentioned above, of the tautomeric form of the hypophosphite ion into one with tricoordinate phosphorus.

The exchange of oxygen between the hypophosphite ion and water in which it is dissolved has also been studied[43]. It was shown that the half-exchange periods for oxygen in the acid at 40° and 100°C are respectively 70 h and less than 0.2 h. The rate of exchange of oxygen for the sodium salt is so low that it cannot be detected even at 100°C. These data must be compared with the results obtained by the same workers in a study of the exchange of hydrogen

atoms [41,42]. The half-exchange period for hydrogen in $H(O_2PH_2)$ at 25°C is 16 min, while for $Na(O_2PH_2)$ at 100°C the period is 21 h. Possibly the lower rate of oxygen exchange for the sodium salt compared with the acid is a consequence of the presence of a hydrogen bond between the OH groups of the acid and water. This explanation is similar to the theory of electrical conduction proposed by Grotthus [44], according to which the hydrogen atoms joined directly to phosphorus form weaker hydrogen bonds with water than the hydrogen atoms of the OH group.

It has been shown [45-47] that the phosphorus atoms in the hypophosphite ion do not exchange with phosphites and phosphates in either acid or neutral solutions. It is interesting to note that the phosphorus exchange between hypophosphorous and phosphoric acid does not occur in the presence of iodine or iodides, although the oxidation of hypophosphorous acid to phosphorous acid by iodine might give rise to phosphorus exchange at a rate comparable to that of the oxidation-reduction reaction. In mixtures of arsenious and arsenic acids iodine promotes arsenic exchange at a rate which may be predicted from kinetic data for the oxidation-reduction reaction.

The absence of exchange between hypophorous and phosphorous acids in the presence of iodine has been explained on the hypothesis that the process consists of two stages: a slow transition of the inactive form of hypophosphorous acid into the active form and then a rapid irreversible oxidation of the active form by iodine. Thus in the first, reversible stage, the exchange cannot occur, while the second (oxidation-reduction) stage is not accompanied by the exchange owing to its irreversibility. The active form of hypophosphorous acid is probably a tautomeric structure based on tricoordinate phosphorus. This result and data for hydrogen exchange between hypophosphorous acid and water are consistent with the conclusions based on the oxidation of hypophosphites, which will be described below.

Hypophosphorous acid and hypophosphites are readily oxidised. On storage in the cold, the crystals of hypophosphorous acid are stable [7] but contaminated crystals readily decompose at room temperature. The decomposition products are mainly phosphine, phosphorus, phosphoric acid, and hydrogen. Similarly, on vigorous heating, hypophosphites decompose, giving rise to phosphine, red phosphorus, phosphites, phosphates, and possibly other compounds. This type of decomposition is evidently a consequence of self-oxidation-reduction.

The kinetics of the reaction between hypophosphite and hydroxide ions, in which phosphite ions and gaseous hydrogen are formed, have been investigated [48]. The rate equation for this reaction is

$$-\mathrm{d}[H_2PO_2^-]/\mathrm{d}t = K[H_2PO_2^-][OH^-]^2.$$

The rate constant K is approximately 3×10^{-4} min^{-1} at 100°C. It has been suggested that free hydrogen is more readily evolved from the hydroxide ion than from the hypophosphite ion [49].

Hypophosphites also decompose in neutral solutions at a moderate rate, evolving hydrogen in the presence of platinum black, palladium, and copper [48,50-55]. These metals are readily deposited in a colloidal state from solutions of their salts under the influence of sodium hypophosphite. The resulting colloidally dispersed metal then catalyses the decomposition of hypophosphite ions in which hydrogen is evolved.

The study of isotope exchange has shown that the hydrogen evolved from neutral hypophosphite solutions in the presence of metallic catalysts originates from water to the extent of 50%. [56] In this case the catalytic decomposition of the hypophosphite should be consistent with the following chemical equation:

A number of studies have been made of the oxidation of hypophosphites by various oxidising agents. The main product of these reactions is phosphite. The rate of oxidation of sodium hypophosphite in an alkaline medium is approximately three times higher than in a neutral medium: in the former case the completion of the reaction requires 60 min and in the latter 180–200 min. [57] The subsequent oxidation of phosphites to phosphates in an acid solution is much slower. The catalytic effect of freshly deposited nickel on the oxidation of sodium hypophosphite has been investigated [58]. It has been shown that the degree of oxidation of hypophosphite is influenced by temperature, oxidation, time, acidity of the solution, and the amount of catalyst.

As stated above, the kinetics of the oxidation of hypophosphorous acid by halogens have been studied and it has been found that the conversion of the inactive form of hypophosphorous acid $(H_3PO_2)_I$ into the active form $(H_3PO_2)_{II}$ determines the rate of oxidation. The interaction between the active form and halogens takes place after each collision. The constant for the equilibrium between the two forms of hypophosphorous acid has been calculated:

$$K = \frac{[(H_3PO_2)_{II}]}{[(H_3PO_2)_I]} = \frac{K_1}{K_2} \simeq 10^{-12}. \qquad (A)$$

The rate of interconversion of the two forms of hypophosphorous acid has been found to be directly proportional to the hydrogen ion concentration and to determine the rate of oxidation in an acid solution.

The kinetics of the oxidation of hypophosphorous acid by iodate ions have been studied [59-61] and a number of investigations have also been made of the slower reactions with bromates and chlorates [62,63]. The kinetics of the reaction between H_3PO_2 and iodate are close to those of the oxidation of hypophosphites by halogens. However, there are a number of complicating side reactions, for example the interaction of iodine with $H(O_2PH_2)$ and the reaction of phosphorous acid with iodine and iodate. Nevertheless in this case too the rate of oxidation is determined by the stage involving the conversion of $(H_3PO_2)_I$ into $(H_3PO_2)_{II}$. This proved to be the case also in a study of the kinetics of the oxidation of hypophosphite by copper(II) [64-67] and mercury(II) [68-70] salts at moderate concentrations of the oxidant in an acid medium.

The kinetics of the oxidation of hypophosphorous acid in an acid medium by chromate [71], silver [72], iron(III) [73], and arsenate [74] ions have been studied at moderate and high concentrations. It has been found that the type and concentration of oxidising agents have in essence no influence on the rate of the process, which increases appreciably with increasing acidity of the solution. This is reflected by the equation

$$\mathrm{d}[H_3PO_3]/\mathrm{d}t = K[H_3PO_2][H^+],$$

in which K is of the order of 0.24 litre $mole^{-1}min^{-1}$ for all the reactions investigated.

The results of all the kinetic studies are consistent with the claim that the active form of the acid is present in extremely low amounts and that the rate of conversion of

the inactive form into the active form, being slow, determines the rate of the entire reaction under readily realisable experimental conditions.

These results are consistent with NMR data, which have shown that 95% or more of the hypophosphite ions are present in the tautomeric form based on tetracoordinate phosphorus. In conformity with Eqn. (*A*), the fraction of $HP(OH)_2$ in hypophosphorous acid is only 10^{-12} relative to $H_2P(O)(OH)$.

IV. ALKALI METAL AND ALKALINE EARTH METAL HYPOPHOSPHITES

Recently hypophosphites have been used extensively in many countries for chemical nickel plating of metals [75]. There is interest in the application of hypophosphites also in many other branches of industry [76]. In view of the increased requirement for hypophosphites there has been a growth in the amount manufactured. Thus during the period 1955–1960 the production of hypophosphites and hypophosphorous acid in the USA [77] increased from 100 000 lbs to 1 million lbs of the equivalent amount of phosphorus annually. In the USSR in 1967 the production of sodium hypophosphite increased by a factor of several tens compared with 1957.

One of the decisive factors on which the level of requirement of hypophosphites depends is their cost. The existing high cost of hypophosphite in USSR, which is responsible for the high cost of chemical nickel plating [78], is caused, on the one hand, by the low yield (about 36% relative to the phosphorus in the charge) of hypophosphite in the industrial preparation of Na_2HPO_2 via $Ca(H_2PO_2)_2$ and, on the other hand, by the relatively small scale of the industrial production. The low yield of hypophosphite in the reaction of phosphorus with hydroxide ions is due to the fact that the phosphorus in the charge is consumed not only in the formation of the hypophosphite but is also converted into phosphite and passes to the gas phase mainly in the form of phosphine.

The methods for the production of hypophosphites described [79-85] do not allow one to infer the particular factors which influence their yields. The maximum yield of hypophosphite of 70% claimed in a Swiss patent [86] is in no way justified. A low temperature of the synthesis of the solutions is specified in many patents, but its relation to the yield is never discussed. A method has been described [87] for the production of alkali metal hypophosphites in the presence of an aqueous suspension of insoluble alkaline earth metal phosphates, phosphites, sulphates, silicates, and oxalates and also aluminium, magnesium, and silicon oxides and various types of clays as catalysts. These suspensions increase the area of contact between the reactants, which in turn activates the reaction. The mixture is heated above the melting points of phosphorus. A highly pure product is obtained in 90% yield without an excess of the alkali metal or side products.

The method of synthesis of hypophosphites by the reaction of white phosphorus with alkali and alkaline earth metal hydroxides is classical (it was described as early as 1816) and is still used in the industrial production of hypophosphites. Different versions of the main reaction of phosphorus with hydroxides have been described [79,86,88-108]. The yield of the reaction products under laboratory and industrial conditions has been very low, but the increasing interest in hypophosphites has led to the method being patented. The conditions for the preparation of sodium hypophosphite reviewed by Uhlir et al. [82] have been developed on the basis of these patents.

The method used to manufacture sodium hypophosphite adopted in the USSR, consists of two stages. In the first state the reaction of yellow phosphorus with $Ca(OH)_2$ results in the formation of calcium hypophosphite via the reaction

$$8P + 3Ca(OH)_2 + 6H_2O = 3Ca(H_2PO_2)_2 + 2PH_3.$$

In the second stage the resulting calcium hypophosphite is decomposed with sodium carbonate and NaH_2PO_2 is obtained:

$$Ca(H_2PO_2)_2 + Na_2CO_3 = 2NaH_2PO_2 + CaCO_3.$$

The technological parameters of this method are very poor, the degree of utilisation of the initial phosphorus being at best 16–18%. The consumption of lime is four times the stoichiometric amount. The rate of synthesis of calcium hypophosphite is low, the concentration of the resulting solutions is 7–8 g litre^{-1}, and the consumption of steam in the evaporation of such solutions is high. The effluent gases from the synthesis (PH_3) are not used. In the method adopted the most important stage, responsible for the low efficiency of the entire industrial cycle, is the synthesis of calcium hypophosphite.

Soviet scientists developed recently a number of improvements to this method leading to a higher yield and a faster process. The existing view that the reaction between yellow phosphorus and calcium hydroxide in an aqueous medium is "sluggish" proved to be incorrect; an increase in the specific surface of phosphorus accelerates the synthesis by a factor of several powers of ten. Above 90–93 °C, the rate of reaction increases very rapidly and near 100 °C the process is completed in 2–3 min in the presence of a high specific surface.

Under these conditions, it is possible to obtain solutions containing 12–13% of calcium hypophosphite. The attainment of high rates and high hypophosphite concentrations during the synthesis makes it possible to reduce by a factor of 15 the consumption of steam in the evaporation of the solutions and to reduce sharply the volume of the reactors. The possibility of a considerable decrease of the consumption of calcium hydroxide has been established. Instead of a 400% excess, one can use an excess of approximately 25% relative to stoichiometry. The employment of closed reactors-emulsifiers makes it possible to utilise the PH_3 obtained in the synthesis by its combustion to P_2O_5 with subsequent synthesis of phosphoric acid, which increases the degree of utilisation of phosphorus to 75–80%.

The following conditions for the synthesis in reactors-emulsifiers must be regarded as optimal: the temperature of synthesis 90–93 °C and molar proportions of phosphorus and lime (P : CaO) of 1 : 0.45, which corresponds to an approximately 25% excess of lime. The amount of water introduced into the synthesis is calculated to give 12–13% solutions.

Morgunova and Averbukh [109] made a detailed study of the synthesis of sodium hypophosphite from (1) yellow phosphorus and sodium hydroxide, (2) yellow phosphorus, calcium hydroxide, and sodium carbonate, (3) yellow phosphorus, sodium hydroxide, and calcium hydroxide, (4) yellow phosphorus, barium hydroxide, and sodium carbonate, and (5) yellow phosphorus, sodium hydroxide, and barium hydroxide. During their investigations, they established that an increase of the yield of sodium hypophosphite to 55–59% of the phosphorus in the charge can be ensured by preparing the sodium hypophosphite solution in a single stage by the reaction of phosphorus with hydroxide

ions in the presence of both Na^+ ions alone and in the joint presence of Na^+ and Ca^{2+}. When Ca^{2+} ions are replaced by Ba^{2+}, the yield falls. The overall amount of hydroxide ions introduced into the process, which can ensure the complete utilisation of the phosphorus in the charge, should be not less than 1.0–0.9 mole per gram-atom of phosphorus. A decrease of the content of phosphite formed during the synthesis is achieved by precipitating it in the form of insoluble alkaline earth metal phosphites. The amount of alkaline earth metal required to precipitate the phosphite may be 0.25–0.30 mole per gram-atom of phosphorus, which is determined by the amount of phosphite formed in the synthesis.

In the synthesis of sodium hypophosphites in the presence of hydroxide ions introduced as the alkaline earth metal hydroxide, Na^+ ions can be introduced both as the hydroxide and as the carbonate. When sodium ions are added as the carbonate, the required amount of hydroxide ions must be introduced in the form of the alkaline earth metal hydroxide. The amounts of reactants in the charge should ensure the molar ratios $P : Na^+ : Ca^{2+}(\text{or } Ba^{2+}) : OH^- = 1 : 0.50–0.60 : 0.25–0.30 : 0.90–1.0$.

V. THE MECHANISM OF THE SYNTHESIS OF HYPOPHOSPHITES IN SOLUTION

There exist various views on the relation between the composition of the gas phase and that of the products formed in the synthesis of hypophosphites in solution[80]. Some investigators believe that the amount of hydrogen evolved is proportional to the amount of phosphite formed in the oxidation of hypophosphite:

$$P_4 + 3OH^- + 3H_2O \rightarrow 3H_2PO_2^- + PH_3; \quad (1)$$

$$H_2PO_2^- + OH^- \rightarrow HPO_3^{2-} + H_2 \uparrow, \quad (2)$$

while others state that hydrogen is formed in an amount proportional to the amount of hypophosphite.

Reactions which agree best with practical results according to the authors have been put forward[81]:

$$P_4 + 4OH^- + 4H_2O \rightarrow 4H_2PO_2^- + 2H_2; \quad (3)$$

$$P_4 + 4OH^- + 2H_2O \rightarrow 2HPO_3^{2-} + 2PH_3. \quad (4)$$

Different amounts of phosphite and phosphine are formed by reactions (3) and (4). There exist also other views on the pathways followed in the formation of phosphites and hydrogen[80], but the presence of both components in the gaseous mixture is never denied. According to one investigation[82] the synthesis of sodium hypophosphite involves other reactions, apart from those quoted above, in which molecular hydrogen and diphosphine are formed:

$$3P_4 + 8OH^- + 8H_2O \rightarrow 8H_2PO_2^- + P_2H_4; \quad (5)$$

$$H_2PO_2^- + 2OH^- \rightarrow PO_4^{3-} + 2H_2; \quad (6)$$

$$15P_2H_4 \rightarrow P_{12}H_6 + 18PH_3. \quad (7)$$

In his most complete and latest monograph on phosphorus, Van Wazer[110] quotes the same reactions as Tsuboi[31].

Soviet investigators[111] made a fairly detailed study of the mechanism of the synthesis of hypophosphite in solution. They showed that, when phosphorus interacts with hydroxide ions, hypophosphite and phosphite are formed simultaneously. Presumably both hydrogen and phosphine can be evolved under these conditions.

Morgunova and Averbukh quote in their paper[111] the free energies of some of the reactions calculated from Latimer's data[112] (Table 2). All the reactions listed in the Table, except the last, are thermodynamically probable. In order to determine which reactions actually occur, the authors studied the composition of the gas phase in the synthesis of hypophosphite solutions.

Table 2. The free energies of certain reactions (Latimer's data[112]).

No. of reaction	Reaction	Free energy, kJ
1	$P_4 + 3OH^- + 3H_2O \rightarrow 3H_2PO_2^- + PH_3$	−336.0
2	$H_2PO_2^- + OH^- \rightarrow HPO_3^{2-} + H_2$	−142.8
3	$P_4 + 4OH^- + 4H_2O \rightarrow 4H_2PO_2^- + 2H_2$	−472.2
4	$P_4 + 4OH^- + 2H_2O \rightarrow 2HPO_3^{2-} + 2PH_3$	−485.2
8	$P_4 + 4OH^- + 8H_2O \rightarrow 4HPO_3^{2-} + 8H_2$	−722.8
9	$P_4 + 6H_2O \rightarrow 3H_3PO_2 + PH_3$	−126.4
10	$H_2PO_2^- + 2OH^- \rightarrow PO_4^{3-} + 2H_2$	−199.5
11	$HPO_3^{2-} + 3OH^- \rightarrow PO_4^{3-} + 2H_2O$	−217.1
12	$3H_3PO_2 \rightarrow PH_3 + 3H_3PO_3$	−125.5
13	$H_3PO_2 + H_2O \rightarrow H_3PO_3 + H_2$	−96.6
14	$4H_3PO_3 \rightarrow PH_3 + 3H_3PO_4$	+3.8

Their investigations showed that the composition of the gas phase depends on which hypophosphite is synthesised. In the synthesis of calcium hypophosphite the gas phase contains more phosphine than hydrogen. Three times as much PH_3 as H_2 is always present in the gas phase. A clear-cut dependence of the change in the composition of the gas phase on time has not been observed.

In the synthesis of sodium hypophosphite the content of hydrogen is approximately three times greater than that of PH_3. The $H_2 : PH_3$ ratio then decreases, reaching in some cases approximately 0.6 at the end of the synthesis. The average $H_2 : PH_3$ and hypophosphite : phosphite ratios in the synthesis of calcium hypophosphite are 0.3 and about 1.4, while in the synthesis of sodium hypophosphite from yellow phosphorus and NaOH the ratios are 1.8 and 3.5 respectively.

Table 3. The contributions of reactions (1), (4), (3), and (8) to the synthesis (%).

Sodium hypophosphite				Calcium hypophosphite			
(1)	(4)	(3)	(8)	(1)	(4)	(3)	(8)
—	35.7	64.3	—	impossible			
88.3	—	—	16.7	impossible			
impossible				26.7	53.4	19.9	—
80.6	—	1.6	17.8	impossible			
—	31.6	63.5	0.4	impossible			

Possible combinations of reactions which ensure the formation of both hydrogen and phosphine in the above proportions and which are the most probable on thermodynamic grounds [reactions (1), (4), (3), and (8) in Table 2] have been elucidated. The possible combinations of reactions in the synthesis of hypophosphites are indicated in Table 3, which shows that the combination of reactions

(4) and (3) is feasible only in the synthesis of sodium hypophosphite solutions and is impossible in the synthesis of calcium hypophosphite. This has also been pointed out in other investigations[82,112]. The synthesis of hypophosphites may involve the simultaneous occurrence of reactions (1), (4), (3), and (8) with formation of hypophosphite. Apart from phosphine, the gas phase contains diphosphine, which causes the self-ignition of the evolved gases in air. Furthermore, a certain amount of elemental phosphorus passes to the gas phase.

VI. HYPOPHOSPHITES AND THEIR CLASSIFICATION

The available literature data are mainly concerned with studies on alkali metal phosphites. The following alkali metal hypophosphites are known[80]: $Li(O_2PH_2).H_2O$, $K(O_2PH_2)$, $Na(O_2PH_2).H_2O$, and the ammonium salts $(NH_4)(O_2PH_2)$ and $(NH_3OH)(O_2PH_2)$. They are all readily soluble in water. However, there are no reliable data for their solubilities[114] except for the solubilities of the sodium salt in two glycols. At 25°C $Na(O_2PH_2)$ dissolves in an amount of 33.01 g in 100 g of ethylene glycol and 9.70 g in 100 g of propylene glycol. The heats of solution of the sodium, ammonium, calcium, and barium salts have been determined by Bright and Carson[113].

The following Group II metal hypophosphites are known[80]: $Mg(O_2PH_2).6H_2O$, $Ca(O_2PH_2)_2$, $Sr(O_2PH_2)_2$, $Ba(O_2PH_2)_2$, and $Ba(O_2PH_2)_2.H_2O$. These salts are also extremely soluble in water, the solubilities of $Ca(O_2PH_2)_2$ and $Ba(O_2PH_2)_2$ at room temperature being respectively 17 and 29 g per 100 g of water.

As a rule, other metal hypophosphites are obtained by the reaction of the metal oxide or hydroxide with hypophosphorous acid. In many cases, when the metal can be readily reduced, an oxidation-reduction takes place instead of the formation of the salt. Such processes occur, for example, when copper and silver oxides are used. However, salts such as copper hypophosphite can sometimes be obtained by cooling or by rapid salting-out with alcohol[114].

The physical properties and solubilities of some hypophosphites which we have found in the literature are compiled in Table 4.

Myants and Matrosov[115] studied the infrared spectra of metal hypophosphites and carried out calculations on various vibrational models. The salts were obtained by the double decomposition of the metal with barium and potassium hypophosphites. Drying in a Fisher pistol over P_2O_5 at 77°C (the salts decomposed at a higher temperature) resulted in only a partial loss of the water of crystallisation. The starting materials and the compositions of the salts obtained are listed in Table 5.

Table 5. The hypophosphites which have been synthesised and investigated.

Starting materials	Composition of resulting salt	Composition of salt after drying
$(NH_4)_2SO_4$ and $Ba(H_2PO_2)_2$	$NH_4H_2PO_2$	$NH_4H_2PO_2$
Li_2SO_4 and $Ba(H_2PO_2)_2$	$LiH_2PO_2 \cdot H_2O$	LiH_2PO_2
Na_2SO_4 and $Ba(H_2PO_2)_2$	$NaH_2PO_2 \cdot \frac{1}{3} H_2O$	NaH_2PO_2
$MgSO_4 \cdot 7H_2O$ and $Ba(H_2PO_2)_2$	$Mg(H_2PO_2)_2 \cdot 6H_2O$	$Mg(H_2PO_2)_2 \cdot H_2O$
$ZnSO_4 \cdot 7H_2O$ and $Ba(H_2PO_2)_2$	$Zn(H_2PO_2)_2 \cdot \frac{1}{2} H_2O$	$Zn(H_2PO_2)_2 \cdot \frac{1}{2} H_2O$

Despite the wide variety of metals, the salts investigated have mainly similar spectra. The infrared spectra of the salts in the solid state (KBr discs) have been investigated in the range 400–3000 cm^{-1} on IKS-14 apparatus; the spectra of aqueous solutions have also been obtained for salts which are readily soluble in water. The presence of two bands due to the vibrations of the P–O bond (antisymmetric at 1115–1200 cm^{-1} and symmetric at 1020–1060 cm^{-1}) is characteristic of all the salts; this shows that the structure of the anion with equalised PO

bonds persists in all cases. The bands in the region of 1150–1160, 1080, and 810 cm^{-1}, which are associated with the variation of the angles α and γ in the phosphorus tetrahedron, remain at the same wavenumbers in the spectra of all the salts. For salts which exist in the form of hydrates, the intense bands in the range 2300–2500 cm^{-1} correspond to the vibration frequency of the water of crystallisation involved in strong hydrogen bonding.

The spectra of the alkali metal salts are similar and can be satisfactorily interpreted in terms of the ionic model. Furthermore, they resemble the spectrum of the tetraalkylammonium salt, which is ionic. This makes it possible to attribute an ionic structure to them.

The spectra of a number of the metal salts show changes relative to those of the alkali metal salts (the spectra of the anion), which depend on the nature of the metal: (1) new bands appear in the range 400–600 cm^{-1}; (2) the P–O bond vibration frequencies exhibit an appreciable bathochromic shift. These changes suggest the formation of the M–O coordinate bond and the similarity of the spectra of all the salts (including the alkali metal salts) shows that the equalisation of the PO bonds persists in all cases.

In the spectra of $Mg(H_2PO_2)_2$, $Ca(H_2PO_2)_2$, and TlH_2PO_2 the shift of the P–O vibration frequencies is slight, which demonstrates that the interaction of the metal with the oxygen atoms of the anion is weak. These salts have a nearly ionic structure. A chain model, in which the metal is linked to one of the oxygen atoms of each anion forming the coordination sphere of the metal, has been proposed for other salts with an appreciable amount of covalent character.

Thallium hypophosphite has been obtained and investigated in detail[8]. The authors concluded that the following method is most suitable for the preparation of large amounts of the pure salt: a TlOH solution is prepared by shaking thin plates of metallic thallium with an 80% excess of water, the mixture being simultaneously bubbled with oxygen. The solution is then filtered and saturated with carbon dioxide; after partial evaporation and cooling, Tl_2CO_3 precipitates and may be recrystallised from water. The thallium carbonate crystals are treated with hypophosphorous acid, and the resulting solution is filtered and concentrated *in vacuo*. A large amount of n-propyl or isopropyl alcohol (3 litres of the alcohol per 100 ml of the saturated salt solution) is added to the residual solution and the resulting mixture is cooled at 5°C for one week. The white acicular crystals formed are washed with fresh isopropyl alcohol and the product is then dried in a vacuum desiccator. The melting point of TlH_2PO_2 has been determined as 114°C. The salt is usually seen to undergo a slight decomposition near its melting point. On heating, thallium hypophosphite gradually blackens. Heating for 6–7 h at 95°C is needed before blackening begins. It has been suggested[8] that under these conditions TlH_2PO_2 is slowly oxidised by atmospheric oxygen to thallium phosphite TlH_2PO_3. Thallium hypophosphite is sensitive to light: the same black colour appears in sunlight as on heating.

The existence of the complex Tl^{3+}–$H_2PO_2^-$ is doubtful[116]; the only evidence for it is the properties of the $H_2PO_2^-$ ligand, which forms complexes with other metals. The following mechanism has been proposed for the formation of the complex of $H_2PO_2^-$ with Tl^{3+} before the oxidation stage:

$$Tl^{3+} + H_3PO_2 \rightleftarrows (TlH_3PO_2)^{3+}$$
$$(TlH_3PO_2)^{3+} + H_2O \rightarrow Tl^+ + H_3PO_3 + 2H^+.$$

The decomposition of the complex is not a simple process; it involves the addition of an oxygen atom to form H_3PO_3, which takes place by the substitution of one hydrogen atom linked directly to phosphorus by an OH group of water.

The properties of anhydrous $Co(H_2PO_2)_2$, $Zn(H_2PO_2)_2$, $Fe(H_2PO_2)_2$, $Cu(H_2PO_2)_2$, and $Ni(H_2PO_2)_2$ have been described[117]. The first two compounds were obtained by crystallisation from aqueous solutions. The salts $Fe(H_2PO_2)_2$ and $Cu(H_2PO_2)_2$ have been prepared by precipitation from acetone solution. Iron hypophosphite is a pale-blue powder insoluble in water. Copper hypophosphite is unstable at room temperature and decomposes with formation of metallic copper a few minutes after precipitation.

Nickel hypophosphite, consisting of an amorphous yellow powder, has been prepared by dehydrating the hexahydrate or by precipitation from acetone solution and dehydration in the presence of P_2O_5.[117] The behaviour of cobalt, zinc, iron, copper, and nickel hypophosphites in relation to anhydrous pyridine has been studied. Cobalt and zinc hypophosphites form the readily crystallising compounds $Co(H_2PO_2)_2Py_2$ and $Zn(H_2PO_2)_2Py_2$. They lose pyridine at 20°C, being reconverted into the corresponding hypophosphites.

It has been found that the interaction of M^{2+} (M = Cu, Co, or Ni) and $H_2PO_2^-$ in aqueous solution at 19° ± 2°C, an ionic strength of 3 ($NaClO_4$), and pH 3.7–3.9 results in the formation of relatively unstable hypophosphite complexes[118] The composition of cobalt and nickel hypophosphites with the ratio $M^{2+}:H_2PO_4^- = 1:1$ has been established by the method of continuous variations. The equilibrium constant for the reaction $M^{2+}H_2PO_2^- \rightleftharpoons MH_2PO_2^+$ (for M = Co) has been calculated as 0.82 ± 0.09.[119]

The synthesis of aluminium hypophosphite by two methods has been described[120]. One of them reduces to heating aluminium hydroxide or an aluminium salt solution with 50% H_3PO_2 at 80–90°C for 1 h with subsequent slow precipitation of $Al(H_2PO_2)_3$. The second method involves heating an aluminium salt with sodium hypophosphite, the precipitation being even slower than in the first method. $Al(H_2PO_2)_3$ is insoluble in water and H_3PO_2. It is soluble in warm sodium hydroxide solution, dilute H_2SO_4, and dilute and concentrated HCl. On heating, aluminium hypophosphite decomposes, without fusion, at approximately 220°C with evolution of phosphine and the formation of a reddish-brown deposit. The conditions under which hypophosphorous acid might reduce aluminium compounds to the metal have not been found.

Scandium, yttrium, and lanthanum hypophosphites $R(H_2PO_2)_3$ have been obtained by the interaction of the hydroxides of the first two elements and of $La_2(CO_3)_3$ with hypophosphorous acid[121]. The resulting hypophosphites are crystalline substances insoluble in water and organic solvents. They crystallise in a system with low symmetry. Scandium hypophosphite decomposes *in vacuo* at 350°C, yttrium hypophosphite at 450°C, and lanthanum hypophosphite at 300–350°C. The infrared spectra of scandium, yttrium, and lanthanum hypophosphites have sharp maxima. The spectra recorded in the range 400–3000 cm^{-1} are mainly those of the anions. The influence of the cations on the spectrum is manifested mainly in the range 400–500 cm^{-1}.

The anhydrous lanthanide hypophosphites having the composition $R(H_2PO_3)_3$ and the double hypophosphites $CeR(H_2PO_2)_6$, where R = Er, Tm, Yb, or Lu, have been synthesised[122,123]. The former are crystalline substances with the colour characteristic of the lanthanide ion, which, however, is less intense than that of the nitrates, chlorides,

and other salts. The results of heating to 105–108°C showed that they do not contain water of crystallisation. Heavy lanthanide hypophosphites are less soluble in water than light lanthanide hypophosphites. They tend to form supersaturated solutions, this tendency being most marked for the light lanthanides.

Lanthanum hypophosphite $La(H_2PO_2)_3.H_2O$ and europium hypophosphite $Eu(H_2PO_2)_3.H_2O$ have been investigated by X-ray diffraction[124] and it has been shown that the chemical properties of these compounds in solutions are somewhat different.

Praseodymium hypophosphite $Pr(H_2PO_2)_3$ crystallises in the form of green prisms when a 1% of H_3PO_2 solution is neutralised with praseodymium oxide and then evaporated on a water bath. The salt is fairly sparingly soluble in water.

The double hypophosphites $CeR(H_2PO_2)_6$, where R = Er, Tm, Yb, or Lu, have been analysed chemically and their thermal decomposition has been studied[123]. It has been established that the decomposition takes place instantaneously in the temperature range 300–370°C. The decomposition products are oxidised in the range 440–600°C.

VII. METAL HYPOPHOSPHITE COMPLEXES

The existence in solution of cationic complexes $MH_2PO_2^{2+}$ formed by lanthanide and hypophosphite ions has been confirmed spectrophotometrically for praseodymium, neodymium, and erbium. The equilibrium constants and the formation constants of the complexes have been calculated[125]. The interaction of lanthanide ions with hypophosphorous acid was studied using an SF-10 recording spectrophotometer. The absorption spectra of solutions of praseodymium(III), neodymium(III), and erbium(III) complexes were recorded in the ranges 420–505, 490–615, and 500–560 nm respectively 10 min after mixing the solutions (this time interval was sufficient for equilibration). The absorption spectra do not change in the course of the next 2–3 h, but for an $H_3PO_2 : M^{2+}$ ratio exceeding 8 or at pH 3.0 a precipitate is formed.

The optical densities of solutions of the hypophosphite complexes at the absorption band maxima of the Pr^{3+} and Nd^{3+} ions are lower and in the case of Er^{3+} higher than the optical densities D_{chl} of solutions of their chlorides. The Pr^{3+} and Nd^{3+} absorption band maxima undergo bathochromic or hypsochromic shifts. The split erbium band has maxima at 522.5 and 519 nm. A study of the influence of the pH on ΔD at the absorption band maxima showed that the formation of lanthanide complexes of $H_2PO_4^-$ begins at a pH greater than 1, reaching a maximum at pH 2.5 for praseodymium and neodymium and at 1.6 for erbium. When the pH of solutions of the praseodymium and neodymium complexes is greater than 6.5 and that of the erbium complex greater than 3, precipitates are gradually deposited from the solutions at a rate which is higher the higher the pH and the greater the $H_2PO_2^- : M^{3+}$ ratio.

The compositions of the complexes have been investigated[125] spectrophotometrically by the isomolar series method and by the restricted logarithmic method. Experiments were performed at pH 2.9–3.4 where the difference between the optical densities of solutions of the complexes reaches a maximum. The formation of highly dissociated complexes with the probable component ratio $H_3PO_2^- : M^{3+} = 1 : 1$ has been established.

The reaction between lanthanide ions and hypophosphorous acid can be represented by the equation

$$M^{3+} + H_3PO_2 \rightleftarrows MH_2PO_2^{2+} + H^+.$$

The values of $\lg K_{eq}$ and $\lg K_{form}$ obtained are listed in Table 6, which shows that those for the praseodymium, neodymium, and erbium complexes differ insignificantly from one another.

Table 6. The logarithms of the equilibrium constants and the formation constants of lanthanide complexes of H_3PO_2.

Complex	K_{eq}	K_{form}
$PrH_2PO_2^{2+}$	0.23±0.03	1.33±0.03
$NdH_2PO_2^{2+}$	0.00±0.04	1.10±0.04
$ErH_2PO_2^{2+}$	0.37±0.03	1.47±0.03

The kinetics of the formation of iron[126] and chromium[127] monohypophosphite complexes have been studied. The existence of the complexes $CrH_2PO_2^{2+}$ and $Fe(H_2PO_2)_2^{2+}$ has been confirmed and their stability constants have been determined. The preparation of tin(IV) hypophosphite has been described[128]. A saturated solution of SnO in H_3PO_2 was saturated with oxygen until colourless $Sn(H_2PO_2)_4$ crystals formed, this being the first example of a solid compound containing tin(IV) and an anion with a high reduction potential. The possibility of the formation of zirconium and hafnium hypophosphite complexes has been studied. It has been shown by ion exchange[129] that the anionic complexes $[Zr(H_2PO_2)_6]^{2-}$ and $[Hf(H_2PO_2)_6]^{2-}$ are formed when hydrated zirconium(IV) and hafnium(IV) oxides are dissolved in an aqueous H_3PO_2 solution (maximum concentration 0.3 N).

The formation of insoluble compounds of the type $M[Zr(H_2PO_2)_6]$ and $M[Hf(H_2PO_2)_6]$ when bivalent metal salts are added (M = Mg, Ca, Mn, Co, Ni, Fe, Zn, or Cd) is of interest. It has been shown[129] that these insoluble bivalent metal hypophosphitozirconates and hypophosphitohafnates do not contain water and decompose at 210–300°C. Apart from the calcium salt, they are all isomorphous. According to infrared spectroscopic data, both terminal and bridging H_2PO_2 groups have been detected in $M[Zr(H_2PO_2)_6]$ and $M[Hf(H_2PO_2)_6]$. Consequently the hypophosphitozirconates and hypophosphitohafnates are polycondensed complexes. It has been found[130] that H_3PO_2 forms with molybdenum(VI) a complex having a high optical density at 400 nm whatever the acid concentration, while the complex with PO_4^{3-} is not formed at a solution acidity of about 1.6 N. A spectrophotometric method for the determination of hypophosphite in the presence of phosphates has been developed on this basis.

Like phosphites, hypophosphites form addition products[131] with hydrogen halides (HCl, HBr, and HI). Whereas phosphates can combine with three molecules of the hydrogen halide, hypophosphites and phosphites can combine with two molecules. A typical compound of this type is $Cd(H_2PO_2)_2.2HCl$. In these compounds the hydrogen halide is linked to the hypophosphite molecule, similarly to water in hydrates, i.e. is coordinated to the metal ion.

Interesting germanium(II) complexes have been described[132]: $Ge(H_2PO_2)_2.GeCl_2$ and $3Ge(H_2PO_2)_2.GeBr_2$. The former salt (m.p. 124°C) was synthesised by heating

activated germanium oxide, obtained by dissolving the normal oxide in alkali and reprecipitating it with 6 *N* HCl and 50% H_3PO_2 in the course of 30 min. After allowing the mixture to stand for 12 h, the crystals were separated, washed with dilute H_3PO_2 and absolute alcohol, and dried *in vacuo* at room temperature. The latter salt (m.p. 129°C) was obtained using GeO, 35% HBr, and 50% H_3PO_2. Crystals separated on slow cooling. The compounds obtained are extremely stable in air, but are hydrolysed in water, forming germanium hydroxide.

When germanium dioxide is heated with H_3PO_2, it is reduced, dissolving with formation of a yellow-green solution. This behaviour is the opposite to that of SnO_2, which, although soluble in H_3PO_2, is not reduced to the bivalent state in the absence of HCl.[132] Everest[133] states that the double salts $Sn(H_2PO_2)_4.SnCl_4$ and $Sn(H_2PO_2)_2.SnCl_2$ exist.

VIII. REDUCING PROPERTIES OF THE HYPOPHOSPHITE ION

Many studies have been made on the reducing properties of hypophosphite ions. Pyrolysis of NaH_2PO_2 in the presence of LiH (molar ratio 1 : 22) or LiOH (molar ratio 1 : 5) has been investigated in the range 210–250°C.[132] The possibility of the following reactions has been suggested:

$$NaH_2PO_2 + LiH \rightarrow NaHPO_2 + Li + H_2 , \quad (15)$$

$$NaH_2PO_2 + 2LiH \rightarrow NaPO_2 + 2Li + 2H_2 , \quad (16)$$

$$6NaH_2PO_2 + 3LiH \rightarrow 2Na_3PO_4 + P_4H_4O + 3LiOH + H_2 , \quad (17)$$

$$NaH_2PO_2 + 4LiH \rightarrow PLi_3 + NaOH + LiOH + 3H_2 , \quad (18)$$

$$NaH_2PO_2 + LiOH \rightarrow NaLiHPO_3 + H_2 , \quad (19)$$

$$NaPO_2 + LiOH \rightarrow NaLiHPO_3 , \quad (20)$$

$$NaH_2PO_2 + 3LiOH \rightarrow NaLi_3H_2PO_4 + 2H_2 , \quad (21)$$

$$2NaH_2PO_4 \rightarrow PH_3 + Na_2HPO_4. \quad (22)$$

The compound P_4H_4O, obtained in reaction (17), is a mixture of red polymeric products. It is insoluble in water, acids, and organic solvents. It has been shown[134] that P_4H_4O is satisfactorily described by the formula $(P_4H_4O)_n$. The possible structure of $(P_4H_4O)_n$ has been considered on the basis of the infrared spectra and possible structural formulae, containing the P–P bond, have been put forward. It has been suggested that P–O–P or –P=O and HO–P– linkages may be formed. P_4H_4O is not formed in the interaction of NaH_2PO_2 with LiOH.

The reduction of $K_3[Co(CN)_6]$ by hypophosphorous acid in 1 *N* HCl solution in an atmosphere of nitrogen, resulting in the formation of $Co(CN)_2.2H_2O$, has been studied[135]. The hypothesis that the reduction reaction proceeds via the intermediate complexes $[Co(CN)_5.OP(O)H_2]^{4-}$ or $[(CN)_5CoOPH_2OCo(CN)_5]_n$ has been confirmed by infrared spectra, which contain absorption bands characteristic of the P–O and P–H groups.

The high reducing capacity of the hypophosphite ion constitutes the basis of many methods for its determination. Thus a procedure has been developed[135] for potentiometric titration with vanadate of hypophosphite and phosphite in their mixtures, based on the oxidation of $H_2PO_2^-$ to PO_4^{3-} (via HPO_3^{2-}) by vanadate in the presence of a silver salt; in the absence of silver, phosphite is not oxidised to PO_4^{3-}.

A volumetric method for the determination of hypophosphite with iodine has been described[137]. It consists in the oxidation of hypophosphite to phosphite:

$$H_3PO_2 + I_2 + H_2O \rightarrow H_3PO_3 + 2HI.$$

Under certain conditions, the resulting phosphite may be oxidised by iodide to phosphate:

$$H_3PO_3 + I_2 + H_2O \rightarrow H_3PO_4 + 2HI.$$

In a strongly acid medium the first reaction mainly occurs.

A procedure has been developed[138] for the determination of hypophosphite ions in acid chemical nickel-plating solutions based on weighing the nickel–phosphorus coating obtained as a result of the reaction of Ni^{2+} by hypophosphite. Phosphite (up to 50 g litre^{-1}) and reducing agents do not interfere with the determination.

It has been established[139] that in a borate buffer IO_4^- oxidises $H_2PO_2^-$, HPO_3^{2-}, SeO_3^{2-}, and TeO_3^{2-} on heating and in all cases IO_3^- is formed. The excess IO_4^- may be titrated iodometrically in a buffer medium and the content of any of the above substances can thus be found. A procedure has been proposed for the photometric determination[140,141] of $H_2PO_2^-$, based on the decrease of the optical density of the solution at 530 nm due to the reduction of Fe^{3+} to Fe^{2+} by the hypophosphite ion.

Sodium hypophosphite may be determined[142], after the preliminary removal of iron from solution, by oxidising NaH_2PO_2 with an iron(III) salt solution, this being followed by the titration of the Fe^{2+} formed with a cerium(IV) sulphate solution. The kinetics and mechanism of the oxidation of phosphite by cerium(IV) in sulphuric acid solution have been studied[143]. Conditions have been described for the oxidation of hypophosphite ions by various oxidants: nitric acid[144], permanganate[145,146], cerium(IV) salts[147,148], dichromate solution in the presence of silver ions[149], bromide-bromate[150], an iron(III) salt[151], and persulphate (catalysed by bivalent copper in perchloric acid solution)[152].

Organic derivatives of hypophosphorous acid—phosphinous and disubstituted phosphinic acids—are of interest. One or two hydrogen atoms attached to phosphorus in hypophosphorous acid can be substituted by alkyl or aryl groups. When one hydrogen atom is substituted, the resulting compounds are called alkylphosphinous or phosphinous acids RHPOOH. Little is known about the monoesters of these acids, but a number of diesters have been obtained. The acids formed as a result of the substitution of two hydrogen atoms attached to phosphorous in hypophosphorous acid are called dialkylphosphinic (diarylphosphinic) acids or "secondary" phosphinic acids.

The free acids $R_2P(O)(OH)$ and the corresponding esters $R_2P(O)(OR)$ are known.

IX. THE APPLICATIONS OF HYPOPHOSPHITES

From the economic point of view, the applications of hypophosphites for the surface treatment of metals are the most important[153]. This advanced method was proposed in the USA after the Second World War[154] and was subsequently extended, investigated theoretically, and continually improved[155].

Investigations showed[156–159] that metallic plates can be coated chemically by nickel, cobalt, or their alloys with the aid of hypophosphite ions, the resulting thin coating (less than 0.025 mm) being extremely hard, non-porous, and strongly attached to the metal. The thickness of the layer of deposited metal may be regulated. A great advantage of the method is the possibility of treating also non-metallic materials—ceramics, glass, and plastics. In semiconductor engineering it is possible to deposit metallic contacts directly onto ceramics or other materials in the manufacture of transistors[159].

Hypophosphites are also used for the electroplating of various articles[160,161].

The reducing properties of hypophosphites permitted their use in the manufacture of explosives[160]. For example, a mixture of equal amounts of barium hypophosphite and potassium chlorate, the latter subjected to preliminary drying at 100°C, rapidly ignites in open air with a weak explosion. In a closed vessel the mixture detonates. It is readily ignited by an electric spark and is very sensitive to impact and friction.

In view of the use of hypophosphites in pharmaceutical practice at the end of the 19th century, their toxicity has been investigated in very great detail[163-167]. No evidence indicating their toxicity to mammals has been obtained; in the mammallian organism they remain unchanged and are rapidly eliminated.

Hypophosphites have been recently finding increasingly frequent applications in analytical chemistry. Thus a method employing hypophosphite has been developed[168] for the titrimetric determination of iron in the presence of copper ions as the catalyst.

Reactions of Electronically Excited Radicals and the Quenching of Excited States by Radicals

A.I.Bogatyreva (deceased) and A.L.Buchachenko

The reactions of electronically excited radicals of different types in liquid and solid phases and the electronic structures of the excited radicals and their kinetic characteristics are discussed. A relation is established between the type of excitation and the type of chemical reaction of the excited radicals. The kinetics and mechanisms of the quenching of excited singlet and triplet states by radicals in solid and liquid phases are discussed.
The bibliography includes 160 references.

I. INTRODUCTION

The interest in the reactions of electronically excited radicals and quenching processes involving radicals has been aroused by the following factors. Firstly, in electronic excitation the atomic skeleton of molecules and radicals changes little; major rearrangements occur only in the electron shell. A consequence of these electronic transformations of the radical is a change in its reactivity. Comparison of the reactivities of radicals in the ground and excited states and determination of a relation between the nature of the excited state and the nature of its chemical reactions is of significant importance for the theory of structure and reactivity. Secondly, excited radicals play a definite role in the degradation of polymers and it is important to know their place and role in the solution of problems concerned with the photoresistant and photolabile polymers. Thirdly, high (nearly unity) quantum yields of reactions are characteristic of radicals and one cannot, therefore, rule out the possibility that radical systems may be promising from the standpoint of utilising solar energy and developing effective methods for its trapping and transformation.

These problems have been studied mainly by empirical procedures, because the reactions of the electronically excited radicals are highly varied and it is extremely difficult to predict theoretically the mode and direction of the reaction and even more so to derive its quantitative characteristics.

This paper surveys the available experimental results obtained for chemical reactions of electronically excited radicals in solid and liquid phases, and an attempt is made to give a general account of such reactions and to establish certain relations. Furthermore, the review deals with the quenching of excited molecules by radicals and with the quenching of excited radicals.

II. PHOTOCHEMICAL REACTIONS OF RADICALS IN THE SOLID PHASE

1. Allyl Radicals

Absorption bands in the region of 230–270 nm, [1-3] 310 nm, [3] 408 nm, [4] and 500 nm [5] have been detected in the absorption spectra of allyl radicals. Quantum-chemical calculations on allyl radicals predict the presence of two absorption bands—in the long-wavelength region with $\lambda_{max} \simeq 450$ nm (a low-intensity electronic transition which is symmetry forbidden), and in the short-wavelength region with $\lambda_{max} \simeq 220$ nm, ($\epsilon \simeq 10^3$–10^4 litre mole^{-1} cm^{-1}). [6-10] Both bands are due to the $\pi \rightarrow \pi^*$ transition. The electronic ground state of the allyl radical is $(b_1)^2 (a_2)$, where b_1 and a_2 are bonding and antibonding orbitals (Fig. 1). The electron transitions from b_1 to a_2 and from a_2 to the antibonding orbital $\bar{b}_1$ give rise to excited states of the radical.

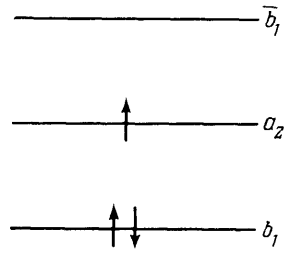

Figure 1. Schematic illustration of the molecular orbitals of the allyl radical.

