The introduction of fluorine may be a result of the formation of a cationoid species in a medium capable of supplying fluoride ions. Thus treatment of *N*-phenylhydroxylamine with HF leads to the formation of *p*-fluoroaniline[189]:

(34)

The reaction in which fluorine is introduced by means of sulphur tetrafluoride (a common reagent) and also its analogues (SeF_4,[190] $C_6F_5SF_3$,[191] R_2NSF_3,[192] and MoF_6[193]) also belongs to nucleophilic substitution processes.

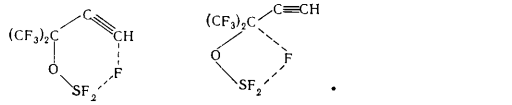
These agents make it possible to convert smoothly the C–OH group into C–F, C=O into CF_2, and COOH into CF_3 or COF depending on the reaction conditions. It is suggested that the formation of the C–F bond is the result of an intramolecular nucleophilic substitution in the intermediate ester:

(35)

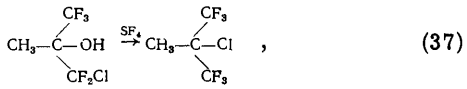
The side processes accompanying the fluorination by SF_4 are not inconsistent with this hypothesis. Thus, when unsaturated residues are present in the alcohol molecule, the following rearrangement is possible[194]:

(36)

Evidently the driving force is the preferential formation on steric grounds of a six-membered transition state rather than a four-membered state leading to the normal product:



On treatment with SF_4, not only fluorination but also dehydration or rearrangement with transfer of the halogen can occur[195]:

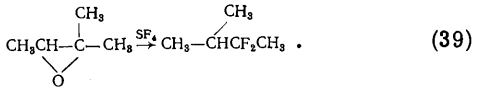


(37)

as well as the formation of ethers together with fluoroalkanes[196]:

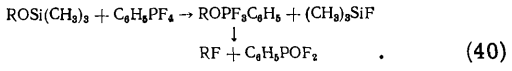
(38)

where R = CH_3, CH_2Cl, or $CHCl_2$. The fluorination of oxirans by SF_4 is also accompanied by rearrangements[197]:



(39)

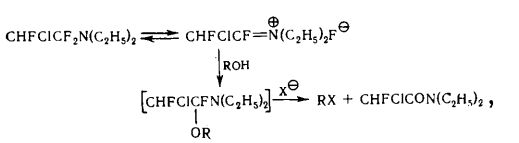
The new fluorinating agent $C_6H_5PF_4$, which smoothly replaces the $-OSi(CH_3)_3$ group by fluorine, probably acts similarly. The formation of intermediates in this case is facilitated owing to the high energy of the Si–F bond[198]:



(40)

The replacement of the hydroxy-group by fluorine with the aid of a mild agent such as the Yarovenko reagent $CHFClCF_2N(C_2H_5)_2$[199] (see Liska's review[200]) evidently also involves attack by the fluoride ion, which, however, is not intramolecular: in the presence of other nucleophilic species in the reaction medium, for example Cl^- or Br^-,

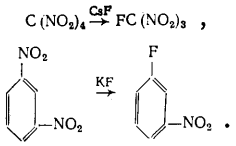
chlorine or bromine are introduced into the organic molecule instead of fluorine. The overall reaction mechanism involves the following stages[201]:



(41)

where X = F, Cl, or Br.

When the organic molecule contains a stable group which is eliminated, the latter can be replaced by fluorine also by means of the usual nucleophilic substitution. Fluorine has been introduced successfully in this way into carbohydrate molecules by the replacement of *p*-toluenesulphonyl[202] or methanesulphonyl[203] residues (see Podesva and Pacak[204] for a review of fluorocarbohydrates). The nitro-group can also be substituted[205,206]:



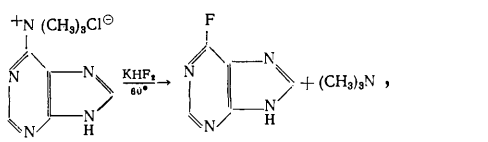
(42)

(43)

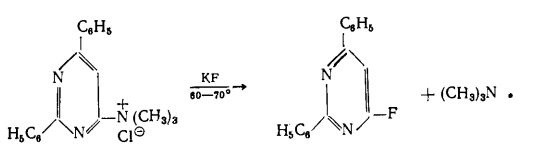
The substitution by fluorine of a nitro-group in purine and 1,2,4-triazole on heating with hydrogen fluoride[207] may involve the activation of the molecule by the protonation of the nitrogen atoms. A similar activation occurs in the *N*-methylation of 4-chloropyridine, which is then involved in halogen exchange with KF at 55°C.[208]

In the absence of activation, this reaction with polychlorinated aromatic (including heterocyclic) compounds requires very severe conditions (200–500°C). It constitutes the main method for the synthesis of polyfluorinated aromatic compounds (see Vorozhtsov's review[209]).

Heating of quaternary ammonium salts with alkali metal fluorides constitutes a promising method for the introduction of fluorine into heterocyclic compounds[210,211]:



(44)



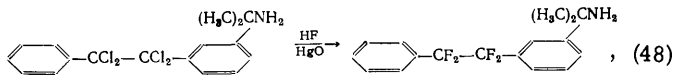
(45)

In many cases substitution of chlorine or bromine by fluorine requires the electrophilic cooperation of a "soft" Lewis acid, which binds the "soft" halogens. Such acids include SbF_3, SbF_5, HgF_2, AgF, and other agents used in this classical method for the introduction of fluorine, which is called the Swarts reaction (see the review of Fialkov and Yagupol'skii[212]). Chromium[213] and titanium[214] can also exhibit an electrophilic cooperation in the exchange of an olefinic halogen:

(46)

(47)

In the electrophilic cooperative action of mercury the halogen atoms in benzyl position are readily exchanged for fluorine[215]:

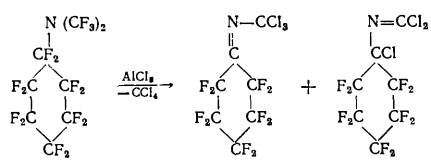


(48)

as well as those in the CBr_3 group linked to the mercury atom[216]:

(49)

However, since phenylmercury fluoride cannot undergo exchange with bromine in any other compound, reaction (49) may include a diahalogenocarbene transfer stage. "Hard" Lewis acids, i.e. derivatives of boron or aluminium, which form high-energy bonds with the "hard" fluorine atom, catalyse the reverse process—the exchange of fluorine for other halogens. Even certain fully fluorinated tertiary amines, which completely lack basic properties, enter into the reaction with $AlCl_3$, all the fluorine atoms in the α-position relative to the nitrogen atom being exchanged with elimination of CCl_4:[217]



(50)

Fluorine atoms in substituted trifluoromethylbenzenes are smoothly exchanged for chlorine with the aid of BCl_3 at 100°C,[218] while in the reaction with $AlCl_3$ the fluorine atoms in both vinyl and allyl positions in octafluorocyclobutene[219] and hexafluoropropene[220] derivatives are replaced.

During the preparation of this review for publication, a number of studies supplementing the data described here were published. The positive and negative ions derived from pentafluoroacetone and its stable enol have been investigated mass-spectrometrically[221]. In combination with ion cyclotron resonance, mass-spectrometry has been used to study the unusual decomposition of the pentafluoroallyl cation[222]. The stereochemical transformations of the corresponding radical have been studied by ESR[223]. New data on the inductive effect of fluorine atoms have been obtained with the aid of photoelectronic spectroscopy of a number of t-butyl alcohols[224]. Quantum-mechanical calculation[225] led to the conclusion that the fluorobenzenium ion is more stable when the fluorine atom is not attached to the sp^3-hybridised carbon atom. Experimental data indicating a greater stability of cycloalkyl carbonium ions containing a fluorine atom at the cationic centre in relation to analogues containing a chlorine atom have been obtained[226]. The one-electron mechanism of the interactions between arylethylenes and lead dioxide in SF_4 or HF has been confirmed by ESR[227].

Examination of new data for the reactions of organofluorine compounds will be the subject of a separate review.

The Siloxane Bond and Its Influence on the Structure and Physical Properties of Organosilicon Compounds

M.G.Voronkov, Yu.A.Yuzhelevskii, and V.P.Mileshkevich

The main characteristics of the structure of the siloxane bond are examined and the results of studies on the structures and properties of oxygen-containing silicon compounds by physical methods are reviewed.
The bibliography includes 405 references.

IV. Physical properties and molecular structures of polysiloxanes 363

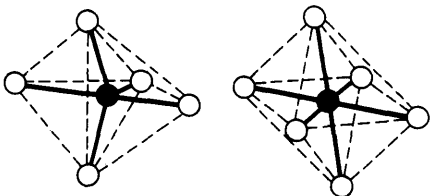
I. INTRODUCTION

Polymeric organic and inorganic silicon compounds have found recently a wide variety of numerous practical applications. The valuable properties of these compounds, the microstructure of which is based on alternating silicon and oxygen atoms, are due primarily to the nature of the siloxane bond $\geq$Si—O† in all silicon(IV) compounds. This bond is formed as a result of σ coupling of the hybridised s and p electrons of the silicon atom with the p electrons of oxygen; there is then the additional possibility of π interaction between the unshared p electrons of the oxygen atom and the $3d$ orbitals of silicon, which has been called p_π—d_π or $(p \rightarrow d)_\pi$ coupling.

The formation by s and p electrons of four tetrahedral σ bonds involving the silicon atom makes the latter similar to its immediate neighbour in the Periodic System—carbon. However, the possibility of $(p \rightarrow d)_\pi$ bonding introduces sharp differences between the structures and properties of the corresponding silicon and carbon compounds, Silicon, an element of the Third Period, has free $3d$ orbitals corresponding to the M shell and is therefore capable of functioning as an electron acceptor in the formation of a donor—acceptor d_π—p_π bond. However, research on organosilicon compounds in the course of more than 100 years has shown that at normal temperatures silicon does not form multiple p_π—p_π bonds.

Since, in contract to the p orbitals, not all the $3d$ orbitals have the same form and relative orientation in space, more than two d orbitals of the silicon atom cannot be used in its combination with the atoms of other elements, probably because of geometrical factors[2-4]. As a result, the maximum coordination number of silicon is six[4]. In hexacoordinate complexes the silicon atom has $3sp^3d^2$-hybridised orbitals and in pentacoordinate complexes it has $3sp^3d$-hybridised orbitals.

The angular functions of the d orbitals enable silicon to form a wide variety of σ and π bonds with other elements. However, according to quantum-chemical calculations the d orbitals in the free atoms of elements in the Third Period are too diffuse for the formation of σ bonds. Such bonds can be formed only when there are electronegative substituents at the silicon atom in the molecule, which can increase its effective positive charge. The $3d$ orbital is then compressed and becomes of comparable size to the $3s$ and $3p$ orbitals[2-4]. Of the five d orbitals only the d_γ orbitals ($3d_{z^2}$ and $3d_{x^2+y^2}$) can be used for the formation of σ bonds. Their hybridisation with the $3s$ and $3p$ orbitals can lead to several structures. The bipyramidal form (I), characteristic of the complexes of pentacovalent silicon, is stabilised by the hybridisation of the s and p orbitals with the d_{z^2} orbital[5]. The octahedral structure (II) is characteristic of the coordination compounds of hexacovalent silicon[5,6].



(I) (II)

The d_ϵ orbitals ($3d_{xz}$, $3d_{yz}$, and $3d_{xy}$) are involved in d_π—p_π bonding. In contrast to the p_π—p_π bond, this type of multiple bond does not prevent free rotation about the σ bond. A consequence of this is the relatively high freedom of rotation about the siloxane bond.

Numerous pieces of physical evidence for the occurrence of the $(p \rightarrow d)_\pi$ interaction between the silicon and oxygen atoms joined by the siloxane bond are considered below. The wide variety of the reactions involving the cleavage of the Si—O bond, related in one way or another to its $(p \rightarrow d)_\pi$ character, are of independent interest and are not considered in this review.

† The term "siloxane bond" was introduced into the nomenclature of organosilicon compounds by Stock[1] in 1917 to designate the linkage between the silicon and oxygen atoms. It is present in all silicon compounds of the type $\geq$Si—O—R, where R = —Si$\geq$H, a hydrocarbon group acyl group, metal, etc.

II. STRUCTURAL AND PHYSICAL CHARACTERISTICS OF THE SILOXANE BOND

1. Interatomic Distances and Valence Angles

The Si—O bond lengths and SiOR valence angles in organic siloxanes are listed in Table 1. According to the tabulated data, the Si—O bond length is 1.64 ± 0.03 Å in the vast majority of organic silicon derivatives. This value is much lower than the Si—O bond length calculated assuming the additivity of the atomic radii (1.83 Å; the atomic radii of silicon and oxygen are 1.17 and 0.66 Å respectively)[56].

Table 1.

*e = electron diffraction, sp = spectroscopic, x = X-ray diffraction.

In the dimeric molecule of dibromotrimethylsiloxyaluminium (compound 41 in Table 1), in trimethylsilylperrhenate (compound 42), and in tetra-alkylammonium (compound 38) and pyridinium (compound 39) siliconates the Si—O bond is longer than in the majority of organosilicon derivatives (1.7—1.8 Å), while in hexafluorodisiloxane (compound 5) and in tetramethylstiboniumtetrakis(trimethylsiloxy)-derivatives of metals (compounds 40) it is shorter (1.56 Å). In inorganic silicon derivatives (silicates) the Si—O distances vary over the range 1.54—1.78 Å.[7,57-61]. The Si—O bond is shortened in all silicon

compounds containing the Si—O—M group, where M is a metal atom with an effective positive charge (silicates, siliconates, and siloxanolates)[62]. In alkali metal trimethylsilanolates (compounds 32) the Si—O bond length is about 1.60 Å.

On the other hand, in the disiloxane linkage in silicate anions, the silicon atoms of which are joined in an anionic oxygen atom (Si—O⁻), the interatomic Si—O distance is longer than usual (1.75—1.85 Å).[59-62] The Si—O bond is lengthened (1.7—1.8 Å) also in organic silicon compounds where the oxygen atom is linked to an electron-accepting substituent (compounds 38—42 in Table 1).

The decrease of the Si—O bond length noted above cannot be accounted for solely by its appreciable ionic character, since the introduction of the appropriate correction for the difference between the electronegativities of the silicon and oxygen atoms leads to 1.77 Å.[62] The shorter length of the Si—O bond convincingly demonstrates its partial double bond character arising as the result of the $(p \rightarrow d)_\pi$ interaction. The degree of double bond character (bond order) depends on the nature of the substituents at the silicon and oxygen atoms. Electron-accepting substituents at the silicon atom, which decrease the energy of the 3*d* orbitals, or metal and oxygen atoms, which increase the effective negative charge of the silicon atom, increase the Si—O bond order. On the other hand, electron-donating substituents at the silicon atom or electron-accepting groups at the oxygen atom decrease the siloxane bond order.

Although no compound is known in which the silicon atom is joined to an oxygen atom by a double bond, presumably the order of the "short" Si—O bonds (1.56 ± 0.03 Å) approaches that of the double bonds Si=O as a result of the additional $(p \rightarrow d)_\pi$ interaction. In long Si—O bonds (1.7—1.8 Å) the degree of $(p \rightarrow d)_\pi$ coupling is reduced to a minimum and they can be regarded as virtually single bonds. On the other hand, in the majority of organosilicon compounds the Si—O bond (1.64 ± 0.03 Å) is 40—50% ionic[62,63] and its order is 1.2—1.5.[62]

The valence angle between the oxygen bonds increases in the sequence H_3COCH_3 (111.43°)[64] < H_3SiOCH_3 (120.6°)[38] < $H_3SiOSiH_3$ (144.0°).[8] This demonstrates an increase of the amount of *s* character of the oxygen σ orbitals. When oxygen combines with one and two silicon atoms (in methoxysilane and disoloxane), its hybridisation is the average between sp^3 and sp^2 and between sp^2 and *sp* respectively. The increase of the SiOSi angle, associated with the transition from the sp^3 hybridisation of the oxygen atom to sp^2 and to *sp*, in the limiting case, probably favours the formation of common mutually perpendicular π orbitals between the two lone pairs of the oxygen atom and the *d* orbitals of the two silicon atoms linked to them (Fig. 1).

The SiOC angles in methoxy- and phenoxy-silanes (compounds 28 and 29) are almost identical. In tetramethoxysilane (compound 27) the SiOC angle (113°) is smaller than in methoxysilane, which indicates a marked weakening of the interaction between the *p* electrons of each of the four oxygen atoms and the *d* orbitals of silicon as a result of the competing mutual influence of the methoxy-groups.

The SiOSi angle varies within very wide limits; from 105° (compounds 16 and 17) to 150—170° in hexahalogenosiloxanes (compounds 4 and 5) and from 125° to 180° in silicates[58,59,61]. The great flexibility of the SiOSi angle, which in the vast majority of silicon compounds is much greater than the tetrahedral valence angle of oxygen in the state of sp^3 hybridisation (109°), is not inconsistent with the presence of the $(p \rightarrow d)_\pi$ bond between oxygen and silicon, since the five orthogonal diffuse 3*d* orbitals of the latter make it possible to form π bonds for any steric orientation of oxygen.

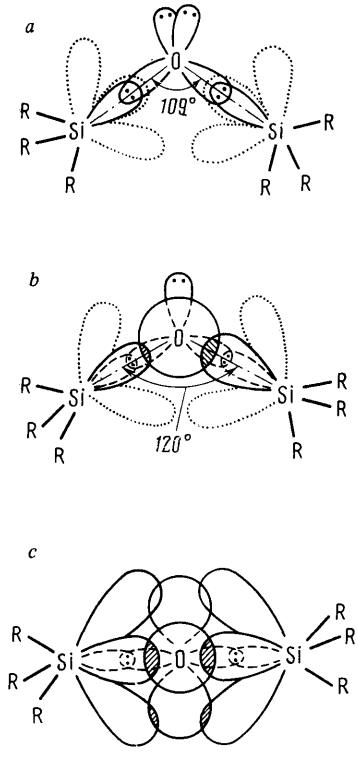

Figure 1. The overlapping of the electron orbitals of an sp^3-, sp^2-, and *sp*-hybridised oxygen atom (*a*, *b*, and *c* respectively) with the orbitals of the silicon atoms in the disiloxane group.

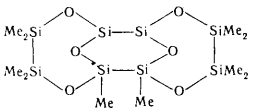
With increase of the SiOSi angle, the SiO bond length diminishes and its order increases. A decrease of the SiO (Si) bond length by 0.02—0.03 Å corresponds to an increase of the SiOSi angle in silicates by 10°.[61]

The SiOSi angles in the planar six-membered rings of the silicate anions $[Si_3O_9]$ (Lazarev[61]) in cyclotrisiloxanes (compounds 10 and 12) and in octamethylspiropentasiloxane (compound 11) are 125—130°. In contrast to the planar cyclotrisiloxanes[14,23-25], cyclosiloxanes containing more than three siloxane units are non-planar[14,20,28,29]. In cyclosiloxanes consisting of more than three siloxane units (compounds 18—22), in silsesquioxanes (compound 25), and also in linear (compounds 8 and 9) and branched (compound 6) siloxanes the SiOSi angle is somewhat greater (130—145°). In the phthalocyaninesiloxane polymer (compound 26) the SiOSi angle is probably close to 180° owing to the steric hindrance due to the phthalocyanine groups[35,36]. In disiloxanes (compounds 1—5) the SiOSi angle varies in the range 135—156° according to electron diffraction data. We may note that indirect spectroscopic methods lead to unduly high values of these angles (155—180°, Table 1). The maximum SiOSi angle

(155.7°) has been observed, as expected, in hexafluorodisiloxane (compound 5), which contains the most electronegative substituents (fluorine atoms) at the silicon atoms.

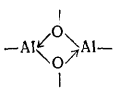


Two types of SiOSi angles were found in compound 23; 133° in the planar six-membered ring and 148° in the nonplanar seven-membered rings.

In contrast to the SiOSi angle, the OSiO angle in the majority of organosilicon compounds varies within narrow limits (110—120°).[14,20,21,23-25,28-33,40-43] In silanediols it amounts to 110° ± 2°.[40-43] In the five-membered ring of compounds 38 and 39, which have an ionic structure, the OSiO angle is 86—90°.[50,51] One oxygen atom of each five-membered ring occupies an equatorial position and the other is in an axial position, the axial SiO bonds (1.794 Å), being significantly longer than the equatorial bonds (1.700 Å).[50]

According to X-ray diffraction data, the geometrical shape of silatrane molecules (compounds 34—37), containing a pentacoordinate silicon atom, is that of a distorted trigonal bipyramid (with respect to the silicon atom) with equatorial oxygen atoms[49]. The SiOC angles in *m*-nitrophenyl-(2,2′,2″-nitrilotriethoxy)silane (compound 36) are 122—123°. The atrane half-rings in silatranes are completely identical, have a non-planar configuration, and are extremely mobile[49].

The SiOM angles (M = metal) in silicates and in organosilicon compounds are always greater than 120°. In the dimeric dibromotrimethylsiloxyaluminium molecule (compounds 41) the four-membered ring



is planar and the SiOAl angle is 130°. Tetramethylstibonium tetrakis(trimethylsiloxy)aluminate (compound 40), which forms orthorhombic crystals with two molecules per unit cell, has an ionic structure: the SiOAl angle is 147°.[52,53] In trimethylsilyl perrhenate (compound 42) the SiORe angle is 164°.[55]

As in t-butoxides, in tetrameric potassium, rubidium, and caesium trimethylsilanolates (compounds 32) the SiOM angle is 123° ± 2°.[44] According to cryoscopic and ebullioscopic data, alkali metal (Li, Na, or K) siloxanediolates are dimerised[65].

2. The Bond Energy

The siloxane bond is one of the most stable bonds formed by silicon and is inferior in this respect only to the Si—F bond. The Si—O bond strength calculated from heats of combustion has been estimated, the results ranging from 101 to 118 kcal mole^{-1} (Table 2). It is much lower than the value (242.4 kcal mole^{-1}) predicted by theory for the $Si^+ - O^-$ ionic bond[66]. The much higher energy of formation of the Si—O bond compared with the less polar C—O bond and the more polar Ge—O, Sn—O, and Pb—O bonds evidently indicates the occurrence of $(p \rightarrow d)\pi$ interaction between silicon and oxygen‡.

According to the data in Table 2, the Si—O (Si) bond energy is probably somewhat greater than the Si—O (C) bond energy.

Table 2. The siloxane bond energies.

* See Refs. 12 and 70—79 for the heats of combustion and formation of compounds containing the Si—O bond.

The heats of formation ΔH, entropies S, and heat capacities C_p of compounds containing the siloxane bond have been calculated very accurately according to an additive scheme[78]. For organosilicon compounds in the ideal gas state at 25° and 1 atm, ΔH_{Si-O} = −52 kcal, C_p = 9.6 cal g^{-1} deg^{-1}, and S = −1.24 eu.[78]

It has been shown for cyclodimethylsiloxanes and cyclomethyl(isopropoxy)siloxanes[79] that the Si—O bond energy in cyclosiloxanes depends on the number of siloxane units in the ring. The Si—O bond energies in cyclotetrasiloxanes and cyclopentasiloxanes, which have relatively unstrained rings, and in linear siloxanes are close to one another. The appreciable strain of the rings in cyclotrisiloxanes leads to an increase of the Si—O bond energy (to 9 kcal mole^{-1}).[79]§ The difference between the Si—O bond energies in cyclotrisiloxanes and cyclosiloxanes with large rings has been confirmed by the heats of their catalytic cleavage reactions. The heat of opening the D_3 ring is 3—4 kcal mole^{-1}.[81-83] Calorimetric measurements revealed a slight (to the extent of about 0.2 kcal mole^{-1}) strain of the rings in D_4 and D_5.[82] When the methyl groups in cyclodimethylsiloxanes are replaced by propyl or 3,3,3-trifluoropropyl groups, the heat of ring cleavage increases. The ring strain energy reaches 5.25 kcal

‡ The bond strength (and force constant) usually increase with increase of bond polarity. In the case of C—O the $(p \rightarrow d)\pi$ linkage cannot be formed (there is no 2*d* orbital). The Sn—O bond has a markedly ionic character and is more than 50% longer (2.30 Å) than the Si—O bond. Therefore the formation of $(p \rightarrow d)\pi$ linkages with participation of the 5*d* electrons of tin is greatly hindered[67].

§ The conclusion reached on the basis of measurements of diamagnetic susceptibility that the ring strain in D_3 and D_4 [80] is identical must be regarded as erroneous. (D = Me_2SiO).

mole^{-1} in F_3¶ and 1.3 and 0.75 kcal mole^{-1} in F_4 and F_5 respectively.[82]

In the compounds $R^1R^2\overset{\overset{\Large O}{\frown}}{Si}CH_2CH_2SiR^3R^4$, where R^1, R^2, R^3, and R^4 = Me or Ph, the ring strain increases on replacement of methyl groups by phenyl groups. The heat of polymerisation of these compounds, which involves the dissociation of the Si—O bond, is 8—12 kcal mole^{-1}.[81]

Since the equilibrium ratio of the cyclosiloxane stereoisomers is in all cases without exception close to the statistical value[84-91], presumably the Si—O bond energy is the same in all the isomers of this cyclosiloxane. This hypothesis agrees well with the conclusion that the rates of polymerisation of F_3,[92] P_3, P_2D,[93] A_2D, A_3, A_2D_2, A_3D, and A_4 [94,95] stereoisomers are similar†. Therefore the enthalpies of the A_3(ΔH_{cis} = 27 kcal mole^{-1} and ΔH_{trans} = 22 kcal mole^{-1}) and A_4 (ΔH_{cis} = 8 kcal mole^{-1} and for the remaining three isomers ΔH = 0) stereoisomers, obtained from the temperature variation of the equilibrium constants for their interconversion[90], appear to be unexpected. The difference between the enthalpies of the A_3 and A_4 stereoisomers is not consistent with their statistical distribution at equilibrium, established in the same study[90].

3. Dipole Moments

The dipole moments μ of linear[96-110] and cyclic[97,100,111-114] siloxanes, silanols[103,115-117], alkoxysilanes, acyloxysilanes[118-131], and silatranes[132-135] have been largely compiled in the handbook of Osipov et al.[136] The experimental dipole moments of the linear siloxanes $Me_3SiO(D)_nMe_3$ and cyclosiloxanes D_n with a large number n of siloxane units in the ring agree well with the values calculated by the empirical formula[97] $\mu = 0.7\sqrt{n}$.

The dipole moment of D_3, which has a planar strained ring, is zero[100]. The configuration of the F_3 stereoisomer has been established on the basis of the dipole moments (expressed in D). The compound with μ = 4.7 D is the *cis*-isomer and that with μ = 2.98 D is the *trans*-isomer[87].

The dipole moments of disiloxanes are comparatively small (0.24—1.03).[96-105] The SiOSi angle calculated from the dipole moments of disiloxanes is much greater than the tetrahedral value: 160 ± 15° [97] (131° [102]) in hexamethyldisiloxane and about 180° [96] in disiloxane (this value is evidently too high).

As already stated, an increase of the SiOSi angle indicates an increase of the Si—O bond order. The dipole moment of the Si—O bond, calculated from the dipole moments of disiloxanes[96,97,100] and branched[13], linear[137], and cyclic siloxanes[100] and alkoxysilanes[118], is 1.2—1.65 D. Judging from the dipole moment, the polarity† of the Si—O bond is much lower than might have been expected bearing in mind the large difference between the electronegativities of silicon (1.89) [63] and oxygen (3.50).[63]

The group dipole moment increases in the series $\mu_{H_3SiO} < \mu_{Me_3SiO} < \mu_{Ph_3SiO}$. The value of μ_{H_3SiO} in disiloxane is 0.28—0.40 D [96] and μ_{Me_3SiO} amounts to 0.95—1.05 D in alkoxytrimethylsilanes[13,101,102] and 1.3 D in hexamethyldisiloxane[101]; μ_{Ph_3SiO} in hexaphenyldisiloxane is 1.2—1.7 D.[104] The smaller group dipole moment of Me_3SiO in alkoxytrimethylsilanes compared with hexamethyldisiloxane is due to the different polarities of the Si—O bond and the different types of $(p \rightarrow d)_\pi$ interactions between the oxygen and silicon atoms.

The dipole moments of methoxymethylsilanes in the series $Me_{4-n}Si(OMe)_n$ are greater than for hexamethyldisiloxane and increase with increase of n:[13]

$$\mu_{(Me_3Si)_2O} < \mu_{Me_3SiOMe} < \mu_{Me_2Si(OMe)_2} < \mu_{MeSi(OMe)_3} < \mu_{Si(OMe)_4}.$$

The dipole moments of tetra-alkoxysilanes $Si(OR)_4$ with branched alkyl groups are smaller than those of tetra-alkoxysilanes with normal alkyl groups and with increase of the degree of branching μ falls. The dipole moments of mixed alkoxysilanes having the general formula $(MeO)_nSi(t\text{-}Bu)_{4-n}$ vary linearly with n.[127]

The dipole moments of methoxymethylsilanes[13,118] and tetra-n-alkoxysilanes[118,129] agree satisfactorily with the values calculated for the tetrahedral model of these compounds, which postulates free rotation about the Si—O bond. In the presence of two or more phenoxy-groups at the silicon atom[128] or of branched alkoxy-groups in trialkoxyphenylsilanes[124], the rotation about the Si—O bond is greatly restricted. Free rotation about the siloxane bond in tetra-n-alkoxysilanes and ethoxypropylsilanes is somewhat hindered[127,128]. The rotation about the Si—O bond is probably only relatively free even in methoxysilanes[128]. A small energy barrier to rotation exists in all alkoxysilanes, but it is not large enough for the estimation of the restriction of free rotation from the dipole moments.

The dipole moments of silanediols show that the internal rotation of the two hydroxy-groups is hindered and that the molecular configuration with an SiOSi angle of 102° is preferred[116].

The high dipole moments of silatranes, which greatly exceed the values calculated without taking into account the donor—acceptor interaction between the silicon and nitrogen atoms[132,135], demonstrate the existence of a transannular N → Si bond.

The dielectric constants ϵ of linear siloxanes are somewhat higher than those of cyclic compounds[139]. The dipole moments of hexa-alkyldisiloxanes are close to that of benzene (2.28). With increase of molecular weight, $\epsilon_{20°}$ increases from 2.18 for hexamethyldisiloxane to 2.79 for $Me_3SiO[SiO(Me)_2]_{300}SiMe_3$ and from 2.39 for D_4 to 2.74 for D_8.[139] Polydimethylsiloxanes with viscosities ranging from 30 000 to 1 000 000 cS have almost identical dielectric constants (ϵ = 2.63 – 2.77).[139] The dielectric constants of polydimethylsiloxanes decrease with increase of temperature and remain virtually constant when the frequency is raised to 10^8 Hz.[139] When the methyl groups at the silicon atoms in cyclodimethylsiloxanes are replaced by polar groups [$F_3CCH_2CH_2$ or $NC(CH_2)_n$ with n = 1 –3], ϵ increases by a factor of 2—4.[87,114] Nevertheless, the dielectric constants of even the most polar cyclosiloxanes, containing CH_2CN groups at the silicon atoms, do not exceed 10,[112] while ϵ_{MeCN} = 37.5.

III. SPECTROSCOPIC CHARACTERISTICS OF THE SILOXANE BOND

1. Vibrational Spectra. The Force Constants and Bond Order

The number of publications devoted to the vibrational spectra of silicon compounds containing siloxane bonds is extremely large. The results of spectroscopic

¶ F = $CF_3CH_2CH_2(Me)SiO$, P = $CH_3CH_2CH_2MeSiO$, and A = PhMeSiO.

† The Si—O bond refraction (1.751 ml mole^{-1}) [138] is much greater than that of the C—O bond in ethers (1.51 ml mole^{-1}).

studies have been summarised in a series of reviews and monographs[57,61,140-149], the most thorough consideration having been given to silicates[61,146]. In this section only the most general features of the vibrational spectra of organosilicon compounds containing Si—O bonds are briefly considered.

Owing to the appreciable ionic character of the siloxane bond, the intensities of the bands and lines due to its vibrations are several times greater than those corresponding to the C—O bond[144,150]. As a result of the strengthening of the Si—O bond due to the $(p \rightarrow d)\pi$ interaction[6-15], the C—O—C and Si—O—Si groups absorb in virtually the same region, despite the greater mass of the atoms in the latter[144,151].

Although the problem of the spectroscopic characteristics of the siloxane bond has attracted the attention of investigators for a long time, it has not so far been possible to calculate theoretically the vibrational spectra of even the simplest compounds containing this bond[61,152,153]. This situation makes it difficult to interpret the spectra and leads to errors (sometimes fairly considerable) in the calculation of the dynamic interaction coefficients K_q, the force constants K_c‡, and the bond orders. Bearing also in mind that there are different approaches to the calculation of the latter parameter[110,154,155], the literature values of the Si—O bond order should be used with some caution.

The fundamental vibrations of the Si—O—Si disiloxane group lie in the following ranges: 450 — 630 cm^{-1} (symmetric vibrations, ν_s) and 930—1170 cm^{-1} (antisymmetric vibrations, ν_{as}). Intense bands in the infrared spectra§ and weak lines in the Raman spectra correspond to the ν_{as} wavenumbers with the opposite relation for the ν_s wavenumbers[140,162,179]. The assignment of the bands and lines corresponding to other vibrations of the siloxane bond is possible only in the simplest cases and is not often encountered in the literature. For example, it has been suggested that the 35 cm^{-1} wavenumber in the infrared spectrum of D_3 corresponds to the $\delta_\perp$ (SiOSi) out-of-plane deformation vibrations[180]. In the far infrared spectra of the higher cyclosiloxanes D_n the $\delta_\perp$ band is displaced towards higher wavenumbers: 50—70 cm^{-1} (n = 4), 80 cm^{-1} (n = 5), 80 and 100 cm^{-1} (n = 6), and 100 and 120 cm^{-1} (n = 7). The $\delta_\perp$ band of hexamethyldisiloxane has been found at 130 cm^{-1} [180] (at 69—86 cm^{-1} in the Raman spectrum) [181]¶.

In the vast majority of spectroscopic studies only antisymmetric Si—O bond vibrations are quoted and discussed. The infrared spectra of disiloxanes, cyclosiloxanes (Table 3), linear[151,182,188,212,214] and branched[211,213,215] siloxanes, silsesquioxanes[201], carbacyclosiloxanes[216], and cyclosiloxazanes[217] contain at least one intense ν_{as} band, the position of which depends more on the structure of the siloxane than on the nature of the substituents at the silicon atom. In the spectra of cyclosiloxanes with a strained ring the band is displaced towards lower wavenumbers. The minimum ν_{as} (Si—O) wavenumber (930 cm^{-1}) has been observed in the infrared spectra of carbacyclosiloxanes with the most strained five-membered ring[216]. In the spectra of cyclotrisiloxanes and six- and seven-membered carbacyclosiloxanes the band is in the region 990—1030 cm^{-1}, [216] and in the spectra of relatively unstrained cyclotetrasiloxanes and eight-membered carbacyclosiloxanes it is displaced towards still shorter wavelengths (1060—1090 cm^{-1}). Estimates of the force constants and bond orders have confirmed that the siloxane bonds in strained rings are appreciably weakened[149,195]. The vibrational spectra of cyclosiloxanes demonstrate the additivity of the intensities, which is probably due to the compensation of the $(p \rightarrow d)\pi$ interaction of the adjacent siloxane bonds[120].

*The numbers of the references quoting the tabulated absorption band wavenumbers are underlined.

The nature of the substituents at the silicon atoms has little influence on the position of the ν_{as} band of the SiO(Si) bond in the spectra of cyclosiloxanes. Only when the methyl groups in D_4 are substituted by hydrogen atoms is it displaced towards shorter wavelengths[209,211] (Table 3),

‡ The values of K_q, and K_c have been quoted in a number of publications[18,142,143,150,154-178].

§ In the infrared spectra of linear and cyclic siloxanes more than 50% of the intensity corresponds to the contribution by the antisymmetric vibrations of the Si—O bonds[182]. The intensity of the ν_{as} vibrations of the Si—O bonds in linear disiloxanes is approximately 10 times greater than the ν_s intensity[183].

¶ Infrared spectra of disiloxanes in the range from 30 to 100 cm^{-1} have been published also by Robinson and Lafferty[184].

while in linear siloxanes such a shift is not observed[142, 211-213]. In the infrared spectra of linear[140,151,182,188,212,214] and branched[213,215] siloxanes and also cyclosiloxanes containing more than four siloxane units (Table 3) the ν_{as}[Si—O(Si)] band is split into two (or more) components. In the spectra of cyclodimethylsiloxanes, starting with D_4, the shift of the absorption maxima towards higher wavenumbers with increase in ring size is relatively small (20—30 cm^{-1}). The spectra of linear polydimethylsiloxanes $Me_3Si[OSiMe_2]_nOSiMe_3$ showed two bands with maxima in the wavenumber ranges 1034—1057 cm^{-1} and 1066—1085 cm^{-1} (n = 1—4) [151] and at 1020 and 1090 cm^{-1} (n = 300—7000) [182] (Table 3). The ν_{as}(Si—O) absorption maxima in the spectra of branched siloxanes have been recorded at 1040 and 1110 cm^{-1}.[211,213,215] In the infrared spectra of the majority of cyclosiloxazanes two bands due to the ν_{as} vibrations of the Si—O bond are also observed. In the spectra of compounds with a six-membered ring these bands are displaced towards longer wavelengths, which probably indicates the strain of the siloxazane ring[217].

The position of the ν_s(SiO) band in the spectra of silsesquioxanes with organic substituents is the same as in the SiO_2 spectrum (an intense broad band in the region of 500 cm^{-1}).[218] In the spectra of the octamers $(RSiO_{1.5})_8$, 3—4 maxima are observed and in the spectra of the hexamers $(RSiO_{1.5})_6$ between 6 and 8 maxima at 360—660 cm^{-1}.[141,219]

In contrast to cyclosiloxanes, the positions of the ν_s(SiO) and ν_{as}(SiO) bands in the spectra of disiloxanes depend to a large extent on the nature of the substituents at the silicon atoms. With increase of the electronegativity of the substituents (in particular following the substitution of the methyl groups in hexamethyldisiloxane by hydrogen or halogen atoms and phenyl or hydroxy-groups) the ν_s(SiOSi) and ν_{as}(SiOSi) bands are displaced towards higher wavenumbers (Table 3). Thus, on passing from hexamethyldisiloxane to disiloxane and to hexachlorodisiloxane, the ν_{as}(SiOSi) change from 1060 to 1100 and 1170 cm^{-1} respectively[185]. The force constants of the Si—O bond calculated from the spectroscopic characteristics of these three compounds are 6.96×10^{-6}, 8.17×10^{-6}, and 9.18×10^{-6} cm^{-2} and the bond orders are 1.13, 1.33, and 1.49 respectively[165]. The main cause of the strengthening of the siloxane bond with increased electronegativity of the substituents at the silicon atoms is believed to be the enhancement of the $(p \rightarrow d)\pi$ interaction due to the increase of the positive charge at the silicon atom[142,149,158,160,164-166,175,185,220].

In the spectra of alkali metals tetramethyldisiloxane-1,3-diolates $(MOMe_2Si)_2O$ (M = Li, Na, or K) the ν_{as}(SiOM) bands are displaced towards higher wavenumbers relative to the ν_{as}(SiOH) band in the spectrum of $(HOMe_2Si)_2O$ (910 cm^{-1}): 980 cm^{-1} (for M = Li), 963 cm^{-1} (for M = Na), and 941 cm^{-1} (for M = K),[198] while the ν_{as}(SiOSi) bands undergo the opposite shift towards lower wavenumbers (Table 3). This shows that, together with the increase of the force constant of the SiO(M) bond on passing from M = H to M = K, the Si—O(Si) bonds are weakened[198].

The Si—O(C) bond in alkoxysilanes is much weaker than the Si—O(Si) bond in siloxanes. The ν_s(SiOC) wavenumber occurs in a shorter wavelength region (700—850 cm^{-1}) than the ν_s(SiOSi) wavenumber[143,148,149,158,162,173,185,192,221].

As a result, the splitting of the Si—O stretching vibration bands into ν_s and ν_{as} in the spectra of alkoxysilanes is much less marked (about 200 cm^{-1}) than for siloxanes (about 500 cm^{-1}). This is associated both with the breakdown of the symmetry in the electronic configuration of oxygen and with the change of the angle between its valence bonds[162].

On passing from hexamethyldisiloxane to methoxytrimethylsilane, the coefficient of dynamic interaction diminishes from 6.96×10^{-6} to 6.17×10^{-6} cm^{-2}.[158,165] The order of the siloxane bond in tetramethoxysilane is unity, because its force constant in this case virtually coincides with the calculated constant for a "single" Si—O bond[177]. The order of the siloxane bond in alkoxyalkylsilane molecules is also close to unity[143,155,165]. On passing from n = 1 to n = 4, there is a linear growth of the intensity of the ν_{as}(SiOC) band in the spectra of the compounds $Me_{4-n}Si(OEt)_n$.[221]

When the methyl groups in methoxytrimethylsilane are substituted successively by chlorine atoms, the ν_{as}(SiOC) band shifts towards shorter wavelengths (from 720 cm^{-1} for Me_3SiOMe to 810 cm^{-1} for Cl_3SiOMe),[158,222,223] while the force constant increases correspondingly from 6.17×10^6 cm^{-2} to 8.23×10^6 cm^{-2}.[158]

This change is proportional to the increase of the force constant on passing from $(Me_3Si)_2O$ to $(Cl_3Si)_2O$. The shift of the ν_{as}(SiOC) band towards higher wavenumbers† is observed also when hydrogen atoms are replaced by chlorine in tetraethoxysilane[227].

Thus, as in disiloxanes, highly electronegative substituents at the silicon atom in alkoxysilanes also cause an appreciable increase in the Si—O bond order. The effect of the $(p \rightarrow d)\pi$ interaction plays a decisive role in this phenomenon[142,149,153,158,160,162,165,224,225]. The occurrence of this effect in methylmethoxysilanes probably has a significant influence also on the nature of the Si—C bonds, namely it leads to their weakening and a decrease of their covalent character[179].

Apart from the corresponding ν_s(Si—O) and ν_{as}(Si—O) lines the tetramethoxysilane spectrum shows an intense polarised line at 640 cm^{-1}, probably due to the fully symmetrical stretching vibrations of the SiO_4 tetrahedron[199,200].

An intense absorption in the region of 1000—1200 cm^{-1}, due to the stretching vibrations of the C—O bonds, is observed in the spectra of all alkoxysilanes and alkoxysiloxanes[153,156,158,167,174,177-179,191,208,221-223,226-244]. This absorption region is extremely stable and depends little on the nature of the substituents at the silicon atoms[153,221,222,227,245].

In the infrared spectra of the silatranes $RSi(OCH_2CH_2)_3N$, containing a pentacoordinate silicon atom, the absorption band due to the C—O bond is in the region of 1100 cm^{-1}.[246] In the spectra of vinyloxy-, phenoxy-, and acetoxy-silanes, where the C—O bond order is enhanced, this band is located at 1180, 1250—1280, and 1200—1270 cm^{-1} respectively[249-251].

Comparison of the vibrational spectra of siloxanes, silanols, and siloxanols containing analogous substituents at the silicon atom shows that the siloxane bond in the SiO(H) group is only a little weaker than in the SiO(Si)

† A slight shift of the ν_{as}(Si—OC) band is observed also when a halogen atom, an alkyl group, a phenyl group, and an alkoxy- or acetoxy-group are introduced in the p-position of the trimethylphenoxysilane ring, which indicates some change in electron density at the silicon and oxygen atoms, but these shifts are too small to yield a correlation[247]. The position of the ν_{as}(Si—OC) band depends little on the nature and position of the substituent in the benzene ring of phenoxychlorosilanes[168,248].

group[158,163,171,172,175]. For example, the force constant of Si—O bond in Me_3SiOH and Me_3SiOD is $K^* = 6.92 \times 10^6$ cm^{-2}, while in $(Me_3Si)_2O$ it is $K^* = 6.96 \times 10^6$ cm^{-2}.[158,163] When silanols are associated via hydrogen bonding, the Si—O(H) bonds are strengthened still more[149,252,253]. Association of silanol molecules shifts also the split ν_{as}[SiO(H)] bands. Thus the infrared spectrum of triethylsilanol shows maxima at 841 and 828 cm^{-1}.[254]

Very intense ν(SiO) absorption bands are observed in the infrared spectra of alkali metals trimethylsilanolates in the range 900—1000 cm^{-1}.[57,158,198] As was to be expected, high force constants indicate an appreciable strengthening of the Si—O(M) bond (M = alkali metal) relative to the Si—O(H) [163,198] or Si—O(Si) [57] bonds. Thus the order of the siloxane bond in Me_3SiONa is 25% higher than in Me_3SiOH and 40% higher than in Me_3SiOMe.[163]

The absorption band characteristic of the SiO—M bond in the infrared spectra of the products of the interaction of $(EtO)_4Si$ with lithium, sodium, potassium, and magnesium, and other metal acetates in an aqueous alcoholic medium shifts towards a longer wavelength with increase of the atomic weight of the metal[255]. The assignment of the ν(SiO) and ν(MO) bond vibrations in the spectra of siloxane derivatives of the elements with organic substituents is usually difficult. So far only ν[SiO(M)] absorption bands have been identified (M is a Group III—VI or VIII element) and these occur as a rule in the range 800—1100 cm^{-1}.[231,256-290]

In the infrared spectra of organosilicon peroxides $R_3SiOOSiR_3$ (R = Me or Et) and also $Me_3SiOOCMe_3$ the bands in the range 750—770 cm^{-1} have been assigned to the symmetric vibrations of the Si—O bond and those at 146 and 175—185 cm^{-1} to the deformation vibrations of this bond[291-293].

2. NMR Spectra

Only the ^{29}Si isotope, which has a magnetic moment ($I = 1/2$), can be used for a direct investigation of the siloxane bond by NMR. Studies on the ^{29}Si chemical shifts, which require a special technique owing to the relatively low natural abundance of this isotope (4.7%) and the low sensitivity of ^{29}Si NMR spectroscopy[294], have so far been extremely limited in scope[295-307]. The chemical shifts in the ^{29}Si and ^{13}C NMR spectra of related silicon and carbon compounds vary in the opposite sequences. The $\delta(^{29}Si)$ chemical shifts vary within wide limits depending on the number of siloxane bonds and the nature of the substituents at the silicon atom. Selected data are presented in Table 4.

The shifts $\delta(^{29}Si)$ for silicon atoms forming a single bond with oxygen are positive (the region of the lowest fields relative to Me_4Si), increasing with increase of the electronegativity of the substituents linked to the oxygen atom. For trimethylsilyl esters of organic and inorganic acids, an almost linear relation is observed between $\delta(^{29}Si)$ and the pK_a of the corresponding acids[299,305]. For silicon linked to two and more oxygen atoms, the $\delta(^{29}Si)$ are negative—with the exception of the acyloxysilanes[303]. The absolute values of the chemical shifts increase steadily with increase of the number of siloxane bonds at the silicon atoms [$\delta(^{29}Si)$ = −113.0—109.0 for quartz].[303] Presumably the increase of the chemical shift in the above sequence is due to the overall transfer of π-electron density at the oxygen atoms to silicon via the $(p \rightarrow d)_\pi$ coupling mechanism[302]. For polydimethylsiloxanes and cyclodimethylsiloxanes D_n (n = 4—6), the $\delta(^{29}Si)$ are in the range between −23.0 and −19.7 p.p.m.; for D_3, the signal is displaced towards lower fields (−9.9 p.p.m.).[302] Thus the ^{29}Si NMR method, like other physical procedures, reveals a significant difference between the state of the silicon atoms forming part of the strained planar cyclotrisiloxane molecule and the silicon atoms in any other unstrained structures. For linear oligomers MD_nM (M = Me_3Si, D = Me_2SiO, n = 0–6), the $\delta(^{29}Si)$ corresponding to the silicon atoms in the M and D fragments change slightly on passing from n = 0 and 1 to n = 3 and then remain constant[302].

Table 4. The chemical shifts in the ^{29}Si NMR spectra of compounds containing the siloxane bond.

Data for the spin—spin interaction constants J between a hydrogen atom and a silicon atom, also involved in bonding with oxygen atoms are relatively few; $J(^{29}Si—H)$,[308-318] $J(^{29}Si—C—H)$,[312,319,320] and $J(^{29}Si—O—C—H)$ [312,319] have been determined. The attempt to trace a correlation between the $J(^{29}SiH)$ and the number of substituents X in the molecules of the $X_{4-n}SiH_n$ series in accordance with the equation

$$J(X_{4-n}SiH_n) = J(SiH_4) + (4-n)\,[J(SiH_3X) - J(SiH_4)]$$

was unsuccessful[311,313]. The greatest deviations from the linear relation were observed for compounds with the most electronegative substituents (X = OR, F, or Cl) like, incidentally, the deviations from the analogous $J(^{13}CH)$ relation for the corresponding carbon compounds[321-323]. The deviations have been explained by the appreciable polarisation of the carbon or silicon atom in these compounds[311,313].

The general equation, which is more suitable for the calculation of $J(^{29}SiH)$ and $J(^{13}CH)$ for compounds of the type HMXYZ (M = C or Si) takes into account the pair interactions of the substituents:

$$J(HMXYZ) = J(MH_4) + A(\alpha_x+\alpha_y+\alpha_z) + B(\alpha_x^2+\alpha_y^2+\alpha_z^2) + C(\alpha_x\alpha_y+\alpha_y\alpha_z+\alpha_z\alpha_x).$$

The maximum deviations of the calculated J from the experimental values do not exceed 6—9 Hz. For M = Si, we have A = 18.26 Hz eV^{-2}, B = 1.78 Hz eV^{-2}, and C = −2.98 Hz eV^{-2}. The parameters α, which constitute a measure of the effective electronegativities of the corresponding substituents, can be determined by means of the above equation from the J for the compounds MH_3X, MH_2X_2, etc. For silicon derivatives, α_X = −1.49 eV when X = OMe, and α_X = −1.76 eV when X = $OSiH_3$.[310] The values of α_X for the series of compounds with M = Si are always smaller than for the corresponding compounds with M = C. This may be due to the higher polarisability of the silicon atom in relation to carbon and at any rate provides no grounds for the interpretation of the experimental findings by taking into account the possibility of π bonding in the silicon compound.

Numerous compounds containing the siloxane bond have been investigated by ^{1}H NMR. Some of the results obtained have been described in other sections and have been examined in another review[324]. Many factors which are difficult to take into account and which influence the proton chemical shift hinder the analysis on the basis of ^{1}H NMR data of the changes in electron density at the silicon and oxygen atoms joined directly. Nevertheless ^{1}H NMR spectroscopy can be used successfully to refine ideas on the nature of the siloxane bond. Systematic studies by ^{1}H NMR on siloxanes[302,325-330], heterosiloxanes[274,276,279,280,331,332], and alkoxysilanes[312,319,333-337] confirm the significant role of π bonding in the structure of these molecules. It has been shown for oligomeric siloxanes of the type $Me_2(X)SiO[Si(Me)_2O]_nSi(X)Me_2$, where X = Me, H, Cl, or $ClCH_2$ and n = 0—6, that the influence of the substituent X can be transmitted through the chain via two or even three siloxane bonds[326]. Relations of the type

$$\tau_i(OCH_2) \text{ or } \tau_i(OCCH_3) = a + b\Sigma\sigma_i^*,$$

(σ^* are the inductive Taft constants for the substituents R), in which the parameter b diminishes with increase of the number n, have been found for the ethoxysilanes $R_{4-n}Si(OEt)_n$.[334] A similar tendency, characterising the decreased ability of the silicon atom to transmit the inductive effect of the substituents to the adjoining bonds with increase of the number of Si—O bonds in the molecule, has also been observed by kinetic methods[338] and by infrared spectroscopy[339] for compounds of different classes. Thus the phenomenon is probably general.

3. Electronic Spectra

Liquid polydimethylsiloxanes are transparent in the visible and near ultraviolet regions. In the range 246—270 nm a number of absorption bands have been observed in the ultraviolet spectra of linear and cyclic polydimethyl- or polymethylphenyl-siloxanes[340].

The attachment of an oxygen atom to a silicon atom linked to a vinyl[341], phenyl[342], or pentafluorophenyl[342] group does not have a significant influence on the absorption of these groups. The λ_{max} for the vinyl group in the ultraviolet spectra of linear and cyclic siloxanes are in the same range (178—180 nm) as for trialkylvinylsilanes and are independent of the number of oxygen atoms joined to the Si—CH=CH_2 group[341].

A bathochromic shift of the absorption band due to the phenyl group relative to the analogous carbon derivatives has been observed in the ultraviolet spectra of methylphenoxysilanes[225]. The position of the absorption maximum of the phenyl group in methylphenoxysilanes $Me_nSi(OPh)_{4-n}$ (n = 1—4) is independent of the number of phenoxy-groups[225,343,344].

The ultraviolet spectra of alkoxy- and trialkylsiloxybenzenes[225,343-345] or their complexes with tetracyanoethylene[345] and the results of quantum-chemical calculations[345] on the structure of phenoxy-derivatives of silicon indicate the occurrence of the $(p \rightarrow d)_\pi$ interaction between the oxygen and silicon atoms.

IV. PHYSICAL PROPERTIES AND MOLECULAR STRUCTURES OF POLYSILOXANES

Owing to the weak intermolecular interaction, the surface tension of polydiorganosiloxanes (particularly polydimethylsiloxanes) is much lower than that of the usual organic liquids with the same densities and boiling points[346,347]. In the series of linear polydimethylsiloxanes it increases from 15 dynes cm^{-1} for hexamethyldisiloxane to 22 dynes cm^{-1} for the polydimethylsiloxane oil with a viscosity of 10^5 cP.[139,347,348] The surface tensions of cyclodimethylsiloxanes D_n (n = 3—7) increase with increase of ring size from 17.3 to 18.3 dynes cm^{-1} at 25°C.[349] The surface tensions of mixtures of polyorganosiloxanes are additive[346].

A relatively high compressibility, which decreases with increase of molecular weight approaching an asymptotic value, is characteristic of the lower polydimethylsiloxanes[350]. With increase of pressure, the compressibility of polydimethylsiloxanes increases more slowly than that of hydrocarbons. At pressures of about 1000 kgf cm^{-2} the compressibility of polydimethylsiloxanes is higher than that of dodecane but at 40 000 kgf cm^{-2} it is lower[350]. At a pressure of 35 000 kgf cm^{-2} high-molecular-weight polydimethylsiloxane does not crystallise[351]. When the methyl groups in the polydimethylsiloxane are replaced by higher alkyl groups, the compressibility gradually falls with increase of the size of the substituent, increasing after substitution by hydrogen atoms[139].

The boiling points as well as the heats of evaporation of the linear polydimethylsiloxane $M_3D_nM_3$, where n = 1—6, and cyclodimethylsiloxanes D_m (m = 3—8) are lower than those of the alkanes having the same molecular weight[139,348]. With increase of n by unity, the heat of evaporation of polydimethylsiloxane increases by only 960 cal mole^{-1}.

With increase of molecular weight, the boiling points of polydimethylsiloxanes increase more slowly than in the case of n-alkanes.

The heat capacities of dimethylsiloxane polymers with a viscosity of 0.65—1000 cS (0.32 – 0.35 cal g^{-1} deg^{-1}) are somewhat lower than those of the corresponding hydrocarbons[139].

The viscosities of low-molecular-weight linear and cyclic polydiorganosiloxanes are somewhat lower than those of hydrocarbons with comparable molecular weights[348,349]. The activation energies for the viscous flow of siloxanes are also lower than for hydrocarbons. The activation energy amounts to 3.8 kcal mole^{-1} for

polydimethylsiloxanes[352], to 5.41 kcal mole^{-1} for siloxane polymers with tetramethylene units in the main chain[353],

$$Me_3SiO[Si(Me)_2(CH_2)_4Si(Me)_2O]_nSiMe_3-$$

and to 6—7 kcal mole^{-1} for saturated hydrocarbons[353]. The average length of the flow segment of high-molecular-weight polydimethylsiloxane corresponds to 7.2 siloxane units[352], while the length of the similar segment for long hydrocarbon chains corresponds to 20—25 units[354].

When the methyl groups in polydimethylsiloxane are replaced by the polar chloromethyl[355], phenyl[108], or chlorophenyl[356] groups, the activation energy for the viscous flow increases, amounting to 4.3 kcal mole^{-1} for polymethylpropylsiloxane, 7.9 kcal mole^{-1} for polymethyl-3,3,3-trifluoropropylsiloxane, and 11.9 kcal mole^{-1} for polymethylphenylsiloxane[357].

With increase of pressure, the viscosity of polydiorganosiloxanes increases more than that of hydrocarbons[358]. With increase of shear rate, the viscosity of polysiloxanes diminishes and at high shear rates the temperature variation of the viscosity becomes insignificant[359].

The low temperature coefficients of the viscosity of polydimethylsiloxanes[108,350,352,353,359] and the decrease of their viscosity with increase of shear rate show that siloxane molecules have a coiled conformation. Indeed the structure of the coiled siloxane molecule with the alkyl groups "sticking out" is responsible for the insignificant molecular interaction, as a result of which the viscosity is also relatively low. With increase of temperature, the molecules uncoil and the intermolecular interaction becomes more intense, which leads to an increased viscosity, partially compensating its usual decrease with temperature. As a result, the temperature coefficient of the viscosity of polymethylsiloxane is much lower than for hydrocarbons.

The coiling of the siloxane chain is probably the cause of the greater deviation of the heats of mixing of polydimethylsiloxanes with benzene from the theoretical values[360].

Indeed the siloxane chain in the polydimethylsiloxane film on the surface of water at 20°C is coiled into a helix containing six monomeric units per turn[347]. With increase of temperature, the length of the turn of the helix increases. Substitution of methyl groups by phenyl groups reduces the tendency of the siloxane chain to coil up[108,347]. This tendency is manifested to an even greater extent when methyl groups are replaced by ethyl groups[347].

The helical shape of the siloxane molecule (Fig. 2) has also been established by electron diffraction[361] and X-ray diffraction[21] methods. An X-ray diffraction study of extended polydimethylsiloxane raw rubber[21] and the finished rubber obtained from it[22] showed that there are six siloxane bonds in the monoclinic cell with the parameters (Å) $a = 13.0$, $b = 8.3$, $c = 7.75$, and $\beta = 120°$. In the polydimethylsiloxane molecule the *trans*-configuration is preferred to the *gauche*-configuration[362,363].

The coiling of the siloxane molecule into a helix has been explained[362,364] by the tendency of the weak Si—O dipoles to undergo intramolecular compensation as a result of which each Si—O dipole is associated with a dipole having the opposite orientation (O—Si). The intramolecular compensation of the individual dipoles has been confirmed by the insignificant change of the dipole moment with increase of the molecular weight of polydiorganosiloxanes.

Bearing in mind the polarity of the Si—O bond, many physical properties of polydiorganosiloxanes (the fact that they are hydrophobic, their compressibility, surface properties, etc.) can be explained solely in terms of the helical macromolecular structure forming a "coil" with "protruding" hydrocarbon groups[139,347,350,360]. However, one should not forget that the effect of the $(p \rightarrow d)_\pi$ bonding in the Si—O—Si system should also weaken the intermolecular interaction.

According to ^{1}H NMR data, segmental motion, which has been attributed to chain drift, takes place in polydimethylsiloxane even at very low temperatures (−136°C).[365-372] The segmental mobility of polydimethylsiloxane raw rubber is much higher than that of natural raw rubber[373]. Comparison of the dielectric properties of polydimethylsiloxane with ^{1}H NMR and X-ray diffraction data suggested[365] that motion of the second kind, preceding the onset of chain rotation, occurs in the crystalline polymer appreciably below the melting point of the crystals. The activation energy for the rotation of the polydimethylsiloxane chain calculated from the ^{1}H NMR data is 8 J mole^{-1}.[365]

The methyl groups in polydimethylsiloxanes rotate unusually readily about the Si—O bonds even at 196°C.[368-371]‡ Such rotation of the methyl groups is probably one cause of the increased distances between the macrochains and of the weakened intermolecular interaction in polydimethylsiloxanes[370]. On the other hand, the rotation of the phenyl groups at low temperatures is fully hindered and even at room temperature their rotation is somewhat retarded[371]. The consequences of the ease of rotation of the methyl groups is the high molar volume and the low density of the cohesion energy[139,350] of polydimethylsiloxane. The average molar volume of the Me_2SiO unit is 75.5 ml mole^{-1}.[374] The low density of the cohesion energy of polydimethylsiloxane, which is appreciably lower than for other polymers, is in fact responsible for the low boiling points, low heats of evaporation, low surface tensions, high compressibilities and low dielectric constants of liquid polydimethylsiloxanes and also for the low heats of fusion and moderate adhesion [energy] of high-molecular-weight polydimethylsiloxanes.

The weakness of the intermolecular forces is also manifested in a number of other properties of polydimethylsiloxanes. The lower ultrasonic velocities in polydimethylsiloxanes compared with the majority of organic liquids having similar densities[139,375,376] indicate a loose packing and a weak intermolecular interaction of the siloxane molecules.

Polydimethylsiloxane becomes rubber-like only when its molecular weight is fairly high (about 10^6) and when its molecular weight is 4×10^5 it flows in the cold although it remains solid. In contrast to other types of raw rubber, unfilled vulcanised polydimethylsiloxane specimens have a very low strength (2—5 kgf cm^{-2}).[377] A characteristic feature of siloxane raw rubbers is also an appreciably smaller decrease of strength with increase of temperature than for other elastomers[377].

Among all the known elastomers, polydimethylsiloxane raw rubber has the lowest glass point (−123°C).[378] The high rate of crystallisation of polydimethylsiloxane raw rubber, which crystallises rapidly at −54°C without supercooling, has also been explained by the weak intermolecular interactions and mobility of the siloxane molecules at low temperatures[379,380].

---

‡ The anomalously high mobility of the methyl groups, attributed to the "out-of-plane" deformations of the Si—O—Si bonds, has also been observed in an X-ray diffraction study of structures containing the planar six-membered siloxane ring[25,29].

The substitution of methyl groups in polydimethylsiloxane by vinyl groups does not affect the mobility of the polymeric chains[371]. The introduction of 3,3,3-trifluoropropyl groups has little effect on the molecular motion[371], but the replacement of the dimethylsiloxane units by methylphenylsiloxane[372] or diphenylsiloxane[371] units greatly hinders such motion. On the other hand, the substitution of methyl groups in polydimethylsiloxane by hydrogen atoms increases the mobility of the siloxane chains[372].

Thus the mobility of the polysiloxane molecules decreases in the sequence

$$[H(Me)SiO]_n > [Me_2SiO]_n > [CH_2{=}CH(Me)SiO]_n > [Pr(Me)SiO]_n > [Me(Ph)SiO]_n > [Ph_2SiO]_n.$$

The results of studies on the polysiloxanes by ^{1}H NMR agree well with data for the thermodynamic flexibility of polymeric siloxane molecules obtained in a study of solutions of the polymers by light scattering, osmometry, and viscometry[381-387]. Although the rotation of the polymeric chain about the Si—O bond is restricted to some extent (the unperturbed mean square distance between the ends of the polymeric molecule is much greater than the value calculated theoretically for free rotation), nevertheless the flexibility of the siloxane molecule is much greater than that of other polymeric chains[381-387].

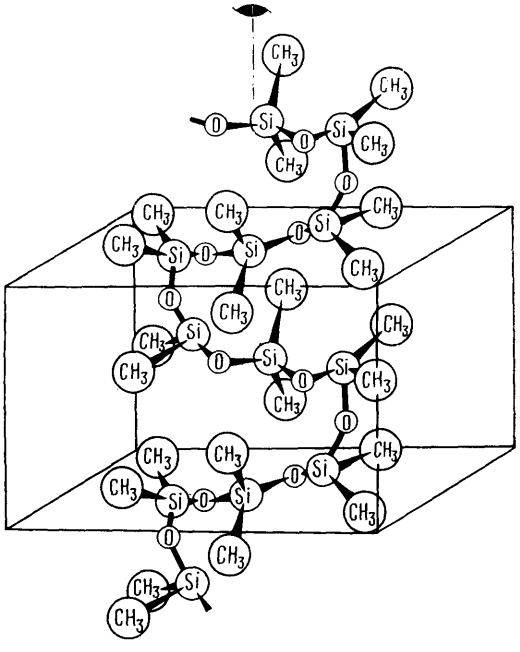

Figure 2. The crystal structure of polydimethylsiloxane[21].

The results of a calorimetric study of the mixing of polydimethylsiloxane with various solvents also led to the conclusion that the molecules of this polymer are very flexible[360,363,364]. This is likewise indicated by the appreciable atomic polarisations P_a and the anomalously short dielectric relaxation times of disiloxanes[99] and cyclosiloxanes[388]. The similarity of the P_a for hexamethyldisiloxane and D_3 [388] demonstrates a significantly lower flexibility of the Si—O bonds in D_3. On the other hand, judging from the value of P_a, the flexibility of the siloxane bonds in the relatively unstrained D_4 ring is much greater and close to their flexibility in linear polydimethylsiloxanes[99].

The great flexibility of the SiOSi angles is responsible for the possibility of the existence of many cyclosiloxanes in the form of several conformers equally probably on energy grounds, which are readily interconverted[28,389,390]. The results of calculations of the overlap integrals of the d and p orbitals for various configurations of siloxane rings agree well with this hypothesis[391].

Two crystalline modifications (orthorhombic and triclinic) and three modifications have been isolated for A$_3$ § and A$_4$ respectively[390].

According to spectroscopic data, only one conformation is possible for dimethylcyclosiloxanes with an odd number of siloxane units ($n > 3$), in which all the silicon atoms are in the same plane and all the oxygen atoms are in another plane parallel to it[392]. When n is even, two (or more) conformations of cyclic siloxanes are possible. The folded D_4 ring can exist in the form of three conformers of different symmetries. One of these is present in the gas and liquid phases[393] and two others in the crystalline state. In the low-temperature modification of D_4, four oxygen atoms and four silicon atoms are located in two separate planes disposed at an angle of 30°.[61] Certain octaorganosilsesquioxanes also exist in the form of two modifications[389].

X-Ray diffraction studies on silicates demonstrate the existence of different equilibrium conformations also in cyclic silicate anions, which is due to the high flexibility of the siloxane chain[61].

Spectroscopic studies and thermodynamic calculations have led to the conclusion that rotation about the Si—O bond in siloxanes is virtually free (the potential barrier does not exceed several tens of kcal mole^{-1}).[9,382,393] Nevertheless rotation about the siloxane bond is apparently always restricted to some extent in all compounds and the energy barrier depends appreciably on the nature of the substituents at the silicon atoms.

The flexibility of the polysiloxane molecule decreases following the substitution of the methyl groups at the silicon atoms by propyl[394], trifluoropropyl[384], or phenyl[384] groups. In the presence of two phenyl groups at the same silicon atom, the flexibility of the siloxane polymer is significantly smaller than that of the methylphenylsiloxane polymer with the same content of phenyl groups.

Thus the thermodynamic flexibility of polymethylphenylsiloxane corresponds to that of the dimethylsiloxane—diphenylsiloxane copolymer containing 25—30 mole % of diphenylsiloxane units[385,386].

The flexibility of the siloxane molecule decreases particularly appreciably on passing from a linear to a "ladder" structure; although the rotational mobilities of the phenyl group in the linear methylphenylsiloxane and the ladder phenylsiloxane $[PhSiO_{1.5}]_n$ polymers are approximately the same, the rigidity of the latter is appreciably greater[395-402]. The number of units (50) in the segment of the ladder phenylsiloxane is ten times greater than in the segment of the methylphenylsiloxane polymer[89,395,401].

The thermodynamic flexibility of polydimethylsiloxane is increased by the introduction of phenylene groups into the siloxane chain[402].

Certain problems of the effect of the nature of the siloxane bond on the properties of oxygen compounds of

---

§ A = $C_6H_5(CH_3)SiO$.

silicon, which were not considered here owing to the limited space available, are dealt with in monographs and reviews[56,403-405].

Nitroacetylenes

K.B.Rall', A.I.Vil'davskaya, and A.A.Petrov

The review examines the methods of synthesis, structures, infrared, ^{1}H NMR, and ultraviolet spectra, and physical and chemical properties of a new class of compounds—nitroacetylenes.
The bibliography includes 83 references.

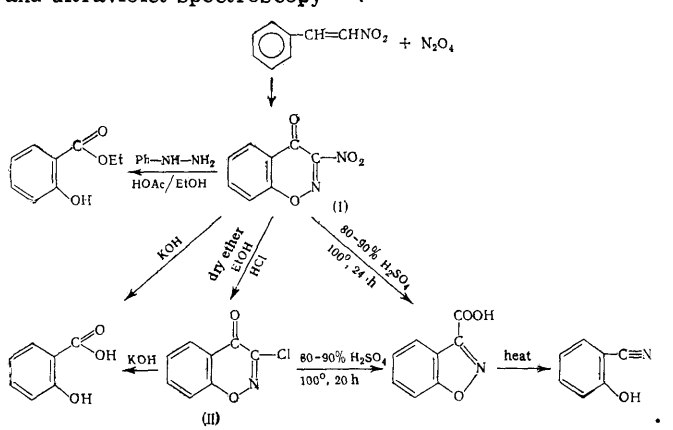
I. INTRODUCTION

Nitroacetylenes constitute a new, still little investigated class of organic compounds which is interesting in view of a combination of the energy-deficient triple bond and the electron-accepting nitro-group. α-Acetylenic nitro-compounds, where the conjugation of the π-electron system with the electrophilic nitro-group leads to extensive possibilities of their employment in organic synthesis, have attracted particular attention.

Whereas extensive data were available as early as 1950 on the methods of synthesis and a wide variety of reactions of ethylenic nitro-compounds, systematic study of acetylenic nitro-compounds did not begin essentially until 1969. This paper surveys the results of studies published until the beginning of 1973.

The first mention of nitroacetylenes dates back to 1903[1] when Wieland obtained by the reaction of nitrogen oxides with cinnamaldehyde a low yield of a yellow crystalline substance having the overall formula $C_8H_4N_2O_4$. On the basis of elemental analysis and the determination of molecular weight, Wieland erroneously attributed to this compound the structure of *p*-nitrophenylnitroacetylene. However, the author did not rule out other possible structures.

p-Nitrophenylnitroacetylene was probably obtained for the first time much later by Novikov et al.[2] by nitrating β-nitrostyrene with nitrogen tetroxide, but attempts to reproduce this reaction were unsuccessful: instead of nitroacetylene, the product isolated was (probably the same as in Wieland's reaction[1]) 1-nitro-2-azachromone (3-nitro-4*H*-1,2-benzoxazin-4-one)[3] (I), whose structure has been demonstrated chemically and by ^{1}H NMR, infrared, and ultraviolet spectroscopy[3-5]:



Later heavy dark-red oils were obtained by the dehydrohalogenation with the aid of amines of 1-bromo-1-nitroalkenes[6] and 1-bromo-1-nitro-2-phenylethylene[7]; the structure of α-nitroacetylenes was attributed to the oils.

Thus, on treatment with diethylamine, 1-bromo-1-nitro-2-phenylethylene was converted into an oil which exploded on distillation, reacted instantly with Baeyer's reagent, and did not decolorise bromine water. The molecular weight and the nitrogen content corresponded to the formula of phenylnitroacetylene. However, these experiments could not be reproduced either[3].

It was not until 1969 that Jäger and Viehe described for the first time a reliable method for the synthesis of t-butylnitroacetylene and its homologues[8]. These investigations were subsequently extended[3].

Among non-conjugated nitroacetylenes, only the hexanitro-derivative has so far been obtained[9].

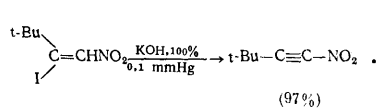
1,1,1,6,6,6-Hexanitrohex-3-yne[9], 1-nitroalk-1-ene-3-ynes[10-13], and a number of nitrobutenyne derivatives of the elements (silicon and germanium)[14] were also obtained recently. Among functional derivatives of nitroacetylenes, only glycols are known[15,16].

II. THE PREPARATION OF NITROACETYLENES

The simplest α-nitroacetylenes were obtained (by analogy with nitroalkenes) by the dehydrohalogenation of halogenonitroalkenes formed as a result of the addition of NO_2X (X = Cl[17-20] or X = I[21]) to acetylenic compounds.

Nitroiodination proved to be most suitable for this purpose. Difficulties arose in the second reaction stage (dehydroiodination), for which various reagents were employed[3]: tertiary amines, sodium acetate in dimethylformamide (DMF), silver oxide in ether, and potassium t-butoxide; the reaction was followed by the intensity of the band due to the triple bond in the infrared spectra of the final product. Potassium hydroxide proved to be the most effective dehydrohalogenating agent.

Thus, by passing 2-iodo-3,3-dimethyl-1-nitrobut-1-ene (III) through a tube with alkali heated to 110-120°C, t-butylnitroacetylene (IV) was obtained (yield 96-97%, purity of the product according to gas-liquid chromatographic data 98-100%):



Nitroacetylenes with isopropyl (V, yield 74%) and n-propyl (VI, yield 28%) groups were obtained similarly. n-Butyl-α-nitroacetylene was isolated from a mixture with the starting material. The formation of phenylnitroacetylene was demonstrated spectroscopically ($\nu C{\equiv}C$ = 2240 cm^{-1}); its low volatility made its further purification difficult[3].

Stereoisomeric mixtures of the initial iodonitroalkenes were usually dehydroiodinated. The use of pure *cis*- and *trans*-isomers did not increase the yield.

1,1,1,6,6,6-Hexanitrohex-3-yne (VII) was obtained in 72% yield by the double decomposition reaction between 1,4-dibromobut-2-yne and the silver salt of trinitromethane[9]:

$$BrCH_2{-}C{\equiv}C{-}CH_2Br + 2AgC(NO_2)_3 \rightarrow \underset{\text{(VII)}}{(NO_2)_3C{-}CH_2{-}C{\equiv}C{-}CH_2{-}C(NO_2)_3} + 2AgBr\ .$$

4-Trialkylsilyl(germyl)-1-nitrobut-1-ene-3-ynes are formed when products of the addition of nitrogen tetroxide and iodine to the corresponding vinylacetylene derivatives of the elements are dehydroiodinated by lead acetate[12-14]. The hydrolytic cleavage of the C–E bond (where E is an element) in butenyne derivatives of the elements leads to 1-nitrobut-1-en-3-yne[11] (VIII):

$$CH_2{=}CH{-}C{\equiv}C{-}Si\,(Ge)\,R_3 \xrightarrow{N_2O_4,I_2} NO_2CH_2{-}CHI{-}C{\equiv}C{-}Si\,(Ge)\,R_3 \rightarrow$$
$$\rightarrow NO_2CH{=}CH{-}C{\equiv}C{-}Si\,(Ge)\,R_3 \xrightarrow{8M\ HClO_4} \underset{\text{(VIII)}}{NO_2CH{=}CH{-}C{\equiv}CH}\ .$$

Acetylenic nitroglycols have been obtained by the condensation of acetylenic aldehydes with nitroalcohols[15,16]:

$$R{-}C{\equiv}C{-}\overset{\overset{O}{\parallel}}{C}{<}_{H} + NO_2CH_2{-}CH_2OH \rightarrow R{-}C{\equiv}C{-}CH(OH){-}CHNO_2{-}CH_2OH\ .$$

III. STRUCTURE AND PHYSICAL PROPERTIES

The study of the physical properties of α-nitroacetylenes led to definite conclusions concerning the conjugation of the highly electrophilic nitro-group with the C≡C bond.

α-Nitroacetylenes are pale yellowish-green liquids with a strong lachrymatory smell resembling that of lower nitro-olefins.

Table 1. Ultraviolet spectra of α-nitroalkylacetylenes and their ethylenic analogues[3].

No.	Compound	$\lambda_1(\pi{-}\pi^*)$ nm	lg ε_1	$\lambda_2(\pi{-}\pi^*)$ nm	lg ε_2	Solvent
1	t-Bu–C≡CNO_2	238	3.90	290	1.5	n-Hexane
2	i-Pr–C≡CNO_2	239	3.84	290	2.2	Cyclohexane
3	n-Pr–C≡CNO_2	235	3.88	290	2.7	n-Hexane
4	t-Bu–CH=$CHNO_2$ (*trans*)	228	4.02	310–320	2.8	n-Heptane
5	i-Pr–CH=$CHNO_2$ (*trans*)	227	3.70	—	—	n-Heptane
6	Me–CH=$CHNO_2$ (*trans*)	225	4.01	295–310	2.9	n-Heptane

The ultraviolet spectra of nitroacetylenes resemble those of *trans*-nitro-olefins. The short-wavelength ultraviolet band of nitroacetylenes undergoes a bathochromic shift relative to nitro-olefins and the extinction coefficient is reduced, which is characteristic of acetylenic systems in relation to their ethylenic analogues[22].

It has been suggested that the absorption at 290 nm (shoulder) is associated with a weak $\pi{-}\pi^*$ transition in the nitro-group of the $C{\equiv}CNO_2$ fragment[22,23].

The asymmetric stretching vibration band of the conjugated nitro-group in the spectra of α-ethylenic nitro-compounds is in the range 1517–1530 cm^{-1} and the band due to the symmetrical stretching vibrations is in the range ~ 1340–1350 cm^{-1}. The difference between the asymmetric and symmetric stretching vibration wavenumbers, which is an important characteristic of nitro-olefins, thus amounts to $\Delta\nu \simeq 180$ cm^{-1}. The substitution of a hydrogen atom at the β-carbon atom in nitroalkenes by a bromine atom leads to an increase of the asymmetric vibration wavenumber, a decrease of the symmetric vibration wavenumber, and an appreciable increase of the difference between them ($\Delta\nu = 218 \pm 7$ cm^{-1})[24,25].

Table 2. Characteristic wavenumbers in the infrared spectra of nitroacetylenes[3].

The symmetric and asymmetric stretching vibration bands of the nitro-group in the infrared spectra of nitroacetylenes are very intense, the latter being displaced towards shorter wavelengths (1510–1515 cm^{-1}) compared with nitro-olefins and halogenonitro-olefins[3,24,25]; $\Delta\nu \simeq$ 165 cm^{-1}. The conjugation of the nitro-group with the multiple bond apparently has the greatest effect on the intensity of the symmetric stretching vibration band of the nitro-group: in the spectra of nitroacetylenes this band is much more intense than the band of the asymmetric vibrations, while in the spectra of nitro-olefins the intensities of these bands are approximately equal (in the spectra of aliphatic nitroalkanes the symmetrical stretching vibration bands of the nitro-group are of moderate intensity)[26].

The infrared spectra of α-nitroacetylenes show a splitting of the absorption band of the triple bond (Table 2), which is characteristic of disubstituted acetylenes (for

example, of trifluoropropyne and perfluorodimethylacetylene[3,27]; see also Table 3). The additional bands are accounted for by mechanical interactions; they are also regarded as overtones or combination bands. However, the reason for the splitting of the absorption band of the triple bond still remains controversial[22,27,28].

Comparison of the infrared spectra of halogenoacetylenes containing t-butyl and trimethylsilyl groups showed that in the latter case $\nu C{\equiv}C$ is reduced by 106–90 cm^{-1}.

In relation to t-butylnitroacetylene, the stretching vibration band of the C≡C bond in trimethylsilylnitroacetylene ($\nu C{\equiv}C$ = 2165 cm^{-1}) undergoes a steady bathochromic shift by about 10 cm^{-1} and its intensity falls, which may be a consequence of the π–d interaction in the $\rangle Si-C{\equiv}C$ group.

The 730 cm^{-1} band, which can be assigned to the C–N stretching vibrations, is constant in the spectra of all nitroacetylenes[3]. The information about the ^1H NMR spectra of nitroalkenes is extremely limited[29,30].

The ^1H NMR spectra of t-butyl-, isopropyl-, and n-propyl-nitroacetylenes proved to be very simple, as expected, and contained only signals corresponding to the protons of the alkyl groups.

Table 4.

Compound	δ, p.p.m.	Δδ, p.p.m.	References
t-Bu–CH=CH_2	1.00	—	31
t-Bu–CH=$CHNO_2$	1.15	0.15	3
t-Bu–C≡CH	1.20	—	31
t-Bu–C≡CNO_2	1.34	0.14	3
t-Bu–C≡C–COOEt	1.32	0.12	3
t-Bu–C≡C–CN	1.32	0.12	3

The shifts of the proton signals of the Me_3C group in the α-position relative to the multiple bond under the influence of various electrophilic substituents (all the compounds were used as solutions in CCl_4), which are listed in Table 4, illustrate the influence of the nitro-group.

IV. CHEMICAL PROPERTIES

α-Nitroacetylenes are extremely unstable. They change on storage or heating much faster than the lower nitroalkenes[32,33], 1-nitrobuta-1,3-diene[34], and also fluoroacetylenes[35].

Under the conditions of gas–liquid chromatography (t = 107–119°C), t-butylnitroacetylene (IV) did not change, isopropylnitroacetylene (V) decomposed to the extent of 30–50%, and n-propylnitroacetylene (VI) decomposed to the extent of 80–90%.

It was found by gas–liquid chromatography and infrared spectroscopy that the half-life at room temperature is 2–3 days for compound (IV), 10 h for unpurified specimens of compound (V), and 1–2 h for compound (VI).

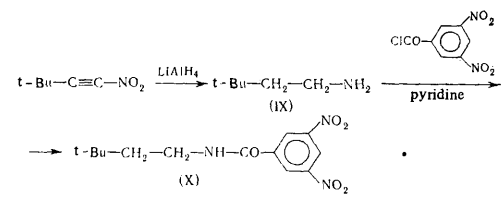
The thermal stability of compound (IV) has been studied in greatest detail. It has been shown that in 20% solution in toluene (IV) decomposes to the extent of 50% at 80–85°C in 30 min, the decomposition being almost complete after 10 h. Compound (IV) distills at 55°C/15 mmHg with partial decomposition. It melts at about –3°C.[3]

In dilute solutions in non-polar solvents (IV) is stable at 110–120°C. The type of transformation of nitroacetylenes on storage and heating has not been established.

The inductive effect of the nitro-group is very strong and comparable to the inductive effect of fluorine[36]. Therefore the oligomerisation of t-butylnitroacetylene and t-butylfluoroacetylene should presumably proceed similarly. Trifluoromethylacetylene is converted on storage into substituted benzene isomers and certain tetrameric products[37,38]. However, after standing for one month at room temperature, the products of the oligomerisation of compound (IV) contained, according to gas–liquid chromatographic data, more than 20 compounds in addition to the starting material, from which only one adduct (yield 1%) corresponding to the formula $C_{12}H_{18}N_4O_8$ (two molecules of t-butylnitroacetylene combined with an N_2O_4 molecule) could be isolated.

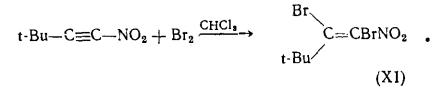
1. Hydrogenation

To demonstrate the structure of compound (IV), it was subjected to catalytic hydrogenation over platinum oxide, which yielded a mixture of the expected amine (IX) and, as shown by ^1H NMR, a dimeric compound corresponding to a symmetrically disubstituted hydrazine[3]. The reduction of compound (IV) by lithium tetrahydroaluminate in ether yielded the amine (IX), which was isolated in the form of the 3,5-dinitrobenzoyl derivative (X)[39]:



2. Bromination

The reaction of t-butylnitroacetylene with bromine in chloroform proceeds with slight evolution of heat and leads to 1,2-dibromo-1-nitroethylene in almost quantitative yield:



(XI)

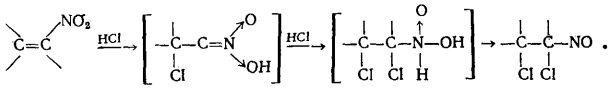
The ^1H NMR spectrum of this compound contains a singlet with δ = 1.5 p.p.m. corresponding to the protons of the t-butyl group, which is displaced to a lower field compared with the initial nitroacetylene[3].

The mechanism of this seemingly elementary reaction requires special consideration. The reaction of bromine with olefins and acetylenes is regarded as electrophilic addition[40]. However, the acceleration of the bromination of substituted tolanes (regardless of the nature of the substituents)[41] suggested that the first stage in these non-catalysed reactions involves the addition of the nucleophilic agent[42]. The situation in the case of nitro-olefins and nitroacetylenes is still more complicated owing to the possibility of acid catalysis[43] by the traces of HBr and HCl present in chloroform and responsible for the nucleophilic attack by bromine.

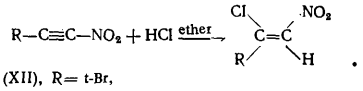
The lack of experimental data precludes the prediction of the stereochemical sequence of both the catalysed and non-catalysed additions to nitro-compounds containing multiple bonds.

3. Hydrochlorination

The interaction of nitro-olefins with anhydrous hydrogen chloride is known to involve a complex sequence of reactions[44] leading to nitro-olefins without an α-hydrogen atom, i.e. 1,2-dichloro-1-nitroisoalkanes[45]:

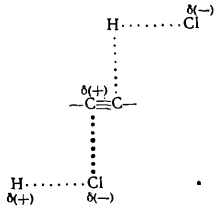


The hydrochlorination of nitroacetylenes (IV) and (V) even in the presence of an excess of HCl proceeds in a different way—with quantitative formation of *cis*-2-chloro-nitro-olefins[3]:



(XII), R= t-Bu,
(XIII), R= i-Pr.

Thus the 1,4-addition expected by analogy with nitro-olefins did not occur with nitroacetylenes. The mechanism of the addition of hydrogen chloride to nitro-acetylenes is probably different from that in the case of nitro-olefins. The *trans*-addition of hydrogen chloride to the triple bond is usually regarded as an electrophilic addition reaction, which is kinetically of third order (a reaction of the type AdE3). The transition state can be represented as follows[3]:



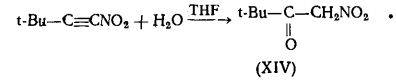
The addition of HCl to activated acetylenic systems, for example to acetylenedicarboxylates, is known to begin with nucleophilic attack[46-48] and to end with rapid protonation. Since nitroacetylenes should be still more electrophilic systems, in this case addition probably proceeds via the same mechanism.

4. Hydration

Water causes the polymerisation of lower nitro-olefins[44,49,50]. By selecting conditions eliminating polymerisation, it was possible to achieve the addition of water to the double bond with subsequent cleavage of the addition product into a carbonyl compound and a nitroalkane. Under alkaline conditions, this reaction is reversible, resulting in the formation of an aldol. The reaction is of the retroaldol type[51,52].

When nitroethylene was treated with a cold dilute sulphuric acid solution, the intermediate nitroalcohol was isolated[53].

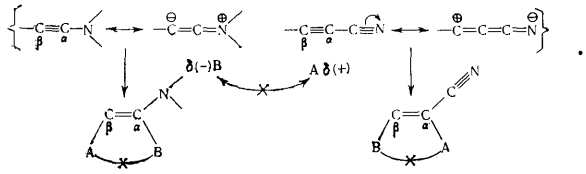
t-Butylnitroacetylene is hydrated much more readily than nitro-olefins and is smoothly converted under mild conditions (tetrahydrofuran, 20°C, 24 h) into 3,3-dimethyl-1-nitrobutan-2-one (XIV)[3]:



(XIV)

5. Nucleophilic Addition

By analogy with nitroalkenes, it was to be expected that nitroacetylenes would tend to undergo nucleophilic addition reactions. Substituted acetylenes conjugated with nucleophilic and electrophilic groups differ in the order in which nucleophiles add to them:



The similarity of the electrophilic properties of the nitro-group and fluorine can be extended also to the chemical behaviour of nitro- and fluoro-acetylenes[54]. The closeness of the electronegativities of the nitro-group and fluorine follows from a comparison of the chemical shifts in the ^{1}H NMR spectra of the M–X systems associated with the electronegativity of the substituent X (Table 5) and also from a study[37] in which the electronegativities of the organic functional groups were calculated from the chemical shifts and the coupling constants of 5-endo-substituted norbornenes.

Table 5. The chemical shifts of the protons in Me–X (solvent CCl_4).[3]

X	NO_2	F	Cl	$Me_2\overset{\oplus}{N}$	CN	H
δ p.p.m.	4.72	4.67	3.46	3.33*	2.32	0.13**

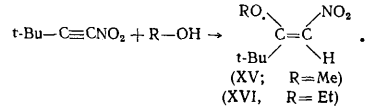
*In CF_3COOH.
**Gas.

The addition of alcohols and amines. α-Nitroacetylenes exhibit a marked electrophilic reactivity The reactions of t-butylnitroacetylene (IV), which is the most stable of the α-nitroacetylenes investigated, with nucleophilic agents proceed without catalysts at temperatures between −30° and 20°C. The electrophilic properties of the triple bond in this compound are much more pronounced than those of the triple bond in the heterosubstituted acetylenes of analogous structure[55] and the double bond in their ethylene analogues[56-58].

It has been shown that, under mild conditions (room temperature, 24 h, no catalyst) in methanol and ethanol, compound (IV) is smoothly converted into the corresponding *cis*-nitrovinyl ethers (yield 95%).

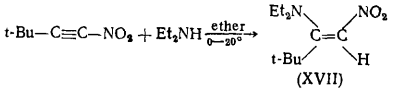
The enhanced intensity of the infrared bands of the double bond (1615, 1618 cm^{-1}) confirms the occurrence of

unhindered conjugation of the double bond with the nitro-group, which is possible only in the *cis*-form of the nitro-vinyl ether[3]:



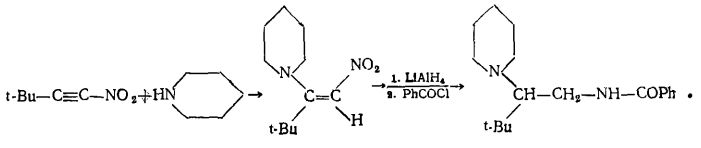
(XV; R=Me)
(XVI, R=Et)

It is known that ammonia and primary and secondary aliphatic amines readily add to nitro-olefins[49] and also cause their polymerisation[50]. The reaction of compound (IV) with aliphatic amines is exothermic and reaches completion with inflammation. However, the reaction with diethylamine in ethereal solution under controlled conditions gives rise to high yields of the expected adducts[3]:



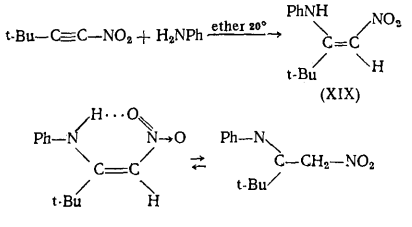
(XVII)

The product of the addition of piperidine to compound (IV) was not isolated in a pure form, but was identified as the benzoyl derivative of its hydrogenation product (XVIII):



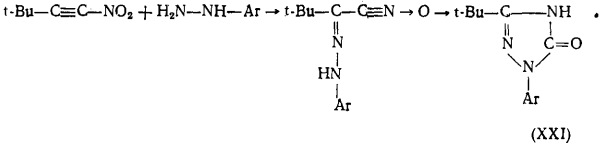
(XVIII)

The reaction with aniline is accompanied by the formation of the normal *trans*-addition product (XXa), which is in equilibrium with its tautomer (XXb)[3]:



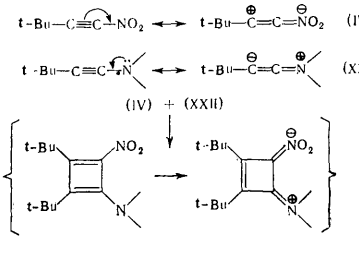
(XXa) (XXb)

Viehe and coworkers[59] showed recently that the reaction of compound (IV) with arylhydrazines results in the formation of 1,3-disubstituted 1,2,4-triazolin-5-ones (XXI):



(XXI)

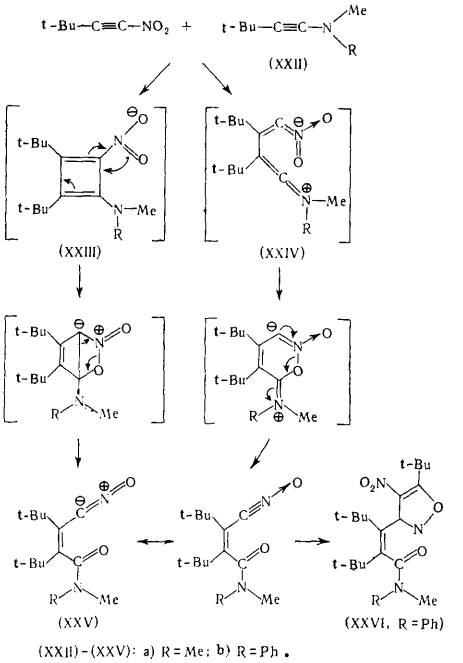
The high and opposed polarisations of t-butylnitro- and amino-acetylenes suggested the possibility of a direct combination of these compounds into the cyclobutadiene system via the mechanism:



The attempts at the synthesis of such systems on the basis of α-nitroenamines, undertaken by Breslow et al.,[60] were unsuccessful.

On the other hand, according to infrared spectroscopic data, the reaction of compound (IV) with (XXIIa) proceeds quantitatively with formation of compound (XXVa) (Scheme 1), which, however, could be isolated in only 29% yield. Compound (XXVc) was isolated similarly (in 21% yield); in this case there is in addition a competing reaction involving the 1,3-dipolar addition of compound (IV) to (XXVb), leading to the formation of an isoxazole derivative (XXVI)[3].

Scheme 1 (Ref.3)

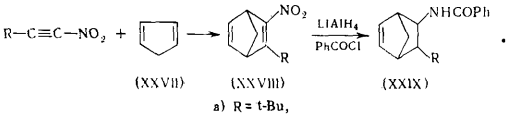


(XXII)-(XXV): a) R=Me; b) R=Ph.

6. Diels–Alder Reactions

The rate of Diels–Alder reactions is known to increase following the introduction of electron-donating substituents into the dienes and of electron-accepting substituents into the dienophiles (the "Alder rule")[61,62]. On this basis, it was possible to postulate that, when the t-butyl group in compound (IV) does not give rise to steric hindrance, the 1,4-cycloaddition of compound (IV) will be facilitated in the case of electron-rich alicyclic dienes.

However, among a large class of dienes [2,3-dimethylbuta-1,3-diene, cyclopentadiene(CPD), cyclohexa-1,3-diene, cyclohepta-1,3-diene, cyclo-octatetraene, tetracyclone, furan, 2,5-dimethylfuran, and diphenylisobenzofuran] only CPD (XXVII), one of the most reactive dienes[61,62], readily reacts with (IV) and also with (V) and (VI) to form the corresponding adducts (XXVIII). The rate of formation of adducts exceeds the rate of dimerisation of CPD.



(XXVII) (XXVIII) (XXIX)

a) R = t-Bu,
b) R = n-Pr,
c) R = i-Pr.

The adducts (XXVIII) and the CPD dimer were separated by column chromatography on silica gel. Compound (XXVIIIa) was obtained in high yield in the form of a yellow liquid, which was oxidised on standing in air. Similar compounds (XXVIII, b and c) proved to be even more sensitive to air. Despite the difficulty of its purification, the product (XXVIIIb) was identified by gas–liquid chromatography and ^{1}H NMR.[3]

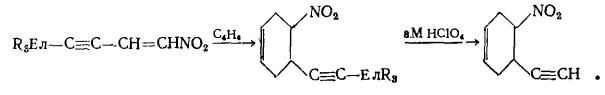
Compared with other dienophiles, nitro-olefins are known to be most reactive in relation to CPD[63,64]. However, in order to obtain information about the relative reactivity of the $-C\equiv C-NO_2$ system, it was necessary to compare, for example, compound (IV) with other acetylenic systems, the pronounced dienophilic properties of which are already known. Since the steric conditions must be the same, compounds (XXX) and (XXXI) were specially synthesised. It was shown[3] that the ratio of the rate constants for the reactions of CPD with (IV) and other members of the series

t-Bu—C≡C—NO_2 (IV); t-Bu—C≡C—COOEt (XXX); t-Bu—C≡C—CN (XXXI); t-Bu—CH=CHNO_2 (XXXII)

exceeds 10^4. The comparison of the reactivities of compound (IV) and the chloride of t-butylacetylenecarboxylic acid would probably be more instructive[3], since the determination of the rate constants for the Diels–Alder reaction of CPD (k) with *trans*-XCH≡CHX[65] and t-BuC≡CY indicates the similarity of the influence of the COCl and NO_2 substituents.

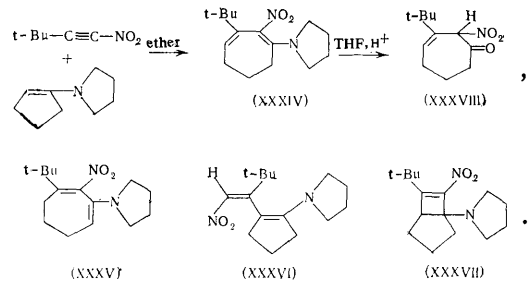
trans-X-CH=CHX					t-BuC≡CY	
Substituent X	COCl	COPh	CN	$COOMe_3$	NO_2	CN
k	6700	18	1,1	1.0	$>10^4$	1.0

4-Trialkylsilyl- and 4-trialkylgermyl-1-nitrobut-1-en-3-ynes (XXXIII) have also been used as dienophiles[11]. However, the condensation of these compounds with alka-1,3-dienes (buta-1,3-diene, CPD) involves only the olefinic group and the adducts formed are readily cleaved in an acid medium at the Si–C or Ge–C bond:



(XXXIII)

The reaction of compound (IV) with *N*-cyclopent-1-enylpyrrolidine is unusual[66]. By analogy with the reactions of enamines with nitro-olefins[67–76] and olefins containing other electrophilic substituents[67,68,77–80] and also with acetylenic systems[66,80–83], the formation of four products might have been expected in this case: a derivative of cycloheptadiene (XXXIV), its tautomer (XXXV), the Stork alkylation product (XXXVI), and a cyclobutene derivative (XXXVII):



However, the ^{1}H NMR spectrum of the resulting adduct showed the presence of the cycloheptadiene structure (XXXIV) alone. The structure of the adduct (XXXIV) was also confirmed by mild acid hydrolysis leading to the α-nitroketone (XXXVIII).

The addition of enamines to nitroacetylenes proceeds in a complex manner in a number of stages, which is confirmed by the difference between the infrared spectrum recorded immediately after the completion of the reaction and that of the product obtained after recrystallisation. An unstable product (XXXVII) is probably formed initially (the mode of addition is determined by the steric hindrance due to the *cis*-t-butyl group), and rearranges to compound (XXXIV) isolated finally. The reaction of nitroacetylenes with cyclic enamines constitutes a convenient synthetic method for the expansion of the ring by two carbon atoms[66].

The data quoted in this review demonstrate the absence of a complete analogy in the behaviour of ethylenic and acetylenic nitro-compounds. The study of nitroacetylenes has only just begun and presumably in the immediate future new interesting evidence will be obtained for the mutual influence of the atoms in compounds of this class and for the relation between their electronic structure and reactivity; also a wide variety of their synthetic possibilities will be discovered.

Chemical Separation of Uranium Isotopes

B.N.Laskorin, A.M.Babenko, E.A.Filippov, and A.F.Trubnikov

A brief survey is made of published work on various methods (electrochemical, chemical, extraction, and ion exchange) for separating the uranium isotopes 235 and 238. Attention is paid mainly to ion exchange using different states of oxidation of uranium in aqueous and organic solutions. The bibliography contains 70 references.

CONTENTS

I. Introduction 381
II. Brief historical survey of chemical methods for separating uranium isotopes 381
III. Separation of uranium isotopes by ion exchange 382

I. INTRODUCTION

The separation of isotopes is based on differences in their physical and chemical properties. Since such differences are small, and diminish with increase in the atomic number of the element, the separation of isotopic mixtures is a very difficult task. Differences in the properties of isotopic varieties are obviously due to the difference in their masses.

Only physical methods—gas diffusion and centrifuging—have been developed for the industrial separation of uranium isotopes[1]. In several countries research has now been started with the aim of developing chemical methods for separating the isotopes of uranium.

II. BRIEF HISTORICAL SURVEY OF CHEMICAL METHODS FOR SEPARATING URANIUM ISOTOPES

During recent years several researches have been published in the foreign periodical press on chemical methods for separating uranium isotopes. Such methods can be classified as (i) electrochemical, (ii) chemical exchange in aqueous solution, (iii) extraction, and (iv) ion exchange. Work on the chemical separation of uranium isotopes was begun and continued during the Second World War by Brewer and Madorsky[2] using countercurrent electrical migration, which involved a difference in the kinetic properties of the ions. Their results were published towards the end of the 1940s.[3,4] In 1953 these workers reported briefly[5] that they had used ionic mobilities to enrich uranium with the light isotope from 0.72% to 2.8%.

A process for fractionating uranium isotopes, patented by Woodward[6] in 1957, was based on isotopic exchange between uranium(IV) and uranium(VI) ions in an acidic aqueous solution. In such solutions the quadrivalent ions become enriched with uranium-238, and the sexivalent ions with uranium-235. When two or more isotopes are present in solution, those of highest atomic weight tend to concentrate in the lower state of oxidation, and the others in the higher state. Woodward conducted isotopic exchange in aqueous hydrochloric acid containing 2% each of uranium(IV) and uranium(VI) (pH 1.5–1.9 for 1 h); after the exchange uranium(IV) was precipitated as the dioxalate, which after several intermediate operations was converted into the tetrachloride and used in the preceding stage of the process, while the filtrate was transformed into uranyl chloride, which was submitted to the following stage of

enrichment. This process of chemical enrichment is difficult to adapt to multistage working, since it involves many intermediate operations (precipitation, filtration, ignition).

Twitchell, Williams, and Clark[7] concentrated uranium-235 by chemical exchange combined with counterflow electrical migration: uranium(IV) and uranium(VI) moved in opposite directions on the latter principle, whose application had given good results in concentrating potassium, chlorine, and copper isotopes. It was shown that uranium(IV) could be transported from cathode to anode by the electrolyte flowing countercurrent to the uranium(VI) migrating to the cathode. After the cell had operated for 1400 h the uranium-235 content had increased from 0.7111% to 0.7171%. However, it was admitted[7] that this method involved many technical difficulties.

A 1958 patent[8] described a chemical method of isotopic fractionation of uranium based on extraction. This started from the suggestion[9] that the achievement of efficient separation entailed that the chemical state of an isotope in the organic phase should differ from its chemical state in the aqueous phase. This requirement was satisfied by a system in which a metal ion in the aqueous phase was in equilibrium with a chelate or other complex of the metal in an organic solvent immiscible with the aqueous solution. It was established that isotopic exchange took place when an acidic aqueous solution of uranium(IV) was in contact with a water-immiscible organic solvent in which was dissolved a water-insoluble chelate complex of uranium(IV), as a result of which uranium-235 was concentrated in the aqueous solution, and uranium-238 was distributed as the chelate complex into the organic solvent. Cupferron was recommended to form a chelate complex of uranium(IV): uranium cupferronate is insoluble in water, but soluble in many organic solvents. The most effective solvent was chloroform, which ensured rapid phase separation. Since isotopic fractionation requires many stages, countercurrent contact between organic and aqueous phases, as is usual in continuous countercurrent extraction, was tested and proposed. During the isotopic fractionation the uranium transferable by the organic phases passes successively from stage to stage in one direction, while the uranium-containing aqueous solution passes in the opposite direction. An aqueous solution enriched with uranium-235 was withdrawn at one end of the apparatus, and an organic solution enriched with uranium-238 at the opposite end.

It was proposed also to accomplish isotopic fractionation by countercurrent contact between solutions passing through a vertical packed column. A glass helix-filled 9-m column of diameter 1 cm was used, the aqueous solution flowed upwards, and the organic solution downwards. Clewett et al.[8] considered that the exchange reaction

$$^{238}UCl_{4\,aq} + {}^{235}U[C_6H_5N(NO)O]_4 \rightleftarrows {}^{235}UCl_{4\,aq} + {}^{238}U[C_6H_5N(NO)O]_4 \quad (1)$$

accomplished in this way might lead to a single-stage separation factor of 1.002.

A brief communication by Spedding and Powell[10] also indicated the possibility of achieving this separation factor. Uranium isotopes were separated in a uranyl solution together with a cation-exchange resin. The uranium band was eluted through a column filled with the copper form of Dowex 50 × 8 sulphonated cation-exchange resin (50–100 mesh) by means of 0.005 M aqueous diammonium magnesium ethylenediaminetetra-acetate. The isotopic exchange is described by the equation

$$^{238}UO^{2+}_{2\,aq} + {}^{235}UO_2R \rightleftarrows {}^{238}UO_2R + {}^{235}UO^{2+}_{2\,aq}, \quad (2)$$

where UO_2R and UO_2^{2+} denote uranyl ions in the exchanger and in the aqueous solution respectively. With a band 28 cm long traversing a distance of 90 cm isotopic changes of 4–5% were reported[10] at both ends of the band, enrichment with uranium-235 being observed in the leading portion of the band.

The results obtained by the above workers on the extraction and ion-exchange separation of uranium isotopes led them to make extremely optimistic forecasts of large-scale enrichment. However, it was reported later[11] that attempts to use the extraction method for separating uranium isotopes had been unsuccessful, since cupferron oxidised rapidly, and the resulting oxidation products prevented normal functioning of the countercurrent column.

Finally in 1969 Rutenberg and Drury[12] refuted the above results. They used new equipment to make accurate measurements of isotopic changes in the system formed by a chloroform solution of uranium cupferronate and an aqueous hydrochloric-acid solution in the uranium band of the above experiment by Spedding and Powell. The single-stage separation factor was found to be far lower than the published value (1.002) in both extraction and ion-exchange systems, respectively 1.00007 ± 0.00001 and 1.00006 ± 0.00005. Calculations showed that the above processes for separating uranium isotopes were unacceptable both technically and economically.

The separation of uranium isotopes by chemical methods has been widely investigated in Japan, where attention has been concentrated on the use of ion-exchange resins. A joint paper on this problem was presented by Kakihana et al.[13] at the Third International Conference on the Peaceful Uses of Atomic Energy held in Geneva in 1964. A brief account was given of the theory of the separation of uranium isotopes by isotopic exchange, together with experimental results for an exchanger in a solution of uranium in aqueous hydrochloric acid.

In March 1970 the Japanese newspaper *Asahi Shimbun*[14] published a report on the Annual Symposium of Japanese Nuclear Scientists containing experimental results on the enrichment of uranium by chemical methods. An ion-exchange column of height 1 m and cross-section 1 cm^2 was used with Amberlite IRA-120B, a sulphonated cation-exchange resin. A single passage of an acid sulphate solution of uranium increased the uranium-235 content by 1.017%; fractions of the enriched uranium solution were withdrawn first from the column. On the basis of these results it is planned to set up a new experimental plant 10–30 times as powerful. Several advantages of the new process are emphasised: (*a*) the technical equipment is considerably simpler; (*b*) use of the aggressive and toxic uranium hexafluoride is avoided; and (*c*) Japanese experts estimate that the capital cost of constructing an industrial plant to produce 1000 tonnes of 3% uranium-235 annually will be less than 10% of the cost of constructing a gas-diffusion plant.

A news item[15] referred to Japanese reports of similar work in France.

III. SEPARATION OF URANIUM ISOTOPES BY ION EXCHANGE

The first experiments on the separation of stable isotopes by ion exchange were made more than thirty years ago by Taylor and Urey[16,17]. Since then many investigations have been made on the separation of lithium, boron, sodium, calcium, and nitrogen isotopes on a sulphonated cation-exchange resin in an aqueous electrolyte

solution. However, low separation factors were obtained except in work[18] on the ion-exchange separation of the isotopes of nitrogen. Experiments on uranium isotopes[19] gave separation factors <1.001. Kakihana et al.[20] explained such results by the almost identical states of the isotopes in the external aqueous solution and in the sulphonated cation-exchange resin: systems in which the isotopes are in different chemical states in the phases must be chosen to obtain higher values.

Japanese work on the chemical separation of uranium isotopes has been based on Kakihana and Kurisu's theory of separation by isotopic exchange between uranium(IV) and uranium(VI). These workers made detailed theoretical investigations on the factors on which the efficiency of separation of the isotopes depends[21,22], and deduced the main equation for the separation factors.

Theoretical and experimental investigations published hitherto are surveyed below.

1. ISOTOPIC EXCHANGE IN VARIOUS CHEMICAL SYSTEMS

(*a*) General Principles

Isotopic exchange can be effected by the transfer of isotopic atoms and of electrons. An example of the former is exchange in complex compounds. The first studies on this problem were made by Grinberg and Filinov[23,24]. Numerous subsequent investigations have established that the rate of isotopic exchange in complexes is greatly influenced by such factors as the nature of the ligand[25,26], the sign of the ionic charges[27], the coordination number[28,29], etc.

Isotopic exchange by the transfer of electrons takes place in redox systems. Reactions of this type involve essentially not the exchange of isotopes but a change in their valency states. For example, the exchange of iron between $FeCl_2$ and $*FeCl_3$

$$Fe^{3+} + {}^{*}Fe^{3+} \rightleftarrows Fe^{3+} + {}^{*}Fe^{2+} \qquad (3)$$

can be regarded as the result of two processes leading to electron transfer from Fe^{2+} to $*Fe^{3+}$:

$$Fe^{3+} \rightleftarrows Fe^{3+} + \bar{e} \quad \text{(conversion of unlabelled } Fe^{II} \text{ into } Fe^{III}) \qquad (4)$$

$$*Fe^{3+} + \bar{e} \rightleftarrows {}^{*}Fe^{2+} \quad \text{(conversion of labelled } Fe^{III} \text{ into } Fe^{II}) \ . \qquad (5)$$

In reality the two stages are not separate, and the electron passes directly from one ion to the other[30]. Such exchange reactions, observed in reversible redox systems, occur at different rates. The rate of exchange is strongly dependent on concentration, acidity, additions of foreign ions, etc.[30]

Investigations on isotopic exchange between uranium(IV) and uranium(VI) in various systems is of great value in connection with the problem of separating uranium isotopes by chemical methods.

(*b*) Hydrochloric-acid Solutions

Detailed investigations of the kinetics and the mechanism of isotopic exchange between uranium(IV) and uranium(VI) were made by Rona[31], who studied the reaction

$$U^{IV} + {}^{*}U^{VI} \rightleftarrows {}^{*}U^{IV} + U^{VI} \ , \qquad (6)$$

where the asterisk denotes the radioactive uranium-233 isotope. The experiments showed that the order of the rate of exchange with respect to the hydrogen-ion concentration was ~3. Rona showed also that the rate of exchange was independent of the addition of neutral salts, the concentration of chloride ions, and illumination. According to Woodward[6], however, light accelerates the reaction considerably (both workers used the light from a tungsten lamp).

In order to understand the mechanism of the above exchange reactions it is important to know the ionic forms of uranium(IV) and uranium(VI). There is weighty evidence that uranium(VI) is present as UO_2^{2+} in moderate acid concentrations[32]. Quadrivalent uranium is assumed to exist as the equilibrium mixture

$$U^{4+} \rightleftarrows U(OH)^{3+} \rightleftarrows U(OH)_2^{2+} \rightleftarrows U(OH)_3^{+} \ . \qquad (7)$$

Rona suggests[31] that, in the uranium(IV–VI) exchange system, the last form $U(OH)_3^+$ will react readily with the uranyl ion to form a complex containing an oxygen bridge between the two ions:

$$U(OH)_3^+ + UO_2^{2+} \underset{\longleftarrow}{\overset{2H_2O}{\rightleftarrows}} Z^{3+} + 2H^+ \ , \qquad (8)$$

where Z^{3+} is a hypothetical intermediate ion, which may have the structure

$$\left[\begin{array}{c} O{=}U{-}O{-}U{-}OH \\ \quad | \quad\quad | \\ \quad OH \quad\ OH \end{array}\right]^{3+} \ .$$

This leads to the possible reaction mechanism of isotopic exchange

$$^{235}U(OH)_3^+ + {}^{238}UO_2^{2+} \rightleftarrows {}^{235}UO_2^{2+} + {}^{238}U(OH)_3^+ \qquad (9)$$

in which Z^{3+} is the intermediate activated complex taking part in the electron transfer

$$\left[\begin{array}{c} HO{-}{}^{235}U^{IV}{-}OH \\ \quad | \\ \quad OH \end{array}\right]^{+} + \left[\begin{array}{c} {}^{238}U^{VI}{=}O \\ \quad \| \\ \quad O \end{array}\right]^{2+} \rightleftarrows \left[\begin{array}{c} O{=}{}^{235}U{-}O{-}{}^{238}U{-}OH \\ \quad\quad | \quad\quad\quad | \\ \quad\quad OH \quad\quad OH \end{array}\right]^{3+} \rightleftarrows$$

$$\rightleftarrows \left[\begin{array}{c} {}^{235}U^{VI}{=}O \\ \quad \| \\ \quad O \end{array}\right]^{2+} + \left[\begin{array}{c} HO{-}{}^{238}U^{IV}{-}OH \\ \quad\quad | \\ \quad\quad OH \end{array}\right]^{+} \ . \qquad (10)$$

This isotopic exchange appears to be an exchange of ligands between uranium(IV) and uranium(VI) ions.

The effect of the concentration of hydrochloric acid on the rate of exchange was studied also by Kakihana et al.[33,34], who investigated the homogeneous exchange between natural uranium(IV) and impoverished uranium(VI) in various acid concentrations at 30, 50, and 70°C.

(*c*) Sulphuric-acid Solutions

Studies of the exchange between uranium(IV) and uranium(VI) in aqueous sulphuric acid were described by Betts[35] in 1948. This exchange occurs essentially between the sulphate complexes, in whose inner sphere sulphate ions are assumed to be accompanied by water molecules. The presence of the latter in the inner sphere, and especially of hydroxide ions, both in hydrochloric-acid and in sulphuric-acid solutions as assumed by Grinberg and Bykhovskii[36], facilitates the transition from U^{4+} to UO_2^{2+}.

Baechmann and Lieser[37] found that, in solutions containing sulphate ions in the dark, the rate of electron exchange between uranium(IV) and uranium(VI) is proportional to their concentrations and inversely proportional to the cube of the hydrogen-ion concentration. The reaction velocity is governed by the stage of disproportionation

of uranium(V), present in small quantities in equilibrium with uranium(IV) and uranium(VI). This conclusion was based on Betts' finding[35] that the rate of electron transfer between the latter valency states in sulphate solutions was far greater, and on Heal and Thomas's discovery[38] of higher uranium(V) concentrations, under illumination. The mechanism of electron transfer is represented by

$$U^{4+} + {}^{*}U^{6+} \rightleftarrows U^{5+} + {}^{*}U^{5+} \quad . \tag{11}$$

Subsequent disproportionation of U^{5+} yields $*U^{4+}$:

$$U^{5+} + {}^{*}U^{5+} \rightleftarrows U^{6+} + {}^{*}U^{4+} \quad . \tag{12}$$

Electron exchange between uranium(IV) and uranium(VI) has been investigated also in several other solutions—oxalate[36], perchlorate[39], and aqueous organic[40-43].

(*d*) Cation-exchange Resin in Hydrochloric-acid Solution

Isotopic exchange in a system comprising a cation-exchange resin in a hydrochloric-acid solution was studied by Shimokawa and Nishio[44]. Granules of Dowex 50 × 4 containing ions of impoverished uranium(IV) were placed in a solution of natural uranium(VI). At the start of the reaction a certain quantity of uranium(VI) ions passed into the resin from the solution, but all the uranium(IV) ions remained in the resin throughout the reaction with aqueous acid concentrations up to 1 *N*. Change in the relative content of the uranium(IV) isotope in the resin was followed mass-spectrometrically. Analysis of the system revealed two possible modes of exchange (on the basis that the reaction was bimolecular[45-47]).

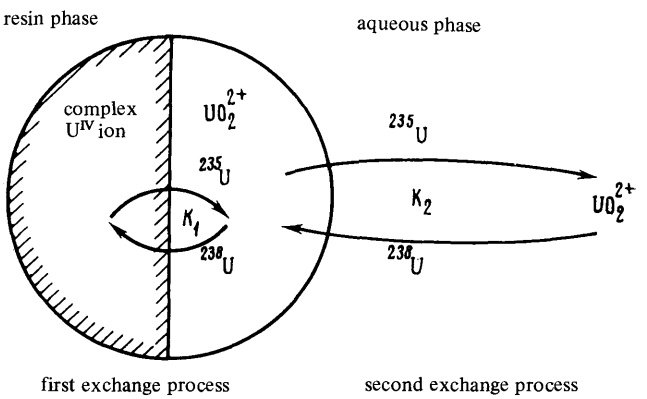

Figure 1. Diagram of two exchange processes.

1. First exchange process. With isotopic exchange between uranium(IV) and uranium(VI) occurring in the resin phase

$$^{235}U^{IV}_{res} + {}^{238}U^{VI}_{res} \overset{K_1}{\rightleftarrows} {}^{238}U^{IV}_{res} + {}^{235}U^{VI}_{res} \tag{13}$$

the isotopic exchange equilibrium constant $K_1 = 1.0007$ (i.e. $1/K_1 = 0.9993$). The fact that K_1 exceeds unity implies that sexivalent uranium is enriched with the 235 isotope when chemical equilibrium is established, and the quadrivalent state with uranium-238.

2. Second exchange process. Isotopic exchange between sexivalent uranium in the resin and sexivalent uranium in solution

$$^{235}U^{VI}_{res} + {}^{238}U^{VI}_{soln} \overset{K_2}{\rightleftarrows} {}^{238}U^{VI}_{res} + {}^{235}U^{VI}_{soln} \tag{14}$$

gives an equilibrium constant $K_2 = 1$. Reaction (13) is more rapid than reaction (14).

Thus isotopic exchange in a system comprising a solution and a cation-exchange resin is represented by the scheme

$$^{235}U^{IV}_{res} + {}^{238}U^{VI}_{soln} \overset{K}{\rightleftarrows} {}^{238}U^{IV}_{res} + {}^{235}U^{VI}_{soln} \quad , \tag{15}$$

whence the equilibrium constant $K = K_1K_2 = 1 + \epsilon$ or

$$K = \frac{^{238}U^{IV}_{res}}{^{235}U^{IV}_{res}} : \frac{^{238}U^{VI}_{soln}}{^{235}U^{VI}_{soln}} . \tag{16}$$

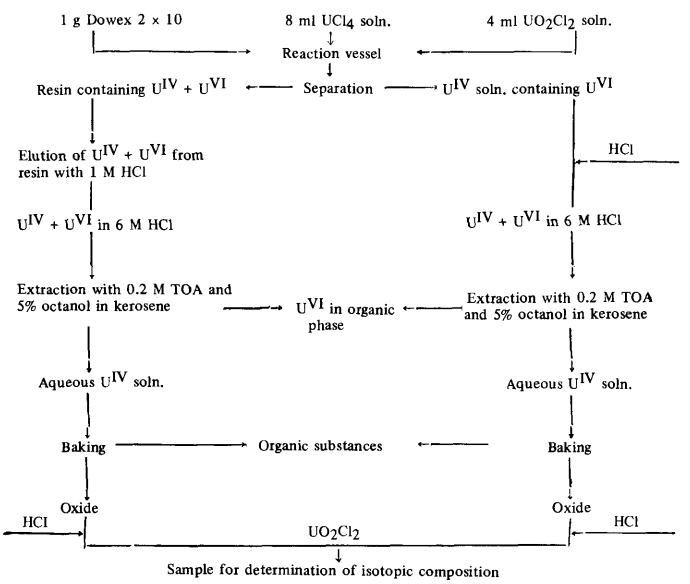
Fig. 1 illustrates diagrammatically the two exchange processes. It follows from Eqn. (15) that uranium-235 is concentrated in the uranium(VI) solution. The rate constant of isotopic exchange was greater in the resin phase than in solution by $\sim 10^3$–10^4, which indicates that the cation-exchange resin catalyses the isotopic exchange of uranium(IV) and uranium(VI).