The photochemical reactions of allyl radicals due to the π–π^* electronic transition can occur by the following mechanisms: (1) intra- or inter-molecular transfer of a hydrogen atom with transformation into an alkyl radical; (2) dissociation of the alkyl radical with elimination of a hydrogen atom.

The photochemical reactions of allyl radicals with γ-irradiated olefins have been investigated[9,10]. The allyl radical CH_2=$CMeCH_2CHMe$ (A), which is transformed under the influence of ultraviolet light (λ = 2537 Å) into the alkyl radical CH_2=$CMeCH_2\dot{C}HMe$ (B) was detected by ESR in 2-methylpent-1-ene (2MP-1) γ-irradiated at 77 K. According to the authors, the photochemical conversion of allyl radicals into alkyl radicals occurs either intramolecularly or intermolecularly. This alternative holds also for all the radicals investigated by Roginskii[11] and

Hamill[12]. To elucidate the possibility, in principle, of an intermolecular transfer of hydrogen atoms, a study was made of the effect of light on the radicals $\dot{C}H_2-CH=CH_2$ formed on γ-irradiation of dilute solutions (frozen glasses) of allyl chloride and allyl bromide in 3-methylpentane (3-MP) [13] and other matrices. On γ-irradiation, allyl radicals are formed as a result of the dissociative capture of slow electrons via the mechanism

$$CH_2=CH-CH_2X + e \rightarrow CH_2=CH-\dot{C}H_2 + X^- \ .$$

Under the influence of light with $\lambda \leqslant 410$ nm, the concentration of allyl radicals falls to zero and 3-MP alkyl radicals appear; the overall concentration of radicals does not change.

The same behaviour has been observed also in other matrices: the decrease in the concentration of allyl radicals under the influence of light is accompanied by a parallel increase of the concentration of alkyl radicals derived from the solvent. These results show that the reactions of allyl radicals proceed without intramolecular isomerisation.

However, two variants of such transformation are possible; the intermolecular abstraction of hydrogen by the excited allyl radical and the dissociation of the latter followed by the interaction with a matrix molecule of the hydrogen atom formed on dissociation. In the former case molecular hydrogen is not formed in the photochemical reaction, while in the latter one H_2 molecule should be evolved for each allyl radical reacting. Gas-chromatographic determination of the yield of molecular hydrogen after the photochemical reaction of allyl radicals showed that the latter do not dissociate, i.e. the allyl → alkyl transformation proceeds via an intermolecular transfer of a hydrogen atom:

$$CH_2=CH-\dot{C}H_2 \xrightarrow{rH,h\nu} CH_2=CH-CH_3 + \dot{r} \ ,$$

where rH is a hydrocarbon.

The photochemical conversion of allyl radicals has also been investigated in olefins (dec-1-ene, oct-2-ene, hept-1-ene, hex-1-ene, and pent-1-ene)[14]. The radiolysis of these olefins results in the formation of alkyl radicals of two types—terminal and central. After being kept for a long time in liquid nitrogen, they are converted into allyl radicals, which are reconverted into alkyl radicals under the influence of light. It is suggested that the transformation occurs as a result of an intramolecular transfer of a hydrogen atom.

To confirm the mechanism involving an intermolecular transfer of a hydrogen atom, a study was made[15] of the effect of light on the allyl type radicals $CH_2=CH-\dot{C}HR$ ($R = C_2H_5$, C_3H_7, or C_4H_9) stabilised in the 3-methylpentane matrix. These radicals were obtained by the radiolysis of solutions of olefins in 3-methylpentane. Under the influence of light, allyl radicals are destroyed and alkyl radicals derived from 3-methylpentane are formed. Molecular hydrogen is not formed in the photolysis of the radicals. Thus in this case too the allyl → alkyl transformation takes place as a result of an intermolecular transfer of a hydrogen atom. Similar results were obtained in another study[16], where the photochemical conversion of radicals in the γ-irradiated isobutene–3-methylpentane system was investigated.

We shall now consider the photochemical reactions of radicals in polymers. Alkyl, allyl, and polyenyl radicals, which may be determined and distinguished on the basis of their ESR spectra, are stabilised in γ-irradiated polyethylene (PE) and polypropylene (PP).[14,16-28] When γ-irradiated polyethylene specimens are kept at room temperature, alkyl radicals are converted into the more stable and long-lived allyl radicals. Under the influence of ultraviolet light ($\lambda = 254$ nm) at 77 K, allyl radicals are reconverted into alkyl radicals[1,17,18], but only up to a limit[1]. The overall concentration of radicals during irradiation remains constant under these conditions.

Fig. 2 presents kinetic curves for the photochemical destruction of allyl radicals and the accumulation of alkyl radicals at 77 K and 25 °C.[1] The limiting ratio of the concentration of alkyl and allyl radicals is independent of the intensity of light and amounts to 43 : 57. The rate of formation of alkyl radicals is proportional to the light intensity and is independent of temperature. The quantum yield of the conversion of the radicals amounts to about 0.1. According to the authors[1], the mechanism of the photochemical reaction involves the transfer of a hydrogen atom via the polymer macromolecule (migration of the valence via the chain):

$$\sim CH_2\dot{C}HCH=CHCH_2CH_2 \sim \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \sim CH_2\dot{C}HCH_2CH=CHCH_2 \sim \ .$$

However, bearing in mind the fairly reliable results obtained in studies on the photochemical reactions of low-molecular-weight allyl radicals, the mechanism involving an intermolecular transfer of a hydrogen atom should probably be adopted in this case too.

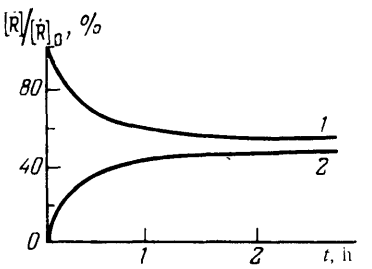

Figure 2. Kinetic curves for the photochemical destruction of allyl radicals and for the accumulation of alkyl radicals: 1) allyl; 2) alkyl.

Since the limiting ratio of the concentrations of alkyl and allyl radicals is independent of the light intensity, one may conclude that the photochemical equilibrium $R^{\cdot}_{all} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^{\cdot}_{alk}$ is established, the rate constants for the forward and reverse reactions depending on the light intensity, i.e. the alkyl → allyl transformation is also a photochemical reaction. This result conflicts with data for the kinetics of the photochemical reactions of allyl radicals in polypropylene[29], where the rate of the photochemical transformation of such radicals into alkyl radicals is independent of temperature and varies linearly with light intensity. As in polyethylene, allyl radicals in polypropylene are not fully converted into alkyl radicals, the limiting concentration of the latter obeying the relation

$$[R^{\cdot}_{alk}]_{lim} = \frac{k_1 I [R]_0}{k_1 I + k_2} \ ,$$

where $[R^{\cdot}]_0$ is the initial concentration of radicals and I the light intensity. The constant k_2 is independent of

light intensity, i.e. the reverse reaction $R^{\cdot}_{alk} \rightarrow R^{\cdot}_{all}$ is not photochemical (in conflict with the previous result). However, if it is assumed that the reaction $R^{\cdot}_{alk} \rightarrow R^{\cdot}_{all}$ is a dark process, then it is necessary to assume that the dark reaction proceeds at a high rate, comparable to that of the photochemical reaction $R^{\cdot}_{all} \rightarrow R^{\cdot}_{alk}$ (this follows from the fact that the limiting concentrations of $R^{\cdot}_{all}$ and $R^{\cdot}_{alk}$ are similar). The hypothesis that at the instant of the photochemical transformation $R^{\cdot}_{all} \rightarrow R^{\cdot}_{alk}$ the alkyl radical contains an excess of vibrational energy and for this reason is reconverted into the initial allyl radical is likewise unjustified and cannot account for the attainment of limiting concentrations of $R^{\cdot}_{all}$ and $R^{\cdot}_{alk}$.

Thus the kinetics and mechanism of the photochemical reactions $R^{\cdot}_{all} \rightleftharpoons R^{\cdot}_{alk}$ have been inadequately investigated. Both the forward and reverse reactions probably involve photochemical stages. This is supported by the finding that, at a higher temperature (above 170 K), allyl radicals undergo complete photochemical recombination under the influence of light (by a second-order reaction)[29]. Evidently, the recombination proceeds via photochemically induced relay transfer of valence with participation of alkyl radicals.

2. Polyenyl Radicals

In polyene radicals the energy of the lowest excited state ($\pi-\pi^*$ transition) depends on the number of π electrons in the radical[39]:

$$h\nu = 4\beta \sin \frac{\pi}{2(N+1)} ,$$

where N is the number of π electrons in the radical and β is the resonance integral. Evidently, with increase of the number of π electrons in the radical, the absorption bands should be displaced towards longer wavelengths. Such data for certain conjugated radicals are presented in Table 1.

Table 1. The parameters of the absorption spectra of certain conjugated radicals.

Radical	Matrix	λ^*_{max}, nm	References
$CH_2{=}CH{-}\dot{C}H_2$	Allyl chloride in 3-MP, allyl bromide in cyclohexane	232, 225, 220	3,6,13
Allyl	PP	255	2,30,31
	PE	258	2,30—32
Dienyl	PP	310	2,30—32
	PE	285	2,30—32
Trienyl	PP	368	2,30—32
	PE	323	2,30—32
Tetraenyl	PE	359	2,30—32
Pentaenyl	PE	396	2,30—32
	Cyclohexane	338	33
	Benzene	315	5,34,35
	Toluene	310	34,36—38

*The λ_{max} for the intense absorption bands of radicals only are quoted.

The positions of the electronic levels are relatively insensitive to substituents. For example, the substitution of hydrogen atoms in the allyl radical shifts the maxima of the short-wavelength bands by 10–12 nm.[5] Different substituents (Cl, Br, OH, alkyl, etc.) cause little change in the positions of the electronic levels of the benzyl and cyclohexadienyl radicals[34,37-39].

The photochemical reactions of polyenyl radicals have been investigated in greater detail in polyethylene and polypropylene. Such radicals, having the general formula

$$\sim CH_2{-}\dot{C}H(CH{=}CH)_n CH_2 \sim \text{ (in PE) and } \sim CH_2{-}\dot{C}Me(CH{=}CMeCH_2)_n \sim$$

are formed when polymers are treated with high radiation doses (about 100 Mrad and more), the number of polyenyl radicals with higher values of n increasing as the dose is increased. The ESR spectra of polyenyl radicals consist of a singlet line, which becomes narrower with increase in the length of the conjugation chain.

During the photochemical reaction the conjugation energy of the π-electron system diminishes[29]. With increase in the length of the conjugation chain, the difference between the conjugation energy of the polyenyl radical and the polyene molecular chain increases in absolute magnitude. The difference ΔG, calculated by Hückel's method, is described by the equation

$$\Delta G = 2\pi\left[\sin^{-1}\frac{\pi}{2n} - \cot\frac{\pi}{2(n+1)}\right].$$

It follows from this that there exists a critical value of n in the polyenyl radical for which the energy of the absorbed light quantum is insufficient to compensate the difference between the conjugation energies of the polyenyl radical and the polyene chain. Calculations showed that, for $n > 5$, the photochemical transformation of polyenyl radicals already becomes unfavourable on energy grounds and such radicals should not be converted into alkyl radicals.

In order to determine experimentally the light wavelength at which the transformation of polyenyl radicals begins, γ-irradiated polypropylene specimens were illuminated at 77 K through various light filters. An appreciable change in the ESR spectrum was observed at $\gamma \geqslant 380$ nm. Under the influence of shorter-wavelength light, the ESR spectrum becomes better resolved. The 380 nm light wavelength is apparently limiting; it corresponds to absorption by the polyenyl radical with $n = 3$ ($\lambda_{max} = 385$ nm). With increase of radiation dose, the number of polyenyl radicals having $n > 3$ increases and there is a corresponding decrease of the fraction of radicals having $n \leqslant 3$, which are incapable of being converted into alkyl radicals. For radiation doses in excess of 500 Mrad, photochemical reactions of polyenyl radicals were not observed. This is probably because such doses lead to the formation of appreciable concentrations of polyenyl radicals with $n \geqslant 5$.

3. Alkyl Radicals

The unpaired electron in alkyl radical occupies the p orbital of the carbon atom; its energy level is located between the σ and σ^* levels. Electronically excited states of radicals can be obtained in $\pi-\sigma^*$ and $\sigma-\pi^*$ transitions, where σ and σ^* are the bonding and antibonding orbitals of σ bonds. These transitions are forbidden on symmetry grounds and the corresponding absorption bands are of low intensity. However, they have been observed for certain alkyl radicals. Thus, flash photolysis of $HgMe_2$ [40,41] led

to the observation of the spectrum of the $\dot{C}H_3$ radical. The longest-wavelength absorption band of the radical is located near 216 nm. It is suggested that in the ground and excited states the radical has a planar configuration (sp^2 hybridisation). Weak absorption bands have also been observed in the spectra of other alkyl radicals[42-44]. Thus alkyl radicals absorb light in the range 200–240 nm.

On photoexcitation, alkyl radicals can dissociate, isomerise, or enter into substitution reactions. The photoinduced isomerisation of the t-butyl radical into the isobutyl radical in γ-irradiated isobutyl bromide has been investigated. The ESR spectrum of the t-butyl radical consists of 10 lines with a splitting constant of 25 G and a binomial intensity distribution. On illumination with ultraviolet light at 77 K, the spectrum is converted into one with five lines, i.e. the t-butyl radical isomerises to the isobutyl radical:

$$CH_3-\dot{C}Me_2 \underset{\text{dark}}{\overset{h\nu}{\rightleftharpoons}} \dot{C}H_2-CHMe_2 \quad .$$

The reverse reaction takes place in the dark.

The t-butyl cation is known[45] to have an intense absorption band at 290–295 nm. On the basis of the properties of molecular orbitals, the t-butyl radical presumably also absorbs ultraviolet light at 290 nm, which gives rise to the photoinduced isomerisation.

When isobutene[43] was γ-irradiated, the ESR spectrum of isobutyl radicals CH_2-CHMe_2 was observed, together with a singlet line, which the authors attribute to the 2-methylallyl radical $\dot{C}H_2-CMe=CH_2$. Under the influence of light ($\lambda > 340$ nm), the t-butyl radical is formed, its appearance being associated with the reaction of the electronically excited allyl radical with matrix molecules. On subsequent irradiation with light of shorter wavelengths ($\lambda \leq 340$ nm), the t-butyl radical isomerises to the isobutyl radical.

When the copolymer of tetrafluoroethylene (TFE) and hexafluoropropene was γ-irradiated[46], an ESR spectrum consisting of eight hyperfine structures (HFS) lines with a splitting of 29 G, due to the radical $\sim CF_2-\dot{C}(CF_3)-CF_2\sim$, was recorded. This radical absorbs light with $\lambda_{max} = 265$ nm, being converted into the radical $\sim CF_2-\underset{\displaystyle \dot{C}F_2}{\underset{|}{CF}}-CF_2\sim$, the spectrum of which consists of three lines (a central singlet and two extreme components with a splitting of about 450 G between the latter). It is suggested that the transformation proceeds via the isomerisation of the excited radical according to the mechanism

$$\sim CF_2-\underset{\displaystyle CF_3}{\underset{|}{\dot{C}}}-CF_2\sim \xrightarrow{h\nu} \sim CF_2-\underset{\displaystyle \dot{C}F_2}{\underset{|}{CF}}-CF_2\sim \quad .$$

Similar transformations of radicals have been observed in polypropylene[43] and have also been explained by isomerisation.

A serious difficulty encountered in the studies discussed above is the lack of a reliable and unambiguous interpretation of the ESR spectra of radicals in solid matrices. In γ-irradiated substances allyl as well as alkyl radicals are formed and one cannot rule out the possibility that the reactions of the former obscure the results of the photochemical transformations of the alkyl radicals. Furthermore, the photochemical reactions of alkyl radicals, which are treated as isomerisations, can be interpreted as intermolecular transfer of a hydrogen atom. For this reason, although the occurrence of photochemical isomerisation is in principle possible, additional evidence is required.

As already stated above, in $\pi-\sigma^*$ excitation of alkyl radicals there is a possibility of a photochemical decomposition of the radicals. A number of studies[47,48] have confirmed this hypothesis. Thus, in the photolysis of polypropylene in the presence of nitroxy-radicals the composition and kinetics of the accumulation of gaseous photolysis products was investigated together with the kinetics of the destruction of the nitroxy-radicals[48]. Hydrocarbons (methane, ethane, propane, propene, and isobutene) were detected in the gaseous products. In the presence of nitroxy-radicals the yield of methane increases by approximately a factor of 250, while the yields of the other products depend little on the presence of these radicals. Under these conditions, the photochemical decomposition of nitroxy-radicals is not accompanied by the formation of methyl radicals from them. Evidently the vigorous formation of methane is due to the photochemical decomposition of polypropylene macroradicals. The latter are formed by the mechanism

$$\dot{R}^* + \sim CH_2-CHMe-CH_2\sim \rightarrow RH + \sim CH_2\dot{C}MeCH_2\sim \,,$$

where $\dot{R}^*$ is an electronically excited nitroxy-radical.

The decomposition of central radicals proceeds when macroradicals absorb a light quantum. Thus an electronically excited radical can decompose at any of the three C–C bonds near the localised free valence. However, the decomposition at two of the bonds leads to the formation of terminal macroradicals, while the decomposition at the third bond yields $\dot{C}H_3$. Terminal radicals undergo cage recombination with a high probability, while the light $\dot{C}H_3$ radical diffuses into the bulk, forming methane. The biradical $\sim CH_2-\ddot{C}-CH_2\sim$ formed is converted into the radical $\sim CH_2-\dot{C}H-CH_2\sim$ as a result of reaction with the polymer, the radical $\sim CH_2-\dot{C}Me-CH_2\sim$ being formed simultaneously. The absorption spectra of alkyl radicals in polypropylene are unknown; presumably they absorb in the same region as t-butyl radicals. A similar conclusion concerning the photochemical decomposition of alkyl radicals in polypropylene was reached in another investigation[49].

In the photolysis of isotactic polypropylene[47] in the range $260 < \lambda < 360$ nm the ESR spectrum reveals the presence of the central radical $\sim CHMe-\dot{C}H-CHMe\sim$. Under the influence of light with $\lambda < 270$ nm, this radical is converted into a methyl radical. A similar reaction has also been observed in polyisobutylene.

Methyl radicals are apparently formed in both cases by the decomposition of alkyl radicals in an excited state with occupied antibonding σ^* orbitals. Under these conditions, the dissociation of C–Me bonds in the radical is accompanied by the rupture of other C–C bonds involving the α-carbon atom with decomposition of the macromolecules. However, owing to cage effects, these processes are less important, while the methyl radical leaves the primary cage comparatively readily and avoids recombination.

The effect of light in the range $240 < \lambda < 270$ nm at 77 K on radicals in γ-irradiated 3-methylpentane, 3-ethylpentane, 3-methylheptane, and 4-methylheptane also causes their decomposition and isomerisation[50]:

$$CH_3\dot{C}HCH\,(CH_3)\,CH_2CH_3 \rightarrow C_2H_5 + \text{molecular products},$$
$$CH_3\dot{C}HCH\,(C_2H_5)\,CH_2CH_3 \rightarrow \dot{C}_2H_5 + \text{molecular products},$$
$$CH_3\dot{C}HCH_2CH\,(CH_3)\,CH_2CH_2CH_3 \begin{cases} \rightarrow \dot{C}_2H_5 + \text{molecular products}, \\ \rightarrow \dot{C}H_2CH_2CH_2CH\,(CH_3)\,CH_2CH_2CH_3 \quad . \end{cases}$$

Considerable amounts of ethane were detected among the gaseous products formed in the photolysis of the radicals[50].

4. Peroxy-radicals

Peroxy-radicals absorb light in the band at 240–280 nm [51,52] owing to the transition of an electron from the n orbital of the oxygen atom to the antibonding π^* orbital ($n-\pi^*$ excitation).

When allyl and polyenyl radicals come into contact with oxygen in γ-irradiated polypropylene, peroxy-radicals are formed[53,54]. Their ESR spectra are identical, consisting of an asymmetric line due to the anisotropy of the g-factor. Under the influence of light with $\gamma > 280$ nm, peroxy-radicals are converted into alkyl radicals, but the overall concentration of radicals remains unchanged. The kinetics of the disappearance of peroxy-radicals are described by the first-order equation

$$ROO^{\bullet} + RH \rightarrow ROOH + \dot{R},$$

the rate of the reaction being independent of temperature. Under the influence of short-wavelength light ($\lambda \leq 280$ nm), the hydroperoxide formed dissociates with formation of free radicals[55].

$$ROOH \rightarrow R\dot{O} + \dot{O}H \quad ,$$
$$\dot{O}H + RH \rightarrow \dot{R} + H_2O \quad ,$$
$$R\dot{O} + RH \rightarrow \dot{R} + ROH \quad .$$

As a result, the experimental overall radical concentration increases almost by a factor of three. In the presence of oxygen, when alkyl radicals are continuously converted into peroxy-radicals, all these reactions lead to a chain process with degenerate photochemical branching.

In consequence of the photochemical reactions of peroxy-radicals, the rate of graft polymerisation increases sharply; thus, at a light intensity of 10^{15} quanta $cm^{-2}\ s^{-1}$ ($\lambda < 300$ nm), the rate constant increases by two orders of magnitude compared with that for the dark reaction.

The oxidation of polytetrafluoroethylene (**PTFE**) subjected to preliminary irradiation *in vacuo* at 300 K results in the formation of the central peroxy-radicals $\sim CF_2-\underset{\underset{O-\dot{O}}{|}}{CF}-CF_2\sim$. Under the influence of light ($\lambda < 280$ nm), these radicals are converted into terminal fluoroalkyl radicals[57,58]. The rate of this reaction obeys first-order kinetics, the effective activation energy being about 1 kcal $mole^{-1}$.[57] The following reaction mechanism has been proposed:

$$\sim CF_2-\underset{\underset{O-\dot{O}}{|}}{CF}-CF_2\sim \rightarrow \sim CF_2\dot{C}F_2 + CO + CF_2O + CF_3CF_2\sim \quad .$$

This process is accompanied by the degradation of the polymer chain: the gaseous photolysis products (CO, CF_2O) were identified mass-spectrometrically[59]. In oxygen the terminal **PTFE** allyl radical is oxidised and converted into the terminal peroxy-radical $\sim CF_2-CF_2-\dot{O}O$, the **ESR** spectrum of which at 77 K is completely identical with that of the central peroxy-radical[60-62]. On illumination *in vacuo*, this radical is reconverted into the initial terminal fluoroalkyl radical. The rate of conversion is described by a first-order kinetic equation with an effective activation energy of about 2–3 kcal $mole^{-1}$. The quantum yield of the destruction of peroxy-radicals is close to unity. It is suggested[62] that terminal **PTFE** peroxy-radicals are converted into terminal alkyl radicals in the following way:

$$\sim CF_2CF_2O\dot{O} \xrightarrow{h\nu} 2CF_2O + \sim CF_2\dot{C}F_2 \quad .$$

The detailed mechanism of the photochemical transformations of peroxy-radicals in **PTFE** is unknown. However, presumably the first stage is, as in polypropylene, the conversion of the peroxy-radical in an electronically excited $n-\pi^*$ state into a peroxide via the mechanism

$$\sim \underset{\underset{O\dot{O}}{|}}{CF_2CFCF_2}\sim \xrightarrow{\sim CF_2\sim} \sim \underset{\underset{OOF}{|}}{CF_2CFCF_2}\sim + \sim \dot{C}F\sim \quad .$$

The fluorine-containing peroxide is probably unstable and decomposes photochemically under the influence of light at longer wavelengths than the polypropylene hydroperoxide:

$$\sim \underset{\underset{OOF}{|}}{CF}\sim \xrightarrow{h\nu} \sim \underset{\underset{\dot{O}}{|}}{CF}\sim + \dot{O}F \quad .$$

The subsequent photochemical decomposition of the oxy-radical leads to the formation of a terminal radical:

$$\sim \underset{\underset{\dot{O}}{|}}{CF_2CFCF_2}\sim \rightarrow \sim CF_2C\begin{matrix}O\\ \diagup\\ \diagdown\\ F\end{matrix} + \sim \dot{C}F_2 \quad .$$

Terminal peroxy-radicals probably decompose similarly:

$$\sim CF_2O\dot{O} \xrightarrow{h\nu} \sim CF_2OOF \xrightarrow{h\nu} \sim CF_2\dot{O} \rightarrow CF_2O + \dot{C}F_2 \quad .$$

In the presence of oxygen all these reactions lead to a branched chain process accompanied by the displacement of the free valence by a relay mechanism and the recombination of the radicals. The photo-induced recombination of peroxy-radicals in **PTFE** has not, in fact, been observed. Determination of the fluoride ions formed on hydrolysis of the gaseous photolysis products from peroxy-radicals established that between 50 and 90 fluoride ions are produced for each peroxy-radical which disappears[52]. This result confirms the chain mechanism of the photochemical reactions of peroxy-radicals.

However, the reaction $R\dot{O}_2 + RH \rightarrow RO_2H + R^{\bullet}$ is probably not the only possible pathway whereby excited peroxy-radicals are destroyed. One cannot rule out also the possibility of the decomposition of radicals via the scheme $R\dot{O}_2^{*} \rightarrow R^{\bullet} + O_2$, for example, or via other mechanisms[63]; the situation in this field is not well defined and clear-cut.

5. Radicals Derived from Alcohols, Ethers, and Carbonyl Compounds

In alcohol and ether radicals $R_1R_2\dot{C}OR_3$ (where R_1, R_2, R_3 are hydrogen atoms or alkyl groups) the lone pair electrons of the oxygen atom are involved in conjugation with the unpaired π electron of the carbon atom and the absorption spectra of these radicals are therefore displaced towards longer wavelengths compared with the spectra of alkyl radicals and alcohol and ether molecules. The absorption band maxima of certain alcohol radicals are listed below.

Radical	λ_{max}, nm	References
$CH_2\dot{O}H$	223	64,65
$CH_3\dot{C}HOH$	231	65,66
$C_2H_5\dot{C}HOH$	250	65
$C_3H_7\dot{C}HOH$	244	65
$C_4H_9\dot{C}HOH$	263	65
$C_5H_{11}\dot{C}HOH$	322	65
$(CH_3)_2\dot{C}OH$	250—400	67

The red limit of the absorption of alcohol and ether radicals is near 340 nm. The extinction coefficients are comparatively small, amounting to about 700–900 litre mole^{-1} cm^{-1}.[65,66] The similarity of the optical absorption spectra of these radicals suggests that, when they absorb light, excited states of the same type are produced. On the basis of the results of CNDO calculations on the $\dot{C}H_2OH$ radical[68], the electronic configuration of its ground state can be formulated in terms of the following sequence of molecular orbitals $(1\sigma)^2\ (2\sigma)^2\ (3\sigma)^2\ (4\sigma)^2\ (1\pi)^2\ (5\sigma)^2\ (2\pi)^1$; the unpaired electron is located in the π orbital (80% at the carbon atom and 20% at the oxygen atom). The transfer of the unpaired electron from the 2% orbital to the lowest vacant orbital (6σ) is responsible for the optical absorption of the $\dot{C}H_2OH$ radical in the region with $\lambda < 340$ nm. The $2\pi \rightarrow 6\sigma$ transition is forbidden on symmetry grounds, in agreement with the low extinction coefficient of the $\dot{C}H_2OH$ radical in the range 200–350 nm. Evidently similar electronic transitions occur also in other radicals derived from alcohols and ethers. The principal photochemical reactions of these radicals involve their photochemical dissociation, the mechanism of which is discussed below.

The photochemical reactions of alcohol and ether radicals have been the subject of numerous investigations[69-98]. The primary radicals are formed in alcohols and ethers either on γ-irradiation or on photolysis in the presence of various additives (peroxides, aromatic compounds, stable radicals, etc.). Together with radicals, electrons giving rise to a singlet ESR spectrum ($g \simeq 2.0015$) are stabilised in all alcohols and ethers after γ-irradiation; they give rise to an intense optical absorption in the range 500–600 nm.[65] Under the influence of visible light, ($\lambda > 500$ nm), they are readily destroyed and only alcohol radicals remain.

Light with $\lambda < 320$–350 nm induces the transformations of primary alcohol radicals into secondary radicals. We shall consider them using as an example the photolysis of methanol radicals. The photolysis of the $\dot{C}H_2OH$ radicals has been studied in greatest detail by Shelimov et al.[76] When the full light of the mercury lamp was allowed to act on H_2O_2 and C_6H_6 solutions in methanol at 77 K, the ESR spectra revealed the presence of $H\dot{C}O$ and $\dot{C}H_3$ radicals. In the dark the concentration of $H\dot{C}O$ radicals remained unchanged, while the $\dot{C}H_3$ radicals were destroyed via the reaction $\dot{C}H_3 + CH_3OH \rightarrow CH_4 + \dot{C}H_2OH$. When illumination was switched on again, the ESR spectrum again revealed the presence of $H\dot{C}O$ and $\dot{C}H_3$ radicals. The $H\dot{C}O$ radicals are destroyed under the influence of light with $\lambda > 320$ nm, by the dissociation reaction

$$H\dot{C}O \xrightarrow{h\nu} \dot{H} + CO \quad , \qquad (1)$$

$$\dot{H} + CH_3OH \rightarrow \dot{C}H_2OH + H_2 \quad . \qquad (2)$$

The second reaction results in an increase of the $\dot{C}H_2OH$ concentration.

Mass-spectrometric analysis of the gaseous photolysis products revealed the presence of H_2 (57%), CO (26%), and CH_4 (17%), the composition of the products being independent of the duration of the irradiation. Shelimov et al.[76] proposed two mechanisms for the photolysis of $\dot{C}H_2OH$. The first involves the dissociation of the C–O bond in the radical and presupposes the following sequence of reactions:

$$\dot{C}H_2OH \xrightarrow{h\nu} \ddot{C}H_2 + \dot{O}H \quad , \qquad (3)$$

$$\ddot{C}H_2 + CH_3OH \rightarrow \dot{C}H_3 + \dot{C}H_2OH \quad , \qquad (4)$$

$$\dot{O}H + CH_3OH \rightarrow \dot{C}H_2OH + H_2O \quad . \qquad (5)$$

In the second mechanism it is postulated that the complex of the radical and the molecule absorbs light:

$$(\dot{C}H_2OH + CH_3OH) \xrightarrow{h\nu} \ddot{C}H_2 + H_2O + H\dot{C}O + H_2 \quad , \qquad (6)$$
$$\ddot{C}H_2 + CH_3OH \rightarrow \dot{C}H_3 + \dot{C}H_2OH \quad .$$

Both mechanisms describe a chain process with photochemical branching: a single paramagnetic species destroyed gives rise to three. Both mechanisms presuppose dissociation with formation of carbene ($\ddot{C}H_2$).

The results of other studies[64,79] in which $\dot{C}H_2OH$ radicals were obtained by the radiolysis of frozen methanol are inconsistent with the conclusions that their photolysis has a branched chain mechanism. It was found that illumination with ultraviolet light leads to a decrease of the concentration of $\dot{C}H_2OH$ and the formation of $H\dot{C}O$ radicals, but the total number of radicals remains unchanged.

In the photolysis of $\dot{C}H_2OH$ radicals[68], a decrease of the overall concentration of paramagnetic species was observed, whence the authors concluded that reactions (3) and (6) are not responsible for the formation of $\dot{C}H_3$, because they should have resulted in an increase of the total number of radicals.

According to Chervonenko et al.[94], the main photochemical process in the photolysis of $\dot{C}H_2OH$ is the dissociation of the radicals at the O–H bond:

$$\dot{C}H_2OH \rightarrow H_2CO + \dot{H} \quad . \qquad (7)$$

This mechanism is supported by the maximum yield of H_2 in the photolysis products of the $\dot{C}H_2OH$ radical relative to other products, and also the finding that large amounts of $\dot{C}_2H_5$ radicals are formed by addition in the photolysis of $\dot{C}H_2OH$ in the presence of ethylene as the acceptor of hydrogen atoms, while the rate of destruction of $\dot{C}H_2OH$ increases markedly owing to the suppression of the competing reaction (2).

The dissociation of the O–H bond in the $\dot{C}H_2OH$ radical is favourable on energetic grounds: its energy is less than 1.5 eV. CNDO calculations on the radical[68] have also shown that, when the π electron is excited to the lowest vacant σ orbital, the O–H bond order diminishes, i.e. the bond is weakened, since this σ orbital is antibonding in relation to the O–H bond.

Thus the dissociation of the O–H bond on π–σ^* excitation of the $\dot{C}H_2OH$ radical constitutes one of the principal mechanisms involved in the transformations of the radical. Other reactions of the radical, leading to the formation of $\dot{C}H_3$, are much less definite and unambiguous.

Two mechanisms have now been proposed for the formation of the methyl radical on excitation of $\dot{C}H_2OH$. The first, involving the dissociation of the radical at the C–O bond, was discussed above and the second proposed by Chervonenko[68], presupposes decomposition according to the following scheme:

$$H_2\dot{C}OH \ldots \underset{\displaystyle CH_3}{\overset{\displaystyle |}{OH}} \xrightarrow{h\nu} H_2CO + H_2O + \dot{C}H_3 \quad . \qquad (8)$$

In this mechanism an important role is attributed to the hydrogen bond between the radical and a neighbouring alcohol molecule.

The first pathway should lead to the "multiplication" of $\dot{C}H_3$ radicals, since the photolysis of $\dot{C}H_2OH$ is a chain process with degenerate photochemical branching. The fact that such "multiplication" is frequently not observed in the photolysis of $\dot{C}H_2OH$ at first sight conflicts with the first mechanism. However, one should bear in mind that according to the photolytic mechanism

$$\dot{C}H_2OH \xrightarrow{h\nu} (\ddot{C}H_2, \dot{O}H) \rightarrow (\dot{C}H_3, \dot{O}H, \dot{C}H_2OH)$$

three radicals are formed in a single "cage" and for this reason the probability of the recombination of any radical pair is high, so that the probability of degenerate branching (i.e. the radical "multiplication" factor) is low. If it is less than the probability of the destruction of radicals as a result of recombination in the bulk phase, a decrease of radical concentration is observed on photolysis. Therefore, the absence of the "multiplication" of $\dot{C}H_3$ radicals on photolysis is not by itself an argument against the first mechanism.

The energy of the C–O bond in the ground state of the $\dot{C}H_2OH$ radical is 3.6 eV, However, CNDO calculation has shown[68] that, on $\pi-\sigma^*$ excitation of the radical, the bond is strengthened and its order increases from 0.40 (in the ground state) to 0.80. The C–O bond is also strengthened on deprotonation of the $\dot{C}H_2OH$ radical, i.e. when it is converted into $\dot{C}H_2O^-$ (in alkaline media). In conformity with this, the yield of $\dot{C}H_3$ radicals in the photolysis of $\dot{C}H_2OH$ in alkaline media decreases. These observations are inconsistent with the first mechanism.

The second mechanism agrees with the facts quoted above and formally provides a quite satisfactory explanation of the composition of the photolysis products. We believe that there is a difficulty in the operation of this mechanism in that the excitation region and the region where the excitation energy is utilised are very remote in the $CH_2OH...\underset{|}{\underset{CH_3}{O}}H$ molecular system. In other words, it is difficult to imagine how the excitation of the CH_2–O fragment in the radical leads to the dissociation of the C–O bond in the alcohol molecule. It is unlikely that the entire process takes place in a single fundamental step. Admittedly it is possible that the excitation energy is transferred from the $\dot{C}H_2OH$ radical to the triplet level of the alcohol molecule with its subsequent dissociation, but the probability of such a spin-forbidden process is hard to estimate. Thus the problem of the mechanism of the formation of $\dot{C}H_3$ radicals on photolysis of $\dot{C}H_2OH$ still remains open.

The photolysis of $CH_3\dot{C}HOH$ radicals in ethanol leads to the formation of $\dot{C}_2H_5$ [79,80,82,88] and $Me\dot{C}O$ radicals (they give rise to an intense asymmetric singlet in the ESR spectrum). H_2, CH_4, CO, C_2H_6, H_2O, and acetaldehyde have been detected in the photolysis products[80,94]. The main pathway in the photochemical transformation of $Me\dot{C}HOH$ radicals involves decomposition at the O–H bond with formation of acetaldehyde and a hydrogen atom:

$$CH_3\dot{C}HOH \rightarrow CH_3CHO + \dot{H} \quad . \qquad (9)$$

Hydrogen is the main product of the photolysis of alcohol radicals and is formed mainly via reaction (9). This conclusion is confirmed by the photolysis of $Me\dot{C}HOH$ at various pH values: in alkaline media, where the radical exists in the form of the radical-anion $CH_3\dot{C}HO^-$, the yield of hydrogen is much lower than in acid media. The quantum yield of reaction (9) has been estimated as (0.3 ± 0.2) from the initial rates of accumulation of H_2.[68]

The rate of formation of H_2 in ethanol is much higher than the rate of destruction of $Me\dot{C}HOH$, i.e. the photolysis of the radicals is a chain process in which photochemical chain propagation stages [reaction (9)] and dark stages, involving the regeneration of the initial radical, alternate:

$$\dot{H} + CH_3CH_2OH \rightarrow H_2 + CH_3\dot{C}HOH \quad . \qquad (10)$$

Chain termination proceeds mainly via radical recombination.

Reaction (9) results in the formation of acetaldehyde, the photodissociation of which leads to the appearance of acyl radicals $Me\dot{C}O$. Apart from $\dot{C}_2H_5$ and $Me\dot{C}O$, methyl radicals have also been detected in the photolysis of alcohol radicals. They are formed on photodissociation of the $Me\dot{C}O$ radical and not via the dissociation of the C–O bond in the alcohol radical via the mechanism

$$CH_3\dot{C}HOH \rightarrow \dot{C}H_3 + \ddot{C}HOH \quad , \qquad (11)$$

which has been discussed in a number of investigations[73,82]. Indeed, methane was detected in the reaction products only after the decomposition of $Me\dot{C}O$ radicals by visible light[68].

$\dot{C}_2H_5$ radicals may be formed in the photolysis of alcohol radicals via two mechanisms [reactions (3), (4), and (8)], which were discussed above. The quantum yield in the formation of $\dot{C}_2H_5$ is 0.03 ± 0.02, i.e. is an order of magnitude lower than the quantum yield of the main reaction [reaction (9)].

The photolysis of alcohol radicals in deuterated ethanols[78] C_2H_5OD, CH_3CD_2OH, CD_3CH_2OH, and CD_3CD_2OH results in the formation of the radicals $\dot{C}_2H_5$, $CH_3\dot{C}D_2$, $CD_3\dot{C}H_2$, and $CD_3\dot{C}D_2$ respectively. However, these results do not allow an unambiguous choice of the mechanism of their formation.

The photolysis of the primary radicals $(CH_3)_2\dot{C}OH$ in isopropyl alcohol results in the formation of $(CH_3)_2\dot{C}H$ [67,79,99] and $R\dot{C}O$ radicals do not appear. The main photolysis products are H_2, C_3H_8, and acetone[68,98]. The primary radicals are photolysed by the same mechanism as in the case of other alcohols. In contrast to straight-chain alcohols, acetone is formed in this case and not an aldehyde. Since aldehydes are precursors of $R\dot{C}O$ radicals, their absence in the photolysis of $(CH_3)_2\dot{C}OH$ in isopropyl alcohol is quite reasonable.

On prolonged photolysis of $(CH_3)_2(\dot{C}H_2)COH$ radicals in t-butyl alcohol[68,73,84,98], new radicals are not formed and gaseous products have also not been observed. The stability of these radicals towards ultraviolet light (λ = 310 nm) can be accounted for by the absence of optical absorption by these paramagnetic species in the region $\lambda \geqslant 300$ nm.[100]

The photolysis of the primary radicals $Me\dot{C}HOCH_2CH_3$ derived from ethyl ether leads to the formation of the $\dot{C}_2H_5$ and $Me\dot{C}O$ radicals[68,82]. The main photolysis product is ethane, and molecular hydrogen is not formed. This implies that the principal mechanism of the photolysis of these radicals is their decomposition at the C–O bond in the β-position:

$$CH_3\dot{C}HOC_2H_5 \rightarrow CH_3CHO + \dot{C}_2H_5 \quad . \qquad (12)$$

Thus both the nature of the excited state of the radical and the mechanism of its decomposition remain the same as for alcohol radicals. Even the quantum yields of reactions (12) and (9) are identical, amounting to 0.3 ± 0.2.[68] As in the case of ethanol, the dissociation of acetaldehyde leads to the formation of the acyl radicals $Me\dot{C}O$, from which $\dot{C}H_3$ radicals are formed. Methane appears (as in ethanol) after $Me\dot{C}O$ radicals are exposed to visible light.

The rates of change of the ESR spectra when $Me\dot{C}HOC_2H_5$ radicals are acted upon by light in alkaline and acid solutions of the ether are the same as in the ether itself. This finding shows that the $Me\dot{C}HOC_2H_5$ radical is not involved in protonation and deprotonation reactions (in contrast to alcohol radicals, see above).

When the $C_2H_5\dot{C}HOC_3H_7$ radicals derived from propyl ether were acted upon by light, the n-$\dot{C}_3H_7$ and $C_2H_5\dot{C}O$ radicals were detected[68]; under the influence of visible light, the latter decompose with formation of $\dot{C}_2H_5$ radicals. H_2, C_2H_6, and C_3H_8 were detected in the gaseous photolysis products. Evidently in this case the photolysis of the radicals also proceeds via mechanisms involving the dissociation of the bond in the β-position relative to the atom with the unpaired electron.

On photolysis of the primary $Me_2\dot{C}OCHMe_2$ radicals in isopropyl ether, $Me_2\dot{C}H$ radicals are formed[68]. When they are kept in the dark at 77 K, the initial radicals are regenerated. As in other ethers, H_2 is not formed. In contrast to straight-chain ethers, in this case acetone is produced, as in isopropyl alcohol, and not an aldehyde. For this reason RCO radicals are absent in the photolysis of $Me_2\dot{C}OCHMe_2$.

When straight-chain alcohols and ethers are photolysed together with $R\dot{C}H_2$ radicals, a single asymmetric line also appears in the ESR spectrum, its intensity decreasing under the influence of light with $\lambda > 500$ nm; alkyl radicals $R\dot{C}H_2$ appear under these conditions.

The interpretation of the singlet is extremely contradictory. Many investigators[75,79,80,86,88,93] attribute it to alkoxy-radicals RO, which are formed either during the isomerisation of RĊHOH radicals or when a hydroxyl hydrogen atom is abstracted from ROH. Both processes are unlikely. It is more reasonable to assume[68,82,92,94] that the singlet is due to acyl radicals RĊO, which are derived from the formyl radical HĊO.

There are many common features in the photochemical behaviour of the species responsible for the singlet and of the HĊO radical. Like the HĊO radical, acyl radicals absorb light in the range 400–650 nm. The values of λ_{max} in the absorption spectra of certain acyl radicals in γ-irradiated acyl chlorides and methyltetrahydrofuran at 77 K are listed below[90]:

Radical	λ_{max}, nm
$CH_3\dot{C}O$	340, 500, 540
$C_2H_5\dot{C}O$	330, 480, 540
$PhCH_2\dot{C}O$	320, 510, 550
$Ph\dot{C}O$	320, 450
$Ph{-}CH{=}CH\dot{C}O$	400, 500, 550

The angle between the bonds in the HĊO radical is about 120°; in its ground state the radical is appreciably bent and the unpaired electron is localised in the sp^2 hybrid orbital of the carbon atom[101,102]; the g-factor of the radical is 2.0008. Acyl radicals have been obtained as a result of the dissociative addition of electrons to the molecules of acid chlorides on γ-irradiation[90]:

$$RCXO + e \rightarrow R\dot{C}O + X^- ,$$

their g-factor being 2.0010 and $a_{\alpha-H} = 5.1$ G. Acyl radicals are σ-electron radicals; as in HĊO, the unpaired electron is localised in the sp^2 hybrid orbital of the carbon atom; the unpaired electron density at the atom amounts to 52%.[103] The weak absorption by acyl radicals RĊO in the range 400–650 nm is probably due to a transition from the state in which the CCO angle is close to 120° to one where it is 180°. In the case of $CH_3\dot{C}O$ this corresponds to the excitation of the electron from the singly occupied σ orbital to the lowest vacant π orbital.[68]

Like HĊO radicals, on σ–π^* excitation acyl radicals dissociation with formation of carbon monoxide and R radicals. The energy of the dissociation

$$R\dot{C}O \rightarrow \dot{R} + CO \qquad (13)$$

is about 0.5 eV.[104] Carbon monoxide adds reversibly in the dark to the primary alcohol and ether radicals with formation of the corresponding acyl radicals $R\dot{C}HOH$ and $R\dot{C}HOR$.[68,92] Under the influence of visible light, the latter again decompose with regeneration of the initial radical.

$\dot{C}H_2COMe$ radicals are stabilised at 77 K in γ-irradiated acetone[105]. The action of light with $\lambda < 340$ nm lowers their concentration and leads to the appearance of lines due to the methyl radical[105–107]. For low conversions, the overall radical concentration hardly changes. A single ESR line, the intensity of which increased linearly with time, was observed simultaneously with the methyl radical.

The following mechanism has been proposed for the photochemical reactions[107]:

$$\dot{C}H_2COCH_3 \xrightarrow{h\nu} CH_2{=}C{=}O + \dot{C}H_3 , \qquad (14)$$

$$\dot{C}H_3 + CH_3COCH_3 \rightarrow CH_4 + \dot{C}H_2COCH_3 . \qquad (15)$$

The single line, which is insensitive to either visible or ultraviolet light, was not identified.

The study of the dependence of the rate of accumulation of methyl radicals on the wavelength of the exciting light yielded a spectrum representing the effect of the light on the acetonyl radical[106] which is virtually identical with the absorption spectrum of acetone (280–340 nm). However, it is difficult to conclude that either the acetonyl radical itself absorbs light in this region or there is energy transfer from the excited acetone molecule to the radical; there is a possibility under these conditions of excitation to a higher electronic state of the radical which then dissociates. These hypotheses require proof.

The photochemical reactions of the radicals obtained from ethyl methyl ketone and the isopropyl methyl ketone are similar, i.e., as in the case of acetone, photolysis ($\lambda \leq 340$ nm) leads to the formation of both methyl and alkyl radicals[108]:

$$CH_3\dot{C}HCOCH_3 \xrightarrow{h\nu} CH_2{=}C{=}O + \dot{C}_2H_5 , \qquad (14a)$$

$$Me_2\dot{C}COCH_3 \xrightarrow{h\nu} Me_2\dot{C}H + CH_2{=}C{=}O . \qquad (14b)$$

However, whereas one can assume that $\dot{C}H_3$ is formed in reaction (14) via the dissociation of the C–C bond in the β-position, this cannot be postulated for reactions (14a) and (14b). Their mechanism remains obscure and is hardly likely to involve a single fundamental step.

Together with alkyl radicals, a singlet appears in the ESR spectra on photolysis of ethyl methyl ketone and isopropyl methyl ketone; the authors[108] correctly attributed it to acyl radicals RĊO, which decompose under the influence of visible light ($\lambda > 400$ nm) with formation of alkyl radicals and carbon monoxide (as in the photolysis of alcohols). H_2, hydrocarbons, and CO were detected among the gaseous photolysis products.

The radicals derived from monocarboxylic acids and anhydrides absorb light in the region $\lambda \leq 350$ nm. The absorption band maxima and the extinction coefficients are listed in Table 2.[109]

The radicals $\dot{C}$–COOH absorb at longer wavelengths than the corresponding acids. This effect is a consequence of the interaction of the unpaired electron at the α-carbon atom with the electrons of the adjacent COOH

group. The $\dot{C}H_2Me_2CCOOH$ radicals, in which the unpaired electron is located at the β-carbon atom, do not absorb light with $\lambda > 300$ nm.

Table 2. Parameters of the absorption spectra of radicals derived from monocarboxylic acids.

Acid	pH	Radical	λ_{max}, nm	ϵ, litre mole^{-1} cm^{-1}
Acetic	3	$\dot{C}H_2COOH$	320	650
	10	$\dot{C}H_2COO^-$	350	800
Propionic	3	$CH_3\dot{C}HCOOH$	300	700
	10	$CH_3\dot{C}HCOO^-$	335	900
Butyric	3	$CH_3CH_2\dot{C}HCOOH$	280	—
	9	$CH_3CH_2\dot{C}HCOO^-$	335	900
Trimethylacetic	3	$\dot{C}H_2Me_2CCOOH$	240	—
	9	$\dot{C}H_2Me_2CCOO^-$	240	1800

It follows from CNDO calculations on the electronic state of the $\dot{C}H_2COOH$ radical[68,110] that its excited state is obtained when an electron passes from a doubly occupied σ orbital to a singly occupied π orbital. The σ bonds in the radicals of acids and anhydrides are then weakened and readily dissociate. Indeed, as will be shown subsequently, such dissociation constitutes the principal mechanism of the photochemical reactions of the radicals.

When light at wavelengths in the range $300 < \lambda < 400$ nm was allowed to act on the $\dot{C}H_2COOH$ radical in acetic acid, the radical was destroyed with the simultaneous increase of the $\dot{C}H_3$ concentration[109-111] and the appearance in the ESR spectrum of an asymmetric singlet. The paramagnetic species responsible for this line are destroyed under the influence of light with $\lambda \geqslant 500$ nm, being converted quantitatively into $\dot{C}H_2COOH$ radicals; there is no doubt that these species are the acyl radicals $\dot{C}H_2(CO)COOH$. The principal gaseous products of the photolysis of $\dot{C}H_2COOH$ radicals are CH_4 and CO_2,[110] which are obtained in equal amounts.

The main photochemical process in the photolysis of the $\dot{C}H_2COOH$ radical is, according to Chervonenko and Roginskii[110], the dissociation of the radicals at the C–OH bond:

$$\dot{C}H_2C(=O)OH \rightarrow CH_2=C=O + \dot{O}H \ . \qquad (16)$$

The dissociation of the C–OH bond in the $\dot{C}H_2COOH$ radical is more favourable on energetic grounds; its energy amounts to about 2.5 eV. CNDO calculation on the radical[68] also showed that the C–OH bond order does not decrease on $\sigma-\pi^*$ excitation.

Presumably the methyl radical is formed by the reactions

$$\dot{C}H_2COOH \rightarrow \dot{C}H_3 + \dot{C}OOH \ , \qquad (17)$$

$$\dot{C}H_3 + CH_3COOH \rightarrow \dot{C}H_2 + \dot{C}H_2COOH \ . \qquad (18)$$

However, the most probably mechanism is apparently photolysis of keten. Calculation by the CNDO method has also shown that the C–C bond in the radical is strengthened on $\sigma-\pi^*$ excitation and its order increases from 0.45 (in the ground state) to 0.63, i.e. reaction (17) is unlikely.

Another mechanism for the formation of the methyl radical has been proposed in other investigations[65,68], presupposing the decomposition of the radical in accordance with the scheme

$$\dot{C}H_2C(O\cdots HO)(OH)(O=)CCH_3 \rightarrow CH_2=C(OH)_2 + CH_3C\dot{O}_2 \ , \qquad (19)$$

$$CH_2=C(OH)_2 \rightarrow CH_2=C=O + H_2O \ , \qquad (20)$$

$$CH_3C\dot{O}_2 \rightarrow \dot{C}H_3 + CO_2 \ . \qquad (21)$$

An important role is attributed in this mechanism to the hydrogen bond between the radical and the adjoining acid molecule. This mechanism resembles that postulated for the photolysis of alcohol radicals; the difficulties in its operation were discussed above.

In propionic acid $Me\dot{C}HCOOH$ radicals are destroyed under the influence of light at wavelengths in the range $300 \leqslant \lambda < 400$ nm and $\dot{C}_2H_5$ radicals accumulate[110]. A singlet is not observed in the ESR spectrum. Photolysis terminates after the complete conversion of $Me\dot{C}HCOOH$ radicals into C_2H_5; the principal gaseous photolysis products are ethane and CO_2.

The formation of the $\dot{C}_2H_5$ radical and the accumulation of C_2H_6 and CO_2 in the gaseous products are consistent with the mechanisms discussed in connection with the photolysis of $CH_2\dot{C}OOH$ radicals derived from acetic acid. The absence of $Me\dot{C}H(C=O)COOH$ radicals can probably be accounted for by the rigidity of the propionic acid matrix in which CO is hardly formed owing to the high probability of the reverse reaction between the keten dissociation products. The photochemical behaviour of the $C_2H_5\dot{C}HCOOH$ radicals derived from butyric acid[110] is analogous to the behaviour of $\dot{C}H_2COOH$ radicals in acetic acid. Under the influence of light at wavelengths in the range $300 < \lambda < 400$ nm, the concentration of primary radicals fell and $\dot{C}_2H_5$ and n-$\dot{C}_3H_7$ radicals appeared. As in other acids, C_3H_8 and CO_2 were detected in the photolysis products. The mechanisms of the formation of n-$\dot{C}_3H_7$ and $C_2H_5CH(\dot{C}O)COOH$ radicals and of the photolysis products are analogous to those discussed previously. The primary radicals $C_2H_5CH_2\dot{C}HCOOH$ derived from valeric acid undergo similar reactions[110].

The photochemical behaviour of the protonated radical-anions $(RCH_2\dot{C}OO)^{2-}$, obtained on γ-irradiation of monocarboxylic acids at 77 K, is somewhat unusual[112]. Under the influence of light with $\lambda \geqslant 380$ nm, these radicals disappear irreversibly without the formation of other paramagnetic species. The mechanism of the photolysis probably consists in the protonation of the radical-anions and liberation of electrons with subsequent capture of the electrons by positive ions:

$$(RCH_2\dot{C}OO)^{2-} H^+ \rightarrow RCH_2COOH + e \ , \qquad (22)$$

$$e + (RCH_2\dot{C}OOH)^+ \rightarrow RCH_2COOH \ . \qquad (23)$$

Other radicals are not formed in the photolysis, so that $(RCH_2\dot{C}OO)^{2-}H^+$ radicals do not dissociate and the recombination of $(R\dot{C}OO)^+$ and e explains the decrease of the concentration of paramagnetic species on photolysis.

After γ-irradiation at 77 K the radicals $R\dot{C}H{-}C(=O)O{-}C(=O){-}CH_2R$ are stabilised in monocarboxylic acid anhydrides[113]. These radicals dissociate under the influence of light at wavelengths in the range $300 < \lambda < 400$ nm similarly to radicals

derived from acids, i.e. with dissociation of the bond in the β-position:

$$R\dot{C}HCOCCH_2R \xrightarrow{h\nu} RCH{=}C{=}O + RCH_2C\dot{O}_2 \quad , \tag{24}$$

$$RCH_2C\dot{O}_2 \rightarrow R\dot{C}H_2 + CO_2 \quad , \tag{25}$$

$$R\dot{C}H_2 + (RCH_2CO)_2O \rightarrow RCH_3 + R\dot{C}HCOCCH_2R \quad . \tag{26}$$

The quantum yield of reaction (24) in acetic anhydride is 0.8 ± 0.2.[113] Hydrocarbons, CO_2, and CO were detected in the gaseous photolysis products. The formation of hydrocarbons and CO_2 can be explained by the proposed mechanism and the detection of appreciable amounts of CO in the products is evidence for the formation of ketens, which effectively decompose under the influence of light with $\lambda \geq 300$ nm, forming CO.

6. Amine and Amide Radicals

When amines are γ-irradiated, radicals are formed by the abstraction of a hydrogen atom from the carbon atom in the α-position with respect to the heteroatom[114,115]. The hyperfine structure in the spectra of such radicals in an adamantane matrix is satisfactorily resolved[116].

As in alcohol radicals, in amine radicals the unpaired electron interacts with the lone pair of electrons at the nitrogen atom, which leads to a bathochromic shift of the absorption spectra of the radicals relative to the initial molecules[117]. The absorption spectra of amine radicals contain an intense broad band, the long-wavelength limit of which is at $\lambda \leq 400$ nm. The structure of the radicals obtained on γ-irradiation of amines and on subsequent illumination with ultraviolet light is indicated below together with the λ_{max} for the absorption bands of the radicals.

Amine	Radical after γ-irradiation	λ_{max}, nm	Radicals formed on illumination with ultra-violet light
CH_3NH_2	$\dot{C}H_2NH_2$	230	$CH_2\dot{N}$
Me_2NH	$\dot{C}H_2NHCH_3$	—	$Me_2\dot{N}$
Me_3N	$\dot{C}H_2NMe_2$	260	$Me_2\dot{N}$, $\dot{C}H_3$
$C_2H_5NH_2$	$CH_3\dot{C}HNH_2$	240	$\dot{C}_2H_5$, $CH_3CH{=}\dot{N}$
$(C_2H_5)_3N$	$CH_3\dot{C}HN(C_2H_5)_2$	250	$\dot{C}_2H_5$
$(C_2H_5)_2NH$	$CH_3\dot{C}HNHC_2H_5$	—	$\dot{C}_2H_5$

The most probable photochemical process on excitation of amine radicals is (as in alcohol radicals) their photodissociation with formation of various products.

The evidence for the mechanisms of the photochemical reactions of amine radicals is weak. Certain hypotheses have been put forward in a number of studies[114,115,118] concerning the photochemical dissociation of the N–R bonds in $\diagup\dot{C}$–NH–R radicals (where R = H, Me, C_2H_5, etc.). The dissociation of the N–R bond is probably the main photochemical reaction of amine radicals. In addition there is also the possibility of the dissociation of the C–N bond in the radical. However, the probability of this reaction is much lower than that of the dissociation of the N–R bond in the β-position (by analogy with radicals derived from alcohols, ethers, and other carbonyl compounds discussed in the previous section).

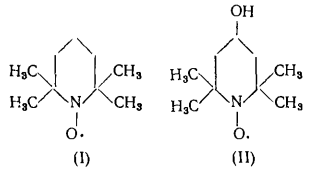
As in alcohols and ethers, the active radical species ($\dot{C}H_3$, $\dot{C}_2H_5$, $Me_2\dot{N}$, $H^{\cdot}$) formed in amines under the influence of light abstract hydrogen in the dark from the matrix molecules with regeneration of the initial photochemically active radicals.

When amine salts, in which there is no lone electron pair (a proton is attached to it), are γ-irradiated, $\diagup\dot{C}\overset{+}{N}H\diagdown^{R_1}_{R_2}$ radicals are formed following the abstraction of a hydrogen atom from the α-carbon atom[119]. Under the influence of light ($\lambda > 260$ nm), there is no photodissociation of radicals, the form of the ESR spectra of the radicals remains unchanged, and gas evolution is not observed. This is associated with the fact that the absorption by radicals of amine salts in which there is no $n-\pi$ conjugation, is displaced towards shorter wavelengths ($\lambda < 260$ nm), compared with the absorption by the corresponding radicals with a lone electron pair. Radicals of the type $\diagup\dot{C}\overset{+}{N}HR_1R_2$ therefore behave similarly to alkyl radicals.

III. PHOTOCHEMICAL REACTIONS OF RADICALS IN THE LIQUID PHASE

1. Nitroxy-Radicals

Nitroxy-radicals of the type



(I) (II)

do not react in the ground state with hydrocarbons up to a temperature of about 100°C, but, on being excited with radiation corresponding to the $\pi-\pi^*$ absorption band of the N–O group ($\lambda_{max} = 240$ nm, $\epsilon = 1500$), the radicals are destroyed even at a comparatively low temperature (about 10°C).[121,122] The main photolysis products are hydroxylamine and ether—the product of the recombination of nitroxy- and alkyl radicals[123]. The yields of each of these radicals are the same, amounting to about 50%.

The kinetic mechanism of the destruction of the radical can be represented as follows:

$$\dot{R} \xrightarrow{h\nu} \dot{R}^* \text{ (excitation of the radical)},$$
$$\dot{R}^* \xrightarrow{f} \dot{R} \text{ (radiative deactivation)},$$
$$\dot{R}^* \xrightarrow{d} \dot{R} \text{ (radiationless deactivation)},$$
$$\dot{R}^* + rH \xrightarrow{r} RH + \dot{r} \text{ (destruction of the radical)},$$
$$\dot{R} + \dot{r} \rightarrow Rr \quad .$$

The rate of destruction of radicals for $\bar{\epsilon}[R]l \ll 1$ is defined by the equation

$$-\frac{d[\dot{R}]}{dt} = \frac{2r[rH]\,n_0\bar{\epsilon}l}{f+d+r[rH]}[\dot{R}]$$

or

$$\lg\frac{[\dot{R}]_0}{[\dot{R}]} = \frac{0{,}87r[rH]\,n_0\epsilon l}{f+d+r[rH]} \quad ,$$

where n_0 is the number of incident photochemically active quanta and $\bar{\epsilon}$ is the effective extinction coefficient.

The quantum yields of the reaction $\gamma = r[rH]/\{f + d + r[rH]\}$ were found from the equation of Bogatyreva et al.[122], and the activation energies for the abstraction of a hydrogen atom from solvents by the electronically excited

radicals (I) were determined from the temperature variation of $(f + d)/r$ (provided that $f + d$ depends only slightly on temperature). These results are listed in Table 3.

The high quantum yields and the low activation energies [the activation energy for the reaction of the radical (I) is 34 kcal mole^{-1} [124]] show that in an electronically excited state the radical (I) is highly reactive.

Table 3. The quantum yields and activation energies E for reactions involving the abstraction of a hydrogen atom by the electronically excited radical (I).[122]

Solvent	10° C	18° C	25° C	E, kcal mole^{-1}
Heptane	0.32	0.37	0.42	2.3
Toluene	0.51	0.61	0.68	2.5
Cyclohexane	0.30	0.37	0.42	3.0
Water	0.16	0.31	0.42	9.1

The quenching of the electronically excited state of the radical (I) by oxygen in heptane and water and by nitric oxide in heptane[122] obeys the Stern–Volmer equation, from which the values of $k_q\tau$ were found, k_q being the quenching rate constant and τ the lifetime of the radical. The constant k_q was assumed equal to the rate constant for the diffusional encounters of radicals and was determined from the broadening of the ESR spectra of the radicals in the presence of oxygen and nitric oxide[125]. The observed values of k_q and the calculated τ are listed in Table 4.

Table 4. The values of k_q and τ for the radical (I).

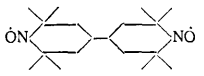
System	k_q, litre mole^{-1} s^{-1}	τ, s
Heptane + O_2	$1.6\cdot10^{10}$	$5.7\cdot10^{-8}$
Water + O_2	$8.7\cdot10^{10}$	$6.3\cdot10^{-8}$
Heptane + NO	—	$4.6\cdot10^{-8}$

The spectrum of the nitroxy-radical (I) contains two absorption bands corresponding to $\pi-\pi^*$ and $n-\pi^*$ excitations[126]. According to molecular spectroscopic data, the lowest excited state is the most stable and long-lived and the radiationless transitions from the highest electronic and vibrational levels to the lowest excited level take place at a high rate[127]. The radical (I) has the $n-\pi^*$ low-excited state. The dipole moment of the radical (I) in the excited state has been determined from the shifts of the $n-\pi^*$ absorption band in different solvents[122]. It was found that, on excitation of the radical, its dipole moment decreases from 3.14 D in the ground state[128] to 1.0 ± 0.8 D in the excited state. On $n-\pi^*$ excitation, there is probably a partial charge transfer from the oxygen atom (from the lone electron pair) to the delocalised π^* orbital. As a result, there is a deficiency of electrons at the reaction centre, which must be the cause of the high reactivity of the radical (I) in the electronically excited state.

Furthermore, this state must be comparatively long-lived, because an activation energy is required for the reaction of the excited radical. These considerations are consistent with experimental results. Evidently, reactions involving the abstraction of a hydrogen atom by the excited nitroxy-radicals proceed in the $n-\pi^*$ state.

The photolysis of the radicals (I) in the solid state takes place in accordance with the mechanism discussed for the photolysis of these radicals in the liquid phase[49].

The photochemical behaviour of the biradical



(III)

is of interest, because it contains two reaction centres whose unpaired electrons are involved in exchange reactions on intramolecular collisions. It was found that the quantum yield of the reaction of the biradical is the same as the quantum yield of the reactions of monoradicals[121], i.e. the quenching due to intramolecular collisions between the radical centres is insignificant. This implies that the period τ_0 between these collisions is greater than the lifetime of the excited radical τ, i.e. $\tau_0 > 10^{-8}$ s.

It was found in the photolysis of the radical (I) in a dense gas (ethane under a pressure of 50 atm) that the lifetime of the electronically excited radical is greater than in the liquid phase. This fact is probably due to the decreased rate of deactivation $(f + d)$ of the radical in the gas phase compared with the liquid phase.

2. Diphenylpicrylhydrazyl (DPPH)

The electronic spectrum of DPPH contains two bands corresponding to the $\pi-\pi^*$ and $n-\pi^*$ transitions with λ_{max} = 330 and 528 nm.[125] As in nitroxy-radicals, the $n-\pi^*$ state is responsible for the photochemical activity of DPPH.

Presumably, on $n-\pi^*$ excitation a possible mechanism of the photochemical destruction of DPPH is one involving the abstraction of hydrogen from solvent molecules. This hypothesis has been confirmed by a series of investigations. Thus, on photolysis of DPPH in methyl methacrylate (MMA) and in MMA solution in benzene in the absence of oxygen, the radical is quantitatively converted into the corresponding hydrazine[129]. The reaction kinetics obey the first-order equation with respect to the radical and MMA and can be described schematically as follows:

$$\text{DPPH} \xrightarrow{h\nu} (\text{DPPH})^*$$

$$\text{DPPH}^* \xrightarrow{f+d} \text{DPPH (deactivation)},$$

$$\text{DPPH}^* + \text{M} \xrightarrow{r} \text{DPPH} - \text{H} + \dot{\text{M}}(\text{P}) \text{ (reaction)},$$

$$\text{DPPH} + \dot{\text{M}}(\dot{\text{P}}) \xrightarrow{k} \text{DPPH} - \text{H} + \text{products (disproportionation)}.$$

Here $\dot{P}$ is the macroradical obtained by the addition of the $\dot{M}$ radical to the monomer. At 25°C $(f + d)/r$ = 2.3 ± 1.1 M, i.e. the quantum yield of the reaction and the reactivity of the excited radical are high.

In the presence of O_2 the reaction kinetics are more complicated: DPPH is destroyed in a zero-order reaction and hydrazine is formed only in small amounts; radical oxidation and decomposition products have been found. Evidently in the presence of oxygen the reactions of DPPH involving MMA peroxy-radicals play a significant role[129].

The photolysis of DPPH in various hydrocarbons has been investigated[130]. The destruction of the radical in the absence of oxygen obeys first-order kinetics and only light corresponding to the 330 nm bond is photochemically active. The rate constant ratio $(f + d)/r$ and the quantum

yields (φ) at 25°C are presented in Table 5. Evidently the quantum yields are fairly high; there is also a correlation between the quantum yield and the energy of the C–H bond dissociated in the hydrocarbons. The rate-limiting stage of the reaction is the abstraction of a hydrogen atom by the excited radical.

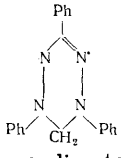
Table 5. The quantum yields of the photochemical destruction of DPPH.[130]

Solvent	$(I+d)/r$	Φ
Hexane	4.71	0.18
Toluene	3.16	0.24
Cyclohexane	2.70	0.27
Methylcyclohexane	1.77	0.36
Cumene	0.66	0.59

DPPH-H is also formed on irradiation of DPPH with light corresponding to the long-wavelength absorption band in acetic acid, in an ethanol–acetone mixture[131], in carbon tetrachloride, and in benzene[132].

3. Triphenylverdazyl

The triphenylverdazyl (TPV) radical



is excited by light corresponding to the absorption bands with λ_{max} = 400 and 710 nm. Both bands are intense ($\epsilon \simeq 10^4$ litre mole^{-1} cm^{-1}); being displaced towards the red in polar solvents, they probably correspond to $\pi-\pi^*$ transitions[133]. The lowest $\pi-\pi^*$ state is probably responsible for the photochemical activity of TPV. The dipole moment of TPV in the excited state, determined from the spectroscopic shifts of the 400 nm band in various solvents, is 9 D, i.e. on photoexcitation the dipole moment of the radical increases by about 6 D.[133,134]

The principal pathways for the photochemical destruction of TPV involve the abstraction of a hydrogen atom from the solvent with formation of the corresponding leuco-base and also the dissociation of the N–N bond with formation of the five-membered ring of 1,3-diphenyl-1,2,4-triazole and aniline.

It has been established that concentration-dependent quenching of the radicals takes place, i.e. the higher the concentration of the radical the slower the photochemical reaction. The quantity $k_q\tau \simeq 5 \times 10^3$ litre mole^{-1} was determined from the kinetic curves for the destruction of the radicals at their different concentrations. The rate constant for the diffusional encounters of radicals can be determined from the concentration-dependent broadening of the ESR line. It is caused by the exchange interaction of the electrons of the colliding radicals[125]. The rate constant for the collisions found from the exchange broadening of the ESR lines is 1×10^9 litre mole^{-1} s^{-1}, i.e. is close to the rate constant for diffusional collisions. If it is assumed that this constant is identical with the quenching constant k_q, then the lifetime of the excited state of the radical is found to be unduly long: $\tau = 5 \times 10^{-6}$ s. On the other hand, if it is assumed that the lifetime of the excited radical is 10^{-7}–10^{-8} s, then k_q is found to be 10^{10}–10^{11} litre mole^{-1} s^{-1}, i.e. exceeds by two–three orders of magnitude the value corresponding to the diffusion-controlled process. Possibly the concentration-dependent quenching is not associated with the diffusion of radicals, but proceeds via an inductive-resonance mechanism. However, an unambiguous choice between these two situations is impossible on the basis of the data quoted above.

4. The Perchlorotriphenylmethyl Radical (TPM)

The stable radical $(C_6Cl_5)_3\dot{C}$ has an absorption spectrum consisting of four bands with maxima at 220 nm ($\epsilon = 1 \times 10^5$), 293 nm ($\epsilon = 7 \times 10^3$), 382 nm ($\epsilon = 7 \times 10^4$), and 510 and 562 nm ($\epsilon = 10^3$ litre mole^{-1} cm^{-1}). Each band is photochemically active[135].

The principal pathway to the photochemical destruction of the radical involves the abstraction of a hydrogen atom from solvent molecules with formation of the corresponding triphenylmethane. The effective rate constants for the destruction of the radical in various solvents are different; there is an approximate correlation between the energies of the C–H bonds dissociated in the solvents and the radical destruction rate constants.

In the photolysis of TPM in the presence of aromatic additives the electronically-excited state of the radical is found to be quenched by these additives. This can occur via two mechanisms: firstly in a charge-transfer complex (since all the additives are effective electron donors) and secondly via energy transfer.

5. π-Complexes and Hydrogen Bonds Involving Electronically Excited Radicals

Data have been obtained for the π-complexes of excited radicals and for hydrogen-bonded complexes[136]. The difference between their heats of formation of the ground (ΔH_g) and excited (ΔH_e) states can be obtained from a thermodynamic cycle involving the excited radical[137]:

$$\Delta H_g - \Delta H_e = h(\nu_0 - \nu_s),$$

where ν_0 and ν_s are the frequencies at the maxima of the electronic bands of the radical in inert and solvating solvents.

The solvation mechanism is as follows:

$$\dot{R} + S \overset{K_g}{\rightleftarrows} \dot{R}_s \quad ,$$
$$\dot{R}^* + S \overset{K_e}{\rightleftarrows} \dot{R}_s^* \quad ,$$

where K_g and K_e are the equilibrium constants for the solvation of the radical in the ground and excited states.

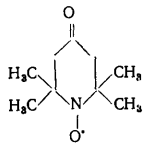
Then

$$\ln K_e/K_g = \frac{\Delta H_e - \Delta H_g}{RT} = \frac{h(\nu_0 - \nu_s)}{RT} \quad , \qquad (27)$$

provided that the entropies of the ground and excited states are identical. The ratio of the equilibrium constants for the solvation of the ground and excited states and the difference between the activation energies for the decomposition of the solvated states can be determined from the spectral shifts by Eqn. (27).

It was found that the formation of a π-complex by the dianisylnitroxy-radical with benzene causes a bathochromic shift of the absorption band in the electronic spectrum of the radical (λ_{max} = 329 nm in heptane and λ_{max} = 336 nm in benzene). $\Delta H_e - \Delta H_g$ = 1.3 kcal mole^{-1} can be found from the shift by Eqn. (27). Thus the π-complex of the excited radical (excimer) is more stable to the extent of 1.3 kcal mole^{-1} than the π-complex of the radical in the ground state[136].

Analysis of the hypsochromic shifts of the $n-\pi^*$ absorption band of aliphatic nitroxy-radicals permits the calculation by Eqn. (27) of the equilibrium constant for association via hydrogen bonding in the excited $n-\pi^*$ state of the radical. It was found that for the radical



$K_e/K_g = 2.9 \times 10^{-3}$ in methanol and $K_e/K_g = 2.5 \times 10^{-4}$ in acetic acid (at 22°C). Thus the equilibrium constant for solvation in the excited $n-\pi^*$ state of the radical is much smaller than in the ground state; accordingly, the solvate of the ground state is much more stable than that of the excited state.

Thus electron transfer from the n orbital of oxygen to the excited π^* molecular orbital weakens the donor–acceptor interaction in the hydrogen-bonded complex and displaces the solvation equilibrium towards the free radicals. Since the lifetime of the excited state is much longer than the vibration period of the nuclei in the hydrogen bond bridge, on excitation the radical may be involved in further reactions as a free non-associated species. This result is of significant importance for the kinetics of the reactions of radicals in the electronically excited state.

IV. THE QUENCHING OF EXCITED STATES BY RADICALS

The deactivation of electronically excited states of molecules by paramagnetic species is of considerable interest to spectroscopists and photochemists; because in the presence of paramagnetic quenching agents different quenching mechanisms operate from those of quenching by diamagnetic molecules; this is caused by the removal of the spin prohibition of electronic transitions in the excited molecule in the presence of paramagnetic species. For example, oxygen is known to be an excellent quenching agent for excited singlet and triplet states. Nitric oxide possesses similar properties. Since for the majority of organic molecules energy transfer to NO is impossible, evidently effective quenching of this molecule involves a reorientation of the electron spin in the excited molecule, but the total spin of the system is retained:

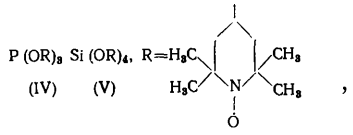
$$^3M(\uparrow\uparrow) + {}^2NO(\uparrow) \rightarrow {}^1M(\downarrow\uparrow) + {}^2NO(\downarrow),$$

where ^3M denotes the triplet state of the molecule, ^1M the ground singlet state, and the arrows indicate the orientations of the electron spins. This mechanism was first proposed by Porter and Wright[138].

However, oxygen and nitric oxide are not always suitable quenching agents, since they are frequently actively involved in chemical reactions and alter their mechanisms. This naturally led to interest in other paramagnetic quenching agents (metal ions and complexes and organic, especially stable, radicals). In this section the quenching of excited states by organic radicals will be considered.

1. The Quenching of Excited States in a Liquid

The quenching of the fluorescence of 2,5-diphenyloxazole, anthracene, 1,2-benzanthracene, and naphthacene in cyclohexane by the radical (I) and the polyradicals (IV) and (V),



was observed by Buchachenko et al.[139] The kinetics of the quenching process obeyed the Stern–Volmer equation and the ratio of the quenching constants for the radical (I) (k_q) and oxygen (k_{O_2}) was 0.53, 0.57, 0.53, and 0.73 respectively for the above electron donors. Evidently, the rate of quenching of excited singlet states is limited by the diffusion of the species. The fluorescence of rubrene and rhodamine B, where the position of the excited singlet level coincides with that of the radicals, was not quenched. Hence it was concluded that the quenching of the excited singlet state of donors occurs only if this state is above the lowest excited level of the quenching radical, i.e., in other words, the quenching by radicals involves energy transfer via an exchange-resonance mechanism.

However, in a later study[140] the quenching of fluorescence by di-t-butylnitrogen oxide (t-$C_4H_9)_2NO$ (VI) was investigated in methylcyclohexane and measurements were made of the lifetime of the excited singlet states and the quenching rate constant; it was shown that both rubrene and rhodamine B are quenched almost as effectively as other donors with high singlet levels. The energies of the excited singlet states and the quenching rate constants are listed in Table 6.

Table 6. The energies of the excited singlet levels and the rate constants for quenching by the radical (V) and oxygen.

Donor	$10^3 E_S$, cm^{-1}	$10^{-9} k_q$, litre mole^{-1} s^{-1}	k_q/k_{O_2}
Naphthalene	32.2	8.2	—
Chrysene	27.7	8.5	3.9
Pyrene	26.9	7.8	3.2
Anthracene	26.7	12.9	2.4
1,2-Benzanthracene	26.0	8.0	3.5
9,10-Diphenylanthracene	25.5	9.2	3.5
Perylene	23.0	12.0	2.4
Naphthacene	21.2	6.4	3.8
Rubrene	18.5	2.1	5.6
Rhodamine B	17.5	4.7	—

Clearly the rate of quenching is diffusion limited and there is no unambiguous relation between the energy of the singlet level (E_S) and the quenching constant k_q. Hence it follows that energy transfer is not the principal quenching mechanism, i.e. the conclusion of Buchachenko

et al.[139] was incorrect. (They did not measure the lifetime of the singlet states τ_S; possibly the quenching of the fluorescence of rubrene and rhodamine B could not be observed owing to the short lifetimes of the excited donors.) One must also rule out quenching due to energy transfer via an inductive-resonance mechanism, since the efficiency of quenching is independent of the overlapping of the absorption bands of the donor and acceptor.

The mechanism of the quenching of excited singlet states $^1M^*$ as a result of a chemical electron transfer reaction with formation of ion pairs is possible:

$$^1M^* + \dot{R} \rightarrow (M^{\cdot-}\dot{R}) \rightarrow {}^1M_0 + \dot{R} \ .$$

Quenching by amines usually involves this mechanism, the quenching efficiency depending strongly on solvent polarity. The quenching has been found to depend[140] only on the viscosity of the solvent, i.e. quenching by the radicals (VI) does not take place via the charge transfer mechanism.

The most probable quenching mechanism involves the removal of spin prohibition in the contact complex ($^1M^*...\ ^2R$), which results in the induction of $S-T$ transitions in the excited molecule and relaxation of the excess energy in the vibrational degrees of freedom (this mechanism will be discussed in detail a little later).

The quenching of the singlet states of fluorenone by the radical (VI) with a diffusional rate constant was observed in a study of the photocycloaddition of fluorenone to ketenimine[141].

The radical (VI) also quenches the fluorescence of pyrene monomers and excimers in benzene solution with nearly diffusional rate constants: 8.4×10^9 and 4.1×10^9 litre mole^{-1} s^{-1} for the monomer and excimer respectively[142]. The rate constants for the quenching of the excited singlets of substituted benzenes by nitric oxides are also the same as the collision rate constants and hardly differ from the constants for the quenching by oxygen[143].

We shall now consider the quenching of triplet states by radicals. Yang and Murov[144] observed that the ketyl radicals formed in solutions in the photochemical reduction of benzophenone behave as quenching agents for triplet states. In a study of photocycloaddition of fluorenone and aromatic aldehydes to olefins and ketenimine[145,146] it was found that the radical (VI) quenches both the singlet and triplet states of fluorenone with a diffusional rate constant. The quenching of triplet exciplexes by the radical (VI) has been observed in a study[147] of the photoaddition of 2-cyclohexenes to 1.1-dimethoxyethylene. In the radiolysis of mixtures of benzene and but-2-ene in the presence of the stable galvinoxyl radical (a phenoxy-radical) excited benzene triplet molecules are quenched[148]. $k_q\tau = 4.8 \times 10^2$, where k_q is the quenching rate constant, close to a diffusional constant (about 5×10^9 litre mole^{-1} s^{-1}) and τ is the lifetime of the triplet benzene molecule. It has been shown[149] that the *NNN'N'*-tetramethyl-*p*-phenylenediamine radical-cation (Wurster's cation) is an effective quenching agent for the triplet states of anthracene molecules. Thus the lifetime of the triplet state of anthracene in methylene chloride solution is 2.8×10^{-6} s in the presence of 1.8×10^{-7} M cation and 6.4×10^{-6} s in the absence of the cation.

It is interesting that in a magnetic field (up to 7000 G) the rate of quenching falls, i.e. the magnetic field inhibits the quenching of the triplet states of molecules by radicals. This inhibition also explains the increase in the intensity of the phosphorescence of the triplet molecules of aromatic hydrocarbons obtained in electrochemical reactions[150]. In this case the electrochemically generated hydrocarbon radical-anions are oxidised by Wurster's radical-cation with formation of triplet states of aromatic molecules. With increase of the magnetic field strength, the electroluminescence intensity rises; this effect can be explained by the fact that the magnetic field inhibits the quenching of the triplets by Wurster's cation.

Incidentally, the influence of the magnetic field on the efficiency of the quenching of the triplets is evidence that the quenching does not occur in every collision between the excited molecule and the quenching agent, i.e. that the rate of quenching is lower than the rate of diffusional collisions. This conclusion was confirmed quantitatively in two investigations[151,152]. The quenching of benzophenone and stilbene triplets by the radical (VI) takes place with a rate constant close to the diffusional value ($\sim 3 \times 10^9$ litre mole^{-1} s^{-1}), while the triplet state of naphthalene is quenched much more slowly (6×10^8 litre mole^{-1} s^{-1}). The perdeuteronaphthalene triplet is quenched still more slowly (3.7×10^8 litre mole^{-1} s^{-1}).[151] Thus the probability of quenching on collision with a paramagnetic species also depends significantly on the probability of the intramolecular radiationless degradation of the excitation energy (cf. naphthalene and deuteronaphthalene).

An interesting dependence of the rate constants for the quenching of triplets of aromatic molecules by the radical (VI) and nitric oxide on the energy of the triplet levels has been observed[152]. With increase in the energy of the triplet level, the rate constants initially decrease and then rapidly increase; the constant has a minimum corresponding to the energy $\sim 14 \times 10^3$ cm^{-1}. Both quenching agents behave in exactly the same way, although the energies of their lowest excited levels differ markedly. The observed relations have been explained by the hypothesis that quenching takes place in charge-transfer collision complexes; however, this hypothesis involves certain difficulties, since it does not explain the identical efficiencies of both quenching agents and is not consistent with the effect of the dielectric constant on the quenching efficiency.

Table 7. The quenching rate constants and the energies of the triplet levels of donors.

Donor	$10^{-8}k_q$, litre mole^{-1} s^{-1}	E_T, kcal mole^{-1}
Stilbene	50	48
Diacetyl	37	55
Benzophenone	26	69
Fluorenone	15	53
Biphenyl	7	69
Phenanthrene	6.4	62
Naphthalene	6.3	61
3-Acetylphenanthrene	6.0	59
1-Bromonaphthalene	5.2	59
Naphthalene-d_8	3.7	60

The quenching of triplets by the radicals (VI) has been investigated in detail[153]. Table 7 presents the quenching rate constants and the energies of the triplet levels. Evidently there is no unambiguous relation between the constants k_q and the position of the triplet level. However, there is a definite tendency as regards quenching efficiency: stilbene is quenched most effectively, $(n-\pi^*)$-excited triplets of ketones are quenched less effectively,

and the efficiency of the quenching of the $\pi-\pi^*$ triplets of aromatic hydrocarbons is lowest. This trend and the absence of a correlation between k_q and E_T constitute powerful evidence against the quenching mechanism involving energy transfer.

The exchange-induced quenching mechanism appears to be the most likely. It involves the removal of spin prohibition and the induction of the reorientation of the electron spin in the excited triplet in the contact complex of the excited molecule and the radical $^3M...R$ as a result of the exchange interaction of the electrons:

$$^3M^* + \dot{R} \rightarrow (^3M\cdots\dot{R}) \rightarrow {}^1M_0 + \dot{R} \ .$$

This process can be called exchange-induced vibrational relaxation rather than energy exchange, since the energy remains in the same initial molecule and is then degraded via its vibrational levels[154]. Evidently the probability of such vibrational relaxation depends on the exchange interactions in the contact complex $^3M...R$ and must be sensitive to the details of the electronic interactions in the complex and to the nature of the electron orbitals involved in complex formation.

The physical validity of this quenching mechanism was recently confirmed from completely different standpoints. In a study of the NMR of various organic molecules in the presence of stable radicals it was observed that even in the ground state all the molecules are involved in complex formation with the radicals[155]. In these short-lived complexes the unpaired electron of the radical is transferred to the orbitals of the molecules involved in the complex, i.e. there is partial merging of the electron shells and formation of common molecular orbitals. The nature of the complexes is extremely varied, but they can be classified in terms of the type of orbitals involved in complex formation ($n-\sigma$, $\pi-\sigma$, $\pi-\pi$, $\pi-n$, etc.) Here n, σ, and π are the orbitals of the lone pairs and σ bonds and π orbitals.

There is no doubt that radicals form complexes of this type with excited molecules and the electronic interactions in these complexes determine the efficiency of the quenching by radicals of excited states such as singlet and triplet states.

2. The Quenching of Excited States in the Solid Phase

Ern and Merrifield[156] showed that the triplet excitons of anthracene are quenched by the radicals formed when crystalline anthracene is irradiated by X-rays. The quenching of the phosphorescence of tetrahydrocarbazole and benzophenone by the radicals (I) in mixtures of alcohol and ether frozen at 77 K has been observed[157]. In the presence of the radicals there was merely a decrease of the intensity of the phosphorescence, while the kinetics of the decrease did not change after switching on the exciting light, i.e. the lifetime of the triplet state was independent of the presence of the quenching radicals and of their concentration. This shows that the quenching proceeds via the mechanism proposed by Perren[158], who suggested that the molecule of the quenching agent creates around itself a sphere of action of specific volume, so that the excited molecule is instantaneously quenched when it enters this sphere; on the other hand, when the molecule is outside the sphere of action of the quenching agent, it luminesces as an unperturbed molecule, i.e. in the same way as in the absence of the quenching agent.

This model yields the following expression for the dependence of the intensity (or quantum yield) of the phosphorescence on the concentration of the quenching agent c:

$$I/I_0 = \exp(-vNc) = \exp(-\alpha c),$$

where I_0 is the phosphorescence at $c = 0$ and $N = 6 \times 10^{20}$ mol. cm^{-3} (when v is expressed in cm^3 and the concentration is on the molar scale). Having determined experimentally the variation of I with c, it is possible to find from this equation the volume v of the sphere of action of the quenching agent.

The radius of the sphere where tetrahydracarbazole is quenched by the radical in alcohol–ether mixtures, determined in this manner, is 10 ± 1 Å, the value for benzophenone being 12.9 ± 0.8 Å. Thus the Perren radii for the quenching of the triplet states of electron donors by nitroxy-radicals are close to the radii corresponding to quenching by the usual molecules[157].

The radiolysis of the stable nitroxy-radical 2,2,6,6-tetramethyl-1-piperidinyloxy-radical has been investigated[159] in a pure form (in the absence of extraneous molecules) and in solid solutions of the radicals in isopropyl alcohol.

After the irradiation of individual radicals in the temperature range 100–300 K, the latter are destroyed by a first-order reaction with a rate constant k proportional to the dose rate γ:

$$N = N_0 e^{-kt} = N_0 e^{-k_1 \dot{\gamma} t} = N_0 e^{-k_1 D},$$

where D is the radiation dose. The constant k_1 obeys the Arrhenius relation with an activation energy of about 0.4 kcal $mole^{-1}$; the values of k_1 are 4×10^{-4} Mrad at 100 K and 1.4×10^{-3} $Mrad^{-1}$ at 300 K.

In the radiolysis of radicals in solid solutions in isopropyl alcohol (at a concentration of 2.4×10^{19}–2.5×10^{20} radicals g^{-1}) the constant k_1 is much higher, amounting to 4×10^{-2} $Mrad^{-1}$. Thus in solid solutions the radicals are destroyed by radiation with a high radiation yield—about 240 radicals are destroyed for 100 eV of the energy absorbed by the radicals; the radiation yield of the destruction of the radicals derived from isopropyl alcohol is much lower: 2–3 radicals for 100 eV. The high efficiency of the radiolytic destruction of stable radicals shows that in the solid state the radicals behave as powerful acceptors of the energy of excited states arising on γ-irradiation. However, the physical causes of such quenching remain unknown.

The influence of radicals on the quenching of excited singlet and triplet states of aromatic amines (diphenylamine, triphenylamine, and carbazole) in solutions frozen at 77 K has been studied[160]. If the radicals in the matrix were obtained photochemically, then an increase of the radical concentration entailed a parallel decrease of the intensity of both the fluorescence and phosphorescence of the amines. Hence it was concluded that the radicals quench the excited singlet states. If the radicals were obtained by the radiolysis of solid solutions, then the quenching efficiency was an order of magnitude lower. In other words, in order to quench the phosphorescence of amines to the same extent, the concentration of the radicals generated by radiation must exceed by an order of magnitude the concentration of the photochemically generated radicals.

This interesting effect was explained[160] by the characteristics of the distribution of the radicals: in photolysis the radicals are generated and located near amine molecules, i.e. there is a high local concentration of the

quenching agent near the molecules being excited, while in radiolysis the distribution of radicals is much more uniform. Nevertheless, even in radiolysis it is not ideally uniform. Indeed, when the Perren radii for quenching by "radiation" radicals are determined, they are found to be about 30–35 Å. They are physically unreal, since the overlapping of the absorption bands of the electron donor and the quenching agent is weak and the inductive-resonance mechanism cannot ensure such effective quenching. The distribution of radicals in space during radiolysis is probably also non-uniform[160].

Table 8. The types of excitation and chemical reactions of radicals.

Excitation	Radicals	Type of reaction	Excitation	Radicals	Type of reaction
$\pi-\sigma^*$	Alkyl	Decomposition	$\sigma-\pi^*$	$R\dot{C}O$	Decomposition
$\pi-\pi^*$ (?)	Alkyl	Substitution (?), isomerisation	$\pi-\pi^*$	Allyl	Substitution
				Polyenyl	»
$\pi-\sigma^*$	$\dot{C}H_2OH$	Decomposition		Triphenylverdazyl	»
	$R\dot{C}HOMe$	»		Perchloro-triphenylmethyl	»
	$\dot{C}H_2COMe$	»	$n-\pi^*$	Nitroxyl	»
	$\dot{C}H_2C(=O)OH$	»		Diphenylpicryl-hydrazyl	»
	$\dot{C}H_2C(=O)OC(=O)CH_3$	»		$R\dot{O}_2$	Substitution, decomp. (?)
	$MeC\dot{H}N(C_2H_5)_2$	»	$n-\pi^*$	Perchlorotriphenyl-methyl	Electron transfer
			$\pi-\pi^*$	Wurster's cation	ditto

Thus radicals are effective quenching agents for excited singlet and triplet states also in the solid phase. The quenching mechanism is probably the same as in the liquid and consists in the exchange-induced removal of spin prohibition and the subsequent vibrational relaxation of the energy of the excited molecule.

V. CONCLUSION

Despite a number of difficulties and ambiguities in the interpretation of the results of experimental studies on the reactions of excited radicals, definite advances have been made in the development of this field. Thus a definite relation has been noted between the nature and type of excitation of the radical and the mode of its reaction; it can be observed in the analysis of the compilation in Table 8.

It is readily seen that the radicals with $\pi-\sigma^*$ or $\sigma-\pi^*$ excitation mainly decompose (alkyl radicals, radicals derived from alcohols, ethers, ketones, carboxylic acids, their anhydrides, and amides, acyl radicals, etc.). In all these cases the σ orbitals of the radicals are involved in excitation; decomposition at the β-bond (for example, $\dot{C}H_2OH \rightarrow CH_2O + H^{\cdot}$) or at the α-bond (for example, the decomposition of acyl radicals and probably alkyl radicals) is most characteristic under these conditions.

The radicals with $\pi-\pi^*$ or $n-\pi^*$ excitation are mainly involved in reactions with transfer of a hydrogen atom (allyl, polyenyl, peroxy, and nitroxy-radicals, DPPH, etc.). Finally, radicals with a low ionisation potential (perchlorotriphenylmethyl) are involved in electron transfer on excitation.

Admittedly the relations noted above are only approximate and qualitative, but they nevertheless show that the transformations of excited radicals are not unduly varied and that there is a definite system in their behaviour. In many instances quantitative characteristics were also found: the quantum yields of the reactions have been determined and the lifetimes of the excited radicals and the quenching constants have been measured; the changes in the dipole moments of a number of radicals on excitation, due to the rearrangement of the electron shell, have been determined.

Ions and Ion-pairs in Nucleophilic Aliphatic Substitution

I.P.Beletskaya

A survey is made of the involvement of ions and ion-pairs formed both by the nucleophilic reagent and by the substrate. Evidence is given for the existence of ion-pairs of different types (contact and solvent-separated) in S_N1 reactions, and the possible participation of the former type in S_N2 processes is examined. A list of 338 references is included.

I. INTRODUCTION

A most important current problem of theoretical organic chemistry is the involvement not only of covalent molecules but also of various ionic intermediates, free ions, and different types of ion-pairs in the reactions of organic compounds. These species change significantly the reactivity of the substrate and the mechanism of the reaction. The participation of carbonium ions in nucleophilic substitutions is based on evidence of the mechanism of unimolecular substitution (S_N1), first put forward by Ingold and his coworkers [1], and whose classic formulation presupposes the formation of a steady concentration of a free ion in the rate-determining stage of the reaction. Later, nucleophilic substitutions involving stable carbonium ions were studied. A vast amount of information has now accumulated on the role and the reactivity of free ions (carbonium ions [2] and carbanions [3,4]), but special attention has been paid during the past decade to the fact that these species are frequently present in solution and take part in a reaction not in the free state but associated with their gegenion. The "ion-pair" concept, well known in the chemistry of electrolytes [5], was introduced into organic chemistry by Winstein (on Grunwald's suggestion).

As early as 1960 Winstein wrote: "It is important to distinguish between ionisation and dissociation, and to consider explicitly the role of different ionic intermediates, representing various stages of ionisation and dissociation" [6]. The idea that ionic intermediates other than the carbonium ion might be present during nucleophilic substitutions occurred to him after he had established that solvolysis in allylic systems is accompanied by intramolecular rearrangement of the initial compound [7]. Proof of the existence of such ionic intermediates, which it was proposed to term "ion-pairs" (internal and external, but in present-day literature contact or intimate and solvent-separated or loose), was obtained from many studies not only of allylic isomerisations but also of rearrangements in systems containing a 2-arylethyl group, from a comparison of rates of solvolysis, racemisation, isotopic exchange in ArC*HXR systems, and randomisation in esters ROC^{18}OAr, and also from a study of salt effects. These results led to the idea [8] that a covalent compound dissociates into free ions in stages involving the formation of at least two types of ion-pairs, return from which may result in isomerisation of either the cationic or the anionic moiety of the molecule:

$$RX \rightleftharpoons \underset{\underset{R^+ + X^-}{\uparrow\downarrow}}{R^+X^-} \rightleftharpoons R^+ \,\Big\|\, X^- \rightleftharpoons R^+ + X^-$$

It was suggested that reactions of type S_N1 may involve not only free ions but also solvent-separated ion-pairs.