(*e*) Anion-exchange Resin in Hydrochloric-acid Solution

The first results for the isotopic exchange of uranium(IV) and uranium(VI) in an anion-exchange resin in aqueous hydrochloric acid were presented at the Third International Conference on the Peaceful Uses of Atomic Energy[13]. The experimental procedure (Scheme 1) involved treating samples of Dowex 2 × 8 with 8 M hydrochloric acid containing natural uranium(IV) and impoverished uranium(VI); after ion-exchange equilibrium had been established, the change in the relative content of uranium-235 was monitored at intervals, both for uranium(IV) in the resin and for uranium(VI) in the solution.

Scheme 1.

Study of electron exchange between uranium(IV) and uranium(VI) in a hydrochloric-acid solution impregnating an anion-exchange resin.



The experimental results showed that quadrivalent uranium is enriched with the 235 isotope, and sexivalent uranium with the 238 isotope. Isotopic exchange can occur in three possible ways:

$$^{238}\overline{U}^{IV} + {}^{235}\overline{U}^{VI} \overset{k_1}{\rightleftarrows} {}^{238}\overline{U}^{VI} + {}^{235}\overline{U}^{IV} \quad , \tag{17}$$

$$^{238}U^{IV} + {}^{235}\overline{U}^{IV} \overset{k_2}{\rightleftarrows} {}^{235}U^{IV} + {}^{238}\overline{U}^{IV} \quad , \tag{18}$$

$$^{235}\overline{U}^{VI} + {}^{238}U^{IV} \overset{k_3}{\rightleftarrows} {}^{235}U^{IV} + {}^{238}\overline{U}^{VI} \quad , \tag{19}$$

$$\frac{d[^{235}\overline{U}^{IV}]}{dt} = k_1\{[^{235}\overline{U}^{VI}][^{238}\overline{U}^{IV}] - [^{235}\overline{U}^{IV}][^{238}\overline{U}^{VI}]\} + k_2\{[^{238}U^{IV}][^{238}\overline{U}^{IV}] - [^{235}\overline{U}^{IV}][^{238}U^{IV}]\} \quad , \tag{20}$$

$$\frac{d[^{235}U^{IV}]}{dt} = k_2\{[^{235}\overline{U}^{IV}][^{238}U^{IV}] - [^{235}U^{IV}][^{238}\overline{U}^{IV}]\} + k_3\{[^{235}\overline{U}^{VI}][^{238}U^{IV}] - [^{235}\overline{U}^{VI}][^{235}U^{IV}]\} \quad , \tag{21}$$

$$\frac{d[^{235}\overline{X}^{VI}]}{dt} = k_1\{[^{235}\overline{U}^{IV}][^{238}\overline{U}^{VI}] - [^{235}\overline{U}^{VI}][^{238}\overline{U}^{IV}]\} + k_3\{[^{235}U^{IV}][^{238}\overline{U}^{VI}] - [^{235}\overline{U}^{VI}][^{238}U^{IV}]\} \quad , \tag{22}$$

where [U] and $[\overline{U}]$ represent uranium concentrations in solution and in the resin phase respectively. For simplicity we introduce the notation

$$[^{235}U^{IV}] + [^{238}U^{IV}] = a \qquad [^{235}U^{IV}] = af^{IV}$$
$$[^{235}\overline{U}^{IV}] + [^{238}\overline{U}^{IV}] = \overline{a} \qquad [^{235}\overline{U}^{IV}] = \overline{a}\overline{f}^{IV}$$
$$[^{235}\overline{U}^{VI}] + [^{238}\overline{U}^{VI}] = \overline{b} \qquad [^{235}\overline{U}^{VI}] = \overline{b}\overline{f}^{VI}$$

for the uranium concentrations and the isotopic fractions. During exchange a, $\overline{a}$, and $\overline{b}$ remain constant, while f^{IV}, $\overline{f}^{IV}$, and $\overline{f}^{VI}$ change. Formulae (20)–(22) become

$$\frac{1}{a\overline{b}} \cdot \frac{d\overline{f}^{IV}}{dt} = \frac{1}{a}\{\overline{f}^{VI} - \overline{f}^{IV}\}k_1 + \frac{1}{\overline{b}}\{f^{IV} - \overline{f}^{IV}\}k_2 \quad , \tag{20'}$$

$$\frac{1}{\overline{a}\overline{b}} \cdot \frac{df^{IV}}{dt} = \frac{1}{\overline{a}}\{\overline{f}^{VI} - f^{IV}\}k_3 + \frac{1}{\overline{b}}\{\overline{f}^{IV} - f^{IV}\}k_2 \quad , \tag{21'}$$

$$\frac{1}{a\overline{a}} \cdot \frac{d\overline{f}^{VI}}{dt} = \frac{1}{a}\{\overline{f}^{IV} - \overline{f}^{VI}\}k_1 + \frac{1}{\overline{a}}\{f^{IV} - \overline{f}^{VI}\}k_3 \quad . \tag{22'}$$

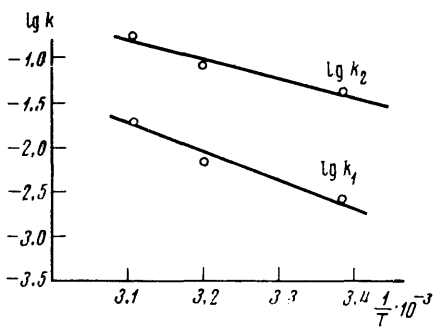


Figure 2. Temperature dependence of reaction rate constant.

The rate constants k_1, k_2, and k_3 can be calculated from Eqns. (20)–(22) by analysing the isotopic composition of samples f^{IV}, $\overline{f}^{IV}$, and $\overline{f}^{VI}$. The apparent reaction rate constant at 30°C was found to be $k_1 = 7.5 \times 10^{-4}$ M^{-1} min^{-1}, which was small in comparison with the value of 3500 [$?3.5 \times 10^{-3}$] M^{-1} min^{-1} in 8 M hydrochloric acid at this temperature. A possible explanation is that the resin phase contains less hydrochloric acid to accelerate this electron exchange[34] than does the acid solution, and that the exchangeable ions do not diffuse so easily in the resin as in the aqueous acid, owing to the effect of functional groups in the anion exchanger.

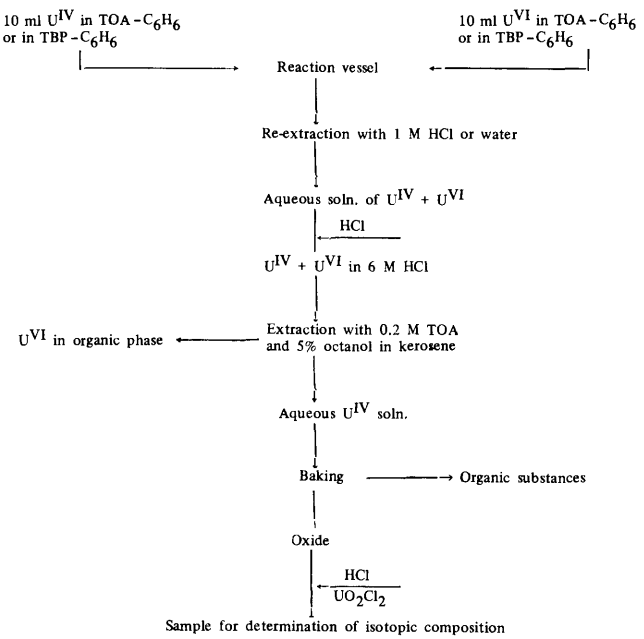
The temperature dependence of the logarithm of the rate constant is plotted in Fig. 2. The activation energy of the electron exchange between uranium(IV) and uranium(VI) in the anion-exchange resin was 22.9 kcal $mole^{-1}$. The closeness of this value to 24–25 kcal $mole^{-1}$ indicates similarity between the activated complexes of this electron exchange in the resin and in 6–10 M hydrochloric acid.

(*f*) Benzene Solution of Trioctylamine (TOA) and Tributyl Phosphate (TBP)

According to Gonda et al. benzene solutions of trioctylamine and tributyl phosphate are extremely promising media for electron exchange between uranium(IV) and uranium(VI).[48] The experimental procedure (Scheme 2) involves mixing equal volumes of benzene solutions of trioctylamine containing respectively natural uranium(IV) and impoverished uranium(VI); a similar operation was made with benzene solutions of tributyl phosphate. In both cases uranium(IV) is enriched with the heavier isotope, and uranium(VI) with the lighter isotope.

Scheme 2.

Study of U^{IV}–U^{VI} electron exchange in TOA–C_6H_6 and TBP–C_6H_6 systems.



The extent of exchange F was determined by means of the equation

$$F = \{f^{IV} - f_0^{IV}\} \cdot \{f_\infty^{IV} - f_0^{IV}\}^{-1} \quad , \tag{23}$$

where f_0^{IV}, f^{IV}, and f_∞^{IV} are the contents of the 235 isotope in uranium(IV) initially, after time t, and finally. The relation between F, the rate of exchange R, and the rate constant k is

$$\ln(1-F) = \ln\{f^{IV} - f_\infty^{IV}\} \cdot \{f_0^{IV} - f_\infty^{IV}\}^{-1} = -R\{[U^{IV}] + [U^{VI}]\} \cdot \{[U^{VI}] \cdot [U^{IV}]\}^{-1}t = -k\{[U^{IV}] + [U^{VI}]\}^{-1}t \quad . \tag{24}$$

The dependence of $\ln(1-F)$ on time is represented by a straight line, from whose slope we can determine R and k.

Rate of exchange increases with decrease in the concentration of trioctylamine or tributyl phosphate in benzene. The explanation is that the complexes of these solutes that are capable of exchange diffuse more easily into dilute than into concentrated solutions. In particular, true rate constants can be determined by measuring exchange in dilute solutions of trioctylamine and tributyl phosphate. The mechanism of exchange when the complex ions are extracted into a benzene solution of trioctylamine is similar to that in an anion-exchange resin.

2. SEPARATION OF URANIUM ISOTOPES IN AN EXCHANGER–SOLUTION SYSTEM CONTAINING URANIUM(IV) AND URANIUM(VI)

(*a*) Separation Factor of Uranium Isotopes

Since isotopic effects in chemical systems met in practice usually balance out, it proved impossible for a long time to obtain for uranium isotopes any appreciable separation factors defining the efficiency of particular systems. Experimental studies made in Japan with the aim of obtaining high separation factors for these isotopes were based on theoretical investigations by Kakihana and Kurisu[21,22,49,50], Ishida[51,52], and Shimokawa[44,53].

The separation factor for uranium isotopes can in general be expressed by the formula

$$^{235}_{238}S=\frac{[^{235}\overline{U}]}{[^{238}\overline{U}]}\cdot\frac{[^{238}U]}{[^{235}U]}=\frac{\Sigma[^{238}U^{IV}]+\Sigma[^{238}U^{VI}]}{\Sigma[^{235}U^{IV}]+\Sigma[^{235}U^{VI}]}\cdot\frac{\Sigma[^{235}\overline{U}^{IV}]+\Sigma[^{235}\overline{U}^{VI}]}{\Sigma[^{238}\overline{U}^{IV}]+\Sigma[^{238}\overline{U}^{VI}]}, \quad (25)$$

where $^{238}U/^{235}U$ is the molar ratio of the isotopes in solution, and $^{235}\overline{U}/^{238}\overline{U}$ the corresponding ratio in the ion exchanger. For a system containing only U^{4+} ions the separation factor is

$$S_1=\frac{\Sigma[^{238}U^{IV}]}{\Sigma[^{235}U^{IV}]}\cdot\frac{\Sigma[^{235}\overline{U}^{IV}]}{\Sigma[^{238}\overline{U}^{IV}]}\ . \quad (26)$$

When only uranyl ions UO_2^{2+} are present, we have

$$S_2=\frac{\Sigma[^{238}U^{VI}]}{\Sigma[^{235}U^{VI}]}\cdot\frac{\Sigma[^{235}\overline{U}^{VI}]}{\Sigma[^{238}\overline{U}^{VI}]}\ . \quad (27)$$

The electron exchange in solution can be written

$$^{235}U^{VI}+{}^{238}U^{IV}\rightleftarrows{}^{238}U^{VI}+{}^{235}U^{IV} \quad (28)$$

and that in the ion-exchange resin is represented by

$$^{235}\overline{U}^{VI}+{}^{238}\overline{U}^{IV}\rightleftarrows{}^{238}\overline{U}^{VI}+{}^{235}\overline{U}^{IV}\ . \quad (29)$$

The equilibrium constants of these electron exchanges are—for the solution

$$K_e=\frac{\Sigma[^{238}U^{VI}]}{\Sigma[^{235}U^{VI}]}\cdot\frac{\Sigma[^{235}U^{IV}]}{\Sigma[^{238}U^{IV}]} \quad (30)$$

and for the ion exchanger

$$\overline{K}_e=\frac{\Sigma[^{238}\overline{U}^{VI}]}{\Sigma[^{235}\overline{U}^{VI}]}\cdot\frac{\Sigma[^{235}\overline{U}^{IV}]}{\Sigma[^{238}\overline{U}^{IV}]}\ . \quad (31)$$

From (26), (27), (30), and (31) we obtain

$$\overline{K}_e=K_e\frac{S_1}{S_2}\ . \quad (32)$$

Mathematical rearrangement yields

$$^{235}_{238}S=S_2\left(\frac{S_1K_eS_2^{-1}+\bar{\rho}}{1+\bar{\rho}}\right)\left(\frac{K_e^{-1}+\rho}{1+\rho}\right)\ , \quad (33)$$

where $\rho=\Sigma[U^{VI}]/\Sigma[U^{IV}]$ and $\bar{p}=\Sigma[\overline{U}^{VI}]/\Sigma[\overline{U}^{IV}]$ are the molar ratios of uranium(VI) and uranium(IV) in the solution and in the ion exchanger respectively. Taking logarithms and rearranging slightly, we convert (33) into

$$\ln^{235}_{238}S=\ln S_2+\ln\left(1+\frac{S_1K_eS_2^{-1}-1}{1+\bar{\rho}}\right)+\ln\left(1+\frac{K_e^{-1}-1}{1+\rho}\right)\ , \quad (34)$$

which is the fundamental equation for the separation of uranium isotopes in a mixture of uranium(IV) and uranium(VI).

In view of Eqn. (32) we can write (34) in the form

$$\ln^{235}_{238}S=\ln S_2+\ln\left(1+\frac{\overline{K}_e-1}{1+\bar{\rho}}\right)+\ln\left(1+\frac{K_e^{-1}-1}{1+\rho}\right)\ , \quad (35)$$

which emphasises the important fact that the greater the difference between ρ and $\bar{\rho}$ the greater the contribution made by K_e to the separation factor. Uranium(IV) is adsorbed preferentially by a cation-exchange resin, and uranium(VI) by an anion-exchange resin. Consequently either resin may be a good secondary phase giving a high separation factor provided that electron exchange (which takes place very slowly in an ordinary aqueous solution) is accelerated by some catalyst, in particular by the resin itself.

(*b*) Separation of Uranium Isotopes by Means of a Cation-exchange Resin

Kakihana et al.[20,54] used frontal analysis to determine separation factors for a sulphonated cation-exchange resin in a hydrochloric-acid solution containing uranium(IV) and uranium(VI). Acid (0.6 M and 2 M) solutions of uranium were passed at 30 ml h^{-1} through a column (of height 100 cm and diameter 1 cm) filled with Dowex 50 × 12 in the hydrogen form (100–200 mesh). Since the experiments were made under non-equilibrium conditions, the separation factor was calculated by means of the approximate formula

$$^{235}_{238}S=1+\frac{D}{Q}\cdot\frac{1}{R_0} \quad (36)$$

in which

$$D=\Sigma d=\Sigma\Delta m\cdot\Delta R \quad (37)$$

is the total change in the uranium-235 content of the exchanger, Δm being the absolute uranium content of the sample, $\Delta R=R_0-R$, where R_0 and R are the uranium-235 contents in the initial solution and in the samples of eluate, and Q is the total quantity of uranium sorbed by the exchanger. The greatest impoverishment with respect to uranium-235 was observed in the early samples containing uranium(IV), and slight impoverishment in samples containing uranyl ions. The reason is that the light isotope is more strongly retained than uranium-238 in the cation-exchange resin. The single-stage separation factor in these experiments was 1.00028–1.00048.

In July 1968 some Japanese workers patented a counter-current method for enriching uranium isotopes by ion exchange, in which electron exchange was effected between uranium(IV) and uranium(VI) in a sulphonated cation-exchange resin in aqueous hydrochloric acid[55]. A solution of uranium(VI) in 1.0 *N* hydrochloric acid flowed upwards into a column in contact with cation-exchange resin granules saturated with uranium(IV), when a certain quantity of uranium(VI) ions remained in the resin. After equilibrium had been established in this counterflow contact, the concentration of uranium-235 in the uranium(VI) solution

had increased by a factor of 1.00035 (the initial concentration was arbitrarily taken to be unity), while its concentration in the uranium(IV) sorbed on the exchanger had decreased by a factor 1/1.00035 = 0.99964. Thus the isotopic exchange constant was

$$K = \frac{^{235}U^{VI}_{soln}}{^{235}U^{IV}_{res}} = \frac{1.00035}{0.99964} = 1.0007$$

at every stage of exchange. After the first contact the 235-enriched uranium(VI) solution was reduced with zinc dust to the quadrivalent state; the product was sorbed on a fresh portion of exchanger in a special column, from which the uranium(IV)-saturated granules entered the second stage of exchange. This stage increased the concentration of uranium-235(VI) in the solution to 1.00035 × 1.00035 = 1.0007, but the concentration of uranium-235(IV) in the resin remained at 1.00035 × 0.99964 = 1. In the next stage the concentration of uranium-235(VI) in solution increased to 1.0007 × 1.00035 = 1.00105, while that of uranium-235(IV) in the resin was 1.0007 × 0.99964 = 1.00034; and so on. Therefore the concentration of uranium-235(VI) gradually increased in the solution leaving the top of the exchange column. The quadrivalent uranium present in the resin discharged from the bottom of the column was oxidised with 1% aqueous hydrogen peroxide to the sexivalent state; uranium(VI) was eluted with 0.5 *N* hydrochloric acid. Oxidation and elution could be combined into a single stage by applying the oxidant and the desorbing solution simultaneously.

An alternative procedure is to combine oxidation and the maintenance of uranium(VI) in the system in the same apparatus. The uranium(IV)-saturated resin then passes down the column as in the previous case, while the oxidant (1% hydrogen peroxide) flows upwards together with the eluant. As a result the resin is converted into the hydrogen form and is discharged at the bottom of the column, while the desorbed solution of uranium(VI) moves upwards in contact with resin granules saturated with uranium(IV); the accompanying isotopic exchange leads to enrichment with uranium-235 of the solution of uranium(IV) emerging from the upper part of the column.

A cascade enrichment scheme, entailing the use of several ion-exchange columns, was proposed on the basis of the above variants. The uranium(VI) feed solution enters the middle of the ion-exchange column and moves upwards in contact with resin granules saturated with uranium(IV). Part of the solution leaving the top of the column is led to a special apparatus for the reduction of uranium(VI), and the resulting uranium(IV) is used to saturate a fresh portion of resin, which is returned to the ion-exchange apparatus and moves downwards, meeting the uranium(VI) solution obtained by oxidative desorption of the resin at the next stage of the enrichment process. The other part of the solution leaving the top of the column is fed to the next ion-exchange column. Thus each ion-exchange column within the cascade is fed by admitting near its midpoint a portion of the uranium(VI) solution emerging from the top of the ion-exchange column of the preceding stage and a portion of the uranium(VI) solution obtained by oxidative desorption in the next stage. A uranium solution enriched with the heavy isotope is obtained from the bottom of the ion-exchange column at one end of the cascade, and a solution enriched with the light isotope from the top of the column at the other end.

Interesting experiments aimed at intensifying the isotopic effect in a cation-exchange resin immersed in a hydrochloric-acid solution of uranium were made by Shimokawa and Kobayashi[56], who fed iron(III) chloride solution to a column filled with the resin saturated with uranium(IV). The latter underwent oxidation to uranium(VI), after which uranyl ions were eluted from the resin:

$$3\,R_4U^{IV} + 10\,FeCl_3 + 6\,H_2O \rightleftarrows 3\,U^{VI}O_2Cl_2 + 4\,R_3Fe^{III} + 6\,FeCl_2 + 12\,HCl \quad . \qquad (38)$$

The change in valency of the uranium is expressed by the electron exchange

$$U^{IV} + 2\,Fe^{III} \rightleftarrows U^{VI} + 2\,F^{II} \quad . \qquad (39)$$

The UO_2^{2+} and Fe^{2+} ions are rapidly eluted from the column on the arrival of fresh portions of iron(III) chloride, because the affinity of the cations for the resin varies in the sequence

$$Fe^{3+},\ U^{IV} > UO_2^{2+},\ Fe^{2+} > H^+ \quad .$$

The rates of the chemical reactions and of elution are so large that a very sharp band is formed between the iron(III) and uranium(IV) forms of the exchanger. This band moves at a constant speed determined by the quantity of uranium(IV) sorbed initially and by the concentration and the rate of supply of iron(III) chloride. The process is shown diagrammatically in Fig. 3. During the initial period of operation of the column some of the eluted uranyl ions penetrate the uranium(IV) form of the resin and exchange with hydrogen ions of the latter. After the equilibrium partition of uranyl ions between resin and solution has been established, the concentration of uranyl ions in the eluate becomes constant: uranium(IV) is firmly retained in the band.

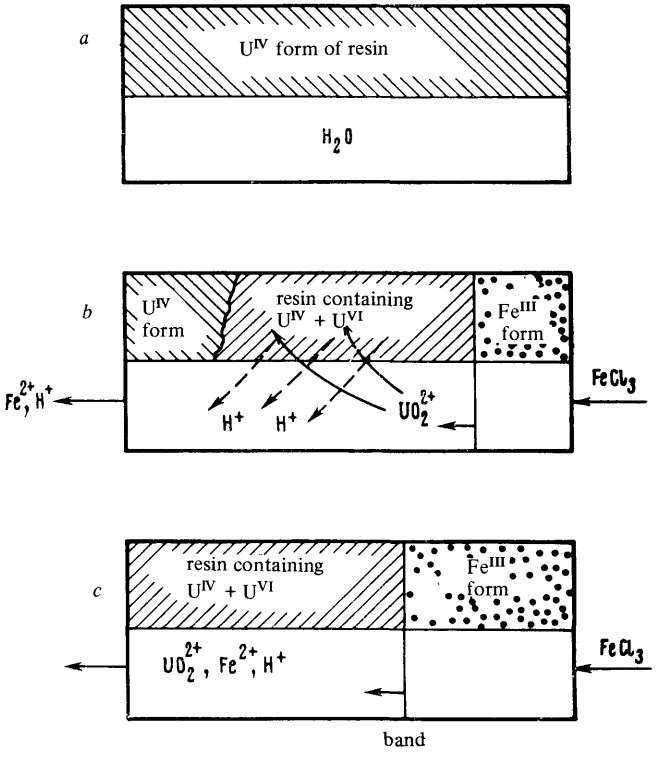


Figure 3. Diagram of movement of band: *a*) before supply of solution; *b*) during initial period of operation of column; *c*) after equilibrium distribution of UO_2^{2+} has been established.

These workers[56] reckoned on strengthening the isotopic effect firstly by the chemical reactions occurring as the band moved along the column and secondly by electron exchange between the two valency states of uranium. The equilibrium constant of isotopic exchange in these experiments was 1.0004–1.0006, regarded as relatively high. It had been reported[57] that such an equilibrium constant should be higher at low temperatures. But the above experiments at 3°C revealed no appreciable fractionating effect; at 20 and 40°C the equilibrium constant of isotopic exchange was respectively 1.0005 and 1.0006.

(*c*) Separation of Uranium Isotopes by Means of an Anion-exchange Resin

Kakihana et al.[58] used Dowex 2 × 10 (100–200 mesh) in the chloride form, in a column of height 100 cm and diameter 1.2 cm, together with solutions in concentrated (8 *N*) hydrochloric acid containing uranium(IV), uranium(VI), and a mixture thereof, flowing at 16 ml h^{-1}. Frontal analysis showed that the separation factor of 0.9993 for solutions containing only uranium(IV) was higher than the value for the mixed solutions (0.9992–0.9986), which can be attributed to the strong influence of the electron exchanges described by Eqn. (19). Indeed, all the experimental results agreed well with theoretical values obtained from Eqn. (35) on the assumption that $K_e = 1.002$.

In 1968 Gonda and Kakihana published experimental results on the fractionation of uranium isotopes in an anion-exchange resin immersed in benzene solutions of trioctylamine and tributyl phosphate[59]. Frontal analysis was used to investigate isotopic exchange for four solutions containing natural uranium (0.72% of uranium-235)— (i) 0.05 M solution of trioctylamine in benzene saturated with uranium(IV), (ii) a mixture of 0.05 M solutions of trioctylamine in benzene saturated respectively with uranium(IV) and uranium(VI), (iii) 0.05 M solution of tributyl phosphate in benzene saturated with uranium(IV), and (iv) a mixture of 0.05 M solutions of tributyl phosphate in benzene saturated respectively with uranium(IV) and with uranium(VI). An ion-exchange column of height 100 cm and diameter 1.3 cm was filled with Dowex 21K (50–100 mesh). Solutions were passed through at 25 ml h^{-1} until the uranium solution had the same composition leaving and entering the column.

In the benzene solution of tributyl phosphate saturated with a mixture of uranium(IV) and uranium(VI) the first samples of eluate obtained on determining the elution sorption curve contained uranium enriched with the lighter isotope (0.732%), by a factor of 1.017 relative to the natural content. This indicates that in this system uranium-238 is more readily sorbed than is uranium-235. The single-stage factor for a solution containing a mixture of valency states was 0.99988, and that for a solution containing only quadrivalent uranium was 0.99989.

The first eluate samples obtained for the elution curve in a benzene solution of trioctylamine saturated with the mixture of valency states were impoverished with respect to the lighter isotope (0.710%, by a factor of 0.987). Hence uranium-235 is more easily sorbed than uranium-238 from a benzene solution of trioctylamine; the single-stage separation factor for this system is 1.00033.

The complete absence of any isotopic effect in the trioctylamine–benzene system saturated only with quadrivalent uranium is due to the similarity in the binding of the latter in the anion-exchange resin and in the solution.

From the above mass-spectrometric results and the fact that uranium(VI) exhibits the greater affinity for the anion-exchange resin in the benzene–tributyl phosphate system, whereas quadrivalent uranium has the greater affinity in benzene–trioctylamine solutions, it was concluded that uranium-235 is concentrated in the quadrivalent state. This is consistent with results for an anion exchanger in 8 M hydrochloric acid containing the mixed valency states[58]. The equilibrium constants of electron exchange in 0.05 M solutions of trioctylamine and of tributyl phosphate in benzene are respectively 1.0010 and 1.0013, both smaller than the equilibrium constant (1.002) in 8 M hydrochloric acid.

3. SEPARATION OF URANIUM ISOTOPES ON A CATION-EXCHANGE RESIN IN A URANYL SALT SOLUTION

Ciric and Zmbov[60,61] studied the separation of uranium isotopes during ion exchange on a cation-exchange resin in an aqueous solution of a uranyl salt. The columns used (l = 1–2 m with S = 0.5 or 1.5 cm^2) were filled with Dowex 50 × 8 or Amberlite IR-120 resin (size of granules 100–200 mesh or 0.1–0.2 mm respectively). The enrichment coefficient was determined by frontal analysis with the application of Glueckauf's equation[62]

$$\varepsilon = \frac{\pi\eta^2}{4\bar{v}s'}\left(1+\frac{\pi\eta}{4}+\frac{5\pi^2\eta^2}{64}+\ldots\right), \qquad (40)$$

where $\eta = (N_0 - N)/N_0$ is the relative enrichment of the more strongly adsorbed isotope in the sample, s' is the gradient of relative enrichment in the sample, $\bar{v}$ is the volume of the sample, and $\epsilon = \alpha - 1$, in which α is the separation factor. We can also apply Spedding's equation[18]

$$\varepsilon = \frac{\sum_{i=1}^{m} V_i C_i (N_0 - N_i)}{QN_0(1-N_0)}, \qquad (41)$$

where V_i, C_i, and N_i are respectively volume, concentration, and content of the more strongly adsorbed isotope in the sample, and Q is the quantity of resin (in equivalents) traversed by the front. Experiments were made with solutions of uranyl nitrate, chloride, and sulphate.

Table 1. Experimental determination of separation factor in systems containing various uranyl salts.

Cation exchanger	Column	Solution		α
		uranyl salt	concn., M	
Amberlite IR-120	l=2 m S=0.5 cm^2	$UO_2(NO_3)_2$	0.3	1.00015±0.00005
		$UO_2(NO_3)_2$	1.0	1.00010±0.00005
		$UO_2(NO_3)_2$	2.0	1.00017±0.00005
		$UO_2(NO_3)_2$	4.0	1.00010±0.00005
Dowex 50 × 8	l=1 m S=1.5 cm^2	$UO_2(NO_3)_2$	2.0	1.0005±0.0002
		UO_2Cl_2	1.0	1.0004±0.0001
		UO_2Cl_2	2.0	1.0006±0.0002
		$UO_2(ClO_4)_2$	1.0	1.0006±0.0001
		UO_2SO_4	2.0	1.00004
		UO_2-tartrate	0.2	.00000

The experimental results show (Table 1) that the separation factor $\alpha = (^{238}U/^{235}U)_{soln}/(^{238}U/^{235}U)_{res}$ varies from unity to 1.0006. The effect of the uranyl salt concentration on the separation factor lies within the limits

of experimental error. The isotopic effect obtained with uranyl nitrate, chloride, and perchlorate is due solely to the ion-exchange reaction[53]

$$^{238}UO_{2\,soln}^{2+} + {}^{238}UO_{2\,res}^{2+} \rightleftarrows {}^{238}UO_{2\,soln}^{2+} + {}^{235}UO_{2\,res}^{2+} \quad . \qquad (42)$$

The strongly hydrated heavier isotope concentrates in the solution, and the lighter isotope in the resin. Lower values were obtained for uranyl sulphate and tartrate, owing to the isotopic effect of the reaction

$$^{235}UO_2^{2+} + {}^{238}UO_2A \rightleftarrows {}^{238}UO_2^{2+} + {}^{235}UO_2A \quad , \qquad (43)$$

where A is an anion forming a complex with the uranyl ion, which partly or completely nullifies the isotopic effect of reaction (42).

4. SEPARATION OF URANIUM ISOTOPES BY A MOVING BAND

Ciric and Zmbov[60,61] used a moving band with non-spreading boundaries, often termed also Spedding's method, to increase the separation of uranium isotopes. The method consists essentially in the movement of a band of constant length through a system of interconnected ion-exchange columns. This procedure enabled Spedding et al.[18] to achieve complete separation of macroquantities of nitrogen isotopes.

The uranyl band can be moved in a cation-exchange resin in two ways: (*a*) a solution containing a doubly charged cation having greater affinity for the exchanger than has the uranyl ion is used to advance the uranyl band in a column filled with Dowex 50 × 8 in the hydrogen form (choice of a suitable cation presents no special difficulty[63]); or (*b*) the band is moved by means of solutions of salts of weak acids whose anions form stable uranyl complexes. In the elution of a uranyl band with an ammonium acetate buffer, for example, the desorption equilibrium

$$2(NH_4^+)_{soln} + (HAc)_{soln} + 2(Ac^-)_{soln} + UO_{2\,res}^{2+} \rightleftharpoons 2(NH_4^+)_{res} + ([UO_2Ac_3]^-)_{soln} + (H^+)_{soln} \qquad (44)$$

and the adsorption equilibrium

$$(H^+)_{soln} + [(UO_2Ac_3^-]_{soln} + 2(H^+)_{res} \rightleftharpoons UO_{2\,res}^{2+} + 3(HAc)_{soln} \qquad (45)$$

are displaced considerably to the right in the lower part of a column filled with the resin in the hydrogen form. As a consequence, both edges of the band are very sharp, so that its length remains constant during elution. Ammonium acetate can be replaced by the citrate, glycollate, lactate, or other ammonium salts.

Table 2.

Cation exchanger	α
Amberlite IR-120	1.00016±0.00005
Dowex 50 × 8	1.0004±0.00001

The original experiments were made in columns (1 m × 0.5 cm^2) filled with Amberlite IR-120 or Dowex 50 × 8, with ammonium citrate solution (0.29 M of pH 4.4) as eluant. The length of the band was 4 cm. The separation factor α was determined by means of Glueckauf's[19] and Spedding's[18] equations, and the results are listed in Table 2.

The next experiment used columns (S = 1.5 cm^2) of Dowex 50 × 8 cation-exchange resin connected in series. The band length was 11 cm with the same eluant. The experiment was terminated after the band had travelled 6.5 m at 10 cm h^{-1}. The uranium-235 content changed from 0.670% in the first few samples to 0.740% in the last sample. An experiment using the same eluant with a band length of 54 cm was terminated after a travel of 14 m. Although the system was far from equilibrium, the uranium-235 content in the last sample was 0.760%.

In another case the initial band length was 8 cm (actually 11 cm because of the slope of leading and trailing edges), elution was effected by ammonium citrate (0.25 M of pH 4.95), and the experiment was stopped after the band had travelled 1.5 m at 3 cm h^{-1}. The uranium-235 contents in first and last samples were 0.640 ± 0.010% and 0.744 ± 0.005%, with α = 1.0004 ± 0.0001.

The experiments described above show that Dowex 50 × 8 gives higher values than does Amberlite IR-120.

5. SEPARATION OF ISOTOPES IN AN ION-EXCHANGE COLUMN WITH APPLICATION OF AN ELECTRIC FIELD

In 1950 some Japanese workers were successful in separating copper and nickel isotopes by applying a constant electric field to an ion-exchange resin. Since then repeated attempts have been made to use ion exchangers to separate isotopes of various elements by electromigration[64-69].

Table 3. Enrichment with uranium-235 by electromigration.

Duration of electromigration, h	400	600	1000
Isotopic ^{235}U content in anodic compartment, %	0.709±0.004	0.715±0.004	0.720±0.007
Quantity of ^{235}U remaining in anodic compartment, mg	728	63	4

The effect produced by applying an alternating electric field was described by Japanese scientists in a paper at the Third International Conference on the Peaceful Uses of Atomic Energy[13]. A borosilicate glass vessel was used, divided by cation-exchange membranes into several compartments. One end compartment was filled with ammonium chloride solution to separate the nitrogen isotopes and to serve as anolyte, while the cathode compartment at the other end was filled with aqueous hydrochloric acid; all the intermediate compartments were filled with a cation-exchange resin. Ion-exchange electromigration of ammonium ions was accomplished by applying an alternating current, when the ammonium ion passed through the cation-exchange resin from anode to cathode, changing the direction of its motion with variation in the a.c. phase. The above experiment showed that the heavier isotope nitrogen-15 reaches the cathode compartment more rapidly than does the lighter isotope nitrogen-14.

This method has been used with the same apparatus for the enrichment of uranium-235, whose content in the initial sample of uranyl nitrate was 0.702 ± 0.005%. Amberlite IR-120 of type 2 (in the hydrogen form) was

used, of diameter 2 cm and length 75 cm; the anodic compartment contained 40 ml of 0.5 M uranyl nitrate solution and the cathodic compartment 40 ml of 0.5 M nitric acid. The results are listed in Table 3. This method may give good results[13] in the enrichment of uranium isotopes.

6. Separation of Uranium Isotopes by Electromigration

Cation-exchange membranes are effective for the separation of lithium isotopes[66], and appreciable enrichment has been observed also with uranium. The use of ion-exchange membranes is attractive because the solvation (or hydration) of isotopic ions is far less in them than in solution. This means that the difference in mass between isotopes may have a greater effect on separation in a membrane than in solution. This method has proved most effective for the separation of lithium isotopes in comparison with potassium, copper, and uranium isotopes[70]. The single-stage separation factor for uranium-235 and uranium-238 was 1.00006.

Thermal Decomposition of Solid Metal Oxides

G.V.Malinin and Yu.M.Tolmachev

Certain aspects of the kinetics and mechanism of the thermal dissociation of solid metal oxides are considered, and two types of decomposition differing in mechanism—radical and molecular—are discussed. The possibility of elucidating characteristic features of these types of dissociation is analysed. A list of 81 references is included.

I. INTRODUCTION

The attention paid by research workers to the thermal dissociation of solid metal oxides is due primarily to the fact that such reactions, together with the dissociation of carbonates and sulphides, form, in Rostovtsev's descriptive expression[1], "a kind of cornerstone of the thermodynamic study of metallurgical processes". A fairly comprehensive literature has appeared on the thermodynamics of the thermolysis of metal oxides (see e.g. the monographs[1-4] and the references in them).

Far fewer kinetic studies have been made on the thermal decomposition of solid oxides. Yet investigation of the formal kinetics and detailed examination of the mechanism of these reactions is important for several reasons. Firstly, establishment of the fundamental kinetics of the thermolysis of solid metal oxides may be of practical value, since it is probable that such processes largely determine the chemistry of the thermal reduction with carbon of many readily dissociated oxides[5-9]. Secondly, the condensate dissociation (Kulikov's term[2]) of oxides belongs to the broad class of reactions

$$A(solid) = B(solid) + C(gas). \quad (1)$$

Investigation of the decomposition of oxides may be expected to clarify many features of such reactions, such as "nucleation", the autocatalytic effect, etc. Here it is noteworthy that, because the volume relations of the initial higher oxides do not greatly differ from those of the oxide products[10], pore formation, which usually complicates the investigation of topochemical reactions[11], has no marked effect. (An original technique permitting extremely delicate monitoring of the variation in the degree of dispersion of metal oxides during various redox reactions has recently been developed by Mardaleishvili et al.[12-14]) Thirdly, the kinetic behaviour of a substance reflects its intrinsic properties. Study of the kinetics of the decomposition of solid oxides and its mechanism will permit a deeper insight into the nature and structure of these compounds.

A most comprehensive survey of kinetic problems of the dissociation of metal oxides was made by Esin and Gel'd[4]. Garner[15] and Young[16] made detailed analyses of experimental results on the thermolysis of silver oxide.

II. FORMAL KINETIC INVESTIGATIONS OF THE THERMAL DECOMPOSITION OF METAL OXIDES

Until recently the kinetics and the mechanism of the thermal dissociation of oxides were investigated almost solely by the formal kinetic method, which consists essentially in finding the time dependence of the reaction velocity, and hence reaching conclusions on the reaction mechanism. Many formal kinetic equations, deduced from very different views on the mechanism of the processes, were suggested to describe the course of the heterogeneous decomposition of solids. Pavlyuchenko[17] reckoned that about forty such equations had been proposed. Kinetic investigation of the thermal decomposition of oxides and solids in general can be regarded as originating in 1905 with the work of Lewis on the thermolysis of silver oxide[18]. He gave a kinetic equation and attempted to explain the mechanism of the reaction.

Formal kinetic investigations have now been made on the decomposition of the oxides of silver[18-25], manganese[5,6,26], copper[8], terbium and praseodymium[27,28], chromium[29], lead[9,30-32], cobalt[7], and uranium[33-39]. Several of these papers, in particular those of Rostovtsev and his coworkers, as well as certain papers by Vlasov and Beketov, do not give formal kinetic equations for the reactions investigated, although they do contain graphs illustrating the dependence of reaction velocity on degree of conversion.

Investigations on the dissociation and the reduction of manganese and copper oxides, of great importance for the theory of metallurgy, were made under the direction of Chufarov[40-42]. Unfortunately, no quantitative data on the formal kinetics of the reactions were given, although indications appeared of their topochemical character. The effects of temperature and oxygen pressure on the rate of decomposition of the oxides were traced, and activation energies determined for the thermolysis of manganese dioxide, manganese sesquioxide, and copper(II) oxide.

Several conclusions can be reached from a general analysis of experimental data on the formal kinetics of the thermal decomposition of solid metal oxides.

If the range of homogeneity of the initial higher oxide is sufficiently wide, the decomposition curves obey the equations of diffusion kinetics within this region. For example, the thermolyses of $PrO_{1.72-y}$ and U_3O_{8-y} [29,38] are well described by the equation

$$\frac{X_0 - X}{X_0 - X_\infty} = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-\frac{n^2\pi^2 Dt}{R^2}\right) , \quad (2)$$

where R is the radius of a spherical oxide particle, t is the duration of the experiment, and X_0, X, and X_∞ are the quantities of oxygen in the oxide initially, at moment t, and after an infinite time respectively. The postulates made in deducing this equation—that the specimen consists of spherical particles of the same radius, that equilibrium corresponding to the final composition of the oxide is rapidly established at the solid–gas interface, and that the diffusion coefficient is independent of X—are obviously not too crude. This work[29,38] enables the relative ease with which oxygen atoms move through the oxide lattices to be assessed: the activation energy for the diffusion of oxygen in $PrO_{1.72-y}$ and in U_3O_{8-y} is respectively 42 and 45 kcal mole^{-1}.

In spite of the apparent complexity, treatment of experimental results by means of Eqn. (2) presents no great difficulty. The dependence of $\lg(X - X_\infty)$ on time when t is large should be linear with a slope of $-\pi^2 D/2.3R^2$. Having evaluated this quantity, we can easily plot the curve even at small values of t, and with R known, e.g. from measurements of specific surface, we can calculate the diffusion coefficient. It is therefore often inadvisable to use various simplified forms of the diffusion equation, e.g. the equation[43-45]

$$\alpha = kt^{1/n} , \quad (3)$$

where α is the degree of conversion and k the specific rate constant.

When the ranges of homogeneity of initial and final oxides are narrow, the decomposition curves are described by extremely diverse equations of topochemical kinetics. The most usual[27,28,30,31] is the "contractile sphere" equation deduced by Roginskii and Shul'ts[46]. The experimental results satisfy the same kinetic equation for a fairly wide range of degrees of conversion, which, from our point of view, underlines the near invariability of the state of aggregation of the substances. Cracking of the fine oxide crystals is improbable, because the volume relations of initial and final oxides do not markedly differ. Nor should sintering greatly complicate the observed pattern, since kinetic examination of the decomposition of oxides is usually made in an inert atmosphere or in a vacuum at moderate temperatures.

Deviations from the curve at low degrees of conversion are due both to the complexity of nucleation processes[15,16,32] and to the possible occurrence of decomposition within the range of homogeneity of the initial higher oxide[26]. The slowing down of the reaction at high degrees of conversion probably has several causes, e.g. the formation of a dense layer of reaction products, through which oxygen must diffuse. Furthermore, dissociation may then occur within the range of homogeneity of the final oxide. An example of such behaviour is the decomposition of higher oxides of uranium to U_3O_{8+x}, the upper limit of which probably extends to the composition $UO_{2.76}$.[47]

Thus the kinetics of the thermolysis of oxides, while having much in common with other reactions of type (1), possesses its peculiarities resulting from the wide dissemination of non-stoichiometric compounds among the oxides.

III. CLASSIFICATION OF THE THERMAL DISSOCIATION OF METAL OXIDES

The mechanism of the dissociation of solid metal oxides is usually regarded as comprising the stages—"(i) formation of oxygen atoms adsorbed at the interface, (ii) their combination to molecules, (iii) desorption of oxygen molecules, and (iv) formation and growth of nuclei of a new phase"[4]—among which Lewis[18] assumed (ii) to be the slowest. Breakdown of the initial higher oxide is now regarded as meeting this criterion.

However, several experimental facts are inconsistent with this simple scheme[48]. Thus because the structure of the transition complex is closely similar to that of the reaction products of an endothermic reaction[49,50], for example, the activation energy of the thermal decomposition of oxides should, according to the above scheme, be similar in magnitude to the heat of reaction

$$M_nO_x \rightarrow M_nO_{x-1} + [O](\text{solid}) , \quad (4)$$

where [O](solid) represents an oxygen atom adsorbed at the interface between initial and final oxides. The energy of interaction of such an atom with the matrix of the solid oxide is difficult to determine, but obviously the heat of reaction (4) should not greatly differ from the heat of reaction

$$M_nO_x \rightarrow M_nO_{x-1} + O(\text{gas}) , \quad (5)$$

which can easily be calculated from tabulated enthalpies of formation. The heat of reaction (5) for oxides undergoing decomposition is usually considerably greater (by 40–50 kcal mole^{-1}) than the heat of reaction

$$2M_nO_x \rightarrow 2M_nO_{x-1} + O_2 . \quad (6)$$

Experimental activation energies of the thermal condensate dissociation of oxides are usually closely similar to the heat of reaction (6), and in any case considerably smaller than the heat of reaction (5)[5-9,18-42].

The reason why this discrepancy was ignored for such a long time probably lies in the history of the development of kinetic investigations. Lewis's early work on the decomposition of silver oxide was followed by a fairly lengthy period (until the end of the 1940s) during which the kinetics of the dissociation of oxides remained almost uninvestigated. But very sound kinetic studies were made during this time on the decomposition of carbonates and hydrates[4,15,16], which showed that in the majority of cases the activation energy of these reactions was equal to the heat of reaction (1) with C representing the CO_2 or H_2O formed. This result is entirely consistent with the theory of the activated complex. By the start of the new period in the kinetic investigation of the thermal dissociation of oxides the view had already become deeply rooted that full identity existed between the decomposition of oxides and the thermolysis of carbonates and hydrates. Since molecular oxygen is an end-product of the former reaction, it was accepted as entirely natural, by analogy with the latter[26], that the activation energy should coincide with the heat of reaction (6).

There remains at least one further extremely interesting problem—the irreversibility of the thermal decomposition of certain oxides—which probably cannot be solved in terms of the existing model. This is of some practical importance, since the irreversibility observed with several higher oxides casts doubt on the significance of determinations of their dissociation pressures, e.g. of oxides of lead[51], manganese[52], and uranium[53].

In view of all the above considerations, further development of the theory of the thermal dissociation of solid metal oxides is obviously necessary on the basis of fresh experimental results.

A very useful method for elucidating the mechanism of a complicated process is to record the reaction intermediates; it has been widely employed in the kinetic investigation of homogeneous chemical reactions [54-56]. Atomic oxygen has recently been increasingly widely recorded as intermediate in several cases of the thermal decomposition of solids, including oxides [30-32,39,48,57-61]. Experiments have shown that the thermal dissociation of some oxides is accompanied by the evolution only of molecular oxygen, whereas both atomic and molecular varieties are evolved in the thermolysis of other oxides. Furthermore, the latter decompositions were found to be reversible, whereas those accompanied by the evolution only of molecular oxygen were irreversible [31,32,39,48,60,61]. (The possibility of the evolution of atomic oxygen in the thermal decomposition of certain solid metal oxides was probably first mentioned by Baikov and Tumarev in 1937. [62] It is interesting that their results are somewhat similar to those just mentioned. These workers found that oxides which were reduced irreversibly by carbon monoxide evolved almost pure carbon dioxide on reaction with carbon, whereas other oxides gave a nearly equilibrium mixture of the monoxide and the dioxide.)

It was proposed [48] that the differences in the behaviour of solid oxides should be used to classify their thermal decomposition into two types, according as both atomic and molecular oxygen or only the latter is evolved. It is noteworthy that the kinetic parameters (activation energy and pre-exponential factor) determined in oxygen (air) usually differ markedly for these two types of reaction. Available data indicate that the first type includes the thermal decompositions $Pb_3O_4 \rightarrow PbO$, $Co_3O_4 \rightarrow CoO$, α-$PbO_x \rightarrow \beta$-PbO_x, $U_3O_8 \rightarrow U_8O_{21}$, $UO_{2+x} \rightarrow UO_{2.00}$, and $CuO \rightarrow Cu_2O$; and the second type includes β-$PbO_2 \rightarrow \alpha$-PbO_x, $Ag_2O \rightarrow Ag$, α-$PbO_x \rightarrow Pb_3O_4$, α-$PbO_2 \rightarrow \alpha$-PbO_x, $UO_3 \rightarrow UO_{2.9}$, $UO_{2.9} \rightarrow U_3O_8$, ϵ-$UO_3 \rightarrow U_3O_8$, $CrO_2 \rightarrow Cr_2O_3$, β-$MnO_2 \rightarrow \alpha$-Mn_2O_3, and α-$Mn_2O_3 \rightarrow \beta$-$Mn_3O_4$. Harano's experiments [57,58] indicated that atomic oxygen was evolved in the thermal dissociation of HgO, ZnO, and PtO_2.

Since the percentage of atomic oxygen in the gas evolved in the thermal decomposition of oxides of the first type is quite high [32], these reactions can well be regarded as a simple method for generating atomic oxygen. The results discussed may have some applied value, since work is now being widely undertaken on the use of oxygen from metal oxides for oxidising fuels [63].

IV. MECHANISMS OF THE TWO TYPES OF DISSOCIATION OF OXIDES

Since the first type of thermal decomposition of oxides involves the evolution of both atomic and molecular oxygen, whereas the second type gives only molecular oxygen, it was suggested [30,48] that the reaction mechanism of the former is similar to that generally accepted, whereas the latter has a different mechanism. Molecular oxygen is evidently formed directly by breakdown of the initial higher oxide in the latter type. This provides a natural explanation of the similarity of the activation energy to the heat of reaction (6) observed with these reactions.

In order that oxygen [atoms] should leave the oxide lattice in pairs (as molecules) during thermal decomposition of the oxide, interaction should occur between oxygen atoms in the initial lattice. Ignoring the form of interaction (the nature of the chemical bond in oxides is a matter of controversy [64]), we can state that the mutual influence will be stronger the shorter the oxygen–oxygen distance, which is shortest in peroxides. In 1958 Pavlyuchenko and Rubinchik [65] concluded from the activation energies and the heats of reaction of certain peroxides that atomic oxygen was not formed in their thermal breakdown. This was confirmed by Harano's experiments [57] and by other results [60].

In contrast to peroxides, it is difficult in oxides to distinguish any pair of oxygen atoms whose interaction would differ significantly from that with other neighbours. However, it may be questioned how marked this difference should be. No criterion is available at the present time.

Several higher oxides contain comparatively short oxygen–oxygen bonds. In the Reviewers' opinion this indicates the possibility of interaction between such atoms. Thus in β-PbO_2 [66] every four pairs of oxygen atoms distant 3.03 Å apart and one pair with a distance of 3.38 Å are accompanied by a pair 2.67 Å apart. It may be suggested that such a pair is able to behave as a unit during the act of breakdown and form an oxygen molecule. The important factor is not so much the absolute value of the shortest oxygen–oxygen distance as its difference from the mean. The energy of the metal–oxygen bond is obviously also important.

A similar idea to the above has recently been put forward by Porai-Koshits and Atovmyan [67]: from the structure of certain compounds containing oxygen or sulphur they concluded that the shortening of the O...O and S...S distance along an edge common to adjoining MX_6 octahedra is a consequence of the mutual attraction of the non-metal atoms. (The presence of such octahedra, linked in various ways, can be monitored in most higher oxides.) This idea seems the more valid as the explanation of the shortened non-metal–non-metal distance once put forward by Pauling [68] is unconvincing in the light of modern data on the effective charges in oxides and sulphides [64]. The mechanism suggested for reactions of this second type is further supported by work [61] showing, from the topotaxy [69] of the reaction $CrO_2 \rightarrow Cr_2O_3$ and formulation of the principle of minimum rearrangement of the lattice (the maximum possible number of previous bonds are preserved in a reaction), that the CrO_2 lattice can be transformed into the lattice of chromic oxide by removing pairs of oxygen atoms. The pairs thus removed lay on a common edge of adjoining MX_6 octahedra (i.e. they were a comparatively short distance apart).

The mechanism suggested for reactions of the second type is consistent also with their irreversibility. Theoretical examination has shown [70] that, if molecular oxygen is formed immediately on breakdown of the initial higher oxide, it is desirable, for the reverse reaction to occur, that oxygen should reach the interface between initial and final oxides in the form of molecules. However, an oxygen molecule is comparatively large, and its insertion would produce appreciable distortions in the oxide lattice. Hitherto there has been no direct experimental evidence of the possibility of the dissolution of molecular oxygen in oxides [71]. Experimental studies of the introduction of large molecules into the lattices of less rigid substances, e.g. graphite, indicate the presence of large sorption hysteresis [72]. If the pressure is raised considerably above the equilibrium value during a reaction of the second

type, oxidation of the lower oxide is observed, but its rate is extremely low. Thus according to Otto[52] the equilibrium oxygen pressure in the β-MnO_2–α-Mn_2O_3–O_2 system at 475°C is 1.4 atm. By raising the pressure almost hundredfold, he was able to observe partial oxidation of the sesquioxide, but no such oxidation was observed during the first 200 h after the pressure had been raised. Equilibrium oxidation of the sesquioxide would have required a year. The less rigid the lattice of the lower oxide, the more readily should oxidation occur. This will probably explain why several higher oxides of metals, e.g. manganese and uranium, can be obtained by oxidising lower oxides if the latter have been obtained in a finely dispersed or an amorphous state. The thermal decomposition α-$Mn_2O_3 \rightarrow \beta$-$Mn_3O_4$ is very characteristic in this respect. The Reviewers' experiments have shown that only molecular oxygen is evolved. However, several investigators regard the thermal decomposition of manganese sesquioxide as reversible. Summarising the results of many workers, Rabkin et al. concluded[73]: "In some cases the conversion of Mn_2O_3 into Mn_3O_4 is a reversible process depending on temperature and time of heating, as well as on the degree of dispersion. However, prolonged heating at a high temperature leads to the formation of Mn_3O_4 showing no tendency to absorb oxygen."

The problem of the irreversibility of thermal decompositions of oxides of the second type can in general be regarded as solved. A series of crucial experiments should be undertaken. Furthermore, the appearance of many studies on the irreversibility of thermal decomposition of several hydrates and carbonates would have been extremely useful, since these systems can be investigated by improved analytical methods, such as infrared spectroscopy, nuclear magnetic resonance, and isotopic exchange.

As has been mentioned, the mechanism of the first type of thermal decomposition of oxides is probably closely similar to the generally accepted condensate dissociation of solid metal oxides. Since very few investigations have been made on the thermolysis of oxides in which the evolution of atomic oxygen has already been established, it is difficult to analyse the laws governing reactions of this type. Nevertheless, one question can usefully be raised. According to the simple scheme of the decomposition of metal oxides[4], the activation energy of such reactions should differ little from the heat of reaction (5) $\Delta H^{\circ}_{T}(O)$. Let us estimate the latter for a few oxides, for which reliable thermodynamic data are available[2,74]. Since heats of reaction usually vary little with temperature, the calculation was made for 298 K. Thus approximate values of 79, 84, and 94 kcal g-atom^{-1} O have been obtained for $\Delta H^{\circ}_{298}(O)$ for the reactions $Pb_3O_4 = 3PbO + O$, $Co_3O_4 = 3CoO + O$, and $2CuO = Cu_2O + O$ respectively. The activation energy of the thermal decomposition of red lead has been given[32] as $E_a = 45 \pm 15$ kcal mole^{-1}; Ashin and Rostovtsev[7] give $E_a = 70$ kcal mole^{-1} for the thermal dissociation of Co_3O_4, and $E_a = 57$ kcal mole^{-1} for the thermolysis of copper(II) oxide[8], the latter of which compares with the value 49 found by Tatievskaya and Chufarov[42]. (The recalculation of the activation energy for the last reaction based by Esin and Gel'd[4] on the results[42] is probably illegitimate.) Chufarov et al.[40,41] calculated the activation energy from the temperature dependence of reaction velocity at zero oxygen pressure in the system. The rate of decomposition of oxides in an atmosphere of the reactant gas can be written

$$v(T) = k(T)S\overline{(m - m_{\infty})}\left(1 - \frac{p}{P_{O_2}}\right), \qquad (7)$$

where $v(T)$ is the reaction velocity, $k(T)$ the rate constant, S the interfacial area, $(M - m_{\infty})$ the quantity of oxygen removed from unit interfacial area, p the oxygen pressure in the system, and P_{O_2} the equilibrium dissociation pressure at the experimental temperature. We see that $v \rightarrow v_{max}$ as $p \rightarrow 0$, and v_{max} is independent of the equilibrium oxygen pressure. Hence the temperature dependence of v_{max} is determined by that of k: i.e. in the formula

$$v_{max.} = A\exp\left(-\frac{E_a}{RT}\right) \qquad (8)$$

E_a coincides with the activation energy of the rate constant.

Thus the first type of thermal decomposition of oxides evidently exhibits the extremely rare relationship that the activation energy is smaller than the heat of reaction. A similar relation is found also in the thermolysis of mercury(II) oxide[75]. Observed activation energies are usually considerably smaller than heats of reaction also in the thermolysis of metal sulphides with the formation of sulphur atoms[76,77].

This can be explained on the hypothesis adopted by Benson for gas-phase dissociations[78], that products of the individual act of breakdown are formed in a frozen state. An approximate calculation shows that the heat of the non-isothermal reaction

$$Pb_3O_4 \rightarrow (3PbO + O)^{*} \qquad (9)$$

in which red lead is at 823 K, while PbO and O are 550 deg cooler, is smaller by 20 kcal than the heat of the isothermal reaction $Pb_3O_4 \rightarrow 3PbO + O$. Unfortunately, it is difficult to have a detailed picture for solid-phase reactions of the act of breakdown—to estimate the energy of interaction of oxygen atoms with the lattice, to determine the numbers of metal and oxygen atoms involved in a single act, etc.

An alternative explanation may be suggested for this aspect of the first type of dissociation of oxides, that a multistage mechanism is involved. The first stage—breakdown of the initial higher oxide—is strongly endothermic, but a large quantity of energy is evolved by the combination of oxygen atoms to form molecules. The latter energy (~ 5 eV, which is considerably greater than the energy of thermal phonons) may not be immediately disseminated as heat, but may be divided into two quanta each of 2–3 eV and transmitted resonantly to the interface, i.e. to the site of breakdown in the periodicity of the lattice. "Molecules" of the higher oxide situated at the interface are excited. The destruction of such excited states requires, of course, a considerably lower activation energy.

Further experimental work is required before final conclusions can be reached, but the mechanism of the thermal decomposition of metal oxides is in any case more complicated than had hitherto been thought.

Finally, we must bear in mind, when considering the sequence metal–oxides–oxygen, that oxides contain not only the main metal–oxygen bonds determining their nature but also certain other bonds. Metal–metal interaction must be taken into account in the lattices of several unsaturated oxides[79], and oxygen–oxygen interaction in those of higher oxides, the latter being especially pronounced in metal peroxides. Furthermore, some molecular character is present in metal oxides such as alumina and titania, evident in the fact that the metal does not interact in the same way with all the oxygen atoms surrounding it[80,81]. A feature of such oxides is that M_xO_y molecules pass into the gas phase when they are heated.

Mono-oxygenase Enzymes and Their Simulation

A.A.Akhrem, D.I.Metelitsa, and M.E.Skurko

Information on reactions catalysed by mono-oxygenases is summarised and classified. The composition and properties of these enzymes are considered, together with the kinetics and the mechanism of their action in the hydroxylation of aliphatic and aromatic compounds and in the epoxidation of alkenes. Methods for imitating the action of mono-oxygenases are discussed and systematised, and the reaction mechanisms of the model systems are examined critically. A list of 193 references is included.