An attempt has been made during recent years to demonstrate that ion-pairs of contact type may take part in S_N2 reactions of non-activated secondary (and even primary) substrates, although efforts to suggest a "unified" mechanism of nucleophilic substitution encounter serious difficulties. However, the idea that a substrate reacts in various forms depending on structure and conditions, with all differences in mechanism determined by the relative rates of individual stages, is an extremely tempting approach. Thus evidence of the existence in solution not only of carbonium ions but also of different types of ion-pairs is based on an analysis of kinetic and stereochemical results.

A completely different situation became evident when the existence of ion-pairs was examined in the chemistry of carbanions. Physical investigations in this field, which has developed vigorously during recent years, have provided direct evidence of the existence of various types of ion-pairs in solutions of salts of carbanions and radical-anions [9]. Especially valuable studies were made by Weissman [10], who in 1958 was the first to obtain physical proof of the existence of ion-pairs from the electron spin resonance spectra of salts of radical-anions, after which further work showed the existence of two types of ion-pairs [11-13]; Smid and his collaborators [14-16] have demonstrated the existence of contact and solvent-separated ion-pairs in a study of the spectra of salts of carbanions. It was Smid's papers which attracted the special attention of organic chemists to this problem. By now it has become possible not only to identify the different types of ion-pairs but also to establish their physical properties, energetics, solvation, and dynamics [17].

The present situation is somewhat paradoxical in that ion-pairs of carbanions have been thoroughly studied by various physicochemical methods, but very little is known of their reactivity in electrophilic substitution [18-20], whereas ion-pairs of carbonium ions are widely enlisted to explain the rules of nucleophilic substitution, although

objective data on their structure are lacking. However, the immense successes achieved in connection with this problem in the chemistry of carbanions have overshadowed the achievements in the field of carbonium ions, although the actual concept of ion-pairs was formulated by Winstein precisely in application to carbonium ions and nucleophilic substitution. The present Review examines the evidence for the existence of ions and ion-pairs in S_N reactions and the role of ion-pairs in uni- and bi-molecular nucleophilic substitution.

II. IONS AND ION-PAIRS MX IN S_N2 REACTIONS

Among nucleophilic substitutions those involving ionic nucleophilic reagents are some of the most important, both practically and theoretically. Here a special position is occupied by the exchange of halogens $RX-X^-$, termed the Finkelstein exchange [1]. The reactivity of the anions—their nucleophilicity in these reactions—is determined by the electronegativity, polarisability, and solvation, which in turn depend on the nature of the reaction centre under attack, the leaving group, and the solvent.

An important factor determining the reactivity of an ion, which for a long time was not taken into account, is the ability to associate with a gegenion [5], which is especially marked in media of low dielectric constant. With incomplete dissociation of the ionophore [21] the reaction rate constant will fall as its concentration increases. This phenomenon has been observed for quite a long time with halogen salts. Thus in 1948–1949 Evans et al. [22,23] discovered that the second-order rate constant for the reaction of n-butyl bromide with lithium bromide in acetone at 25°C decreases by a factor of 3.6 with increase in the lithium bromide concentration by a factor of 400, and explained this on the hypothesis that the reactant species was the bromide ion. A similar observation was made at that time by Moelwyn-Hughes in a study of the reaction of methyl bromide with potassium iodide in acetone [24].

Table 1. Relative RX + Hal^- reaction rate constants.

RX*	Solvent**	Cl⁻	Br⁻	I⁻	Ref.
n-PrBr	acetone	11	5	1	27

MeOTs***	83.3Py-DMF	2.8	1.5	1	29
EtOTs	HMPA	14 4	2.0	k_2 M^{-1} min^{-1}	30

*Bs = p-$SO_2C_6H_4Br$; Ts = p-$SO_2C_6H_4CH_3$.
**DMF = dimethylformamide; Py = pyridine; HMPA = hexamethylphosphoramide.
***K_{eq} was obtained from the kinetic data.

In many later papers, however, the degree of dissociation of the salts was disregarded, with a consequent distortion of the true reactivity of the halide ions [25]. In work on the Finkelstein exchange in $RHal-Hal^-$ systems in acetone Ingold et al. [26] observed in 1955 that the reaction rate constant increases with decrease in the lithium halide concentration, which they attributed to a negative salt effect. They regarded this as confirmed by the diminution in rate on the addition of lithium perchlorate, actually due to suppression of dissociation of the lithium halide. The reaction sequence of halide ions obtained by these workers—$I^- > Br^- > Cl^-$—was analogous to that observed in water and protonic media [25], which for a long time was considered an effect of polarisability varying in the same sequence. However, Winstein et al. [27] recalculated these results taking into account the degree of dissociation of the lithium halide, and found that the reaction sequence of halide ions in aprotic solvents was exactly the opposite, and the observed nucleophilicity diminished in the sequence $Cl^- > Br^- > I^-$ (Table 1). The ion-pair $\rightleftharpoons$ ions equilibrium constant increases in this sequence in acetone, but depends in general on the nature of the solvent [31]. The results obtained by Winstein et al. [27] show that the difference in reactivity between lithium and tetrabutylammonium halides towards n-butyl p-bromobenzenesulphonate in acetone is determined solely by the difference in their dissociation (Table 2). If the degree of dissociation is ignored, the true reactivity sequence for the reaction of methyl toluene-p-sulphonate in a mixture of pyridine and dimethylformamide is reversed when the salt concentration is increased to 0.35 M. [29]

Table 2. Observed and true rate constants for reaction of n-butyl p-bromobenzenesulphonate with lithium and tetra-n-butylammonium halides.

Salt	10^4K_{diss}	10^3k_{obs}, M^{-1} s^{-1}	$k_2 = 10^3k_{obs}/\alpha$, M^{-1} s^{-1}

Inspection of available results shows that salts of alkali metals with various anions are strongly associated into ion-pairs in ambipolar aprotic solvents [31,32], and neglect of this effect distorts the results significantly. With lithium bromide in acetone, for example, the order of the reaction with respect to the nucleophile is distorted [33]. For the reaction of 1-iodo-2,4-dinitrobenzene with potassium iodide in acetone [34] disregard of association to ion-pairs leads to an apparent change in the mechanism from S_N2 to S_N1.

It is no less important for the assessment of true reactivity to take into account the dissociation of alkoxides [35], wnich, in aprotic solvents such as dimethyl sulphoxide, are frequently used as nucleophiles in aromatic substitution and as bases in the elimination and generation of carbanions. Alkoxides are present in dimethyl sulphoxide predominantly as ion-pairs [35].

Crown polyethers have recently been used to increase the degree of dissociation of metal halides and alkoxides [36]. Addition to 18-crown-6 to a solution of potassium fluoride in acetonitrile increases sharply the observed nucleophilicity (and basicity), leading e.g. to ready substitution of fluorine for bromine in benzyl bromide [37]. Potassium ethoxide in the presence of dicyclohexyl-18-crown-6 is able to intervene in nucleophilic aromatic substitution, converting o-dichlorobenzene into o-chloroanisole in 40–50% yield [38]. In the presence of a crown polyether the nucleophilicity of the acetate ion is sharply increased, and

alkyl derivatives AlkX (where X = Cl, $OSO_2C_6H_4CH_3$, and especially Br) are readily converted into acetates [39]. Addition of a crown polyether has a similar influence on the reaction of alkyl halides with the cyanide ion [40].

It was accepted in most of the studies, however, that a free ion was the active species in nucleophilic substitution, and that the contribution by ion-pairs to the reactivity could be neglected, i.e. that $k_i \gg k_{ip}$ and that $k_{obs} = \alpha k_i$. Nevertheless, this contribution $(1 - \alpha)k_{ip}$ may be comparable with the contribution by the free ion αk_i if dissociation of the salt is slight ($\alpha \ll 1$) even when $k_i \simeq 10k_{ip}$. During recent years several workers [41-50], notably Beronius, have used Acree's equation [51] to estimate the reactivity both of free ions and also of ion-pairs in nucleophilic substitutions involving halides:

$$k_2 = \alpha k_i + (1-\alpha)k_{ip}; \qquad K_{eq} = \frac{c_\alpha^2 f_\pm^2}{1-\alpha},$$

where k_i is the reaction rate constant of the free ion, k_{ip} that of an ion-pair, α the degree of dissociation, $f_\pm$ the activity coefficient of the ion, and K_{eq} the equilibrium constant.

It was natural to expect that k_i would be independent of the nature of the cation, unlike k_{ip}. It has in fact been shown [27,50] that k_i has the same value for various cations. However, Lichtin et al. [41] did observe some dependence of k_i on the nature of the cation, with a regular increase in the ratio k_i/k_{ip} as K_{eq}^{-1} increased (Table 3). Although we usually find that $k_i \gg k_{ip}$, [50] the accompanying data show that the two rate constants may be comparable. Thus in the case of tetraethylammonium chloride $k_{ip} = \frac{1}{2}k_i$. In such cases, of course, it is not permissible to neglect the part played by ion-pairs and calculate $k_2 = k_{obs}/\alpha$, as is usually done [27,52-55].

Table 3. Rate constants for reactions of ions and ion-pairs of *p*-nitrobenzyl bromide with various bromides and chlorides.

MX	$10^5 k_i$, $M^{-1}\,s^{-1}$	$10^5 k_{ip}$, $M^{-1}\,s^{-1}$	$\frac{k_i}{k_{ip}}$	MX	$10^5 k_i$, $M^{-1}\,s^{-1}$	$10^5 k_{ip}$, $M^{-1}\,s^{-1}$	$\frac{k_i}{k_{ip}}$
p-$NO_2C_6H_4CH_2Br$+$M^{36}Cl$ in liq. SO_2, at 0°C				*p*-$NO_2C_6H_4CH_2Br$+ $M^{82}Br$ in liq. SO_2

Et_4NCl	3.17	1.61	1.97	Et_4NBr	7.07	2.86	2.5

Ion-pairs are the sole reactant species [42] in the reaction between 1-alkylpyridinium iodides and methyl toluene-*p*-sulphonate in chloroform, dichloroethane, and methyl formate. In solvents of high dielectric constant such as acetone and acetonitrile, however, ions and ion-pairs make comparable contributions to the observed rate-constants (e.g. for 4-cyano-1-ethylpyridinium iodide in acetonitrile k_i and k_{ip} have the respective values 0.175 and 0.12 $M^{-1}\,s^{-1}$).

For the reaction of *p*-nitrobenzyl chloride with lithium chloride in acetone the contribution by k_{ip} is <1% of that by k_i according to Beronius [43]; similarly, k_{ip} can be neglected in the reaction of n-butyl bromide with lithium bromide in acetone [45] or in a mixture of acetone with a large quantity of water [48]. When the lithium salts are replaced in these reactions by the corresponding tetrabutylammonium halides, however, the contribution by ion-pairs cannot be neglected in calculating the true rate constants, since k_{ip} amounts to 10% and 20% of k_i respectively. It was shown, in agreement with Lichtin's results [41?], that k_i is somewhat higher for lithium chloride than for tetrabutylammonium chloride (2.4 and 2.0 $M^{-1}\,min^{-1}$ respectively).

The complexity of determining the true value of k_i lies in the uncertainty attached to the salt effect. An attempted estimate by Beronius for the reaction of iodoalkanes with the iodide ion in aqueous ethanol [47] revealed that the assumption of minimum and maximum salt effects (on $f_{RX}f_{X^-}/f_{\neq}$) produced a marked change in k_{ip} from negative to large positive values of 30–50% of k_i.

It must be noted also that the values of K_{eq} calculated from electrical conductivity data, and hence the estimated contribution by ion-pairs, depend not only on the accuracy of the measurements (the conductivity of electrolytes in non-aqueous media has only recently been measured accurately) but also on the method of calculating them [56].

Considerable attention has been paid to the reactivity of ions and ion-pairs of ambident anions. Thus Smith et al. [57,58] determined the rate constants for the methylation of the ion and the sodium ion-pair of fluorenone oxime in a mixture of acetonitrile and t-butyl alcohol by methyl iodide, and found the ion to be more reactive than the ion-pair by a factor of 500.

It is especially interesting to estimate the true rate constant k_i and the contribution by ion-pairs in the reactions of ambident organic ions such as enoxide ions containing two nucleophilic centres joined by a single mesomeric system. Brändstrom showed [59] that both the ion and the ion-pair are kinetically active in the methylation of alkali-metal enoxides in alcohol†. A similar observation was made by Forsblad [60] in a study of the alkylation of alkali-metal methyl $o\beta$-dihydroxycinnamates. With the dipiperidinium bisenoxide in methanol the ion-pair was more active than the free ion in both *C*- and *O*-alkylation, probably because of selective solvation of the anion by hydrogen bonding. Thus the diminution in reactivity due to formation of a hydrogen bond may be greater than that resulting from electrostatic interaction with a gegenion of large radius and low charge density.

The most thorough study of the dual reactivity of ions and ion-pairs of ambident enoxide ions in alkylation has been reported in a series of papers [61-66]. At concentrations <0.1 M in hexametapol [hexamethylphosphortriamide, HMPT] the only reactive species is the "free" enoxide ion of acetoacetic ester [61] and other acyclic β-keto-esters [62], and its rate of alkylation by ethyl toluene-*p*-sulphonate parallels the basicity of the ambident anion. In a less basic medium such as dimethylformamide not only the ion but also ion-pairs of alkali-metal enoxides of acetoacetic ester take part in the reaction [63]. The rate constant of the reaction involving the anion was determined from experiments in the presence of macrocyclic polyethers. The greater reactivity of the ion-pair of sodium ethyl acetoacetate than of the potassium enoxide definitely indicates that the solvent-separated form of the ion-pairs of alkali-metal enoxides undergoes alkylation in dimethylformamide. In the presence of a crown polyether in such a weakly polar and feebly basic medium as dioxan [64], and even in the more strongly basic tetraglyme [65], contact ion-pairs of alkali-metal enoxides of acetoacetic ester take part in the reaction. This conclusion is based on the excellent linear

† Alkylation of an enoxide ion at a carbon atom can be regarded not only as an S_N2 reaction but also as an S_E reaction, and this field overlaps the study of carbanionic reactions.

correlation between $\lg k_{ip}$ and the reciprocal of the crystallographic radius of the cation—a relation that is typical of contact ion-pairs.

It is interesting that the stereochemical results of the *O*-alkylation of alkali-metal enoxides of acetoacetic ester depends on the nature of the ionic species involved [66], since the ion and the solvent-separated and contact ion-pairs may have different conformations.

III. PROOFS OF THE EXISTENCE OF CARBONIUM IONS IN S_N1 REACTIONS

Proofs of the existence of carbonium ions in nucleophilic substitutions are usually based on study of the kinetics and the stereochemistry of an S_N1 type of reaction. The classic theory of such reactions requires that the observed constant should be independent of the concentration and the nature of the nucleophile [1]:

$$RX \underset{k_1,\ \text{slow}}{\overset{}{\rightleftharpoons}} R^+ + X^- \xrightarrow[k_2,\ \text{rapid}]{N^-} RN;$$

$$w = \frac{k_1 k_2 [RX][N^-]}{k_{-1}[X^-] + k_2[N^-]};$$

when $k_2[N] \gg k^{-1}[X^-]$, we have $w = k_1[RX]$. Such regularities have been observed in the reactions of t-butyl bromide with various nucleophiles in nitromethane [67-69].

Another criterion of the involvement of carbonium ions in reactions is the "common-ion effect" [70-76] (the mass-action effect" or, as defined by Winstein [7], "external return"), depression of the observed constant on introduction of a common ion or on its accumulation during the reaction. The mechanism of the effect involves return of the ion as a result of reaction with the gegenion to form the initial compound, and operates when the contribution $k_2[N^-]$ is comparable with $k_{-1}[X^-]$. The common-ion effect is the more strongly developed the more stable is the resulting carbonium ion [71,77-81]. The common ion is thus acting as a nucleophilic "trap" for the carbonium ion. A foreign nucleophile such as the azide ion may be used as ionic trap, and would not affect the rate of the process but would influence the composition of the products, since the rate-determining stage in S_N1 processes does not coincide with the stage governing the products formed:

$$RX \underset{\text{slow}}{\rightleftharpoons} X^- + R^+ \begin{cases} \xrightarrow{HOS^-} ROS \\ \xrightarrow{N^-} RN \end{cases}.$$

Precisely this result was obtained for the reactions of di- and tri-phenylmethyl derivatives with sodium azide and tetrahydroborate used as traps [72-74,82-86].

Use of a nucleophilic trap combined with change in the nature of the leaving group provides another indication of formation of a carbonium ion in S_N1 reactions:

$$\left.\begin{matrix} RCl \\ RBr \end{matrix}\right\} \rightleftharpoons R^+ \begin{cases} \xrightarrow{HOS^-} ROS \\ \xrightarrow{N^-} RN \end{cases}.$$

Thus the reaction of diphenylmethyl chloride and bromide with the azide ion in 90% aqueous acetone yielded mixtures of the same products, although the reaction velocities of these halides differed thirty-fold [74,82].

An important criterion of formation of a carbonium ion is the stereochemical result of the reaction: a racemic product formed from an optically active compound undoubtedly indicates an S_N1 mechanism [1]. Because of the participation not only of free ions but also of ion-pairs in reactions of S_N1 type, however, the stereochemistry of these processes may in general be extremely diverse, as will be seen later, varying from substantial inversion to complete retention of the stereochemical configuration.

Finally, mention may be made of a further criterion, which is especially significant for diagnosing the mechanism of solvolytic reactions and consists in the influence of structural effects on the reaction velocity.

Schleyer et al. [87] recently proposed the addition of sodium azide as a test for the mechanism of solvolytic reactions. It is quite clear that, if the reaction velocity is unaffected by such addition, the solvent, being the weaker nucleophile, is incapable of nucleophilic participation in the rate-determining stage, i.e. that the reaction takes place by an S_N1 mechanism.

With sufficiently stable carbonium ions an S_N2C^+ mechanism [68] is possible, when the carbonium ion is formed in the pre-equilibrium stage and reacts slowly with the nucleophile: $k_2[N] \ll k_1[X^-]$. This probably occurs most often in the reactions of triphenylmethyl derivatives. However, such reactions may involve not only free ions but also ion-pairs, whose concentration in the solution may not be stationary, since these compounds may already be present in an ionised and partly dissociated state.

IV. IONS AND ION-PAIRS IN SOLUTIONS OF TRIPHENYLMETHYL DERIVATIVES

In strongly acid solutions even carbonium ions such as isopropylium, which are classified as unstable, can exist for a long time [88]. The more stable triarylmethyl cations are formed in theoretical yield by the action of sulphuric acid on the corresponding carbinols, and are entirely stable in these solutions [89]. Carbonium ions can be obtained from triarylmethyl derivatives also in other media or in the presence of Lewis acids [90].

In less strongly ionising media a covalent compound is in equilibrium with ion-pairs, as is shown by spectral investigations. Thus according to Evans [91] triphenylmethyl chloride dissolved in nitromethane and other nitroalkanes does not dissociate but merely undergoes ionisation (in nitromethane $K_{ion} \simeq 4 \times 10^{-4}$); tri-*p*-tolylmethyl chloride behaves similarly in nitrobenzene [92]. In dichloroethane solution triphenylmethyl chloride is capable only of ionisation ($K_{ion} \simeq 7.9 \times 10^{-3}$), whereas tri-*p*-tolylmethyl chloride undergoes partial dissociation [93]. The establishment of two equilibria in this case follows from the linearity of the plots of $([R^+] + [R^+Cl^-])/[RCl]$ against $([RCl])^{-1/2}$. In fact

$$RCl \overset{K_1}{\rightleftharpoons} R^+Cl^-;$$

$$R^+Cl^- \overset{K_2}{\rightleftharpoons} R^+ + Cl^-;$$

$$RCl \overset{K_3}{\rightleftharpoons} R^+ + Cl^-;$$

$$K_3 = \frac{[R^+]^2}{[RCl]} = K_1 K_2;$$

$$\frac{[R^+] + [R^+Cl^-]}{[RCl]} = K_1 + \frac{[R^+]}{[RCl]} = K_1 + K_3 \frac{1}{\sqrt{[RCl]}}.$$

Triphenylmethyl bromide is assumed to be completely dissociated in *m*-cresol solution [94]; the degree of dissociation is diminished by the addition of benzene or hexane to the *m*-cresol [95]. Dissociation is increased in chlorinated ethanes compared with nitroalkanes, but no direct relation is observed between the dissociating or ionising power of a solvent and its dielectric constant [93]. Liquid sulphur dioxide is a good ionising solvent, in spite of its low

dielectric constant (ϵ = 15.4 at 0°C).[96,97] Solutions of triphenylmethyl chloride in liquid sulphur dioxide conduct electricity, and comparison of spectral and conductivity data[98] permitted calculation of the ionisation constant and of the constant of dissociation of the ion-pair into free ions (K_1 = 0.013 and K_2 = 0.003 M at 0°C)[99,100]. Liquid sulphur dioxide is a stronger ionising solvent that nitrobenzene by a factor[97] of 5×10^{10} ($K_1 = 2 \times 10^8$ and 0.004 respectively).

It has recently been shown[101] that the ionisation of triphenylmethyl chloride in ether, assessed from the rate of isotopic exchange with $*Cl^-$, is promoted by lithium perchlorate, which in this solution forms aggregates of diverse structure. The dissociation and ionisation of triarylmethyl halides is increased by complex formation with Lewis acids[90,102]. The influence of salts on these processes diminishes in the sequence[103]

$$SbCl_5 \gg FeCl_3 \gg SnCl_4 \gg BiCl_3 > HgCl_2 > SbCl_3 .$$

The complexes $(XC_6H_4)_3CCl.HgCl_2$ (where X = H, *p*-Cl, *p*-CH_3) in nitromethane undergo not only ionisation but also dissociation[104,105], and the bromides dissociate still more readily under these conditions[106]. Similar results were obtained in other solvents[105]. Spectroscopic results indicate that solvents form the sequence—nitromethane > chlorobenzene > benzene—according to their ability to ionise the complex; the ability of a solvent to solvate both the anion and the carbonium ion must, of course, be taken into account, as well as the possibility of variation in the extinction coefficient of the carbonium ion under the influence of solvation[107]. Furthermore, the ratio of dissociated to covalent form may change during the reaction as a consequence of the common-ion effect[108].

Increase in ionicity on passing from triarylmethyl halides to the perchlorates is indicated by conductivity data[109-111] and by the absorption spectra[112,113]. Triethyl perchlorate is completely ionised and partly dissociated in chlorinated solvents—chloroform, dichloromethane, and the dichloroethanes[114].

The presence of ions and ion-pairs in a solution of tropylium isothiocyanate

$$RNCS \rightleftharpoons R^+NCS^- \rightleftharpoons R^+ + NCS^-$$

has been demonstrated by nuclear magnetic resonance[115]. The ratio between the covalent form and the ionic species depends on the composition of the solvent and the temperature. Thus in trideuteroacetonitrile only free ions are formed, whereas in its mixture with deuterochloroform (1 : 3) at 40°C ion-pairs are also present.

In order to describe the reactivity of dissociating and ionising organic compounds it is necessary to estimate separately the contributions made by each of the reactant species, as in the case of metal halides.

In media of low dielectric constant nucleophilic substitutions can take place in the triarylmethyl series by an S_N1 mechanism, when dissociation (or ionisation) occurs in the limiting stage, and ions and ion-pairs are present in steady concentrations. Nucleophiles capable of forming a hydrogen bond with the leaving group may assist the ionisation; since they may be associated in these media, their observed kinetic order is complicated[99,116-118]. At one time this and other complications connected with the return mechanism gave rise to bitter controversy between Ingold et al.[119-123] and Swain et al.[124-128]. Kinetic complications may arise also from aggregation of the ion-pairs[129,130].

It may be assumed that in these media the S_N1 mechanism involves only the formation of solvent-separated ion-pairs. This hypothesis is supported by the absence of depression of the rate constant by the common ion in the methanolysis of diphenyl-*p*-tolylmethyl toluene-*p*-sulphonate in a mixture of oxolan and methanol (10%), and by the considerable acceleration of this reaction on the addition of lithium perchlorate[131].

A considerable number of studies have now been made on the reactivity of free triarylmethyl cations. They originally covered the most stable amino-substituted triarylmethane dyes, whose rates of reaction were not very high[132-135]. However, application of the stopped-flow method extended considerably the range of carbonium ions investigated[136-140]. Study of the effect of additions of salts on the reaction of triarylmethyl cations with water[141,142] showed that variation in the rate was due to association of the carbonium ion with the anion of the added salt, in particular to formation of ion-pairs with the perchlorate anion.

A special position among this work is occupied by Ritchie's superb investigations[143-150], which included a study of reaction rates and equilibria for triarylmethyl and also substituted tropylium and benzenediazonium ions with various nucleophiles in several solvents. Unusual results were obtained, which have not yet been fully explained. This work showed firstly that the "stability–reactivity" principle breaks down. Although the required opposition between the stability of an ion pK_{R^+}[151] and its rate of reaction with nucleophiles was observed in a series of ions, Brønsted's equation was on the whole inapplicable, and in several cases no correlation was evident between the logarithms of rate and equilibrium constants. Absence of correlation was also mentioned earlier between $\lg k$ for the reaction of triarylmethyl cations with water and pK_{R^+} with variation in the number of *para*-substituents from 1 to 3.[136] However, a "reactivity–stability" correlation was observed in the hydride reduction of triarylmethyl cations[137,138].

Secondly, Ritchie discovered the surprising fact that carbonium ions differing considerably in stability had the same selectivity. The distribution of products of competing S_N1 reactions had shown that the selectivity of a carbonium ion towards nucleophiles depended on its stability. In 1966 a linear relation‡ was found[152] for a series of S_N1 reactions between $\lg k_1$ and $\lg(k_N/k_S)$ (where k_N and k_S are the reaction rate constants with the azide ion and with water respectively; the ratio $k_N[N_3^-]/k_S$ can be found from the distribution of the reaction products $[RN_3]/[ROH]$. This relation was extended by Schleyer et al.[153] and by Harris et al.[154].

Ritchie's results show that the rate of reaction of a carbonium ion increases with the nucleophilicity of the other reactant, but the ratio k_N/k_S remains almost constant for all the carbonium ions investigated. The reactions of substituted tropylium ions with hydroxide ions and with water may be cited as examples (Table 4). Although reactivities varied by 10^2, and stabilities by $10^{2.5}$, the k_{OH^-}/k_{H_2O} ratios were very closely similar[143]. A possible explanation[155] is that the reaction velocity is governed by desolvation of the nucleophile, which is independent of the cation.

---

‡ It must be borne in mind that a linear dependence may be distorted by the return mechanism, although it is supposed[154] that the fractional return is small in aqueous ethanol, in which the correlation was obtained.

The quantity $N_+ = \lg(k_N/k_{H_2O})$, where k_N is the reaction rate constant in a given solvent and k_{H_2O} the rate constant for reaction of the same cation with water in pure water, was proposed[147] as a measure of the nucleophilicity of the nucleophile N in the solvent. The nucleophilicity sequence thus obtained, quite apart from the absolute values, differed very markedly from published results determined in relation to other substrates[156-159].

Table 4. Comparison of stability of substituted tropylium ions with their reactivity towards OH^- and H_2O.

Cation	pK_{R+}	k_{H_2O}, s^{-1}	k_{OH^-}, $M^{-1}s^{-1}$
$C_7H_7^+$	4.76	2.6	$3.1\cdot10^5$
$C_6H_5C_7H_6^+$	4.86	1.0	$7.9\cdot10^4$
p-$ClC_6H_4C_7H_6^+$	4.55	1.2	$1.4\cdot10^5$
p-$CH_3C_6H_4C_7H_6^+$	5.75	0.27	$4.0\cdot10^4$
p-$Me_2NC_6H_4C_7H_6^+$	6.90	0.02	$1.7\cdot10^3$

Dorfman et al.[160] have recently obtained unique data on the reactivity of the benzyl cation. They used pulsed radiolysis to generate benzylium from various benzyl derivatives, and to determine rate constants for its reactions with methanol, ethanol, and the bromide and iodide ions as ($k_2^{24°}$, $M^{-1}s^{-1}$) respectively 7.4×10^7, 1.3×10^8, 5.2×10^{10}, and 4.9×10^{10}.

V. PROOFS OF THE EXISTENCE OF ION-PAIRS IN S_N1 REACTIONS

1. Special Salt Effect

An attempt to test the possible involvement of various types of ionic intermediates in solvolytic reactions led Winstein et al. to undertake a series of studies of salt effects in the solvolysis of sulphonates and halides[8,161-170]. In the normal salt effect additions of such a salt as lithium perchlorate, not containing a common ion, produce an increase in the titrimetrically determined solvolysis rate constant: $k_t = k_t^0(1 + b[\text{Salt}])$, where b is a measure of the normal salt effect. Such a relation has been observed in the solvolysis of several primary and even secondary systems in aqueous acetone and in acetic acid[161,164]. In some cases, however, the introduction of small quantities of lithium perchlorate produced a sharp increase in reaction velocity (Fig. 1). This phenomenon was termed a "special salt effect" and was observed e.g. with *o*- and *p*-methoxyphenethyl toluene-*p*-sulphonates in alcoholic acetic acid[162] and with *trans*-2-*p*-methoxyphenyl-cyclopentyl and -cyclohexyl *p*-bromobenzenesulphonates, *p*-methoxy-α-methylphenethyl toluene-*p*-sulphonate, *erythro*-*p*-methoxy-$\alpha\beta$-dimethylphenethyl *p*-bromobenzenesulphonate[163], and 2,4-dimethoxyphenethyl toluene-*p*-sulphonate in acetic acid[165]. With further increase in the lithium perchlorate concentration only the normal salt effect was observed in conformity with the equation $k_t = k^0_{ext}(1 + b[LiClO_4])$, so that the special salt effect is defined by the ratio k^0_{ext}/k^0_t (Fig. 1).

Winstein and his coworkers suggested that the solvolytic product ROS could be formed from the carbonium ion or from the solvent-separated ion-pair, and return to the covalent form could take place at all stages—external ion return k_{-3} involving the anion X^- and hence depending on its concentration, external ion-pair return k_{-2}, and internal ion-pair return k_{-1}:

$$\underset{(I)}{RX} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{(II)}{R^+X^-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{(III)}{R^+\|X^-} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \underset{(IV)}{R^+ + X^-}$$
$$k_S^{III}\downarrow HOS \qquad k_S^{IV}\downarrow HOS$$
$$ROS \qquad ROS$$

It was assumed also that exchange of anions could occur only by means of a solvent-separated ion-pair, which would be converted into a different, more reactive ion-pair, with suppression of the return stage k_{-2}:

$$R^+\|X^- + M^+\|Y^- \rightleftharpoons R^+\|Y^- + M^+\|X^-$$

(exchange involving the ion-pair $M^+\|Y^-$), and

$$R^+\|X^- + Y^- \rightleftharpoons R^+\|Y^- + X^-$$

(exchange involving the ion Y^-). However, the effect of lithium perchlorate on the ratio k_1/k_{-1} corresponds to the normal salt effect.

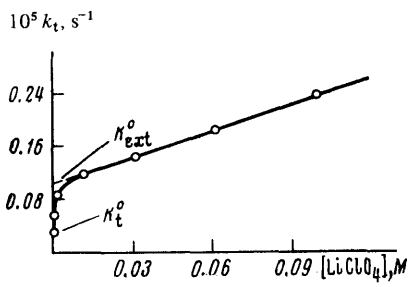

Figure 1. Typical dependence of solvolysis rate constant on $LiClO_4$ concentration in presence of a special salt effect. The points represent values of k^0_t, and the broken line indicates k^0_{ext}.

Thus the action of lithium perchlorate consists in the usual "chemical capture", which, unlike capture by other nucleophiles (N^-), does not yield a stable compound RN but a well ionised compound formed in solution by a reactive ionic intermediate. This mechanism of the action of lithium perchlorate is confirmed by the suppression of the special salt effect on addition of a salt having a common ion, e.g. lithium toluene-*p*-sulphonate in the reaction of an alkyl toluene-*p*-sulphonate[166] because of competition for the ion-pair (III). It is noteworthy that lithium toluene-*p*-sulphonate exhibits a positive salt effect in the acetolysis of *p*-methoxy-α-methylphenethyl toluene-*p*-sulphonate. The absence of depression of k_t by the toluene-*p*-sulphonate anion suggests absence of a return stage involving the free ion, i.e. an intramolecular return stage.

Depression of the constant by a common ion may in principle be absent in two cases—(i) with very reactive ions, for which $k_S^{IV} \gg k_{-3}$ and (ii) when a solvolytic reaction involves only a loose ion-pair ($k_S^{III} \gg k_3$). In several

other reactions, e.g. in the acetolysis of *p*-methoxy-α-methylphenethyl or norbornyl toluene-*p*-sulphonate, the addition of lithium toluene-*p*-sulphonate led to a decrease in the solvolytic constant[168]. An exhaustive kinetic analysis by Winstein et al. yielded a formula for the titrimetric solvolysis constant in the absence of a common-ion effect ($k_{-3}[X^-] = 0$) and with complete depression ($k_{-3}[X^-] \gg k_S^{IV}$). Under certain conditions this method permits not only detection of ion-pairs but also quantitative calculation of the fractional return at different stages.

Winstein repeatedly emphasised that the presence of a special salt effect proves the existence of return stages, but a return mechanism is possible even in the absence of a special salt effect.

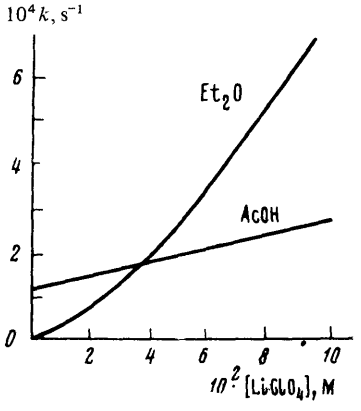

Figure 2. Dependence of ionisation rate constant for *p*-methoxy-$\beta\beta$-dimethylphenethyl toluene-*p*-sulphonate on the concentration of lithium perchlorate in diethyl ether and in acetic acid.

The bromide ion can also function as a trap for a solvate-separated ion-pair[167]. Formation of a bromo-derivative from *p*-methoxy-$\alpha\beta$-dimethylphenethyl *p*-bromobenzenesulphonate and *p*-methoxy-α-methylphenethyl toluene-*p*-sulphonate in acetic acid is a first-order reaction, and the exchange is subject to a normal salt effect.

Especially large salt effects are observed in slightly polar and weakly ionising media. Acetic acid, in which most of the studies of salt effects have been made, is a weakly polar but quite strongly ionising solvent[169,170]. The rate of ionisation of *p*-methoxyneophyl [*p*-methoxy-$\beta\beta$-dimethylphenethyl] toluene-*p*-sulphonate in ether increases on addition of 0.1 M lithium perchlorate by the immense factor of 10^5 (in acetic acid and in diethyl ether *b* has the respective values 12.2 and 298 000).[169] At a certain concentration of the lithium salt (>0.036 M) ether becomes a more strongly ionising medium than is acetic acid (Fig. 2). In solvents of this type it is supposed[170] that the added salt, present as an ion-pair, coordinates with the substrate to form a quadrupole:

$$RX + M^+Y^- \rightleftharpoons [R^+X^-M^+Y^-]$$

and such electrophilic assistance promotes the ionisation of RX.

The use of lithium perchlorate in poorly dissociating solvents may lead to distortions of the dependence $\lg k = f([LiClO_4])$. This may be responsible for the criticism of Winstein's work resulting from a study of the effect of additions of salts on the rate of reaction of triphenylmethyl chloride with methanol in benzene[171] which disregarded the dissociation of the added tetrabutylammonium chloride and perchlorate.

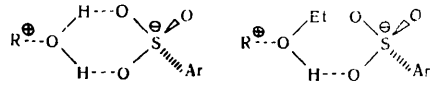
2. Distribution of Products in Competing Reactions. Nucleophilic "Traps" for Ion-pairs

Effect of leaving group

One method already noted for demonstrating the existence of a carbonium ion is the use of nucleophilic "traps", which affect the composition of the products without changing, in the case of a classic S_N1 process, the reaction velocity[2,74,83]. Competition between a strong nucleophile and the solvent for an ionic intermediate is expressed by a competition factor[172], which is easily determined from experimental data on the yield of products: $F_N = k_N/k_S = [RN]/[ROS][N]$, where F_N increases with the stability of the cationic intermediate[152,153,173]. For an unstable carbonium ion, exhibiting poor selectivity, the factor F_N should approach unity.

As already mentioned, one test for an S_N1 mechanism is that F_N should be unaffected by the nature of the leaving group. Thus the ratio $[RN_3]/[ROH] = 1.94$, the same for the reactions of diphenylmethyl chloride and bromide in aqueous acetone[74]. However, F_N depends§ not only on the nature of R in RX but also on that of the leaving group[175], which suggested that certain S_N1 reactions involve not the free carbonium ions but ion-pairs.

Thus the alkene/alcohol ratio in the reaction of t-butyl derivatives depends on the nature of the leaving group[176]. This result, may, of course, be due to partial involvement of an S_N2 mechanism. Variation in selectivity depending on the leaving group has been observed also in the reaction of 2-adamantyl arenesulphonates in aqueous alcohol[177]. The ROC_2H_5/ROH ratio diminished with increase in stability (with rise in $\lg k$), although the opposite relation might have been expected with attack on a free carbonium ion, in view of the great nucleophilicity of ethanol. Ion-pairs



are assumed to be involved in the reactions, and of these the pair separated by a water molecule is the more stable. The nature of the leaving group has a considerable effect on $F_N = k_{N_3^-}/k_{H_2O}$ in the reactions of triphenylmethyl chloride and bromide in 80% acetone[175]. The yield of hydrocarbon relative to that of the alcohol increases on passing from the chloride to the bromide in the reactions of diphenylmethyl and especially 1-phenylethyl halides with sodium tetrahydroborate in aqueous diglyme[178]. The

§ Detailed analysis[174] of various effects on the competition factor (not only by the structure of the substrate, the nature of the leaving group, and the nucleophile but also by the medium, the temperature, and even the rate of stirring) shows that a cautious approach must be made to comparing values obtained in different investigations.

leaving group has been found to affect the composition of the solvolysis products in the reactions of cyclobutyl arenesulphonates [179].

The selectivity factor in the solvolysis of triphenylmethyl chloride (0.013 M) in the presence of sodium azide (0.039 M) in 95% aqueous dioxan changed sharply on the addition of lithium nitrate and especially perchlorate [180] (0.089 M $LiClO_4$ increased [ROH]/[RN_3] from 20.2/79.8 to 41/59), which can be regarded as an argument in support of the formation from $R^+\|Cl^-$ of the more stable and less selective ion-pair $R^+\|ClO_4^-$. However, another possible explanation [180] is the influence of the ionic strength on the rates of the two "product-determining" reactions and the greater retardation by the salt effect of the ion–ion reaction (of the triphenylmethyl cation with the azide anion) than of the ion–dipole reaction (of this cation with water).

Comparison of stability of ion-pairs based on competitive substitution

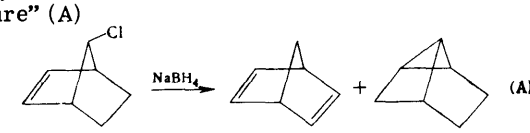
The solvolysis of 1,1- and 3,3-dimethylallyl [3-methylbut-2-enyl] chlorides yields mixtures of primary and tertiary alcohols, which suggests a common ionic intermediate. However, the action of sodium tetrahydroborate in aqueous ethanol results in different ratios (12.0 and 6.25) of the hydrocarbons $(CH_3)_2C:CH.CH_3$ to $CH_2:CH.CH(CH_3)_2$. [181] This difference is not due to simultaneous reaction by mechanisms S_N1 and S_N2 or S_N2', since doubling the concentration of sodium tetrahydroborate produces no significant change in these ratios. Hence it may be concluded that ion-pairs of similar but not identical structure are formed: i.e. they are distinguished by charge delocalisation in the cationic component, which is significant for attack by the hydride ion.

An interesting comparison was made [182] of reactivities and product compositions in the hydrolysis in aqueous diglyme of cyclopropylmethyl (V) and cyclobutyl (VI) methanesulphonates and of their 1-methylated derivatives in the presence of sodium tetrahydroborate or sodium azide. The reactivity of (V) was almost tenfold that of (VI), but the alcohols formed were almost identical in composition—almost equal quantities of (V)–OH and (VI)–OH with a little allyl alcohol. The suggested that a common intermediate was formed in the limiting stage, which might be a "non-classical" bicyclobutonium ion. However, the competition factors $F_N = k_N/k_{H_2O}$ (N = BH_4^-, N_3^-) were different, larger for (V)¶. Furthermore, different ratios of hydrocarbons are formed also with sodium tetrahydroborate: the ratios of methylcyclopropane to cyclobutane obtained on reaction with (V) and (VI) are respectively 3 and 2. Hence the reaction involves not a free carbonium ion but an ion-pair, having similar but not identical structures with (V) and (VI). Reactivity and selectivity data indicate that the ion-pair of (V) is more stable than that of (VI): i.e. a primary pair is more stable than a secondary pair. The same conclusion is reached from a study of competition factors for 1-methylated (V) and (VI): introduction of the methyl group diminishes selectivity, so that, in contrast to the free carbonium ions, the selectivity (and probably the stability) of the ion-pairs diminishes in the sequence—primary > secondary > tertiary.

An analogous relation has been found [174] for the sulphonates and halides of several "classical" systems for the study of S_N1 processes. However, it was noted that ambiguity was associated with use of the F_N criterion for assessing the mechanism in the intermediate region, where results could be interpreted in terms either of competition between S_N1 and S_N2 mechanisms or of the ion-pair S_N2 mechanism suggested by Sneen [183], since in this case the relation between competition factor and structure might be quite complicated.

Nucleophilic "traps" for ion-pairs

The use of lithium tetrahydroaluminate in ether as a nucleophilic trap for the "non-classical" carbonium ion in the reaction of 7-chloronorbornadiene led to the formation not only of norbornadiene but also of a "non-classical structure" (A)



which was regarded [184] as formed from a contact ion-pair, since it is difficult to assume an S_N1 mechanism in this solvent or S_N2 attack by a hydride ion on the double bond.

An interesting "trap" for ion-pairs in the reactions of diphenylmethyl and *p*-chlorodiphenylmethyl chlorides in 80% acetone is cobalt(II) nitrate [185]. Since this salt greatly affects the rate of solvolysis but has no effect on the polarimetric constant, it was deduced that racemisation involves ion-pairs of the same type (probably contact), while "capture" involves solvent-separated ion-pairs.

3. Stereochemistry

Comparison of rates of racemisation, solvolysis, and isotope exchange

The idea of the participation of ion-pairs and the occurrence of a return stage in solvolytic processes of S_N1 type were used by Winstein et al. [186] to explain the difference between the rate constants for loss of optical activity and for the solvolytic reaction of *exo*-norbornyl *p*-bromobenzenesulphonate ($k_\alpha > k_t$). These workers discovered a rule, which has since been confirmed: the fractional return increases as the nucleophilicity of the solvent decreases (Table 5). With $\alpha\beta$-dimethylphenethyl toluene-*p*-sulphonate as example it was shown [187] that the "excess" of racemisation was due to return of an ion-pair, not of the free ions, since the addition of sodium toluene-*p*-sulphonate hardly affected the ratio k_α/k_t, which had the respective values 2, 4.5–5, and 1.18 in ethanol, acetic acid, and formic acid. In the solvolysis of *threo*-*p*-methoxy-$\alpha\beta$-dimethylphenethyl *p*-bromobenzenesulphonate the ratio varies from 4.1 in acetic acid to 16 in a mixture of 10% of formic acid with dioxan [188]. Both constants increase on the addition of lithium perchlorate in conformity with the equation for the salt effect, in which $b_\alpha = 16.2$ and $b_t = 21.6$.

An analogous proof of the existence of ion-pairs in the reactions of dimethylphenyl systems is based on comparing k_α (determined polarimetrically) with k_t or the rate

¶ It is significant that the rate of reaction in the presence of sodium azide varies little, only a slight positive salt effect being observed, which does not support an S_N2 mechanism.

constant k_e for exchange between the halides and a radioactive halide ion. Thus the rate of loss of optical activity by the compounds $C_6H_5CHClC_6D_5$ and $C_6H_5CDClC_6D_5$ exceeds the aggregate rate of solvolysis and exchange with the radioactive chloride ion[189]: k_α/k_t has the values ~3, 20, and 100 in 50% acetone, nitromethane, and liquid sulphur dioxide respectively.

Table 5.

Solvent	AcOH	EtOH	75% Acetone
k_α/k_t	3.45	2.94	1.40

Winstein and his coworkers[6,190-195] made a series of determinations of the constants k_α, k_t, and k_e using *p*-chlorodiphenylmethyl chloride in various aprotic and other solvents. Values of the constants obtained by extrapolating to zero salt concentration were compared. Table 6, which lists the dielectric constants of the solvents together with the values obtained for the rate constants and the ratio k^0_α/k^0_e or k^0_α/k^0_t, shows that $k_\alpha > k_t$ or k_e in all the solvents, i.e. that the rate of return exceeds the rate of chemical capture. The value of k_α is strongly dependent on the ionising power of the solvent. It is interesting that a linear dependence of $\lg k^0_\alpha$ on $\lg k_1$ for the solvolysis of *p*-methoxy-$\beta\beta$-dimethylphenethyl toluene-*p*-sulphonate was obtained[196] for all six solvents at 75°C: $\lg k^0_\alpha = 4.22 + 2.02 \lg k_1$.

Table 6. Effect of solvent on the constants k^0_α, k^0_t, and k^0_e and their ratios for the reaction of *p*-chlorodiphenylethyl chloride with the chloride ion.

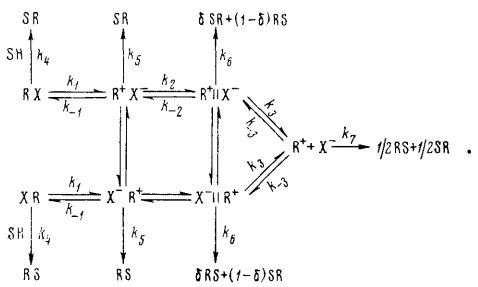
t, °C	Solvent	ε	$10^6 k^0_\alpha$, s^{-1}	$10^6 k^0_t$, s^{-1}	$10^6 k^0_e$, s^{-1}	k_{2e}**, $M^{-1}\,s^{-1}$	k^0_α/k^0_t	k^0_α/k^0_e
25	AcOH	6	68	1.8	—	—	38	—
25	80% CH_3COCH_3	30	60	23.1	—	—	2.6	—
75	CH_3NO_2	37	145	—	3.25	1.03	—	44
11	CH_3CN	37	60.7	—	0.2	1.23	—	304
11	$HCONMe_2$	37	18.9	—	5.0	2.00	—	4
11	CH_3COCH_3*	21	1.38	—	0.03	1.90	—	50

*Both processes, characterised by k_α and k_e, are slightly accelerated by lithium salts (chloride and perchlorate) and very strongly accelerated by the corresponding tetrabutylammonium salts, but their ratio varies little.
**The rate constant k_{2e} for bimolecular exchange with covalent RCl is found as the slope of the dependence of k_e on [MCl] at a low concentration of the isotopically labelled salt: $k_e = k^0_e + k_{2e}[(C_4H_9)_4NCl]$. The value of k_{2e} is almost the same in all solvents.

The ratio of the constants (k^0_α/k^0_t or k^0_α/k^0_e), of course, represents the ratio of the lower limit of the rate of ionisation to the rate of chemical capture, since part of the return may occur with retention of stereochemical configuration. As already noted, this ratio is strongly dependent on the nature of the solvent and decreases with increase in its nucleophilicity. For solvolytic reaction this occurs as a consequence of increase in the rate constant k_N for reactions of the ion-pair with the solvent. Initial attack on the pair $R^+\|X^-$ by a solvent molecule is assumed also for exchange, with formation of an intermediate that is more reactive in exchange, e.g. $RO.CH:N^+(CH_3)_2$ [or the less stable $CH_3C:N^+R$ and $(CH_3)_2C:O^+R$]. The results indicate that most of the ion-pairs in the majority of the ambipolar aprotic solvents used are converted back into the initial compound, and only a proportion of them undergo exchange.