I. INTRODUCTION

It is well known that molecular oxygen is relatively inert, and is unable directly to oxidise amino-acids, steroids, hydrocarbons, and other compounds in living organisms. Indeed, the reaction between an oxygen molecule and a hydrocarbon $RH + O_2 \rightarrow R\cdot + HO_2\cdot$ is strongly endothermic ($Q_{H-O_2} - Q_{R-H} = 47 - 93 = -46$ kcal mole^{-1} [1]) and can occur at a measurable rate only at very high temperatures. Under conditions approximating to biological the oxygen molecule cannot be converted into two active atoms, since the strength of the O=O bond is 117.2 kcal mole^{-1} [1]. Oxygen will become an active oxidant when it undergoes stepwise reduction to the radicals $HO_2\cdot$ and $HO\cdot$ and to hydrogen peroxide. Stepwise reduction of molecular oxygen may take place thermally, radiolytically, or in the concerted oxidation of organic compounds[2]. The active oxidants—H_2O_2, $HO\cdot$, $\cdot O_2H$—operate very non-selectively on substrates, so that a large number of reaction products are formed. Yet micro-organisms are able to assimilate various hydrocarbons and other compounds, and to oxidise them under mild conditions with extraordinary selectivity[3-7]. Such complicated organic molecules as steroids can be transformed selectively into hydroxy-derivatives (hydroxylated) by micro-organisms[8,9]. The hydroxylation of various substrates—amino-acids, steroids, hydrocarbons, heterocyclic compounds, etc. — is one of the most important among physiological processes. It can now be accepted as proved that hydroxylation is accomplished by means of enzyme systems—termed mono-oxygenases--belonging to the class of oxidoreductases. Enzymes of this type, discovered in 1954 by Mason[10-13], have the distinguishing feature that, during reactions which they catalyse, one atom of an oxygen molecule is consumed in oxidising the substrate (S), while the other atom is reduced to water, so that the overall hydroxylation is represented by the equation $S + O_2 + DH_2 \rightarrow SO + H_2O + D$, where DH_2 is the cosubstrate, which is dehydrogenated by the reaction. If the substrate itself acts as cosubstrate ($SH_2 + O_2 \rightarrow SO + H_2O$), the mono-oxygenase is said to be "internal" [14].

Mason himself names the type of enzymes he had discovered "mixed-function oxidases", thereby stressing that the enzymes belonged to the class of oxidases and registering the unusualness of the insertion of oxygen into a substrate. Hayaishi [12-14] suggested the term "mono-oxygenases", which is now widely used, since it enables mono-oxygenases to be distinguished from dioxygenases, which insert two oxygen atoms together into a substrate.

Mono-oxygenase enzymes have recently been intensively studied, and the research results are reflected in several reviews, devoted mainly to biological aspects of the action of mono-oxygenases[4,11,15]. The aim of the present Review is to describe the mono-oxygenases known at the present time, to classify them according to types of reactions and structure, to assess their role in biological oxidation, and to discuss their composition and properties. We would like to lay special emphasis on the role of models in the study of the mechanism of reactions catalysed by mono-oxygenases. We have considered mainly recent papers, since they provide the newest information and cover that obtained earlier. Generally accepted biochemical abbreviations are used in the Review.

II. OCCURRENCE, SITE AND ROLE OF MONO-OXYGENASES IN BIOLOGICAL OXIDATION

All intracellular respiratory processes can be divided into two classes—(i) oxidation associated with the accumulation of energy and (ii) free oxidation, unconnected with the formation of high-energy (macroergic) compounds. Concerted phosphorylating oxidation provides an energy supply for the cell and is affected by means of a poly-enzymic complex whose structure is completely obscure. This complex consists of several electron carriers, whose reduction potentials at pH 7.0 lie between those of the initial donor (NAD–NADH = −0.320 V) and the final acceptor (O_2–H_2O = 0.815 V). Thus a large potential difference arises, and the initial energy of oxidation of the substrate is involved in the process. This energy is partly (~40%) consumed in forming adenosine triphosphate.

The energy of hydrolysis of ATP is used by the cell in biosynthetic reactions, which otherwise would be thermodynamically disadvantageous. The role of oxygen in concerted oxidation is to accept electrons liberated by dehydrogenation. Degradative metabolism in the cell and this function of oxygen are now quite well known, and are described in detail in handbooks of biological chemistry[16].

Free oxidation, unconnected with the formation of high-energy compounds, is effected by means of enzymes, which can be divided into two classes—oxidases and oxygenases—but proteins—the oxygen carriers haemoglobin, myoglobin, and haemocyanin—are excluded from consideration. Oxidases are dehydrogenases, using oxygen as electron acceptor and reducing it to hydrogen peroxide[17]. Depending on the nature of the prosthetic groups oxidases are flavoproteins, metal flavoproteins, or copper proteins.

Table 1. The most studied mono-oxygenases.

Enzyme	Electron donor	Occurrence	Ref.
steroid mono-oxygenases			
Squalene 2,3-mono-oxygenase EC 1.12.1.3	NADPH	liver	28, 29
11β-Mono-oxygenase EC 1.14.1.6	NADPH	adrenal mitochondria	30—32
$C_{(21)}$-Mono-oxygenase EC 1.14.1.8	NADPH	adrenal-gland endoplasmic retirulum	33, 34
Cholesterol 20-mono-oxygenase EC 1.14.1.9	NADPH	adrenal mitochondria	35, 36
1α, 1β, 2β, 6α, 6β, 7α, 7β, 15α, 16α, 18α-Mono-oxygenase	NADPH	liver endoplasmic reticulum	37—40
Mono-oxygenases of amino-acids and their derivatives			
L-Kynurenine 3-mono-oxygenase EC 1.14.1.2	NADPH NADH	liver mitochondria	41, 42
Dopamine β-mono-oxygenase EC 1.14.2.1	ascorbate	adrenal glands	43, 44
p-Hydroxyphenylpyruvate 1-mono-oxygenase EC 1.14.2.2	aldehyde formed	liver cytoplasm	45, 46
Phenylalanine 4-mono-oxygenase EC 1.14.3.1	tetrahydrobiopterin	liver cytoplasm	47, 48
Proline 4-mono-oxygenase	ascorbate		49, 50
other mono-oxygenases			
gem-α-Mono-oxygenase	NADPH	liver endoplasmic reticulum	51
Aliphatic-acid ω-oxygenase	NADPH	liver endoplasmic reticulum	52—54
Arene *p*-mono-oxygenase	NADPH	liver endoplasmic reticulum	55, 56
Alkane mono-oxygenase	NADPH	liver endoplasmic reticulum	53, 57—59
p-Hydroxybenzoate hydroxylase EC 1.14.1.12	NADPH	*Pseudomonas desmolytica*	60
Camphor 5-mono-oxygenase	NADPH	*Pseudomonas putida*	61, 62

In contrast to oxidases, oxygenases catalyse reactions during which oxygen combines with the substrate. If one oxygen atom is attached, the enzyme is a mono-oxygenase; if two oxygen atoms are introduced into the substrate, the enzyme is termed a dioxygenase. As already noted, one oxygen atom is consumed in oxidising the substrate in the actions catalysed by mono-oxygenases, while the other oxygen atom is reduced to water. It is the latter atom which serves as electron acceptor, as with oxidases. This explains the term "mixed-function oxidase". This function of oxidases requires the presence of a cosubstrate, which undergoes dehydrogenation during the reaction. If the substrate itself acts as cosubstrate, the enzyme is termed an internal mono-oxygenase. Thus mono-oxygenase enzymes catalyse reactions in which the role of oxygen is not restricted to serving as electron acceptor but involves incorporation into the substrate, i.e. oxidation of the latter. Examples of internal mono-oxygenases are—lysine oxygenase[14,18], lactate decarboxylase[19], tryptophan oxygenase[20], and arginine oxygenase[21].

Reactions catalysed by mono-oxygenases are widely represented in biological systems. A special respiratory chain comprising free-oxidation enzymes is localised in microsomes in the liver, where most foreign compounds and several natural metabolites undergo transformations leading to non-toxic polar products, which are then excreted by the kidneys. The mono-oxygenase-catalysed hydroxylation of medicinal, carcinogenic, and toxic substances is of great interest for pharmacology, oncology, and toxicology[4,22]. A hydroxylation chain similar in composition to the microsomal chain functions in adrenal mitochondria, where it is involved in the synthesis of steroid hormones. Malfunctioning of such processes underlies several pathological conditions.

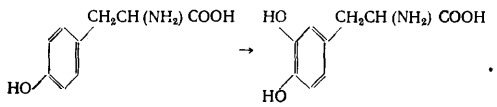
Several micro-organisms hydroxylate hydrocarbons, using them as nutrients[3,5-7,23,24]. This ability has been examined during recent years with the aim of producing foodstuffs and fodder from petroleum hydrocarbons and natural gas[23,24]. The American Mobil Oil Company in 1967 patented the enzymic oxidation of all classes of hydrocarbons[6]. The universal character of the oxidation is explained by the use of various strains of four species of micro-organisms—*Pseudomonas*, *Nocardia*, *Bacillus*, and *Mycobacterium*.

Hydroxylation of foreign compounds can be accomplished not only in the endoplasmic reticulum of liver cells but also in the lungs, gastrointestinal tract, skin, and kidneys[25-27]. The endoplasmic reticulum is a system of membranes ~80 Å thick located in the cytoplasm. On differential centrifugation, fragments of these membranes form the so called microsomal fraction remaining in the supernatant liquid after the separation of heavy particles—nuclei and mitochondria.

Complicated hydroxylating systems, wherever they are found—in mammalian liver microsomes, in adrenal mitochondria, or in bacteria— are in all cases multicomponent in character. Table 1 lists the most important mono-oxygenases studied during recent years.

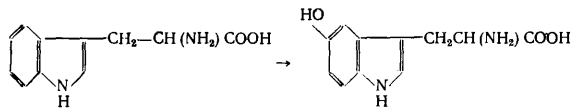
The review by Maslova et al.[4] has discussed in detail aspects of the physiological role of the mono-oxygenases of liver microsomes, induction of the synthesis of the microsomal hydroxylating system, and its hormonal regulation. We would like to consider only the part played by mono-oxygenases in the physiological state of the brain. During recent years great advances have been made in investigating enzymes of the central nervous system, especially those affecting metabolism of the biogenetic amines involved in the specific functions of nerve cells. Such amines include tyramine, dopamine, adrenaline, noradrenaline, serotonine, etc. Their biosynthesis and catabolism are regulated by the activity of enzyme systems, in particular mono-oxygenases, and govern the normal physiological state of the brain[63]. In the nerve endings and in certain compartments of the cerebrum tyrosine

hydroxylase catalyses the hydroxylation of tyrosine to 3',4'-dihydroxyphenylalanine[64]:



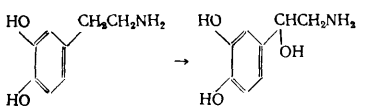
The purified enzyme was obtained from the medullary layer of bovine adrenal glands[64]. The search for multiple forms of tyrosine hydroxylase is continuing. This enzyme is active under aerobic conditions in the presence of tetrahydrofolic acid or 2-amino-5,6,7,8-tetrahydro--4-hydroxy-6,7-dimethylpteridine and of Fe^{2+} and K^+ ions[65]. It is inhibited *in vitro* by amino-acids and their derivatives, in particular by noradrenaline, catechols, and indoles. Normally it hydroxylates only tyrosine. In Parkinson's disease the hydroxylation is assumed to be possible of dihydroxyphenylethylamine, whose injection into animals causes "chemical sympathectomy", i.e. cessation of the functions of the nerve cells mediated by pulses of noradrenaline, and also complete inhibition of the activity of tyrosine hydroxylase[66].

Tryptophan hydroxylase, which catalyses the hydroxylation of tryptophan to 5'-hydroxytryptophan



has been detected in brain[67-70], especially in the stem[71]. The purified enzyme has been obtained from bovine brain[71]. The presence of 2-amino-5,6,7,8-tetrahydro-4-hydroxy--6,7-dimethylpteridine is necessary for functioning of the enzyme. In contrast to the liver enzyme, brain tryptophan hydroxylase hydroxylates only *L*-tryptophan at position 5. The hydroxylation of tryptophan limits the rate of biosynthesis of serotonine in the brain[72].

Dopamine β-hydroxylase, which catalyses the hydroxylation of dopamine to noradrenaline



was identified as early as 1964. It catalyses the concluding stage in the biosynthesis of noradrenaline, which mediates the nervous impulses in the synapses of the sympathetic nervous system. The development of certain forms of psychic depression is attributed to an insufficiency of adrenaline. Many psychotropic agents change the noradrenaline content of the brain. Accumulation of excess of noradrenaline in a cell inhibits further hydroxylation of dopamine.

III. TYPES OF REACTIONS CATALYSED BY MONO-OXYGENASES

The reactions catalysed by mono-oxygenases are extremely diverse (Table 2). Liver microsomes are able to metabolise substances of various structures, i.e. to effect various reactions, among which the most common is the hydroxylation of aliphatic compounds. In practice this is the most important reaction in the microbiological transformation of steroidal compounds[8,9]. Steroid hydroxylases of micro-organisms are known for almost all positions in the steroid system—ring system, side-chain, angular methyl groups—but all the hydroxylations studied in the steroid series occurred at a saturated carbon atom. Steroid hydroxylases are met not only in micro-organisms but also, as already noted, in animal tissues[78-80]. Fermentation by micro-organisms usually introduces one oxygen atom—more rarely two atoms—into the steroid molecule. Liver microsomes oxidise the terminal groups of aliphatic hydrocarbons to primary alcohols[53] and effect the ω-hydroxylation of aliphatic acids to ω-hydroxy-acids[53,81-84]:

$$CH_3(CH_2)_nCOOH \rightarrow HOCH_2(CH_2)_nCOOH.$$

The second most common reaction catalysed by mono-oxygenases is the hydroxylation of aromatic systems[47,48,55,56,60,85] with the formation of phenols. This reaction plays an important part in the metabolism of aromatic amino-acids. The position of the entering hydroxy-group is often determined by the presence of functional substituents in the aromatic ring.

Table 2. Reactions catalysed by mono-oxygenase enzymes.

Type of reaction	Reaction	Ref.
1. Hydroxylation of aliphatic compounds		12, 14, 30–40, 73, 74
2. Hydroxylation of aromatic compounds	$ArH \rightarrow ArOH$	47, 48, 55, 56, 60, 64, 67–70
3. Epoxidation		8, 9, 75
4. Formation of lactones		76
5. Deamination		4
6. Oxidative *N*-, *O*-, and *S*-dealkylation	$C_6H_5OCH_3 \rightarrow C_6H_5OH + CH_2O$ 	14
7. *N*-Hydroxylation and *N*-oxidation		77
8. Formation of sulphoxides		12

Epoxidation occurs in microbiological transformations of unsaturated steroids[8,9]. Enzymic formation of α-oxides has now been described from Δ^5-, $\Delta^{9(11)}$-, Δ^{11}-, and Δ^{14}-steroids. The epoxidation and the hydroxylation of steroids are very often accomplished by the same enzyme system[8]. Fat-soluble amines are deaminated in the presence of mono-oxygenases, being converted into ketones and ammonia. Amphetamine and its analogues undergo this reaction in the animal liver. Mono-oxygenases catalyse also *N*-, *O*-, and *S*-dealkylation, hydroxylate at a nitrogen atom, and oxidise substrates at nitrogen and sulphur atoms.

With all their variety the reactions of mono-oxygenases have an important common feature: only one oxygen atom is transferred to the substrate by the reaction.

IV. COMPOSITION AND PROPERTIES OF MONO-OXYGENASE ENZYME SYSTEMS

Hydroxylating enzyme systems are complicated multicomponent protein structures. All mono-oxygenases can be divided into two large groups: the first group includes *enzymes containing no metal ion or complex*; the second group comprises *enzymes containing one or more metal atoms*, which are therefore metal proteins.

Examples of this first group of enzymes are imidazolyl acetate mono-oxygenase [14] (the electron donor for which is NADH, while the prosthetic group contains flavin adenine dinucleotide (FAD) and is a flavoprotein), kynurenine 3-mono-oxygenase [41,42,86,87], salicylate hydroxylase [73], *p*-hydroxybenzoate hydroxylase [74], and *L*-lysine mono-oxygenase [88]. The prosthetic groups of these enzymes are usually FAD-containing proteins [89-93]. The kinetics and the mechanism of the action of enzymes of this group will be discussed in detail in Section V.

Enzymes of the second group, which contain a metal ion, are more numerous and have been more thoroughly studied. Among them is tyrosinase, a copper protein, the cosubstrate being an *O*-dihydroxyphenol reaction product [94]. Dopamine β-mono-oxygenase contains two copper atoms per enzyme molecule [95]. Phenylalanine hydroxylase, containing 1–2 iron atoms per enzyme molecule, has now been well studied [96-100]; the enzyme isolated from rat liver exists in two forms separable by electrophoresis, each of which may be either a monomer, a dimer, or a tetramer (with respective molecular weights 51 000–55 000, 110 000, and 210 000). The dimers dissociate into the monomeric form when the enzyme is diluted and the temperature is raised from 0 to 30°C.[96] The stoichiometry of the reaction of phenylalanine hydroxylase can be expressed

Tetrahydropterin + Phenylalanine + O_2 → Quinonoid dehydropterin + Tyrosine + H_2O.

Tetrahydropterin is the cosubstrate undergoing dehydrogenation. The iron atom is present in the enzyme in the high-spin form of Fe^{3+}. The hydroxylase is inhibited by loss of the iron atom or on addition of a compound which chelates the metal. The electron spin resonance spectrum of purified phenylalanine hydroxylase is characterised by a signal with $g = 4.23$, which is due to the high-spin form of the iron ion. Addition of a substrate to the enzyme leads to disappearance of this signal, which indicates that the iron has been reduced to Fe^{2+}. [98] The enzyme inactivated by removal of iron is reactivated by the addition of iron(II) chloride. The study of phenylalanine hydroxylase isolated from human liver by autopsy has begun quite recently [99,100]. Two forms of the enzyme—dissolved at 6000 *g* and precipitated at the same acceleration—are obtained [100]. Much in common is found between the properties of the enzymes isolated from human and rat livers. The Michaelis constant K_m varies with pH and the 2-amino-5,6,7,8-tetrahydro-4-hydroxy-6,7-dimethylpteridine concentration; at the optimum pH it is 5×10^{-4} M. [100]

Enzymes containing as prosthetic group the so called cytochrome P-450 form the largest group studied intensely during recent years. These enzymes can in turn be divided into three subgroups depending on their occurrence in Nature—mono-oxygenases in microsomes of the mammalian liver [102-112], in mitochondria of the adrenal glands, and of bacterial origin [60-62, 89-93, 118, 119]—between whose enzyme systems exist substantial differences, although they all usually contain cytochrome P-450. Scheme 1 shows for comparison the electron-transfer chains established in the three subgroups of enzymes [4].

Scheme 1

liver microsomes

NADPH → flavoprotein II → non-haemin Fe protein → cytochrome P-450 → O_2
↓
cytochrome c

adrenal mitochondria

NADPH → flavoprotein III → non-haemin Fe protein → cytochrome P-450 → O_2
(adrenodoxin)

bacterial mono-oxygenases

Methylene hydroxylase
NADPH → flavoprotein → putidaredoxin → cytochrome P-450 → O_2
ω-Hydroxylase
NADPH → flavoprotein → rubredoxin → unidentified cytochrome → O_2

Scheme 1 shows that the electron (hydrogen) donor is NADPH, or NADH in the case of bacterial mono-oxygenases. Hydrogen is transferred from the donor to the flavin group of the protein reductase together with an electron pair by a mechanism of hydride migration. The protein reductase is equally capable of two- and one-electron transfers. The next link in the chain of electron transfer is a protein generally containing iron and sulphur atoms, termed a non-haemin iron protein adrenodoxin with mitochondrial, putidaredoxin with methylene hydroxylase, and rubredoxin in alkane carboxylic acid systems. The role of the iron protein may be different in different cases: although its presence is not necessary in the last system, it is highly specific with methylene hydroxylase and cannot be replaced by any other protein. Putidaredoxin and adrenodoxin play a very direct part in the transfer of electrons along the chain, and we shall discuss them in greater detail later. There is as yet no direct indication of the participation of non-haemin iron in electron transfer in microsomes, although it is supposed to act as a component between flavin and cytochrome P-450.

The terminal electron carrier in microsomal, mitochondrial, and bacterial chains is cytochrome P-450, which has now been isolated from liver microsomes [101-105], adrenal mitochondria [113-116], and bacteria [118,119]. It is a haem protein, which in the reduced state forms with a molecule of carbon monoxide a stable complex having an absorption maximum at 450 nm. The cytochrome is oxidised fairly readily by molecular oxygen, and can be reduced again with NADPH or dithionite. It contains not only iron but also copper. Treatment with proteases, amides, ketones, phenols, and anilines converts the cytochrome into a form possessing no enzymic activity, with the Soret band of the carbonyl complex at 420 nm, which is characteristic of other cytochromes. The spectrum of the oxidised form of cytochrome P-450 contains absorption maxima at 360, 416, 535, 570, and 650 nm. The enzyme from liver microsomes contains a mixture of low-spin and high-spin forms of iron. The spectrum of the reduced enzyme is distinguished by a low absorption coefficient and displacement of the Soret band to shorter wavelengths with maxima at 412 and 557 nm. In the oxidised state, cytochrome P-450 from liver microsomes gives an e.s.r. signal with components g_x, g_y, and g_z of the *g*-factor of 1.91, 2.25, and 2.41 respectively. This signal characterises a low-spin state of tervalent iron in an asymmetric environment. The low-spin form of the cytochrome passes into a high-spin form with an anisotropic e.s.r. signal either at low pH or on treatment with thiol inhibitors. The cytochrome from liver microsomes contains a lipid component, which confers on it the ability to combine with hydrophobic compounds. It has recently been shown [120] that reduced cytochrome P-450 from microsomes forms with molecular oxygen a complex having an absorption maximum at 440 nm, twenty times as rapidly

as the carbonyl derivative: the rate constants for the interaction of cytochrome P-450 with molecular oxygen and with carbon monoxide at 25°C are respectively 4.4×10^6 and 2.4×10^5 M^{-1} s^{-1}. Cytochrome P-450 isolated from the mitochondria of adrenal glands differs little from liver samples. Specimens from the two sources have analogous optical and e.s.r. spectra [114].

The cytochrome isolated from camphor-oxidising microorganisms is now the most thoroughly studied [118,119,121]. Its optical and e.s.r. spectra have been well investigated, as well as its Mössbauer spectra, for which the natural cytochrome was enriched with the iron-57 isotope. In the presence of the substrate (camphor) the oxidised cytochrome consists of a mixture of high-spin ($S = 5/2$) and low-spin ($\frac{1}{2}$) haem iron Fe^{3+}. Removal of camphor converts the former into the latter form of iron. Anaerobic reduction of cytochrome P-450 gives the high-spin form of Fe^{2+} ($S = 2$), no paramagnetic effects being observed even in a strong field. The Mössbauer spectra of cytochrome $P\text{-}450_{camph}$ are analogous to those of oxygenated haemoglobin. Cytochrome $P\text{-}450_{camph}$ is a protein of molecular weight 45 000 consisting of a polypeptide chain and iron protoporphyrin IX. Axial coordination of haem P-450 still remains an open question: it is assumed merely that cysteine sulphur and histidine nitrogen are axial ligands. The reduced enzyme gives a complex with molecular oxygen, which has been observed by optical methods [118,121]: a new spectral band appears with maxima at 555, 418, and 355 nm. [118] This is accompanied by disappearance of the e.s.r. signal having $g = 2.26$, characteristic of the low-spin Fe^{3+} form. The complex cytochrome $P\text{-}450_{camph} \rightarrow O_2$ is fairly stable at low temperatures (4–8°C), but is slowly converted into the high-spin form of Fe^{3+} on standing. Thus the haem nature of P-450 cytochromes has now been firmly established, as has their direct participation in the hydroxylation of various substrates. Formation of an oxygenated derivative of the cytochromes on enzymic hydroxylation has been proved.

Cytochrome P-450 is preceded in the electron-transfer chain by so called iron- and sulphur-containing proteins, which are distinguished from other iron-containing proteins by the fact that the metal is not attached to complexing organic ligands [122]. In rubredoxin a single iron atom is coordinated with four cysteine sulphur atoms. The biological role of rubredoxin is not always clear: it consists mostly in electron transfer. In steroid-hydroxylating systems this protein is termed adrenodoxin. It has been isolated in a free form [117] and has been well characterised. Adrenodoxin contains 2 g-atoms of iron and 2 moles of labile sulphur per mole of protein; its molecular weight is 12 500 and its simple polypeptide chain contains 114 amino-acids. The structure of the active centre is dinuclear–tetrahedral. The most recent value [114] for the redox potential of adrenodoxin is −0.27 V at pH 7.0. Adrenodoxin can be completely reduced by dithionite, NADPH, or adrenodoxin reductase.

A protein named putidaredoxin, which contains both iron and sulphur, plays an especially important part in the hydroxylation of camphor: it ensures transfer of a second electron to the ternary complex of cytochrome with the substrate and oxygen [119]. Putidaredoxin is very specific, and cannot be replaced by another sulphur-containing protein, e.g. adrenodoxin, a component of steroid 11 β-hydroxylase. Yet NADH dehydrogenase can be replaced by a different dehydrogenase, in the electron-transfer chain of the camphor-hydroxylating system, without loss of enzymic activity. Physicochemical investigation of putidaredoxin (by magnetic susceptibility, electron spin resonance, electron–nuclear double resonance, Mössbauer spectra, and circular dichroism spectra) indicates the presence of two iron atoms in the oxidised form in a high-spin state ($S = 5/2$). Thus it has been established that in several cases a non-haemin protein takes part in the transfer of electrons during the hydroxylation of a substrate, although its presence is not necessary in a paraffin-acidifying system.

Non-haemin proteins are preceded in the electron-transfer chain by protein reductases, usually flavoproteins capable of transferring two electrons. The reductase isolated from a system effecting the enzymic ω-oxidation of aliphatic acids contains FAD as prosthetic group (1 mole $mole^{-1}$ protein) and has molecular weight 55 000. [84] The reductase is very specific, interacting with rubredoxin to give a complex of dissociation constant 2.1×10^{-7} M. The activation energy of the enzyme-catalysed reduction of rubredoxin by NADH is 5.4 kcal $mole^{-1}$.

Thus hydroxylating enzyme systems are composite multicomponent protein structures. Every component effects the transfer of electrons. Many obscurities and mysteries still remain in the structure and properties of individual parts of enzyme systems.

V. KINETICS AND MECHANISM OF THE ACTION OF MONO-OXYGENASES

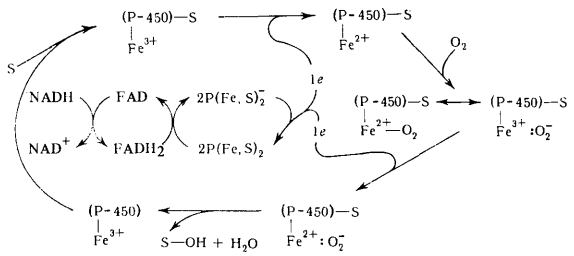
Kinetic study of the reactions of mono-oxygenases and measurement of the rates of individual stages in the composite enzymic process will provide valuable information on the mechanism of the action of these enzymes. It must be remembered, however, that study of the mechanism on extracts and even on purified preparations almost always yields only tentative conclusions on the mechanism of the oxidising stage.

Quantitative data have now been obtained for various stages in the oxidation of camphor in the presence of methylene hydroxylase [118,121,123,124]. Cytochrome P-450 reacts at very high rates with molecular oxygen to give a complex. The rate constant of formation of the camphor complex of this enzyme is 3.7×10^6 M^{-1} s^{-1} at 8°C [123], and the equilibrium constant of the complex is 0.47×10^6 M^{-1}. The enzyme–substrate complex itself has been isolated in the crystalline state [124]. It has been firmly established that oxidised cytochrome adds camphor, after which it acquires an electron. The enzyme–substrate complex then adds oxygen to form an enzyme–substrate–O_2 ternary complex, which acquires a second electron to form oxidised camphor and oxidised cytochrome. The rate of addition of camphor and oxygen to the enzyme exceeds hundredfold the rate of formation of the product. From the kinetic measurements and analysis of the functions of the component parts Scheme 2 has been suggested for the action of the methylene-hydroxylating system (S is the substrate, and S–OH the oxidised substrate). A distinguishing feature of Scheme 2 [121] is that both electrons for the reduction of oxygen are supplied by putidaredoxin.

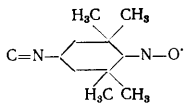
Study of the redox cycle of cytochrome P-450 from liver microsomes has shown that it involves formation of an oxygenated intermediate of the reduced cytochrome. This intermediate was detected by differential spectrophotometry, and the kinetics of its appearance has been studied. The rate constant of the reaction between cytochrome and oxygen has recently been measured, by stopped-flow flash photolysis, as 4.4×10^6 M^{-1} s^{-1} at 25°C. [120] Scheme 3 shows the course of electron transfer

in liver microsomes during hydroxylation of the substrate[103]. Here the electron donor for the oxygenated form of reduced cytochrome P-450 is cytochrome b_5.

Scheme 2

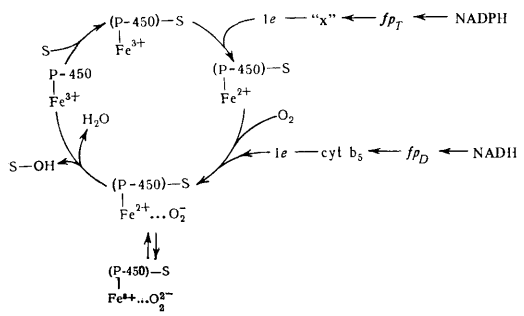


The spin-label method[110-112] has recently been used to study the molecular structure and the mechanism of the action of cytochrome P-450. The enzyme from liver microsomes interacted with the isocyanide spin-label



with the appearance of absorption bands around 435 and 455 nm characteristic of isocyanide derivatives of cytochrome. The e.s.r. spectra of liver microsomes treated with the spin-label suggest considerable retardation of the molecular motion of the latter, caused by its hydrophobic environment. The frequency of molecular rotation of the label increases on addition of the substrate to be hydroxylated (hexobarbital). The form of the e.s.r. spectra of the label indicates that the haem molecules to which it is attached are far apart and do not form dimeric structures. The active centre of cytochrome P-450 is assumed to be a haem group surrounded by non-polar amino-acid residues, whose spatial arrangement relative to the haem changes in definite fashion on interaction of the cytochrome with substrates.

Scheme 3



Considering now the mechanism of the action of metal-free mono-oxygenases, we note that the stopped-flow technique has been used to elucidate certain aspects of the reaction mechanism of salicylic hydroxylase from *Pseudomonas putida*[92]. With pH 7.0 at 25°C the rate constant of attachment of the enzyme to the substrate is 1.8×10^7 M^{-1} s^{-1}, while that of the reverse reaction is 62 s^{-1}. Denoting the enzyme, flavin, and substrate as E, F, and S respectively, we can write the reaction

$$EF{-}S + NADH + H^+ \rightarrow X_1 \xrightarrow{k=230\ s^{-1}} EFH_2{-}S + NAD^+$$
$$EFH_2{-}S + O_2 \rightarrow X_2 \xrightarrow{k=21\ s^{-1}} EF + \text{catechol} + CO_2 + H_2O$$

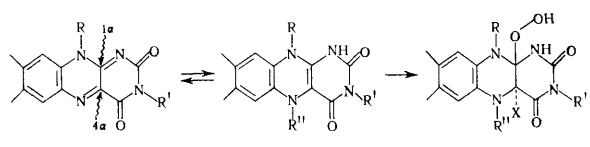
in which EF–S and EFH_2–S are the oxidised and the reduced complexes respectively, while X_1 and X_2 are kinetically active species. The rate of reduction of flavin in the presence of salicylate exceeds the rate in its absence by a factor exceeding 2000. The limiting stage of the whole process is oxidation of the reduced complex by an oxygen molecule.

Use of the stopped-flow method to study the kinetics of the formation of the enzyme–substrate complex of *p*-hydroxybenzoic hydroxylase shows[89] that the rate of complex formation is very high, and the reaction itself takes place in two stages

$$EF + S \underset{k_2}{\overset{k_1}{\rightleftarrows}} EF \sim S \underset{k_4}{\overset{k_3}{\rightleftarrows}} EF{-}S$$

the first of which is far more rapid than the second (k_3 = 480 s^{-1} and k_4 = 140 s^{-1}). The multistage character may be due to isomerisation of the enzyme–substrate complex or to conformational changes in the enzyme. Examples of the multistage formation of complexes with substrates are known also for enzymes of other classes[125-128]. Thus multistage interaction of enzyme with substrate has been found in ribonuclease–cytidine 3-phosphate, chymotrypsin–proflavin, lysozyme–oligosaccharide, etc. systems. The reaction of *p*-hydroxybenzoic hydroxylase from the microorganism *Pseudomonas fluorescens* with a 2,4-dihydroxybenzoate in the presence of NADH and molecular oxygen has now been studied in stages. The anaerobic reduction of the complex of *p*-hydroxybenzoic hydroxylase with the 2,4-dihydroxybenzoate by NADH has been studied spectrophotometrically by the stopped-flow technique, and formation of at least three intermediate compounds has been shown during the process. All three intermediates absorb in the long-wavelength region, and exhibit no e.s.r. signals. Oxidation of the reduced enzyme–substrate complex by oxygen has also been studied, and an intermediate—an oxygenated form of the flavin prosthetic group attached to the enzyme—has been clearly recorded. The second intermediate was identified as an oxidised "enzyme–product" complex; it undergoes conversion at a rate close to the maximum rate of an enzymic process. The suggested[90] oxygenated intermediate of flavins has been detected quite recently when completely reduced flavin and the flavoprotein interact with singlet molecular oxygen[129]. The structure of the oxygenated flavin was established from the absorption spectra and by means of a high-resolution mass spectrometer fitted with a computer. The oxygenated form is characterised by absorption at 500–680 nm and a peak at 375 nm.

Scheme 4

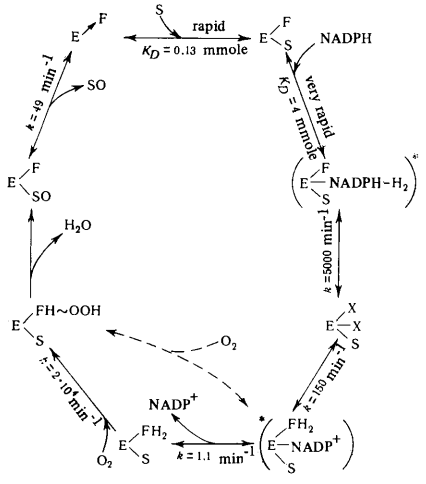


where X = $-OCH_3$; $-SCH_2CH(NH_2)COOCH_3$

Scheme 4 represents the formation of oxygenated flavin with oxygen in its first excited state ($^1\Delta g$). Oxygen attacks position 1α, with formation of a hydroperoxy-derivative of flavin. The mechanism depicted in Scheme 5 was suggested[90,91] on the basis of kinetic investigations for the interaction of *p*-hydroxybenzoic hydroxylase with the 2,4-hydroxybenzoate substrate, F being flavin attached to the enzyme E, the X unidentified species, and SO 2,3,4-trihydroxybenzoate, while the asterisk denotes charge-transfer complexes. Scheme 5 shows that the slowest

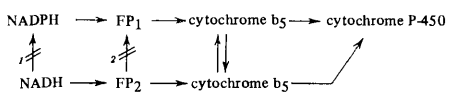
stage in the reaction is charge transfer in the enzyme–substrate–NADP complex ($k = 1.1$ min^{-1}). The other stages occur much more rapidly. Formation of an oxygenated flavin derivative in the enzyme–substrate complex precedes transfer of an oxygen atom to the substrate.

Scheme 5



Investigation of the prestationary and steady-state kinetics of the reactions of mono-oxygenase enzymes provides indications of the limiting stage in the overall enzymic process and of the intermediate complexes responsible for activating molecular oxygen. Experience shows that hydrophobic interaction of the substrate with hydrophobic (e.g. lipid) portions of the enzyme molecules alone is insufficient for the enzymic reaction to occur[109–111]: the inert oxygen molecule must be activated during the reaction. This main function of mono-oxygenases is accomplished by cytochrome P-450, which forms an oxygenated intermediate compound with molecular oxygen, and by the flavin groups of mono-oxygenases free from metal ions, which form with molecular oxygen a 1α-hydroperoxy-derivative of flavin, as has definitely been proved quite recently. Thus the oxygen molecule is activated by two-electron reduction either by an iron ion or by flavin reduced in the electron-transfer chain. The two-electron reduction of oxygen involving cytochrome P-450 in Scheme 3 contains many obscurities connected with the source of the second electron for reduction, since the interaction of NADPH and NADH-specific electron-transfer chains is still not clear[130]. Recently exchange of equivalents undergoing reduction, between NADPH and NADH-specific electron-transfer chains, has been discussed[131]. In Scheme 6 this exchange occurs with the aid of cytochrome b_5. Exchanges *1* and *2* do not take place.

Scheme 6



In spite of great achievements in the kinetic study of enzymic reactions of mono-oxygenases and their individual stages, the central problem—the mechanism of the activation of oxygen—cannot yet be regarded as solved, since the structure of the active oxygen in cytochrome P-450 is completely unknown. It is clear only that transfer of an oxygen atom to the substrate is not always the limiting stage. Since direct examination of the transition state is impossible with most enzymic reactions, it becomes necessary to study model systems and model reactions reflecting individual aspects of the complicated enzymic process. Only model reactions and model systems will enable details of the activation of molecular oxygen to be elucidated.

Three methods—theoretical considerations, investigation of the properties of enzymes, and study of the mechanisms of chemical reactions and their catalysis—are available for solving the problem of establishing the mechanism of enzymic action[132]. According to Jencks, "... to understand the mechanism of catalysis of an enzymatic reaction one would first like to understand the mechanism of the non-enzymatic reaction and the means by which this reaction can be accelerated". In Section VI we shall discuss in detail problems involved in modelling the action of mono-oxygenase enzymes.

VI. METHODS OF SIMULATING MONO-OXYGENASE ENZYMES

With all the complexity of enzymes, they obey the same thermodynamic and kinetic laws as do ordinary catalysts, so that even simple catalysts simulate in some measure certain aspects of the action of enzymes. Concerning the modelling of enzymes it is Shilov's opinion that "this concept can most usefully be applied in the light of the purpose of the investigation rather than on the basis of the degree of similarity between the catalyst studied and the enzyme which this catalyst simulates". Many reviews have been published[132–138] on the simulation of enzymes. A combined approach may yield significant results, as occurred for the enzymic fixation of molecular nitrogen[137]. By learning from Nature and using chemical concepts, we can discover novel, sometimes surprising reactions.

The action of a mono-oxygenase transfers one atom of an oxygen molecule to a substrate molecule. It is therefore most advisable to study firstly ways in which oxygen is transferred to a substrate by various systems and their mechanisms. The investigation of mono-oxygenases has shown that an oxygen atom can be incorporated into a substrate only after the oxygen molecule has acquired two electrons. All systems which transfer oxygen to a substrate can be divided into two broad groups: the first group includes metal ions and complexes, whose oxidation provides two electrons for the oxygen; the second group comprises compounds of peroxide character, in which oxygen has already been activated, since it possesses these two electrons. In the former case oxidation of the substrate involves that of the metal ion or complex. In the latter case an oxygen atom is transferred directly to the substrate from the peroxy- or hydroperoxy-compound. Imitation of enzymic oxygen transfer will be more complete the wider the range of reactions which can be accomplished by the suggested model for mono-oxygenase (Table 3). *N*-Oxides, ozone, and oxo-anions of metal salts are also able to transfer oxygen to a substrate.

Henceforward we shall discuss in detail the reactions of each group of suggested model systems and the mechanism of their action. The most interesting are the first group of systems, containing a metal ion or complex together with molecular oxygen. Table 3 lists several such systems (with aromatic substrates the proportions of isomeric phenols formed are given in the sequence—*ortho* : *meta* : *para*).

Table 3. Systems containing a metal ion or complex and molecular oxygen.

System	Substrate	Products	Ref.
Fe^{2+} + ascorbate	dehydroepiandrosterone	7-hydroxyandrostenones	139
Fe^{2+} + ascorbate	cortexolone	cortisol + cortisone	140,141
Fe^{2+} + ascorbate + EDTA	anisole	methoxyphenols 43:18:39	142
Fe^{2+} + 2,4,5-triamino-6-hydroxypyrimidine	anisole	methoxyphenols 49:13:38	143
Fe^{2+} + thiosalicylic acid	acetanilide	phenols 57:3:40	144
Fe^{2+} + thiosalicylic acid	toluene	cresols 61:13:16	144
Fe^{2+} + thiosalicylic acid	napthalene	1-naphthol 11% 2-naphthol 9%	144
Fe^{2+} + *N*-benzyl-1,4-dihydronicotinamide	arene	hydroxyarene	145

Table 4 sets out the reactions of peroxy-acids and of several peroxy-compounds [158–173] with a series of substrates, to which oxygen is transferred on the pattern of the action of mono-oxygenases containing flavoproteins but no metal ion or complex. Reactions of peroxy-acids with alkenes are omitted from Table 4, for their mechanism and kinetics have been thoroughly studied [174]. Aromatic substrates are treated as in Table 3.

Table 4. Reactions of peroxy-acids and peroxide compounds.

*L_1 = Hexametapol; $L_2 = H_2O$.

Model systems of the first type (Table 3) can in turn be divided into two subgroups: the first subgroup—tin(II) hydrogen orthophosphate, tin(II) and molybdenum(III) chlorides, and hexacarbonylmolybdenum—contains a metal ion capable of transferring not one but two or more electrons; the second subgroup includes a metal ion capable of one-electron transfer and a redox-active ligand—ascorbic acid, thiosalicylic acid, tetrahydropterin, and pyrimidines. Table 3 shows that model systems of the first type effect the hydroxylation of aliphatic [139–141, 151, 154] and aromatic [142–147, 155, 156] compounds, and also oxidise triphenylphosphine to its oxide [157]. Furthermore, systems containing an Fe^{2+} ion and a redox-active ligand can convert alkenes into epoxides [138]. Thus model systems of the first type accomplish many of the reactions catalysed by mono-oxygenases (Table 2). The most important task is to recognise the species containing active oxygen and capable of accomplishing all the reactions enumerated in Table 3. The radicals HO· and HO_2· are possible active species, but these free radicals cannot be the activated forms of oxygen in enzyme systems, since they would destroy the cell. They can be stabilised by metal ions: HO_2· is converted into FeO_2^{2+} (complex III) on interaction with Fe^{3+}, but HO· forms FeO^{2+} (complex II). In such a stabilised state the radicals HO· and HO_2· may be oxygen carriers in biological oxidation. An important characteristic of a species attacking an aromatic substrate is the distribution of isomers and the orienting influence of the substituent in the benzene ring. For all the cases listed in Table 3 the distribution of isomeric phenols differs significantly from that typical of HO· radicals generated by various methods—with Fenton's reagent,

radiolytically, etc.[2]—which means that these radicals are not the active intermediate for all the systems investigated. Several workers have suggested that the radical $HO_2^{\cdot}$ may act as attacking species for the $TiCl_3 + O_2$ and $Sn^{2+} + O_2$ systems[152]. The distribution of isomeric phenols indicates that the substrate is attacked by a less electrophilic species than HO· ; yet it is well known that $HO_2^{\cdot}$ is more electrophilic than HO· (with electron affinities respectively of 3.04 and 2.65 eV—Ref. 1, p. 207). Thus either the radical $HO_2^{\cdot}$ is unable to function as the active species or it does so in a less electrophilic state than that of HO· , as a consequence of interaction with the solvent (hydrogen bonding). It is noteworthy also that $HO_2^{\cdot}$ may be less active towards aliphatic and aromatic substrates than is HO· .[2,175] The hydroxylating ability of the former radical towards aromatic compounds has been convincingly proved by one of the Reviewers[2], yet the activity of HO· towards indigodisulphonate exceeds that of $HO_2^{\cdot}$ by factors of 10^6.[175]

Study of the $Sn^{2+} + O_2$ system is of great value in the choice between the radical $HO_2^{\cdot}$ and other attacking species. It is well known that the Sn^{2+} ion can be oxidised either successively through Sn^{3+} or directly to Sn^{4+} with simultaneous loss of two electrons[176]. In the two-electron oxidation oxygen is transferred to the substrate according to the equations

$$Sn^{2+} + O_2 \rightleftarrows [Sn^{2+}O_2]$$
$$[Sn^{2+}O_2] + S \rightarrow Sn^{4+}O + SO$$

a simple scheme suggested by Ullrich[152]. It has been proved, however, that in aqueous solution oxidation of the Sn^{2+} ion by molecular oxygen has a radical-chain mechanism[176,177]:

$$Sn^{2+} + O_2 \xrightarrow{H^+} Sn^{3+} + HO_2^{\cdot}$$
$$Sn^{2+} + O_2 \xrightarrow{H^+} Sn^{4+} + HO_2^{\cdot}$$
$$Sn^{2+} + HO_2^{\cdot} \xrightarrow{H^+} Sn^{3+} + H_2O_2$$
$$Sn^{2+} + H_2O \xrightarrow{2H^+} Sn^{4+} + 2H_2O$$
$$Sn^{3+} + Sn^{3+} \rightarrow Sn^{2+} + Sn^{4+} .$$

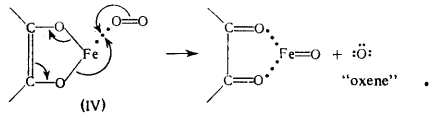
The retarding effect of inhibitors—4-methyl-3,6-di-*p*-tolyliminocyclohexa-1,4-dienylamine, potassium trioxalatocobaltate, etc.—confirms the radical-chain mechanism of the oxidation of tin(II) in aqeuous solution[176]. Thus in aqueous solutions or in aqueous-alcohol and aqueous-acetone mixtures the hydroxylating species may be either the $HO_2^{\cdot}$ radical or a complex of oxygen with the Sn^{2+} or Sn^{3+} ion. The kinetics of the oxidation of Sn^{2+} by oxygen has been investigated in an aprotic solvent (acetone), as well as the hydroxylation of cyclohexane under these conditions, in order to choose between these possibilities[154]. The $HO_2^{\cdot}$ radical cannot be formed during the oxidation of Sn^{2+} in acetone: thus cyclohexane is hydroxylated by tin-oxygen complexes, since the radical-ion O_2^-, formed by the transfer of one electron from the tin ion to oxygen, is devoid of hydroxylating power. The stoichiometry of the reaction in acetone is that one Sn^{2+} ion oxidises two oxygen molecules, which means that simultaneous transfer of two electrons from the tin(II) ion to oxygen, as is assumed by Ullrich, is impossible. The Sn^{2+} ion is oxidised by oxygen in two steps:

$$Sn^{2+} + O_2 \rightleftarrows \underset{(I)}{[Sn^{2+} \cdots O_2]} \rightleftarrows \underset{(II)}{[Sn^{3+} \cdots O_2^-]} \rightarrow Sn^{3+} + O_2^-$$
$$Sn^{3+} + O_2 \rightarrow \underset{(III)}{[Sn^{3+} \cdots O_2]} \rightarrow Sn^{4+} + O_2^-$$
$$O_2^- + O_2^- \rightarrow \text{Recombination} .$$

Such a scheme for the oxidation of Sn^{2+} in acetone is supported by the observed stoichiometry and also by the high rate constant of 100 $M^{-1}\ s^{-1}$ at 25 °C for the recombination of O_2^- radical-ions[178]. The O_2^{2-} ion is not usually formed in aprotic media, since it is stable only in aqueous solutions and in crystals[179]. Tin-oxygen complexes—$[Sn^{2+} \ldots O_2]$, $[Sn^{3+} \ldots O_2^-]$, or $[Sn^{3+} \ldots O_2]$—may possess hydroxylating power in an aprotic medium. It is difficult to choose between these three forms of activated oxygen; it is clear only that the activated oxygen in the complex has a radical character, since the hydroxylation of cyclohexane in acetone is retarded by the addition of inhibitors of radical reactions.

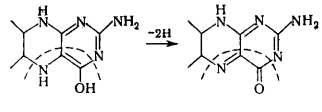
It is important to note that direct participation of the metal ion in hydroxylation and its effect on the distribution of isomers in the hydroxylation of aromatic compounds have been reliably established with other systems, e.g. Fe^{2+}–EDTA–O_2, so that the authors[145] speak of the hydroxylating power of the $[Fe^{2+} \ldots O_2]$ complex. Comparison of the distribution of isomers for a given substrate, e.g. toluene, obtained with oxygen and the Fe^{2+}, Sn^{2+}, Ti^{3+}, and Cu^+ ions shows that the isomeric composition of the cresols is strongly dependent on the metal ion[145]. If the radicals $HO_2^{\cdot}$, formed in the oxidation of all the above ions in aqueous solution, had been the hydroxylating species, the nature of the cation would not have influenced the distribution of isomers. Hence the hydroxylating species is a complex of the metal cation with oxygen, which shows variation in electrophilic strength on passing from one metal to another. The variation in the electrophilicity of species attacking the substrate is responsible for the difference in distribution of isomers. At high ionic concentrations the distribution becomes random—40 : 40 : 20—probably owing to a change in the mechanism of hydroxylation[145].

It is very important how an oxygen atom is transferred from the metal complex to the substrate. Hamilton noted that most reactions catalysed by mono-oxygenases and certain of their models are analogous to those of the very reactive carbenes CR_2 and nitrenes NR, which have six electrons around the carbon or nitrogen atom. Carbenes are incorporated at carbon-hydrogen bonds into aliphatic and aromatic compounds and add to alkenes to give cycloalkanes[138,143,180]. Reactions of the same type are accomplished by mono-oxygenases and their models. An oxygen atom, which has six electrons in the outer shell, may be the analogue of a carbene or a nitrene. However, oxygen cannot be generated in the enzymic processes. Hamilton therefore suggested that the oxygen atom is transferred to the substrate from an oxenoid complex, so called by analogy with carbenoids, which contain a combined carbene transferable to a substrate in the transition state. The oxygen molecule forms an oxenoid by interaction with a complex of the Fe^{2+} ion and a redox-active ligand such as ascorbic acid, tetrahydropteridine, etc. :



(IV)

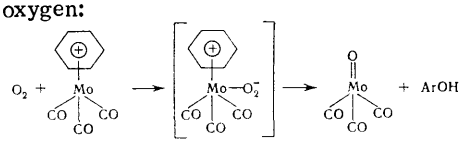
A complex similar to (IV) can be formed from tetrahydropteridine, involving the atoms segregated by the broken curve[138]:



The function of the Fe^{2+} ion in the complex (IV) consists in combining in the transition state with the reducing agent and oxygen to transfer electrons to the latter. In this complex (IV) transfer of a singlet oxygen atom from the bound oxygen molecule to the substrate probably becomes possible in such a way that radical intermediates are not formed. Transfer of a triplet oxygen atom to the substrate is energetically less advantageous, since a triplet product SO, less stable than the singlet product, would then be formed.

Hamilton's suggested oxenoid mechanism of oxygen transfer to a substrate explains satisfactorily the ability of mono-oxygenases to catalyse hydroxylation and epoxidation. The oxenoid complex may vary in electrophilicity depending on the nature of the metal and the ligand. Moreover, this complex, which attacks the substrate, may be radical or even nucleophilic in character. This property of the oxenoid complex helps us to understand the different distribution of isomers and the different orienting influence of substituents in the benzene ring on the hydroxylation of aromatic substrates. In individual cases the electrophilic character of the active centre in an enzyme system transmitting oxygen to an aromatic substrate can be assessed on the basis of model experiments. Thus the microsomal hydroxylation of toluene yields the isomeric cresols in the proportions 59 : 13 : 28, almost identical with the distribution obtained on hydroxylation with molecular oxygen in the presence of thiosalicylic acid and Fe^{2+} ions [144]. This suggests that the active centre of the microsomal hydroxylating system (cytochrome P-450) forms with molecular oxygen a complex which acts on the substrate as a moderately electrophilic reagent. The hydroxylation of toluene by such a strong electrophilic reagent as trifluoroperacetic acid gives the proportions 78 : 2 : 20 of isomeric cresols[161]. Hence the complex which attacks the substrate in the microsomal hydroxylating system is less electrophilic than trifluoroperacetic acid, which effects the same reaction.

A reaction has recently been investigated in which molecular oxygen and the substrate to be oxidised (benzene, naphthalene, or 2-methylnaphthalene) are activated simultaneously on the same active centre, a molybdenum atom[155, 156]. These aromatic compounds are oxidised by molecular oxygen neither under physiological conditions nor even at quite high temperatures. In the presence of a complex of molybdenum with carbon monoxide (hexacarbonylmolybdenum) in acetonitrile at 70–80°C, however, they undergo oxidation to phenols and naphthols. Arenes form with this carbonyl arenetricarbonyl complexes $ArHMo(CO)_3$ in which, as in hexacarbonylmolybdenum itself, the metal is present in the zerovalent state. The molybdenum atom is able to add an oxygen molecule and transmit to it one or more electrons, i.e. to activate molecular oxygen. At the same time the aromatic ligand in the arenetricarbonyl complex carries an effective positive charge, in contrast to the uncomplexed arene: i.e. it becomes capable of nucleophilic substitution. Thus the arene, having become more electrophilic, is attacked by oxygen, and the oxygen in the complex is more strongly nucleophilic than is free molecular oxygen:



The actual transfer of an oxygen atom to the aromatic molecule may be supposed to occur by Hamilton's "oxenoid" mechanism, with intermediate formation of a thermodynamically unstable arene epoxide, which isomerises into a phenol. Study of the kinetics of the hydroxylation of aromatic compounds in the $Mo(CO)_6$–O_2 system shows that oxygen is directly involved in the reaction: the rate of accumulation of phenols is directly proportional to the partial pressure of oxygen. With all the substrates the formation of phenols is preceded by that of the arenetricarbonyl complex $ArHMo(CO)_3$, which in the case of naphthalene limits the overall rate of the process. The ArH–$Mo(CO)_6$–O_2 system resembles "internal" mono-oxygenases in its type of action, since the oxygen atom not inserted into the substrate is stabilised by the metal, which is oxidised by the reaction. Unfortunately, the variation in reactivity of the aromatic molecules investigated in this system cannot be used to make deductions on the nature of the attacking species, since the complicated sequence of reactions is limited at different stages with different substrates.

It has recently been shown that peroxy-acids are capable of the oxygen-transfer reactions typical of mono-oxygenases [15, 108]. In several cases the products formed from the same substrate by the action of peroxy-acids are identical in character with those obtained by microsomal or microbiological oxidation [108, 167]. Thus identical products are obtained by the microsomal oxidation of 4-methyl-2,6-di-t-butylphenol and by its reaction with *m*-chloroperbenzoic acid. The sequence of changes undergone by naphthalene on oxidation with peracetic acid [167] is completely analogous to the microbiological transformation of this hydrocarbon by five different species of microorganisms [181]. As already noted, some mono-oxygenases do not contain metal ions, and activate oxygen by forming intermediates with the flavin components of the hydroxylating system. These intermediate compounds are essentially hydroperoxides [89–91, 129]. Peroxy-acids and certain other peroxy-compounds are therefore able to imitate the transfer of oxygen to a substrate characteristic of mono-oxygenases [108, 158–171, 173] (Table 4). It is very important to compare the rates of transfer of oxygen by peroxy-acids and by peroxy-derivatives of flavoproteins, which requires knowledge of the rate constants for reaction of such acids with various substrates. The reactions of peroxy-acids with alkenes have been characterised quantitatively [174], but no single rate constant had been measured until recently for their reactions with aromatic and aliphatic compounds. Only recently have determinations been made of the rate constants for the reactions of peracetic acid with naphthalene and with anisole [163, 167], which were measured in the presence of a mixture of acetic acid with dichloroethane or dichloromethane. The activation energies for peracetic acid with aromatic compounds are higher than in Prilezhaev's reaction, in good agreement with the increase in nucleophilic strength on passing from arenes to alkenes. An electrophilic peroxy-acid molecule undergoes a bimolecular reaction with a nucleophilic aromatic molecule, as with an alkene. No intermediate complex of a peroxy-acid with an aromatic molecule can be detected [163, 167]. The existence of such a complex has been proved kinetically for the reaction of peracetic acid with propene [182].

The bimolecular rate constants for the reactions of peroxy-acids with aromatic compounds show that the transfer of the oxygen atom from the acid to the substrate is quite rapid: thus at room temperature (20°C) the constant for trifluoroperacetic acid with naphthalene is 10^{-3} M^{-1} s^{-1} [163], while a molecule of 1-naphthol at the same temperature reacts with peracetic acid with a rate constant of ~0.33 M^{-1} s^{-1}. [163] Roughly similar rates are

observed for the reaction of hydroperoxy-derivatives of the flavin part of *p*-hydroxybenzoic hydroxylase with a 2,4-dihydroxybenzoate [90,91].

The autoxidising dihydroalloxazines [171], which react with oxygen to form hydroperoxy-derivatives, are similar to metal-free mono-oxygenases in their action on substrates which can be hydroxylated.

Peroxo-complexes of sexivalent molybdenum

(where L_1 and L_2 are ligands), discovered in the laboratory by Sajus [183], have recently been used [172,173] to simulate the transfer of oxygen by mono-oxygenases. Kinetic study of the interaction of such complexes having two ligands (L_1 = Hexametapol and $L_2 = H_2O$) and only one ligand L_1 has shown that both complexes form an intermediate compound with the substrate, which breaks down with the formation of glycidol. One molecule of the peroxo-complex epoxidises two molecules of allyl alcohol. The rate constants k_2* of decomposition of the intermediate complex have been determined at 50°C, together with the Michaelis–Menten constants

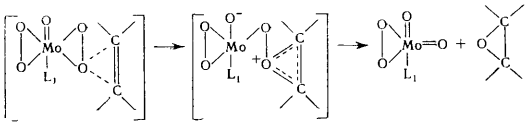
$$K_m = \frac{k_{-1} + k_2^*}{k_1}$$

where k_1 and k_{-1} are the rate constants of formation and dissociation of the intermediate complex. Table 5 gives the constants which we have obtained for both complexes at 50°C. The value $k_2 = 2.4 \times 10^9 \exp(-18300/RT)$ gave the enthalpy of activation as $\Delta H^{\neq} = 17.7$ kcal mole^{-1} and the entropy of activation as $\Delta S^{\neq} = -18.0$ cal mole^{-1} deg^{-1}. [172]

Table 5.

	K_m, M	k_2^*, s^{-1}
$MoO(O_2)_2L_1$	0.81	$9.71 \cdot 10^{-4}$
$Mo(O_2)_2L_1L_2$	0.78	$4.17 \cdot 10^{-4}$

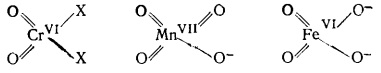
The closely similar quantitative data obtained for the two complexes and the steric hindrance to direct involvement of the molybdenum atom in interaction with the substrate suggest that the mechanism of the epoxidation of allyl alcohol by the molybdenum peroxo-complexes may be



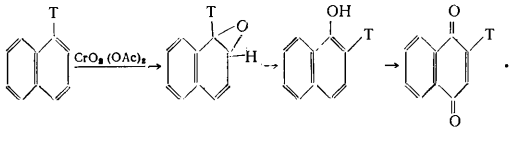
A significant feature of this mechanism is the involvement of the peroxo-oxygen atom in complex formation with allyl alcohol and the absence of direct involvement of the molybdenum atom in complex formation, which had been suggested by French workers [184]. The former mechanism is supported by the closely similar rate constants and values of K_m for the complexes with one and with two ligands, as well as by the good agreement between the activation functions of the limiting stage of the reaction and the thermodynamic functions of the epoxidation of allyl alcohol by other peroxide reagents that form a complex by means of the peroxide oxygen (Ref. 174, p. 1761).

It may be supposed, as in the above reaction scheme, that transfer of the oxygen atom to the allyl alcohol molecule takes place by an "oxenoid" mechanism. The electrophilic character of the epoxidising species is indicated by the ability of the peroxo-complex $MoO(O_2)_2L_1$ to hydroxylate naphthalene to 1-naphthol [173], the reaction being conducted in dichloroethane at 70°C. 1-Naphthol is an intermediate, undergoing further reactions with the peroxo-complex.