Rates of exchange of chlorine and loss of optical activity have similarly been compared for the compounds $C_6H_5CHClCH_3$ and $C_6H_5CHClCH(CH_3)_2$ in various solvents[197]. In all cases k_α exceeds k_e, although their ratio is, of course, influenced by the variation in structure and solvent. Detailed investigation of the solvolysis of 1-phenylethyl chloride in 60% aqueous dioxan showed[198] that addition of lithium perchlorate produces a considerable increase in rate†, whereas lithium chloride has hardly any effect on the rate (k_α and k_t), which indicates an ionisation process, not dissociation. The ratio k_α/k_t remains almost unchanged: 1.18, 1.40, and 1.42 in the absence of additive and in the presence of 0.23 M LiCl and 0.23 M $LiClO_4$ respectively. An explanation was based[198] on Winstein's concept of equilibrium among various ionic intermediates, including solvated ion-pairs.

A similar relationship ($k_\alpha > k_t$) has been observed[199] in the solvolysis of 1-phenylethyl chloride in trifluoroethanol and in aqueous ethanol. Both solvent-separated contact ion-pairs, whose interaction with the solvent was accompanied by inversion, were regarded[199] as taking part. Thus the general scheme involves several equilibria and processes:



The results show that, of 100 contact ion-pairs in trifluoroethanol (97–100%), 80 undergo return, 18 are solvolysed (through solvent-separated ion-pairs), and 7 invert the configuration; the corresponding proportions in 60% ethanol are 70, 28, and 1.4.

Exchange in the systems comprising 1-phenylethyl chloride or bromide with the corresponding halide ions, as well as reactions with other nucleophiles, were studied by Pocker[200,201] in liquid sulphur dioxide and in nitromethane. Here, too, it was found that the rate of racemisation k_α exceeded the rate of exchange k_e together with the rate of the accompanying dehydrochlorination k_D.

† With *p*-chlorodiphenylmethyl chloride in 80% acetone k_t is larger in the absence of lithium perchlorate than in its presence in small concentrations: i.e. the dependence of the rate constant on the concentration passes through a minimum.

The ratio of return with racemisation to chemical capture was respectively 9 and 4 in the two solvents. However, as also with diphenylethyl bromide, a significant proportion of the exchange under these conditions took place by an S_N2 mechanism [202], when it was found that $k_{2\alpha} = 2k_{2e}$: i.e. every act of bimolecular exchange was accompanied by inversion of configuration, in conformity with theory.

The unimolecular racemisation rate constant for phenyl-*p*-tolylmethyl chloride in nitromethane exceeds the rate constant for reaction with various nucleophiles by a factor of 20 (in conformity with an S_N1 mechanism the same constant $k_1 \simeq 2 \times 10^{-7}$ was obtained at 0°C for various nucleophiles—the azide and chloride ions, pyridine, triethylamine [200]).

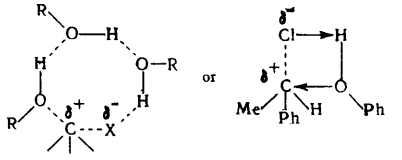
The involvement of ion-pairs in the "solvolysis" of s-butyl chloride in dimethylformamide in the presence of $Li^{36}Cl$ (the products are but-1- and but-2-ene and s-butyl formate) is also confirmed by comparing the rates of solvolysis, racemisation, and exchange [203].

Stereochemical "anomalies"

Various "anomalies" in the stereochemical results of unimolecular reactions are readily explained by the involvement of ion-pairs. Thus in several S_N1 solvolytic reactions inversion of configuration predominates over racemisation. For example, the methanolysis of 1-ethyl-1,3-dimethylbutyl phthalate, i.e. substitution at a tertiary carbon atom, is accompanied 54% by inversion and 46% by racemisation [204]. Such a result is usually attributed to shielding by the leaving group from nucleophilic attack, which in effect acknowledges the participation of ion-pairs in the reaction.

An analogous stereochemical effect of the leaving group, leading to predominant though not exclusive inversion, has been observed in the acetolysis of isomeric 4-t-butylcyclohexyl trifluoromethanesulphonates (triflates) (I). [204] The main product was an alkene, with only a certain quantity of acetates, inversion amounting to 94% for the equatorial compound and 75% for the axial compound. This suggested [205] that contact ion-pairs, not free carbonium ions, were involved in the reaction. The same conclusions had been reached earlier to explain incomplete inversion in the reactions of vinyl trifluoromethanesulphonates [206-208].

From the point of view of the mechanism and the possibility of the involvement of ion-pairs the greatest interest attaches to nucleophilic substitutions with retention of stereochemical configuration when this is not due to neighbouring-group participation but is a consequence of direct attack by the nucleophile [209,210]. A series of studies by Okamoto et al. [211-219] on the stereochemistry of the solvolysis of optically active 1-phenylethyl chloride showed extremely diverse results depending on the composition of the solvent. Thus solvolysis in the methanol–phenol–triethylamine system gave both products (of phenolysis and of methanolysis) with inversion of configuration when the initial phenol content has been 50% (by weight); from a phenol content of 85–95% both ethers exhibited complete retention of configuration; but in 75% phenol the methyl ether was formed with inversion, and the phenyl ether with retention [217]. A possible explanation suggested by Okamoto [217,218] was oriented coordination of attack by a solvent molecule on an ion-pair on the side of the leaving group. This explanation much resembles Cram's scheme [3] put forward to explain the retention of configuration at a carbanionic centre in reactions involving ion-pairs:



Retention of configuration can be explained also by differences between the uniform solvation of a carbonium ion and the possibly unsymmetrical solvation of an ion-pair on the side of the carbonium centre. If such solvation partly acquires the status of a bond, i.e. achieves directionality and some overlap of orbitals, though weaker than in nucleophilic attack‡, a situation may arise in which it is easier for the nucleophile to attack the carbonium centre from the direction of the leaving group than on the opposite side, which is shielded by a solvent molecule. Such a hypothesis was used to explain the partial retention of configuration in the reaction of optically active 2-bromooctane with the thiocyanate ion in dimethyl sulphoxide [220]. The considerable retention of configuration in the S_N1 reaction of *laevo*-biphenylyl-1-naphthylphenylmethyl benzoate in aqueous acetone, aqueous dioxan, and absolute alcohol was explained [221] on the same basis.

Retention of configuration by participation of the solvent was used by Okamoto [222] to explain the stereochemical result of the reaction of 1-phenylethyl chloride with a carboxylic acid in acetonitrile, when the fractional retention increased with the content of this solvent. Reaction was assumed to involve the "tail-solvated" ion-pair $CH_3CN...R^+...X^-$, in which the reaction centre interacts more strongly with the solvent than with the leaving group. However, the solvated ion-pairs considered here are not solvent-separated, and their involvement in the reaction presupposes that the S_N1 (or S_N2?) reaction may occur through another ionic intermediate, a solvated contact ion-pair. Solvation of an ion-pair from the "tail", as a result of which the reaction of 1-phenylethyl chloride with silver nitrate in diethyl ether takes place with retention of configuration, was considered also by Kornblum [223], but in acetonitrile the same reaction was accompanied by inversion; competition probably takes place between the solvent and the nitrate ion.

Complete retention of configuration was observed in the nucleophilic substitution of axial bromine in *trans*,*trans*-2-bromodecahydronaphthalene by the action of acetonitrile in the presence of silver perchlorate or tetrafluoroborate to give *N*-*trans*,*trans*-decahydro-2-naphthylacetamide [224]. Retention was observed in the solvolysis of menthyl toluene-*p*-sulphonate in aqueous alcohol (58%) and in trifluoroethanol (83%). [225]

There was a tendency [226,227] to explain the considerable retention of configuration in the acetolysis and the formolysis of *anti*-2,3-dideutero-7-norbornyl *p*-bromobenzenesulphonate (90% and 95% respectively) by frontal collapse of the ion-pair formed. An S_N1 mechanism is clearly indicated by the lack of effect of added sodium acetate on the stereochemical result of acetolysis. On the other hand, the lower percentage retention accompanying formolysis may be some argument that retention of configuration is not a consequence of the development of

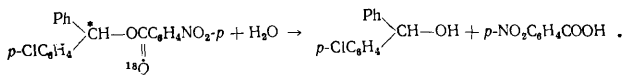
‡ This shows how blurred is the boundary between electrostatic solvation and formation of a covalent bond, leading to S_N1 and S_N2 mechanisms in solvolytic reactions.

synartesis and the formation of a non-classical carbonium ion. Thus reaction of a solvate-separated ion-pair and exchange in it of an anion without change in configuration provide yet another possibility. In other words, it must be supposed that attack on a contact ion-pair that is not solvated at a carbon atom takes place from the "tail", for exchange of an anion in a solvent-separated pair occurs at the front. However, the possibility of explaining retention of configuration by "non-classical" participation cannot be completely excluded[228].

Thus steric orientation is considerably more ambiguous in S_N1 than in S_N2 reactions, and can be explained only in terms of ion-pairs.

4. Isomerisation of Anionic Component

A powerful method for proving the occurrence of various types of ion-pairs in solvolytic reactions, proposed by Goering[229], consisted in simultaneous study of rates of randomisation (equilibration), racemisation, and solvolysis of labelled (at carbonyl or ethereal oxygen atoms) optically active alkyl *p*-nitrobenzoates, e.g.[209]



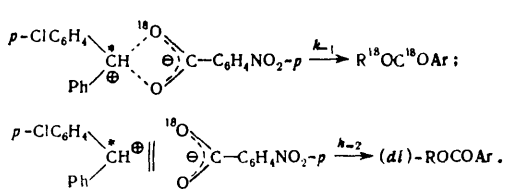
Analysis of the initial compound at various degrees of conversion revealed "scrambling" (equilibration) of the tracer in the returned product and loss of stereochemical configuration; however, these processes take place at different rates:

$$ROCOAr \xrightarrow{k_t} ROH + ArCOOH; \quad (1)$$

$$ROC^{18}OAr \xrightarrow{k_{eq}} R^{18}OC^{18}OAr; \quad (2)$$

$$(d \text{ or } l)\text{-}ROCOAr \xrightarrow{k_{rac}} d, l\text{-}ROCOAr. \quad (3)$$

Thus for *p*-chlorodiphenylethyl *p*-nitrobenzoate in 80% and 90% aqueous acetone the rate of randomisation exceeds the rate of the solvolytic reaction ($k_{eq} > k_t$). The fact that k_t does not coincide with k_{eq} and k_{rac} implies that processes (2) and (3) result not only from the return of ions to the original covalent compound but also from the return of other ionic intermediates, as the difference between k_{eq} and k_{rac} indicates the existence of at least two such ionic intermediates. Usually $k_{eq} > k_{rac}$: e.g. for the system under discussion their ratio is 1.5 and 2.5 in 80% and 90% acetone respectively. This suggests that equilibration of the label has already occurred at the stage of return of the contact ion-pair, but racemisation on return of a solvate-separated ion-pair (the anionic component "slides" over the surface of the cation), while the solvolytic reaction involves solvate-separated ion-pairs and free ions:



The results show that in 90% acetone 72% of the ion-pairs formed are converted back into the original covalent compound, and 81% of the return occurs with retention of configuration. The rate constant k_{eq} may not represent the total return of ion-pairs (on the assumption that part takes place without randomisation) but be its lower limit.

Proof that return of an internal ion-pair may occur with complete retention of stereochemical configuration and proof of the existence of various types of ion-pairs were obtained in a study of the effects of additions of sodium azide on k_t, k_{eq}, and k_{rac}.[210] The presence of this additive was found to increase the rate of solvolysis, somewhat to diminish the rate of randomisation, and completely to suppress racemisation of the initial compound.

Table 7. Values of k_t, k_{eq}, and k_{rac} in the hydrolysis of *p*-chlorodiphenylethyl *p*-nitrobenzoate in 80% acetone at 99.0°C, in the presence and in the absence of sodium azide

(80% acetone with $c_0 \simeq 0.028$ M at 99.6°C).

10^3k, h^{-1}	NaN_3 absent	0.14 M NaN_3
k_t	4.41	30.0
k_{eq}	6.5	5.9
k_{rac}	2.76	0.0

These results are consistent with the view that sodium azide is a nucleophilic "trap" for external ion-pairs. Exchange of anions between the ion-pairs

$$R^+\|X^- + Na^+\|N_3^- \rightleftharpoons R^+\|N_3^- + Na^+\|X^-$$

produces a more reactive ion-pair, which almost completely suppresses return from the solvent-separated ion-pair. Hence loss of stereochemical configuration is a consequence of return of this particular ion-pair (Table 7). Some change in k_{eq} under the influence of sodium azide implies that part of the randomisation is due to the return of loose ion-pairs. The fractional return increases with increase in the stability of the ion-pair. Thus k_t = 0.0064 h^{-1} and k_{eq} = 0.0187 h^{-1} even for diphenylethyl *p*-nitrobenzoate in 90% acetone (at 118.6°C).

Table 8. Effect of water content of acetone on proportion and stereochemistry of return for

Acetone	90%	80%	90%	70%
k_t (rel.)	1	9	1	45
k_{eq}/k_t	2.1	1.46	2.59	0.57
k_{rac}/k_{eq}	0.38	0.43	0.45	0.71

Increasing the water content in aqueous acetone affects both the fractional return (k_{eq}/k_t) and the stereochemistry of return (k_{rac}/k_{eq}).[230] The rates of solvolysis of

p-chlorodiphenylethyl and 1-*p*-methoxyphenylethyl *p*-nitrobenzoates increase, while the ratio k_{eq}/k_t decreases (for the latter compound in 70% acetone it even becomes <1) and k_{rac}/k_{eq} increases (Table 8). This observation is fully consistent with the above hypothetical shift in equilibrium, in a more strongly ionising medium, from contact to loose ion-pairs.

The fractional return from a solvate-separated ion-pair depends on its stability. A more stable ionic intermediate is in general less susceptible to nucleophilic attack, and is therefore more strongly racemised. Another possible explanation is that the forces of interaction between the ionic components become weaker in such an ion-pair, which increases the fractional return with racemisation. This may be illustrated by comparing results obtained for the solvolysis of 1-phenylethyl *p*-nitrobenzoate in 70% acetone, when no appreciable racemisation was observed, and for that of the 1-*p*-methoxyphenylethyl ester, which was more reactive by a factor of ~30 000, and 71% return occurred with racemisation [230]. Thus increase in the stability of $R^+\|X^-$ leads to increases both in the ionisation constant and in the fractional return k_N/k_S (the ratio of the rate constants for reaction with its own gegenion and for reaction of the ion-pair with the solvent).

Winstein et al. [162] noted an increased contribution by return of the solvent-separated pair accompanied by increase in the rate of solvolysis in acetic acid on passing from 1-phenylethyl to 1-*p*-methoxyphenylethyl toluene-*p*-sulphonate, as shown by the increase in the salt effect from normal to special ($k^0_{ext}/k^0_t = 1$ and 3.2 respectively). A similar relationship was observed for *para*-substituted diphenylethyl *p*-nitrobenzoates [231]: k_t increased rapidly in the sequence Cl < H < CH_3 < CH_3O ($\rho = -3.9$ in agreement with an S_N1 mechanism), while k_{eq}/k_t showed little change, and k_{rac}/k_{eq} increased with k_t, i.e. with increase in stability of the ionic intermediate.

The species through which return takes place to the original compound is recognised from the common-ion effect, the salt effect, and the rate constants k_{eq} and k_{rac}. Thus it was deduced from the absence of depression by a common ion that with 1-*p*-methoxyphenylethyl toluene-*p*-sulphonate return occurs only from solvent-separated ion-pairs, whereas free ions are also involved in the case of the 1-(2,4-dimethoxyphenyl)ethyl ester [188]. The special salt effect and the greater selectivity observed in the solvolysis of *threo*-*p*-methoxy-$\alpha\beta$-dimethylphenethyl toluene-*p*-sulphonate in comparison with the $\alpha\beta$-dimethylphenethyl ester correspond also to the nature of the ion-pairs involved in return: in the former case solvolysis is accompanied by the return of 83% of loose and 38% of contact ion-pairs; whereas in the latter case return takes place only from contact ion-pairs, although the total amount of return (78%) is the same in the two cases [188]. Passing from 2-phenylpropyl to 2-*p*-methoxyphenylpropyl toluene-*p*-sulphonate is also accompanied by an increase in the fractional return from loose ion-pairs [232].

A more complex question is the effect of additions of sodium azide on the ratios k_{eq}/k_t and k_{rac}/k_{eq}. Thus, in contrast to the above reaction of *p*-chlorodiphenylethyl *p*-dinitrobenzoate, the addition of sodium or tetrabutylammonium azide in the reactions of 1-*p*-methoxyphenylethyl [230] and phenyl-*p*-tolylmethyl [231] *p*-nitrobenzoates leads not only to an increase in k_t but also to a considerable decrease in the fractional return (k_{eq}/k_t), though the stereochemistry of return (k_{rac}/k_{eq}) remains almost unchanged, for which no simple explanation is available. It may be linked [230,231] with a diminution in the forces of interaction in the contact ion-pair (resulting from increased delocalisation of charge in the cationic component), so that racemisations may already occur on return of the contact ion-pair.

Redistribution of the label in the anionic component was used by Winstein et al. [233] to prove the presence of ion-pairs in the reactions of non-activated secondary alkyl sulphonates, such as 1-methylheptyl and *trans*-4-t-butylcyclohexyl toluene-*p*-sulphonates, for which bimolecular attack on the contact ion-pair is assumed in conformity with Sneen's mechanism [183]. Randomisation was demonstrated, and k_{eq} was unaffected by addition of the same anion. The proportion of this process

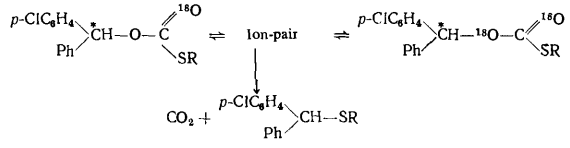
$$ROS^{18}O_2Ar \underset{}{\overset{k_{eq}}{\rightleftharpoons}} R^{18}OS^{18}O_2Ar$$

increases as the solvent becomes less strongly nucleophilic (Table 9).

Table 9.

Solvent	MeOH	AcOH	HCOOH	CF_3COOH
$\frac{k_{eq}}{k_{eq}+k_t}$	1.1 (75°)	6.5 (75°)	8.1(25°)	19.9 (25°)

Equilibration of the label and loss of optical activity in the initial compound have been observed in the decomposition of *p*-chlorodiphenylmethyl *S*-alkyl(or aryl) thiocarbonates in various solvents [234] (S_Ni mechanism), with the ratio of the constants depending on the nature of the solvent. The results indicate that return of the ion-pairs took place predominantly with retention of configuration ($k_{eq} > k_\alpha$): [235]



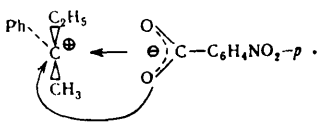
In the corresponding reaction of $RCH(CH_3)OCOCl$ in dioxan, however, no exchange of the tracer between ethereal and carbonyl oxygen atoms was observed [236]. The above results on equilibration of the oxygen label in the carboxylate and other anions show that this process occurs mainly at the stage of return of internal ion-pairs.

Similar results were obtained for isomerisation in a system containing thiocyanate, another ambident anion. Optically active *p*-chlorodiphenylmethyl thiocyanate underwent isomerisation in various solvents with complete retention of configuration [236–240]:

i.e. most probably as a result of return of a contact ion-pair.

Thus considerable return was usually observed with secondary alkyl *p*-nitrobenzoates ($k_{eq}/k_t = 2.2-3.2$ for 90% acetone), and a substantial proportion of the return (38–53% depending on structure) involved racemisation, but different rules were obtained for tertiary alkyl systems. In the reaction of α-ethyl-α-methylbenzyl-*p*-nitrobenzoate

$k_{eq} < k_t$ ($k_{eq}/k_t = 0.6$),[241] although both constants increased on passing to the tertiary alkyl, and only 8% of the return involved racemisation. The reason for the diminished return is not clear, although it may be linked with greater instability of a tertiary than of a secondary ion-pair due to an enhanced tendency to dissociation. The greater stereospecificity of return was attributed[242] to a heightened barrier to rotation of the anion around the sterically hindered cation



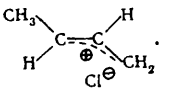
Fundamentally, however, the situation was unchanged: solvolytic reactions of tertiary systems involve ion-pairs capable of conversion into the original compound.

Return, as indicated by randomisation, was observed with triphenylmethyl *p*-nitrobenzoate dissolved in anhydrous acetone[242], i.e. in the absence of reaction. However, contradictory results were obtained for the effect of the azide ion[242-244]. According to Swain et al.[242] lithium azide converts the whole of the ester into triphenylmethyl azide and completely inhibits return (k_{eq} falls to zero), from which it was concluded that rearrangement took place in the intermediate that was captured by the azide ion. According to Winstein et al.[243], however, tetrabutylammonium azide does not suppress return, although in 99.2% acetone its addition, without changing the overall rate of the process, completely suppressed solvolysis: i.e. then $k_t = k_{N_3^-}$. In contrast to the quaternary ammonium azide, the lithium salt greatly diminishes return and sharply increases $k_t = k_{N_3^-}$. Since lithium perchlorate exerts an unusually marked influence on the rate of ionisation, it is supposed that in aprotic media lithium salts are able to form quadrupoles with ion-pairs, thereby promoting ionisation.

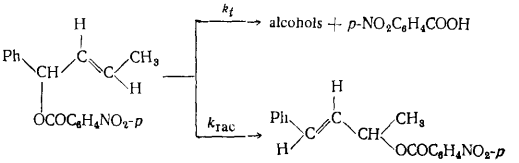
5. Isomerisation in Allyl Systems

Evidence of the occurrence of ion-pairs in solvolytic reactions and of a return mechanism is provided by isomerisation of the allyl fragment during the reaction of unsymmetrically substituted allyl systems, which have been studied in very great detail[245-253]. The intramolecular character of the isomerisation must first be demonstrated before the presence of ion-pairs can be assumed in these reactions. The actual idea of the existence of ionic intermediates other than free carbonium ions, through which both solvolysis and intramolecular rearrangements can be effected, was first put forward[7] in a study precisely of the allyl rearrangement: acetolysis of 1,1-dimethylallyl chloride was shown to be accompanied by its rearrangement into 3,3-dimethylallyl chloride, the rate of rearrangement being unchanged (allowing for the salt effect) when the reaction was conducted in the presence of the chloride ion. On the addition of $*Cl^-$ only a small proportion of the label entered the initial compound[25].

Thus the observed isomerisation is due to return of an ion-pair. The action of aqueous silver nitrate on *cis*- and *trans*-but-2-enyl and 1-methylallyl chlorides gives mixtures of isomers (nitrates and alcohols) with retention of geometrical configuration, which was attributed to a fairly high barrier opposing rotation in the ionic intermediate[245]

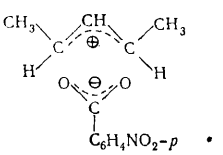


Solvolysis of 1-phenylbut-2-enyl *p*-nitrobenzoate in aqueous acetone[246,247], dioxan, and methanol[248,249] is accompanied by its intramolecular isomerisation into the less reactive α-methylcinnamyl ester:

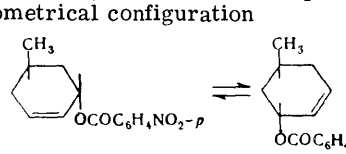


Use of the labelled optically active ester showed[247] that, in 90% aqueous acetone at 99.4°C, the relative rate constants (in 10^2 h^{-1}) were $k_t : k_{rac} : k_{eq} = 5.16 : 7.04 : 10.88$: i.e. under these conditions 65% of the return was accompanied by loss of stereochemical configuration. As noted earlier, the fractional return, i.e. the ratio k_{eq}/k_t, diminished with increase in the water content of the acetone, but, in contrast to other alkyl benzoates, the fractional return with racemisation k_{rac}/k_{eq} also decreased (to 16% in 70% acetone at 49.04°C).

The solvolysis of optically active *trans*-1-methylbut-2-enyl *p*-nitrobenzoate in aqueous acetone also was accompanied by randomisation and racemisation of the starting material, since the rate of loss of optical activity $k_\alpha = k_t + k_{rac}$ exceeded considerably the rate of solvolysis ($k_\alpha/k_t = 5.4$ and 2.17 in 90% acetone at 99.6°C and in 60% acetone at 59.9°C respectively)[250,251], so that by the time of 50% reaction the initial ester has been 95% racemised. The intramolecular character of the isomerisation (racemisation) was proved by the absence of exchange between the anions and *p*-nitrobenzoic acid and by the lack of effect of salt additions on k_t and k_α. It it interesting that $k_{eq} = k_{rac}$ (in 80% and 60% acetone): i.e. the two processes take place via the same symmetrical ion-pair (probably a contact pair, since exchange is absent), in which the two oxygen atoms and the two allyl carbon atoms are equivalent (cationic and anionic components are assumed to be located in perpendicular planes)



A similar relation was observed in the solvolysis of *cis*-5-methylcyclohex-2-enyl *p*-nitrobenzoate[252]. In the allyl isomerisation of the optically active *trans*-ester in 80% acetone, however, which also takes place with retention of the geometrical configuration



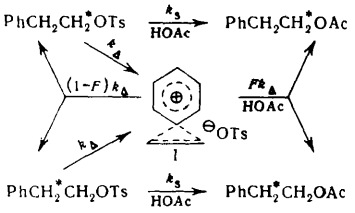
the rate of randomisation is double the rate of racemisation[253]. This system thus presents a more general situation, with two intermediates present in equilibrium: one is common to the two enantiomers, and its return leads both to racemisation and to randomisation; the other is not common, and only equilibration without loss of stereochemical configuration takes place in it (i.e. return occurs

without change in the carbon reaction centre). However, the reason for the differing behaviour of the two geometrical isomers is obscure.

6. Rearrangements with Aryl Participation

The concept of ion-pairs proved necessary to explain results connected with aryl migration and the stereochemistry of solvolysis in systems containing a 2-arylethyl fragment. From the very first steps in investigating the problem of "non-classical" (bridging) carbonium ions and anchimeric assistance it was demonstrated that this problem is closely connected with that of the formation of ion-pairs in these reactions [186,254].

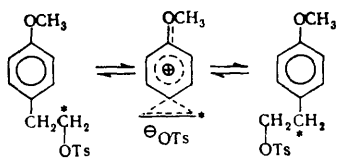
If migration of an aryl group during solvolysis in such systems is intramolecular, i.e. if it is independent of addition of a common ion, investigation of the rate of migration can be used to determine the fractional return from ion-pairs ("non-classical") formed with anchimeric assistance (k_Δ). Occurrence of a migration process can be assessed by using an unsymmetrically substituted system or, most simply, by examining the distribution of an isotropic tracer in a (carbon or hydrogen) labelled symmetrical system:



$$k_t = k_s + Fk_\Delta$$

The acetolysis rate constants for phenethyl toluene-p-sulphonate at 90°C are [255] $k_S = 8.92 \times 10^{-7}$ s^{-1} and $k_\Delta = 1.18 \times 10^{-6}$ s^{-1}, while the ion-pair return rate constant is 8.00×10^{-7} s^{-1}, which is comparable with k_S.

Many papers have appeared [255-270,273] on the effect of the aryl group and the medium on the distribution of a radioactive label in the initial compound, with calculations of the proportions of the process occurring with and without anchimeric assistance (k_Δ and k_S). Unfortunately, the nature of the ionic intermediate from which return occurred was not always studied. Return may involve not only ion-pairs but also free ions depending on structure and solvent, and these processes may occur together [271]. In some cases, however, the intramolecular character of return has been proved [255]. Thus solvolysis of carbon-labelled p-methoxyphenethyl toluene-p-sulphonate results in dissemination of the tracer both in the solvolysis product and in the initial ester [258], the latter process being a consequence of intramolecular rearrangement:



The intramolecular character of the rearrangement has been shown also in the acetolysis of β-methylphenethyl p-bromobenzenesulphonate [272] and p-methoxy-2-methylphenethyl toluene-p-sulphonate [232]. Hence participation of ion-pairs is possible even in the reactions of primary alkyl systems, providing that the substrate contains groups capable of assisting ionisation.

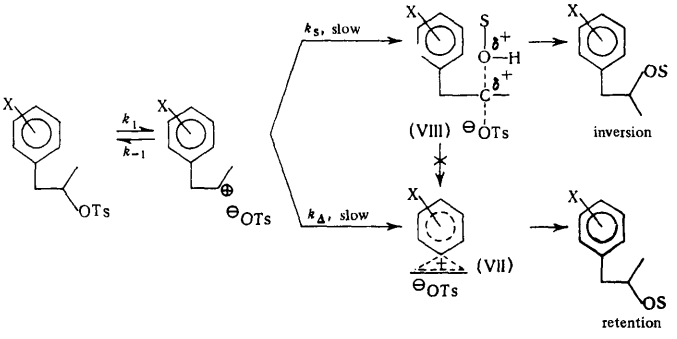
Results for the trifluoroacetolysis of phenethyl toluene-p-sulphonate [271], in which the path with anchimeric assistance is greatly enhanced, ($k_\Delta/k_S = 23\,000$), can be explained only if all three types of ion-pairs are involved in the process. Their contributions to the total return are indicated by the scheme

$$\mathrm{ROTs} \underset{15\%}{\rightleftharpoons} \mathrm{R^{\oplus}OTs^{\ominus}} \underset{87\%}{\overset{85\%}{\rightleftharpoons}} \underset{\text{Product}}{\mathrm{R^{\ominus}\,\|\,{}^{\ominus}OTs}} \overset{11.8\%}{\rightleftharpoons} \underset{\text{Product}}{\mathrm{R^{\ominus}}} + {}^{\ominus}\mathrm{OTs}\ .$$

Similarly for the p-methoxyphenethyl ester [258,271]

$$\mathrm{ROTs} \underset{8\%}{\rightleftharpoons} \mathrm{R^{\oplus}OTs^{\ominus}} \underset{95\%}{\overset{92\%}{\rightleftharpoons}} \underset{\text{Product}}{\mathrm{R^{\oplus}\,\|\,{}^{\ominus}OTs}} \overset{2.5\%}{\rightleftharpoons} \underset{\text{Product}}{\mathrm{R^{\oplus}}} + {}^{\ominus}\mathrm{OTs}\ .$$

Thus systems with a bridging capability undergo solvolysis in two ways—attack by the solvent on the substrate and attack by the aryl group on the carbonium centre—corresponding to the rate constants k_S and k_Δ. In the case of secondary substrates the first process gives a product with inversion of configuration [272]. The present Review will not discuss the mechanism of stabilisation of the carbonium centre by neighbouring groups, nor methods of resolving the observed constant k_t into k_S and k_Δ (we mention merely that this is effected both from the percentage rearrangement and the stereochemistry and from a correlation analysis [274,275]). Nor shall we consider the controversial question [276,277] of the existence of two rapidly rearranging classical ion-pairs instead of a "non-classical" ion-pair. The fundamental question here will be the presence of a stage of intramolecular return, indicating that structure (VII) is an intermediate, not the transition state of the dissociation stage.



An important aspect of the reaction mechanism, especially in secondary systems, is possible participation by ion-pairs even at a stage not involving anchimeric assistance. In these systems both processes (attack by the solvent and by the aryl group) may be supposed to involve not the covalent compound but an intimate ion-pair formed in a pre-equilibrium stage [277]. It is possible also that an ion-pair differing from (VII) (e.g. a nucleophilically solvated ion-pair) may be formed along the k_S path, from which return may occur also (this is important, since return from (VII) diminishes the anchimerically assisted proportion of the process). It is important only to remember that the k_S and k_Δ paths do not intersect [255]: i.e. the ion-pairs formed (VIII) are unable (e.g. because solvation prevents aryl attack) to pass into (VII) (otherwise it would have been impossible to explain the good agreement between kinetic results and analyses of the products).

However, a test for the reaction mechanism shows the possibility of direct S_N2 attack by the azide ion on the covalent compound in primary and secondary systems [270,278].

Table 10.

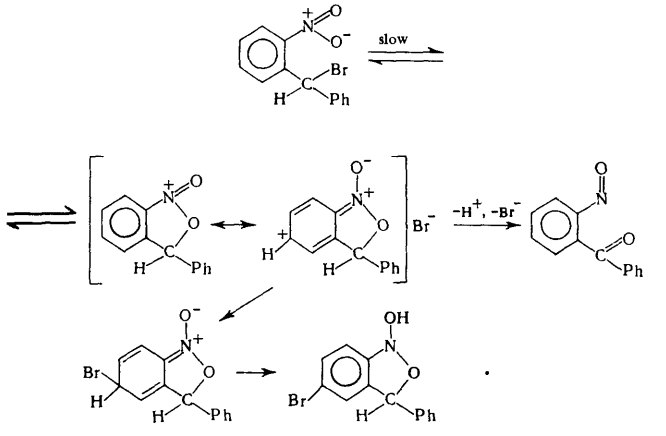
	CF_3COOH	HCOOH	AcOH
erythro-	92	61	29
threo-	89	49	22

Although proofs of the existence of ion-pairs have been obtained mainly in connection with aryl-group participation, k_Δ processes involving other β-donor groups may reasonably be expected to occur similarly. An example is the rearrangement of *erythro*- and *threo*-isomers of 4-chloro-1-methylpentyl toluene-*p*-sulphonate [279], in which considerable retention of configuration was observed. Table 10 shows that the fractional retention increases with increase in the ionising power of the solvent and decrease in its nucleophilicity. The concept of ion-pairs is especially reasonable for explaining rearrangements in primary systems, where the formation of free carbonium ions is unlikely.

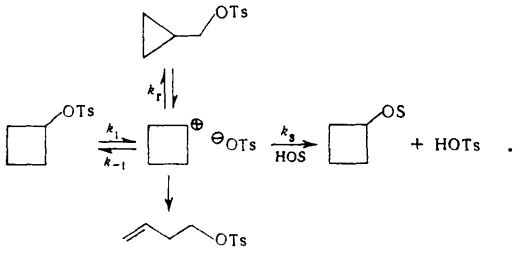
7. Other Cases of Isomerisation of the Cationic Component

Besides the above cases of allyl rearrangement and migration of an aryl group, other examples are known of rearrangements in the cationic component, which also are easily explained by the formation of ionic intermediates.

The nature of the product is changed by a curious isomerisation discovered recently [280]. In the solvolysis of *o*-nitrodiphenylmethyl bromide in 90% aqueous acetone, acidification with aqueous hydrobromic acid yields 5-bromo-3-phenyl-1-2,1-benzisoxazole instead of *o*-nitrosobenzophenone, which is the reaction product in neutral solution. The two reactions are assumed to occur via the same ion-pair formed by intramolecular attack by the nitro-group. Abstraction of a proton from this ion-pair (by the action of water or of added sodium acetate) yields the ketone, and reversible return of the pair in acid medium is accompanied by entry of bromine into the ring to give a product converted into the isoxazole derivative:



The formation of ion-pairs (probably of contact type) explains the isomerisation observed in the solvolysis of cyclopropylmethyl [281] and cyclobutyl [179,282] arenesulphonates:



It has been shown above, on the basis of the effect of the leaving group and data on competing reactions, that free ions are not formed, and the ratio k_r/k_S depends on the nature of the leaving group [179], as should be the case in reactions involving an ion-pair.

VI. CONTACT ION-PAIRS IN S_N2 REACTIONS

The concept of ion-pairs has thus provided explanations of the relations among rates of solvolysis, racemisation, randomisation, and rearrangement, as well as the special salt effect, in solvolytic reactions of type S_N1. Formation of ionic intermediate has recently been considered also in S_N2 reactions of secondary alkyl systems. Since 1965 the possibility has been discussed that bimolecular nucleophilic substitution may result from nucleophilic attack not on the covalent compound but on a contact ion-pair formed in the pre-equilibrium stage:

$$RX \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R^+X^- \xrightarrow[\text{slow}]{N^-,k_2} RN + X^- .$$

Since secondary compounds should be less reactive than primary compounds by an S_N2 mechanism, and less reactive than tertiary compounds by an S_N1 mechanism, Sneen supposed [183,283-294] that the nucleophile may be attacking a contact ion-pair. He based this suggestion on two facts—(i) formation of the completely inverted alcohol on the hydrolysis of optically active 1-methylheptyl methanesulphonate [283] and (ii) the non-coincidence of the rate-determining stage and the stage governing the ratio of the products (alcohol and azide) of the solvolysis of this compound in the presence of sodium azide in 25% and 30% aqueous dioxan [284].

In the classic S_N1 mechanism the reaction velocity is indeed unaffected by addition of sodium azide, since attack occurs after the rate-determining stage. Addition of the azide ion may than serve as a test for the S_N1 character of a solvolytic process [87], since, if reaction does not occur by an S_N2 mechanism even with a strong nucleophile, this should apply even more to a weaker nucleophile (water, alcohols). In the classic S_N2 mechanism the rate should increase in proportion to the increase in concentration of sodium azide:

$$RX \begin{cases} \xrightarrow{k_S} ROS \\ \xrightarrow{k_N\cdot[N_3^-]} RN_3 \end{cases} ; \quad k_{obs} = k_S + k_N[N_3^-] .$$

An intermediate case was observed with s-octyl sulphonates: the rate of reaction measured by the consumption of the initial compound increases with the sodium azide concentration, but considerably less rapidly than in

an S_N2 process (the order with respect to the azide ion lies between zero and unity). However, the selectivity with respect to the azide ion is about a thousandfold that for an S_N1 reaction. Thus addition of the azide ion provided Sneen and his coworkers with a convincing argument that an S_N2 reaction results from attack by the nucleophile on a contact ion-pair, which explained both the stereochemical inversion, the kinetic data, and the distribution of the products. Application of the steady-state principle to the scheme

$$RX \underset{\text{rapid}}{\rightleftharpoons} R^+X^- \begin{cases} \xrightarrow[\text{slow}]{k_S} ROS \\ \xrightarrow{k_N} RN_3 \end{cases}$$

yields the equation

$$k_{obs} = \frac{k_1 (k_S + k_N \cdot [N_3^-])}{k_{-1} + k_S + k_N \cdot [N_3^-]},$$

showing that k_{obs} is a complicated function of k_1, k_{-1}, k_S, and k_N. The ratio k_N/k_S is determined from the proportions of products formed in the presence of various concentrations of sodium azide:

$$\frac{k_N [N_3^-]}{k_S} = \frac{[RN_3]}{[ROH]}.$$

This approach removes objections based on the variation of the reactivity of sodium azide with concentration. Of course, F_N can be determined from the plot of $[RN_3]/[ROH]$ against $[N_3^-]$ if the latter is a straight line. However, the dependence would not be linear over a wide concentration range, since sodium azide may be incompletely dissociated in these solutions. Indeed, according to Ritchie [145] the graph for the reaction of di-*p*-methoxyphenylmethyl 2,4,6-trimethylbenzoate in methanol is not linear. The observed fractional order with respect to the azide ion may then be a consequence of its incomplete dissociation. However, this aspect has not been discussed in the publications of Sneen and his collaborators. It is noteworthy that departures from the first order with respect to the bromide ion, observed in a study of the rate of racemisation of 1-phenylethyl bromide in acetone, were due to the existence of lithium bromide in this solvent not only as ions but also as ion-pairs [33], although they could easily have been attributed to an ion-pair S_N2 mechanism.

The ratio of the observed rate constant to the solvolytic rate constant k_{NA} in the absence of sodium azide, allowing for a possible slight positive salt effect (assumed to correspond to that produced by salts such as lithium perchlorate, sodium nitrate, and sodium bromide), is given by

$$\frac{k_{obs}}{k_{NA}} = \frac{(x+1)(1+m[N_3^-])}{(x+1+m[N_3^-])}$$

$$m = \frac{k_N}{k_S}, \quad x = \frac{k_{-1}}{k_S}$$

$$k_{NA} = k_{NA}^0 (1 + b \cdot [NaN_3]).$$

The S_N2 and S_N1 mechanisms are extreme cases of this equation (as $x \to \infty$ and 0 respectively). The variation of k_{obs}/k_{NA} at intermediate values of x is represented by curve *1* in Fig. 3. The experimental constant for 1-methylheptyl methanesulphonate coincides with the value calculated for 25% and 30% dioxan with $x = 2.4$ and and 2.59 on the assumption that $b = 1.08$ and 1.04 respectively [287]. However, Schleyer et al. [295] have shown that observed rate constants obtained at different concentrations can be described by the equation for an S_N2 reaction (i.e. they can be correlated with the distribution of products) on the assumption that sodium azide exerts a negative salt effect ($b = -0.3$ and -1.0 for 25% and 30% dioxan respectively). The dependence of the ratio k_{obs}/k_{NA} on the sodium azide concentration will then be linear, in conformity with an S_N2 mechanism. However, values of b for closely similar media may then differ very greatly. Furthermore, Schleyer et al. [295] showed that the reaction of 1-methylheptyl *p*-bromobenzenesulphonate and of isopropyl toluene-*p*-sulphonate with the azide ion in 80% aqueous ethanol is the usual S_N2 type of process, in which the rate-determining stage coincides with the stage determining the composition of the products.

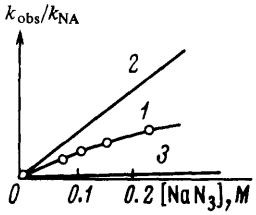


Figure 3. Dependence of k_{obs}/k_{NA} on $[NaN_3]$ for the reaction of 1-methylheptyl methanesulphonate with the azide ion and with water in 25% aqueous dioxan based on experimental value of $k_N/k_S = 8.22$ and different values of x: 1) 2.40; 2) ∞ (S_N2 mechanism); 3) 0 (S_N1).

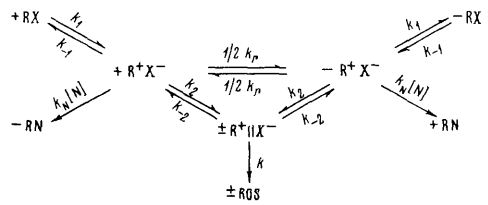
The above procedure was applied by Sneen et al. to various systems, e.g. the reaction of *p*-methoxybenzyl chloride with water and the azide ion in 70% aqueous dioxan and that of benzoyl chloride with *o*-nitroaniline and water in 50% aqueous acetone [288]. On the assumption of a positive salt effect calculated and observed ratios k_{obs}/k_{NA} can be reconciled with $x = 1.98$ and 1.1 respectively ($m = 21.6$ and 4.42 from experiment).

An S_N2 mechanism with nucleophilic attack on a contact ion-pair has been suggested by Sneen et al. for the reactions of 1-arylethyl halides in ethanol [289] and of sulphonium salts [290]. The proposed scheme explains also results obtained in allyl systems [292–294]. In the solvolysis of 1-methylbut-2-enyl chloride in the presence of azide or thiocyanate ions in absolute ethanol $x = k_{-1}/k_S = 4.0$ for both ions [291]. This was regarded as supporting the scheme, which can in general be written



where k_r is the allyl isomerisation rate constant.

A similar view was expressed by Streitwieser et al. [296], who showed [297] that acetolysis of 1-methylheptyl toluene-*p*-sulphonate entails inversion but is accompanied by racemisation of the initial compound, the rate of which is

increased by the presence of lithium toluene-*p*-sulphonate [296]. According to Streitwieser solvolysis and substitution are not independent processes, but occur via the same ionic intermediate, together with slight rearrangement

$$ROTs \rightleftharpoons R^+OTs^- \rightleftharpoons R'^+OTs^- \rightleftharpoons R'OTs$$
$$\searrow \quad \swarrow$$
$$\text{Solvolysis products}$$

The observed effect of additions of lithium perchlorate on the rates of solvolysis, racemisation, and rearrangement were attributed to "capture" of the ion-pair, similar to that effected by the azide ion. Thus in the reactions of non-activated secondary systems, in contrast to Winstein's description of S_N1 processes, all events (anion exchange, return, solvolysis) involve contact ion-pairs, which in Winstein's scheme played no part in chemical "capture". It is significant also that the limiting stage is not the formation of these ion-pairs but their further transformation. The reason for these differences is that nucleophilic attack on a secondary ion-pair is more favoured than is its further ionisation and dissociation.

When the various secondary systems for which Winstein's scheme was used are recalled, many questions arise, to which it is difficult to give an unequivocal answer. It must be admitted, for example, that all processes involving solvent-separated ion-pairs formed in the limiting stage should be more rapid than any process described by an ion-pair S_N2 mechanism, otherwise it would be impossible to explain why they did not result from attack on a contact ion-pair. Unfortunately, no comparison was made of the rates of various processes under identical conditions.

It was shown in the same year (1965) that the reaction of 1-methylheptyl bromide with silver nitrate in acetonitrile, with formation of an alkene and an alkyl nitrate, entails inversion of the stereochemical configuration (the optical purity of the alkyl nitrate was 87%) [298]. A similar rule was observed in the reaction of the bromide with silver perchlorate in benzene: formation of the alkyl perchlorate was 80% accompanied by inversion of configuration [299]. The slow stage was considered to be attack by the nucleophile on the complex $RX\ldots Ag^+$, and a quadrupole $[N^-\ldots R^+\ldots X^-\ldots Ag^+]$ was assumed, in the traditions of the English school, to be involved in the reaction. Such a structure had been suggested earlier as a transition state [300]. The reactions of alkyl halides with silver nitrate or silver perchlorate in acetonitrile had the same mechanism (not S_N1Ag^+ [1]). [301] However, it is easily seen that the differences from Sneen's treatment are mainly terminological [302,303].

In view of the possibility that ion-pairs of contact type may take part in nucleophilic substitution Winstein's scheme should be expanded, and should include in modified form the various mechanisms that can in principle operate with variation in the relative rates of the different stages:

$$\begin{array}{ccccccc}
 & S_N^I1 & & S_N^{II}1 & & S_N^{III}1 & \\
 & k_1 & & k_2 & & k_3 & \\
RX & \rightleftharpoons & R^+X^- & \rightleftharpoons & R^+\,\|\,X^- & \rightleftharpoons & R^+ + X^- \\
\text{(I)} & k_{-1} & \text{(II)} & k_{-2} & \text{(III)} & k_{-3} & \text{(IV)} \\
S_N^I2 \downarrow & k_S & S_N^{II}2 \downarrow & k_S^{II} & S_N^{III}2 \downarrow & k_S^{III} & S_N^{IV}2 \downarrow \; k_S^{IV} \\
\text{ROS} & & \text{ROS} & & \text{ROS} & & \text{ROS}
\end{array}$$

Participation of ion-pairs in reactions of secondary systems, including Sneen's ion-pair mechanism ($S_N^{II}2$), follows from the efforts by Shiner et al. [304-310] to determine the mechanism of solvolytic reactions from α- and β-deuterium isotope effects. For example, the α-effect in the reactions of isopropyl *p*-bromobenzenesulphonate [305], 1-methylbut-2-enyl derivatives [306], cyclopentyl *p*-bromobenzenesulphonate [310], etc. is close to unity in aqueous ethanol, but increases to 1.22–1.23 as the ionising power of the solvent increases and its nucleophilicity diminishes (ethanol with a high water content, aqueous trifluoroethanol, carboxylic acids). This was regarded as evidence of a change in mechanism from "purely" S_N2 to S_N^I1 or $S_N^{II}2$, in the limit $S_N^{II}1$; the classification is based on a scheme which differentiates between the mechanisms of the formation of a contact ion-pair in the limiting stage (S_N^I1) and of its conversion into a solvent-separated ion-pair ($S_N^{II}1$). α-Deuterium effects of 1.00–1.05, ~1.15, and 1.22 are regarded as representing S_N^I2, S_N^I1 or $S_N^{II}2$, and $S_N^{II}1$ mechanisms respectively (the last indicates conversion of a contact into a solvent-separated ion-pair). A large isotope effect is associated with formation of a carbonium ion [311]. However, the presence of a certain effect of the azide ion on the rate of reaction of secondary systems would probably indicate $S_N^{II}2$, not an S_N^I1 mechanism.

Nevertheless, it seems to the Reviewer premature to regard the criterion proposed by Shiner and his coworkers as absolutely reliable, and to try to identify reaction mechanisms on the basis of relatively small (1.08–1.22) α-deuterium isotope effects. Other grounds also exist for a cautious attitude to this criterion. Thus the observed isotope effect develops differently at different stages [312], and would depend on the relative rates of conversion of the ion-pair and of the return stage, since

$$\frac{k_2^D}{k_{-1}^D} \Big/ \frac{k_2^H}{k_{-1}^H} \neq 1.$$

Furthermore, this approach does not apply to reactions in which elimination and rearrangement occur as well as substitution [313], and such competing processes usually accompany reactions in secondary systems [314]. Finally, the maximum isotope effect was assigned to an $S_N^{II}1$ reaction on the basis of results [305] that have since proved incorrect [315].

Bordwell et al. [316-319] give arguments supporting the involvement of ion-pairs in S_N2 nucleophilic substitution at a tertiary carbon atom in the allylic systems

$$p\text{-}MeC_6H_4SO_2 \diagdown \quad H \diagup C{=}C \diagdown \quad H \diagup C(Me_2)X \xrightarrow[\text{MeOH or DMF}]{N^-} RN$$

in which X = Cl, Br, OSO_2CH_3; N = OCH_3, OH, N_3, SCN, $S{:}C(NH_2)_2$. With the first order with respect to the nucleophile (which corresponds to an S_N1 mechanism) the dependence of reaction velocity on salt effect, polarity of medium, nature of nucleophile, leaving group, and the β-deuterium effect is different from that found for a system having a primary carbon atom. Introduction of an arenesulphonyl group is assumed to inhibit the dissociation but not the formation of ion-pairs.

Sneen's mechanism has recently been supported [320] by examination of the kinetic chlorine isotope effect $^{35}k/^{37}k$ in the reaction of *p*-methoxybenzyl chloride with sodium azide in 70% aqueous acetone. The isotope effect varied with the nucleophile concentration, which should not occur [320] in S_N1 and S_N2 processes, but is consistent with an ion-pair S_N2 mechanism.

An attempt was made to transfer Sneen's mechanism to reactions of non-activated primary systems [321,322]. It had earlier been suggested, in the reactions of AlkX with silver salts AgY (where Y = NO_3^-, $OSO_2C_6H_4CH_3$, etc.), that an ion pair Y^-R^+ is formed in the slow stage [323,324], and recombines or forms an alkene in the rapid stage. Scott [321] concluded that reactivity and selectivity data for methyl halides with various nucleophiles in water were best explained by the involvement of contact ion-pairs in the slow stage (i.e. that $k_{obs} = K_{eq} k_2$). However, such a hypothesis gives rise to grave objections [325]. Abraham's calculation [326] of the free energy required to form a primary ion-pair in water makes the hypothesis improbable, although ion-pairs may be formed with isopropyl and t-butyl bromides. Furthermore, the α-deuterium isotope effect in primary systems is close to unity [313].

Kohnstam and his coworkers [327,328] disputed the involvement of contact ion-pairs in the S_N2 mechanism and opposed attempts to establish a "unified" mechanism of nucleophilic substitution. In their view the influence of sodium azide on the hydrolysis of s-octyl methanesulphonates could be described, within the framework of the classic mechanisms, as occurring in a boundary region in which reaction took place simultaneously by S_N1 and S_N2 mechanisms§. These workers showed [328] that the hydrolysis of *para*-substituted (methoxylated and phenoxylated) benzyl chlorides and diphenylmethyl chloride takes place by an S_N1 mechanism, and that addition of sodium azide produces only a slight change caused by the salt effect; when the *para*-position is occupied by hydrogen or a nitro-group, however, the mechanism changes to S_N2, and the rate of disappearance of the initial compound is increased considerably by the addition of sodium azide. Table 11 shows the effect of such addition (0.05 M) on the hydrolysis of p-$XC_6H_4CH_2Cl$.

Table 11.

X	MeO	PhO	NO_2	Ph_2CHCl
$\frac{k_{RX}}{k^0_{RX}}$	1.74	20	5430	1.14

The same view arose [329] from a study of the reaction of 1-phenylethyl bromide with potassium and sodium ethoxides in alcohol: the results were described better by competition between $E1$, $E2$, S_N1, and S_N2 mechanisms involving the covalent compound than by Sneen's ion-pair S_N2 mechanism. Analysis of carbon and α-hydrogen isotope effects ($^{12}k/^{14}k$ and k_H/k_D)¶ led to the conclusion [330] that the hydrolysis of benzyl and p-methylbenzyl chlorides in the presence of sodium azide is a classic S_N2 process, while the corresponding reaction of 1-methylheptyl p-bromobenzenesulphonate is described by competition between S_N2 and S_N1 processes with the former predominating.

§ In the cases which they studied, however, the possibility of the formation of a free carbonium ion (by the S_N1 path) is doubtful.

¶ Theory predicts a considerable carbon isotope effect in an S_N2 process, a small effect in an S_N1 process, and the opposite behaviour of the α-hydrogen isotope effect [304].

Thus Sneen's ion-pair S_N2 mechanism has both protagonists and antagonists, and at the present time can be regarded only as debatable [331]. In the Reviewer's opinion recent very significant results have cast doubt on the existence of such a mechanism. Although the chief argument for an ion-pair S_N2 mechanism has been the fractional order with respect to sodium azide, as well as inversion of configuration in the final product, the result may be due to the existence of sodium azide not only as free ions but also as ion-pairs. One author considers [332] that use of concentrations of this salt instead of activities of the azide ion in the kinetic equations is responsible. He showed that such a change will linearise the non-linear relations between k_{obs}/k_{NA} and $[N_3^-]$ in the reaction of 1-methylheptyl methanesulphonate in 25% and 30% aqueous dioxan. However, the slopes of the dependence on $a_{N_3^-}$ of $[RN_3]/[ROH]$ and k_{obs}/k_{NA} differ in both media (addition of sodium azide has a smaller effect on the rate than on the yield—Fig. 4): i.e. there is indeed a difference between the stages determining the rate and the formation of products. However, this difference has been attributed [320] to the occurrence of solvolysis by an intermediate (borderline) mechanism [333]†.

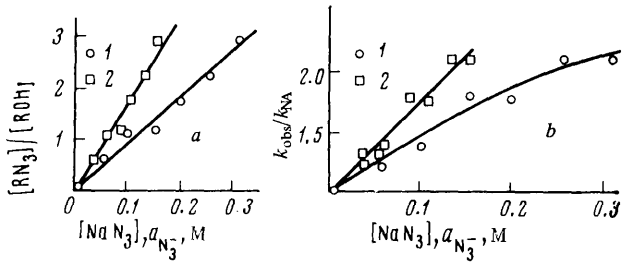


Figure 4. Effect of: 1) concentration of sodium azide; 2) activity of azide ion on reaction of 1-methylheptyl methanesulphonate with sodium azide and water in 30% aqueous dioxan: *a*) ratio of products; *b*) k_{obs}/k_{NA}.

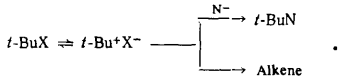
---o0o---

In the present Review we have discussed the involvement of ion-pairs only in S_N reactions, although it has been noted that in secondary systems they are often accompanied by elimination processes. In tertiary systems elimination may become predominant, so that we have almost ignored such systems. Yet in these cases also there are clear indications that ion-pairs, as well as carbonium ions, may take part in the reaction. Thus Winstein et al. [335] showed that, in the solvolysis of t-C_4H_9X compounds in water, a small quantity of an alkene is formed, which is approximately the same for all X, but in a less strongly dissociating solvent (ethanol) the proportion of elimination is sharply increased, and varies significantly with X in the sequence $S(CH_3)_2 < I < Br < Cl$.

† The nature of this mechanism was at one time widely discussed. Cases are known in which the total effect of competing S_N1 and S_N2 mechanisms is unable to describe behaviour characteristic of the "intermediate" region [334].

The yield of alkene in the solvolysis of t-butylethylmethylsulphonium salts in ethanol and in acetic acid increased on passing from the perchlorate to the bromide [336]. All these results were interpreted in terms of ion-pairs:



Finally, we have only mentioned the participation of ion-pairs in reactions at an sp^2-hybridised carbon atom, although study of the solvolytic reactions of the "vinyl cation" is providing increasing evidence of the involvement of ion-pairs even in these reactions [337].

The theoretical foundations of organic chemistry first formulated by Ingold and his school were based mainly on a study of nucleophilic substitution in aliphatic systems, and were then transferred with additions to other types of substitution. There was a period when it seemed that this field, having become classical, was almost exhausted. This was apparent in a change in the number of publications on the theory of nucleophilic substitution and in the increasing attention paid to other types of reactions, which exhibited interesting and novel features. However, as had already happened repeatedly, new ideas and a new standard of research revealed that established views, in this case concerning S_N2 and S_N1 mechanisms, were inadequate. Whatever the fate of the ion-pair S_N2 mechanism, around which heated arguments are currently raging, it is evident that the whole field of nucleophilic substitution will survive the new stage of development, primarily because of the great attention paid by investigators to the role of various types of ionic intermediates. New ideas have led to a new terminology, and writers on mechanisms of solvolytic reactions prefer to speak of the nucleophilic participation of the solvent in the reaction—which is more or less strongly developed depending on the nature of substrate and solvent, and may be completely absent—not about S_N2 and S_N1 mechanisms [313]. The nucleophilic intervention of the solvent in the solvolysis of several secondary systems has been estimated relative to trifluoroacetic acid, whose intervention was equated to zero [338]. The same approach can in principle be extended to other nucleophilic substitutions. However, the new terminology should not conceal the fundamental problem of elucidating the nature of the species involved in the primary stages.

7,7,8,8-Tetracyanoquinodimethane in Addition, Substitution, and Complex Formation Reactions

B.P.Bespalov and V.V.Titov

The review is devoted to the properties of 7,7,8,8-tetracyanoquinodimethane, one of the strongest of the known organic π acids. Data concerning the methods of synthesis of 7,7,8,8-tetracyanoquinodimethane and its analogues and the physicochemical properties of compounds of this series are surveyed. The addition, substitution, and complex formation reactions of 7,7,8,8-tetracyanoquinodimethane, its spectroscopic, electrical, and magnetic properties, and the structures of its complexes and radical-ion salts with organic and inorganic electron donors are examined.
The bibliography includes 232 references.

I. INTRODUCTION

The semiconducting properties of molecular complexes or charge-transfer complexes have been widely investigated in the last 20 years. Although organic semiconductors have not so far found extensive practical applications, in contrast to inorganic semiconductors, interest in these compounds has been stimulated by the synthesis of several new powerful electron acceptors, such as tetracyanoethylene (TCNE), 7,7,8,8-tetracyanoquinodimethane (TCNQ), and tetracyano-*p*-benzoquinone. Although the first two compounds are somewhat inferior as regards their electron-accepting properties to the last, their comparatively easy synthesis led to a vigorous investigation of their chemical properties as well as the physical properties of their complexes.

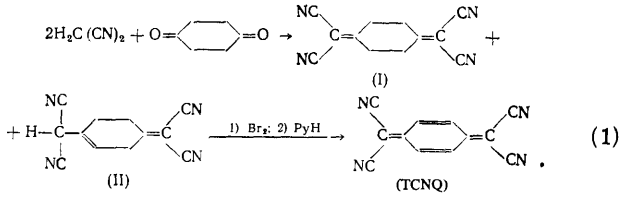
In this connection TCNQ is of particular interest. As a result of the presence in its molecule of four powerful electron-accepting groups, nucleophilic addition reactions, which are rarely encountered among unsaturated compounds, as well as addition reactions proceeding via a one-electron transfer stage are characteristic of this substance. The addition reactions are particularly interesting from the standpoint of modern ideas on the mechanisms of heterolytic substitution reactions. As a result of its powerful electron-accepting properties combined with a comparatively large conjugation system in the molecule (eight π electrons), TCNQ forms a stable radical-anion and gives rise to stable radical-ion salts with many organic and inorganic electron donors, some of which exhibit the highest electrical conductivity observed for organic compounds.

Several TCNQ radical-anion compounds exhibiting "a metallic" temperature variation of the electrical conductivity have been synthesised in recent years. In order to account for the conduction mechanism in such systems, the most modern and fundamental ideas of solid state physics have been resorted to. Thus TCNQ has been the object of intense study by workers in both chemistry and physics.

So far there has been no review dealing with the entire wide variety of properties of both TCNQ itself and its complexes; several of the published reviews deal only with narrow questions concerning the properties of TCNQ complexes. The bibliography on TCNQ and its complexes includes about 600 items. The present review covers the most interesting data relevant to the methods of synthesis and the physicochemical properties of TCNQ and its analogues as well as complexes and radical-ions based on them, which have been published up to the beginning of 1975. Some of the studies on TCNQ, particularly early ones, have been described in reviews which are referred to in the corresponding sections of the present survey.

II. THE SYNTHESIS OF 7,7,8,8-TETRACYANOQUINODIMETHANE AND ITS ANALOGUES AND THEIR PHYSICOCHEMICAL PROPERTIES

Although the reports about the properties of TCNQ complexes refer to 1960, its synthesis was described for the first time in 1962.[1] In the first stage malononitrile is condensed with cyclohexane-1,4-dione and then TCNQ is obtained by bromination and dehydrobromination in the presence of pyridine (in a single stage) [reaction (1)], the overall yield of the product reaching 80%:

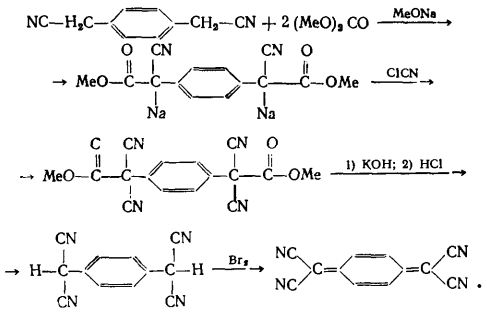


(1)

The first stage may be carried out either in benzene solution in the presence of small amounts of acetic acid and ammonium acetate or in an aqueous medium in the presence of β-alanine. In the first case a mixture of isomers (I) and (II) is formed (this is unimportant for the next stage) in a yield of 75.1%. The second case involves the formation of only isomer (I) in 97% yield. The second stage, the dehydrogenation of compound (I) or a mixture

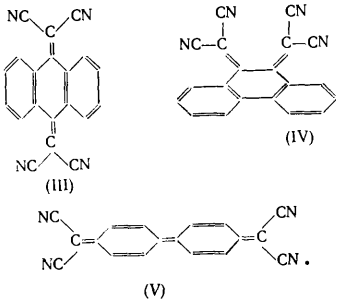
of (I) and (II), may be carried out with the aid of various reagents: *N*-bromosuccinimide, bromine, selenium dioxide, or *N*-chlorosuccinimide; the purest product was obtained by using bromine[1].

Alkyl derivatives of TCNQ were synthesised by a similar procedure: 2-methyl-, 2-propyl-, and 2,5-dimethyl-TCNQ.[2] The starting materials for their synthesis were the alkyl derivatives of cyclohexane-1,4-dione obtained by reducing the corresponding alkyl derivatives of the dimethyl ether of hydroquinone with sodium in liquid ammonia and subsequent demethylation:



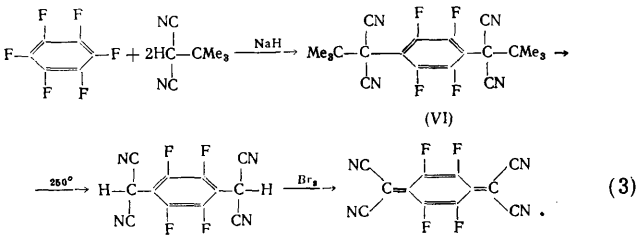
(2)

About 20 TCNQ derivatives with different substituents in the ring (alkyl, alkoxy-, halogeno-, and aryl) have been synthesised by the method based on reaction (2) and on the basis of condensed aromatic hydrocarbons—15,15,16,16-tetracyano-9,10-anthraquinodimethane (III), 15,15,16,16-tetracyano-9,10-phenanthroquinodimethane (IV), and 13,13,14,14-tetracyano-1,12-diphenoquinodimethane (V):[3]



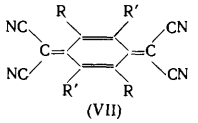
TCNQ was obtained recently (in 80% yields) by the single-stage condensation of cyclohexane-1,4-dione with $(CN)_2CO$ or phosgene in the presence of HCN or NaCN.[4]

The starting materials for the synthesis of 2,3,5,6-tetrafluoro-TCNQ were t-butylmalononitrile and hexafluorobenzene, which in the presence of sodium hydride give rise to the condensation product (VI), the latter being converted into 2,3,5,6-tetrafluoro-TCNQ after hydrolysis and treatment with an excess of bromine [reaction (3)]:[5]



(3)

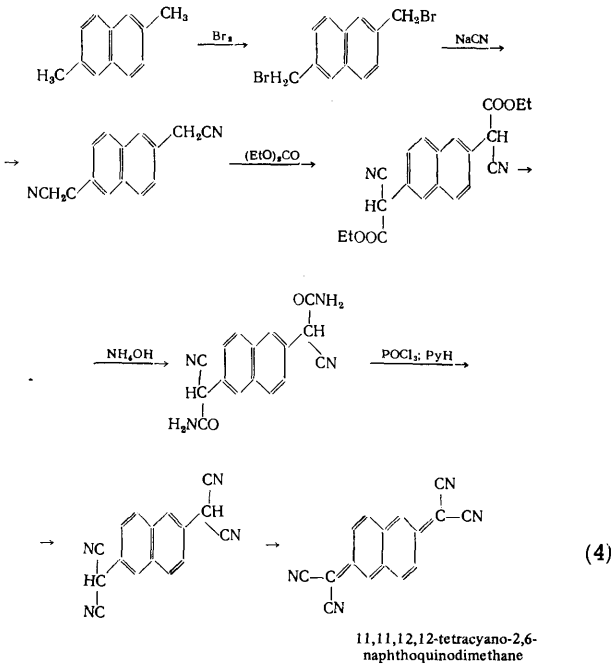
A whole series of substituted TCNQ derivatives (VII) were obtained using polyhalogeno- and cyano-benzenes[5]:



(a) R=H, R'=CN; (b) R=F, R'=CN; (c) R=R'=CN; (d) R=H, R'=F; (e) R=F, CN; R'=F; (f) R=F, CN, R'=CN; (g) R=F, H, R'=F.

Two naphthalene analogues of TCNQ have been synthesised: 11,11,12,12-tetracyano-1,4-naphthoquinodimethane and 11,11,12,12-tetracyano-2,6-naphthoquinodimethane. The former was obtained from *cis*-2,3,5,8,9,10-hexahydro-1,4-naphthoquinone via reaction (1).[6]

The synthesis of 11,11,12,12-tetracyano-2,6-naphthoquinodimethane is much more complex [reaction (4)].[2] The starting material for this purpose was 2,6-dimethylnaphthalene into which four CN groups were introduced in succession: the abstraction of two methine hydrogen atoms led to a common system of conjugated double bonds in the molecule. 11,11,12,12-Tetracyano-2,6-naphthoquinodimethane was synthesised recently also via reaction (2) and the method of preparation of the initial 2,6-naphthylenedimalononitrile was considerably improved[7]:



(4)

11,11,12,12-tetracyano-2,6-naphthoquinodimethane

The interaction of diphenyldiazomethane with TCNQ leads to 2-diphenylmethyl-TCNQ.[8]

Data on the electron-accepting capacity of TCNQ, its analogues, and derivatives (and for comparison of TCNE[9]) are presented in Table 1. The principal characteristic of the strength of the acceptor is its electron affinity E_A. The values of E_A for TCNQ and TCNE, determined by the magnetron method, are 2.75 and 2.76 eV respectively[10].

Another widely used method for the determination of E_A is based on the proportionality of the electron affinity of the acceptor to the half-wave potential in its polarographic titration. The E_A for 11,11,12,12-tetracyano-1,4- and 11,11,12,12-tetracyano-2,6-naphthoquinodimethanes were determined in this way[6]. Since there are no E_A values in the literature for the remaining acceptors, we quote here the literature data for polarographic titration under standard conditions: in 0.1 M lithium perchlorate solution in acetonitrile relative to the saturated calomel electrode.

It follows from the data in Table 1 that the introduction of fluorine or the CN group enhances sharply the electron-accepting properties of TCNQ. Alkyl derivatives of TCNQ as well as 11,11,12,12-tetracyano-1,4-naphthoquinodimethane are clearly weaker electron acceptors (particularly the latter) than TCNQ itself. According to X-ray diffraction data, the CN groups in 11,11,12,12-tetracyano-1,4-naphthoquinodimethane are not in the same plane as the naphthalene ring owing to the steric interaction with the hydrogen atoms in the 5- and 8-positions[11]. In the electronic spectrum of 2-diphenylmethyl-TCNQ the absorption band exhibits a fairly considerable hypsochromic shift (Table 1), which indicates a non-planar conformation of its molecule. However, all the TCNQ derivatives listed in Table 1 are fairly powerful electron acceptors and form complexes and radical-ion salts with organic and inorganic electron donors[2,6]. Since all the electron acceptors have similar structures, we shall henceforth consider only TCNQ, because investigators have concentrated attention on its properties and those of its complexes.

Table 1. The properties of TCNQ and its derivatives ($E_{1/2}^{-}$ and $E_{1/2}^{=}$ are the half-wave potentials in polarographic titration with formation of an anion and dianion respectively; E_A is the electron affinity).

*Chatterjee's data[6].
**Farragher and Page's data[10].

TCNQ is a crystalline yellow-brown substance melting at 296—298°C and subliming readily above 250°C. In the solid state it is stable in air but in solutions it is sensitive to moisture[1]. According to X-ray diffraction data, the TCNQ unit cell has the following parameters: $a = 8.906$ Å, $b = 7.060$ Å, $c = 16.395$ Å, and $\beta = 98.54°$; its density is 1.315 g cm^{-3}. The bond lengths and angles in the TCNQ molecule are shown in Fig. 1. The distance between the planes of adjacent molecules in the crystal is 3.45 Å.[12]

The electronic spectrum of the acetonitrile solution of TCNQ shows one absorption band (395 nm, $\epsilon = 6.36 \times 10^4$)[1]; four maxima, at 304, 341, 402, and 424 nm, were found for the single crystal in polarised light along the a and b axes[13]. Quantum-chemical calculations on the TCNQ molecule[14-17] lead to a system of electronic transitions consistent both with the experimentally observed electronic absorption bands and with the photoelectronic spectra of TCNQ.[18,19]

The infrared[20-22] and Raman[23] spectra of TCNQ have been investigated in detail. The most intense infrared lines are at 3050 [ν(C—H)], 2220 [ν(C≡N)], 1540 [ν(C=C)], 1545 {ν[C=C(CN$_2$)]}, and 861 cm^{-1} [γ(C—H)] and in the Raman spectrum the most intense lines are at 3050 [ν(C—H)], 2225 [ν(C≡N)], 1602 {ν[C=C(CN)$_2$]}, 1554 [ν(C=C)], and 1210 [δ(C—H)].

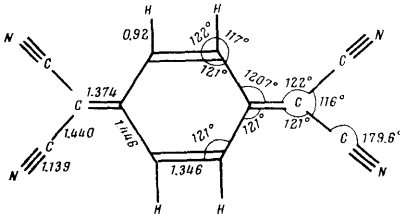

Figure 1.

According to ^{14}N nuclear quadrupole resonance data, the nitrogen atoms in the TCNQ molecule can occupy two non-equivalent positions. The average frequency of the quadrupole interaction constant is 4021 kHz for TCNQ. The observed asymmetry in the position of the nitrogen atoms can be explained by the non-equivalence of the polarisation of the π orbitals of the nitrile group parallel and at right angles to the plane of the ring[24].

According to its electrical properties, the TCNQ single crystal is a typical organic semiconductor (the conductivity at 20°C is 2×10^{-12} Ω^{-1} cm^{-1} and the activation energy for dark conduction is 0.6 eV [25-27]). Furthermore, TCNQ single crystals exhibit photoconduction[25,26]. Measurements of the electrical characteristics of TCNQ single crystals prepared in different ways showed that the single crystals, both grown *in vacuo* and obtained on cooling solutions, contain an admixture of the sodium salt of TCNQ owing to the leaching of glass; the dark conductivity is relatively insensitive to this impurity, while the photoconductivity depends strongly on its concentration[26].

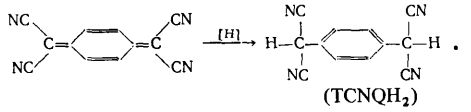
A special investigation of the influence of the admixture of the lithium salt of TCNQ on the electrical properties of TCNQ itself revealed the opposite effect of this additive: 1—2% of the salt impurity increased the dark current but hardly affected the photoconductivity[27]. This difference between the effects of impurities can probably be accounted for by their amount: whereas in the first instance we are probably dealing with 0.1—0.01%, in the second the concentration of the impurity is 1—2%.

III. CHEMICAL PROPERTIES

1. Addition Reactions

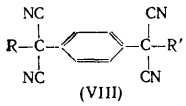
Whereas 1,4-addition reactions in which 3-substituted hydroquinones are formed are characteristic of p-benzoquinone, a structural analogue of TCNQ, 1,6-addition reactions are characteristic of TCNQ. The simplest example of such a reaction is the reduction of TCNQ by

thiophenol, mercaptoacetic acid, or hydriodic acid with formation of *p*-phenylenedimalononitrile ($TCNQH_2$): [1]



($TCNQH_2$)

TCNQ readily reacts with sulphur dioxide in aqueous acetonitrile to form the sulphonic acid (VIIIa). [1] In the absence of catalysts TCNQ does not react with halogens: in the reaction with chlorine in the presence of catalytic amounts of triethylamine or NMe_4Cl, the dichloro-derivative (VIIIb) was obtained:



(VIII)

(a) R=H, R′=SO_3H; (b) R=R′=Cl; (c) R=R′=Br; (d) R=R′=C(Me)$_2$CN; (e) R=H, R′=4-$C_6H_4NR''_2$; (f) R=H, R′=4-OH-2-R″C_6H_3; (g) R=H, R′-2-pyrrolyl; (h) R=H, R′=3-indolinyl; (i) R=H, R′-1-azulenyl; (j) R=HgOAc, R′=4-$C_6H_4NMe_2$.

The analogous bromo-derivative (VIIIc) is formed only when bromine interacts with the disodium salt of $TCNQH_2$.

The addition product (VIIId) was isolated in the thermal decomposition of $\alpha\alpha'$-azobisisobutyronitrile in the presence of TCNQ.

NN-Dimethylaniline also forms a 1,6-addition product (VIIIe, R″ = Me) with TCNQ. [1] A more detailed study of the interaction of TCNQ with a series of aromatic amines [28,29] showed that only the *para*-position relative to the amino-group is active in this reaction even in the case of amines such as *NN*-dimethyl-1-naphthylamine. A series of addition products (VIIIe) with R″ = H, Me, Et, Pr, Bu, or Ph were obtained. The only aromatic amines which react with TCNQ are those whose ionisation potential I_D is less than 7.8–8.0† eV or, what amounts to the same thing, amines which form complexes with TCNQ whose spectra contain a charge-transfer band above 600 nm (in chloroform).

TCNQ reacts with phenols very slowly to form compounds (VIIIf). The use of sodium phenoxide leads to an appreciable acceleration of the reaction [31]. This is apparently associated with the fact that the electron-donating properties of phenols are inadequate ($I_D > 8$ eV) and only phenoxide ions, the concentration of which is extremely low under the usual conditions (in acetonitrile), are involved in the reaction.

Pyrrole and indole react with TCNQ to form addition products (VIIIg) and (VIIIh) respectively. If the 2- and 5-positions in pyrrole are occupied, the 3- or 4-position is reactive. If the 3-position in indole is occupied, substitution takes place in the 2-position, but the reaction proceeds under more severe conditions [31].

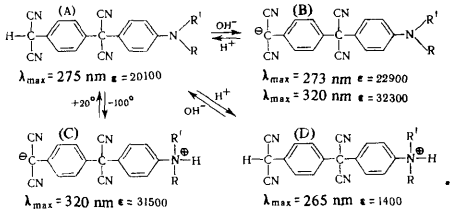
In acetonitrile TCNQ reacts readily with azulene; as in the case of TCNE, [32] this involves the formation of 1-substituted azulene derivatives (VIIIi). [33] An organomercury compound (VIIIj) was obtained by the reaction of TCNQ with *p*-*NN*-dimethylaminophenylmercury acetate [28].

It is noteworthy that, whereas the reactions involving the addition of chlorine and sulphur dioxide resemble nucleophilic reactions involving addition to the double bond and the addition of the dimethylacetonitrile radical resembles radical addition reactions, the interaction with aromatic amines, phenols, nitrogen-containing heterocycles, azulene, and *p*-dimethylaminophenylmercury acetate apparently begins with the addition of the electron donor to TCNQ with formation of the radical-ion TCNQ salt; the site where a hydrogen atom is substituted in the donor molecule is similar to that in electrophilic substitution under mild conditions [28]. The formation of $TCNQH_2$ in the reaction of TCNQ with triarylphosphine proceeds in accordance with this mechanism via the intermediate $TCNQ^{\cdot}$ radical-anion:

$$Ar_3P + TCNQ + H_2O \xrightarrow{H^+} Ar_3PO + TCNQH_2 .$$

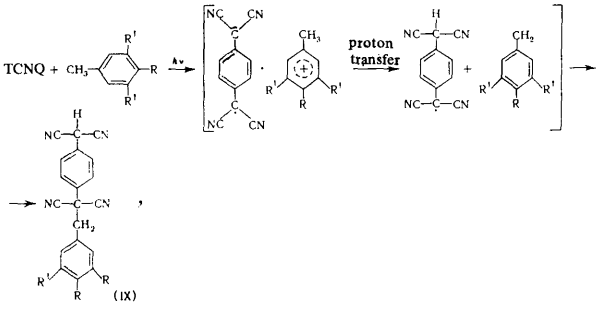
This was demonstrated in a kinetic study of the reaction using optically active arylphosphines [35].

The majority of compounds (VIII) contain the acid malononitrile hydrogen atom, which can be readily split off: as a result, these compounds are sensitive to the pH of the medium. This is particularly clearly seen for compounds (VIIIe), which can exist in four different forms in solution, differing in their electronic absorption spectra and capable of being reversibly converted into one another [reaction (5), compound (VIIIe), R = R′ = CH_3; (A) = undissociated compound, (B) = anion, (C) = inner salt, (D) = ammonium salt] [36]:



(5)

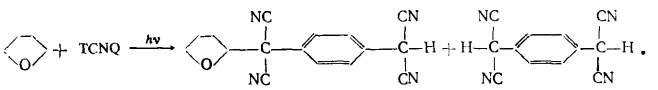
On illumination with light corresponding to the charge-transfer band of the TCNQ complexes with toluene, *p*-xylene, and mesitylene, compounds having the general formula (IX) are formed, probably via a stage involving the photoinduced addition of a proton to TCNQ: [37]



(IX)

where R and R′ = H or Me.

Yet another example of radical addition to TCNQ is its interaction with tetrahydrofuran:



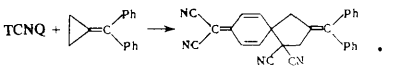
The reaction proceeds when a mixture of the initial compounds is illuminated by ultraviolet light or in the presence of peroxides [38].

In contrast to *p*-benzoquinone [39], TCNQ does not form Diels–Alder adducts with dienes: the reaction with cyclopentadiene and methylbuta-2,3-diene results in the formation of a polymeric product only [1].

An unusual reaction involving addition to TCNQ was discovered recently [40]. When TCNQ interacts with

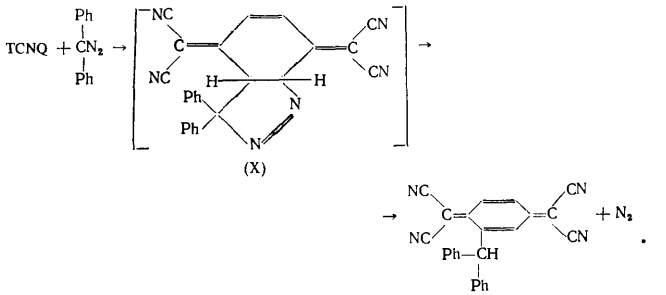
† The ionisation potential was determined by the photoionisation method; other methods give a somewhat higher value of I_D.

2,2-diphenylmethylenecyclopropane, the addition product with the structure shown below is formed in 60% yield:



2. Substitution Reactions

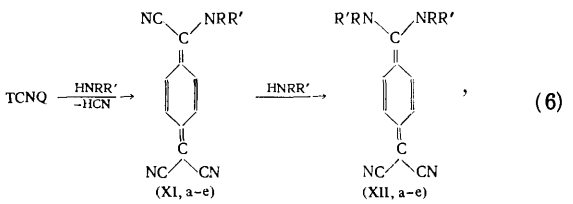
In principle two types of substitution reactions with TCNQ are possible: the substitution of hydrogen and of CN groups. The only example of reactions of the first type is the interaction of TCNQ with diphenyldiazomethane already mentioned [8]:



(X)

This involves the formation of 2-diphenylmethyl-TCNQ, probably via the intermediate cyclic derivative (X).

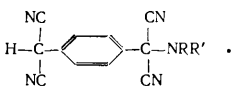
Among reactions of the second type, mention may be made of the interaction of TCNQ with primary and secondary aliphatic and aromatic amines [reaction (6)]: [41]



(XI, a-e) (XII, a-e) (6)

where R = R′ = H (a), R = H and R′ = Bu (b), NRR′ = *N*-pyrrolidinyl (c), R = H and R′ = 4-C_6H_4OMe (d), and R = H and R′ = NH_2 (e).

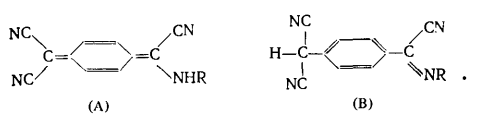
It is noteworthy that the reactions involving substitution of the cyano-groups in TCNQ apparently proceed via the formation of an intermediate product of 1,6-addition to the quinonoid system of TCNQ [compound (XIII)], which splits off HCN rapidly at room temperature and is converted into the corresponding compound (XI):



(XIII)

The spectra of intermediates of type (XIII) were observed for films, obtained by the simultaneous sputtering of TCNQ and electron donors (*p*-phenylenediamine or *m*-phenylenediamine) onto a support cooled to 77 K, when the film was heated slowly to room temperature [42].

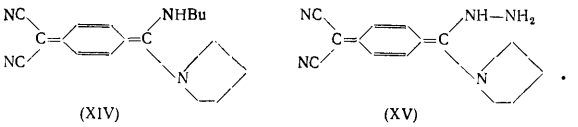
Aliphatic compounds (XI) [for example (XIb)] exist in the form of two isomers—(A) and (B): [41]



(A) (B)

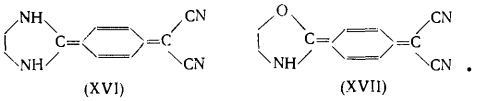
The *p*-anisidine derivative (XId) was obtained only in form (B). [41] Judging from the electronic spectra, *p*-phenylenediamine also gives rise to form (B), while *m*-phenylenediamine reacts with formation of the quinonoid form (A). [42]

Mixed derivatives of TCNQ have also been obtained by reaction with amines [compounds (XIV) and (XV)] [41]:



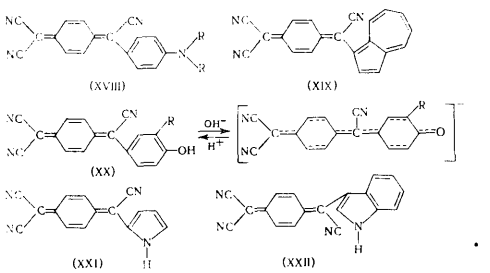
(XIV) (XV)

Bifunctional amines (for example, ethylenediamine and monoethanolamine) are capable of substituting two cyano-groups in TCNQ [compounds (XVI) and (XVII)] [41]:



(XVI) (XVII)

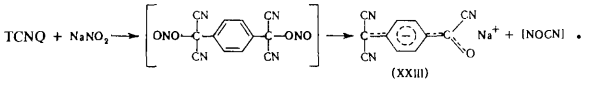
The products of the substitution of a cyano-group in TCNQ [compounds (XVIII)–(XXII)] have been obtained by ultraviolet irradiation of the corresponding products of the 1,6-addition reaction [compounds (VIII, e–i)]. They all have a deep colour (red for the product of the reaction with phenol and blue for all others); the position of their long-wavelength absorption band depends on the nature of the electron-donating group and varies from 500 to 700 nm. The absorption band itself is due to intramolecular charge-transfer [29,31,33]:



(XVIII) (XIX) (XX) (XXI) (XXII)

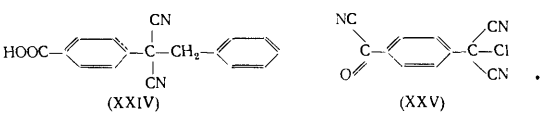
Compound (XX) contains an acid proton, which splits off reversibly in an alkaline medium to form an intensely blue anion [31].

Another example of substitution reactions of TCNQ is its interaction with sodium nitrite, which leads to the formation of an orange-red salt (XXIII) via a hypothetical intermediate addition product:



(XXIII)

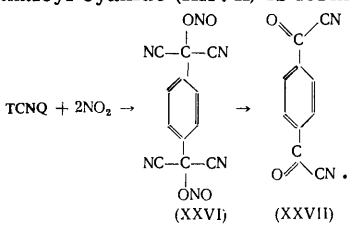
Like chlorination, benzylation of the salt (XXIII) (followed by hydrolysis) leads to the formation of the addition products (XXIV) and (XXV) respectively [41]:



(XXIV) (XXV)

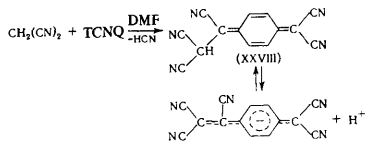
N_2O_4 reacts with TCNQ similarly to $NaNO_2$. When the reaction was carried out in acetonitrile at 0°C, an unstable intermediate, to which structure (XXVI) was attributed,

was obtained in 75% yield. On heating it *in vacuo* at 130°C, terephthaloyl cyanide (XXVII) is formed[41]:



(XXVI) (XXVII)

The substitution product (XXVIII) was obtained by the reaction of TCNQ with malononitrile in dimethylformamide (DMF):[43]



(XXVIII)

Compound (XXVIII) is a strong acid ($pK_a = 0.60$) and readily dissociates in solution to form an intensely blue carbanion; in strongly acid solutions, where the dissociation is suppressed, the colour of compound (XXVIII) differs little from that of TCNQ. Thus nucleophilic reactions involving 1,6-addition to the conjugated double bond system, which in many instances are the first stage of the CN substitution reactions, are most characteristic of TCNQ. The mechanism of these processes has been inadequately investigated, although it is of definite interest, since in some cases the reaction apparently proceeds via one-electron oxidation of the donor with formation of an intermediate radical-ion salt.

3. Complex Formation Reactions

The ability of quinones to form stable solid complexes with aromatic amines has been known for a long time[44]. TCNQ, a strong π acid, forms three types of complexes with electron-donating compounds[45]. Since these complexes are of much interest from the standpoint of their semiconducting properties, the dark conductivities σ are listed below as their characteristics. The first type includes classical molecular complexes in which mainly aromatic hydrocarbons are used as electron donors ($\sigma = 10^{-3}-10^{-14}\ \Omega^{-1}\ cm^{-1}$, Table 2).[45]

The second type of TCNQ complexes includes simple radical-ion salts having the general formula $M^{n+}(TCNQ^{\cdot-})_n$, where M^{n+} is a metal cation or organic cation with n charges, which represent the limiting case of molecular complexes: here the electron is completely transferred from the donor to the acceptor molecule ($\sigma = 10^{-4}-10^{-12}\ \Omega^{-1}\ cm^{-1}$).[45] We may note that such compounds are referred to in the literature as both strong complexes and as simple radical-ion salts. The electronic spectra of their solutions contain the absorption bands of the donor radical-cations and the $TCNQ^{\cdot-}$ radical-anion.

The third type of TCNQ complexes includes complex radical-ion salts having the general formula $M^+(TCNQ^{\cdot-}) \cdot (TCNQ^0)$, or $M^{2+}(TCNQ^{\cdot-})_2 \cdot (TCNQ^0)$. In solution these salts dissociate with formation of the donor cation, the $TCNQ^{\cdot-}$ radical-anion, and the neutral molecule $TCNQ^0$. However, in the crystal the electron is delocalised over both acceptor molecules and the radical-anion is of the form $(TCNQ^{\cdot-})_2$. As a rule these salts give rise to an intense ESR signal; their spin concentration may reach 1–1.5 spins per donor–acceptor pair. The complex radical-ion salts have a strikingly high conductivity[45]: $\sigma = 10^{-3}-10^{2}\ \Omega^{-1}\ cm^{-1}$.

It is noteworthy that there is no sharp boundary between weak molecular complexes and radical-ion salts. Thus the complex of TCNQ and *NNN'N'*-tetramethyl-*p*-phenylenediamine dissociates in acetonitrile with formation of a radical-ion pair[45].

Table 2. Molecular TCNQ complexes with aromatic donors[45].

Hydroquinone[c]	THF		180—185		
4,6,8-Trimethylazulene	THF	85	160—167	10^9	

[a] Kosower's data[46]. [b] Beukers and Szent-Gyorgyi's data[47]. [c] Molar ratio donor : TCNQ = 1 : 2.

A comparative study of the electronic spectra of a solution of this complex relative to those of the perchlorate of Wurster's Blue and the lithium salt of TCNQ showed that it is dissociated to an extent greater than 80%. The study of the polarisation absorption spectra of single crystals of the complex confirmed its partially ionic character[48]. Similar conclusions were reached also about the structure of TCNQ complexes with *NNN'N'*-tetramethylbenzidine and benzidine[49].

Table 3. TCNQ complexes forming clathrate compounds with solvents[50,51].

Donor	Solvent	Donor : acceptor : solvent molar ratio	Donor	Solvent	Donor : acceptor : solvent molar ratio
Benzidine	CH_2Cl_2	1,0:1,1:1,6	3,3'-Dichlorobenzidine	CH_2Cl_2	1,0:0,8:0,16
Benzidine	C_2H_5Br	1,0:1,1:1,6		CH_2Cl_2	1,0:1,0:0,23
Benzidine	MeCOMe	1,0:0,8:0,8	*o*-Toluidine	$CHCl_3$	1,00:1,07:0,52
3,3'-Diaminobenzidine	CH_2Cl_2	1,0:1,0:0,45	*o*-Toluidine		

It was found that certain solvents form clathrate compounds with TCNQ complexes (Table 3)[50,51]. Their crystal structures[52] and electrical properties[53] have been investigated.

The ability of TCNQ to undergo readily one-electron reduction under the influence of certain metals, metal iodides, or the iodides of organic cations has been used to synthesise simple TCNQ radical-ion salts[45]. Thus copper or silver readily react with TCNQ in acetone or acetonitrile at room temperature:

$$Cu + TCNQ \rightarrow Cu^+ TCNQ^{\cdot-},$$

$$Ag + TCNQ \rightarrow Ag^+ TCNQ^{\cdot-},$$

$$MI + TCNQ \rightarrow M^+ TCNQ^{\cdot-} + \frac{1}{2} I_2,$$

where M is the metal or organic cation.

It has been shown that the TCNQ + $I^- \rightleftharpoons TCNQ^{\cdot-} + \frac{1}{2}I_2$ system is reversible. The standard reduction potential of TCNQ is 0.581 V relative to the standard hydrogen electrode[54].

There are several ways of synthesising simple radical-ion TCNQ salts[45]. The first procedure (*a*) involves the interaction of metal iodides with TCNQ. TCNQ salts with lithium, sodium, potassium, copper, etc. have been obtained in this way. The maximum yield of the salt is reached when the reactant ratio corresponds to the equation

$$3LiI + 2\ TCNQ \rightarrow 2Li^+TCNQ^{\cdot-} + Li^+ + I_3^- .$$

In the second method (*b*) TCNQ radical-ion salts are obtained by the exchange reaction between the lithium salt of TCNQ, which is readily soluble in water or acetonitrile, with a soluble metal salt or the salt of an organic cation. Examples of the syntheses of certain salts by this procedure[47] are presented below:

$$Li^+\ TCNQ^{\cdot-} + FeSO_4 \xrightarrow{H_2O} Fe^{++}(\ TCNQ^{\cdot-})_2 \cdot 3H_2O ,$$

$$Li^+\ TCNQ^{\cdot-} + AgNO_3 \xrightarrow{H_2O} Ag^+\ TCNQ^{\cdot-} , \qquad (7)$$

$$Li^+\ TCNQ^{\cdot-} + Et_3NH^+I^- \xrightarrow{CH_3CN} Et_3NH^+\ TCNQ^{\cdot-} ,$$

$$Li^+\ TCNQ^{\cdot-} + \text{(N-Me iodide)} \xrightarrow{CH_3CN} \text{(N-Me TCNQ}^{\cdot-}\text{ salt)} .$$

Table 4. The constants and methods of synthesis of simple TCNQ salts.

Cation	Method of synthesis	Solvent	Yield, %	Decomp., temp., °C	Resistivity, Ω cm
Li^+	(*a*)	CH_3CN	98	>300	$2\cdot10^5$
Na^+	(*a*)	CH_3CN	59	>300	$3\cdot10^4$
K_+	(*a*)	CH_3CN	70	>300	$5\cdot10^3$
Cs^+	(*b*)	CH_3CN	67	—	$3\cdot10^4$
Ba^{++}	(*a*)	CH_3CN	70	—	$8\cdot10^5$
Cu^+	(*a*)	CH_3CN	54	—	$2\cdot10^2$
Cu^{++}	(*b*)	CH_3CN	80	—	$2\cdot10^2$
$Cu(NH_3)_2^{++}$	(*b*)	CH_3CN	94	—	$7\cdot10^2$
NH_4^+	(*a*)	THF–MeOH	60	210—215	$6\cdot10^4$
Et_3NH^+	(*b*)	H_2O	81	~180	10^9
$(n\text{-}Bu)_4N^+$	(*b*)	H_2O	—	135	10^{12}
Morpholinium	(*a*)	CH_3CN	35	~220	10^9
$Ph_3(Me)P^+$	(*b*)	H_2O	99	~170	$4\cdot10^{10}$
Pyridinium	(*c*)	CH_3CN	59	158—195	10^8
N-Methylpyridinium	(*b*)	CH_3CN—EtOH	—	~235	10^5
N-Methylquinolinium	(*b*)	CH_3CN—EtOH	76	240—244	10^7
5,8-Dihydroxyquinolinium	(*d*)	$CHCl_3$	72	168—169	15

The third method (*c*), the interaction of an amine with $TCNQH_2$ and with TCNQ, has been considered in detail in connection with the synthesis of complex TCNQ salts [see reaction (9)] and the fourth method (*d*) involves the direct interaction of an amine with TCNQ. Table 4 presents data concerning the method of synthesis and certain characteristics of a number of simple TCNQ salts[45].