A team of American workers have emphasised the similarity between oxygen transfer by mono-oxygenases and by several oxo-compounds of metals of variable valency [185]



where X = OH, Cl, $OCOCH_3$. Indeed, chromyl acetate (X = $OCOCH_3$) epoxidises alkenes, potassium permanganate hydroxylates hydrocarbons [186], and chromyl chloride acetate accomplishes both reactions; oxo-compounds of lead $Pb(OCOCH_3)_{4-n}(N_3)_n$ are used for oxygenating the steroid androsta-4,9(11)-diene-3,17-dione, which is epoxidised and hydroxylated simultaneously [187]. It is well known also that the activity of a heterogeneous catalyst in oxidation is due to the presence of an M=O bond [188]. Oxygen transfer by such an oxo-compound as chromyl diacetate shows the surprising peculiarity that, in the hydroxylation of substituted aromatic substrates, this reagent can cause migration of a group from the position hydroxylated to a neighbouring position [185]:



Such migration of a substituent in an aromatic ring is very characteristic of the action of mono-oxygenases [189], and occurs in the hydroxylation of aromatic compounds by trifluoroperacetic acid [162]. Intermediate formation of arene oxides has been shown in the microsomal oxidation of aromatic compounds, without which the migration of substituents in aromatic compounds cannot be explained [162, 189–191].

Thus oxo-compounds of transition metals imitate an important feature of the action of mono-oxygenases. This suggested that in many other cases the species transferring oxygen to the substrate contains an oxo-group [185]; for example, the oxygen-transferring structures

are assumed for the iron ion. However, this hypothesis is not always confirmed in practice. The oxygen-carrying peroxo-complex of molybdenum $MoO(O_2)_2L_1$, where L_1 is hexametapol, contains two peroxo-groups and one oxo-group. Use for epoxidation of a complex labelled with the oxygen-18 isotope in the oxo-group gave an epoxide from which this isotope was absent: i.e. the oxo-group of the molybdenum(VI) complex plays no part in oxygen transfer [192]. Thus the oxo-form of the bond between metal and

oxygen is not universally present in all oxygen-transferring species.

All the reactions discussed in this Section simulate in some measure the transport of an oxygen atom to the substrate by mono-oxygenases. However, systems that generate free radicals can in no way be regarded as models, since active free radicals are incompatible with the living cell. Biochemical oxidations may involve not free radicals but their complexes with ions of metals of variable valency, e.g. complexes of HO· and HO_2· radicals with trebly charged iron ions. The study of models containing a metal ion or complex and oxygen shows that the most probable attacking species is a metal–oxygen complex. This is quite remarkable, since complex formation between oxygen and the active centre of mono-oxygenases (cytochrome P-450) has now been convincingly demonstrated. It has been shown by physical methods that the cytochrome binds the oxygen molecule by complex formation of the latter with an iron ion in the reduced state.

The study of model systems ($Fe^{2+} + O_2$, $Sn^{2+} + O_2$) has yielded numerous data confirming the hydroxylation of substrates by complexes of these ions with oxygen—involvement of the metal ion in hydroxylation, its effect on the distribution of isomers in the hydroxylation of aromatic substrates, absence of effect of added hydrogen peroxide on the reaction, the hydroxylation of arenes and the epoxidation of alkenes effected by the same system, which eliminates the HO· radical as attacking agent, the hydroxylation of substrates in aprotic media, where the formation of HO_2· is excluded, and other facts.

Hamilton's "oxenoid" mechanism appears the most probable and universal for transfer of an oxygen atom to the substrate, providing a satisfactory explanation of all experimental results obtained for model reactions and systems. The oxenoid mode of oxygen transfer most probably operates also with peroxide compounds such as peroxy-acids and peroxo-complexes of metals. These compounds well simulate oxygen transfer by mono-oxygenases having a flavin group in the active centre. Peroxy-acids, like mono-oxygenases, cause migration of a substituent from the position at which oxygen is inserted into the ring of an aromatic substrate to a neighbouring position.

The intense study of the reactions of mono-oxygenases, the isolation and purification of this group of enzymes, the investigation of the structure and the functions of component parts of the composite enzyme system, the wide use of physical methods in studying the state of the metal ion in the active centre: all this has in many cases established great certainty as to the mechanism of the action of these enzyme systems. Investigations of the prestationary and steady-state kinetics of the reactions of various mono-oxygenases have played a very important part in establishing the mechanisms discussed in this Review. However, even such a frontal attack by research workers in this field has not revealed the ultimate mechanism of the activation of molecular oxygen. Not only study of the action of the mono-oxygenases themselves but also detailed study of model systems have played a great part in elucidating individual features of this mechanism. Examination of models will enable us to ascertain the structure of the species transferring oxygen to the substrate, and perhaps indicate ways in which oxygen may be chemically activated under physiological conditions. The yields of reaction products obtained by means of model systems are still quite low, but systems have been found enabling us to follow the kinetics of the accumulation of reaction products and the valency changes undergone by metal ions occupying a leading role in these systems.

The practical value of mono-oxygenase enzymes is very great for the most diverse fields of toxicology, pharmacology, and oncology. Recent results threaten a revolution in the synthesis of several physiologically active substances. Thus 11 β-hydroxylase and Δ^{1-2}-dehydrogenase have recently been used to effect the two-step transformation of the readily available Reichtein's substance S into prednisolone [193]. This conversion is achieved by means of enzymes fixed on gel matrices and placed in two columns connected in series. Hydroxylation of substance S to cortisol takes place in the first column, and dehydrogenation to prednisolone in the second column. It may be hoped that the number of examples of such transformations by means of mono-oxygenase enzymes will increase.

Silicon-containing Ureas

V.P.Kozyukov, V.D.Sheludyakov, and V.F.Mironov

In the review an attempt is made for the first time to survey studies on the synthesis, properties, and likely practical applications of silylureas. In view of the significant differences in the methods of their synthesis and properties, *N*-silylureas are examined separately from the carbofunctional compounds in which the urea moiety and the silicon atom are separated by a group of atoms.
The bibliography includes 230 references.

CONTENTS

I. Introduction 413
II. *N*-Silylureas 413
III. Silylisoureas 423
IV. Carbofunctional organosilicon derivatives of urea 424

I. INTRODUCTION

Urea (carbamide) and its derivatives are some of the most widely used organic compounds. In recent years there has been a vigorous development of the chemistry of organic derivatives of the elements based on urea and in particular of its organosilicon derivatives. The introduction of an organosilyl substituent into the urea molecule alters sharply its physical and chemical properties. This applies especially to N-silyl derivatives. In particular, the hydrogen bonds are greatly weakened, which has found practical applications in the chromatography and separation of many urea derivatives. The high silylating capacity of *N*-silylureas has made them some of the most important auxiliary reagents in organic syntheses. There are good prospects also for practical applications of polymeric materials based on silicon-containing ureas.

N-Silylureas are of independent interest for the development of theoretical ideas on the tautomerism of amides, since, in contrast to organic derivatives of urea and amides, many physical properties of these compounds suggest that they exist in both the amide and isoamide forms.

II. *N*-SILYLUREAS

1. METHODS OF SYNTHESIS

a. Interaction of Silanes and Halogenosilanes with Ureas

The NH group in amines is known to react with halogenosilanes to form the corresponding *N*-silyl derivatives. However, this reaction is greatly hindered in the presence of the C=O group next to the amino-group[1-3], as happens in ureas, amides, urethanes, semicarbazides, and other similar compounds. When urea is acted upon by triorganohalogenosilanes under moderately mild conditions, silicon-substituted ureas are not formed[2,3] and the latter can be obtained only when metallated urea derivatives are used[4]:

$$Me_3SiCl + K[NHCONH_2] \rightarrow Me_3SiNHCONH_2 + KCl ,$$

or when the reaction is carried out in the presence of hydrogen halide acceptors[5-7].

Under severe conditions, the interaction of triorganohalogenosilanes with urea apparently leads to the formation of isocyanatosilanes in consequence of the decomposition of the intermediate quaternary salts[8]:

$$R_3SiCl + H_2N\overset{\overset{O}{\|}}{C}NH_2 \rightarrow [R_3SiNH_2\overset{\overset{O}{\|}}{C}NH_2]^+Cl^- \rightarrow R_3SiN{=}C{=}O + NH_4Cl$$

(when R = Ph, the reaction was carried out in the melt and for R = Me in an autoclave at 280–300°C).

When organotrihalogenosilanes, $SiCl_4$, and $SiBr_4$, react with urea or its alkyl and aryl derivatives, only hydrolytically unstable complexes are formed, for example[9,10]:

$$SiCl_4 \cdot 6H_2NCONH_2;\ SiBr_4 \cdot 6H_2NCONH_2;\ Si_2Cl_6 \cdot 10H_2NCONH_2$$
$$SiCl_4 \cdot 6H_2NCONHMe;\ SiCl_4 \cdot 6H_2NCONHPh;\ SiCl_4 \cdot 6H_2NCONMe_2.$$

The complexes do not have a distinct melting point and decompose into the initial components on dissolution in organic solvents, subliming with decomposition on heating to 150–200°C. The replacement of a halogen atom in silicon tetrahalide by an alkyl or alkoxy-group (but not by a hydrogen atom) reduces the coordination number with respect to urea by unity[10]:

$$MeSiCl_3 \cdot 5H_2NCONH_2;\ PhSiCl_3 \cdot 5H_2NCONH_2;\ SiHCl_3 \cdot 6H_2NCONH_2 .$$

The type of bond in the complexes formed has been studied inadequately because of the difficulties in the determination of their molecular weight and conductivity and in carrying out an exact X-ray diffraction analysis due to the decomposition of the complexes in solution and on fusion and also because of the difficulty of growing their crystals. X-Ray diffraction analysis of $SiCl_4.6H_2NCONH_2$ powder indicates a cubic crystal lattice with 7.79 Å faces[10]. The adducts of other halogenosilanes with urea have a similar lattice, which in the case of $SiBr_4$ has somewhat greater dimensions (8.11 Å). Bearing in mind the branching and considerable bulk of halogenosilane molecules and also the polarity of the silicon–halogen bond, the formation of clathrate compounds of the lattice type channel variety (the channel diameter is usually 5.1 Å), in which the halogenosilane molecule would be located within the crystal lattice of urea, is unlikely. The large number of urea molecules per halogenosilane molecule also rules out the possibility that they are incorporated as additional electron-donating ligands in the inner

sphere of the complex, partly with retention of Si–Cl bonds, as happens, for example, in the complex $SiCl_4 \cdot C_5H_5N$.[9]

On the basis of infrared spectra, which indicate a weakening of the N–H bond in the adducts, and also the identical compositions of the complexes of halogenosilanes with urea and *NN*-dimethylurea (1 : 6 in both cases for $SiCl_4$), it has been suggested[10] that ureas are linked to halogenosilanes only by one of the two amino-groups, while the other is probably involved in the formation of a hydrogen bond with another urea molecule.

In contrast to halogenosilanes, monoalkylsilanes $RSiH_3$, starting from n-hexylsilane, and di-n-alkylsilanes R_2SiH_2, starting from diethylsilane, form with urea true crystalline clathrate compounds[11–13]. In the first case the $RSiH_3$ molecules are located in the channels of the hexagonal crystal lattice of urea, like carboxylic acids, in the form of oriented double molecules[13]. The occluded di-n-alkylsilane molecules are distributed in a sequence, like their hydrocarbon analogues (paraffins)[11]. The lowest members of the above series do not form adducts with urea even at low temperatures (–15°C). Both types of clathrate compounds (with $RSiH_3$ and R_2SiH_2) are less stable than the analogous paraffin compounds, which is manifested by their dissociation into the initial components at a lower temperature. Unbranched di-n-alkoxysilanes form with urea analogous but more stable clathrate compounds[14]. Thioureas do not form adducts with the above organosilicon compounds[13,14].

Unbranched silanes such as trisilane, tetrasilane, and others (in contrast to the branched isomers) form clathrate compounds with both urea and thiourea[15], which are stable in air below their dissociation temperatures (–15°C for Si_3H_8 and 5°C for Si_4H_{10} in the adducts with urea). The stability of the adducts increases with increases in the silane chain length and falls on passing to urea and thiourea.

The clathrate compounds of higher silanes (starting from Si_5H_{12}) are stable even at room temperatures and the silanes in such compounds lose their capacity for self-ignition in air. In terms of their relative stabilities, compared with other organic and organosilicon clathrate compounds, they occupy the last place[15]: aliphatic acids > paraffins > di-n-alkoxysilanes > di-n-alkylsilanes > mono-n-alkylsilanes > silanes. The molecular diameters of certain types of silanes and their ability to form clathrate compounds with urea are indicated in the Table[11].

The formation of clathrate compounds by halogenosilanes with urea.

Silane	Molecular diameter		Formation of clathrate compounds	Silane	Molecular diameter		Formation of clathrate compounds
	max.	min.			max.	min.	
$RSiH_3$	5.1	4.3	+	$RSiCl_2R$	6.7	5.4	—
$RSiH_2R$	5.1	4.3	+	$RSiH_2OMe$	5.1	4.3	+
$RSiHCl_2$	6.6	5.4	—	$RSiH(OMe)_2$	8.5	4.3	—
$RSiCl_2$	6.6	5.7	—	$RSiH(OMe)R$	8.5	4.3	—
$RSiHClR$	6.6	5.4	—	$RSiH_2Cl$	5.3	4.3	*

Note: the + and – signs denote that the clathrate compounds are or are not formed; the asterisk (*) shows that the clathrate compounds can be formed in a non-solvating medium.

The selectivity of the action of urea with respect to normal (unbranched) silanes can be used for the preparative separation or purification of a mixture of normal silanes and isosilanes[15] as well as their alkyl and alkoxy-derivatives[11].

b. Transamination Reactions

The transamination reaction by Larsson's method[16], applied for the first time to the silylurea series in 1959 by Benneville and coworkers[5,17], proved to be a convenient procedure for the introduction of an organosilyl residue into urea with formation of the Si–N bond:

$$H_2NCONH_2 + Me_3SiNHCMe_3 \xrightarrow[12\,h]{110^\circ} Me_3SiNHCONH_2\,(89\%) + Me_3CNH_2 ,$$

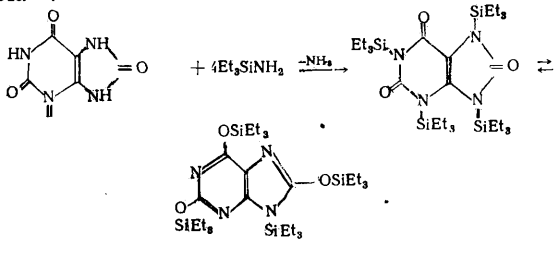
$$MeNHCONHMe + Me_3SiNHCMe_3 \rightarrow Me_3SiNCONHMe + Me_3CNH_2 .$$
$$\quad\quad\quad

resulting monotrimethylsilylacetamide can be readily removed at the end of the reaction by vacuum distillation[27].

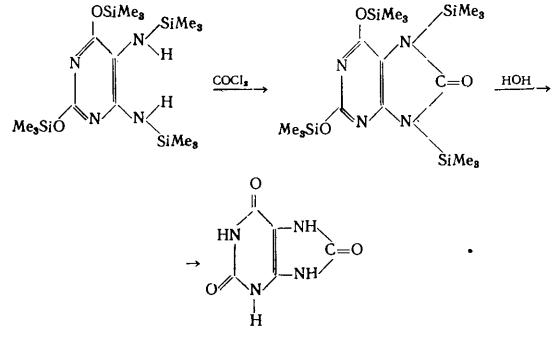
It is noteworthy that the possibility of the rapid and quantitative silylation of urea, amines, amides, and other compounds with extensive hydrogen bonding is important for organic and biological chemistry, since it makes it possible to convert high-melting non-distilling and sparingly soluble compounds into stable and volatile silyl derivatives, which are readily soluble in organic solvents and are susceptible to separation and chromatographic analysis[28,31]. The introduction of the trimethylsilyl residue as a temporary protecting group is extensively used in a wide variety of organic syntheses[32-35].

N-Silylureas, particularly those of the aromatic series, are themselves powerful silylating agents like carboxylic acid silylamides[22,25,26,36] (see also the chemical properties of *N*-silylureas). *NN'*-Diphenyl-*N*-trimethylsilylurea is particularly suitable as a donor of the trimethylsilyl group[22].

The resulting diphenylurea does not dissolve in the majority of organic solvents and therefore can be readily removed from the reaction mixture by filtration. The insolubility of diphenylurea is apparently also the reason why the equilibrium in silyl–proton exchange reactions is in this case almost wholly displaced to the right. Silylureas which could not be obtained with the aid of HMDS[18] are readily formed when a mixture of *NN'*-diphenyl-*N*-trimethylsilylurea is stirred with the corresponding urea derivative in acetonitrile at 30–35°C.[22] The reaction reaches completion in the course of several minutes or several hours for particularly sparingly soluble compounds. In particular, *NN'*-bis(trimethylsilyl)thiourea and *NN*-dimethyl-*N'*-trimethylsilylurea were obtained in this way in yields of 82 and 79% respectively. A series of cyclic analogues of urea were also synthesised by the silylation of the amide group. Thus, when uric acid is heated in triethylaminosilane, tetra(triethylsilyl)uric acid, which can exist in both lactam and lactim forms, is formed in 90% yield[37]:



When 5,6-diaminouracil reacts with HMDS, the product is 2,4-bis-(*O*-trimethylsilyl)-5,6-bis(trimethylsilylamino)-uracil, which cyclises on reaction with phosgene to form a uric acid derivative[38]; the latter cannot be obtained without using a silyl protecting group:



c. Reactions of Isocyanatosilanes with Amines

Organosilicon derivatives of urea of different structures, $R_3SiNHCON\langle$, $R_2Si(NHCON\langle)_2$, $RSi(NHCON\langle)_3$, and $Si(NHCON\langle)_4$ (where R = alkyl, aryl, or alkoxy-group), are as a rule formed in high yields by the reaction of the corresponding mono- or poly-isocyanatosilanes with aliphatic and aromatic primary and secondary amines†[18,39-50], for example:

$$Me_3SiN{=}C{=}O + Et_2NH \xrightarrow{55-60^\circ} Me_3SiNHC(=O)NEt_2 \quad (91\%)\ .$$

Exceptions are amines of low basicity (diphenylamine, HMDS) which do not react with Me_3SiNCO even under severe conditions[41], and the reaction of H_3SiNCO with NH_3 at −78°, which leads to the formation of monosilanes SiH_4 and an involatile solid residue[48].

Amines can be arranged in the following sequence in terms of their reactivities in the reaction with isocyanatosilanes[40]: $AlkNH_2 > Alk_2NH > ArNH_2 > ArNHR > Ar_2NH$. In the series of isocyanatosilanes $Si(NCO)_4$ is more reactive than in its alkyl and aryl derivatives[41,45,49].

Silylsemicarbazides were obtained by the reaction of isocyanatosilanes with hydrazines[21]:

$$Me_3SiN{=}C{=}O + H_2NNH_2 \rightarrow H_2NNHC(=O)NHSiMe_3 \quad (90\%)\ .$$

d. The Interaction of Aminosilanes and Silazanes with Organic Isocyanates

Reactions with monoisocyanates. The reactions of organoaminosilanes and silazanes with organic isocyanates, discovered in 1964 independently by several groups of workers (Zhinkin[52], Klebe[53], Oertel[54,55], and Fink and coworkers[56-58]), constitute a convenient method for the preparation of *N*-silylureas. According to the reports of Wannagat and coworkers[18,21,59,60] concerning the interaction of organic isocyanates with compounds containing simultaneously Si–N and N–H bonds (silylamines, silylhydrazines, and silylhydroxylamines) published before 1964, it was believed that the reaction involves only the N–H bond with migration of the hydrogen atom to the nitrogen atoms of the isocyanate group, for example:

$$(Me_3Si)_2NH + PhNCO \rightarrow (Me_3Si)_2NCONHPh\ .$$

However, the evidence quoted in this connection for the structure of the resulting compound, i.e. data obtained from their hydrolysis to the corresponding organic urea derivatives, cannot be regarded as convincing, since even when the reaction involves the Si–N bond, hydrolysis should yield the same results owing to the silyl–proton exchange in the *N*-silylureas[53].

A detailed study of this reaction by the above workers[26-36,52-58,61-65] and primarily by Zhinkin and coworkers[52,61-63,66,67] showed that organoaminosilanes and silazanes containing not only primary but also secondary and tertiary hydrogen atoms, i.e. compounds without N–H bonds, react with isocyanates. When Si–N and N–H bonds are present

† In early studies on reactions of isocyanatosilanes with amines it was concluded erroneously that the reaction proceeds via the elimination of the silyl group with formation of organic urea derivatives[49,51].

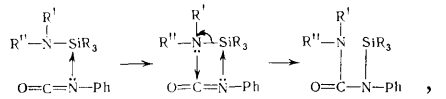
simultaneously, the latter does not take a direct part in the reaction with isocyanate, which involves preferentially the Si–N bond. The only exception‡ is the reaction of isocyanates with aminosilanes containing a primary nitrogen atom, which was shown by a study of the structure of the final product to proceed via the classical isocyanate condensation mechanism, i.e. with migration of the hydrogen atom from the nitrogen atom of the aminosilane to the nitrogen atom of the isocyanate group[62,66,70]:

$$R_3SiNH_2 + PhNCO \rightarrow R_3SiNHC(O)NHPh \quad (R=Et, Bu, Ph) .$$

When other organoaminosilanes and organosilazanes react with isocyanates in 1 : 1 proportion, the Si–N bond dissociates and the triorganosilyl group migrates to the nitrogen atom of the isocyanate with formation of organosilicon urea derivatives[26,36,52–56,58,61–63,66,71,72]:

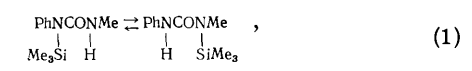
$$R_2NSiMe_3 + R'NCO \rightarrow R_2NC(O)N(R')SiMe_3 ,$$
$$(Me_3Si)_2NH + R'NCO \rightarrow Me_3SiNHC(O)N(R')SiMe_3 ,$$
$$RNHSiMe_3 + R'NCO \rightarrow RNHC(O)N(R')SiMe_3 ,$$
$$(Me_3Si)_2NR + R'NCO \rightarrow Me_3SiN(R)C(O)N(R')SiMe_3 .$$

The reaction mechanism apparently involves the formation of an unstable complex comprising four units, in which the shift of electron density to the nitrogen atom of the aminosilane or silazane weakens the Si–N bond and leads to its dissociation as well as the dissociation of the C=N π bond in the isocyanate group[63,66,73,74]:



where R′ = H or alkyl and R″ = H, alkyl, aryl, or SiR_3.

It follows from ^{1}H NMR data that silylureas with a proton and a triorganosilyl group at the N and N′ atoms respectively can be involved in the presence of a solvent in intramolecular (Scheme 1) or intermolecular (Scheme 2) proton–trimethylsilyl exchange[53]:



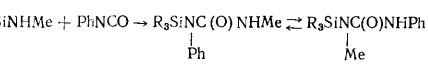
(1)

(2)

Depending on the solvent and the nature of the groups at the silicon and nitrogen atoms, the equilibrium can be displaced towards one of the isomers.

The occurrence of silyl–proton exchange was also confirmed by a study of the products of the addition of optically active *N*-(methylphenyl-α-naphthylsilyl)methylamine to phenyl isocyanate[73,74]. It was shown that the reaction proceeds with retention of the configuration at the silicon atom (its stereospecificity is greater than 90%) and the resulting optically active silylurea (IIIa) undergoes rapid racemisation in tetrahydrofuran (THF) solution and slow racemisation in benzene solution, the latter being greatly accelerated on heating§.

After compound (IIIa) has been allowed to stand for many hours, its ^{1}H NMR spectra show that it has been converted into (IIIb) as a result of the intermolecular exchange of the Me_3Si groups:



where R_3Si = (c-$C_{10}H_7$)(C_6H_5)(CH_3)Si.

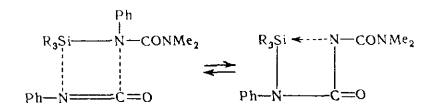
In view of the possibility of the silyl–proton exchange in silylurea, one cannot rule out the possibility that the above anomalous reaction (in the series of reactions of isocyanates with aminosilanes) with primary aminosilanes[62,66,70] in reality involves the Si–N bond and not the N–H bond, the final reaction product being formed as the result of the fast intermolecular or intramolecular silylation of the *N*-phenyl-*N*-trimethylsilylurea produced initially, which is in the present case facilitated by the presence of the free NH_2 group:

N-Silylureas formed on interaction of equimolar amounts of isocyanate and aminocyanate (or silazane) can readily enter into further reaction with the excess isocyanate and, depending on whether the urea contains only Si–N bonds or both Si–N and N–H bonds, the reaction proceeds in different ways. Silylureas without N–H bonds, obtained from tertiary silylamines R_2NSiMe_3, react with isocyanate in the same way as the initial silylamines, i.e. with migration of the triorganosilyl group to the nitrogen atom of the isocyanate. High yields of the corresponding silyl derivatives of biurets are then formed[36,57,63–65]:

The same compounds can be obtained also when an excess of isocyanate reacts directly with tertiary silylamines[63].

When silylbiurets are heated (for example in the course of their distillation), they decompose into the initial components[57], so that, depending on the temperature conditions, the compounds can be in equilibrium with the initial silylurea and isocyanate, the equilibrium can be established several times but does not result in racemisation[74].

A mechanism similar to that for the reaction of isocyanates with aminosilanes was proposed for the formation of silylbiurets and the reverse reaction involving the elimination of the isocyanate[74]:



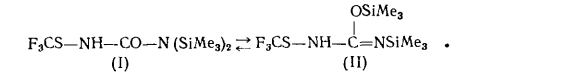
The Si–N bond in silylbiurets is more resistant to hydrolysis than in silylureas and further reaction involving this bond with the excess isocyanate does not proceed or proceeds with difficulty[57]. Fink explains this finding by

---

‡ According to Haas's data[68,69], the reaction of trifluoromethylsulphenyl isocyanate with HMDS also involves the cleavage of the N–H bond and not the Si–N bond:

$$(Me_3Si)_2NH + F_3C(S)NCO \rightarrow F_3C(S)NHC(O)N(SiMe_3)_2 .$$

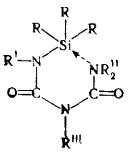
Although the ^{1}H NMR spectrum of the resulting urea has two kinds of resonances due to the Me_3Si groups, like *NN*-bis-silylamides, the authors attribute this to the hindered rotation about the C–N bond and believe that the product has structure (I) and not (II):



This conclusion was also confirmed by infrared spectroscopic data.

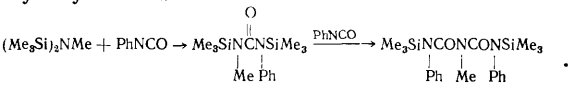
§ Kaufmann et al.[74] showed for the 1 : 1 adduct of PhNCO and the optically active silylamine (α-$C_{10}H_7$)(C_6H_5)(CH_3)SiN.$(CH_3)_2$ that silylureas without N–H bonds do not racemise.

the stabilisation of the molecule due to intramolecular coordination with formation of the following stable cyclic structure[57,64]:

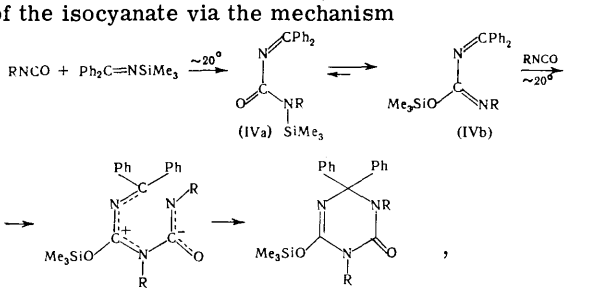


Since these compounds regenerate free isocyanate on heating and exhibit all the reactions characteristic of the isocyanate group, they have been patented as "latent" isocyanates, which are less susceptible to hydrolysis and are less volatile than free isocyanates[64].

Silylureas without N–H bonds, formed from *N*-alkylsilazanes, react with isocyanates via the same mechanism as tertiary silylamines[52,53,62,63,66]:

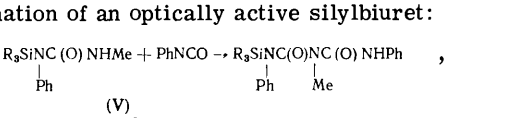


The interaction of isocyanates with diphenylmethylene-*N*-trimethylsilylamine proved to be specific[75]. For a 1 : 1 reactant ratio, the reaction proceeds selectively with cleavage of the Si–N bond to give silylureas, but, in the presence of an excess of the isocyanate, the products are not silylbiurets, as usually happens, but triazinone derivatives. The authors[75] explain this by 1,4-cycloaddition of the isomeric (imide) form of silylurea (IVb) to the C–N bond of the isocyanate via the mechanism

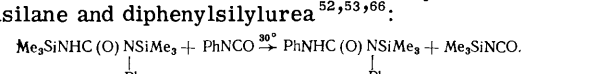


where R = Me, Ph, or PhC(O). This reaction confirms the possibility of the existence of silylureas in the isoamide form. The occurrence of the tautomeric equilibrium (IVa) ⇌ (IVb) has also been confirmed by a study of the temperature-induced changes in the ^{1}H NMR spectrum of compound (IV).[75]

The mode of reaction involving ureas containing both Si–N and N–H bonds has been studied inadequately, in many cases not at all owing to the instability of the addition products. Thus, according to the data of Kaufmann et al.,[73] when an excess of isocyanate is allowed to react with the optically active silylurea (V), the reaction involves the N–H bond with retention of the configuration and the formation of an optically active silylbiuret:



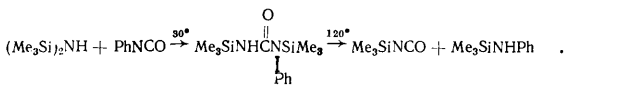
However, in the case of the silylurea containing the N–H bond and obtained from HMDS and PhNCO (1 : 1), further reaction with a second isocyanate molecule under the same mild condition leads to the formation of isocyanatotrimethylsilane and diphenylsilylurea[52,53,66]:



The same products were isolated also after the direct interaction of HMDS with PhNCO in proportions of 1 : 2.[52,63,66]

At an elevated temperature the composition of the products of the reaction of aminosilanes with isocyanates is as a rule anomalous, which is evidently due to the thermal instability of the intermediate silylureas, their tendency towards tautomeric transformations, and a number of other factors.

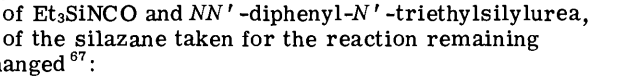
Thus at about 120°C HMDS reacts with PhNCO to form Me_3SiNCO and $PhNHSiMe_3$.[61,66] Since the same products are formed on heating *N*-phenyl-*NN'*-bis(trimethylsilyl)urea to 120°C,[61] the reaction evidently proceeds via the intermediate formation of this compound:



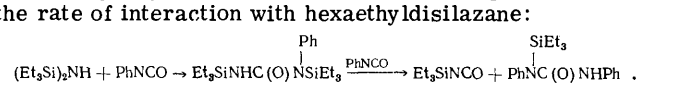
Other hexaorganodisilazanes, with the exception of hexaethyldisilazane, react similarly with PhNCO at elevated temperatures, silazanes containing different groups at the silicon atoms forming two isocyanates and two triorganosilylamines in approximately equal amounts[67]:

where R and R'' = Me or MeO and R' and R''' = Me, MeO, or Ph. The nature of the organic group linked to the silicon atom does not have a significant influence on the course of this reaction.

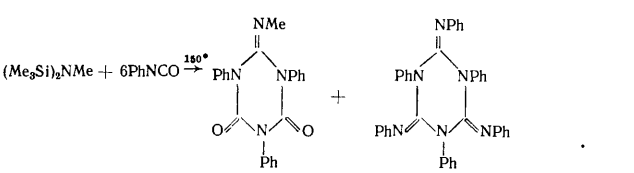
Hexaethyldisilazane reacts differently with PhNCO. Regardless of the temperature conditions, the interaction of equimolar amounts of the reactants leads to the formation of Et_3SiNCO and *NN'*-diphenyl-*N'*-triethylsilylurea, half of the silazane taken for the reaction remaining unchanged[67]:



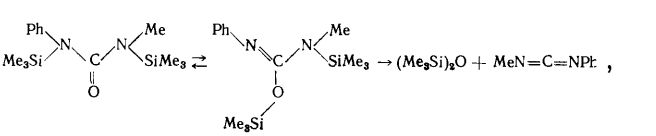
The authors[67] explained this course of reaction by the fact that the rate of interaction PhNCO with *N*-phenyl-*NN'*-bis(triethylsilyl)urea formed in the first stage is faster than the rate of interaction with hexaethyldisilazane:



The reaction of isocyanates with *N*-alkylated disilazanes at elevated temperatures is unusual. For example, Itoh et al.[76] showed that heptamethyldisilazane reacts with an excess of PhNCO to form the triazine derivatives (VI) and (VII):

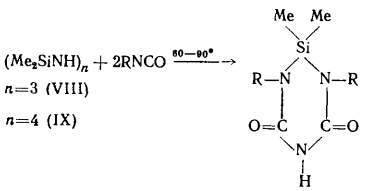


They suggest that the formation of (VI) is due to the β-elimination of the iso-form of the initial silylurea (1 : 1 adduct) to give methylphenylcarbodiimide:



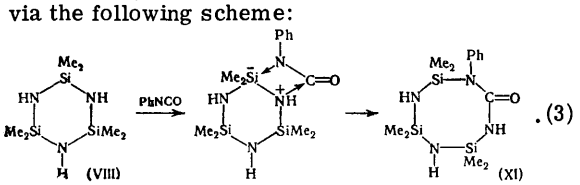
which then undergoes a cyclisation reaction with two molecules of PhNCO to give compound (VI). The formation of compound (VII) can be accounted for in two ways: (1) the 1 : 2 adduct of heptamethyldisilazane with PhNCO undergoes a similar decomposition (with decarboxylation) to diphenylcarbodiimide, which then trimerises and (2) PhNCO is decarboxylated with subsequent trimerisation of the resulting diphenylcarbodiimide.

Fink showed [56,77,78] that the interaction of organic isocyanates with cyclic silazanes proceeds in the same way as the interaction with silylamines via the Si–N bond, while in the presence of the N–H bond the latter is not involved in the reaction. Thus the cyclosilazanes (VIII) and (IX) react vigorously with organic isocyanates, forming derivatives of 1,3,5-triaza-2-silacyclohexanediones [56,77,78], which are cyclic analogues of silylbiurets:

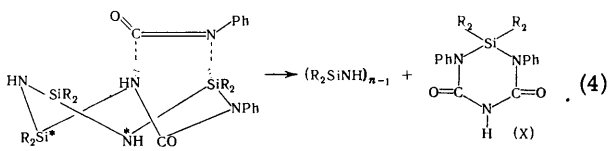


The structures of the compounds obtained were demonstrated by hydrolysis (when R = Ph, 1,5-diphenylbiuret is formed), ^{1}H NMR spectra, and X-ray diffraction [79].

According to the proposed reaction mechanism [56,77], there is initially a cycloaddition to the Si–N bond of the silazane via the following scheme:

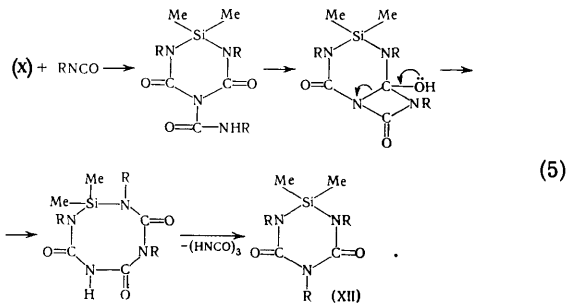


The heterocycle (XI) formed can react further in two ways: by combining with another molecule of PhNCO via the Si–N bond adjoining the PhN–Si group or it can react via Scheme 4, where the transannular interaction between the Si* and N* atoms lead to ring contraction and the elimination of cyclosilazane:



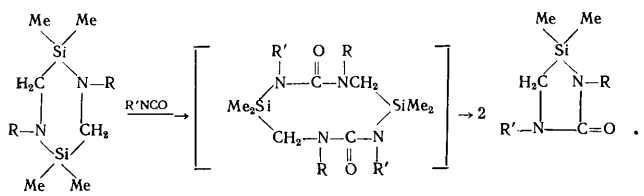
When an excess of the isocyanate (in relation to two moles of PhNCO per Me_2SiNH structural unit) is used, the number of moles of compound (X) formed is inconsistent with the theoretical value. Depending on the ratio of the initial reactants and the type of silazane, a greater or smaller amount of unidentified product is formed, which has been interpreted as supporting a stepwise reaction involving the Si–N bonds of the silazane, since the formation of such products on simultaneous reaction via all the Si–N bonds could not be explained.

At an elevated temperature (120–160°C) further reaction of the isocyanate with 1,3,5-triaza-2-silacyclohexanediones (X) or the direct reaction of cyclosilazanes with a large excess of the isocyanate leads to the formation, via a stage in which unstable macrocyclic compounds are produced, of 1,3,5-trisubstituted derivatives of 2,2-dimethyl-1,3,5-triaza-2-silacyclohexanediones (XII) [56,77]. The reaction can be regarded as cycloaddition to the RNSi–N bond in accordance with Eqn. (3) or as transacylation by the isocyanate [reaction (5)] via the formation of an eight-membered ring with subsequent elimination of cyanuric acid:



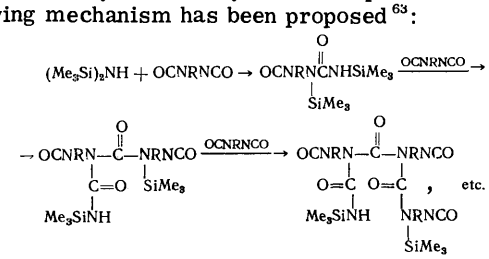
The use of an excess of diisocyanate in this reaction leads to compounds (XII) with free NCO groups [56,80,81] [for example, R-3-NCO-4-MeC_6H_3, $-(CH_2)_6NCO$, or $-C_6H_4CH_2C_6H_4NCO$ respectively for *p*-tolylene, hexamethylene, and diphenylmethylene diisocyanates].

Cyclic aminosilanes, derived from the recently discovered heterocyclic 2,5-disilapiperazine system [82], react vigorously with isocyanates to form five-membered silacycloureas. Ten-membered products resulting from the insertion of two molecules of isocyanate, which rearrange to five-membered rings by virtue of the ease of the transannular interactions between the Si and N atoms, are evidently formed in the first stage [82]:

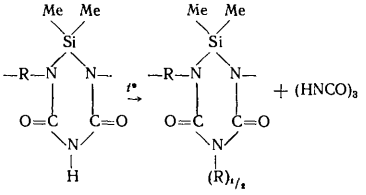


Reactions with di-isocyanates. The reactions of organoaminosilanes and silazanes with diisocyanates proceed similarly to the reactions with these compounds with monoisocyanates and lead to the formation of monomeric or polymeric silylureas and silylbiurets depending on the conditions, the reactant ratio, and the functional groups in the aminosilane [63,66,78,83–87], aromatic diisocyanates being more reactive than aliphatic diisocyanates [66].

It has not been possible to achieve the reaction between hexamethylene diisocyanate and HMDS [63]. At 30–35°C there is no interaction and at 80°C the diisocyanate polymerises. Under these conditions, HMDS is completely recovered from the reaction. When an excess of the diisocyanate (up to tenfold) is used, a polyisocyanate is also formed. Evidently at elevated temperatures HMDS behaves merely as a catalyst for this process. The following mechanism has been proposed [63]:

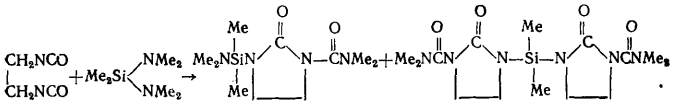


The reaction of hexamethylcyclotrisilazane with diisocyanates at 110°C leads to the formation of transparent, elastic, linear polymers with structural units (XIII), which decompose on heating above 110°C with elimination of cyanuric acids, giving cross-linked polymers with the structural units (XIV), exhibiting a high resistance to the action of acids[77]:



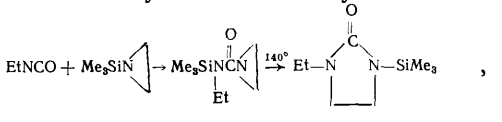
(XIII) (XIV)

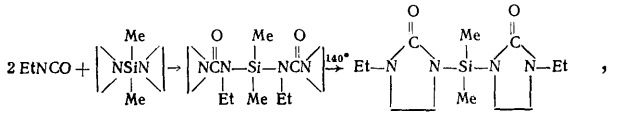
An interesting reaction with formation of cyclic silylurea derivatives (*N*-silylimidazolidinones) was discovered by Scherer and Schmidt[88]:



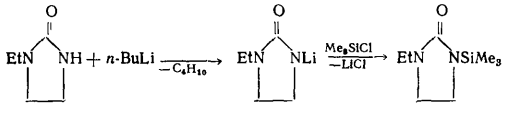
(70%) (20%)

According to the data of the same workers[89], derivatives of *N*-silylimidazolidinone can be obtained also in a different way: by a thermal rearrangement with the expansion of the rings of the silylureas formed in the reaction between monoisocyanates and *N*-silylaziridines:

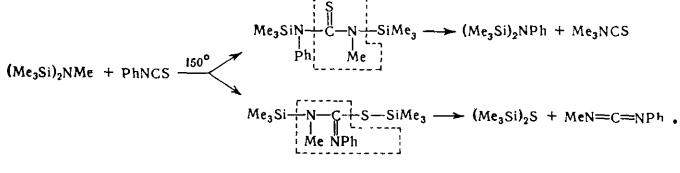




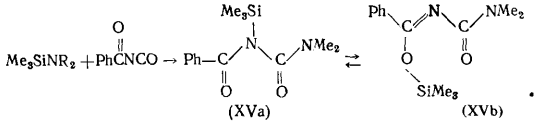
or via the lithio-derivative of imidazolidinone:



Reactions with isothiocyanates. The addition of silylamines and silazanes to isothiocyanates[53-55,57,61,62,66,74,90] proceeds via the same mechanism as the addition to isocyanates but much less vigorously[66,90] and leads to the corresponding organosilicon thiourea derivatives. It has been shown for the reaction of hexamethyldisilazane with PhNCS[90] that, in contrast to isocyanates, under severe conditions there is a possibility of addition not only to the C=N but also the C=S bond, which has been confirmed by the composition of the decomposition products of the intermediates:

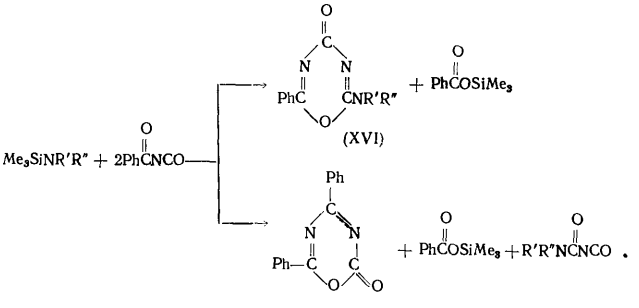


Reactions with acyl isocyanates. A characteristic feature of the reaction of aminosilanes with acyl isocyanates consists in the ability of the latter to be involved not only in 1,2- but also in 1,4-addition. Thus the reaction of dialkyl-*N*-trimethylsilylamines and benzoyl isocyanate in proportions of 1 : 1 gives a high yield of *NN*-dialkyl-*N'*-benzoyl-*N'*-trimethylsilylurea (1,2-addition), which is believed to be involved in the tautomerism (XVa) ⇌ (XVb) on the basis of ^{1}H NMR data[91-93]:



(XVa) (XVb)

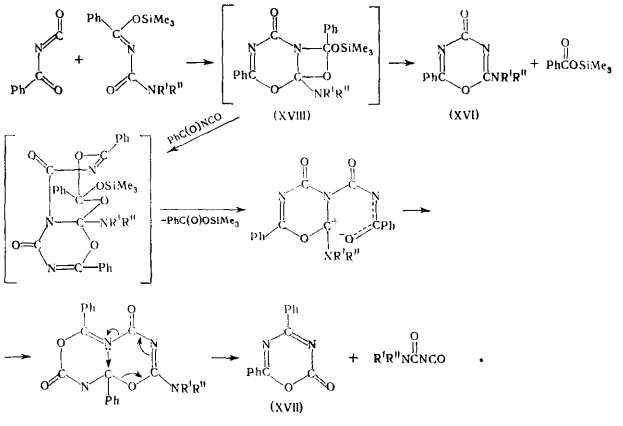
When a second acyl isocyanate molecule acts on the resulting urea or the silylamine reacts with two moles of the acyl isocyanate, the products are (in contrast to the reaction with isocyanates) derivatives of oxadiazinone [(XVI) and (XVII)], benzoyloxytrimethylsilane, and *NN*-dialkylcarbamoyl isocyanate and not silylbiurets:



(XVI)

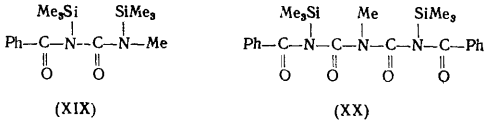
(XVII)

This reaction is regarded as proof of the existence of the iso-form of silylurea. The formation of the oxadiazinones (XVI) and (XVII) can be accounted for by the 1,4-addition of precisely this form of silylurea to benzoyl isocyanate[91,92]. The reaction mechanism evidently includes the formation of an unstable 1 : 1 adduct (XVIII) and its subsequent reactions via the following mechanism[91,92]:



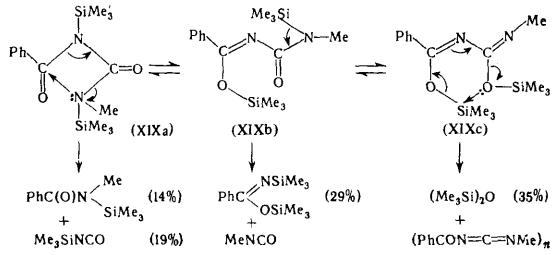
(XVIII) (XVI) (XVII)

In contrast to dialkyl-*N*-(trimethylsilyl)amines, heptamethyldisilazane $(Me_3Si)_2NMe$ forms with benzoyl isocyanate 1 : 1 (XIX) or 1:2 (XX) adducts depending on the reactant ratio[93]:

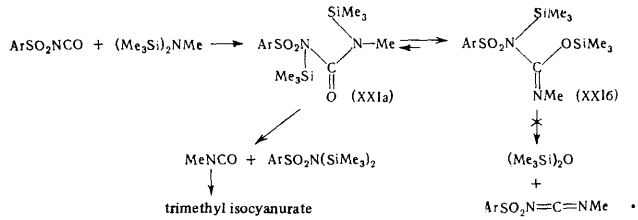


(XIX) (XX)

According to ^{1}H NMR data, the adduct (XIX) is a mixture of at least two isomers and the composition of the products formed on its pyrolysis indicates the possibility of the existence of three isomers of (XIX)[93]:



Reactions with sulphonyl isocyanates. Sulphonyl isocyanates react with aminosilanes (in proportions of 1 : 1) to give a quantitative yield of *N*-silyl-substituted sulphonated ureas, among which the main species is the carbonyl form (XXIa)[94]. This is confirmed by infrared spectroscopic and ^{1}H NMR data and also by the composition of the products of the pyrolysis of the compounds in which an organic isocyanate (or its trimer) and *NN*-bis(trimethylsilyl)sulphonamide are formed, in contrast to the pyrolysis of the analogous adducts of isocyanates and aminosilanes:

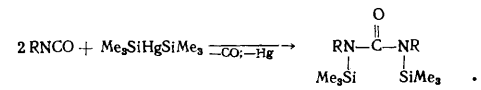


In conclusion of this section, one may note that, apart from the direct interaction of aminosilanes with isocyanates, *N*-silylureas are also formed in the reaction of aminosilanes with carboxylic acid azides[95]. At a low temperature in the presence of catalytic amounts of $AlCl_3$ or close to the decomposition temperature of the azide, this reaction proceeds as a double decomposition with formation of silyl azides and acid amides:

$$RC(O)N_3 + Me_3SiNR'R'' \rightarrow Me_3SiN_3 + RC(O)NR'R''$$

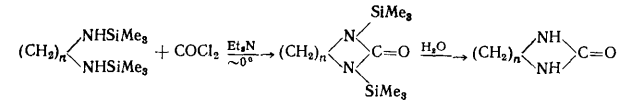
When this temperature is exceeded, the acid azide decomposes with liberation of the isocyanate, which then reacts further with the silylamine present to give a silylurea. In particular, high yields of trimethylsilyl-substituted derivatives of *N*-butyl-*N'*-phenyl- and *N*-benzyl-*N'*-phenylureas were obtained in this way (the position of the silyl residue in the ureas was not determined).

The interaction of isocyanates with bis(trimethylsilyl)-mercury in hexametapol yielded bissilylureas[96]:

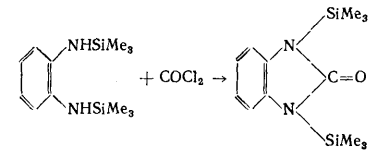


e. Other Methods of Synthesis

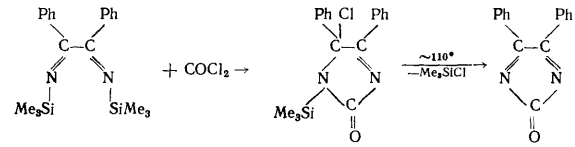
Birkofer et al.[38] showed in 1960 that cyclic derivatives of silylurea are formed in 60–75% yield in the reaction of phosgene with bissilyl-substituted tri- and tetra-methylenediamines in the presence of triethylamine. In the hydroxysis or methanolysis of these compounds organic derivatives of urea, which could not be synthesised by direct phosgenation of $\omega\omega'$-diamines, were obtained in quantitative yields:



Under the same conditions, *NN'*-bis(trimethylsilyl)-*o*-phenylenediamine reacts with $COCl_2$ to give *NN*-bis(trimethylsilyl)benzimidazol-2-one[38]:



while benzylbis(trimethylsilyl)imine is converted at −10°C into the thermally unstable silylimidazoline[97], which decomposes on heating to 4,5-diphenylimidazol-2-one:



In contrast HMDS reacts with phosgene mainly according to the mechanism

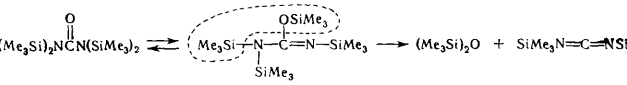
$$6(Me_3Si)_2NH + 3COCl_2 \rightarrow 2(Me_3Si)_2NH + 5Me_3SiCl + 3Me_3SiNCO + NH_4Cl$$

and not to give silyl-substituted ureas as might have been expected[18]. The interaction of metallated HMDS with $COCl_2$ also did not lead to the formation of the expected tetrasilylurea[18,98,99]. The stable bis(trimethylsilyl)carbodiimide and hexamethyldisiloxane were isolated as the main products of this reaction, the mechanism of which the authors were unable to elucidate:

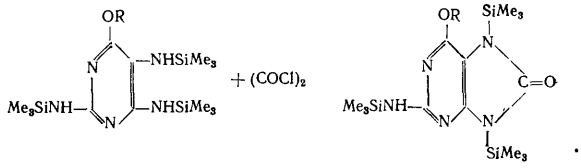
$$2(Me_3Si)_2NNa + COCl_2 \rightarrow 2NaCl + (Me_3Si)_2O + Me_3SiN{=}C{=}NSiMe_3$$

The attempts to obtain tetrasilylurea via the lithio-derivative of bis(trimethylsilyl)urea were also unsuccessful[98,99]. Despite the formation of lithium chloride, the same products were isolated from the reaction mixture:

Tetrasilylureas are nevertheless evidently formed as intermediates in these reactions, but, owing to their thermal instability, they decompose to the above compounds. Bearing in mind the tendency of *N*-silylureas (and silylamides in general) to undergo tautomerism and also the thermal instability of the compounds with the Si–N–C–X bond system (X = electronegative groups) observed previously[7,100], the following mechanism of the decomposition reaction appears to be most likely:



On treatment with oxalyl chloride, 2,4,5-tris(trimethylsilylamino)pyrimidines form compounds with a urea moiety in the ring system—silylpurines[101]:



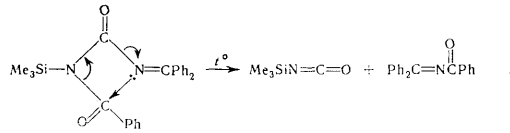
2. PHYSICAL PROPERTIES

Depending on the substituents at the silicon and nitrogen atoms, *N*-silylureas are liquid, oily, or crystalline substances, which are in most cases readily soluble in acetone, carbon tetrachloride, chloroform, ether, dioxan, and THF and more sparingly soluble in benzene, toluene, xylene, and petrol[18,41,53,66]. Their solubility in petroleum ether is as a rule low. Partly nitrogen-substituted derivatives, such as $Si(NHCONHPh)_4$ and $(OCN)_2Si(NHCONHPh)_2$, do not have distinct melting points and like urea are sparingly soluble in organic solvents.[41] Crystalline products sublime on heating *in vacuo*, and this can be used for their purification[18,41,53].

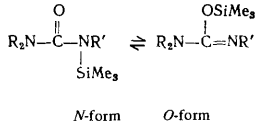
The thermal stability of *N*-silylureas was not specially studied, but it evidently varies within wide limits and depends mainly on the structure and the presence of secondary impurities. Thus the compounds $Me_3SiNHC(O)NPh_2$ and $Me_2Si(NHCONPh_2)_2$ decompose fully at about 250°C to isocyanatosilane and diphenylamine. This reaction was proposed for the synthesis of isocyanatosilanes[6]. On heating urea with HMDS at 90–110°C in the presence of $(NH_4)_2SO_4$, Me_3SiNCO is formed in a yield in excess of 90%, which is also evidence for the thermal instability of the intermediate silylurea.

On the other hand, the compound $Me_3SiNHC(O)NEt_2$ is stable in the absence of moisture up to 300°C and $Me_3SiNHC(O)NBu_2$ and $Me_3SiNHC(O)NMe_2$ merely sublime on heating to 220°C.[41] On the other hand, according to the data of other workers[18], in the presence of HMDS the complete decomposition of the latter compound to Me_3SiNCO and Me_2NH occurs already at the boiling point of HMDS (about 126°C).

Tetrakis(trialkylsilyl)ureas could not be obtained, probably owing to their thermal instability[98,99]. The decomposition of *N*-acyl-*N*-silylureas on heating proceeds with formation of isocyanatosilane and *N*-(diphenylmethylene)benzamide[75]:



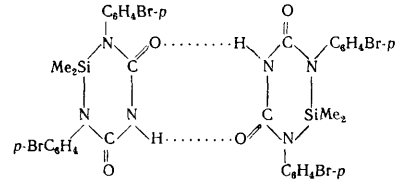
By analogy with *N*-trimethylsilylamides of carboxylic acids, which are capable of amide–isoamide tautomerism involving the Me_3Si group[30], Klebe et al.[53] suggested the possibility of the same type of tautomerism also for silicon-containing ureas:



N-form *O*-form

Comparison of the infrared and ultraviolet spectra of the compounds[11,18,41,52,56,61–63,66,70,102] with those of model molecules does not, however, allow unambiguous conclusions in this respect. All the compounds have absorption bands in the range 1500–1700 cm^{-1}, characteristic of secondary and tertiary amides. The study of a number of *N*-organosilyl-*N'*-phenylureas[70] showed that in the solid state they apparently contain only hydrogen-bonded N–H groups, while in solution there exist also associated N–H groups, to which the 3413 and 3517 cm^{-1} bands correspond. The 3413 cm^{-1} band was assigned to the phenyl–NH group and the 3517 cm^{-1} band to the silyl–NH group. The 3280, 3323, 3324, 3341, and 3349 cm^{-1} bands, observed in the spectra of suspensions of these compounds, were assigned respectively to bound phenyl–NH and silyl–NH groups. The comparatively high stretching vibration wavenumbers of the free NH group and their appreciable displacement on passing from solutions to suspensions (from 176 to 194 cm^{-1} for various substituents at the silicon atom), demonstrates the amphoteric nature of the silyl–NH group and the greater mobility of its proton compared with that of the phenyl–NH group (the corresponding shift is 133 cm^{-1}). One of the explanations of this finding involves the participation of the lone electron pair of the nitrogen atom in the formation of a bond with silicon and hydrogen, the degree of involvement of this pair depending on the nature and strength of the intermolecular interaction. In the formation of a hydrogen bond the lone electron pair is probably located at the silicon–nitrogen bond[70].

According to X-ray diffraction analysis, the molecules of 2,6-di(*p*-bromophenyl)-1,1-dimethyl-1-sila-2,4,6-triazacyclohexanedione (the product of the reaction of the *p*-bromophenyl isocyanate with HMDS) are dimerised in the crystal by hydrogen bonding[79]:



The spectra of silylureas obtained by the interaction of Et_2NSiMe_3 or silazanes with phenyl isocyanate do not contain the intense band due to the stretching vibrations of the silicon–nitrogen band, which is observed in the spectra of the initial compounds at 925 and in the range 900–950 cm^{-1} respectively. Its disappearance is explained by the fact that the corresponding vibration in silylureas is no longer characteristic and is not observed in the same part of the spectrum[63]. Other workers assign the bands at 850, 848, and 840 cm^{-1} to the ν_{as} vibrations of the Si–N bond in $(Me_3SiNH)_2CO$, $(Me_3Si)_2NC(O)NHPh$, and $Si(NHCONH_2)_4$ respectively[18].

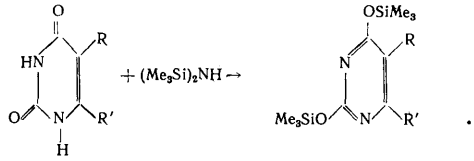
The infrared spectrum of tetraureidosilane $Si(NHCONH_2)_4$ has an absorption band at 2175 cm^{-1}, which is the most intense in the sublimate formed on heating the urea *in vacuo* at 160°C. It is assigned to the ν_{as} stretching vibrations of the N=C=N group, the formation of the latter being explained by partial decomposition via the reaction[18]

$$Si(NHCONH_2)_4 \rightarrow 4H_2O + Si(N{=}C{=}NH)_4 .$$

The ^1H NMR spectra of a number of silylureas have been published[52,66,73,75,89,92–94]. The study of the nature of the Me_3Si signal as a function of temperature showed that in the case of a number of silylureas, for example $Me_3SiN(Me)C(O)NMe_2$ and $PhSO_2N(SiMe_3)C(O)NMe_2$, the

signal due to the protons of this group does not split at low temperatures[92]. This is evidence for the absence of appreciable tautomerism or for the presence of a mixture of *O*- and *N*-forms with their very rapid interconversion even at low temperatures. On the other hand, the signal for other compounds, for example $PhC(O)N(SiMe_3)C(O)NR_2$ [76,92] and $Ph_2C{=}NC(O)N(SiMe_3)R$ [75] splits into two at temperatures below −43°C, which has been interpreted as supporting the 1,3-transfer of the Me_3Si group, i.e. the presence of the *O*-silyl form of ureas (amide–isoamide tautomerism). As already mentioned above, the formation of the isoamide form is also indicated by a number of chemical reactions of silylureas[75,76,92].