The methods of synthesis of complex TCNQ radical-ion salts are illustrated by Eqn. (8) for the synthesis of a complex triethylammonium radical-ion salt (XXIX) (the yield of the salt is indicated in brackets)[45]:

$$\text{(a)}\ Et_3NH^+\ TCNQ^{\cdot-} + TCNQ \rightarrow Et_3NH^+(\ TCNQ)_2^{\cdot-}\ \text{(XXIX)}\ \ (50\%) ,$$
$$\text{(b)}\ 3Et_3NH^+I^- + 2\ TCNQ \rightarrow \text{(XXIX)}\ \ (50\%) , \qquad (8)$$
$$\text{(c)}\ 2Et_3N + TCNQH_2 + 3\ TCNQ \rightarrow \text{(XXIX)}\ \ (90\%) ,$$
$$\text{(d)}\ Et_3N + 2\ TCNQ \rightarrow \text{(XXIX)}\ \ (77\%) .$$

In the first method (*a*) one mixes hot solutions of a simple TCNQ salt and neutral TCNQ; the complex TCNQ salt crystallises on cooling. This method is used when the complex salt is much less soluble in the given solvent than the simple salt.

In the second method (*b*) the complex salt is obtained from TCNQ and a metal iodide or the iodide of an organic cation, the iodide ion reducing TCNQ.

In the synthesis of complex TCNQ salts by the third method (*c*), the starting materials are TCNQ and $TCNQH_2$ [reaction (9)]:

$$R_3N + TCNQH_2 \rightarrow R_3NH^+ + TCNQH^- \longrightarrow R_3NH^+ + TCNQ^{\cdot-} + TCNQH^{\cdot}$$
$$\downarrow R_3N \qquad 2R_3NH^+ + 2\ TCNQ^{\cdot-} \quad \downarrow 2TCNQ \quad \leftarrow R_3N \qquad (9)$$
$$2R_3NH^+ + TCNQ^- \downarrow TCNQ$$
$$2R_3NH^+ + 2TCNQ^{\cdot-} \xrightarrow{2\ TCNQ} 2\,[R_3NH^+(\ TCNQ)_2^{\cdot-}] .$$

In one of the versions of this method (*b'*) durohydroquinone is used as the proton and electron donor:

$$2 \times \text{(quinoline)} + \text{(durohydroquinone)} + 4\ TCNQ \rightarrow$$
$$2\,[\text{(quinolinium)}^+(TCNQ)_2^{\cdot-}] + \text{(durosemiquinone)} .$$

Table 5. The constants and methods of synthesis of certain complex TCNQ salts.

*The composition of the complex was $(cation^+)_2.(TCNQ^{\cdot-})_2$. .TCNQ, while in the remaining cases the composition was $(cation^+).(TCNQ^{\cdot-}).TCNQ$.

**The resistivities of single crystals in three crystallographic directions are quoted.

The fourth method (*d*) is used to synthesise complex salts of TCNQ and aliphatic amines. The solvent apparently serves as the proton donor in this case, although the reaction mechanism has not been elucidated[45]. Data concerning the synthesis and properties of complex TCNQ radical-ion salts are presented in Table 5.

New methods for the synthesis of TCNQ salts have been described recently. Thus thin polycrystalline films of alkali metal (M) salts of TCNQ having the 1 : 1 (M = Li, Na, K, or Rb) and 2 : 3 (M = Cs) compositions were obtained by the successive vacuum sputtering of the metal and TCNQ.[54]

The interaction of TCNQ with distannane leads to the oxidation of the latter and the formation of a radical-ion salt[55]:

$$R_3Sn{-}SnR_3 + 2TCNQ \xrightarrow{THF} 2\,(R_3Sn)^+\,(TCNQ)^-,$$

where R = Me or Bu.

Although the following reaction can hardly be regarded as a method for the synthesis of the radical-ion salts, it too leads to the formation of a salt[56]:

$$2Ph{-}C{\equiv}CCu + 2TCNQ \rightarrow 2Cu^+\,(TCNQ)^- + Ph{-}C{\equiv}C{-}C{\equiv}C{-}Ph\ .$$

There is an extensive literature on the synthesis of TCNQ complexes and salts, but we shall consider only reports of studies which in our opinion are of greatest interest and which make it possible to illustrate the wide variety of electron-donating compounds employed.

TCNQ complexes with aminoazo-dyes have been investigated[57]. Numerous simple and complex TCNQ salts with cationic dyes (primarily cyanine dyes) have been studied[58-60] and simple and complex TCNQ salts with *N*-methylpyrazine and its benzo-derivatives[61], with hydroxy- and halogeno-derivatives of piperidine and pyrrolidine[62], and with polyepichlorohydrin[63] have been synthesised. Simple and complex TCNQ salts with arenechromium compounds (for example with dibenzenechromium) have been obtained[64] and numerous TCNQ complexes with *p*-aminobenzenesulphonamide and its derivatives have been investigated[65]. TCNQ radical-ion salts with cobalt complexes[66], platinum, palladium, and nickel complexes[67], and copper, iron, and nickel chelates[68] have been synthesised.

Ternary (1 : 1 : 1) TCNQ complexes with dyes containing the molecule of a second acceptor [iodine[69] and 9-dicyanomethylene-2,4,7-trinitrofluorenone (XXX)] have been investigated[70]. The latter complex dissociates in solution into the dye cation, the TCNQ anion, and the neutral molecule of compound (XXX). The structure of this complex consists of a collection of parallel stacks of the donor and the acceptor, the TCNQ and (XXXX) molecules alternating in the acceptor stack[71].

IV. PHYSICOCHEMICAL PROPERTIES OF 7,7,8,8-TETRACYANOQUINODIMETHANE COMPLEXES

1. Crystal Structure

Both the optical and electrical properties of TCNQ complexes depend directly on their crystal structure and for this reason we shall consider initially the structures of solid TCNQ complexes. Since data on the structures of the complexes have been recently surveyed in a review[72], we shall only briefly enumerate the principal characteristics of the structures of TCNQ complexes, including the results of studies in recent years.

Molecular TCNQ complexes have a structure which differs sharply from that of the radical-ion salts. Like complexes containing other well-known electron acceptors, they consist of infinite stacks in which donor and acceptor molecules alternate. The molecular planes of the donor and acceptor are approximately parallel and the distances between them (3.4–3.7 Å) are typical for weak intermolecular bonds (Table 6). The bond lengths and the valence angles in the molecules hardly change under these conditions. It has recently been found[76] that there is a direct proportionality between the donor–acceptor distance in TCNQ molecular complexes and the difference between the ionisation potential of the donor and the electron affinity of the acceptor (after Briegleb[82]).

Table 6. The donor–acceptor distances in TCNQ complexes.

Donor	Donor-acceptor distance, Å	References
Hexamethylbenzene	3.65	72
Anthracene	3.50	72

NNN'N'-Tetramethyl-*p*-phenylenediamine	3.27	72
Carbazole*	3.44	80
NN-Dimethyldihydrophenazine**	3.22	81

*The crystal consists of domains in each of which the donor molecules are oriented in the same way[80].
**In the stack the donor and acceptor form a pair with an interplanar distance of 3.22 Å; the distance between the pairs is 3.54 Å.

The TCNQ–benzidine complex and its clathrate compounds with solvents consist of infinite stacks of alternating donor and acceptor molecules forming structures of three types. The first type, a complex without the solvent[83], consists of uniform stacks with an interplanar distance of 3.22 Å. The complex containing dichloromethane is made up to stacks in which the distance between the donor and acceptor is the same (3.22 Å) and the solvent molecules are accommodated in the channels between the stacks[84]. Complexes containing acetonitrile, acetone, and methylene chloride are constructed in exactly the same way. A third type of structure has been demonstrated for the complex containing benzene[85]. In this case the stacks consist of donor and acceptor dimers with an interplanar distance of 3.09 Å, benzene molecules being distributed in the channels between the stacks. Complexes containing toluene, nitrobenzene, and benzonitrile have similar structures.

TCNQ radical-ion salts are constructed differently. Since there are no fundamental differences between the structures of simple and complex TCNQ salts, we shall consider their structures by arranging the salts in groups based on different types of packing of anions.

Both simple and complex TCNQ salts consist in most cases of individual infinite stacks of anions. If the donor molecules are fairly planar, they can also form an infinite stack parallel to that of the acceptor. For spherical cations (for example, metal and ammonium cations), the donors are arranged in separate structures consisting of chains between the stacks of anions and parallel to the latter. Data for the structures of the TCNQ salts are

compiled in Table 7, in which the crystalline modification of the salt, the type of packing of the anions, the distance between neighbouring acceptor molecules, and the resistivity of the salt are indicated. The resistivity of TCNQ salt single crystals is minimal in the direction of the stack of anions and the anisotropy of the conductivity as a function of direction in the crystal can reach 10^4 (Table 6), so that the resistivity of the salt depends on the way in which the stack of anions is constructed.

The first group of salts have the highest resistivities (Table 7, compounds 1–5). The study of the structures of these salts showed that they do not contain stacks of anions at all, individual pairs or tetrads of anions separated by cations being present.

Table 7. The crystal structures of TCNQ radical-ion salts.

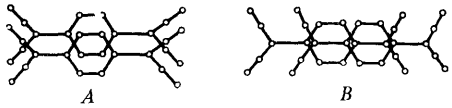

Figure 2.

The second most numerous group of salts (Table 7, compounds 6–24) contains inhomogeneous stacks of anions consisting of dimers, triads, or tetrads comprising the acceptor. The arrangement of neighbouring anions in the dimers is illustrated in Fig. 2*a*. In this arrangement the overlapping of the π orbitals of neighbouring molecules is optimal and in the majority of salts the arrangement of neighbouring anions in the dimers is of this type or similar. Examples of the arrangement of the anions in the stack between adjacent dimers are illustrated in Fig. 2*b*. The molecules are displaced along the long or short molecular axis relative to the optimal arrangement, which leads to an increase of the interplanar distance between neighbouring anions and this in turn leads to the variation of the resistivities of these salts from 10^5 to 1 Ω cm. In some cases, although the distance between the dimers is the same as that between the anions within the dimers (Table 7, compounds 11 and 12), the TCNQ molecules are displaced even more markedly than shown in Fig. 2*b* and there is almost no interaction between the dimers.

When the anions are grouped into tetrads, the latter usually consist of two dimers with optimal overlapping of the anions; the overlapping between pairs is as a rule intermediate between types (*a*) and (*b*) and that between tetrads is of type (*b*) or similar. There also exist tetrads in which the anions are distributed at the same distance, for example in the methyltriphenylarsonium salt of TCNQ.

It is noteworthy that formally complex salts should contain neutral TCNQ molecules. The study of the crystal structures of the salts and also comparison of the bond lengths and angles in the acceptor molecule showed that the charge in the complex salts is as a rule uniformly distributed between TCNQ and $TCNQ^0$, but this does not lead to the appearance of any new structural features in such salts. 2 : 3 Salts (Table 7, compounds 22–24), which have been combined into the second group, constitute an exception. Triads, in which the central acceptor molecule is neutral and two anions are present on either side of this molecule at the same distances have been detected in the structure of these salts. Since in many cases the accuracy of the determination of this structure is low, it is difficult to establish whether the stack contains neutral TCNQ molecules or whether the charge is distributed uniformly among all the acceptor molecules, so that this subgroup of salts may be much more extensive.

Uniform stacks of anions are characteristic of the third group of salts (Table 7, compounds 25–28); here the resistivity of the salt decreases with decrease of the distance between the anions. The third group includes also the structure of TCNQ salts, which exhibit a "metallic" temperature variation of the conductivity (the conductivity increases with decrease of temperature). In all these salts there is phase transition at a certain temperature and they are converted from an "organic one-dimensional metal" into a dielectric. Table 8 presents data for the structures of these salts, their conductivities, and their phase transition temperatures. Very short interplanar spacings in the stacks of anions and cations and correspondingly the highest conductivity known for organic compounds are characteristic of these salts.

Table 8. The crystal structures of TCNQ radical-ion salts with metallic type of conductivity.

Donor (cation)	Donor: acceptor	Distance between neighbouring species in stack		T_{trans}, K	$\sigma_{300\,K}$, Ω^{-1} cm^{-1}	References
		anions	cations			
Tetraselenofulvalene	1:1	*	*	40	800	106
Tetrathiofulvalene	1:1	3.17	3.47	58	600	107
Tetrathiotetracene	1:2	3.18	3.52	90	20—160	108
N-Methylphenazinium	1:1	3.26	3.36	200	140	109
Quinolinium	1:2	3.22	3.50	240	100	109
Acridinium	1:2	3.25	3.42	150	—	109

*According to preliminary data [106], the structure of the TSF–TCNQ complex is very close to that of the TTF–TCNQ complex.

Salts with infinite stacks of anions, each of which contains a free electron, may be regarded as quasi-one-dimensional metals; we shall return to the properties of these systems in discussing the electrical and magnetic properties of TCNQ complexes.

2. Spectroscopic Properties

As mentioned above, the electronic absorption spectra of TCNQ molecular complexes contain, apart from the absorption bands of the donor and acceptor, also a charge-transfer band (TCB). The appearance of the latter is a characteristic feature of the formation of complexes and spectroscopic evidence for the formation of complexes with TCNQ is frequently used [67,110–113]. Table 9 indicates the positions of the charge-transfer bands for a number of TCNQ molecular complexes with various aromatic donors. Evidently the position of this band can vary within very wide limits.

With increase of the strength of the donor (with decrease of its ionisation potential), TCNQ complexes become increasingly more ionic and in the case of a radical-ion salt an overall spectrum of the donor and acceptor ions is observed. The spectra of complexes of intermediate strength [stability?] contain bands due to the donor cation and the $TCNQ^-$ anion in addition to those of the donor and acceptor and the charge-transfer band. This was clearly demonstrated in a study of the electronic absorption spectra of complexes of a single donor with a series of acceptors. Thus,1,6-diaminopyrene forms molecular complexes with chloranil, bromanil, and iodanil, while TCNQ gives rise to radical-ion salts [118]. Similar results were obtained for a series of complexes of poly-(*p*-dimethylaminostyrene) [119].

Table 9. The positions of the charge-transfer band in the spectra of TCNQ complexes.

*A = chloroform, B = methylene chloride, and C = polycrystalline film.

A very large number of studies have been made on the spectra of TCNQ radical-ion salts. It was established initially that the $TCNQ^-$ radical-anion in acetonitrile solution has a fairly complex spectrum, consisting of two main bands with λ_{max} = 420 nm (ϵ = 24 300) and 842 nm (ϵ = 43 300) and several weak bands with λ_{max} = 665, 680, 744, and 760 nm. [45] It follows from these results that the intensity ratio of the bands with λ_{max} = 420 and 842 nm for simple TCNQ radical-ion salts is 0.5, which is one of the main characteristics of simple TCNQ salts. For comparison, one may point out that the absorption spectrum of the 11,11,12,12-tetracyano-2,6-naphthoquinodimethane radical-anion has bands with λ_{max} = 1105 nm (ϵ = 66 200), 938 nm (ϵ = 23 500), 838 nm (ϵ = 5800), 518 nm (ϵ = 12 600), and 418 nm (ϵ = 25 500). [2]

In aqueous solutions the $TCNQ^-$ radical-anion forms dimers, which has been established in a spectrophotometric study of solutions of the lithium salt of TCNQ in water.

In other solvents (methylformamide, methanol, acetonitrile) dimerisation was not observed. The dimer has an absorption band with $\lambda max = 643$ nm.[120] The equilibrium constant for the dimerisation reaction $2\,TCNQ^- \rightleftharpoons (TCNQ)_2^{2-}$ proved to be 1.2×10^4 litre mole^{-1} at 14°C.[121]

The study of the reflection spectra of crystalline simple radical-ion TCNQ salts showed that they differ appreciably from those of the solutions. The reflection spectrum contains three types of lines, designated as the α, β, and charge-transfer lines. Data for some complexes are presented in Table 10 (compounds 1–16). Some investigators regard the α and β bands as the absorption bands of the monomeric TCNQ anions[124,125] which have been strongly displaced relative to their positions in the spectrum of the solutions (420 and 842 nm in acetonitrile), while others regard them as the absorption bands of $TCNQ^-$ dimers (380 and 647 nm in water)[120–130]. The charge-transfer band has been assigned to charge transfer between $TCNQ^-$ anions.

A more thorough recent study of the reflection spectra of simple TCNQ salts and comparison of the spectra with the crystal structure of the salts make it possible to divide the salts into three groups[123]. For the first group of salts, the α and β bands are probably those of the dimers (Table 10, compounds 1–10). The second group occupies an intermediate position. For the third group, the α and β bands are more likely to be those of monomeric $TCNQ^-$ anions which have been strongly displaced (compounds 13 and 14). Although new data for the structure of TCNQ salts (for example Refs. 89–92) throw doubt on the validity of the assignment of the individual salts to a particular group, the overall approach appears to be extremely promising for the elucidation of the dependence of the spectroscopic properties of TCNQ salts on their structure and also for the investigation of the nature of the interaction between the anions in the columns.

The study of the reflection spectra of complex crystalline TCNQ salts showed that they too contain three types of bands (Table 10, compounds 17–24)[131]. Those of highly conducting complex salts show only one explicit electronic absorption band in the range 2000–3500 nm. It has been suggested that this is a band corresponding to charge transfer between neutral TCNQ and its radical-anion[129].

The study of the mirror reflection spectra of single crystals of two complex TCNQ salts with triethylamine and 3,3′-diethylthiocarbocyanine in polarised light showed that the charge-transfer band as well as a band at longer wavelengths are polarised in the direction of the chains of $TCNQ^-$ anions and are due to electron transfer between two $TCNQ^-$ radical-anions (the first band)[127] and between a radical-anion and a neutral TCNQ molecule (the second band)[127].

A bathochromic shift of the α and β bands was observed in a study of the electronic spectra of the lithium and potassium radical-ion salts at a high pressure, which was explained by a shift of the equilibrium between the monomeric and dimeric forms of the $TCNQ^-$ anions[132]. A similar bathochromic shift was observed also for the charge-transfer band[133] owing to the decrease of the distance between the $TCNQ^-$ anions on compression. It was found that the effect of the magnetic field is similar to that of the solvent on the absorption spectra of salts on passing from a non-polar to a polar solvent[134].

The study of the infrared spectra of the TCNQ complexes and radical-ion salts showed that the spectrum of acceptor, both neutral[135] and anionic[136,137], persists in both cases. The $TCNQ^-$ vibrations differ from those of TCNQ by a comparatively slight frequency shift. The frequency of the C≡N vibrations shifts by 25–30 cm^{-1} towards lower values, which is characteristic of all TCNQ salts and the band itself usually splits into 3–4 components, separated from one another by 10–15 cm^{-1}. The type B_{2u} and B_{3u} C=C vibration frequencies differ from one another much more markedly than for TCNQ: 1515 and 1590 cm^{-1} instead of 1540 and 1545 cm^{-1}.[127] A broadening of the bands in the range 1100–1600 cm^{-1} is characteristic of highly conducting TCNQ salts and the half-width of the bands can reach 150 cm^{-1}.[137] A study of the infrared spectra of the complexes and the radical-ion salts in the range 20–400 cm^{-1} showed that there is an absorption head in the region of 40 cm^{-1}, interpreted as corresponding to direct allowed transitions from the ground to the excited band, which is probably also the conductivity band[138].

It is noteworthy that molecular vibrations which are forbidden in free molecules can frequently become allowed in charge-transfer complexes. Thus the band (1565 cm^{-1}) due to the stretching vibrations of the C=C bond in TCNQ becomes allowed in the 1:1 TCNQ–hexamethylbenzene complex and the band (1296 cm^{-1}) due to the stretching vibrations of the C–CH_3 bonds of hexamethylbenzene appears in the spectrum of the 1:2 complex[135].

The use of NMR for the investigation of TCNQ complexes is of interest. Thus, by measuring the chemical shift of the hexamethylbenzene protons in the complex with TCNQ relative to the positions of the signals for the pure donor, it was possible to determine the equilibrium constant for this complex[139]. An NMR study of highly conducting TCNQ salts[140,141] demonstrated the localised nature of the electronic states in the salts at low temperatures.

3. Electrical and Magnetic Properties

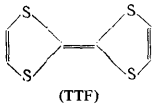
TCNQ complexes as well as the complexes of other well known acceptors as a rule exhibit semiconducting properties. The temperature variation of their conductivity can be described by the equation

$$\sigma = \sigma_0 e^{-\epsilon/kT},$$

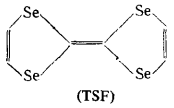
where σ is the conductivity at a given temperature T (on the absolute scale), σ_0 a number characterising the conductivity of $T = \infty$, k the Boltzmann constant, and ϵ the thermal activation energy.

The first studies on TCNQ complexes were in fact devoted to the investigation of the electrical properties of these compounds [142,143]. Most of the data published since that time have been summarised in the monograph of Gutmann and Lyons [144], where the properties of TCNQ complexes are discussed among those of other organic semiconductors. The electrical properties of TCNQ complexes are also discussed in two other reviews, one of which is likewise devoted to organic semiconductors [145] and the other deals with the problem of high-temperature superconductivity [146].

The resistivities of TCNQ complexes were quoted previously in Tables 2, 4, 5, 7, and 8. The TCNQ complexes of tetrathiofulvalene (TTF), [107] *trans*-*cis*-dimethyl-TTF, [147] tetramethyl-TTF, [148] and tetraselenofulvalene (TSF) [106] exhibit the highest conductivities.



(TTF)



(TSF)

While the mechanism of conduction by TCNQ complexes with high resistivities has been fairly thoroughly investigated [144] (these complexes differ little from those of other widely used acceptors), the elucidation of the mechanism of conduction in highly conducting TCNQ salts is at present the most interesting task (salts with "metallic conductivity" will be discussed separately).

Hitherto most studies have dealt with the synthesis of new TCNQ complexes [49,62,63,66,147-150], which are as a rule characterised by their conductivities. At the same time more thorough studies are being made of the electrical properties of TCNQ complexes synthesised previously. Thus two activation energies (for temperatures below and above 400 K) have been obtained from the temperature variation of the conductivity of single crystals of simple alkali metal salts of TCNQ in the temperature range 300 to 540 K. A change from hole to electronic conductivity was observed for the sodium and potassium salts when the activation energy changed [151], which clearly indicates the occurrence of two conduction mechanisms in these salts. A first-order phase transition in the range 350–400 K was recently observed [152] for the same salts, which may be associated with the change in the activation energy for conduction. A more complex change in activation energy was found for the triethylammonium$^+$-$(TCNQ)_2^-$ salt [153,154]; here the activation energies pass through a maximum at 222 K. The activation energies for conduction, determined for different crystallographic directions in single crystals of triphenylmethylphosphonium$^+$-$(TCNQ)_2^-$ [155,156] and triphenylmethylarsonium$^+$-$(TCNQ)_2^-$ [157] also differ.

Thus the activation energy may depend on the temperature and the direction of motion of the carriers, which is probably associated with a more complex mechanism of conduction than in the usual semiconductors. Studies on the changes in conductivity and in activation energy for conduction in TCNQ salts as a function of pressure are of interest from this standpoint [158-160]. As a rule the conductivity increases with increase of pressure, while the activation energy falls.

It is significant that, even at the highest pressures, metallic conductivity was not observed in the salts [159], i.e. the overall variation of the conductivity with temperature remained characteristic of semiconductors.

In order to investigate the conduction mechanism, it is important to determine the type of charge carriers and their mobility. However, the mobilities found in measurements of the Hall effect for single crystals of a number of highly conducting TCNQ salts [161-163] are low (0.6 to 0.004 $cm^2 V^{-1} s^{-1}$) and do not permit preference to be given to any one conduction mechanism.

The thermo-e.m.f.'s of a number of TCNQ salts have been measured [161,164,165]. The sign of the thermo-e.m.f. of highly conducting quinolinium, acridinium, and *N*-methylphenazinium salts indicates electronic conductivity, while that of the complex triethylammonium salt indicates hole conductivity. It is therefore impossible to reach unambiguous conclusions concerning the mechanism of conduction in TCNQ salts with low resistivities. Whereas some investigators discuss the observed conductivities and activation energies within the framework of the band model [153], others postulate a jump mechanism [165,166]. The latter is probably preferable, since the majority of data indicate the presence of a system of localised current carriers, the motion of which at any stage must include a thermally activated jump. At least the low-temperature conductivities of a number of highly conducting TCNQ salts are described satisfactorily by this model [167-170].

It is noteworthy that the discrepancy between the electrical properties of TCNQ complexes, frequently found in studies by different investigators, can be accounted for by the lack of purity criteria for these compounds. Thus the *N*-methylphenazinium salt of TCNQ synthesised from highly pure components, exhibits a higher conductivity at an elevated temperature than stated previously and at low temperatures (below 100 K) its conductivity is ten times lower than that described in an earlier investigation [171]. Another cause is a marked influence of gaseous impurities, which may play a significant role in measurements on polycrystalline specimens. Thus, when simple alkali metal radical-ion salts are heated *in vacuo*, the conductivity falls, the activation energy for conduction increases, and the thermo-e.m.f. changes sign [161,172], which can be explained by the influence of atmospheric oxygen, playing the role of an electron-accepting impurity.

The magnetic properties of TCNQ complexes are also being vigorously investigated. Although molecular complexes and simple radical-ion salts are as a rule diamagnetic, the complex salts are paramagnetic. A qualitative correlation may be traced between the concentration of unpaired spins and the conductivity of TCNQ complexes (Table 11). [112]

The presence of an ESR signal of TCNQ complexes indicates a radical-ion nature of the complex, a phenomenon which is frequently used to determine the type of intermolecular bond (i.e. whether the given substance is a molecular complex or a radical-ion salt) [173,174].

The study of the ESR spectra of a large number of radical-ion salts [175-180] showed that complex TCNQ salts give rise to a fairly intense ESR signal; the number of unpaired spins per complex molecule varies from 1.5 to 10^{-2}. For simple salts, the concentration of free spins is much lower, which can be explained by the very strong

pair interaction between ions of the same kind. On the other hand, in the crystal lattices of highly conducting TCNQ salts the ions form infinite stacks with the same interionic distances; such salts as a rule give rise to an intense ESR signal. Complex salts with a low conductivity have a weak ESR signal for the same reasons as in the case of simple TCNQ salts.

Table 11. The number of unpaired spins per donor–acceptor pair in TCNQ complexes.

Complex	Number of unpaired spins per complex molecule	Conductivity at 300 K, Ω^{-1} cm^{-1}
N-Methyl-2,3-benzoquinolinium$^+$-$(TCNQ)_2^-$	1.3	2.8×10^{-2}
N-Methyl-3,4-benzoquinolinium$^+$-$(TCNQ)_2^-$	0.05	4.3×10^{-3}
N-Methyl-7,8-benzoquinolinium$^+$-$(TCNQ)_2^-$	0.056	8.0×10^{-3}
Hexamethylbenzene-TCNQ: single crystal	7.5×10^{-4}	–
polycrystalline powder	1.8×10^{-3}	–
1,2-Benzopyrene-TCNQ: single crystal	4.0×10^{-5}	–
polycrystalline powder	1.8×10^{-3}	1.9×10^{-12}
3,4-Benzopyrene-TCNQ: polycrystalline powder	6.3×10^{-4}	2.4×10^{-11}

TCNQ complexes with benzidine, which form clathrate compounds with solvents[51], constitute an interesting example of the mechanical generation of spins. The crystals of the complex are not paramagnetic both in the presence and absence of a solvent. However, when the crystals of a complex containing the solvent are ground to a powder, a strong ESR signal ($g = 2.0027$) is observed.

A careful study of the ESR spectra of various TCNQ salts over a wide range of temperatures showed that the behaviour of one set of triplets in the spectra is independent of temperature and is due to impurities and defects in the crystal lattice. Those in another set represent thermally excited triplet states, the concentration of which depends on temperature[181,182]. Similar results were obtained in a study of the dynamics of the nuclear polarisation of protons in simple alkali metal salts of TCNQ[183] and in the complex triphenylmethylarsonium salt of TCNQ.[184] Triplets of a new type, existing in the temperature range from 4 to 80 K, were observed in the ESR spectrum of the latter salt[182]. The authors suggest that this triplet is formed by two unpaired electrons delocalised over the neighbouring chains of $TCNQ^-$ anions.

The occurrence of a phase transition in the triphenylmethylphosphonium$^+$-$(TCNQ)_2^-$ and triphenylmethylarsonium$^+$-$(TCNQ)_2^-$ salts was confirmed with the aid of ESR.[185]

The method of double electron–electron resonance has been used recently to investigate triplet states[186,187]. The study by this method of the triplet excitons in TCNQ ion-radical salts of triphenylmethylphosphonium and cyanine dyes in the temperature range 150–350 K demonstrated that the formation of triplets is an activated process.

The temperature variation of the magnetic susceptibilities of simple[188,189] and complex[190] TCNQ salts and of salts with high[191] and moderate[192,193] conductivities has been studied. Whereas at high temperatures the magnetic susceptibility may increase slightly or fall with decrease of temperature, it increases sharply starting from 50 K. The low-temperature increase of suceptibility is not associated with the presence of paramagnetic impurities and reflects the intrinsic properties of the complexes.

We may note that the magnetic properties of TCNQ salts, as well as their electrical properties, depend on their structures. Thus, when the highly conducting ($\sigma = 380\ \Omega^{-1}$ cm^{-1}) *N*-methylphenazinium salt of TCNQ, which gives rise to a strong ESR signal, was recrystallised, a non-magnetic phase with $\sigma = 7.67 \times 10^{-5}\ \Omega^{-1}$ cm^{-1}) was obtained; by crystallisation, it can be reconverted into the initial form[194].

Yet another aspect of studies of the electrical properties of TCNQ complexes should be noted. In 1964 Little suggested[195,196] the possibility of an exciton mechanism of superconductivity in which there is attraction between conductivity electrons owing to exciton exchange (electronic excitations) and not phonon exchange. According to certain estimates, an exciton mechanism should lead to much higher temperatures of the superconductivity transition (above 300 K).

The manifestation of an exciton superconductivity mechanism requires a certain combination of two subsystems: one conducting and another dielectric with the appropriate exciton spectrum. Complex radical-ion salts proved to be promising for the synthesis of systems satisfying the requirements of Little'e model, since infinite stacks of anions in the highly conducting salts are effective conducting systems and polarisable cations can constitute dielectric systems. TCNQ salts of dyes were in fact synthesised for this purpose[58,59,197,198]. These salts did not exhibit superconductivity, but behaved as typical organic semiconductors; this was readily accounted for after the investigation of their crystal structure which does not contain infinite uniform stacks of TCNQ anions.

A sensational report of an extremely high conductivity of the TCNQ–tetrathiofulvalene (TTF) complex (10^6 Ω^{-1} cm^{-1}), observed at 60 K, appeared recently; on cooling from 300 to 60 K the conductivity, being of the metallic type, increased by a factor of 500.[199] The authors regarded this conductivity as a result of fluctuations leading to temporary transitions to the superconducting state of the complex near the structural transition temperature. This report led immediately to vigorous studies on this compound. Repeated measurements of the conductivity of the complex, carried out by different investigators[200–202], including measurements by the contactless method at high frequencies, failed to confirm such a high increase of conductivity; at 60 K it increases by a factor of 10 to 150, probably depending on the purity of the test specimen.

Conductivity of the metallic type has now been observed for a fairly large set of TCNQ complexes (Table 8), which can be divided into two groups. A low phase transition temperature (<100 K), a symmetrical cation, and a high conductivity are characteristic of the first group (complexes with tetraselenofulvalene, tetrathiofulvalene, and tetrathiotetracene). In this group the TTF–TCNQ complex has been investigated in greatest detail; using it, we shall trace the changes in the properties of such complexes as a function of temperature.

The study of the crystal structure of the TTF–TCNQ complex at room temperature showed that, as for all highly conducting TCNQ salts, infinite columns of anions and cations with interplanar distances of 3.17 Å between neighbouring anions and 3.47 Å between neighbouring cations are characteristic of this complex[107]. At 40 K the structure of the complex remains unchanged and there is only a slight decrease of the distances between the neighbouring anions and cations, to 3.11 and 3.43 Å respectively[203].

In terms of the variation of its thermo-e.m.f., the TTF–TCNQ complex behaves as a metal in the temperature range from 140 to 56 K; at 56 K the Seebeck coefficient becomes abruptly zero, changing sign at lower temperatures[204].

The study of the magnetic properties of the complex showed[205] that the substance is diamagnetic at $T < 20$ K and paramagnetic at $T > 20$ K, the magnetic susceptibility increasing monotonically with increase of temperature to 359 K. The spectroscopic properties of the TTF–TCNQ complex have been investigated: the polarisation absorption spectra[206] and the reflection spectra of single crystals[207]. The overall form of the spectrum is typical for TCNQ radical-ion salts. A plasma absorption head was observed at 1.4 μm. The transition to the dielectric state below 60 K was confirmed also by heat capacity measurements[208]. On the basis of all the above findings, it is suggested that a metal–dielectric transition of the pyerls (structural) type probably occurs in this group of salts[209].

The second group includes the simple *N*-methylphenazinium salt of TCNQ and the complex quinolinium$^+$-$(TCNQ)_2^-$ and acridinium$^+$-$(TCNQ)_2^-$ salts. A comparatively high-temperature metal–dielectric transition has been observed (from conductivity measurements; below the transition temperature the conductivity is of the semiconductor type) for these salts, which contain asymmetric cations. The study of other properties of the salts—magnetic susceptibility[210], heat capacity[211], and optical properties[212]—demonstrated the occurrence of a phase transition at 14 K for the quinolinium$^+$-$(TCNQ)_2^-$ salt and in the region of 10–30 K for the *N*-methylphenazinium salt of TCNQ. It is suggested that at low temperatures (<~15 K) these salts are in the state of a disordered Mott–Hubbard dielectric, which behaves as a one-dimensional disordered metal above the phase transition temperature (~15–~200 K).[212] The non-metallic type of temperature variation in this temperature range may be associated with the spatial localisation of electrons, arising owing to the disorder in the crystal lattice, which in turn can be accounted for by the asymmetry of the cations[210].

Although all known TCNQ salts with the metallic type of conductivity are converted into dielectrics at a low temperature, the question of the possible superconductivity of these compounds (for example, near the phase transition temperature) still remains unresolved. The instability of such quasi-one-dimensional electronic systems had been demonstrated theoretically before the systems were obtained experimentally[209] and further studies on these salts should show whether or not they are capable of superconductivity. Furthermore, these salts constitute an excellent model of a quasi-one-dimensional metal and the study of such systems is extremely interesting from the standpoint of solid state physics.

In connection with this problem, mention may be made of several other investigations. It has been shown that organic compounds, including TCNQ, influence the temperature of the transition to the superconducting state in thin metallic films[213]. Thus TCNQ sputtered onto a thin vanadium film (50–200 Å) reduced the temperature of its transition to the superconducting state, while electron-donating compounds, for example anthracene, increased it by 0.05–0.1 K. The material obtained by the simultaneous sputtering of aluminium and TCNQ behaves similarly[214].

In conclusion mention should be made of studies undertaken to create conducting polymeric materials. Using various polymeric molecules as electron donors, TCNQ complexes and radical-ion salts have been obtained. A large number of materials of this type have been patented[215–222], their resistivities amounting to 100–1000 Ω cm. Another method for the synthesis of conducting materials involves the addition of the lithium salt of TCNQ to a polymer containing amino-groups. Whereas the initial polymers have resistivities of about 10^{16} Ω cm, the materials obtained by this procedure have a resistivity of about 10^8 Ω cm, although the amount of added salt does not exceed 5%.[223–225].

A review published recently[226] is devoted to complexes of polymeric donors with various acceptors, including TCNQ. We shall merely mention that the polymeric complexes have still been very little investigated and a large field of research awaits investigators in this connection. The electrical[227–230] and magnetic[231] properties of polymeric TCNQ complexes are being mainly studied at the present time. The first attempts are being made to relate the electrical properties of the complexes to their structures[232]. If TCNQ complexes do find applications, they are most likely to be complexes based on polymeric donors.

---o0o---

We have examined the principal aspects of research on TCNQ carried on at the present time. The study of reactions of TCNQ with nucleophilic agents, via intermediate one-electron oxidation, is the most interesting and promising in the chemical sense; such organic reactions have so far been inadequately investigated. The stable $TCNQ^-$ radical-anion is also an interesting object of study in reactions with radical and electrophilic reagents.

The electrical properties of TCNQ complexes have been primarily investigated in studies on the properties of crystals with conductivity of the metallic type. The problem of the possible superconductivity of such systems is extremely important. Crystals of this kind are also interesting from the standpoint of the physical properties of a quasi-one-dimensional electronic system.

Advances in the Chemistry of Aliphatic Diazosulphones

A.L.Fridman, Yu.S.Andreichikov, V.L.Gein, and S.S.Novikov

Methods for the synthesis of α-diazosulphones are examined and a systematic account is given of the literature data on the physicochemical properties and ultraviolet, infrared, and NMR spectroscopy of this interesting class of aliphatic diazo-compounds. Much attention is devoted to chemical reactions of α-diazosulphones via the intermediate formation of carbonium ions and sulphonyl carbenes as well as reactions involving the nitrogen of the diazo-group. In many cases a comparative description is given of the chemical properties of α-diazosulphones and α-diazoketones. The review constitutes the first compilation of the chemistry of α-diazosulphones available in the literature.
The bibliography includes 76 references.

I. INTRODUCTION

A number of interesting reviews have been published recently on the chemistry of aliphatic diazo-compounds[1-8], dealing mainly with methods of synthesis, properties, and structures of diazoalkanes or diazocarbonyl compounds, but the chemistry of α-diazosulphones has not been considered. Nevertheless this class of aliphatic diazo-compounds has been attracting attention because of the presence in the molecule of both the sulphonyl and diazo-groups. The combination of these groups makes it possible to synthesise new types of sulphones, whose preparation by other procedures is difficult. Furthermore, α-diazosulphones are of theoretical interest as regards the comparison of their reactivities with those of α-diazoketones, diazophosphines, and silyldiazoalkanes.

The first diazosulphonyl compound—potassium diazomethionate—was synthesised by Pechmann and Mank in 1895.[9] After that not a single new method of synthesis of α-diazosulphones and not a single new compound of this class were described until 1962.

A fruitful stage in the chemistry of α-diazosulphones began in 1962, when the Dutch chemists Strating and Lensen[10] described a method for the preparation of monosulphonyldiazomethanes and the German investigators Klages and Bott[11] published a report on bis-(phenylsulphonyl)diazomethane. Subsequent advances in the synthesis of diazosulphones (of which about 50 are now known) stimulated an increase of interest in the structure and properties of these compounds.

The aim of the present review is to give a systematic account of the literature data on the methods of synthesis, structures, and chemical properties of diazosulphones.

II. METHODS OF SYNTHESIS

The classical method of synthesis of α-diazoketones[12] by the interaction of carboxylic acid chlorides with an excess of diazomethane,

$$RCOCl \xrightarrow{CH_2N_2} RCOCHN_2 + CH_2Cl + N_2 ,$$

leads to positive results only in the case of toluene-*p*-sulphonyl chloride[13], which give rise in this reaction to tolylsulphonyldiazomethane and α-chloro-α-tolylsulphonylmethane:

$$CH_3C_6H_4SO_2Cl \xrightarrow{CH_2N_2} CH_3C_6H_4SO_2CHN_2 + CH_3C_6H_4SO_2CH_2CH_2Cl.$$

The interaction with 2-phenylethanesulphonyl chloride takes place in the presence of base via the intermediate 2-phenylthioacetaldehyde *SS*-dioxide to give benzylethylene sulphone[14]:

$$C_6H_5CH_2CH_2SO_2Cl \xrightarrow{CH_2N_2} \begin{cases} \not\rightarrow\ C_6H_5CH_2CHSO_2CH_2N_2 \\ \rightarrow\ [C_6H_5CH_2CH{=}SO_2] + C_6H_5CH_2CH{-}CH_2 \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad SO_2 \end{cases}$$

α-Diazosulphone is not formed under these conditions[15]. Evidently diazomethane is incapable of attacking the sulphur atom in view of its inadequate electrophilic properties. This is why α-diazosulphones, with the exception of potassium diazomethionate, remained unknown for a long time.

It is noteworthy that the synthesis of α-phenyl-α-(*p*-toylsulphonyl)diazomethane from toluene-*p*-sulphonyl chloride and phenyldiazomethane is described in one of the latest communications[16]:

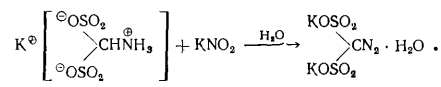
$$CH_3C_6H_4SO_2Cl + C_6H_5CHN_2 \xrightarrow{-HCl} CH_3C_6H_4SO_2\overset{C_6H_5}{\underset{|}{C}}N_2 .$$

We believe that this procedure for the preparation of α-diazosulphones requires a detailed study, since it has been described for only one example and the diazo-derivative was not isolated in a pure form.

The main methods for the synthesis of α-diazosulphones were developed in the 1960s. They include the oxidation of the hydrazones of disulphonylketones, the introduction of the diazo-group into an activated methylene group with the aid of tosyl azide, and the alkaline cleavage of *N*-nitrosourethanes and α-diazo-β-oxosulphones. The above methods are not equivalent as regards ease, universality, and simplicity. However, considered together, they make it possible to obtain α-diazosulphones with various substituents.

1. Diazotisation of Aminomethionic Acid Salts

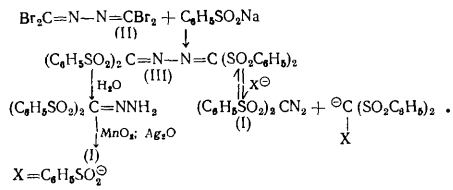
The method consists of the diazotisation of potassium aminomethionate[9] (or the sodium salt[17]) with nitrite ions at an elevated temperature:



It has been described only for two compounds. However, one cannot rule out the possibility that it can be used to diazotise other derivatives of aminomethionic acids.

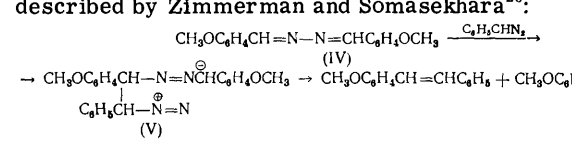
2. Oxidation of Bis(arenesulphonyl)formaldehyde Hydrazone

The method has been developed for the synthesis of bis(benzenesulphonyl)diazomethane (I).[18,19] It is obtained from carbonyl bromide azine (II) and sodium benzenesulphinate:



The bis(benzenesulphonyl)formaldehyde azine (III) formed in the first stage is hydrolysed to the corresponding hydrazone, which is oxidised with activated manganese dioxide or silver oxide to bis(benzenesulphonyl)diazomethane. Bis(benzenesulphonyl)methane is isolated as a side product, being formed according to the authors via the Wolff–Kishner reaction:

The interaction of the azine (II) with sodium benzenesulphinate in the absence of moisture and subsequent treatment of the reaction mixture with alumina also make it possible to obtain a high yield of the diazosulphone (I). The intermediate azine (III) probably reacts readily with the nucleophilic agent ($X^{\ominus}$) present in the reaction mixture. A similar base-catalysed decomposition of *p*-methoxybenzylideneazine (IV) by phenyldiazomethane has been described by Zimmerman and Somasekhara[20]:



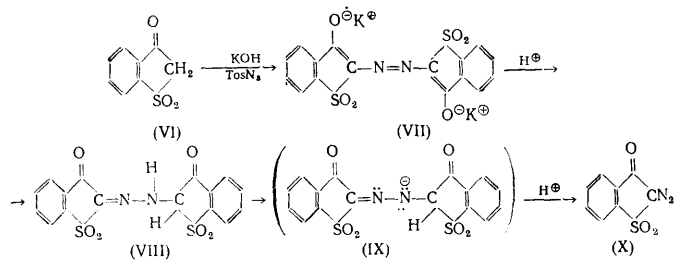
In this case phenyldiazomethane attacks the azine (IV). The resulting unstable intermediate adduct (V) decomposes into 1-(*p*-methoxyphenyl)-2-phenylethylene and *p*-methoxyphenyldiazomethane with evolution of nitrogen.

It is noteworthy that the above method of synthesis of α-diazo-β-disulphones can probably by used also to prepare substituted bis(arenesulphonyl)diazomethanes, but the initial bis(arenesulphonyl)formaldehyde hydrazones are difficult to obtain.

3. The Reactions of Tosyl Azide with Compounds Containing an Activated Methylene Group

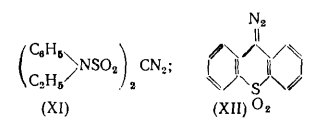
The method was described in 1964 for the synthesis of bis(arenesulphonyl)- and bis(alkanesulphonyl)-diazomethanes[21]. Thus bis(toluene-*p*-sulphonyl)diazomethane is obtained by treating an aqueous alcoholic solution of bis(toluene-*p*-sulphonyl)methane and sodium hydroxide with an ethereal solution of tosyl azide:

Subsequently in 1965–1970 the method was used to synthesise α-diazo-β-oxosulphones[22–25] and 4-benzenesulphonyl-1,3-dioxo-2,4-bisdiazoalkanes[26]. In particular, the interesting synthesis of 2-diazo-2,3-dihydrothionaphthen-3-one 1,1-dioxide (X) has been achieved by this reaction[22]:

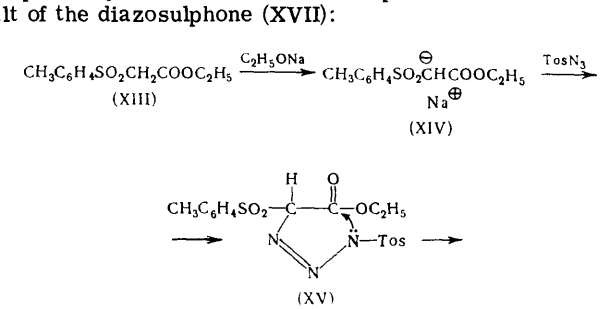


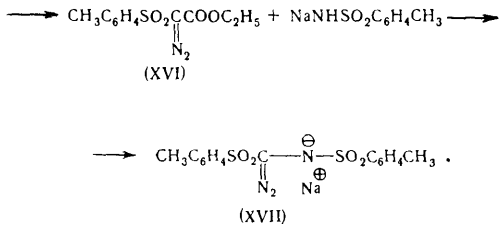
In the first stage 2,3-dihydrothianaphthen-3-one 1,1-dioxide (VI) is converted under the influence of tosyl azide in an alkaline medium into a dipotassium salt of the azo-compound (VII). On being acidified, compound (VII) is converted into the hydrazone (VIII), which is further converted on being refluxed in ethylene glycol into the diazosulphone (X) via the intermediate (IX). The diazosulphone can be converted into the dipotassium salt (VII) on treatment with alkali and the initial compound (VI). Triethylamine[24] or potassium ethoxide[27] can be used as bases and acetonitrile as the solvent[26].

The bis(ethylphenylanilide) of diazomethionic acid (XI)[21] and 9-diazothioxanthene *SS*-dioxide (XII)[27] have been synthesised by this method:



Depending on the solvent and the base, the reaction of tosyl azide with ethyl toluene-*p*-sulphonylacetate (XIII) proceeds in two ways. When equimolecular amounts of sodium ethoxide and tosyl azide are used in an absolute ethanol–ether mixture at 0°C, the sodium salt of *N*-(toluene-*p*-sulphonyl)toluene-*p*-sulphonyldiazoacetamide (XVII) is formed almost immediately. The authors believe that the carbanion (XIV), formed initially from the sulphone (XIII) under the influence of the base, reacts with tosyl azide to form the intermediate adduct (XV). Its decomposition leads to the formation of ethyl toluene-*p*-sulphonyldiazoacetate (XVI) and the sodium salt of toluene-*p*-sulphonamide. The interaction of these two compounds yields the final reaction product—the sodium salt of the diazosulphone (XVII):





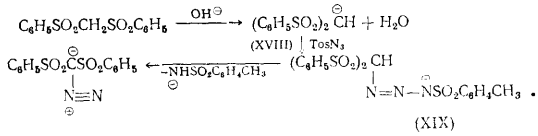
(XVI)

(XVII)

The intermediate diazosulphone (XVI) can be isolated when equimolecular amounts of tosyl azide and the sulphone (XIII) interact in methylene chloride in the presence of triethylamine[25]. The possibility of isolating the diazosulphone (XVI) can be accounted for in this case by the weak solvation of the reaction products by solvent molecules.