The presence of only the *O*-form has been established for certain cyclic silylureas. For example, silylation of uracil derivatives with HMDS results in the formation of silyl derivatives which have the structure of siloxypyrimidines and not *N*-silyluracils[23,103]:



3. CHEMICAL PROPERTIES

The majority of silylureas are unstable with respect to hydrolysis[18,41,52,55,57,61–63,66,68,69,73,95,104] and readily deliquesce in moist air[66]. They are hydrolysed with dissociation of the Si–N bond and the formation of organosilanols (or organosiloxanes) and organic urea derivatives[41,68,73,75,95]:

$$2\,Me_3SiNHC(O)NR_2 + H_2O \rightarrow (Me_3Si)_2O + 2H_2NC(O)NR_2 \quad .$$

On the other hand, in contrast to asymmetric ureas, *NN'*-bis(trimethylsilyl)urea is hydrolysed by water with considerable difficulty[18]. According to the authors, electron density is in this case redistributed in the direction which lowers the double bond character of the linkage between the Si and N bonds and this ultimately reduces the susceptibility of the silicon atom to nucleophilic attack. Incidentally, one cannot rule out the possibility that hydrolysis is slow because the reaction takes place in a heterogeneous medium owing to the sparing solubility of the silylurea in water.

N-Silylureas, particularly aromatic derivatives, are powerful silylating agents, like carboxylic acid silylamides[22,25,26,36]. Their reactions with amines and hydroxy-compounds are rapid even at room temperatures and lead to the quantitative formation of the corresponding silyl derivatives with removal (or in some cases without removal) of one of the components of the equilibrium mixture. For example, $Me_3SiN(Ph)CONHPh$ and *NN'*-dimethylurea are completely converted after 1 min at 20°C[22]:

$$Me_3SiN(Ph)CONHPh + MeNHCONHMe \rightarrow Me_3SiN(Me)CONHMe + PhNHCONHPh \quad .$$

Experiments with compounds containing an active hydrogen atom at a carbon atom (acetylacetone, nitromethane, and malononitrile) showed that these too are capable of undergoing the silyl–proton exchange with silylureas[22].

Alcoholysis

When silylureas are treated with an alcohol, solvolysis takes place with formation of alkoxysilanes and organic urea derivatives[25,88,89,105], for example:

$$Me_3SiNHC(O)NMe_2 + EtOH \rightarrow Me_3SiOEt + H_2NC(O)NMe_2 \quad .$$

The methanolysis of optically active silylureas and biuret is accompanied, with rare exceptions[74], by the reversal of the configuration at the silicon atom[73], which indicates an S_N2 mechanism for this reaction:

$$(+)\text{-}R_3Si^*NCONHMe + MeOH \rightarrow (+)\text{-}R_3Si^*OMe + PhNHCONHMe \quad ,$$

$$(-)\text{-}R_3Si^*NCONCONHPh + MeOH \rightarrow (+)\text{-}R_3Si^*OMe + PhNHCONCONHPh \quad ,$$

where $R_3Si^* = (\alpha\text{-}C_{10}H_7)PhMeSi^*$.

Aminolysis

The compounds readily enter into a reversible reaction with amines, which is fully displaced to the right owing to the sparing solubility of the resulting urea or biuret derivatives, and, like alcoholysis, is accompanied by the reversal of the configuration[73].

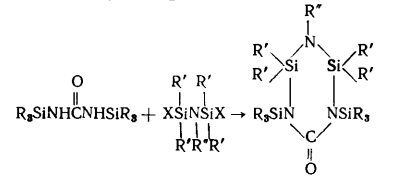
$$(+)\text{-}R_3Si^*NCONHMe + Me_2NH \rightleftarrows (+)\text{-}R_3Si^*NMe_2 + PhNHCONHMe \quad .$$

Silylureas react with acids according to the mechanism[74]:

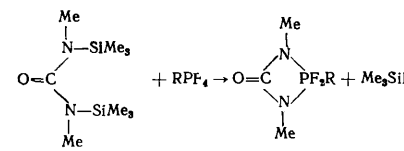
$$R_3SiNC(O)NMe_2 + PhCOOH \rightarrow R_3SiOC(O)Ph + PhNHC(O)NMe_2 \quad .$$

Kaufmann et al.[74] showed that, in contrast to silylamines and *N*-silylthioureas, the Si–N bond in silylureas is not cleaved under the influence of *p*-nitrobenzoyl chloride.

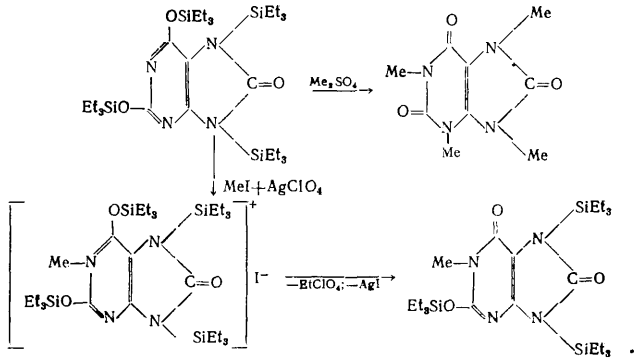
1,3-Dihalogenosilazanes react with *NN*-bis(trimethylsilyl)ureas to form cyclic products[106]:



When acted upon by fluorophosphoranes, asymmetric disilylureas form fluorophosphadiazetidinediones with cleavage of the Si–N bond[107]



Silyl derivatives of uric acid react with dialkyl sulphates or methyl iodide to form alkyl derivatives of uric acid[101]:



4. APPLICATIONS

The interest in silylureas is due to their ability to form compositions which are self-hardening at the normal temperature, their high silylating activity, and many other valuable properties.

According to patent data, monomeric *N*-triorganosilylureas are effective agents for the treatment of fabrics, paper, leather, and non-fibrous materials (for example, cellophane) in order to make them hydrophobic and creaseless, to reduce their brittleness, and to improve other characteristics[5,17]. *N*-Silylureas can be used in the synthesis of plastics[54], lubricating oils, and hydraulic liquids[36,55], for the stabilisation of poly(vinyl chloride)[42], as vulcanisers for the cold-hardening of polysiloxanes[108], and for other purposes[109,110]. Some of these compounds exhibit pharmacological and pesticidal properties[17,36,54,65,-111,112]. Silylureas with unsaturated groups in the molecule have been patented in connection with the synthesis of block copolymers and the vulcanisation of polyorganosiloxane elastomers[72].

The polysilylureas formed when isocyanatosilanes react with polyamines can be thermoplastic or thermoreactive, depending on the type of the initial reactants; they have been suggested for the formation of moulded articles, laminated materials based on fibreglass, and for many other purposes[43,113-115]. Polysilylurea films have a high breakdown voltage and tensile strength[83,85].

Polysilylureas obtained from organic polyisocyanates and silylamines have many valuable properties. Polymeric materials of this kind can be used to synthesise elastomers[116], fibres, and films[117] and for other purposes[87,118]. The susceptibility of the Si–N bond to hydrolysis does not preclude their employment since, on being acted upon by atmospheric moisture, the film is only partly hydrolysed on the surface and the liberated siloxane plasticises the material.

The polyureidosilazanes, obtained when linear or cyclic silazanes are treated with organic polyisocyanates, adhere effectively to metals, glass, and rubber, are resistant to the action of water, organic solvents, acids, and alkalis, and have satisfactory dielectric and other properties[78,86,119].

Monomeric and polymeric silylbiurets[64,65,84,120] have been patented as antifoaming and anti-ageing agents, as agents accelerating vulcanisation, and as plasticisers and herbicides.

III. SILYLISOUREAS

Silylisoureas were obtained for the first time in 1968 by the reaction of cyanic acid esters with aminosilanes or silazanes[121,122]. This reaction proceeds mainly similarly to the reaction of aminosilanes with isocyanates, i.e. with cleavage of the Si–N bond and addition to the multiple bond of the cyanate. However, in contrast to isocyanates, cyanic acid esters can also enter into an exchange reaction involving the Si–N bond of the aminosilane similar to the Brown cleavage reaction. Dialkylaminosilanes are known[123] to enter into a similar reaction with bromocyanogen, forming bromosilane and dialkylcyanamide. When there is a possibility of competing reactions involving the Si–N and N–H bonds, as happens in the case of secondary aminosilanes, the Si–N bond is cleaved first. The interaction of cyanates with various types of aminosilanes is to some extent specific.

The reaction of cyanic acid esters with dialkyl-*N*-trimethylsilylamines in 1:1 proportions results in the quantitative yield of *NN*-dialkyl-*N'*-trimethylsilylisoureas[121]:

$$ROC{\equiv}N + R'_2NSiMe_3 \rightarrow ROC(=NSiMe_3)NR'_2 ,$$

where R = aryl and R′ = alkyl. The same compounds can be obtained by the silylation of *NN*-dialkylisoureas with chlorotrimethylsilane[121].

When the resulting isourea is acted upon further by the cyanate, the products are 2-dialkylamino-4,6-diaryloxy-*s*-triazines and aryl trimethylsilyl ethers:

$$ROC(=NSiMe_3)NR'_2 + 2ROC{\equiv}N \rightarrow \text{2-dialkylamino-4,6-diaryloxy-}s\text{-triazine} + Me_3SiOR .$$

Thus, in contrast to isocyanates, cyanic acid esters do not form 1:2 adducts with dialkyl-*N*-trimethylsilylamines, since the first stage of this reaction is an addition process and the second is a process of the type of the Brown reaction.

The reaction of alkyl-*N*-trimethylsilylamines with aryl cyanates in proportions of 1:1 results in the initial formation of *N*-alkyl-*O*-aryl-*N'*-trimethylsilylisourea (possibly in a mixture with its isomeric form). However, these compounds cannot be isolated, since under the influence of the cyanate they are immediately converted into *N*-alkyl-*O*-aryl-*N'*-cyanoisoureas with elimination of the Me_3Si group:

$$RNHSiMe_3 + ArOCN \rightarrow \left[ArO{-}C(=NR){-}NHSiMe_3 \rightleftarrows ArO{-}C(NHR){=}NSiMe_3 \right] \xrightarrow{ArOCN} ArO{-}C(NHR){=}N{-}CN + ArOSiMe_3 .$$

In addition, phenol, carbodiimide, and polymerisation products of the latter are formed in small amounts.

The reaction with HMDS proceeds similarly. In this case too it was impossible to isolate the 1:1 adduct, which is converted under the influence of ArOCN into *O*-aryl-*N*-cyano-*N'*-trimethylsilylisourea. At an elevated temperature a silylated cyanoguanidine is formed in addition. The reaction can be represented as follows:

$$ArOCN + (Me_3Si)_2NH \rightarrow \left[ArO{-}C(=NSiMe_3){-}NHSiMe_3 \right] \xrightarrow[ArOSiMe_3]{ArOCN} \left[ArO{-}C(NHSiMe_3){=}N{-}C{\equiv}N \right] \rightleftarrows \left[ArO{-}C(=NSiMe_3){-}NH{-}C{\equiv}N \right] \rightleftarrows \left[ArO{-}C(=NSiMe_3){-}N{=}C{=}NH \right] .$$

On the other hand, the reaction of methyl-*NN*-bis(trimethylsilyl)amine with ArOCN (in proportions of 1 : 1 or 1 : 2) is of the double addition type with formation of the 1 : 2 adduct—the diaryl ester of N^2-methylimino-N^1N^3-bis(trimethylsilyl)carbamic acid. Only in the presence of an up to sixfold excess of the cyanate are the Me_3Si groups exchanged for CN with formation of the diaryl ester of N^1N^3-dicyano-N^2-methyliminocarbamic acid, which tends to polymerise:

$$(Me_3Si)_2NMe + 2PhOCN \rightarrow \begin{matrix} PhO-C=NSiMe_3 \\ | \\ Me-N \\ | \\ PhO-C=NSiMe_3 \end{matrix} \xrightarrow[-PhOSiMe_3]{+PhOCN} \begin{matrix} PhO-C=N-CN \\ | \\ Me-N \\ | \\ PhO-C=N-CN \end{matrix} .$$

Silylisoureas are colourless viscous oils, which can be distilled without decomposition in a high vacuum. Their infrared spectra contain intense bands in the ranges 1745–1755 and 1685–1698 cm^{-1}, which are characteristic of the stretching vibrations of the double bond of the silylated imido-group $\diagdown C{=}NSi \diagup$.

At high temperatures (for example under the conditions of gas-chromatographic analysis) the silylisoureas decompose via the mechanism

$$RO-\underset{\underset{NR'_2}{|}}{C}=N-SiMe_3 \xrightarrow{t^\circ} ROSiMe_3 + R'_2N-C\equiv N .$$

On treatment with alcohols or on prolonged standing in air, they are desilylated to organic isoureas. The reaction with acid chlorides also proceeds with the cleavage of the Si–N bond and the formation of acyl isoureas and chlorosilanes[121].

IV. CARBOFUNCTIONAL ORGANOSILICON DERIVATIVES OF UREA

1. METHODS OF SYNTHESIS

Silicon-containing derivatives in which the urea moiety and the silicon atoms are separated by a group of atoms have been less thoroughly investigated. The majority of the methods for their preparation reduce mainly to the familiar procedures of organic chemistry for the synthesis of alkyl (or aryl)-substituted urea derivatives (isocyanate condensation transamination, and other reactions) and are based on the employment as the starting materials of the corresponding isocyanates and amines or compounds containing an amino-group.

a. Isocyanate Condensation Reactions

Two versions of isocyanate condensation via a combination of organic and organosilicon starting materials are possible: (1) the interaction of carbofunctional organosilicon isocyanates with organic or organosilicon amines and (2) the interaction of organic isocyanates with carbofunctional silicon-containing amines.

Until 1959, the first reaction was illustrated by only one example[124]:

where X = Cl, MeO, EtO, or H and n = 1 or 2.

A wide variety of both mono- and di-silyl-substituted ureas became available recently after the development of convenient methods for the preparation of carbofunctional organosilicon isocyanates[125]. In particular, the first and simplest representatives of aliphatic silicon-containing ureas $R_3Si(CH_2)_nNHCONH_2$ [7,126–130] and also ureas with a disiloxane bond of the type $[H_2NCONH(CH_2)_nSiMe_2]_2O$ [6,7] were obtained recently from these compounds.

Carbofunctional organosilicon isocyanates as a rule react exothermically with amines to form the corresponding urea derivatives in virtually quantitative yields [6,7,126,127,130–136]:

$$R_3Si(CH_2)_nNCO + Bu_2NH \rightarrow R_3Si(CH_2)_nNHC(=O)NBu_2 ,$$

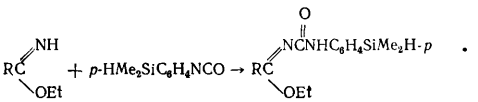
where R = Me, Et, or Ph and n = 1 or 3.

ω-Isocyanatoalkylsilanes with an NCO group in the γ-position are more reactive than α-isocyanatoalkylsilanes[130,135].

When isocyanates react with hydrazine and its derivatives, silylsemicarbazides are formed[134,137,138]:

$$[OCN(CH_2)_3SiMe_2]_2O + R_2NNH_2 \rightarrow [R_2NNHC(=O)NH(CH_2)_3SiMe_2]_2O,$$

and the reaction with aminoethers gives a high yield of carbamidoiminoethers[139]:



Organosilicon isocyanates react just as easily with acid hydrazides to form the compounds $R_3Si(CH_2)_n$. .$NHCONHNHCOAr$.[130]

The interaction with acid amides is more difficult[130]. For example, benzamide and sulphonamides form the substituted ureas $R_3Si(CH_2)_nNHCONHCOPh$ and $R_3Si(CH_2)_n$. .$NHCONHSO_2Ar$ only after prolonged heating with isocyanate in dimethylformamide (DMF) in the presence of triethylamine as the catalyst.

Symmetrical silicon-containing ureas have been obtained on heating carbofunctional organosilicon isocyanates with water in DMF[140]:

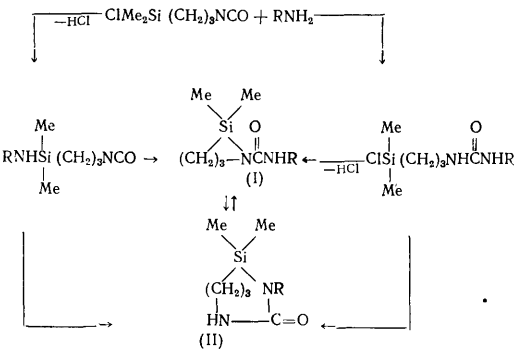
$$R_3Si(CH_2)_nNCO + H_2O \rightarrow [R_3Si(CH_2)_nNHCOOH] \xrightarrow{-CO_2} R_3Si(CH_2)_nNH_2 \xrightarrow{R_3Si(CH_2)_nNCO} \rightarrow R_3Si(CH_2)_nNHC(=O)NH(CH_2)_nSiR_3,$$

where R = Me, Et, or Pr and n = 1 or 3. In the presence of an excess of water an organosilicon amine is formed in this reaction.

In contrast to the reactions with amines and alcohols, where α-isocyanatomethylsilanes have a reduced reactivity compared with γ-isocyanatoalkylsilanes, in the reaction with water these compounds have virtually the same reactivities[140]. Evidently the overall electropositive effect of the R_3SiCH_2 group in α-isocyanates is manifested in two ways: on the one hand, the electrophilicity of the carbonyl carbon atom is reduced and the rate of reaction of the isocyanate with water is diminished and, on the other, the basicity of the resulting amine is enhanced, as a result of which the rate of the secondary reaction (the reaction with the isocyanate) rises.

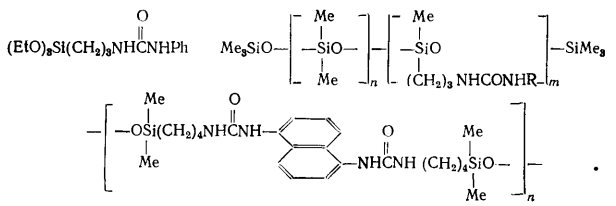
Isocyanates with other reactive groups or atoms at the silicon atom can interact with amines via these groups too. Thus the reaction of $ClMe_2Si(CH_2)_3NCO$ with an excess of a

primary amine results in the formation of 1-alkylcarbamido-1-aza-2-silacyclopentanes (I), which are in a state of tautomeric equilibrium with 1,3-diaza-4-silacycloheptan-2-ones (II)[7,141]:

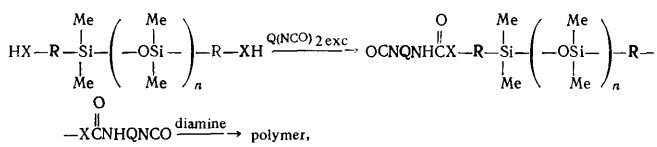


The reactions of organosilicon diisocyanates with diamines, hydrazines, and dihydrazides yielded respectively polysilylureas[142-144], polysilylureylenes[142,145], and polyacylsemicarbazides[146,147].

The reaction of organic isocyanates with carbofunctional organosilicon amines has been little investigated, although it has been shown for the synthesis of monomeric, oligomeric, and polymeric ureas that it is of a general type[148-151]. In particular, compounds having the following formulae have been obtained:



A number of oligomeric and polymeric compounds containing in the chain alternating siloxane, urethane, and urea units have also been synthesised by the isocyanate condensation reaction using organic diisocyanates[150,151]:



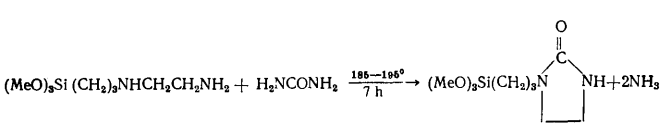
where R and Q = alkylene or arylene and X = O or NH.

b. Transamination Reactions

Silicon-containing ureas are formed in satisfactory yields on prolonged heating of high-boiling organosilicon amines with the urea[152]:

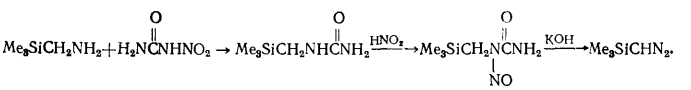
$$2\,(EtO)_3Si\,(CH_2)_3NH_2 + H_2NCONH_2 \xrightarrow[7.5\ h]{185^\circ} [(EtO)_3Si\,(CH_2)_3NH]_2CO + 2NH_3.$$

When organosilicon diamines are used in the reaction, cyclic silylureas are formed[153,154]:



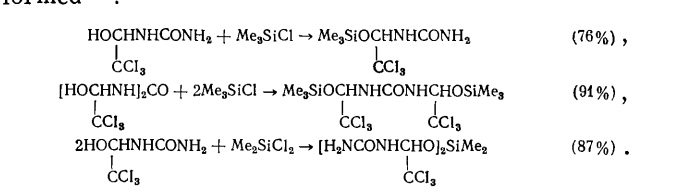
Hydrolysis of such cyclic or linear compounds with alkoxy-groups at the silicon atom leads to the formation of polysiloxanes with urea units in the side chain. Copolymers of these compounds with silanes and siloxanes containing hydrolysable groups at the silicon atom have also been obtained[153,154].

Using the transamination reaction, Seyferth and coworkers[155,156] synthesised *N*-nitroso-*N*-trimethylsilylurea, which is a convenient starting material for the synthesis of the unusually stable trimethylsilyldiazomethane. The synthesis was carried out in accordance with a scheme similar to that used in the synthesis of a diazomethane from *N*-methyl-*N*-nitrosourea:



c. Silylation of Urea Derivatives

When the products of the condensation of chloral with urea are acted upon by chlorosilanes in the presence of an excess of pyridine, high yields of siloxyureas are formed[157]:



Similar derivatives were obtained by treating mono- and di-(hydroxymethyl)ureas with chlorotrimethylsilane and triethylamine[104]. A study of the reaction of mono(hydroxymethyl)urea with Me_3SiCl has shown that, even for an equimolar reactant ratio, Me_3SiCl reacts with the hydrogen atoms of both OH and NH_2 groups:

$$H_2NCONHCH_2OH + Me_3SiCl \xrightarrow[-Et_3N\cdot HCl]{Et_3N} Me_3SiNHCONHCH_2OSiMe_3 \qquad (39\%).$$

When Me_3SiCl is allowed to react with di(hydroxymethyl)-urea, only the hydrogen atoms in the hydroxy-groups are substituted:

$$O{=}C\,(NHCH_2OH)_2 + 2Me_3SiCl \xrightarrow[-Et_3N\cdot HCl]{Et_3N} O{=}C\,(NHCH_2OSiMe_3)_2 \qquad (44\%).$$

Silylation of the hydroxymethyl groups in *NN'*-di(hydroxymethyl)urea proceeds readily also when the latter is acted upon by HMDS, *N*-trimethylsilylacetamide, *NO*-bis(trimethylsilyl)acetamide, diethyl-*N*-trimethylsilylamine, and dimethyl-*N*-trimethylsilylamine at about 35°C in acetone, pyridine, or ethyl acetate, dialkyl-*N*-trimethylsilylamines being the most effective silylating agents[158]. This reaction has been used to silylate the products of the condensation of urea with formaldehyde in order to decompose intramolecular and intermolecular hydrogen bonds in aminoplastics, which leads to the formation of products soluble in organic solvents to which gel-chromatographic research techniques are applicable[158].

According to Kreshkov et al.,[159] the hydroxy-groups in urea-formaldehyde resins can react with alkoxysilanes, probably via the following mechanism:

By combining urea-formaldehyde resins with polyethoxypolysiloxanes, silicon-modified polymers were obtained using this procedure[159].

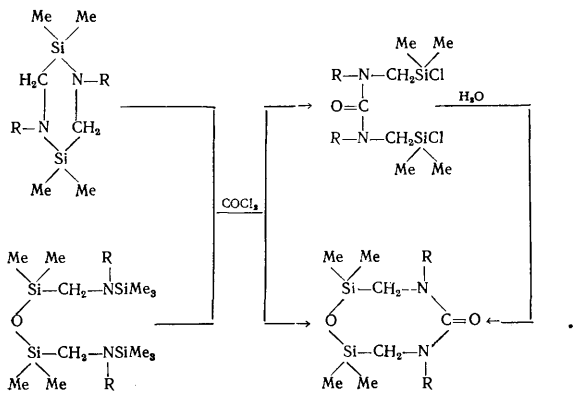
d. Other Reactions

Montgomery[160,161] synthesised symmetrical silicon-containing derivatives by heating aminoalkylsilanes with carbonyl sulphide in an autoclave:

$$PhMe_2SiCH_2NH_2 + COS \xrightarrow[4\ h]{100^\circ;\ 1\ atm} [PhMe_2SiCH_2NH]_2CO + H_2S\ ,$$

$$Me_3SiOSi(Me)_2CH_2NH_2 + COS \xrightarrow{100^\circ;\ 8.6\ atm} [Me_3SiOSi(Me)_2CH_2NH]_2CO + H_2S\ .$$

Linear and cyclic compounds were obtained by treating piperazine rings with phosgene and by synthesis from *N*-silylated α-diamines of the disiloxane series[162]:



When urea is acylated with the chlorides of organosilicon acids, the products are acylureas with a silicon atom in the acyl residue[163,164].

A number of other methods known only in organic chemistry can be used to synthesise organosilicon ureas. In particular, ureas are formed when carbofunctional organosilicon amines are treated with carbamoyl chlorides[6,7]:

$$Me_3SiCH_2NH_2 + Ph_2NC(O)Cl \xrightarrow[-Et_3N\cdot HCl]{Et_3N} Me_3SiCH_2NHC(O)NPh_2 \qquad (62\%)$$

and on oxidising the corresponding amines with lead tetraacetate in the presence of an amine[6,7]:

$$Me_2EtSi(CH_2)_3CNH_2 \xrightarrow[DMF]{Pb(OAc)_4} [EtMe_2Si(CH_2)_3NCO] \xrightarrow{AllNH_2} Me_2EtSi(CH_2)_3NHC(O)NHAll.$$

A number of cyclic urea analogues having the structure of uretidinediones were obtained by the reaction of halogenoalkylsilanes with metal cyanates in DMF. The formation of these compounds is due to the dimerisation of the isocyanates, which are the primary reaction products, under the influence of the cyanate salt[165-167]:

$$R'R_2Si(CH_2)_nCl \xrightarrow[-MCl]{MOCN} [R'R_2Si(CH_2)_nNCO] \rightarrow R'R_2Si(CH_2)_nN(C(O))_2N(CH_2)_nSiR_2R'\ ,$$

where R and R′ = Me, Et, or Ph, n = 1 or 3, and M = K or Na.

When bishalogenoalkylsilanes are used in this reaction, the analogous oligomeric compounds are formed:

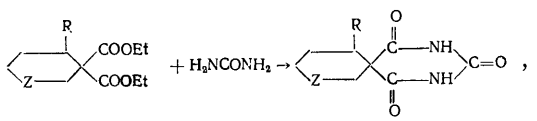
$$Cl(CH_2)_nSiR_2O[SiR_2(CH_2)_nCl] + KOCN \rightarrow OCN(CH_2)_nSiR_2O[SiR_2(CH_2)_nNCO] +$$

$$+ OCN\left[-(CH_2)_nSiR_2O[SiR_2(CH_2)_nN(C(O))_2N-]\right]_m(CH_2)_nSiR_2O[SiR_2(CH_2)_nNCO.$$

Silicon-containing uretidinediones were obtained in low yields also by treating carbofunctional organosilicon amines with phosgene[7]. Finally, silyl-substituted barbiturates were obtained by the condensation of urea with organosilyl malonates[168,169]:

$$Me_3Si-R-C(R')(COOEt)_2 + H_2NCONH_2 \rightarrow Me_3Si-R-C(R')(C(O)NH)_2C(O)\ ,$$

where R = $-CH_2-$ and R′ = H, Me, or allyl[168] or R = $-C_6H_4-$ and R′ = H or Et[169], and with spirobarbiturates[170]:



where Z = $SiMe_2$ or CH_2SiMe_2 and R = H, Me, or Et.

2. PROPERTIES

Carbofunctional organosilicon ureas are colourless viscous liquids or crystalline substances. Some decompose appreciably on vacuum distillation[171]. They are readily soluble in benzene, acetone, and DMF and are insoluble in water and petroleum ether[130,171].

Silicon-containing acylureas and semicarbazides are crystalline substances soluble in DMF and alcohol and sparingly soluble or insoluble in water, benzene, and carbon tetrachloride[130].

The infrared spectroscopic data for silylureas[6,7,130-132,133,141,142,172], silylsemicarbazides[137], and silylpolyacylsemicarbazides[146] agree well with the amide structure of these compounds. The characteristic absorption bands of the C=O group (amide band I) in the infrared spectra of asymmetric ureas of the type $R_3Si(CH_2)_nNHCONR_2$ are in the region of 1630 cm^{-1}.[130] The analogous bands in the spectra of polysilylureas are at 1650 cm^{-1}.[132]

An appreciable decrease of the carbonyl absorption wavenumber (1690 cm^{-1}) has been observed for uretidinediones (cyclic compounds) $R_3Si(CH_2)_nNC(O)N(CO)(CH_2)_n$. .$SiR_3$ compared with compounds of analogous structure but without silicon (1780–1790 cm^{-1}). A similar decrease of the C=O vibration wavenumber is known to occur in the spectra of organosilicon ketones $R_3Si(CH_2)_nC(O)Me$. Evidently, in this case there is an appreciable decrease of the amount of double bond character of the linkage joining the carbonyl group owing to the intramolecular coordination of its oxygen atom to silicon[165]. The bond formed is fairly stable, as shown by the constancy of the extinction coefficient of the C=O band when the concentration of the substance is reduced from 0.1 to 0.0001 M.

NMR data for a number of silylureas have been published[7,141].

When organosilicon ureas are pyrolysed, an isocyanate and an amine are formed, as from their hydrocarbon analogues[6]:

$$Me_3SiCH_2NHC(=O)NPh_2 \xrightleftharpoons{250\div300^\circ} Me_3SiCH_2NCO\,(70\%) + Ph_2NH.$$

3. APPLICATIONS

Carbofunctional organosilicon ureas are of interest primarily for the preparation of modified polymeric materials. The study of various types of polymers (polyamides, polyimides, etc.) has shown[173] that the introduction of, for example, polysiloxane units into the organic polymeric chain in an amount of 3–5% entails a number of significant changes in the properties (a decrease of the yield temperature, an improvement in solubility and dielectric parameters) and makes polymeric materials hydrophobic and resistant to hydrolysis. When a large number of siloxane units (from 15 to 20%) are introduced, there is in addition an appreciable improvement in thermal stability.

The foregoing applies equally to carbofunctional organosilicon materials in which the organic and organosilicon fragments are linked chemically. Polymeric materials of this kind have been proposed for the preparation of coatings, resins for laminated plastics, stable water-repellent impregnation for cotton and paper fabrics[152,153], and self-vulcanising rubbers[174]. Monomeric and polymeric silylureas can be used as adhesives[152–154,175–177], antifoaming agents[160,161], auxiliary substances in the synthesis of glass fibre-reinforced plastics[135,178,179], surface-active substances[149,175,176,180], hardening agents for epoxy-resins[181], and other purposes[149,151–154,178,180,182–187]. Some of these compounds exhibit physiological activity[163,164,168–170,188].

Silicon-carbamide polymeric materials, obtained by the copolymerisation of urea-formaldehyde prepolymers with organosilicon polymers or oligomers[159,189], have been proposed for the preparation of varnish films, adhesives, cast articles, and laminated plastics with better dielectric parameters and improved thermal stability and water resistance compared with the usual urea-formaldehyde materials. Silyl ethers of hydroxymethyl derivatives of urea have been recommended for the preparation of rubbers which undergo self-cross-linking under the influence of moisture[190,191] and as intermediates in the preparation of medicines, textiles, and resins[192].

The use of compositions of monomeric or polymeric organic urea derivatives with silicon-containing compounds (components not linked chemically) is also a promising application[193–225]. For example, the introduction of 0.05–5% of urea, diphenylurea, or tolylurea into a vulcanisate improves the thermal stability of silicon elastomers[203]. The compositions are used to treat textiles in order to make them hydrophobic and crease-resistant[195,219,221,223,225], to improve the water resistance of aminoplastics[208], to bind polyurethanes to the support[213], as coatings[220,222], adhesives[215], lubricants[214,218], and binders for articles made of fibreglass[140], and for many other purposes.

Studies on the use of organosilicon products as auxiliary substances in the manufacture of various urea-based materials are also noteworthy[201,206,226]. Urea and its derivatives can be used in their turn as auxiliary products in the preparation of silicon-containing compounds, for example as ligands which reduce the activity of platinum catalysts in the addition of hydropolysiloxanes to olefinic silicones[227] and as solvents in the reduction of halogenosilicones with sodium hydride[228–230].

Microbiological Degradation of Lignin

O.P.Grushnikov and O.N.Antropova

The problems of the microbiological degradation of lignin, closely related to the solution of a number of important theoretical and practical problems, have been continually attracting attention in recent years. The most recent studies in this field are analysed in the present review. Particular attention has been devoted to a critical examination of hypotheses about the possible pathways in the microbiological degradation of lignin.
The present review is the first attempt in the Soviet scientific literature at a survey of data concerning the problem of the microbiological degradation of lignin.
The bibliography includes 151 references.

1. INTRODUCTION

The microbiological degradation of plant materials, an important component of which is lignin, plays a significant role in the carbon turnover in nature. Studies on the degradation of lignin as a result of the activity of micro-organisms [1-14], which to a large extent differs from the degradation of other plant components, have widely developed in the last 10–15 years. These investigations are closely related to studies in a number of important fields, among which the following should be mentioned: (1) humus formation and the problem of soil fertility (see the relevant reviews [12,15-17]); (2) the formation of peat and coal; (3) the conservation of wood during storage (see the review of Cartwright and Findlay [18]); (4) the possibility of employing wood infected by fungii; (5) the metabolic transformations of plants in man and animals; (6) the use of the fungal mycelia to accumulate protein products; (7) delignification of plant raw materials in order to develop rational methods for the preparation of cellulose; (8) decontamination of natural waters by the removal of lignin-containing waste (see the relevant reviews [19,20]).

There is no need to stress the great theoretical and practical importance of the above studies. Furthermore, recent studies on the microbiological degradation of lignin yielded valuable information about its structure, which makes it possible to treat microbiological activity as one of the promising methods for the investigation of lignin.

Despite the importance of these studies, in the latest monograph on the chemistry of lignin [21] unjustifiably little attention was devoted to problems of its microbiological degradation. Furthermore, there are no reviews in the Soviet chemical literature on this field.

In view of the large amount and great variety of available data, it is impossible to consider here all the above aspects of the microbiological degradation of lignin. Attention will be concentrated below on studies which yielded information about the structure of natural lignin, i.e. lignin isolated from plant tissue.

II. WOOD DECOMPOSING FUNGI

Since the aims of the present review are restricted to the analysis of the results of studies on the microbiological degradation of lignin important for the determination of its structure, among the different biological agents causing decomposition of lignin (wood-decomposing fungi, soil and water micro-organisms, intestinal bacteria) only wood-decomposing fungi will be considered, their action on wood, lignin, and its model compounds having been fairly thoroughly investigated.

Most fungi causing the decay of wood belong to one of the classes of higher fungi (*Basidiomycetes*), but there are also certain wood-decomposing fungi which belong to the class of *Ascomycetes*. Two main types of wood-decomposing fungi, usually referred to as brown rot and white rot, are distinguished. When wood is infected by brown rot, cellulose and other carbohydrate components are preferentially decomposed, while lignin remains relatively unchanged and the decaying wood acquires a brown colour. Infection with white rot results in the decomposition of all the components of wood, and as decay proceeds the residue becomes paler in colour, compared with healthy wood. A list of fungal species belonging to these two groups has been published [1,22] and in addition 126 species of wood-decomposing fungi have been characterised in detail in a review by Nobles [23].

In 1928 Bavendamm [24] observed that white rot fungi cultured on an agar medium containing gallic or tannic acid produce a dark zone around and below the mycelial films, while brown rot fungi do not generate such a zone. This reaction, which has been called the Bavendamm reaction, was subsequently widely used to classify the wood-decomposing fungi. Bavendamm attributed the ability of fungi to degrade lignin to the production of phenol oxidase. This conclusion was confirmed in a study by

Davidson et al.[25], who tested 210 species of wood-decomposing fungi in the Bavendamm reaction and established that 96% of the white rot fungi produced the coloured zones, while 80% of the brown rot fungi did not.

A considerable number of studies[23,26-31] were devoted to the determination of enzymes catalysing the oxidation of the simplest phenolic compounds to quinones, which polymerise to give the coloured complexes in the Bavendamm test. It was noted that the enzymes responsible for this reaction are laccase†[27-29], tyrosinase‡[28,29], and peroxidase§[31], but complete certainty with regard to this problem has not yet been reached.

It is noteworthy that hitherto no systematic studies have been made on the enzymes of wood-decomposing fungi. The available literature data are of a general kind and frequently contradictory. The studies in this field have been examined in detail in monographs by Schubert[7] and Shivrina[32]. It was established that white rot fungi produce two main enzymes: laccase and tyrosinase. Furthermore, Lyr showed that 14 of the 182 species of wood decomposing fungi which have been investigated produce peroxidase[33] and proposed a method for its detection[34]. These enzymes catalyse the abstraction of electrons from phenolic substrates. In the presence of laccase and peroxidase one reducing equivalent is removed from the substrate, while in the presence of tyrosinase two reducing equivalents are eliminated simultaneously.

Since the lignin-decomposing white rot fungi produce in most cases intracellular phenol oxidising enzymes, while the taxonomically related brown rot fungi, which do not produce these enzymes, do not decompose lignin, the relation between the capacity to degrade lignin and the phenol oxidase activity of the wood-decomposing fungi appears to be evident[23,31,35-37]. However, later it was shown that brown rot fungi do produce intracellular phenol oxidising enzymes: tyrosinase and an enzyme of the laccase type[38-43], as well as peroxidase[44]. Furthermore, there is evidence[45-50] that the degradation of lignin is due to enzymes which are not phenol oxidases. For this reason, Kirk and Kelman[51] undertook a study of the ability of 18 different white and brown rot fungi to degrade lignin and produce intracellular phenol oxidase capable of oxidising simple phenolic compounds. Among the fungal species investigated, there were "typical" and "atypical" white and brown rot fungi. The results of the investigation showed that the inability of wood-decomposing fungi to oxidise phenols in an agar medium cannot be used as proof that they cannot utilise lignin.

Thus the role of phenol oxidases in the biodegradation of lignins still remains uncertain. The results of the above studies[31,43,44,51] show that both the lignin decomposing white rot fungi and the brown rot fungi which do not decompose lignin produce phenol oxidising enzymes and that certain brown rot fungi produce more phenol oxidases than white rot fungi. One may therefore conclude that, if the phenol oxidising enzymes from the white rot fungi do not act on lignin in a manner different from that of the phenol oxidising enzymes of the brown rot fungi, the above differences in the ability of both groups of fungi do degrade lignin may depend on the presence of certain other enzymatic systems.

The results of macroscopic studies[52-58] showed that the microbiological degradation of woody tissue begins with the cell lumens in which the fungal hyphae are located and spreads to the region of the middle lamella. In particular, Schmid and Liese[57] established in the course of an electron microscope analysis that woody material is removed essentially layer by layer, which makes the cell walls gradually thinner, while lignin in the middle lamella and in the corners of the cells is apparently relatively resistant to enzymatic attack. On the other hand, Wilcox[58] established that the action of the cellulolytic enzymes of the white rot fungus *Polyporus versicolor* is initially restricted to the surfaces of the cell walls adjoining the lumen, and, as cellulose is removed, gradually spreads to other layers of the cell wall. On the other hand, the cellulolytic enzymes of the brown rot fungi *Poria monticola* and the lignin decomposing enzymes of the white rot fungus can penetrate the cell wall and act within it. The author attributed these differences in the cellulolytic enzymes to their molecular size and chemical properties.

It is noteworthy that, although the principal characteristics of the degradation of wood by various species of brown rot fungi are general, nevertheless the action of each species has its characteristic features due to different enzymatic activities[59]. This is responsible for the differences in the rate of decomposition of wood by various species of brown rot fungi.

III. REACTIONS OF NATURAL AND ISOLATED LIGNINS UNDER THE INFLUENCE OF WOOD DECOMPOSING FUNGI

Studies on the changes in lignin under the influence of wood-decomposing fungi were made either on preparations isolated after incubating various isolated lignins with white rot fungi in synthetic liquid culture media or on preparations extracted by neutral solvents from wood subjected to the action of white rot. In most cases the preparations isolated from liquid culture media and from decayed wood undergo analogous changes in relation to the initial control lignin (cf. Tables 1 and 2) and can therefore be treated together. However, one should bear in mind[13] that (1) the regeneration and purification of the preparations after the incubation of isolated lignins with microorganisms can lead to a series of additional changes and (2) that lignin isolated from decayed wood may differ from the control preparation not only in consequence of the changes due to the action of fungi but also due to the method of extraction, which usually differs from the method used to isolate the control preparation.

A study of the action of various brown rot fungi on sprucewood established that nitrobenzene oxidation of decomposed wood gives a higher yield of vanillin compared with healthy wood[60]. Leopold[61] investigated the products of the nitrobenzene oxidation of wood at different stages with decomposition by brown rot fungi and observed a successive decrease of their yield, although the oxidation products contained the same aldehydes and in virtually the same proportions as the products of the oxidation of healthy wood. The author believes that the decrease of the yield of vanillin is due to the preferential enzymatic attack on the "open" lignin structures, i.e. not condensed in the 5-position of the aromatic ring, which constitute the main source of vanillin in nitrobenzene oxidation. A decrease

§ Donor: hydrogen-peroxideoxidoreductase, EC 1.11.1.7.

of the yield of vanillin in the nitrobenzene oxidation of pinewood decomposed by brown rot fungi was also noted by Enkvist et al.[62]

Higuchi et al.[63] studied lignin preparations isolated from beechwood which had been acted upon by various brown and white rot fungi in the course of five months. The authors established that the overall yield of aldehydes in the nitrobenzene oxidation of decayed wood is lower than in the case of healthy wood, and that the yield with respect to lignin is lower for wood subjected to the action of white rot fungi than for wood subjected to the action of brown rot fungi. Moreover, an increase of the molar proportions of syringaldehyde and vanillin in the products of the nitrobenzene oxidation of decayed wood in relation to healthy wood was observed.

The decrease of the yield of vanillin in the nitrobenzene oxidation of the isolated lignins subjected to the action of white rot fungi was also pointed out by Ishikawa et al.[64] They investigated the changes in the native Brauns lignin and milled-wood lignin (MWL), isolated from pinewood and sprucewood, as a result of their incubation with white rot fungi. In the experiments a study was made of both "phenol oxidase-rich" (*Polyporus hirsutus*, *Polyporus versicolor*, and *Poria subacida* J247) and "phenol oxidase-deficient" (*Poria subacida* N199, *Fomes fomentarius*, *Fomes annosus*, and *Trametes pini*) white rot fungi. It was established that the degradation of lignin by the white rot fungi leads to a decrease of the number of methoxy-groups and an increase of the content of the overall and phenolic hydroxy-groups, carbonyl groups, and carboxy-groups (Table 1).

Table 1. Results of an analytical study of the initial lignins and lignins acted upon by white rot fungi* (according to Ishikawa et al.[64]).

Lignin	Fungal species	Yield, %	Content, %			Content, moles per lignin unit with mol. wt. of 180			Yield of vanillin, %
			C	H	OCH_3	OH_{phen}	CO	COOH

*Culture conditions: synthetic liquid medium containing 1% of lignin, 26–29°C, 13 days.

The study of the infrared spectra of lignin subjected to the action of white rot fungi revealed an increase in absorption at about 1670 cm^{-1}. The increase was attributed to the accumulation in the lignin of conjugated carbonyl and (or) conjugated carboxy-groups. Other investigators[65–67] noted that fungal attack enhances the absorption in the range 1710–1735 cm^{-1}. This band was also assigned to conjugated carbonyl and (or) carboxy-groups.

Ishikawa and Oki[68] showed that native spruce lignin acted upon by H_2O_2 and purified peroxidase preparations isolated from horseradish, radish, and lumps of *Collybia velutipes* N8 mycelia undergoes changes analogous to those discussed above, except that the content of methoxy-groups remains constant.

Ishikawa and Oki[69] investigated the changes undergone by ethanol-lignin from Japanese cedar under the influence of a purified enzymatic solution obtained from mycelial clusters or mycelium-free culture filtrates from *Collybia velutipes* N8 and *Polyporus versicolor*. It was established that enzymatic hydrolysis of ethanol-lignin leads to an almost quantitative removal of ethoxy-groups with a simultaneous increase of the number of alcoholic OH groups and a slight increase of the content of phenolic hydroxyls. No changes were observed in the infrared and ultraviolet spectra as a result of the enzyme action. At the same time a study was made of the transformations of a number of aromatic ether compounds under the influence of a purified enzymatic solution (the results are discussed in Section V). The results enabled the authors to conclude that during fungal attack alkyl–alkyl and alkyl–aryl ether linkages are hydrolysed enzymatically in ethanol-lignin.

Table 2. Results of an analytical study of sprucewood MWL and lignin preparations extracted from sprucewood acted upon by *P. subacida* (according to Hata[66]).

Preparation	Yield, % of lignin in decayed wood	Content, %			Content, moles per lignin unit with mol. wt. of 180			
		C	H	OCH_3	OH_{tot}	OH_{phen}	CO	COOH
MWL	—	62.81	5.88	15.24	1.18	0.25	0.14	0.017
DL-I*	1.1	60.44	5.67	12.32	1.42	0.30	0.21	0.053
DL-II**	2.7	58.54	5.23	11.75	1.67	0.40	0.28	0.106

*Lignin extracted with an acetone–water mixture from wood acted upon by *P. subacida* for 3 months.
**Lignin extracted with an acetone–water mixture from wood acted upon by *P. subacida* for 6 months.
***Lignin extracted with water from wood acted upon by *P. subacida* for 6 months.

On the basis of ultraviolet and infrared spectroscopic studies native spruce lignin and lignin extracted by acetone from sprucewood powder acted upon by *Poria subacida*, Fukuzumi[70] concluded that there is an appreciable increase in the number of carbonyl groups in lignin subjected to enzymatic action. Hata[66] investigated preparations of lignin extracted from sprucewood acted upon by *Poria subacida* BII. Compared with spruce MWL, the preparations isolated contained fewer methoxy-groups and more phenolic hydroxyls, carbonyl groups, and carboxy-groups (Table 2). In addition, it was established that, as a result of enzyme action, the number of coniferaldehyde and guaiacylcarbinol groups in lignin diminishes. In the nitrobenzene oxidation of degraded lignins a smaller amount of vanillin and a greater amount of vanillic acid (compared with spruce MWL) is produced, and with increase of the duration of enzyme action, this tendency becomes more pronounced (Table 3). However, the overall yield of these products from degraded lignin is lower than from MWL. In hydrolysis by a dioxan–water

mixture (180°C, 50 min and 140°C, 60 min) degraded lignin gives a higher yield of vanillic acid and a lower yield of coniferyl alcohol, coniferaldehyde, and vanillin compared with MWL. Furthermore, a very small amount of ferulic acid, not detected in the products of the hydrolysis of MWL is produced. The study of free radicals in MWL and in degraded lignins showed that their numbers are approximately the same, but the radicals belong to different types.

Konishi and Inoue [71-74] showed that the enzymes produced in culture filtrates by the fungus *Coriolus versicolor* convert MWL isolated from Sugi sapwood into a water-soluble state without a significant change in its molecular weight, but do not break down lignin into low-molecular-weight compounds. Compared with the initial MWL, the water-soluble lignin contains more COOH groups and fewer alcoholic OH groups. The above changes were attributed to enzymatic attack on the side chains of the phenylpropane units of lignin, which evidently proceeds via a radical reaction.

Table 3. Yields of nitrobenzene oxidation products (% of lignin) (according to Hata [66]).

Preparation	Vanillic acid	Vanillin
Sprucewood MWL	2.2	24.1
DL-I*	4.8	14.9
DL-II**	6.7	10.2

*The designations of the preparations are the same as in Table 2.

Steelink [75,76] established that the action of brown or white rot fungi on wood increases by a factor of 2–3 its content of free radicals and that the wood of deciduous trees attacked by fungi has a higher concentration of free radicals than the wood of conifers. These data were confirmed in a study by Kreitsberg et al. [77]

Ferm et al. [78] investigated the transformations of MWL from Liquidambar (sweetgum) under the influence of partly purified preparations of horseradish and peroxidase and laccase from *Polyporus versicolor* and also of an unpurified enzyme from the brown rot fungus *Poria cocos*. Experiments on the enzymatic oxidation of lignin were carried out in a methylcellosolve–water mixture which dissolves MWL and has only an insignificant influence on the stability of the enzyme preparations employed. ESR showed that each enzyme preparation causes the formation of free radicals of the phenoxy-type. The formation of radicals of a similar type was observed previously [79] on incubation of syringyl compounds with phenol oxidising enzymes (see Section V). Furthermore, Ferm et al. [78] reported the preliminary results of a study of the changes in the molecular weight distribution of lignin and lignosulphonate under the influence of phenol oxidising enzymes. It was shown by gel permeation chromatography that phenol oxidising enzymes cause an increase in molecular weight. On this basis, the authors suggested that phenol oxidising enzymes can be involved in later stages of the microbiological degradation process and not in the initial depolymerisation reactions.

Ishihara and Miyazaki [80] investigated the changes in the molecular weight of maple MWL as a result of incubation with laccase B obtained from the filtrate of a *Polyporus versicolor* culture and concluded on the basis of the results that this enzyme can polymerise and depolymerise lignin, the first function being dominant.

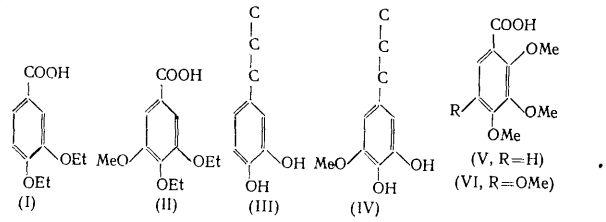
Kirk and Lundquist [67] made a comparative study of MWL preparations isolated from healthy cambium and cambium acted upon by *Polyporus versicolor* (32% weight loss) of sweetgum wood. They established that these preparations do not show distinct differences as regards elemental composition and the content of OCH_3 groups, ultraviolet and infrared spectra, $\Delta\epsilon$ curves, molecular weight distribution curves, and the composition of the ethoxybenzoic acids formed on degradation of lignin by the ethylation–oxidation method [81]. The results showed that the lignin isolated from decayed wood by mechanical milling (27% yield) does not undergo significant changes. This, however, does not allow a conclusion concerning the degree of change of the entire lignin remaining in the decomposed wood. Nevertheless the authors suggested that in the decay of wood by the fungus *Polyporus versicolor* only a limited proportion of the lignin is subjected to enzyme action and is removed before the decay spreads to other parts of the lignin.

Kirk and Lunquist also investigated the substances extracted from healthy and decayed wood with a 2:1 benzene–ethanol mixture and then with 96% ethanol (their yields were 3.3 and 3.6% of the wood respectively). The high-molecular (molecular weight >400) fractions (the so called "extractive lignin") obtained as a result of gel filtration on Sephadex G-25 were investigated by ultraviolet and infrared spectroscopy. The experimental results showed that these preparations consist of lignin and revealed differences between the extractive lignin from healthy and decayed wood. An appreciable absorption at 1730 cm^{-1} was noted in the infrared spectrum of lignin extracted from decayed wood. It was established that this band is due to the chemical changes caused by the fungi and not by the presence of non-lignin impurities. The band could not be assigned accurately, although the authors suggest that absorption in this region may be attributed to non-conjugated carbonyl groups and non-conjugated carboxy-groups. It is interesting to note that the changes in lignin leading to the appearance of the 1730 cm^{-1} band in its infrared spectrum are not accompanied by appreciable changes in the ultraviolet spectrum. This is clearly evidence that enzyme action does not result in the formation of appreciable amounts of chromophoric systems whose spectroscopic properties differ greatly from those of the chromophores present initially in the lignin (aryl-conjugated carboxy-groups, aryl-conjugated carbonyl groups, *p*-benzoquinonoid residues, and others).

Interesting results were obtained in recent years in studies by oxidative degradation methods on the lignin remaining after wood has been acted upon by brown rot fungi (the so called enzymatically liberated lignin).

According to the results of a number of investigators [60,62,82-87], the action of brown rot fungi on lignin greatly reduces its content of methoxy-groups. Kirk and Adler [81,88] undertook a study of the structural changes leading to a decrease of the content OCH_3 groups. They investigated the lignin liberated enzymatically from sweetgum wood acted upon by the brown rot fungus *Lenzites trabea*. After preliminary ethylation, the lignin preparations were subjected to oxidative degradation. The resulting ethoxybenzoic acids were identified by gas chromatography and mass spectrometry. The acids (I)

and (II) were detected in the degradation products of the enzymatically liberated lignin, which indicates the presence in the latter of the *o*-diphenol structures (III) and (IV).



These structures are formed as a result of the fungal demethylation of the lignin units of the guaiacyl and syringyl type respectively. Furthermore, Kirk and Adler boiled a preparation of the enzymatically liberated lignin with 0.2 M HCl solution in a dioxan–water mixture. This treatment led to the cleavage of the alkyl aryl ether linkages with formation of phenolic OH groups. Subsequent ethylation and oxidative degradation gave higher yields of acids (I) and (II). Thus fungal attack does not lead to the demethylation of units with a free phenolic hydroxyl alone. However, non-phenolic residues are demethylated to a smaller extent than the corresponding phenolic residues. It was also established that both phenolic and non-phenolic structures of the syringyl type are demethylated more vigorously than the corresponding structures of the guaiacyl type. The preferential demethylation of units of the syringyl type can evidently be explained by the fact that they contain two methoxy-groups, so that the demethylating enzymatic system is better able to come into contact with them.

Thus *Lenzites trabea* demethylates both free and etherified units of the guaiacyl and syringyl type in lignin. According to the authors [81,88], the demethylation can occur as a result of the direct oxidation of the methyl group, which is then eliminated as formaldehyde, leaving behind a free phenolic OH group.

Kirk et al. [89] made a comparative study of methoxylated aromatic carboxylic acids formed in the degradation of enzymatically liberated lignin and MWL from sweetgum by the method of Larsson and Miksche [90-92]. The acids (V) and (VI), formed from structures hydroxylated as a result of fungal action, were identified among the degradation products of the enzymatically liberated lignin. Hydroxylation takes place in the *ortho*-position relative to the side chains of the phenylpropane units of lignin. However, neither the mechanism of this process nor the lignin units which undergo hydroxylation (initial guaiacyl and syringyl units or the newly formed *o*-diphenol units) are so far known.

IV. LOW-MOLECULAR-WEIGHT PRODUCTS OF THE MICROBIOLOGICAL DEGRADATION OF LIGNIN

Henderson [93] showed that incubation for six months of sprucewood and birchwood fillings, subjected to preliminary extraction, with the white rot fungi *Polystictus versicolor* and *Trametes pini* led to the liberation of vanillic acid in the first case and a mixture of vanillic and syringic acids in the second. Higuchi et al. [63] reported the presence of coniferaldehyde, vanillin, and syringaldehyde in the alcohol–benzene extract of beechwood powder infected by white rot fungi. Fukuzumi [70] investigated the products of the enzymatic degradation of native sprucewood lignin by the fungus *Poria subacida* using paper chromatography and reported the presence of 4-hydroxy-3-methoxypyruvic acid. Furthermore, β-coniferyl guaiacylglyceryl ether and a compound resembling vanillic acid were detected in the acetone and methylene chloride extracts of sprucewood powder decomposed by the same fungus.

An extensive study on the low-molecular-weight products of the enzymatic degradation of lignin was carried out by Ishikawa et al. [64] They incubated native lignin and MWL preparations isolated from pinewood and sprucewood with various white rot fungi in liquid culture media. The acid fractions of the ether extracts of the lignin degradation products were studied by paper chromatography. The products identified are listed in Table 4.

Table 4. Low-molecular-weight products formed when pinewood and sprucewood lignin is acted upon by white rot fungi* (according to Ishikawa et al. [64]).

*Conditions: culture medium containing 1% of lignin, 27°C, 28 days. Solvent for paper chromatography—butanol saturated with 3% ammonia.

**A—species rich in phenol oxidase (*Polyporus hirsutus*, *Polyporus versicolor*, and *Poria subacida* J247).

***B—species deficient in phenol oxidase (*Poria subacida* N199, *Fomes fomentarius*, *Fomes annosus*, and *Trametes pini*).

****Medium without lignin after degradation by fungi of group A or B.

The results of this investigation showed that ferulic acid, 4-hydroxy-3-methoxyphenylpyruvic acid, guaiacylglycerol, and its coniferyl ether are probably more readily metabolised by phenol oxidase-rich microorganisms (group A), compared with other intermediates. The presence of β-coniferyl guaiacylglyceryl ether in the enzymatic degradation products of lignin and also the formation of coniferaldehyde, α-hydroxypropiovanillone, and vanilloyl methyl ketone in the acidolysis of the phenolic fraction of the lignin degradation products constitutes proof, according to the authors, that lignin contains β-coniferyl guaiacylglyceryl ether linkages.

As noted above, Kirk and Lundquist [67] extracted the cambial components of sweetgum wood, both healthy and acted upon by *Polyporus versicolor*, with a 2:1 benzene–ethanol mixture and then with 96% ethanol. The extracted products were subjected to gel filtration on Sephadex G-25

and the resulting low-molecular-weight (monomeric) fraction was separated by paper chromatography. Vanillin, syringaldehyde, vanillic and syringic acids, coniferylaldehyde and sinapaldehyde were identified in the monomeric fraction of the substances extracted from the decayed wood. Since the same substances were found in approximately the same amounts also in products extracted from the healthy wood, the authors suggest that their formation cannot be attributed to fungal attack. Evidently the low-molecular-weight compounds are formed as a result of hydrolysis during decay and not as a result of the decomposition of the phenylpropane units of lignin.

Kirk and Lundquist attempted to detect in the monomeric fraction of the substances extracted from decayed wood guaiacylglycerol, syringylglycerol, and 4-hydroxy-3-methoxyphenylpyruvic acid, i.e. the compounds which Ishikawa et al.[64] identified among the products of the enzymatic degradation of lignin. These compounds were not detected, which, according to Kirk and Lundquist, requires the amendation of the results of earlier studies. However, since *Polyporus versicolor* is a phenol oxidase-rich species of the white rot fungi, the results of Kirk and Lundquist are not inconsistent with those of Ishikawa et al. (Table 4).

Ishihara and Miyazaki[80] incubated maple MWL with a preparation of laccase B obtained from the filtrate of a *Polyporus versicolor* culture for 4 days at 30°C. 2,6-Dimethoxy-*p*-benzoquinone, the formation of which has been observed previously in the enzymatic degradation of a number of model compounds[94] (see Section V), was identified among the low-molecular-weight degradation products of lignin.

Antropova and coworkers[95] investigated 548 strains of wood decomposing fungi belonging to different taxonomeric groups¶. In these experiments the sulphate lignin from aspenwood served as the only source of carbon. The results of the chromatographic study of the monomeric lignin degradation product revealed some specificity in the action of the fungi investigated. Thus aldehydes and certain acids predominated in the cultures of *Mucor* species, while the main products of the metabolism of fungi of the *Trichoderma* species were ketones and benzoic and vanillic acids. *Aspergillus* species produced coniferaldehyde, *p*-hydroxybenzaldehyde, dehydrodivanillin, ketones, and acids, including certain acids which had not been detected in the presence of *Mucor* and *Trichoderma* species. Alcohols, absent in the presence of fungi of the *Mucor*, *Trichoderma*, and *Aspergillus* species, as well as phenols, certain aldehydes, ketones, and acids were detected in the products of the metabolism of fungi of the *Penicillium* and *Fusarium* species.

The study of the lignin-decomposing properties of micromycetes led to the discovery of two most active strains, *Mucor* sp. 15157 and *Penicillium* sp. 50311, exhibiting laccase and phenolase activities respectively[96].

In the degradation of lignin by *Mucor* sp. 15157 the following products were detected in the culture liquid: *p*-hydroxybenzoic, benzoic, *p*-hydrozycinnamic, vanillic, syringic, sinapic, protocatechuic, homoprotocatechuic, cinnamic, 4-hydroxy-3-methoxyphenylpyruvic, and ferulic acids, vanillin, protocatechuic aldehyde, and a number of unidentified substances. In the determination of the quantitative yield of the main lignin decomposition products *p*-hydroxybenzoic acid was detected in an amount of 0.4% on the 7–12th day of the growth of the fungus, while on the 18th day the yield reached 2.0%. Vannillic acid appeared on the 7th day in an amount of 0.06%, its amount gradually increasing and reaching 0.13% on the 20th day, while on the 23rd day it rose sharply to 3.5% after which it fell and varied in the range 0.06–0.1%. Syringic acid appeared only on the 28th day, in an amount of 0.04–0.1%. The yield of the remaining substances varied in the range 0.04–0.1%.

In the degradation of lignin by *Penicillium* sp. 50311 the following substances were detected in the culture liquid, *p*-hydroxybenzoic, benzoic, vanillic, 4-hydroxy-3-methoxyphenylpyruvic, ferulic acid, sinapaldehyde, vanillyl alcohol, 3-hydroxyphenyl-1-propanol, guaiacyl-3-propanol, guaiacyl-2-propanol, pyrogallol, and phenol. The amount of vanillic acid in the culture liquid gradually increased: its content on the 10th day was 0.09%, reaching a maximum level of 0.89% on the 18th day, after which it gradually fell; the same happened with *p*-hydroxybenzoic acid: its content was 0.06% on the 3rd day, 0.5% on the 30th day, after which it fell. The amount of syringic acid reached a maximum of 3.5% on the 30th day, after which it decreased to 0.06%.

V. MICROBIOLOGICAL DEGRADATION OF PHENOLIC COMPOUNDS STRUCTURALLY RELATED TO LIGNIN. POSSIBLE PATHWAYS IN THE MICROBIOLOGICAL DEGRADATION OF LIGNIN

The studies on the enzymatic transformations of phenolic compounds structurally related to lignin discussed below yielded information, which led to hypotheses concerning the mechanism of the transformations of lignins in the course of fungal attack.

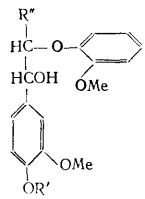
As early as 1956, Minami and Fukuzumi[97] pointed out the reducing function of *Polystictus sanguines*, having detected benzaldehyde in the metabolic products of benzoic acid. Later Fukuzumi et al.[98] reported the reduction of veratric acid to veratraldehyde as a result of incubation with *P. sanguines*.

Henderson and coworkers[99] investigated the transformations of certain aromatic acids under the influence of *Polystictus versicolor* and showed that these fungi produce an intracellular alcohol dehydrogenase. *Polyporus versicolor* reduced *m*- and *p*-methoxybenzoic, veratric, and β-naphthoic acids to the corresponding aldehydes and alcohols. Only alcohols were detected among the products of the enzymatic transformations of *o*-methoxybenzoic and benzoic acids. The corresponding alcohols were also obtained from *o*- and *p*-hydroxybenzaldehydes. 2,4-Dimethoxybenzoic, phenylacetic, and α-naphthoic acids were not reduced. The rate of reaction varied as a function of the position and nature of the substituent in the aromatic ring. Furthermore, it was shown that 2,4-dimethoxybenzoic, and *o*-, *m*-, and *p*-methoxybenzoic acids were demethylated to a slight extent to the corresponding hydroxy-compounds, while cinnamic, benzoic, and phenylacetic acids were hydroxylated in the *p*-position, the last two acids only to a limited extent. Some degradation of the aromatic structure was observed in the course of the metabolic transformations of cinnamic, β-naphthoic, and *p*- and *o*-hydroxybenzoic acids.

¶ Some of the *Mucor*, *Aspergillus*, and *Penicillium* species comprise soil fungi and are incapable of decomposing wood by themselves.

Shimazono and Nord[100] established that *P. versicolor* under aerobic conditions reduces *p*-methoxybenzoic acid to the corresponding aldehyde and alcohol. Raman and Shanmugasundaram[101] reported that cultures of the fungus *Aspergillus niger* convert in the presence of glucose up to 50% of benzoic acid, 35% of *o*-aminobenzoic acid, and 10% of *p*-aminobenzoic acid into the corresponding aldehydes. *o*- and *p*-Hydroxybenzoic acids were not reduced to the aldehydes. Furthermore, under anaerobic conditions benzaldehyde was reduced to benzyl alcohol, but other aldehydes did not undergo a similar reaction.

Henderson and coworkers[102] established that *Polystictus versicolor* produces an intracellular alcohol oxidase, which can oxidise primary aromatic alcohols (benzyl alcohol and its *p*-methoxy, *m*-methoxy, 3,4-dimethoxy-, 4-hydroxy-3-methoxy, *o*-hydroxy-, and *p*-hydroxy-derivatives, 4-hydroxy-3-methoxycinnamyl alcohol, and β-naphthylmethanol) to the corresponding aldehydes, but does not oxidise secondary alcohols [1-(3,4-dimethoxyphenyl)ethanol, 1-(4-hydroxy-3-methoxyphenyl)ethanol, and 1-(4-methoxyphenyl)ethanol].



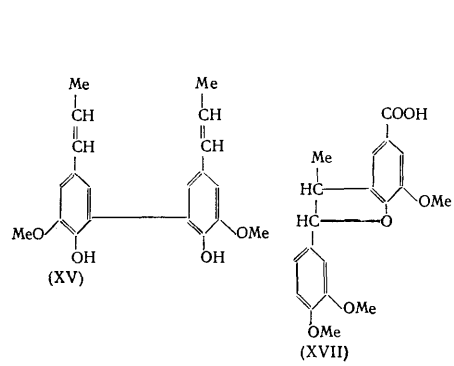
(VII; R′=R″=H)
(VIII; R′=H; R″=CH_2OH)
(IX, R′=CH_3; R″=H)
(X, R′=CH_3; R″=CH_2OH)

In the course of a study of the fungal metabolic transformations of model compounds for lignin, Henderson and coworkers[103] established that the mycelial cells of *P. versicolor* metabolised the β-guaiacyl ether of guaiacylglycol (VII), and β-guaiacyl guaiacylglyceryl ether (VIII) but did not metabolise the β-guaiacyl ether of veratrylglycol (IX) and β-guaiacyl vertrylglyceryl ether (X). The authors noted that the fungus can methylate the phenolic OH groups. Thus the metabolic transformations of compound (VII) yielded veratryl alcohol. Veratraldehyde and veratryl alcohol were also formed as a result of the metabolic transformations of *p*-hydroxybenzoic acid, protocatechuic acid, vanillin, and vanillyl alcohol. None of the compounds (VII)–(X) was oxidised by the intracellular alcohol oxidase of *P. versicolor*.

Ishihara and Miyazaki[104] subjected vanillic acid to the action of the unpurified enzyme from *P. versicolor* and isolated from the reaction mixture a yellow crystalline product melting at 225–226°C. The study of the ultraviolet, infrared, NMR, and mass spectra and analysis of the oxidative degradation products established that this compound is 6-(4′-carboxy-2′-methoxyphenoxy)-2-methoxy-1,4-benzoquinone[105].

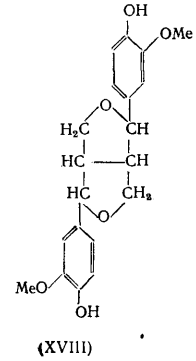
On the basis of the results of the study of the enzymatic degradation of lignin, Fukuzumi[70,106] suggested that lignin decomposes via β-ethers of guaiacylglycerol, β-hydroxyconiferyl alcohol, and 4-hydroxy-3-methoxyphenylpyruvic acid under the action of enzymes from *Poria subaciua*. Fukuzumi suggested that compounds resembling vanillic acid are formed as a result of the cleavage of the side chain of guaiacylpropanones under the influence of the fungal oxidase. He confirmed the presence of homogentisic acid in the culture medium of *P. subacida*.

Ishikawa et al.[107] investigated the transformations of a number of aromatic compounds related to lignin under the influence of *Polyporus versicolor* and *Fomes fomentarius*, which belong to the class of phenol oxidase-rich and phenol oxidase-deficient species of white rot fungi. Vanillyl alcohol (XI), guaiacylmethylmethanol, 4-hydroxy-3-methoxyphenylpyruvic acid (XII), coniferaldehyde (XIII), coniferyl alcohol (XIV), dehydrodi-isoeugenol (XV), guaiacylglycerol (XVI), and its β-guaiacyl ether (VIII) together with certain veratryl and *p*-hydroxyphenyl analogues of these compounds, as well as Erdtman's acid (XVII), pinoresinol (XVIIIa), and symplocosigenol (XVIIIb) were used as substrates.



(XV)

(XVII)



(XVIII)

The studies established that in general guaiacyl compounds were metabolised faster while *p*-hydroxyphenyl compounds were somewhat more resistant to fungal attack under the same conditions. *p*-Hydroxycinnamic, *p*-hydroxyphenylpyruvic, ferulic, and 4-hydroxy-3-methoxyphenylpyruvic acids, coniferyl aldehyde, coniferyl alcohol, isoeugenol, and guaiacylglycerol were particularly rapidly metabolised. After the incubation of these compounds with *P. versicolor* for 4–5 days, only small amounts of the substrate were detected in the filtrates. However, the amount of the metabolic products accumulated in the reaction medium was also comparatively small. It is likewise noteworthy that a proportion of the compounds investigated were converted into polymers. *p*-Hydroxycinnamic, *p*-hydroxyphenylpyruvic, ferulic, and 4-hydroxy-3-methoxyphenylpyruvic acids, Erdtman's acid, coniferaldehyde, coniferyl alcohol, isoeugenol, dehydrodi-isoeugenol, simplocosigenol, and pinoresinol were more readily polymerised by the fungus *P. versicolor* than by *F. fomentarius*. The principal metabolic products formed from the substrates tested are listed in Table 5.

The main products of the enzymatic degradation of the compounds employed are vanillin and vanillic acid, their yield being higher for the degradation monomers and not dimers. Since the authors did not report their control experiments involving the incubation of the medium and substrate alone, this suggested[13] that vanillin and vanillic acids might have been formed as a result of the autoxidation of the specimens or contamination of the substrates.

Both *P. versicolor* and *F. fomentarius* converted β-guaiacyl guaiacylglyceryl ether (VIII) into guaiacylglycerol (VI) and guaiacol. The guaiacylglycerol formed in this way was converted further by both fungi into vanillic acid via 4-hydroxy-3-methoxyphenylpyruvic acid (XII) and vanillin, but the acid (XII) was not detected in the culture medium of *P. versicolor*.

p-Hydroxyphenyl derivatives undergo similar transformations (*p*-hydroxybenzaldehyde and *p*-hydroxybenzoic acid are formed from *p*-hydroxycinnamic and *p*-hydroxyphenylpyruvic acids, while *p*-hydroxybenzaldehyde is oxidised to *p*-hydroxybenzoic acid).

It was noted at the same time that guaiacyl compounds are reduced under the influence of enzymes. In particular, in the presence of *F. fomentarius* vanillyl alcohol (XI) was detected in the products of the metabolic transformations of vanillin, vanillic acid, acetovanillone, and isoeugenol. Furthermore, *p*-hydroxybenzoic, *p*-hydroxycinnamic, and ferulic acids as well as *p*-hydroxybenzaldehyde were converted enzymatically into the corresponding aldehyde or alcohol.

Table 5. Products of the enzymatic degradation of a number of phenolic compounds structurally related to lignin (according to Ishikawa et al.[107]).

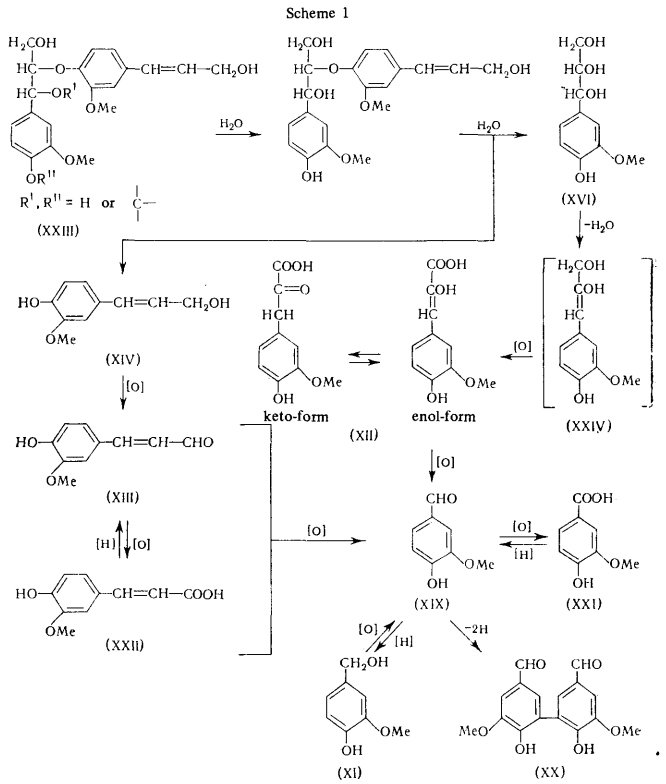
*Compound relatively resistant to fungal attack.

It was also noted that the action of both fungi leads to partial demethoxylation of a number of methyl derivatives of the *p*-hydroxyphenyl and guaiacyl compounds investigated with subsequent oxidation of the demethylated products. (Subsequent studies[108-111] demonstrated the demethylation of various methoxylated aromatic compounds, occurring as a result of fungal attack.)

The results obtained in studies on the enzymatic degradation of lignin and structurally related phenolic compounds enabled Ishikawa, Schubert, and Nord to suggest that the initial stage in fungal attack leads to the loss of methoxy-groups and the cleavage of certain types of ether bonds as well as the degradation of vanillin forming lignin structures. The low-molecular-weight products formed as a result are degraded further to vanillic acid, which can then be metabolised via the formation of protocatechuic acid.

The β-aryl guaiacylglyceryl ether units (XXIII) of lignin are degraded via guaiacylglycerol (XVI), β-hydroxyconiferyl alcohol (XXIV), and 4-hydroxy-3-methoxyphenylpyruvic acid (XII). The enolic form of this acid, which is most sensitive to the action of oxidases, is converted further into vanillin and vanillic and oxalic acids as a result of the oxidative cleavage of its propane side chain. Coniferyl aldehyde and ferulic acid, which are also formed on decomposition by fungi of the lignins in the wood of conifers, are converted similarly into vanillin and vanillic acid (Scheme 1). However, the hypothesis that compounds

Scheme 1



with the phenylpropane structure are intermediates in the degradation of lignin by white rot fungi and that an appreciable proportion of the polymeric lignin breaks down in the way shown in Scheme 1 is based essentially only on the detection of small amounts of monomeric phenylpropane compounds formed when isolated lignin is incubated with white rot fungi (see Section IV). Nevertheless, small amounts of these products might have been formed from the "side groups" or from secondary structural elements and not from the block of the phenylpropane units of the polymer itself. Furthermore, despite the quantitative importance of the β-aryl glyceryl ether linkages in lignin, the available data show, that their cleavage can liberate only a small amount of monomeric aromatic compounds even when appreciable depolymerisation takes place. (For example acidolysis of lignin, which leads to the quantitative cleavage of β-alkyl aryl ether linkages, the yield of monomeric degradation products is about 11% of the lignin[112].) Thus one may conclude that the cleavage of the β-aryl arylglyceryl linkages by the white rot fungi evidently cannot result in the liberation of appreciable amounts of monomeric products.

Ishikawa et al.[113] also investigated the enzymatic degradation of guaiacylglycerol (XVI), β-hydroxyconiferyl alcohol (XXIV), and 4-hydroxy-3-methoxyphenylpyruvic acid (XII) by purified enzyme preparations obtained from the mycelial clusters and the filtrates of *Fomes fomentarius* and *Collybia velutipes* cultures freed from mycelia. These preparations included mainly tyrosinase, an enzyme of the laccase type, and peroxidase. The authors observed enzymatic transformations of compounds

(XVI), (XXIV), and (XII) to vanillic acid via vanillin. Furthermore, the formation of (XII) from (XVI) and (XXIV) and the formation of compounds of type (XXIV) from (XVI) was demonstrated. The results were regarded by the authors as further evidence indicating that guaiacylglycerol, formed in the enzymatic degradation of the β-aryl guaiacylglyceryl ether linkages of conifer lignin, is converted further into vanillic and oxalic acids via β-hydroxyconiferyl alcohol, 4-hydroxy-3-methoxyphenylpyruvic acid, and vanillin as a result of the oxidative cleavage of the propane side chain.

Ishikawa and Oki [68] investigated the degradation of a number of aromatic compounds by purified preparations of peroxidase obtained from horseradish, radish, and clusters of *Collybia velutipes* N8 mycelia. The enzymatic transformations of the compounds under the influence of peroxidase involved both dehydropolymerisation and oxidative cleavage of the side chains. An example of the first process is provided by the formation of polymers from vanillin, acetovanillone, guaiacylmethylmethanol, eugenol, isoeugenol, ferulic acid, coniferyl aldehyde, guaiacylglycerol, coniferyl alcohol, Erdtman's acid, dehydrodi-isoeugenol, pinoresinol, symplocosigenol, and β-guaiacyl guaiacylglyceryl ether, while the formation of vanillin and dehydrodivanillin from vanillyl alcohol, ethyl vanillyl ether, β-hydroxyconiferyl alcohol, and 4-hydroxy-3-methoxyphenylpyruvic acid is an example of the second process. (It is noteworthy that the methyl derivatives of all these compounds were regenerated quantitatively from the peroxidase solutions after incubation for 2 h.) The authors showed that the degradation is accelerated by the addition of H_2O_2 and an increase of the enzyme concentration, being inhibited by heating (the optimal pH is 5.3 to 5.5).

Ishikawa and Oki [69] subjected a number of aromatic ether compounds (β-guaiacyl guaiacylglyceryl ether, ethyl vanillyl ether, and methyl veratrylmethyl ether) to the action of purified enzyme solutions obtained from mycelial clusters or filtrates of the *Collybia velutipes* N8 and *Polyporus versicolor* cultures freed from mycelia. It was established that the ether linkages in these compounds are hydrolysed with the formation of the corresponding alcohols. In particular, after incubation of compound (VIII) with a 30-day filtrate of the *C. velutipes* culture (25°C, second day), 20–30% of the substrate was converted into guaiacylglycerol. The study of the action of inhibitors and the pH on the enzymatic hydrolysis of ethyl vanillyl ether to vanillyl alcohol led the authors to the conclusion that the enzyme responsible for the hydrolysis of aromatic ether compounds is not of the metal-containing type such as laccases and peroxidases. Fukuzumi and Shibamoto [49] studied the degradation of β-guaiacyl veratrylglyceryl ether by the partly purified enzyme from *Poria subacida*. The reaction was carried out at pH 4.0 in an acetate buffer solution at 30°C in the course of two days. Chromatographic studies of the reaction mixture revealed the presence in the latter of guaiacol and an unidentified compound, which the authors believed to be veratrylglycerol or 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone.

In the course of subsequent experiments Fukuzumi et al. [50] showed that the amount of guaiacol liberated when compound (X) is acted upon by the partly purified enzyme from the mycelium of *F. subacida* increases significantly when the reaction is performed in the presence of the reducing coenzyme NADH (reduced nicotinamide-adenine dinucleotide). The authors also reported the formation of guaiacylglycerol (XVI) on incubation of compound (X) with the enzyme of *P. subacida* in the presence of NADH. The latter finding shows that, apart from the enzymatic cleavage of the β-alkyl aryl ether linkage, *para*-demethylation takes place. However, the identification of compound (XVI) was based exclusively on thin-layer chromatographic data with one solvent system and therefore cannot be regarded as adequate. Fukuzumi et al. [50] reported that the enzyme system employed in these experiments does not attack the β-alkyl aryl ether linkage in compounds containing the α-keto-group, while the β-ether linkage in ethylene glycol and glycerol structures is cleaved. Evidently the presence of the hydroxybenzyl-group in the side chain is a factor which determines the possibility of the cleavage of the β-ether linkage by the enzyme system from *P. subacida*.

The authors suggested that the cleavage of the β-alkyl aryl ether linkage can proceed via two possible mechanisms, one of which invoves the direct hydroxylation of the β-carbon atom in the presence of NADH and oxygen. This reaction should lead to the formation of guaiacol and veratryl- or guaiacyl-dihydroxyacetone (the latter was not identified by the authors, who suggest that it may be reduced to guaiacylglycerol). The second involves a hydrolytic reaction of β-guaiacyl guaiacylglyceryl ether, which is formed via the demethylation of the initial substrate and is more readily hydrolysable than β-guaiacyl veratrylglyceryl ether. The low yield of guaiacol in the enzymatic cleavage of compound (X) in the presence of NADH (at most 30%) is caused, according to Fukuzumi et al., by an enzyme stereospecific in relation to the *erythro*- and *threo*-forms of β-guaiacyl veratrylglyceryl ether.

Thus the results of the above studies indicate the possibility of the existence of an enzyme system which cleaves β-aryl arylglyceryl linkages in lignin. However, the methodological defects of these experiments make it impossible to characterise sufficiently rigorously this enzyme system and the mechanism of its action on lignin.

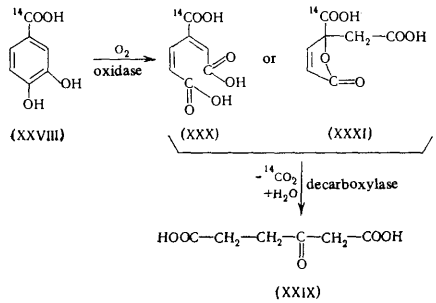
The studies described indicate the ability of the white rot fungi to convert β-aryl guaiacylglyceryl ethers or possibly other structural elements of lignin into monomeric benzenoid compounds of the type of vanillin and vanillic acid. Further transformation of these compounds by the white rot fungi may evidently involve different pathways, an important stage of which is cleavage of the aromatic ring. Data have been published showing that fungal attack involves the cleavage of aromatic rings. Thus Fukuzumi et al. reported that incubation of benzoic acid with the mycelial clusters of *Polystictus sanguineus* results in the formation of acetoacetic acid (XXV) [97] and α-oxogluaric acid [114], which were absent from the control experiment. Subsequently Fukuzumi [115] observed that *Poria subacida* completely metabolised gentisic acid (XXVI) to carbon dioxide. Crowden [116] established that *Polyporos tumulosus* metabolised fully *p*-hydroxyphenylpyruvic, *p*-hydroxyphenylacetic, *p*-hydroxymandelic, *p*-hydroxybenzoic, and protocatechuic acids, and to an extent greater than 50% homogentisic (XXVII), 2,5-dihydroxymandelic, and gentisic (XXVI) acids.

Moore and Towers [117,118] investigated the degradation of phenylalanine and tyrosine by the wood decomposing fungi *Schizophyllum commune*, *Sporobolomyces roseus*, and *Ustilago hordei*. Incubation of the mycelial cells of *S. commune* or of washed cell suspensions of *S. roseus* with ring-labelled phenylalanine led to the formation of $^{14}CO_2$. All three organisms converted labelled phenylalanine into cinnamic, benzoic, *p*-hydroxybenzoic, and protocatechuic acids; furthermore, phenyl-lactic and phenylacetic acids were detected in the metabolic products

of *S. commune*. Among the three fungi investigated, only *S. roseus* exhibited tyrosinase activity, converting tyrosine and *p*-coumaric acid into *p*-hydroxybenzoic and protocatachuic acids. On the basis of the results, the authors suggested the following sequence in the enzymatic degradation of phenylalanine and tyrosine: initial deamination to the corresponding acrylic acid derivatives whose side chain is then oxidised with formation of the corresponding C_6-C_1 acids. Further hydroxylation leads to the formation of protocatechuic acid (XXVIII)—the final aromatic compound in the sequence—which then undergoes ring cleavage. The presence of phenyl-lactic and phenylacetic acids in the metabolic products of *S. commune* indicates the existence of yet another pathway, apart from that discussed above, to the degradation of phenylalanine by this organism.

Haider and Flaig [47,119-121] established that, under the influence of *Polystictus versicolor* or the enzyme system isolated from this fungus, protocatechuic acid (XXVIII) is converted into β-oxoadipic acid (XXIX). According to the authors' views, the fungal transformation (XXVIII) → (XXIX) (Scheme 2) proceeds via the same mechanism as the analogous transformation under the influence of bacteria [122-126].

Scheme 2



According to this mechanism, protocatechuic acid oxidase catalyses the initial conversion of protocatechuic acid into *cis*, *cis*-β-carboxymuconic acid (XXX), which can be converted by a number of bacteria under the influence of the specific lactone-forming enzyme into the lactone of β-carboxymuconic acid (XXXI). Both the acid (XXX) and its lactone (XXXI) are then converted into β-oxoadipic acid (XXIX) as a result of the action of two different enzyme systems usually designated as decarboxylase.

Thus the data obtained in the course of the above experiments show that the aromatic ring is cleaved when the compound either contains or can be converted into an *o*- or *p*-dihydroxybenzene derivative. In the microbiological degradation of *o*-dihydroxybenzenes the cleavage can proceed via two different mechanisms. The aromatic ring can be ruptured either between the hydroxy-groups or directly next to a hydroxy-group. *p*-Dihydroxybenzenes undergo ring fission between the carbon atom linked to an OH group and the adjacent carbon atom linked to a substituent [127,128]

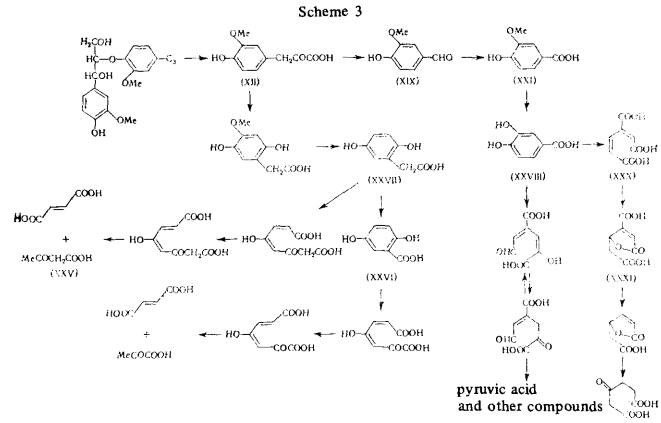
Haider and Grabbe [129] investigated the degradation of labelled biosynthetic [^{14}C] lignin by white rot fungi and concluded that this process probably does not proceed via the initial cleavage of the C–C and C–O bonds in the side chains but involves the fission of the aromatic rings still bound in the polymer. This conclusion did not, however, receive additional experimental confirmation.

Summarising studies on the microbiological degradation of lignin, Haider [48] concluded that the degradation of wood-decomposing fungi involves the following stages without the participation of phenol oxidases: (1) the shortening of the side chain leading to the formation of phenolic aldehydes, which can then be oxidised to the corresponding acids or reduced to the corresponding alcohols; (2) the cleavage of the methyl ether linkages and the elimination of methoxy-groups; (3) the cleavage of aromatic rings.

At the same time phenol oxidases oxidise the lignin decomposition products to coloured polymerisation mixtures. The first stage of this process is dehydrogenation leading to the formation of reactive radicals and quinones.

On the basis of the results of the above investigations, Christman and Oglesby [12] proposed a mechanism for the degradation of the β-aryl guaiacylglyceryl ether linkages in conifer lignin as a result of the action of white rot fungi (Scheme 3).

Scheme 3



Kirk et al. [130] investigated the action of two white rot fungi, *Polyporus versicolor* and *Stereum frustulatum*, on model compounds for lignin: β-guaiacyl guaiacylglycerol ether (VIII) and β-guaiacyl veratrylglyceryl ether (X). Of the two white rot fungi tested, one (*P. versicolor*) is typical and the other (*S. frustulatum*) is atypical. According to the authors [130], these fungi represent extreme varieties of white rot fungi in relation to the formation of phenol oxidising enzymes.

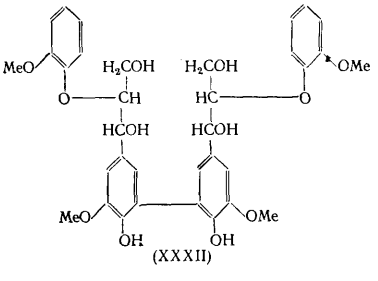
The study established that in the synthetic liquid medium the guaiacyl model (VIII) is converted under the influence of both fungi into a number of products, among which the *oo'*-dihydroxybiphenyl dehydropolymer (XXXII) predominates. This biphenyl derivative was also the main product when compound (VIII) was incubated with laccase. The veratryl model (X) was not changed either by the two fungi tested, in the synthetic aqueous medium, or by purified laccase. However, in a medium containing wood powder compound (X) was oxidised by both fungi to α-guaiacoxy-β-hydroxypropioveratrone (XXXIII). Separate experiments undertaken to elucidate the role of wood powder in this oxidation showed that lignin in wood behaves as a substrate for the formation of radicals when acted upon by the phenol oxidases produced by both fungi.

Thus the fact that β-guaiacyl guaiacylglyceryl ether is susceptible to the action of the white rot fungi tested, while β-guaiacyl veratrylglyceryl ether remains unchanged under the same conditions evidently shows that the phenolic OH group and not the β-ether linkage is involved directly under the above culture conditions. This conclusion is supported also by the finding that β-guaiacyl DL-glyceryl ether is not changed by either of the fungi tested in the synthetic liquid medium. The observed dimerisation of the guaiacyl model to the biphenyl dehydrodimer under the influence of both white rot fungi and the conversion of

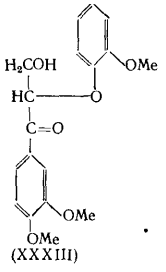
β-guaiacyl veratrylglyceryl ether into the corresponding veratrone in the presence of wood are oxidation reactions and, according to the authors, result from the action of phenol oxidases.

Kirk et al.[94] continued the study of the action of *P. versicolor* and *S. frustulatum* using the β-guaiacyl ether of syringylglycol (XXXIV) as the substrate. The syringyl and not the guaiacyl model was chosen to avoid the condensation reactions catalysed by phenol oxidase, involving the *ortho*-position with respect to the phenolic OH group.

The study established that compound (XXIV) was oxidised by filtrates of the *P. versicolor* culture or by the whole cultures of *S. frustulatum* to α-guaiacoxyacetosyringone (XXXV). Filtrates of the *P. versicolor* culture cleaved the alkyl–phenyl C–C bond in compounds (XXXIV) and (XXXV) with formation of guaiacoxyacetaldehyde (XXXVI) and guaiacoxyacetic acid (XXXVII) respectively.



(XXXII)

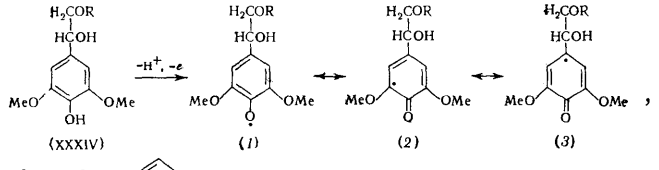


(XXXIII)

The syringyl halve of both initial compounds were converted into 2,6-dimethoxy-*p*-benzoquinone (XXXVIII) by filtrates of *P. versicolor* cultures and whole cultures of *S. frustulatum*. Furthermore it was shown that laccase, isolated from filtrates of *P. versicolor* cultures, catalysed all the above reactions.

At the same time it was established that whole cultures of *P. versicolor* and *S. frustulatum* reduced guaiacoxyacetaldehyde and guaiacoxyacetic acid to 2-guaiacoxyethanol, which accumulated in the reaction medium and was resistant to further changes by any of the above organisms. Since 2-guaiacoxyethanol was formed when whole cultures of both fungi acted on the β-guaiacyl ether of syringylglycol and α-guaiacoxyacetosyringone, the above alkyl–phenyl cleavage can evidently be achieved by whole cultures.

The authors proposed mechanisms for the main reactions occurring in the enzymatic degradation of the model compound (XXXIV). The oxidation of the β-guaiacyl ether of syringyl glycol (XXXIV), catalysed by fungal phenol oxidase, leads to the formation of a free radical, which can exist in at least three main resonance forms. They are analogous to the mesomeric forms R_a, R_c, and R_d of the coniferyl alcohol radical formed, according to Freudenberg's theory[131], during the biosynthesis of lignin.



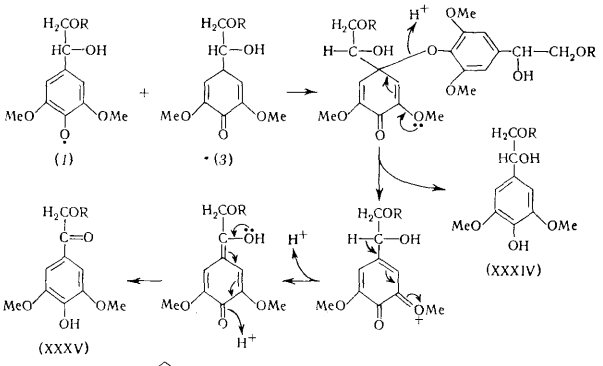
(XXXIV) (1) (2) (3)

where R =

The mesomeric forms of the radical produced can either undergo disproportionation reactions or can recombine to dimeric products, which can then be altered by stabilisation reactions. The formation of biphenyl derivatives by *ortho–ortho* coupling [including the radical form (2)], observed for guaiacyl compounds[94,132,133], is limited to a large extent by the methoxy-groups in the syringyl compounds, i.e. the fraction of the radicals in form (2) is insignificant in the subsequent reactions[134,135].

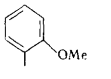
The mechanism of the oxidation of the β-guaiacyl ether of syringylglycol, which constitutes essentially a disproportionation reaction, is presented in Scheme 4.

Scheme 4



(1) (3) (XXXIV) (XXXV)

where R =



The initial stage of the above process involves the coupling of the phenoxyl (1) and the methylenequinonoid (3) radical forms. The distribution of the electron pair of the methoxyl oxygen atom over the cyclohexadienone ring leads to the elimination of a molecule of the β-guaiacyl ether of syringylglycol (XXXIV). Subsequent stabilisation of the molecule formed is achieved by the loss of a proton from the benzyl carbon atom. Rearomatisation leads to the formation of α-guaiacoxyacetosyringone (XXXV).

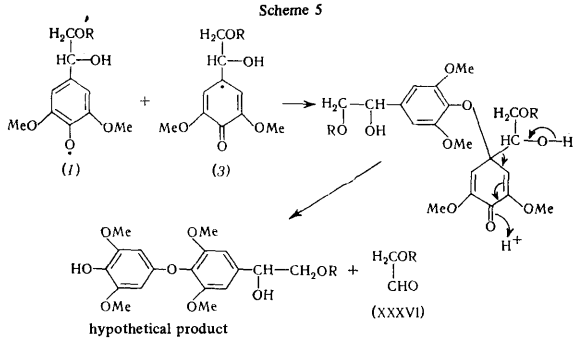
Scheme 5 presents the mechanism for the formation of guaiacoxyacetaldehyde (XXXVI) from the β-guaiacyl ether of syringylglycol.

The initial coupling of the radicals in the mesomeric forms (1) and (3) is followed by the transfer of a proton from the benzyl OH group to the *p*-methylenequinonoid half. The subsequent cleavage of the benzyl–ring C–C bond liberates the side chain in the form of the aldehyde and leads to the rearomatisation of the initial molecule.

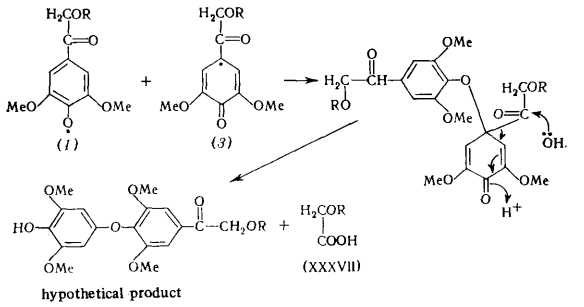
There is also a possibility of the coupling of two radicals in the mesomeric form (3). The dehydrodimer formed yields 3,3′,5,5′-tetramethoxy-*p*-biphenyl, as a result of the elimination of both side chains, which is converted on further oxidation into cerulignone. The latter was detected in very small amounts by Kirk et al.[94] in the products of the oxidation of model compound (XXXIV) by laccase from *P. versicolor*. However, this reaction is apparently limited by steric hindrance.

A similar mechanism (see Scheme 6) was proposed to account for the formation of guaiacoxyacetic acid (XXXVII) from α-guaiacoxyacetosyringone (XXXV).

Scheme 5



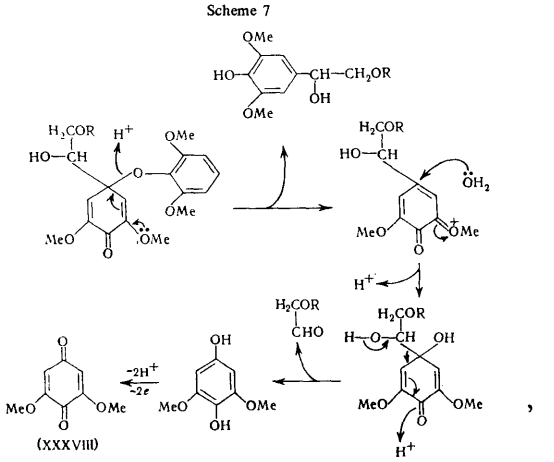
where R = 
Scheme 6



where R = 
After the coupling of the phenoxyl (1) and *p*-methylenequinonoid (3) forms of the radical, produced as a result of the oxidation of the phenol, nucleophilic attack by a water molecule on the carbonyl substituent in the cyclohexadienone ring leads to its migration, yielding guaiacoxyacetic acid (XXXVII) and diphenyl ether. There is a possibility of the recombination of two *p*-methylenequinonoid radicals in form (3) with subsequent elimination of both side chains; this leads to the formation of 3,3′,5,5′-tetramethoxy-*p*-biphenyl, which is then oxidised to cerulignone. The later was obtained in a very small yield in the oxidation of compound (XXXV) by laccase from *P. versicolor*.

The formation of 2,6-dimethoxy-*p*-benzoquinone (XXXVIII) by the oxidative cleavage of the β-guaiacyl ether of syringylglycol is illustrated in Scheme 7.

Scheme 7



where R =

The initial stage in this process is also the coupling of the phenoxyl and *p*-methylenequinonoid forms of the radical, leading to an unstable cyclohexadienone derivative (this stage is not included in Scheme 7). The distribution of the electron pair of one of the methoxyl oxygen atoms over the cyclohexadienone ring leads to the elimination of a molecule of the β-guaiacyl ether of syringylglycol. Next, there is nucleophilic attack by water on the 4-position of the cyclohexadienone ring with subsequent loss of the proton. The elimination of guaiacoxyacetaldehyde with rearomatisation of the dienone half yields 2,6-dimethoxyhydroquinone, which is oxidised enzymatically to the corresponding *p*-quinone. A similar mechanism can account for the formation of a quinone from two molecules of α-guaiacoxyacetosyringone.

On the basis of the results of these investigations, Kirk, Harkin, and Cowling put forward the so called "phenol oxidase" hypothesis to account for the mechanism of the depolymerisation of lignin by white rot fungi. According to this hypothesis, the phenol oxidising enzymes present in the hyphae of the white rot fungi, and probably liberated from them when the latter penetrate the woody tissue, catalyse the oxidation of the phenolic OH groups in the lignin macromolecule. The resulting unstable free radicals are then stabilised by reactions which condense certain lignin structures but at the same time lead to the cleavage of the carbon–carbon bonds between the side chains and the rings of other oxidised phenylpropanoid units. The subsequent elimination of the terminal aliphatic component exposes additional phenolic OH groups to continuing degradation by enzymatic oxidation. The overall effect of these processes should theoretically lead to fragments of certain components of the lignin macromolecule and to the condensation of the residue.

It is interesting to note that the alkyl–phenyl cleavage reactions on which the proposed hypothesis is based, were first observed in the course of detailed studies on the biosynthesis of lignin. In particular, Freudenberg et al.[136] showed that in the enzymatic dehydogenation of sinapyl alcohol its condensation stops at the syringaresinol dimer and that the continuing enzyme action led to the breakdown of the dimer. The detection among the degradation products of 2,6-dimethoxy-*p*-benzoquinone is evidence that the oxidative dissociation of the alkyl–aryl carbon–carbon bonds took place. Furthermore, the authors reported that, when the oxidation of lignin by purified laccase is continued, 2-methoxy-*p*-benzoquinone is formed.

Structural elements of a new important type—the 1,2-diarylpropane-1,3-diol structures—were detected in lignin comparatively recently[137–139]. The mechanism of their formation in the enzymatic dehydrogenation of *p*-hydroxycinnamyl alcohols, proposed by Lundquist and Miksche[137], involves the alkyl–phenyl cleavage. Subsequently additional experimental confirmation was obtained for this mechanism[139,140]. Finally, in the course of a study of the products of the enzymatic dehydrogenation of propioguaiacone, Pew and Connors[141] identified a triphenyl derivative, the formation of which involves in all probability the cleavage of the alkyl–phenyl bond.

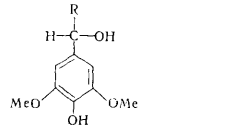
On the basis of the schematic formula of the fragment of the lignin molecule proposed by Freudenberg[131,142], Kirk et al.[94] calculated that 41% of the phenylpropane units of lignin are sensitive to the types of cleavage described above.

In order to elucidate the role of peroxidase and laccase in the degradation of lignin, Gierer and Opara [143] investigated the action of these enzymes on monomeric (guaiacol, 2,6-dimethoxyphenol, and aryl glyceryl ethers) and dimeric (1-guaiacyl-2-syringylethanol, pinoresinol, and dihydrodehydrodi-isoeugenol) phenolic compounds structurally related to lignin. The enzyme action led to the formation of products of a higher molecular weight, as a result of carbon–carbon and carbon–oxygen coupling. Non-phenolic model compounds were not involved by either enzyme system. This is evidence that their catalytic effect is oxidative and not hydrolytic.

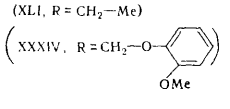
The results of the above study showed that both enzyme systems function mainly if not exclusively by catalysing oxidative coupling with formation of aryl–aryl or aryl–O–aryl bonds. No evidence was obtained for the cleavage of the ether linkages—the coupling products contained all the alkyl–aryl bonds present initially, including the aryl methyl and β-alkyl aryl ether linkages. Thus the degrading effect of the enzymes must be related to the oxidative coupling reactions which they catalyse. Such dehydrogenation reactions, which model compounds of p-hydroxy-α-carbonyl [94,144] and p-hydroxy-α-carbonyl [94,145] types are caused to undergo by laccase [94] or peroxidase [144,145], were examined above.

The identical compositions of the coupling products obtained with peroxidase–H_2O_2 and with laccase and the lack of substrate specificity in both enzymes are evidence that only the first stage of these reactions—the abstraction of hydrogen from the phenolic hydroxyl—are catalysed by the enzymes. The subsequent couplings evidently take place spontaneously. The authors point out that in the course of the above investigation no experimental evidence was obtained for the direct involvement of either enzyme in the microbiological degradation of lignin. However, this does not rule out the possibility that the oxidative coupling reaction can constitute the first step in the reaction sequence where peroxidase and laccase are involved in the microbiological cleavage of lignin in combination with other still unknown enzymes.

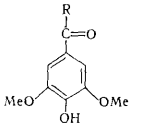
As mentioned above, Kirk and coworkers, who investigated the enzymatic degradation of a number of lignin model compounds, suggested the existence of free-radical intermediate compounds, which might arise as a result of the loss of one electron from the corresponding phenols. Furthermore, it has been noted that decayed wood is characterised, according to ESR data, by a higher free radical concentration [75–77]. In order to establish which lignin structures form the most stable types of free radicals in enzymatic degradation, Caldwell and Steelink [79] oxidised a number of syringyl derivatives, including the benzyl alcohols (XXXIX)–(XLI) and (XXXIV), the α-carbonyl compounds (XLII)–(XLIV) and (XXXV), syringylpropane (XLV), and syringaresinol (XLVI) with H_2O_2 in the presence of horseradish peroxidase and established that these compounds give rise to stable intermediate phenoxy-radicals.



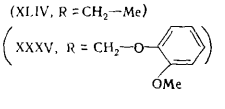
(XXXIX, R = H)
(XL, R = Me)
(XLI, R = CH_2–Me)



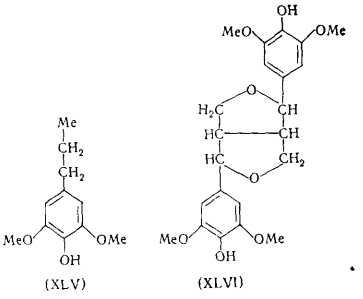
(XXXIV, R = CH_2–O–)



(XLII, R = H)
(XLIII, R = Me)
(XLIV, R = CH_2–Me)



(XXXV, R = CH_2–O–)

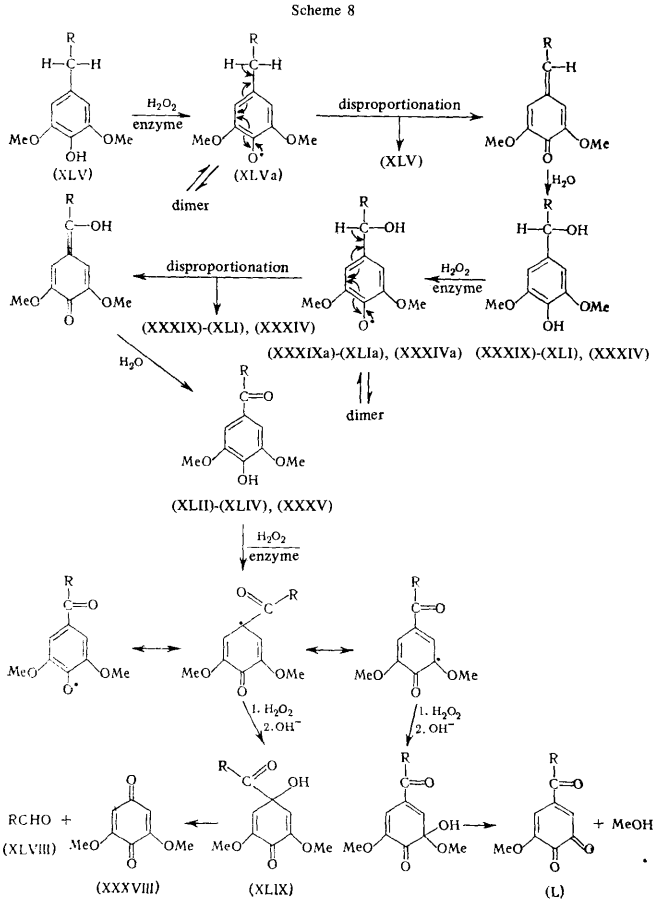


(XLV) (XLVI)

The results of these investigations showed that the phenoxy-radicals are formed most readily from α-carbonyl syringyl derivatives, less readily from α-carbinol, and α-alkyl ether derivatives, and slowly from alkyl derivatives.

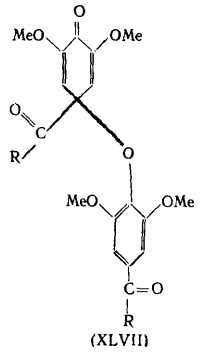
In order to establish the sequence of the reactions occurring in the oxidation of the compounds tested, the reaction mixture was examined simultaneously by ESR and optical spectroscopy. In addition, aliquots of the reaction mixture were periodically subjected to thin layer chromatographic separation in order to identify the reaction products. The mechanism proposed for the enzymatic oxidation of the compounds investigated on the basis of the results is presented in Scheme 8.

Scheme 8



The peroxidase–H_2O_2 system probably abstracts the phenolic hydrogen atom from the substrate. The resulting phenoxy-radical, which is in equilibrium with the hydroquinone-ether dimer (XLVII), then disproportionates, yielding a phenol with a higher oxidation potential. This

second phenol does not undergo further oxidation until the entire initial substrate is used up. This process is repeated until the side chain is split off.



(XLVII)

Thus enzymatic oxidation proceeds via a sequence of separate stages. The abstraction of the hydrogen atom probably determines the rate of reaction in each change of the oxidation state of the substrate. The disproportionation of two radical forms (or a dimeric form) is rapid.

It is noteworthy that Pew [132] reported earlier that H_2O_2 and peroxidase are capable of hydroxylating the α-position of syringylpropane. Caldwell and Steelink showed that this reaction is also a one-electron transfer process. The reaction of peroxidase and H_2O_2 with compound (XXXIV), which the authors investigated, is of special interest. The oxidation of this compound by laccase was studied in detail by Kirk et al. [130], who showed that the main product is compound (XXXV) with additional formation of a certain amount of (XXXVI), (XXXVIII), and of unidentified products. The high yield of compound (XXXV) is probably due to its insolubility in water, which prevented its further oxidation. Since Caldwell and Steelink oxidised compound (XXXIV) in a water–methanol medium, in which compound (XXXV) dissolved, they obtained a high yield of the phenoxy-radical from (XXXV) and of compound (XXXVIII).

According to Scheme 8, the quinone (XXXVIII) and the aldehyde (XLVIII) are formed in the last oxidation stage. Caldwell and Steelink suggested two possible ways for the decomposition of the radicals formed from compounds (XLII)–(XLIV) and (XXXV)—via the intermediate (XLIX) or its hyperoxide precursor, which can yield directly compounds (XXXVIII) and (XLVIII), and also via the *o*-quinone (L), which can be a source of a small amount of an unidentified red substance.

Later Young and Steelink [146] established that, when horseradish peroxidase and H_2O_2 are allowed to act on 4-substituted 2,6-dimethoxyphenols and also MWL and alkaline lignins from the wood of deciduous trees, phenoxy-radicals are formed, the lignin substrates being degraded by the same oxidation mechanism as the simple phenolic substrates.

The results of the above studies suggest that the α-carbonyl groups in units with a free phenolic hydroxyl are most sensitive to the fungal attack on the lignin macromolecule. If the decomposition of all the lignin units with a free phenolic hydroxyl proceeds via the free-radical mechanism proposed by Caldwell and Steelink, then this can explain the appreciable depolymerisation of lignin on the basis of a series of one-electron hydrogen abstraction steps. On the other hand, one must emphasise [147] that the main dehydrogenation stage is regulated by the structure of the phenolic substrate and also by the oxidation potential of the enzyme or the chemical oxidant. In biological systems the possibility of such oxidation depends largely on factors such as the presence of the appropriate enzymes, the pH of the medium, and the presence of oxidants, for example O_2 or H_2O_2. The combination of these factors determines the preferential occurrence and extent of the polymerisation or degradation reactions under the influence of the same enzyme–oxidant system.

Sergeeva and coworkers [148] investigated the action of the brown rot fungus *Fomitopsis pinicola* I on coniferin, glucovanillin, vanillin, syringaldehyde, and coniferyl alcohol. Syringaldehyde and vanillin did not undergo any changes as a result of the enzyme action, while coniferyl alcohol was oxidised to vanillin. The action of the fungus *F. pinicola* I on coniferin and glucovanillin led to the dissociation of the β-phenylglucosidic linkage with formation of coniferyl alcohol and vanillin respectively. These primary decomposition products underwent further oxidation. Thus vanillic acid and a further two unidentified acids were detected together with vanillin in the products of the decomposition of glucovanillin after exposure to the action of the fungus for 10 days. Coniferyl alcohol and coniferaldehyde were detected in the coniferin decomposition products after 10 days, and after more prolonged enzyme action (45 days) vanillin was found as well.

The authors suggest that coniferyl alcohol is formed from coniferin and vanillin is formed from glucovanillin under the influence of the fungus *F. pinicola* I via an intermediate stage involving the formation of unstable phenoxy-radicals. The hypothesis has been put forward, that when *F. pinicola* I acts on wood, the dissociation of β-phenyl-glucosidic lignocarbohydrate linkages can lead to the formation of stable phenoxy-radicals. The subsequent oxidation of coniferyl alcohol to coniferaldehyde and of coniferaldehyde to vanillin also evidently proceeds via free-radical intermediates. The authors believe that the abrupt increase in the concentration of paramagnetic centres observed on extensive enzymatic decomposition of wood [77] may be a consequence of the oxidation of the lignin structures and the formation of stable phenoxy-radicals. On the basis of the content of functional groups and the infrared spectroscopic data for sprucewood and birchwood obtained in the course of successive stages of their degradation by *F. pinicola* I, Kreitsberg and coworkers [149,150] concluded that the number of quinhydrone structures in the lignin macromolecule increases, the biolignin isolated from degraded sprucewood containing more of these structures than the analogous preparation from birchwood.

In conclusion of the discussion of the possible pathways in the microbiological degradations of lignin, certain general comments have to be made. As already mentioned, there is evidence for the presence in the wood decomposing fungi of an enzyme system capable of cleaving β-aryl arylglyceryl ether linkages in lignin. However, the dissociation of these bonds does not evidently lead to the liberation of appreciable amounts of monomeric products, although it can cause the depolymerisation of lignin.

For this reason the so called "phenol oxidase hypothesis", put forward by Kirk, according to which the phenol oxidising enzymes of the wood decomposing fungi catalyse the oxidation of the phenolic OH group of the lignin macromolecule, appears to have more justification. As a result, unstable free radicals are formed and are then stabilised in the course of reactions leading to the condensation of certain lignin structures and the simultaneous cleavage of carbon–carbon bonds between the side chains and rings of other oxidised phenylpropane units. According to Caldwell and Steelink, the degradation of lignin takes

place as a result of a series of one-electron transfer processes leading ultimately to the removal of the side chains.

One should bear in mind that, in consequence of the wide variety of linkages between the monomeric units in lignin [151], its complete decomposition may not involve a direct attack on each linkage with the resulting liberation of low-molecular-weight compounds. Direct attack on the general structural elements of the polymer, such as aromatic rings, is more likely and the dissociation of the linkages between the phenylpropane units may take place indirectly. However, the available data are inadequate to reach definite conclusions.

Thus the studies examined in the present review do not unfortunately permit an unambiguous conclusion either about the enzyme systems present in wood-decomposing fungi or about the mechanism of the microbiological degradation of lignin, although the solution of these problems is evidently necessary for successful research in the fields of study discussed in the introduction.

Free Radicals Derived from Phosphorus Compounds

V.V.Pen'kovskii

Studies on phosphorus-containing free radicals and radical-ions are discussed in the review and data on the geometrical and electronic structures of phosphinyl, phosphonyl, and phosphoranyl radicals and radical-ions derived from compounds of tri-, tetra-, and penta-coordinate phosphorus are presented. The main types of radical reactions of phosphorus and their mechanisms are considered.
The bibliography includes 225 references.

CONTENTS

VII.	Radical-anions derived from phosphorus compounds	460

I. INTRODUCTION

The autoxidation of white phosphorus, the process to which phosphorus owes its name, proceeds via a branched radical-chain mechanism[1]. The autoxidation of phosphine is also a radical-chain reaction[2]. Nevertheless free radicals derived from phosphorus compounds remained little studied for a long time, since in the first stages of the development of phosphorus chemistry investigators concentrated their attention on the study of heterolytic reactions. In 1945 Kharasch et al.[3] established that free radicals are involved in the reaction of PCl_3 with oct-1-ene; somewhat later a free-radical mechanism was proposed by Soborovskii et al.[4] for the joint oxidation of PCl_3 and hydrocarbons. At the beginning of the 1960s many reactions of phosphorus compounds were regarded as having a free-radical mechanism[5,6].

In 1961 Horsfield et al.[7] detected by ESR the $\dot{P}O_3^{2-}$ radical-ion on γ-irradiation of $Na_2HPO_3.5H_2O$ crystals. Subsequently numerous phosphorus-containing free radicals were detected by ESR and it was shown that their formation is indeed an intermediate stage in a number of reactions. At present the study of free radicals derived from phosphorus compounds and of their role in chemical reactions is being prosecuted vigorously and on a large scale.

Free radicals derived from phosphorus compounds can be divided into three groups: phosphinyl ($R_2\dot{P}$), phosphonyl ($R_2\dot{P}O$), and phosphoranyl ($R_4\dot{P}$). The aminyl and iminoxy- or nitroxy-radicals correspond to the first and second

groups respectively, while the third group has no analogues among nitrogen radicals. Furthermore, radical-cations derived from phosphines ($R_3P^{\cdot+}$) and their derivatives and also radical-anions containing tri- or tetra-coordinate phosphorus are known. The properties of the radical-anions of tri-coordinate phosphorus resemble those of phosphonyl radicals and those of tetra-coordinate phosphorus resemble the properties of phosphoranyl radicals.

II. PHOSPHINYL RADICALS

1. Generation

Phosphinyl radicals can be generated by the homolytic dissociation of the P–X bond on heating, irradiation, or abstraction of the substituent X by another radical. For example, $\dot{P}F_2$ radicals are generated on irradiation of ND_4PF_6 with γ-rays[8], on irradiation of PF_3 with electrons in a sulphur hexafluoride[9] or xenon hexafluoride (XeF_6)[10] matrix, on thermal dissociation of P_2F_4 and PF_2H [11,12] (they cannot be obtained on heating PF_3), and on ultraviolet irradiation of PF_2H in an argon matrix[12]. $\dot{P}Cl_2$ radicals were obtained by the ultraviolet irradiation of PCl_3 at −196°C [13], the condensation of PCl_3 or PBr_3 and lithium vapours in argon at −258°C yielded $\dot{P}Cl_2$ and $\dot{P}Br_2$ radicals [14], and $\dot{P}I_2$ radicals were produced by the photolysis of P_2I_4 and PI_3 in hexane or cyclohexane[15].

The simplest phosphinyl radical $\dot{P}H_2$ was identified by flash photolysis [16,17], $\dot{P}F_2$ was identified by mass spectrometry[18], and $\dot{P}Cl_2$ was identified by infrared spectroscopy[14]. All these radicals and many other phosphinyl radicals were also studied by ESR [8–10,12,19–22]; the parameters of their ESR spectra are presented in Table 1. Phosphinyl radicals with alkyl groups at the phosphorus atom have not so far been detected by any physical method.

2. Structure

The unpaired electron in the $\dot{P}H_2$ radical is in the *p* orbital of phosphorus at right angles to the plane of the bonds; the ground state[17] of the radical is $^2B_1$ and its electronic configuration is $KL\,(1a_1)^2\,(1b_2)^2\,(2a_1)^2\,(1b_1)^1$. The unpaired electron in $\dot{P}F_2$ is also in similar *p* orbitals of phosphorus and fluorine; these are typical π-electron radicals. According to the most reliable data[10], the values of a_P for both radicals are almost the same (Table 1). Therefore the delocalisation of the unpaired electron in $\dot{P}F_2$ should be small and the observed slight splitting by ^1H and ^{19}F nuclei is due to the σ–π interaction. $\dot{P}Cl_2$ radicals should have analogous properties. The ESR spectra of PBr_2 and $\dot{P}I_2$ have not been studied.

The infrared spectra of $\dot{P}Cl_2$ and $\dot{P}Br_2$ have shown[14] that these radicals are non-linear; according to the calculation of the normal vibrations, the valence angle in both radicals is close to 120° and the force constants of the P–X bond are approximately the same as for PCl_3 and PBr_3 molecules. Thus in these cases too the stabilisation of the radical by the delocalisation of the unpaired electron over the halogen atom should be small.

Kilcast and Thomson[23] calculated the equilibrium geometry and the distribution of spin density in the simplest phosphorus radicals by the unrestricted Hartree–Fock method in terms of the CNDC/2 approximation; the valence angles and bond lengths were found by minimising the total energy. The results of the calculation on phosphinyl radicals are presented in Table 2. As was to be expected, the spin density in $\dot{P}F_2$ and $\dot{P}Cl_2$ is concentrated mainly in the phosphorus *p* orbital. Accordingly the electrons involved in the formation of bonds are appreciably displaced towards the ligand atoms; for example, the charges on the fluorine atoms are −0.26. Owing to the repulsion of these charges, the valence angle in $\dot{P}F_2$ is greater than in $\dot{P}H_2$. The bonds are elongated compared with the initial phosphines. Comparison of the calculation[23] with experimental ESR data showed that the values of a_P found previously[8,12] were erroneous. A non-empirical calculation on $\dot{P}F_2$ with inclusion of the 3*s* and 3*p* orbitals of fluorine and the 3*d*, 4*s*, and 4*p* orbitals of phosphorus in the basis set confirmed this conclusion[24]. The equilibrium geometry of $\dot{P}Cl_2$ calculated by Kilcast and Thomson[23] is not entirely reliable, since it does not apparently correspond to the true total energy minimum.