The method for the introduction of the diazo-group into bis(arenesulphonyl)methanes with the aid of tosyl azide has been modified recently[28]. The authors suggested that an alkaline aqueous alcoholic solution of the initial bis-(arenesulphonyl)methane be added to a threefold excess of tosyl azide in alcohol. This enables one to obtain stable yields of diazosulphones, while the initial procedure makes it possible to isolate the hydrazones of bis(arenesulphonyl)-formaldehyde in a low yield and only insignificant amounts of bis(arenesulphonyl)diazomethanes.

The reaction involves the formation of the carbanion (XVIII) and the product (XIX) resulting from its coupling with tosyl azide as well as the cleavage of the latter into bis(arenesulphonyl)diazomethane and the toluene-*p*-sulphonamide anion. In particular, bis(mesitylenesulphonyl)-diazomethane has been synthesised by this method:



(XIX)

In view of the critical comments by Heyes and Holt[28] concerning the method for the reduction of the diazo-group into bis(arenesulphonyl)methanes proposed by Klages and Bott[21], we analysed the above investigations and concluded that the method of Heyes and Holt is more effective, since it makes it possible to obtain α-diazo-β-disulphones in high yields and is less laborious.

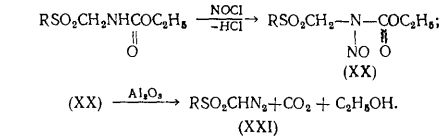
4. Cleavage of *N*-Nitrosourethanes

The alkaline cleavage of *N*-nitrosourethanes is widely used for the synthesis of diazoalkanes and α-diazoketones. This method of synthesis has been most thoroughly developed also in relation to diazosulphones. It is sufficient to point out that the vast majority of alkyl- and aryl-α-diazosulphones[29] and also certain α-alkyl-α-sulphonyldiazomethanes[16] and β-sulphonyldiazo-compounds[30] have been synthesised by this procedure.

The synthesis consists of two stages.

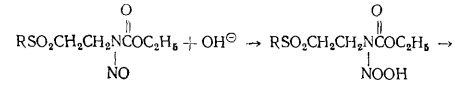
(1) Nitrosation of the initial urethane. Nitrosyl chloride is used as the nitrosating agent. The synthesis of the initial *N*-arenesulphonyl- and *N*-alkanesulphonyl-methylurethanes has been thoroughly worked out[31,32] and does not present much difficulty.

(2) The cleavage of *N*-nitrosourethane to diazosulphone by alumina. The reaction is carried out on a chromatographic column:



(XXI)

The cleavage of *N*-nitrosourethanes with alkali is preferable for the synthesis of certain β-diazosulphones[30]. The reaction can be described schematically as follows:



5. The Cleavage of α-Diazo-β-Oxosulphones

The method reduces to the cleavage of α-diazo-β-oxosulphones with triethylamine in dry methanol[24]:

$$RSO_2CN_2COR^1 \xrightarrow{(C_2H_5)_3N} RSO_2CHN_2 + R^1COOH.$$

The resulting diazosulphone is isolated in the form of triphenylphosphazine:

$$RSO_2CHN_2 + P(C_6H_5)_3 \rightarrow RSO_2CHN{-}NP(C_6H_5)_3 .$$

It is noteworthy that the cleavage reaction is undergone only by α-diazo-β-oxosulphones in which there is an electron-donating substituent (OCH_3, CH_3) in the *para*- and *ortho*-positions of the aryl residue relative to the sulphonyl group. The cleavage of α-acetyl- and α-benzoyl-(*p*-nitrobenzenesulphonyl)diazomethane by triethylamine in methanol leads to products of unknown structure. The cleavage of the above α-diazo-β-oxosulphones to *p*-nitrobenzenesulphonyldiazomethane proceeds without difficulty on alumina in a chloroform–ethanol mixture.

The synthesis of α-diazosulphones by the above method is of limited applicability owing to the low yields of the final products (30–45%) and the difficulties associated with their isolation from the reaction mixture.

III. GENERAL CHARACTERISTICS, STRUCTURE, AND SPECTRA

1. The Characteristics of Diazosulphones

Diazosulphones are bright-yellow substances, the majority of which crystallise readily. Derivatives of monosulphonyldiazomethane[29] and also α-diazo-β-oxosulphones[22–24] can be stored for a long time in the dark at −20°C. Their stability varies widely and is approximately proportional to their melting points. Liquid benzenesulphonyldiazomethane decomposes in the course of several days. The introduction of alkyl substituents in the *p*-position of the benzene ring reduces the stability of α-diazosulphones and they decompose completely in the course of several hours at room temperature. The stability of these compounds increases in ethereal solutions. Crystalline aryl-substituted α-diazosulphones are more stable, although they too decompose slowly at room temperature and in the light. Certain α-diazosulphones (for example phenylmethanesulphonyldiazomethane) show no change in the melting point on storage in the dark in

the course of four months. Derivatives of bis(alkanesulphonyl)- or bis(arenesulphonyl)-diazomethanes are even more stable[21]. They can be stored for a long time in the light at room temperature.

On the other hand, β-diazosulphones are extremely unstable and can exist only in solution[30]. However, their stability increases after the introduction of a phenyl substituent at the α-carbon atom. Thus, as in the case of α-diazoketones, the accumulation of electron-accepting substituents in the diazosulphone molecule and their greater proximity to the diazo-group stabilise the diazo-derivative and increase its thermal and photolytic stabilities.

Derivatives of monosulphonyldiazomethane, α-diazo-β-oxosulphones, and bis(alkanesulphonyl)- and bis-(arenesulphonyl)-diazomethanes are soluble in ether, dichloromethane, and other organic solvents. Potassium diazomethionate is readily soluble in water and slightly in dimethyl sulphoxide. In contrast to diazoalkanes and many α-diazoketones, diazosulphones have no odour. The toxicity of diazosulphones has not been investigated. It has only been noted that these compounds possess no dangerous properties[29]. We believe that it is desirable to investigate the physiological activity of diazosulphones, particularly their carcinogenic and antitumour activities, since these have been shown by other aliphatic diazo-compounds.

Table 1. Parameters of the infrared and ^{1}H NMR spectra of certain diazosulphones.

2. Structure and Spectra

Infrared and NMR spectroscopic data[29] (Table 1) reveal a similarity between the structures of the diazo-groups of α-diazosulphones and α-diazoketones. The diazo-group of α-diazosulphones absorbs in the infrared in the region of 2115 ± 15 cm^{-1} and the absorption does not in fact differ from that of α-diazoketones, but is displaced towards higher wavenumbers compared with diazoalkanes. This indicates an increase of the multiplicity of the bond between the nitrogen atoms in the diazo-group of α-diazosulphones compared with diazoalkanes, i.e. the contribution of structure (XXII) to the resonance hybrid is greater than that of structure (XXIII).

$$\underset{\text{(XXII)}}{RSO_2\overset{\ominus}{C}H-\overset{\oplus}{N}\equiv N} \longleftrightarrow \underset{\text{(XXIII)}}{RSO_2CH=\overset{\oplus}{N}=\overset{\ominus}{N}}.$$

The sulphonyl group in α-diazosulphones is responsible for absorption in the region of 1330 and 1140 cm^{-1} in the infrared spectra. In the NMR spectra of α-diazosulphones[29] (Table 1) the CHN_2 proton gives rise to a signal between τ = 4.57 and 4.98. The α-proton in α-diazoacetone gives rise to τ = 4.82. In the series of aryl-substituted α-diazosulphones *para*-substituents have some influence on the position of the absorption band of the diazo-group in the infrared spectra and on the α-proton chemical shift. Electron-donating substituents, for example the methoxy-group, promote an increase of electron density at the α-carbon atom. This is indicated by infrared and NMR spectroscopic data. Thus the absorption of the diazo-group in the infrared spectra of *p*-methoxybenzenesulphonyldiazomethane and *p*-nitrobenzenesulphonyldiazomethane is at 2103.3 and 2108.2 cm^{-1} respectively and the α-proton signals in the NMR spectra have τ = 4.75 and 4.57 respectively. Naturally an increase of electron density of the α-carbon atom of the diazosulphone leads to enhanced shielding of the α-proton and hence to higher chemical shifts.

Owing to the magnetic anisotropy of the benzene ring, the chemical shifts of the α-protons of aryl-substituted α-diazosulphones are smaller than for the alkyl-substituted derivatives[29].

The introduction of a second arenesulphonyl group into the α-diazosulphone molecule tends to increase the contribution of structure (XXII) to the resonance hybrid of the α-diazosulphone, as shown, for example, by the shift of the absorption band of the diazo-group in the infrared spectrum towards higher wavenumbers by 20–30 cm^{-1}. Thus the diazo-group in bis(benzenesulphonyl)diazomethane[21] absorbs in the region of 2130 cm^{-1}, while that in benzenesulphonyldiazomethane absorbs in the region of 2104 cm^{-1}. The substitution of the α-hydrogen atom in diazosulphones by an acyl or alkoxycarbonyl residue also tends to shift the infrared absorption band of the diazo-group towards higher wavenumbers. This is illustrated by α-acetyl-α-(*p*-nitrobenzenesulphonyl)diazomethane[24], *p*-nitrobenzenesulphonyldiazomethane[29], and ethyl toluene-*p*-sulphonyldiazoacetate[25] (Table 1).

Table 2. Parameters of the ultraviolet spectra of certain α-diazosulphones* *m*-$XC_6H_4SO_2CHN_2$.

X	ν_{max}, nm	lgε	X	ν_{max}, nm	lgε
CH_3O	390	1.87	CF_3	383	1.84
CH_3	390	1.79	NO_2	385	1.97
Cl	385	1.84			

*The spectra were recorded in solution in 40% dioxan–water.

The introduction of the methylene group into α-diazosulphones leads to the breakdown of conjugation between the diazo- and sulphonyl groups, i.e. to a decrease of the contribution of structure (XXII) to the resonance hybrid. All these factors are clearly reflected in the infrared spectra of β-diazosulphones, where the absorption of the diazo-group is displaced towards lower wavenumbers by 30–50 cm^{-1} compared with α-diazosulphones. For example, 1-phenyl-2-(toluene-*p*-sulphonyl)diazomethane[30] and 9-diazothioxanthene SS-dioxide[21] absorb in the region of 2050 and 2075 cm^{-1} respectively.

The ultraviolet spectra of α-diazosulphones have not been investigated in detail[33–35]. Those of *m*-substituted aryldiazosulphones, whose parameters are presented in

Table 2, [34] show that diazosulphones absorb in the region of 390 nm, which corresponds to the $n \rightarrow \pi^*$ transition in the diazo-group.

Table 3. The influence of the solvent on the frequency of the $n \rightarrow \pi^*$ transition in the ultraviolet spectra of $RSO_2.CHN_2$.

R	Solvent	ν_{max}, cm^{-1}	$\lg \varepsilon_{max}$
m-$CH_3C_6H_4$	CCl_4	25000	1.88
	C_2H_5OH	25300	1.84
	40% dioxan-H_2O	25600	1.79
m-$CH_3OC_6H_4$	CCl_4	24700	1.88
	C_2H_5OH	25200	1.86
	40% dioxan-H_2O	25600	1.87
$(CH_3)_3C$	CCl_4	25600	1.21
	C_2H_5OH	25800	1.23
	40% dioxan-H_2O	26300	1.26

The polarity of the solvent influences the energy of the $n-\pi^*$ transition, which is reflected in the position of the absorption maximum of the diazo-group. Table 3 shows that more polar solvents shift the absorption maximum of α-diazosulphones towards shorter wavelengths.

Like α-diazoketones, α-diazosulphones form hydrogen bonds[35,36]. In both cases the methine hydrogen of the diazo-fragment serves as the proton donor and the acceptor is the sulphonyl or carbonyl group. α-Diazosulphones are more powerful proton donors and weaker proton acceptors than α-diazoketones.

IV. CHEMICAL PROPERTIES

Three types of reactions are characteristic of diazosulphones: (1) reactions with evolution of nitrogen; (2) reactions involving the nitrogen of the diazo-group; (3) substitution of the α-hydrogen atom.

Reactions of the first type have been most completely investigated and those of the second and particularly of the third type much less so. In discussing the chemical properties of diazosulphones, one must bear in mind that these compounds have been studied for only 10–15 years and therefore many interesting reactions of this class of compounds have still not been investigated.

The chemical reactions of diazosulphones known at present are summarised below in relation to different types of reaction mechanisms.

1. Reactions Involving the Formation of Carbonium Ions

Reactions of this series include those of diazosulphones with water, acids, t-butyl hypochloride, sulphuryl chloride, and nitrogen oxides.

The study of the hydrolysis of α-diazosulphones[34,37-40] in water and water–dioxan mixtures showed that the acid-catalysed decomposition proceeds via the bimolecular *A*-2 mechanism. The initial diazosulphone is reversibly protonated in the first stage, while in the second, rate-determining stage the resulting diazonium ion interacts with a molecule of the nucleophilic agent to form the final reaction product:

$$RSO_2CHN_2 \overset{H^\oplus}{\rightleftharpoons} RSO_2CH_2N_2^\oplus$$

$$RSO_2CH_2N_2^\oplus + \text{nucleophilic agent} \xrightarrow{\text{slow}} \text{product} + N_2 .$$

Studies in recent years established[41] that the hydrolysis of 4-methylbenzenesulphonyldiazomethane in a water–dioxan mixture in the presence of perchloric acid involves the protonation of the oxygen of the sulphonyl group and the *A*-1 mechanism, and the *A*-2 mechanism in the presence of hydrochloric acid in view of the more marked nucleophilic properties of chloride ions.

Electron-accepting substituents diminish and electron-donating substituents increase the rate of hydrolysis of aryl-substituted α-diazosulphones[34]. Similar observations had been made previously in the series of α-diazoketones[42] and aryldiazomethanes[43].

It is noteworthy that the hydrolysis of α-methyl-α-(toluene-*p*-sulphonyl)diazomethane[16] in a water–dioxan mixture under the influence of perchloric acid takes place differently and, depending on the reaction time, gives rise to different products. After 30 min, the reaction mixture contains toluene-*p*-sulphinic acid, acetaldehyde, and toluene-*p*-sulphonylethylene, and after 36 h acetaldehyde and 1,2-di(toluene-*p*-sulphonyl)ethane. The latter is formed as a result of the reaction of toluene-*p*-sulphonylethylene with the toluene-*p*-sulphinic acid present in the reaction mixture.

The decomposition of potassium diazomethionate[44] in aqueous solutions is catalysed by strong inorganic acids. However, the reaction begins only at a fairly high acid concentration. The hydrolysis is particularly rapid in the presence of sulphuric and perchloric acids. The addition of chloride ions reduces appreciably the reaction rate. The mechanism of the decomposition of potassium diazomethionate has not been described. Presumably in the first stage of the reaction the stronger acid displaces diazomethionic acid from its salt and the former is then cleaved.

In inert solvents α-diazosulphones form with inorganic and organic acids the esters of the corresponding α-hydroxymethyl sulphones. Certain differences between the reactivities of mono- and di-substituted α-diazosulphones and α-diazo-β-oxosulphones have been noted.

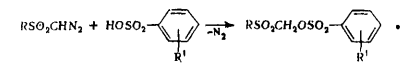
The reactions of monosubstituted α-diazosulphones with 70% perchloric acid[45,46] in methylene chloride give rise to the formation of the covalent perchlorates (XXIV) in 45% yield and α-hydroxymethyl sulphones (XXV) in 10% yield:

$$RSO_2CHN_2 + HClO_4 \begin{cases} \xrightarrow{CH_2Cl_2} RSO_2CH_2N_2^\oplus \cdot ClO_4^\ominus \rightarrow RSO_2CH_2OClO_3 \\ \qquad\qquad (XXVI) \qquad\qquad (XXIV) \\ \xrightarrow[CH_2Cl_2]{H_2O} RSO_2CH_2OH \\ \qquad\qquad (XXV) \end{cases}$$

In acetonitrile or propionitrile the yield of the perchlorate (XXIV) is lower and sulphonylmethylamides of acetic and propionic acids ($RSO_2CH_2NHCOAlk$; Alk = CH_3 or C_2H_5) are formed. The authors believe that the ion pair (XXVI), formed as a result of attack by perchloric acid, is readily converted into the perchlorate (XXIV) owing to the low polarity of the solvent. The hydroxy-derivative (XXV) is formed as a result of competition between water and perchloric ions in attacking the diazonium ion. When the ion pair (XXVI) is attacked by the alkyl cyanide, which is facilitated by the solvation of (XXVI) by the polar solvent molecules, and the resulting intermediate adduct (XXVII) is hydrolysed, sulphonylmethylamides are formed:

$$(XXVI) + R^1CN \rightarrow \underset{(XXVII)}{RSO_2CH_2\overset{\oplus}{N}CR^1ClO_4^\ominus} \rightarrow RSO_2CH_2NHCOR^1 + HClO_4 .$$

On interaction with α-diazosulphones, aromatic sulphonic acids give rise to sulphonates derived from α-hydroxymethyl sulphones[45,47]:



The trifluoromethanesulphonates derived from α-hydroxymethyl sulphones, which are readily formed when α-diazosulphones react with trifluoromethanesulphonic acid, are of considerable interest[48]:

$$CH_3C_6H_4SO_2CHN_2 + HSO_3CF_3 \rightarrow CH_3C_6H_4SO_2CH_2OSO_2CF_3 + N_2 .$$

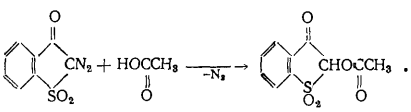
These compounds react readily with various nucleophilic agents via an S_N2 mechanism with formation of α-substituted sulphones. α-Diazosulphones react without difficulty with nitric and hydrochloric acids[29,49], forming derivatives of these acids:

$$RSO_2CHN_2 + HX \rightarrow RSO_2CH_2X + N_2 ;$$
$$X = Cl^{\ominus},\ ONO_2^{\ominus} .$$

The reaction of di(benzenesulphonyl)diazomethane with hydriodic acid[50] results in the formation of di(benzenesulphonyl)methane instead of the expected di(benzenesulphonyl)iodomethane. Evidently the intermediate di(benzenesulphonyl)iodomethane is reduced by a second molecule of hydriodic acid to di(benzenesulphonyl)methane:

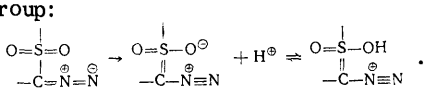
$$(C_6H_5SO_2)_2CN_2 \xrightarrow[-N_2]{HI} [(C_6H_5SO_2)_2CHI] \xrightarrow[-I_2]{HI} (C_6H_5SO_2)_2CH_2 .$$

α-Diazo-β-oxosulphones are less reactive with respect to acids than α-diazosulphones. Thus 2-diazo-2,3-dihydrothianaphthen-3-one 1,1-dioxide reacts with acetic acid only on heating and in the presence of copper as the catalyst[22]:



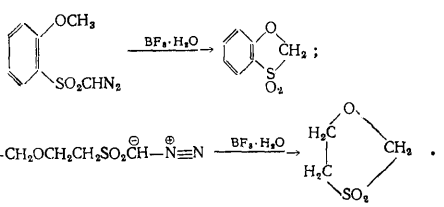
Bis(arenesulphonyl)diazomethanes are even more resistant to acids. For example, bis(benzenesulphonyl)-diazomethane[19] can be recrystallised from glacial acetic acid.

This behaviour of α-diazo-β-oxosulphones and bis-(arenesulphonyl)diazomethanes can be accounted for by the capture of the proton attacking the α-carbon atom by the sulphonyl group:

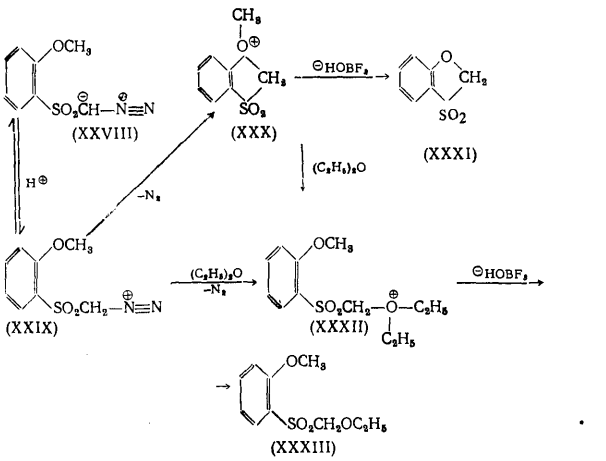


Similar observations were made also in the series of α-diazoketones. However, owing to the greater reactivity of the sulphonyl group, these phenomena are more pronounced in the case of α-diazosulphones.

Under the influence of acids, some α-diazosulphones cyclise. Thus *o*-methoxybenzenesulphonyldiazomethane and the benzyl ether of hydroxyethanesulphonyldiazomethane in ethereal solutions are converted under the influence of hydrated boron trifluoride into 1,3-benzoxathiolan 3,3-dioxide and 1,3-oxathiolan 3,3-dioxide respectively[51]:



In the first reaction stage the initial diazosulphone (XXVIII) is protonated and the resulting diazonium ion (XXIX) splits off nitrogen, being converted into the oxonium ion (XXX). The latter is converted into the final product—1,3-benzoxathiolan 3,3-dioxide. When (XXIX) or (XXX) reacts with the solvent, the intermediate oxonium ion (XXXII) is formed and then converted into α-ethoxy-α-(*o*-methoxybenzenesulphonyl)methane (XXXIII):



When ethyl ether is excluded from the reaction mixture and the reaction is carried out in methylene chloride, the yield of the oxathiolan (XXXI) increases to 72% compared with 65%.

Potassium diazomethionate reacts with hydrogen halides to form salts of halogenomethionic acids[9,52]:

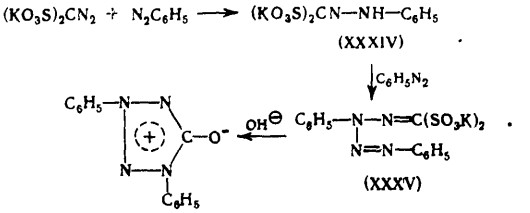
$$(KO_3S)_2CN_2 + HHal \xrightarrow{Hal=I,Br} (KO_3S)_2CHHal + N_2 .$$

When potassium diazomethionate was allowed to react with iodine[9], the potassium salt of diiodomethanedisulphonic acid was isolated:

$$(KO_3S)_2CN_2 + I_2 \rightarrow (KO_3S)_2CI_2 + N_2 .$$

It is noteworthy that the relatively little investigated methionic acid derivatives formed in these reactions are of significant interest as chemical reagents.

Potassium diazomethionate reacts with aromatic diazo-compounds. Thus the reaction with benzenediazonium acetate gives rise to the phenylhydrazone (XXIV)[53] which is converted in the presence of an excess of benzenediazohydroxide into potassium diazobenzenephenylhydrazonomethanedisulphonate (XXXV). The latter is converted under the influence of alkali into 1,3-diphenyltetrazolone[54]:



Sodium diazomethionate readily reacts with sodium bisulphite to form the salt of methanetrisulphonic acid[9,17]:

$$(NaO_3S)_2CN_2 + NaHSO_3 \rightarrow (NaO_3S)_2CHSO_3Na .$$

The interaction of α-diazosulphones with t-butyl hypochlorite proceeds via an ionic mechanism. Various products may be obtained, depending on the solvent[55]:

$$RSO_2CHN_2 + (CH_3)_3COCl \begin{cases} \xrightarrow[\text{or } CH_2Cl_2]{(CH_3)_3COH} RSO_2CH(Cl)OC(CH_3)_3 + N_2 \\ \text{(XXXVII)} \\ \xrightarrow{C_2H_5OH} RSO_2CH(Cl)OC_2H_5 + N_2 \\ \text{(XXXVIII)} \end{cases}$$

The first stage of this interesting reaction involves the addition of the electrophilic chlorine of t-butyl hypochlorite to the α-carbon atom of the diazosulphone with formation of the ion pair $RSO_2CH(Cl)N_2^+.BtO^-$ (XXXVI) solvated by t-butyl alcohol. The sulphone (XXXVII) is formed as a result of the displacement of nitrogen either by the t-butoxide anion or by t-butyl alcohol. In ethanol the sulphone (XXXVIII) is produced as a result of the solvolysis of the ion pair (XXXVI). It is noteworthy that the decomposition of (XXXVI) is accompanied by the formation of several side products, the composition of which has not so far been established.

In contrast to α-diazosulphones, α-diazoketones react with t-butyl hypochlorite to form acetals[55]:

$$RCOCHN_2 + (CH_3)_3COCl \xrightarrow{C_2H_5OH} RCOCH\begin{matrix}OC_2H_5\\OC_2H_5\end{matrix}.$$

This can be accounted for by the different capacities of the chlorine atom in α-alkoxy-α-chloromethylsulphones (XXXVII) or (XXXVIII) and α-alkoxy-α-chloromethylketones (XXXIX) for nucleophilic substitution[56]:

$$RCOCH(Cl)OC_2H_5 + C_2H_5OH \xrightarrow[-HCl]{} RCOCH(OC_2H_5)_2,$$

$$RSO_2CH(Cl)OC_2H_5 + C_2H_5OH \not\rightarrow RSO_2CH(OC_2H_5)_2.$$

The driving force of the reaction of α-diazosulphones with sulphuryl chloride in ether[57] is attack on the diazo-derivative by the chloronium cation formed when sulphuryl chloride reacts with ether. The resulting diazonium ion (XL) is converted in ether into the oxonium ion (XLI). As a result of nucleophilic attack by the chloride ion, the latter is converted into α-alkoxy-α-chloro-sulphone:

$$SO_2Cl_2 + ROR \rightarrow SO_2 + Cl^{\oplus} + Cl^{\ominus} + ROR;$$

$$R^1SO_2CHN_2 + Cl^{\oplus} \rightarrow \underset{\text{(XL)}}{R^1SO_2CHClN_2^{\oplus}};$$

$$(XL) + ROR \xrightarrow[-N_2]{} R^1SO_2CHCl\overset{\oplus}{O}R_2;$$

$$(XLI) + Cl^{\ominus} \rightarrow R^1SO_2CHClOR + RCl.$$

It is noteworthy that there has recently been a growth of interest in reactions of diazo-derivatives with compounds which behave as donors of positive halogenonium ions. Many of these reactions make possible new methods for the synthesis of acetals and halogeno-derivatives of ethers, sulphones, heterochain compounds, and heterocyclic compounds. As an example, one may quote the reactions of diazomethane and diazoacetic ester with bromotrinitromethane[58], which lead respectively to 3-nitroisoxazoline *N*-oxide and ethyl α-bromo-ββ-trinitropropionate:

$$BrC(NO_2)_3 \begin{cases} \xrightarrow{CH_2N_2} H_2C\begin{matrix}C(NO_2)_2\\ \\ N^{\oplus}-O^{\ominus}\\ O\end{matrix}\!\!\!

of silver oxide and leads to the formation of *p*-methoxyphenyl methoxymethyl sulphone:

$$CH_3OC_6H_4SO_2CHN_2 \xrightarrow[-N_2]{h\nu,\ CH_3OH,\ Ag_2O} CH_3OC_6H_4SO_2CH_2OCH_3 .$$

The formation of a sulphonylcarbene is also observed in the thermal decomposition of benzenesulphonyldiazomethane in benzene[65]. Together with a carbene dimerisation product—1,2-di(benzenesulphonyl)ethylene, a small amount of the product resulting from the insertion of the carbene in the C–H bond of benzene—benzenesulphonylphenylmethane—is formed[65]. Apart from these products, the ester of benzenesulphonic acid and benzenesulphonylmethanol (XLIX) is produced. The authors believe that its formation can be accounted for by the decomposition of the initial diazosulphone into the benzenesulphonyl radical $RSO_2^{\cdot}$, which captures oxygen. The resulting sulphonyl oxide radical $RSO_2^{\cdot}$ reacts with the benzenesulphonylmethyl radical formed by the reaction

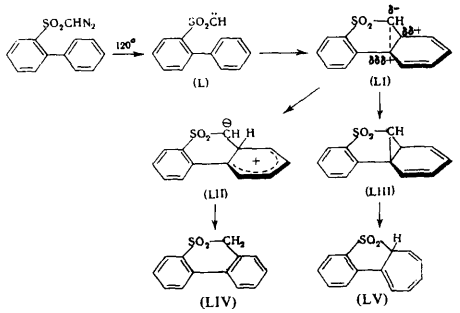
$$C_6H_5SO_2CH: + RH \rightarrow C_6H_5SO_2CH_2\cdot + R\cdot$$

The dimerisation of the above radicals gives rise to the final ester (XLIX). Compound (XLVII) is not in fact formed in the photolysis of (XLVI) in benzene, the yield of (XLVIII) remains the same, and the yield of (XLIX) increases appreciably:

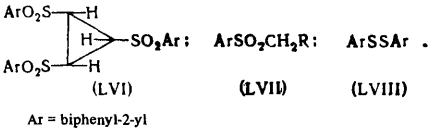
$$C_6H_5SO_2CHN_2\ (XLVI) \xrightarrow{C_6H_5SO_2CHN_2} C_6H_5SO_2CH{=}CHSO_2C_6H_5\ (XLVII)$$
$$C_6H_5SO_2CHN_2\ (XLVI) \xrightarrow{C_6H_6} C_6H_5SO_2CH_2C_6H_5\ (XLVIII)$$
$$C_6H_5SO_2CHN_2\ (XLVI) \rightarrow C_6H_5SO_2CH_2OSO_2C_6H_5\ (XLIX)$$

The photolysis and thermolysis of compound (XLVI) in cyclohexene[65] lead to an *exo*- and *endo*-7-benzenesulphonylnorcaranes in proportions of 68 : 32; compounds (XLVII) and (XLIX) were not detected. The thermal decomposition of benzenesulphonyldiazomethane in cyclohexane leads to the formation of the insertion product $C_6H_{11}CH_2SO_2C_6H_5$ in 43% yield and of compound (XLIX) in 6.9% yield. The photolysis of the diazosulphone (XLVI) in the same solvent gives rise to the same insertion product in 12% yield and to compound (XLIX) in 39% yield.

The thermal decomposition of biphenyl-2-sulphonyldiazomethane at 120°C leads to intramolecular products resulting from the insertion of a carbene (L) in a C–H or C–C bond[66]. According to the authors, this reaction proceeds via an intermediate intramolecular complex (LI), which is converted into the σ-complex (LII) or into the intermediate norcaradiene (LIII). The latter is converted into the product resulting from insertion in a C–H bond [compound (LIV)] or a C–C bond [compound (LV)]:



Apart from the two cyclic sulphones (LIV) and (LV), the authors detected the cyclopropane derivative (LVI), the sulphone (LVII), and the disulphide (LVIII):



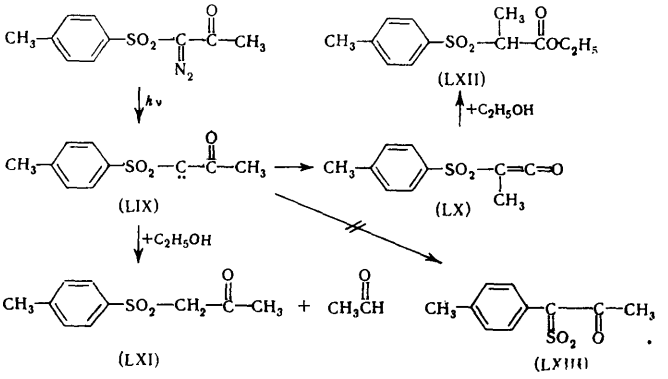
Ar = biphenyl-2-yl

The formation of compound (LVIII) can be explained by the decomposition of the initial diazosulphone into aryl-substituted sulphonyl groups with subsequent reduction and dimerisation. The sulphone (LVII) is produced as a result of the insertion of the sulphonylcarbene in a C–H bond of the solvent and the cyclopropane (LVI) is normally formed as a result of the trimerisation of an arenesulphonylcarbene.

The formation of sulphonylcarbenes on ultraviolet irradiation of di(benzenesulphonyl)diazomethane in polar solvents made it possible to develop an interesting method for the synthesis of ylids[19]:

$$(C_6H_5SO_2)_2CN_2 \xrightarrow[-N_2]{} (C_6H_5SO_2)_2C: \xrightarrow{(CH_3)_2SO} (CH_3)_2\overset{\oplus}{S}-\overset{\ominus}{C}(SO_2C_6H_5)_2 .$$

Attempts to carry out the Wolff rearrangement for compounds in the series of α-diazo-β-oxosulphones during their photolytic or thermal decomposition have been described. However, the study of the photolysis of α-acetyl(toluene-*p*-sulphonyl)diazomethane[67] in ethanol showed that the carbene (LIX) formed after the elimination of nitrogen rearranges either into the keten (LX) (an α-ketocarbene-like behaviour) or reacts with ethanol, being converted into acetyl(toluene-*p*-sulphonyl)methane (LXI) and acetaldehyde. On interaction with ethanol, methyl(toluene-*p*-sulphonyl)keten (LX) gives rise to ethyl α-(toluene-*p*-sulphonyl)propionate (LXII):

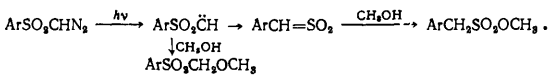


The product of the addition of ethanol to acetyl tolyl sulphene (LXIII) was not isolated. This is evidence that the rearrangement of the carbene (LIX) into the sulphene (LXIII), resembling the Wolff rearrangement, does not occur in this case.

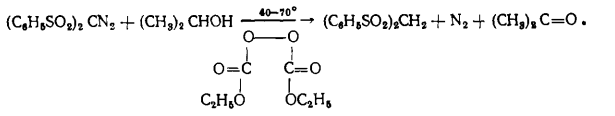
The thermolysis of α-benzoylbenzenesulphonyldiazomethane at 100–110°C in mesitylene[25] leads to formation of phenylbenzenesulphonylketen (LXIV), which is converted in the presence of amines into *N*-substituted phenylbenzenesulphonylacetamides:

$$C_6H_5SO_2CN_2COC_6H_5 \rightarrow \underset{C_6H_5SO_2}{\overset{C_6H_5}{>}}C{=}C{=}O\ (LXIV) \xrightarrow{H_2NR} \underset{C_6H_5SO_2}{\overset{C_6H_5}{>}}CH-C(=O)NHR .$$

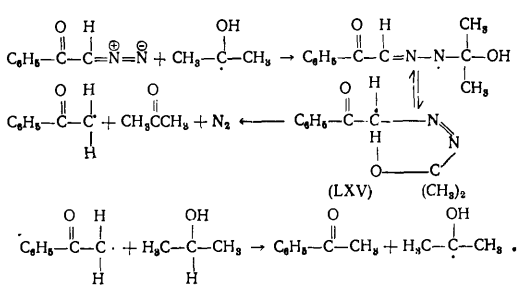
When aryl-substituted α-diazosulphones were irradiated in methanol at −10°C in an atmosphere of nitrogen[67], the methyl ether of arenesulphonylmethanol and (in a low yield) the methyl ester of α-arylmethanesulphonic acid were isolated. The last compound is probably formed as a result of the Wolff rearrangement of the arenesulphonylcarbene into an aryl sulphene, which then interacts with methanol:



When di(benzenesulphonyl)diazomethane is heated with isopropyl alcohol in the presence of diethyl peroxydicarbonate, the products are radicals which react with the above diazosulphone to form the product of the reductive elimination of nitrogen[69]:

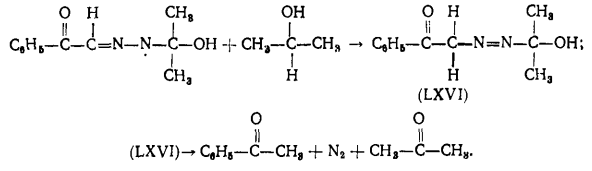


The reaction with α-diazoketones proceeds similarly. The following mechanism has been proposed:



The decomposition of diethyl peroxydicarbonate results in the elimination of a proton from isopropyl alcohol with formation of the isopropyl radical, which reacts with the diazoketone to form a hydrazonyl radical with an unpaired electron at the nitrogen atom. The latter is in equilibrium with the C-radical form (LXV). The radical (LXV) decomposes into acetone, nitrogen, and a benzoylmethyl radical. The interaction of the last species with the solvent leads to the product of the reductive elimination of nitrogen and the initial isopropyl alcohol.

According to an alternative mechanism, the hydrazonyl radical formed in the first stage reacts with the solvent to produce the azo-compound (LXVI), which decomposes with evolution of nitrogen into the final reaction product and acetone:

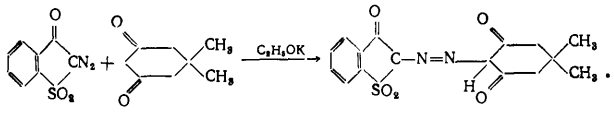


3. Reactions Involving the Nitrogen of the Diazo-Group

An important section of the chemistry of diazosulphones comprises reactions involving the nitrogen of the diazo-group; some of these were studied previously for other diazo-derivatives.

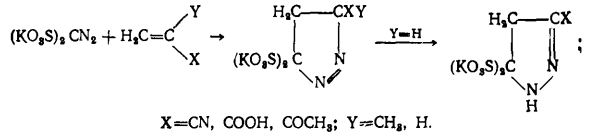
Triphenylphosphine reacts with diazosulphones to form triphenylphosphazines[19,24,27,29,30], which can be used to identify diazosulphones and to obtain them in a pure form:

α-Diazo-β-oxosulphones react with compounds containing an activated methylene group to form azo-derivatives[22]:



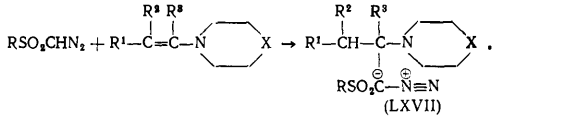
Diekmann[19] observed the formation of the phenylhydrazone of di(benzenesulphonyl)formaldehyde in the reaction of di(benzenesulphonyl)diazomethane with phenylmagnesium bromide:

The reaction involving the formation of pyrazolines, which is well known in the series of diazoalkanes[70], has also been described for diazosulphones in relation to the interaction of potassium diazomethionate with a number of unsaturated compounds[71]:

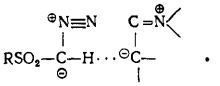


X=CN, COOH, $COCH_3$; Y=CH_3, H.

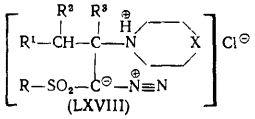
It has recently been observed that α-diazosulphones readily add to the double bonds of substituted enamines[72] with formation of products of the *C*-alkylation of the α-carbon atom of the diazosulphone [compound (LXVII)], but not pyrazolines (as happens with α-diazoketones):



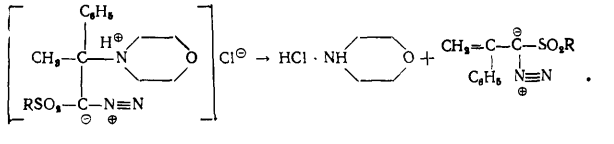
This difference in the behaviour of α-diazosulphones and α-diazoketones was explained by the greater capacity of the methylidyne protons of α-diazosulphones for the formation of hydrogen bonds with enamines in the transition complex:



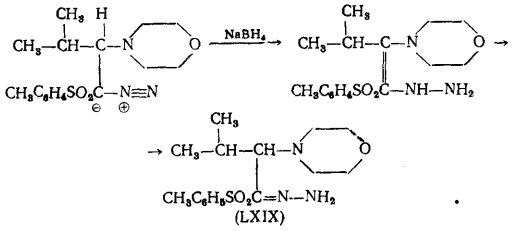
The adduct (LXVII) is stable, forming with hydrochloric acid in ether the hydrochloride (LXVIII), which can undergo further reactions:



Thus, for $R^1 = R^2 = H$, $R^3 = C_6H_5$, and X = O, morpholine hydrochloride is split off in chloroform at room temperature and an unsaturated diazosulphone—3-diazo-2-phenyl-3-(toluene-*p*-sulphonyl)prop-1-ene—is formed:

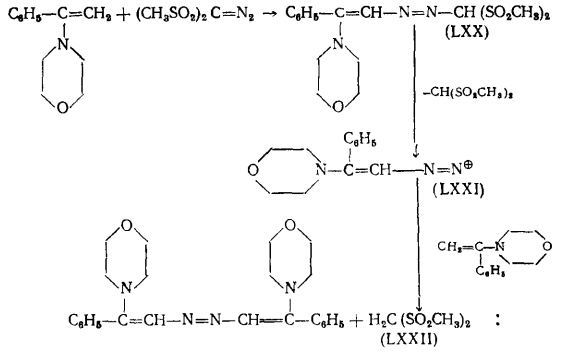


The diazosulphone (LXVII) (R = $CH_3C_6H_4$, $R^1 = R^2 = CH_3$, R^3 = H, and X = O) is reduced with sodium tetrahydroborate in methanol to 1-hydrazino-3-methyl-2-morpholino-1-(toluene-*p*-sulphonyl)but-1-ene, which isomerises to the hydrazone (LXIX) under the influence of hydrochloric acid:



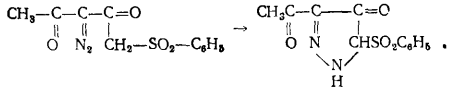
(LXIX)

The reaction of di(alkanesulphonyl)diazomethanes with enamines proceeds via a different mechanism. In the reaction of di(methanesulphonyl)diazomethanes[73] with α-morpholinostyrene the initial product is the azo-compound (LXX), which splits off the anion of di(methanesulphonyl)methane, forming the diazonium ion (LXXI). The latter reacts with a second enamine molecule to form 1,6-dimorpholino-1,6-diphenyl-3,4-diaza-1,3,5-hexatriene and di(methanesulphonyl)methane (LXXII):



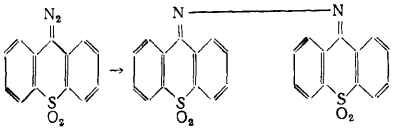
(LXXII)

The interesting intramolecular cyclisation of 3-diazo-5-benzenesulphonylpentane-2,4-dione to the corresponding pyrazolone (LXXIII) under the influence of potassium ethoxide[74] belongs to the class of reactions proceeding without the evolution of nitrogen:

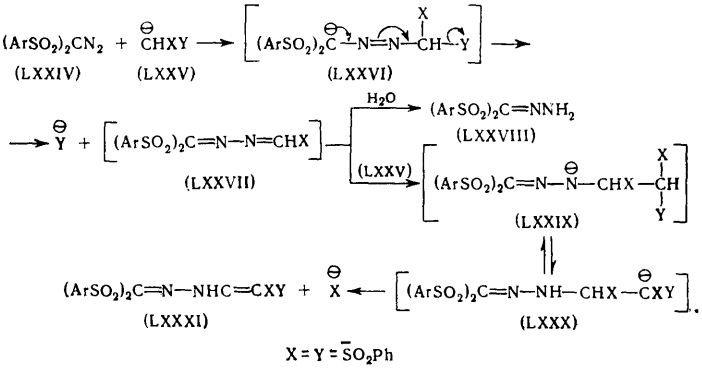


(LXXIII)

Under the same conditions, 9-diazothioxanthene *SS*-dioxide forms the azene derived from 9-oxothioxanthene *SS*-dioxide[27]:



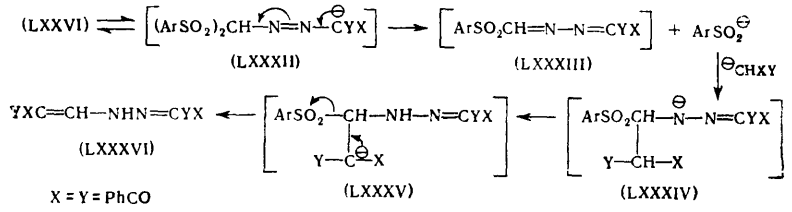
Heyes and Holt[28] described recently an interesting reaction between di(arenesulphonyl)diazomethanes and the sodium salt of di(benzenesulphonyl)methane. It proceeds in tetrahydrofuran at 0°C and leads to the formation of sodium benzenesulphinate and a vinylhydrazone (LXXXI):



X = Y = SO_2Ph

The authors explain the formation of vinylhydrazones by the coupling of the aryldiazosulphone (LXXIV) to the carbanion (LXXV). The coupling of diazosulphones to triphenylphosphine and phenylmagnesium bromide has already been mentioned. According to the authors, this reaction is a first example of reactions where the nucleophilic agent substitutes a hydrogen atom at a carbanionic centre. The elimination of the arenesulphinate ion from the adduct (LXXVI) probably leads to the azine (LXXVII), which hydrolyses to the hydrazone (LXXVIII) in aqueous solvents. In a non-aqueous medium the nucleophilic attack on the azine (LXXVII) by a second carbanionic species leads to the formation of the adduct (LXXIX), whose tautomer (LXXX) can split off a sulphinate ion to form the vinylhydrazone (LXXXI).

If the carbanion contains carbonyl groups, then the adduct (LXXVI) is probably converted into the tautomer (LXXXII). Otherwise it is impossible to explain the splitting off of the sulphinate ion [(LXXXII) → (LXXXIII)]. This view is supported by the finding that the remaining sulphonyl group is split off from the azine (LXXXIII) with subsequent attack by a second carbanionic species, probably in accordance with the scheme (LXXXIII) → (LXXXIV) → (LXXXV) → (LXXXVI). The tetracarbonylvinylhydrazone (LXXXVI) is formed via a mechanism involving the formation of a tetrasulphonylvinylhydrazone:



X = Y = PhCO

---o0o---

From the time when α-diazosulphones began to be studied on a wide scale, 12 years have elapsed. However, during this brief period the fundamentals of their chemistry have been worked out, their characteristics have been discovered, and practical applications of this interesting class of compounds have been outlined.

The interest in α-diazosulphones is due to various causes. In the first place one should mention that these compounds are valuable preparative reagents, which permit the introduction of the sulphonyl group into various organic compounds. α-Diazosulphones lead to interesting heterocyclic system, such as sulphonylfuroxans[60], oxathiolans[51], etc.[54,71]. They serve as the starting materials for the synthesis of sulphonylcyclopropanes[63,64].

The study of the biological activity of α-diazosulphones is of considerable interest. The stable and relatively non-toxic potassium diazomethionate, which exhibits antitumour activity, is striking in this respect. By analogy with α-diazoketones, α-diazosulphones can evidently exhibit mutagenic and anticonvulsant activity[75].

The presence of the nitrogen atom, which can be split off on heating or under the influence of chemical agents, permits the use of α-diazosulphones, particularly potassium diazomethionate, as agents for the formation of sponge rubber[76].

A number of characteristics of the chemical behaviour of α-diazosulphones have been discovered. Thus, in contrast to α-diazoketones, α-diazosulphones do not as a rule undergo the Wolff rearrangement, add readily to the double bond of enamines with retention of the diazo-group, react in a characteristic manner with t-butyl hypochlorite, etc.

Further elucidation of the differences between the structures and chemical properties of the diazo-group in α-diazosulphones and other aliphatic diazo-compounds will help deepen our knowledge of this field of chemistry.