Table 1. Parameters of the ESR spectra of phosphinyl radicals.

Radical	*g*-Factor	Type of splitting	Isotropic splitting constants, G		References
			a_P	a_X	
$\dot{P}H_2$	2.0087	2×3	80	18	19
$\dot{P}F_2$	2.0108	2×3	36	60.5	8
	1.9952	2×3	47	65	12
	2.0020	2×3	84.6	32.6	10
$\dot{P}Cl_2$	2.014	2×7	71	5	13
$\dot{P}HPh$		2	251		20
$\dot{P}Ph_2$	2.0036	2×4	12.0	5.8	21
$\dot{P}(OEt)_2$	2.002	2	78.5		22

Table 2. The distribution of spin densities and equilibrium structures of phosphinyl radicals.

Radical	Spin density at the $3p_\pi$ atomic orbital of phosphorus	∠XPX	R_{PX}, Å
$\dot{P}H_2$	1.000	91.5° *	1.52
$\dot{P}F_2$	0.937	112°	1.73
$\dot{P}Cl_2$	0.718	140°	1.95

*Experiment[17]: ∠HPH = 91.7°, R_{PH} = 1.429 Å.

The $Ph\dot{P}H$ radical is distinguished by an exceptionally high constant a_P, but the reasons for this anomaly have not been elucidated. The lower value of a_P for $\dot{P}Ph_2$ is due to the delocalisation of the spin density over the radical. Wong and Wan[21] suggest that it is delocalised only over one benzene ring, where the protons in the *ortho*- and *para*-positions are equivalent; however, this interpretation of the observed spectrum is fairly controversial.

3. Reactions of Phosphinyl Radicals

All phosphinyl radicals, particularly those containing alkyl groups, are very unstable. Pellon[25], who determined the chain transfer rate constants for phosphinyl radicals in the polymerisation reactions of styrene and methyl methacrylate, established the following stability series for phosphinyl radicals: $Ph\dot{P}H > (NCCH_2CH_2)_2\dot{P} > C_8H_{17}\dot{P}H \simeq NCCH_2CH_2\dot{P}H$.

Two types of reactions are characteristic of phosphinyl radicals: (1) the abstraction of an atom from an adjacent neutral molecule; (2) addition to a double bond.

Reactions involving the abstraction of an atom (usually a hydrogen atom) normally take place when the radical interacts with the solvent, for example in the photolysis of triphenylphosphine in benzene in an atmosphere of nitrogen [26]:

$$Ph_3P \xrightarrow{h\nu} Ph_2\dot{P} + Ph^{\cdot} , \quad (1)$$

$$Ph_2\dot{P} + C_6H_6 \rightarrow Ph_2PH + Ph^{\cdot} . \quad (2)$$

Various mechanisms have been proposed for the reactions of $\dot{P}Ph_2$ with alcohols [26-28]. Wong et al. [29] established that they too involve the abstraction of a hydrogen atom from the α-carbon atom of the alcohol molecule (but not from the hydroxy-group, as shown in experiments with MeOD). Diphenylphosphine is partly oxidised to diphenylphosphine oxide. The data concerning the presence of alkyldiphenylphosphine [26] and phosphonium salts [27] in the reaction products were not confirmed [29].

Reactions involving the addition of phosphinyl radicals to double bonds are commonest and have been most thoroughly investigated. For example, $\dot{P}H_2$ reacts with olefins on ultraviolet irradiation or on heating to 80–100° of a mixture of PH_3, the olefin, and benzoyl peroxide [5]:

$$\dot{P}H_2 + R_2C{=}CH_2 \rightarrow H_2PCH_2\dot{C}R_2 . \quad (3)$$

The resulting radical reacts with another PH_3 molecule:

$$H_2PCH_2\dot{C}R_2 + PH_3 \rightarrow H_2PCH_2CHR_2 + \dot{P}H_2 . \quad (4)$$

The phosphine molecule can then give rise to the radical $H\dot{P}CH_2CHR_2$, which also adds to the olefin molecule; the reaction products are a mixture of primary, secondary, and tertiary phosphines. The addition reaction of phosphinyl radicals is reversible, since but-2-ene undergoes *cis–trans* isomerisation in the presence of $PhPH_2$, $n\text{-}Bu_2PH$, and $PH_2CH_2CH_2CN$, and azobisisobutyronitrile at 70°C. [30]

The reactions of PH_3, $PH_2CH_2CH_2CN$, and $PH(CH_2CH_2.CN)_2$ with cyclohexane [31], of phenylphosphine with allylamine, allyl acetate, and 2-methyl-5-vinylpyridine [32], and of PH_3 with fluoroolefins [33] proceed similarly, the phosphinyl radical always adding to the least substituted carbon atom. A kinetic study [34] of the reaction of tetrafluoroethylene with an excess of dimethylphosphine in the gas phase at 212–288°C showed that it is initiated by the bimolecular abstraction of a hydrogen atom from the dimethylphosphine molecule and proceeds subsequently via a free-radical chain mechanism in accordance with reactions (3) and (4); chain termination takes place as a result of the recombination of the dimethylphosphinyl radicals.

If the initial phosphine is unsaturated, the addition of phosphinyl radicals to a double bond can be modified; its products are telomers and polymers with phosphorus atoms in the chain. For example, phenylallylphosphine polymerises in this way on ultraviolet irradiation [5].

The mechanism of the reactions of PCl_3 with olefins should be analogous in principle [3]. In reality the yield of the products of the addition $\dot{P}Cl_2$ to olefins is low; high-boiling products are formed [35]. The reaction probably proceeds mainly via a different mechanism (see Section IV). The difference in the behaviour of $\dot{P}H_2$($\dot{P}Alk_2$, $Ar\dot{P}H$) and $\dot{P}Cl_2$ is probably due to the fact that the process involving the dissociation of the P–H bond and the addition of $\dot{P}H_2$ is exothermic (the dissociation of the P–H bond instead of C–H results in an energy gain of about 13 kcal $mole^{-1}$), while the corresponding reaction of PCl_3 is thermally neutral [5]. These considerations are confirmed by the absence of $\dot{P}F_2$ radicals in the thermolysis of PF_3. [12]

Phosphinyl radicals can also add to the C=N bond; the reaction of diethylphosphine and diphenylphosphine with isonitriles (in the presence of azobisisobutyronitrile as an initiator) is known [36]:

$$R_2\dot{P} + R'N{=}C \rightarrow R_2P\dot{C}{=}NR' \xrightarrow{} R_2PC{\equiv}N + \dot{R}' , \quad (5)$$

$$R_2\dot{P} + R'N{=}C \rightarrow R_2P\dot{C}{=}NR' \xrightarrow{R_2PH} R_2PCH{=}NR' + R_2\dot{P} . \quad (6)$$

Pathway (5) is preferred when R′ = CH_2PH or t-Bu and pathway (6) is preferred when R′ is another alkyl radical.

Finally, phosphinyl radicals can add to triple carbon–carbon bonds; for example, $PH_2CH_2CH_2CN$ and $PH(CH_2.CH_2CN)_2$ interact with hept-1-yne via a radical mechanism [32].

III. PHOSPHONYL RADICALS

1. Generation

The $(MeO)_2\dot{P}O$ and $(EtO)_2\dot{P}O$ radicals were detected by ESR on irradiation of single crystals of dimethyl and diethyl phosphites with X-rays [37]; in this case the main process is selective homolysis, so that only two types of radicals, uniformly distributed in the crystal, are formed. $(EtO)_2\dot{P}O$ can also be generated by the ultraviolet irradiation of triethyl phosphite at −196°C. Initially there is a homolytic dissociation of the O–C bond with formation of the $(EtO)_2\dot{P}O$ radical, which is then converted into $(EtO)_2PO$. [38]

Davies et al. [39] obtained $(RO)_2\dot{P}O$ radicals (R = Me, Et, i-Pr, or n-Bu) by the ultraviolet irradiation of solutions of the corresponding phosphites and di-t-butyl peroxide. When phosphites are treated with $TiCl_3 + H_2O_2$, products of the dissociation of the C–H bond in one of the alkyl groups are obtained instead of phosphinyl radicals. Thus the dissociation of the C–H bond is slower than the dissociation of the P–H bond.

The phosphinyl radicals $(MeO)_2\dot{P}O$ are also formed in the low temperature γ-irradiation of trimethyl phosphate [40], probably in consequence of the elimination of the MeO^- anion from the primary $(MeO)_3PO^{\cdot-}$ radical-anion (see Section VII). The $\dot{P}OCl_2$ radical was detected by ESR in γ-irradiated $POCl_3$ [41] and the $Ph_2\dot{P}O$ (Geoffroy and Lucken [42]) and $Me_2\dot{P}O$ (Begum and Symons [43]) radicals were detected in irradiated diphenylphosphinous acid and trimethylphosphine oxide respectively.

2. Structure

Table 3 lists the g-factors for phosphonyl radicals, the ^{31}P hyperfine splittings, and the spin densities ρ_S and ρ_p in the 3s and 3p orbitals of phosphorus. Evidently the latter are fairly large, so that the unpaired electron is not localised at the oxygen atom; this is confirmed by the difference between the ESR spectra of the $(EtO)_2\dot{P}O$ and $(EtO)_2\dot{P}O$ radicals [39]. With the exception of $Me_2\dot{P}O$ in the solid phase, splitting by protons is not observed, although the spin density in the $Ph_2\dot{P}O$ radical is undoubtedly delocalised over the benzene rings. The numerical values lead to the conclusion that the phosphonyl radicals are non-planar [37,42], but more accurate information about their structures is not available in the literature.

Chemical polarisation of ^{31}P nuclei was observed for the first time in the reaction of the t-BuO· and BzO· radicals with dialkyl phosphites [44]. This phenomenon was used as a method for the investigation of the generation and subsequent reactions of phosphonyl radicals derived from alkyl phosphites in the thermal decomposition of dicyclohexyl peroxydicarbonate (DCP) and dilauryl peroxide (DLP) [45-48], in the thermal decomposition of di-t-butyl peroxide [45,47], and in the ultraviolet photolysis of aldehydes and ketones [44,46] or phenylazotriphenylmethane [47]. Phosphonyl radicals are formed in all these reactions as a result of the abstraction of a hydrogen atom from the phosphite molecule; the hypothesis of the "adhesion" of the radicals derived from DCP and DLP to P=O bonds and the formation of radicals of the type $(RO)Ph(OMe)_2\dot{O}$, put forward by Pobedimskii et al. [46], was disproved by Levin et al. [47] In the ultraviolet photolysis of phenylazotriphenylmethane phosphonyl radicals recombine with phenyl and triphenylmethyl radicals into singlet radical pairs with formation of phosphonates [47]; other reactions proceed similarly [45,47]. Chemical polarisation of ^{31}P nuclei in the reaction products of phosphonyl radicals released from cages was observed in the thermal decomposition of benzoyl peroxide in the presence of 2,2,6,6-tetramethylpiperidine *N*-oxide or toluene [45]. The reaction of dimethyl phosphite with peroxides is of quasifirst order; the activation energies for the reactions with DCP and DLP are 29.5 and 33 kcal mole^{-1} respectively [48].

Table 3. Parameters of the ESR spectra of phosphonyl radicals.

Radical	g-Factor	$a_{iso}(^{31}P)$, G	ρ_s	ρ_p/ρ_s	References

*$a_{iso}(^{35}Cl) = 18$ G.
**at −196°C; $a_H = 19$ G.

Phosphonyl radicals are relatively stable between −50° and −10°C. The reaction involving the abstraction of an atom from neighbouring molecules is apparently more characteristic of these species than of phosphinyl radicals. For example, at −28° they readily abstract the bromine atom from EtBr, t-BuBr, $PhCH_2Br$, and $CH_2=CHCH_2Br$, without adding to the double bond in the last case; the abstraction of a Cl atom proceeds with greater difficulty and is observed only for t-BuCl. In all cases the abstraction of a halogen was confirmed by ESR spectroscopy of the corresponding alkyl radicals [39]. Phosphonyl radicals can also abstract a hydrogen atom from the molecule of the initial phosphite, initiating a radical-chain reaction, but this process is slower than the abstraction of a bromine atom.

Phosphonyl radicals add to olefins in a manner resembling the addition of phosphinyl radicals [49,50]:

$$(RO)_2P(O)H + \dot{R}'' \rightarrow (RO)_2\dot{P}O + R''H \quad , \qquad (7a)$$

$$(RO)_2\dot{P}O + R'CH{=}CH_2 \rightarrow (RO)_2P(O)CH_2\dot{C}HR' \quad , \qquad (7b)$$

$$(RO)_2P(O)CH_2\dot{C}HR' + (RO)_2P(O)H \rightarrow (RO)_2P(O)CH_2CH_2R' + (RO)_2\dot{P}O. \qquad (7c)$$

The reactions proceed at 100–110°C in 55–75% yields [5]. The addition of phosphonyl radicals to acetylenes [51] and unsaturated silanes [52] has been described. The polymerisation of the monobutyl ester of vinylphosphinous acid also proceeds with participation of phosphonyl radicals, since it is initiated by azobisisobutyronitrile or heat and the infrared spectra indicate a heterochain structure of the phosphorocarbon polymer [53]. The process probably proceeds mainly via a polyaddition reaction.

The reduction of aryldiazonium salts by hypophosphorous acid to aromatic hydrocarbons takes place via a radical-chain mechanism [54]. In the chain initiation stage the hydrogen in the P–H bond adds to the aryl residue [55]; the resulting $H_2\dot{P}O_2$ radicals are probably of the phosphonyl type. Gragerov and coworkers [56] established that the initiation process is of second order with respect to the acid; during the process, chemical polarisation of phenyl protons is observed, probably in the singlet radical pairs $\overline{PhN_2 \cdot H_2PO_2}$.

In contrast to phosphinyl radicals, phosphonyl radicals do not abstract a hydrogen atom from an aromatic ring but add to it. Thus the $(EtO)_2\dot{P}O$ radicals, generated on heating diethyl phosphonate with di-t-butyl peroxide, add to the *para*-position of methyl benzoate with a yield of 65% [5], to the 9-position of anthracene and phenanthrene, to naphthalene and carbazole with formation of a mixture of isomers, and to dibenzofuran [57]. There is no reaction with pyridine and ferrocene.

Arbuzov and Kataeva [58] demonstrated by ESR the formation of triphenylmethyl radicals in the reaction of bromotriphenylmethane with $NaOP(OEt)_2$. Triarylchloromethanes also give rise to free radicals in this reaction [59]. Evidently phosphonyl radicals are formed together with these species, but cannot be detected owing to their rapid recombination.

Levin and coworkers [45,47] investigated the recombination reaction of phosphonyl radicals by the method based on the chemical polarisation of ^{31}P nuclei. The recombination products are the subphosphates $(RO)_2POP(O)(OR)_2$ and the hypophosphates $(RO)_2\overset{\overset{O}{\|}}{P} - \overset{\overset{O}{\|}}{P}(OR)_2$; chemical polarisation of ^{31}P nuclei is observed in both and the multiplet effect (E/A) was noted for tetracoordinate phosphorus. Consequently phosphonyl radicals are ambident: they can recombine both via phosphorus and via oxygen. This conclusion has been confirmed by the isomerisation of hypophosphates to subphosphates at 180°C. [60] Phosphonyl radicals recombine in singlet radical pairs.

The interaction of fluorenylidenetriphenylphosphorane with sodium results in the elimination of phenylsodium and the formation of a radical (I); the reaction of triphenylphosphazophenyl with sodium probably gives rise to the radical $Ph_2\dot{P}{=}NPh$ via the same mechanism [61]. Both radicals are formal analogues of phosphinyl radicals with a P=C or P=N bond instead of P=O.

IV. PHOSPHORANYL RADICALS

1. Generation

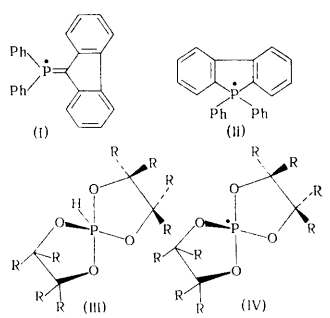
There exist three main methods for the generation of phosphoranyl radicals: the dissociation of the P–X bond in compounds of pentacovalent phosphorus; the one-electron reduction of phosphonium salts, and the addition of radicals to compounds of tervalent phosphorus.

Pentaphenylphosphorane can dissociate into the $\dot{P}Ph_4$ and $\dot{P}h$ radicals [62]. Razuvaev and Osanova [63] established that in chloroform and carbon tetrachloride the reaction products are PPh_4Cl and benzene, while in pyridine the product is phenyldiphenylenephosphine. Razuvaev et al.[64] showed with the aid of a deuterium label that the phenyl group is displaced from the axial and equatorial positions of the PPh_5 molecule with equal ease. In a study of the decomposition of $Ph_4P^{14}C_6H_5$ and $Ph_4PC_6D_5$ in benzene and of pentaphenylphosphorane in hexadeuteriobenzene the same workers [65] established that $\dot{P}Ph_4$ is formed preferentially "in the cage": the fraction of free radicals released into space is 5–6%. The rate of their release, determined [66] by fixation with diphenylpicrylhydrazyl and diphenylpicrylhydrazine, is 2.4×10^{12} species s^{-1} ml^{-1}.

The homolytic dissociation of the P–F bond is not characteristic of phosphorus pentafluoride and its derivatives. The reports [67,68] of the generation of $\dot{P}F_4$ on γ-irradiation of NH_4PF_6 crystals or KPF_6 powders are erroneous (see Section VII). The formation of the $\dot{P}Cl_4$ radical on dissociation of a P–Cl bond in the PCl_5 molecule has not been observed directly, but the reactions of PCl_5 with olefins and alkanes [69] proceed via this stage; the phosphorane $Cl_4PCH_2CH_2R$ is the product in the first case, while PCl_3, HCl, and an alkyl choride are produced in the second.

Bis-(2,2′-biphenylene)phosphorane decomposes in benzene at room temperature with formation of the phosphoranyl radical (II) [70], in which the unpaired electron is apparently delocalised over the π-electron system (a_P = 17.9 G). When spirophosphoranes (III) are acted upon by t-butoxy-radicals, the spirophosphoranyl radicals (IV) are formed [71,72] (see Scheme A).

Scheme A



Cathodic reduction of phosphonium salts leads to the formation of phosphoranyl radicals, which decompose with elimination of one of the ligands and retention of the configuration [73]. The rate of elimination of the ligand decreases in the sequence diphenylmethyl > benzyl > cinnamyl > hydroxymethyl > allyl > β-hydroxyethyl > t-butyl > isopropyl > n-butyl > ethyl > phenyl > methyl. The one-electron mechanism of the reduction of phosphonium salts with formation of phosphoranyl radicals has been confirmed by a polarographic method [74].

Nesmeyanov and coworkers [75] established that the one-electron reduction of tetraphenylphosphonium bromide to the $\dot{P}Ph_4$ radical can occur when the bromide is treated with lithium alkyls; the formation of radicals was confirmed by ESR. The subsequent reaction of the $\dot{P}Ph_4$ radicals depends on the type of electron-donating ion; the reaction products may be triphenylphosphine, phenyldiphenylenephosphine, or even triphenylphosphazophenyl (in the reaction with lithium n-butylamide).

The formation of phosphoranyl radicals from phosphorus(III) compounds was postulated as early as the 1950s by Kamai and Kharrasova [76] for the reaction of mixed alkyl phosphites with carbon tetrachloride, by Ramirez and McKalvie [77] for the reaction of triphenylphosphine with bromoform on ultraviolet irradiation, and by Walling and coworkers [78–80] for the reactions of phosphites and tertiary phosphines with the RO· or RS· radicals. The last two types of reactions have been reviewed [81]. Walling and Rabinowitz [79] proposed the following mechanism for the reaction of trialkyl phosphites with di-t-butyl peroxide:

$$t\text{-}Bu_2O_2 \rightarrow 2\dot{O}Bu\text{-}t \quad , \tag{8a}$$

$$(RO)_3P + \dot{O}Bu\text{-}t \rightarrow (RO)_3\dot{P}OBu\text{-}t \quad , \tag{8b}$$

$$(RO)_3\dot{P}OBu\text{-}t \rightarrow (RO)_3PO + t\text{-}Bu^{\cdot} \quad . \tag{8c}$$

Stage (8c) has been called β-decomposition. Triphenylphosphine interacts with t-butoxy-radicals via the same mechanism [80]. However, in the reaction of tributylphosphine with di-t-butyl peroxide 80% of the reaction product consists of dibutyl t-butylphosphinate and only 20% of tributylphosphine oxide [82]. Thus another pathway is possible in the transformation of phosphoranyl radicals – α-decomposition:

$$R_3\dot{P}OBu\text{-}t \rightarrow R_2POBu\text{-}t + R^{\cdot} \quad . \tag{9}$$

The formation of discrete phosphoranyl radicals via mechanism (8b) was confirmed by different methods. Bentrude and Wielesek [83] showed using a ^{14}C label that this process is irreversible and in addition stereospecific [84]. Levin and coworkers [45,85,86] observed negative chemical polarisation of the ^{31}P nuclei of tributyl and triphenyl phosphates in the reactions of the corresponding phosphites with t-butoxy-radicals, which demonstrated unambiguously the formation of phosphates from singlet radical pairs incorporating phosphoranyl radicals. Negative chemical polarisation of the ^{31}P nuclei of both possible decomposition products of phosphoranyl radicals—$CCl_3P(O)(OEt)_2$ and $BrP(O)(OEt)_2$—and also of triethyl phosphite, in conformity with the possiblity of α-decomposition, has been observed in the photolysis of the triethyl phosphite–bromotrichloromethane system [86].

Finally, phosphoranyl radicals obtained from phosphorus(III) compounds have been detected directly by ESR. Following the irradiation of PF_3, PCl_3, $MePCl_2$, Me_2PCl, and PH_3 in solid matrices, the ESR spectra of $\dot{P}F_4$ [9,10], $\dot{P}Cl_4$ [13], Me_nPCl_{4-n} (n = 1 or 2) [13], and $\dot{P}H_4$ [87] in solid matrices were observed. Kochi and Krusic [89–91] identified phosphoranyl radicals by ESR in the low-temperature photolysis of t-butyl peroxide in the presence of phosphine and mono-, di- and tri-methylphosphines and established that they are rapidly converted into secondary radicals containing two t-butoxy-groups and stable in the course of several minutes.

The stability of primary phosphoranyl radicals is appreciably influenced by the extent to which the phosphorus atom is sterically hindered. For example, the reaction of t-butoxy-radicals with trimethylphosphine results in the formation of the phosphoranyl and methyl radicals (α-decomposition), while only the ethyl radical is formed in the reaction with triethylphosphine [22,91].

Davies et al. [92-94] recorded the ESR spectra of a large number of radicals obtained from trialkyl phosphites via mechanism (8a)–(8b). The formation of phosphoranyl radicals has been confirmed by ESR in the reaction of t-butoxy-radicals with PEt_3, Et_2POEt, and $EtP(OEt)_2$, [95] with *NN*-dimethylamides of phosphorus(III) acids [96,97], and with chlorophosphines and phosphorochloridites [98]. According to the results of Davies et al. [93], methyl and n-butyl radicals do not react with trialkyl phosphites; the ESR spectra of the radicals $(RO)_2(R'O)\dot{P}Me$ were observed in a study [94] of the decomposition of azomethane in the presence of alkyl phosphites at −70°C, but their formation is probably reversible.

2. Structure

The parameters of the ESR spectra of phosphoranyl radicals are listed in Tables 4 and 5. The hyperfine splittings by the two pairs of ^{19}F nuclei are different in the ESR spectra of $\dot{P}F_4$. [9,10] Consequently $\dot{P}F_4$ must be a structural analogue of the phosphorane PF_4H [99] and must have the structure of a trigonal bipyramid with two fluorine atoms in the axial positions and two in the equatorial positions; the *s* orbital of phosphorus contributes appreciably to the unpaired electron orbital, like the σ orbital of the P–H bond in phosphorane. This model has been confirmed by the observed [100] linear correlation between the a_P constants for $\dot{P}F_4$ and spirophosphoranyl and phosphonyl radicals on the one hand and the spin–spin interaction constants $^1J_{PH}$ for the NMR spectra of the corresponding phosphoranes on the other:

$$a_P = 1.52\,{}^1J_{PH} - 350\ .$$

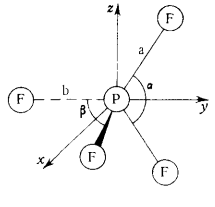
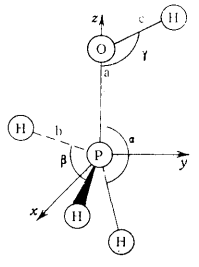
Higuchi [101] carried out a quantum-chemical calculation on $\dot{P}F_4$ by the valence bond method and the molecular orbital method in Hoffmann's approximation: comparison of the structural parameters and the calculated spin densities shows that the valence angles in $\dot{P}F_4$ are virtually identical with those in PF_4H. The interatomic distances and the valence angles of $\dot{P}F_4$ have been optimised [23,102] within the framework of the unrestricted Hartree–Fock method (the CNDO/2 approximation) and it has been established that the trigonal bipyramidal structure of $\dot{P}F_4$ is somewhat distorted (Scheme B, Table 6) owing to the marked repulsion of the charges of the fluorine atoms.

Scheme B



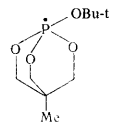


Calculation shows that the unpaired electron orbital of $\dot{P}F_4$ consists largely of the *s* orbital of phosphorus and the p_Z orbitals of the axial fluorine atoms; the d_{Z^2} orbital

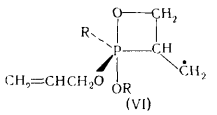
of phosphorus makes a contribution. The calculated *s*-orbital spin density of the phosphorus atom is therefore very large and agrees well with experiment[9,10]. However, the difference between the *s* spin densities at the axial and equatorial fluorine atoms is found to be much lower than follows from ESR data[9,10]; the total spin projection does not eliminate this discrepancy[102]. The higher constants for the splitting by the axial ^{19}F can probably be accounted for by the spin polarisation owing to the high spin density at the $2p_z$ orbitals.

The ESR spectra of $H_3\dot{P}OBu\text{-}t$, $Me\dot{P}H_2OBu\text{-}t$, and $Me_3\dot{P}OBu\text{-}t$ also showed that the ligands are non-equivalent[91], so that these radicals too must have the structure of a trigonal bipyramid close to that of the corresponding phosphoranes. The t-butoxy-group must occupy an axial position and the methyl group in $Me\dot{P}H_2OBu\text{-}t$ must be in an equatorial position according to the Muetterties rule[103]. The hyperfine splitting constant a_P for these radicals is smaller by a factor of two than for $\dot{P}F_4$, which indicates a decrease of the amount of *s* character of the unpaired electron orbital. This phenomenon was initially attributed to the distortion of the trigonal bipyramidal structure of the radicals owing to the decrease of the electronegativity of the ligands[92-94]. However, even a not unduly rigorous calculation on $H_3\dot{P}OMe$ by the CNDO/2 method[104] leads to the conclusion that the equilibrium structure of this radical is very close to that of a trigonal bipyramid. A recent calculation[102] of the optimal geometrical structures of the radicals $\dot{P}H_3OH$ and $\dot{P}H_2(OH)_2$ by the unrestricted Hartree–Fock method in terms of the CNDO/2 approximation showed that this conclusion[92-94] is erroneous: in both radicals the angle between the axial ligands is close to 180° (see Table 6). The calculated spin densities at the axial and equatorial hydrogen atoms in $\dot{P}H_3OH$ are very different, in contrast to the calculation on $\dot{P}F_4$; the use of spin projection yields values very close to the experimental results for $PH_3OBu\text{-}t$.

Scheme C



(V)



(VI)

R = t-BuO, EtO, or Me

R′=CH_2=$CHCH_2$.

According to a calculation[87], the $\dot{P}H_4$ structure is also close to that of an undistorted trigonal bipyramid; the equivalence of the hydrogen atoms observed in the ESR spectrum of $\dot{P}H_4$ has been explained by the fact that the energy barrier to the transition to the configuration with C_{3v} symmetry is very low—about 6 kcal mole^{-1}.

In the light of these data the hypothesis of a tetrahedral structure of the $\dot{P}Ph_4$ radical put forward by Razuvaev et al.[64] will be valid only subject to the condition that the interaction of the phosphorus atom with the benzene rings can alter significantly the geometrical structure of the phosphoranyl radical. This possibility has not been ruled out; Buck and coworkers[105] observed that a_P = 9.7 G (lower by two orders of magnitude than the usual value, see Tables 4 and 5) for the ESR spectrum of the $Ph\dot{P}(OMe)_2OBu\text{-}t$ radical obtained in the low-temperature interaction of dimethyl phenylphosphonate with t-butoxy-radicals and explained this finding by the transition of the radical to a tetrahedral configuration with almost the entire spin density concentrated in the benzene ring. Davies et al.[106] confirmed this result in a study of the ESR spectrum of the $C_6D_5\dot{P}(OMe)_2OBu\text{-}t$ radical; the a_P constants for the $Ph_2POEtOBu\text{-}t$ and $Ph_3POBu\text{-}t$ radicals are also reduced (23.0 and 45.0 G respectively). However, for very electronegative substituents at the phosphorus atoms, the constant a_P for phenylphosphoranyl radicals increases to a value characteristic of the trigonal bipyramidal configuration: for example, a_P = 1009 G for the ESR spectrum of $PhPCl_2OBu\text{-}t$. This spectrum shows a splitting due to the two equivalent ^{35}Cl (and ^{37}Cl) nuclei, which are evidently in the axial positions.

Table 6. Geometry of phosphoranyl radicals according to quantum-chemical calculations.

Radical	Valence angles, deg			Intraatomic distances, Å			Refs.
	α	β	γ	*a*	*b*	*c*

*Assumed.

**Local minimum; errors in minimisation.

It follows from the ESR data[98] that the chlorine atom in the $(t\text{-}BuO)\dot{P}(OEt)_2Cl$ radical is in the axial position, i.e. is more apicophilic than the alkoxy-groups; this can also be accounted for by the electronegativity factor and by the weaker p_π–d_π P–Cl interaction†.

For the ESR spectra of the $(RO)_4\dot{P}$ radicals, where R is an alkyl substituent, we have g = 2.003–2.004 and a_P = 897 ± 11 G [93,94,107]; for the spirophosphoranyl radicals (IV) at −70°C, a_P = 910 G [71,72]. The constant a_P increases with the electronegativity of R also in bicyclic phosphoranyl radicals; thus a_P = 954.4 G for $(CF_3CH_2O)_2$.(EtO)(t-BuO)$\dot{P}$ [94] and 973.2 G for the radical (V) [93]. The constants a_P for the $(R'O)_2(R''O)R\dot{P}$ radicals, where R′ and R″ are alkyl groups, are also very close (Table 5); the $(t\text{-}BuO)_3\dot{P}Me$ radical is an exception, but these results are probably inaccurate. With decrease of the electronegativity of the ligands, a_P falls and proves to be

†The hydrogen atom in the $\dot{P}H(OMe)_3$ and $\dot{P}H(OH)(OMe)_2$ radicals is in the axial position[213,214], which is consistent with the Muetterties rules[103] when account is taken of the marked apicophilic properties of H.

anomolously high only for $\dot{P}H_4$. It has therefore been suggested that McDowell et al. [87] did not obtain the $\dot{P}H_4$ radicals but some other paramagnetic species [40,98].

3. Reactions of Phosphoranyl Radicals

It is evident from the literature data [80,82] that phosphoranyl radicals are capable of two types of reactions—β-decomposition via mechanism (8c) and α-decomposition, for example:

$$R_3\dot{P}OBu\text{-}t \rightarrow R_2POBu\text{-}t + R^{\cdot} . \qquad (9)$$

These two pathways in the transformations of phosphoranyl radicals can be traced also in the study of Davies et al. [94] The primary radical, for example H_3POBu-t, decomposes via mechanism (9), after which a secondary radical is formed:

$$H_2POBu\text{-}t + \dot{O}Bu\text{-}t \rightarrow H_3\dot{P}(OBu\text{-}t)_2 . \qquad (10)$$

With increase of temperature, this radical probably decomposes via the β-mechanism:

$$H_2\dot{P}(OBu\text{-}t)_2 \rightarrow t\text{-}BuOP(O)H_2 + Bu\text{-}t . \qquad (11)$$

In the presence of an excess of t-butoxy-radicals the reaction can proceed further with formation of the t-BuOP.(O)R and $\dot{P}(BuO\text{-}t)_2$ radicals; one of them has been detected by ESR. [22]

Kinetic studies on the formation of phosphoranyl radicals via mechanism (8b) showed that this reaction is 500–1000 times faster than the abstraction of a hydrogen atom from solvent molecules [5]. The method of competitive reactions has been combined [92-94] with the recording of ESR spectra, which made it possible to determine the rate constants for the overall process $t\text{-}Bu\dot{O} + P(OR)_3 \rightarrow OP(OP)_3 + t\text{-}Bu$ and the β-decomposition of the phosphoranyl radicals [mechanism (8c)] and also the activation energies for these reactions. The kinetic parameters obtained are listed in Table 7. In agreement with the data of Bentrude and Wielesek [83], stage (8b) is irreversible and determines the rate of the entire reaction between the phosphite and the dialkyl peroxide, since the decomposition reaction (10) is slower than the β-decomposition and cannot compete with the latter [94]. The decomposition reaction of PR_3OBu-t and $\dot{P}R_2OBu\text{-}t)_2$ is of first order at 0°C and bimolecular at temperatures between −50° and −60°C. [21,98]

Table 7. Kinetic parameters of the β-decomposition of phorphoranyl radicals.

Radical	$k_{(-60^\circ)}$, s^{-1}	lg A	ΔH, kcal mole^{-1}
$(EtO)_4\dot{P}$	0.36	12.86	12.95
$(t\text{-}BuO)_4\dot{P}$	510		
$(t\text{-}BuO)\dot{P}(OEt)_3$	257	12.95	10.34
$(t\text{-}BuO)\dot{P}(OCH_2CF_3)$	4.5	8.25	7.4
	43.6		

The phosphoranyl radical in which one of the alkoxy-groups has been replaced by a chlorine atom shows a smaller tendency towards β-decomposition, which is believed to be due to the stabilisation of the ground state and the destabilisation of the transition state [98]. Phosphoranyl radicals in which phosphorus is incorporated in a five-membered ring exhibit an even greater resistance to β-decomposition. For example,  does not split off the t-butyl group at 30°C. The spirophosphoranyl radicals (IV) are stable up to 120°C and their β-decomposition is so slow that there is sufficient time for the radicals to dimerise before this happens [71,72]. Both rings of (IV) are probably rigidly fixed. The unusual stability of the radicals (IV) enables them to add to hex-1-ene at −50°C, like phosphinyl radicals.

Phosphoranyl radicals containing prop-2-enoxy- or but-2-enoxy-groups at the phosphorus atom can cyclise with formation of the radicals (VI) in addition to undergoing β-decomposition [107]. The presence of t-butoxy-groups prevents the formation of the five-membered ring and the radicals derived from tri(pent-3-enyl) phosphite do not cyclise at all. a_P = 180 G and $a_{H_\alpha} = a_{H_\beta}$ = 20 G for the ESR spectra of the radicals (VI).

Davies and coworkers [93,94] explained the dual nature of the decomposition of phosphoranyl radicals on the basis of three factors: (1) the stereoselectivity of the decomposition; (2) the comparative stability of the secondary radicals; (3) pseudorotation. It is suggested that, in view of the appreciable weakness of the axial bonds, α-decomposition entails their dissociation while in β-decomposition the equatorial O–C bond is ruptured. It is then evident that the $Me_3\dot{P}OBu$-t radical will decompose via mechanism (10) only, in agreement with the data of Krusic et al. [91] It is also evident that the $R_2\dot{P}(OR)_2$ radical must be much more stable than $\dot{P}(OR)_4$, since the latter can undergo β-decomposition immediately. The $Et\dot{P}(OR)_3$ radical must be more stable than $Et_3\dot{P}OR$, since the dissociation of the P–O bond is more difficult than that of the P–C bond, in agreement with the results of Davies et al. [95]

Furthermore, the rate of β-decomposition is influenced by the nature of the radical removed: the lower its intrinsic stability the greater the difficulty of the β-decomposition and the more stable is the phosphoranyl radical. Consequently the rate constant for the decomposition of $\dot{P}(OBu\text{-}t)_4$ is higher by a factor of 1500 than that for the decomposition of $\dot{P}(OEt)_4$, while the $(PhO)_3\dot{P}OBu$-t radical cannot be detected by ESR at all [93]. In this case steric effects are unimportant, since the rate of decomposition of $\dot{P}(OBu\text{-}t)_4$ is only an order of magnitude higher than that for $t\text{-}BuO\dot{P}(OMe)_3$. [94]

Finally, in order to interpret the decomposition pathway of the phosphoranyl radical, one can employ the concept of pseudorotation proposed by Berry [103]. For example, the t-butoxy-group in the $\dot{P}(OMe)_3OBu$-t radical can enter the equatorial position by pseudorotation and subsequently, by virtue of the comparative stability of the secondary radicals, β-decomposition proceeds via this group [95]. In order to account for the decomposition of the $Et\dot{P}(OEt)_2(OBu\text{-}t)$ and $Et_2\dot{P}(OEt)(OBu\text{-}t)$ radicals with elimination of the ethyl radical [95], the decomposition of the $(t\text{-}BuO)_2\dot{P}(NMe_2)_2$ radical via the α-mechanism, and the characteristics of the reactions of t-butoxy-radicals with phosphoramidites containing five-membered rings, the concept of pseudorotation was also resorted to.

However, it is by no means universal. In the first place pseudorotation in phosphoranyl radicals is frequently inconvenient on energy grounds. Thus the activation energy for the reaction of triethylphosphine with t-butoxy-radicals via the α-mechanism is 1.34 kcal mole^{-1}, that for the α-decomposition of $Et_2\dot{P}(OEt)(OBu\text{-}t)$ is 8.16 kcal mole^{-1} [95], while the energy of pseudorotation in $\dot{P}F_4$ has been estimated theoretically as 25 kcal mole^{-1}, the value for $\dot{P}H_3OH$ being higher still [102]. The broadening of the

components observed in the $\dot{P}H_3OBu$-t ESR spectrum above −70°C [104] is not due to pseudorotation but to the permutation of all the hydrogen atoms. The energy of this process in $\dot{P}H_3OH$ is 1.8–3.4 kcal mole^{-1} [102] and in $\dot{P}H_3OBu$-t the energy is 5.3 kcal mole^{-1} [104]. Even in those cases where pseudorotation in phosphoranyl radicals is possible, it evidently takes place slowly and at best can compete with bond dissociation.

Bentrude and Min [108] obtained evidence for the trigonal bipyramidal structure of phosphoranyl radicals and for the inadequacy of the concept of pseudorotation on the basis of chemical data. They investigated the reactions of phosphites with benzyl radicals via the mechanism

$$PhCH_2\dot{O} + (EtO)_2POR \rightarrow (PhCH_2O)\dot{P}(OR)(OEt)_2 \rightarrow \underset{52\%}{RO(OEt)_2PO} + \underset{44\%}{PhCH_2O(EtO)_2PO} \quad (12a)$$

$$R\dot{O} + (EtO)_2POCH_2Ph \rightarrow (PhCH_2O)\dot{P}(OR)(OEt)_2 \rightarrow \underset{41\%}{RO(OEt)_2PO} + \underset{49\%}{PhCH_2O(EtO)_2PO} \quad (12b)$$

where R = $CH_2C_6H_4Me$-p; the numbers denote the yields of phosphine oxides in reactions (12a) and (12b) respectively. Evidently the alkoxy-groups in the intermediate phosphoranyl radicals are non-equivalent. The new substituent probably enters the axial position, in accordance with the Muetterties rule. If this factor is considered together with the yields of the products, it is found that the β-dissociation in the axial position is 1.3 times faster than in the equatorial position. In this case the pseudorotation factor is unimportant, since pseudorotation is slower than the β-decomposition. The attempt to account for the results [108] by competition between the β-dissociation processes in two axial positions is also invalid, since the introduction of a methyl group in the *para*-position of one of the aryl groups does not affect the ease of β-decomposition.

So far we have considered only the addition of fairly electrophilic radicals to phosphines and their derivatives. On this basis, it has been suggested [109] that a necessary condition for this reaction is a highly polar transition state. However, Davidson [110] established that diphenyl phosphonites react via the β-decomposition mechanism with methyl, isopropyl, and phenyl radicals; the reaction with t-butyl radicals is very slow and that with benzyl radicals does not occur. Fu and Bentrude [111] studied the kinetics of the reaction of trimethyl phosphite with phenyl radicals, which are intermediate between the alkoxy- and alkyl radicals both as regards electrophilic properties and the strength of the P–R bond. The formation of the phosphoranyl radicals $Ph\dot{P}(OMe)_3$ fully predominates in this reaction; next in importance is β-decomposition. The yield of the phosphonate is 99%, i.e. the phosphite absorbs all the kinetically free phenyl radicals. The interaction of methyl radicals with trimethyl phosphate is slower than that of phenyl radicals and triphenylmethyl radicals do not react with the phosphate at all. Fu et al. [112] determined the rate constant k for the molecular interaction of trimethyl phosphite with phenyl radicals ($k = 4.6 \times 10^6$ litre mole^{-1} s^{-1}) and estimated the activation energy for this process as 3.6 kcal mole^{-1}. The addition of phenyl radicals, like that of alkoxy-radicals, is irreversible: $BuOP(OMe)_2$ cannot be obtained from $PhP(OMe)_2$ and $\dot{O}Bu$. Fu et al. [112] suggest that the reaction of $P\dot{h}$ with the phosphite is exothermic; this should be even more true of the reactions of $R\dot{O}$ with phosphites.

Bentrude and coworkers [113–115] examined in detail the energetic aspect of the reactions of phosphorus(III) compounds with alkoxy-radicals. The decisive factor in these reactions is the thermodynamics of the formation of phosphoranyl radicals. The role of polar transition states may be neglected; for example, in the reaction of t-butoxy-radicals with the compounds $XC_6H_4P(OCH_3)_2$, where X = *p*-MeO, H, *p*-Cl, or *m*-CF_3, the polarity of the substituents hardly affects the rate of reaction [$k_{65°} = (3.1 - 3.7) \times 10^8$ litre mole^{-1} s^{-1} for X = H]. The formation of phosphoranyl radicals from the initial products is exothermic and their β-decomposition is more favourable on energy grounds than their α-decomposition owing to the stability of the P–O bond; this probably accounts also for the high reactivity of t-butoxy-radicals with respect to phosphorus(III) compounds. The heat of formation of the radical $\dot{P}X_3Z$ depends on the energy of the rehybridisation of the orbitals, bond energies, and the energy of resonance stabilisation. Thus the preferential occurrence of the α- or β-decomposition of $\dot{P}X_3Z$ is determined by the value of $\bar{D}_{PX_3}$, which is a measure of the P–X bond strength; when $\bar{D}_{PX_3} <$ 75 kcal mole^{-1}, the main reaction product is the phosphite or phosphonite. The formation of α- or β-decomposition products in the reaction with $PhCH_2\dot{O}$ radicals [108] has been explained by the weakening of the C–O bond and the decrease of the free energy of β-decomposition. As was to be expected, the probability of α-decomposition increases in the sequence X = Me < t-Bu < $PhCH_2$. Pseudorotation can be the rate-limiting stage of the process only in the α-decomposition of phosphoranyl radicals. Account must also be taken of the entropy effects.

4. Reactions Involving Phosphoranyl Radicals

Only the mechanisms of the reactions of $\dot{P}Ph_4$ and phosphoranyl radicals formed in the reactions with alkoxy- or phenyl radicals were examined previously. However the range of reactions involving phosphoranyl radicals is much wider. All the reactions involving the autoxidation of phosphines and phosphites have free-radical mechanisms. The oxidation of triethyl phosphite and secondary and tertiary phosphines by nitric oxide [5] and of triethyl phosphite by pyridine *N*-oxide [116], as well as other reactions proceed via the formation of phosphoranyl radicals with subsequent β-decomposition. It is usually believed [5,6] that the radical initiating the oxidation is initially converted into a peroxy-radical, this being followed by the formation of the phosphoranyl radical, whose decomposition initiates the chain:

$$\dot{R} + O_2 \rightarrow RO_2^{\cdot}, \quad (13a)$$

$$PEt_3 + RO_2^{\cdot} \rightarrow Et_3\dot{P}OOR, \quad (13b)$$

$$Et_3\dot{P}OOR \rightarrow Et_3PO + RO^{\cdot}, \quad (13c)$$

$$RO^{\cdot} + Et_3P \rightarrow Et_3\dot{P}OR. \quad (13d)$$

Ultimately $Et_2P(O)OEt$ and $EtP(O)(OEt)_2$ are also formed. Reaction (13b) is bimolecular; $k_{-95°} = 200$ litre mole^{-1} s^{-1} and $\Delta E = 3$ kcal mole^{-1} for PPh_3. [177] However, in these reactions oxygen can add directly to the phosphine or phosphite molecule; this process is possible for triphenyl phosphine and triethyl phosphite, while PCl_3 and $P(OBu\text{-}t)_3$ do not absorb oxygen without an initiator [117]. Phosphoranyl radicals can also combine with O_2; for example $(EtO)_4P\dot{O}O$ radicals ($g = 2.022$ and $a_P = 9.25$ G) and $(t\text{-}BuO)(EtO)_3P\dot{O}O$ radicals ($g = 2.021$ and $a_P = 9.45$ G) were detected [95] at −70°C in the presence of oxygen. Such radicals are stable at −50°C for a few minutes. When the entire oxygen has combined, only the ESR spectrum of the primary phosphoranyl radical is observed [118].

Peroxy-radicals are probably formed also in the oxidation of PCl_3. [4,119]. This reaction is self-initiated with formation of $\dot{P}Cl_2$ and $\dot{C}l$ and then proceeds via the mechanism

$$PCl_3 \xrightarrow{Cl} \dot{P}Cl_4 \xrightarrow{O_2} Cl_4POO\cdot \xrightarrow{PCl_3} 2POCl_3 + Cl\cdot \quad (14)$$

When a hydrocarbon is added to PCl_3 in the presence of O_2, the products are PCl_3 and $PCl_3O\dot{O}$ and ultimately $POCl_3$ and $RPOCl_2$; the compounds $RPCl_2$ were obtained at 575–600°C. [5]

It has already been mentioned (see Section II) that the role of phosphinyl radicals in the reaction of PCl_3 with olefins is insignificant. This reaction proceeds via the formation of the phosphoranyl radicals $Cl_3PCHR'CH_2Cl$ by the addition of $\dot{C}l$ and PCl_3 to the olefin molecule [120]. The reaction of PCl_3 with *p*-xylylene proceeds via the same mechanism; a radical of the benzyl type is formed initially and then reacts with PCl_3 [5]:

The phosphoranyl radical adds to *p*-xylylene as a result of which poly-*p*-xylylene is formed even at −78°C.

The characteristics of the radical reactions of thiols and disulphides with phosphines and phosphites are the same as those of organic peroxides [5,78,112]. The reactivity of phosphorus compounds decreases in this case in the following sequence: $P(n\text{-}Bu)_3 > P(OEt)_3 > PPh_3 > P(OPh)_3$.

Phosphoranyl radicals may also be formed in the reaction of SCl_2, S_2Cl_2, $SOCl_2$, and SO_2Cl_2 with trialkyl phosphites. However, the radical mechanism of these reactions still has to be demonstrated [5].

Apart from the abstraction of a hydrogen atom and an alkyl group and the formation of the radicals discussed in Section V, the reactions of phosphoranyl compounds with phenyl radicals can entail the formation of phosphoranyl radicals by the addition of the phenyl radical to be phosphoranyl oxygen; however, they rapidly disproportionate [121].

V. σ-RADICALS WITH THE PHOSPHORUS ATOM IN THE α- AND β-POSITIONS

When phosphorus acid esters react with hydroxy-radicals in aqueous solutions (for example on treatment with Fenton's reagent), radicals of the type $(R'O)_2P(O)\dot{O}CHR$ or $R'(R'O)P(O)\dot{O}CHR$ (R = H, Me, or Et), which have been detected in a flow system by ESR, are formed [122,123]; the same radicals have been detected in other studies [124], [125] on low-temperature irradiation of trialkyl phosphates. Estimates of Q^H_{CH} for these radicals show that the phosphoryl group has a greater inductive and a weaker mesomeric effect than the acetyl group: a_P = 10–32 G [122,123]; thus the spin population of the 3*s* orbital of phosphorus $\rho_S(^{31}P)$ = 0.003–0.009. The overall spin density at phosphorus in $(R'O)R'P(O)\dot{O}CHR$ radicals is 0.08–0.09; splitting by phosphorus in $(R'O)R''\dot{P}(O)CH_2\dot{C}HR$ radicals has not been observed [123].

β-phosphoryl radicals formed via mechanism (7b) have been detected by ESR [38]. Their $\rho_S(^{31}P)$ is much lower than for phosphonyl radicals (about 0.03); $\rho_S(H)$ for the CH_2 group is of the same order of magnitude—lower than for Et and $(RO)_2P(O)\dot{O}CH_2$. [124] The decrease of spin density at the protons has been explained by the fact that the P–C bond screens the *p* orbital of the unpaired electron and rotation about the C–C bond in the $(RO)_2P\dot{O}CH_2$.$\dot{C}HR'$ radical is hindered.

These results are consistent with the general conclusion of Krusic and Kochi [126] that the conformation with the MR''_3 group displaced from the plane and the maximum overlapping of the electron cloud of the C–M bond and the *p* orbital of the unpaired electron is preferred for radicals of the type $R_2\dot{C}CR'_2MR''_3$ (M is an element in the Third or higher Period). This phenomenon can be explained satisfactorily by the delocalisation of the unpaired electron as a result of hyperconjugation [127]; then the splitting by the ^{31}P nucleus will be proportional to the spin density at the α-carbon atom and $\cos^2\theta$, where θ is the angle between the C–M bond and the axis of the unpaired electron orbital. Damerau et al. [128,129] obtained in aqueous solutions radicals of the type $(RO)_2P(O)CH.$ $.(OR')\dot{C}Cl_2$, which are characterised by a high value of a_P (60–69 G), very sensitive to changes in R and R′, in contrast to a_H; with increase of temperature, a_P decreases sharply in accordance with the hyperconjugation model. The authors [129] estimated θ = 57.2° from the value of a_P. For the radicals $(RO)_2P(O)C\dot{R}'OH$, [128] $a_P \simeq$ 30 G, is independent of temperature, and is probably due to spin polarisation [129].

On the basis of the *g*-factors for the $R_2\dot{C}CR'_2MR''_3$ radicals, Kawamura and Kochi [130] suggested that in these radicals there is a possibility of a direct delocalisation of the unpaired *p* electron over the *d* orbital of M. However, such delocalisation must be insignificant in principle [131]. In the case of phosphorus it does not occur at all, since *g* = 2.0027 for $(MeO)_2P(O)C(OH)Me\dot{C}H_2$ [128], and for $\dot{P}O_3^{2-}$ it is less than 2.002 (see Section VII, 1), while delocalisation over the *d* orbital should lead to a decrease of the *g*-factor.

Low-temperature irradiation of trialkylphosphines yielded radicals of the type $R_2P - \dot{C}R'_2$ [132]; the splitting by the ^{31}P nucleus in their ESR spectra was interpreted as a result of spin polarisation.

Arbuzov et al. [133] investigated the ESR spectra of the phosphonohydrazyl radicals $Ph_2N\dot{N}P(O)R_2$ (R = Ph, OPh, or OEt) in solution. The sum of the constants for the splitting by the two ^{14}N nuclei is lower than for diphenylpicrylhydrazyl; part of the spin density is probably delocalised over the phosphoryl group. A similar result was obtained from the ESR spectra of thiophosphonohydrazyl radicals [134].

VI. RADICAL-CATIONS DERIVED FROM PHOSPHORUS COMPOUNDS

1. Generation

The radical-cations $\dot{P}H_3^+$ [135], $Et_3P^{\dot{+}}$ [135], $Bu_3P^{\dot{+}}$ [135], and $Me_3P^{\dot{+}}$ [136] were obtained by the low-temperature γ-irradiation of phosphine and trialkylphosphines in sulphuric acid at −196°C; irradiation of a mixture of orthophosphoric and sulphuric acids gave $^+\dot{P}(OH)_3$ [137] and not the phosphoranyl radical $\dot{P}(OH)_4$. The dimeric radical-cations $(R_3P)_2^{\dot{+}}$ were detected after irradiation of pure trialkylphosphines [137,138].

Many reactions of phosphines may include a stage involving one-electron oxidation with formation of radical-cations. Ramirez and Dershowitz [139] reported the appearance of ESR signals in the reaction of triphenylphosphine with cloranil. However, these signals were not due to the radical-cations $Ph_2^{\dot{+}}$ but to products of their addition to the oxygen atom in the chloranil molecule [140,141]. The ESR signals in the reaction between triethylphosphite and chloranil have the same origin [141]. ESR signals were also recorded in the triphenylphosphine–sulphur [142], triphenyl-

phosphine–benzoquinone[143], and triphenylphosphine–2,5-dichlorobenzoquinone[144] systems. In the last two cases they are due to semiquinone radicals—derivatives of phosphobetaines; similar stable 4-R-2,6-di-t-butyl-phenoxy-radicals (R = PPh_2, $POPh_2$, $PSPh_2$, etc.) were also investigated[145].

The ESR spectra of the products of the addition of the corresponding radical-cations to 2-methyl-2-nitrosopropane were detected in the reaction of $P(OEt)_3$ and $P(NMe_2)_3$ with 9,10-phenanthrenequinone; in the presence of an excess of $P(NMe_2)_3$, the spectrum of the adduct of the dimeric radical-cation was observed[146].

The anodic oxidation of triphenylphosphine in methanol results in the formation of triphenylphosphine oxide[147], probably via the radical-cation stage. Triarylphosphines can also be converted into the radical-cations $Ar_3P^{\cdot+}$ and then into triarylphosphine oxides under the influence of tetracyanoethylene and tetracyano-*p*-quinodimethane.[148] Dimroth and coworkers[149-151] obtained radical-cations derived from 2,4,6-triphenylphosphabenzene (TPB) and its analogues with two and three C_6D_5 groups by oxidation with phenoxy-radicals, $Pb(OAc)_4$, $Pb(OBz)_4$, or $Hg(OAc)_2$. 1,1-Dimethoxy-, 1,1-diaryloxy-, and 1,1-diaryl-TPB are also readily oxidised to the radical cations[152-154].

Lucken and Mazeline[155] obtained the radical-cation $Ph_3\overset{+}{P}\dot{C}H_2$ by the low-temperature irradiation of triphenylmethylphosphonium chloride; Lyons and coworkers[132,140,156] obtained the radical-cations $R_3'\overset{+}{P}\dot{C}Me$ (R = H, Me, or COPh) in irradiated phosphonium salts‡. After treating aqueous solutions of phosphonium salts with Fenton's reagent, Lucken[157] recorded the ESR spectra of $(HOCH_2)_2\overset{+}{P}\dot{C}HOH$ and $(HOCH_2)_3\overset{+}{P}\dot{C}HOH$.

Buck and coworkers[158,159] generated the radical-cations $Ph_3\overset{+}{P}\dot{C}Ph_2$ and $Ph_3\overset{+}{P}\dot{C}(C_6H_4OMe\text{-}p)_2$ by the anodic oxidation of the corresponding ylides, by the cathodic reduction of the dications obtained by treating the ylides with $AgBF_4$, and by the reaction of the dications with the ylides.

2. Structure

The simplest radical-cation $PH_3^{\cdot+}$ is characterised by an appreciable isotropic interaction of the unpaired electron with the ^{31}P nucleus (Table 8).

According to the theory of the dependence of the valence angles φ in the AB_3 radicals on the nature of the A–B bond[127], the following relation holds between φ and the hybridisation parameter $\lambda = \sqrt{\rho_p/\rho_s}$:

$$\varphi = \arccos\left[\frac{1}{2}\left(\frac{3}{2\lambda^2+3}-1\right)\right] \qquad (16)$$

The use of Eqn. (16) yields $\varphi = 114°$ for $PH_3^{\cdot+}$. Boyd and Whitehead[160] found φ ranging from 112 to 120°, depending on the choice of parameters, when they optimised the $PH_3^{\cdot+}$ geometry by a modified CNDO/2 method. These estimates of φ are probably too high, since the possible involvement of 3*d* orbitals in the formation of bonds was ignored in deriving Eqn. (16) and in the calculations[160]. The inclusion of the 3*d* orbitals of phosphorus in the basis set reduces the total $PH_3^{\cdot+}$ energy and decreases the equilibrium value of φ, as shown by the non-empirical calculation of Aarons et al.[161]; however, the numerical values of φ obtained for $PH_3^{\cdot+}$ in their study are also not entirely reliable owing to the limited basis set employed and the fixed bond length R_{PH}. Gorlov et al.[162] carried out a similar optimisation of the interatomic distances and valence angles in $PH_3^{\cdot+}$ by the UHF – CNDO/2 method; according to their data, $\varphi = 109°27'$ and $R_{PH} = 1.523$ Å, the spin density of the phosphorus *s* orbital being 0.122 after spin projection and the barrier to the $PH_3^{\cdot+}$ inversion being about 15 kcal mole^{-1}. Although these results are not final either, there is no doubt that the $PH_3^{\cdot+}$ radical-cation is non-planar.

Table 8. ESR parameters of radical-cations derived from phosphorus compounds.

The valence angles in the radical-cations derived from alkylphosphines, found by Eqn. (16), are greater than for $PH_3^{\cdot+}$, although, according to Walsh's rules for the effect of the ligand electronegativities on the valence angles, their decrease was to be expected; the hyperconjugation of phosphorus with the alkyl groups probably has an effect here[135]. The dimeric radical-cations $(R_3P)_2^{\cdot+}$ have a more pyramidal structure than the monomeric radical-cations. Possibly the radical identified[87] as $\dot{P}H_4$ was in reality the dimeric radical-cation $P_2H_6^{\cdot+}$.

Powell and Hall[148] established that the reactions of optically active arylphosphines with tetracyanoethylene and with tetracyano-*p*-quinodimethane yield the racemic phosphine oxides; consequently the $PH_3P^{\cdot+}$ radical-cation must be planar or must be characterised by a very low inversion barrier. Since the $PH_3^{\cdot+}$ radical-cation is pyramidal, the flattening of the $Ph_3P^{\cdot+}$ structure must be due to the unusual nature of the interaction between the phenyl groups and the phosphorus atom.

A delocalisation of spin density due to the $p_\pi - d_\pi$ interaction is in principle possible in radical-cations where the phosphorus atom can form part of the *p*-electron system. It is observed, for example, in the TPB radical-cation[150-152]. The splitting constants are 22 – 27 G for the ^{31}P nucleus and 2.4 G in each case for the *meta*-protons of the TPB ring and the *ortho*- and *para*-protons of the benzene ring. In the radical-cations derived from 1,1-diaryloxy- and 1,1-diaryl-TPB the unpaired electron is not delocalised over the substituents at the phosphorus atom[152-154]: $a_P = 20$ G.

The rotation of the methylene group in $Ph_3\overset{+}{P}\dot{C}H_2$ is probably hindered[155], also in agreement with the concept of the $p_\pi - d_\pi$ interaction. However, the splitting by the ^{31}P nucleus in the ESR spectra of the radical-cations

‡Irradiation of $Ph_3\overset{+}{P}\bar{C}(Me)COOH$ gives rise to the ESR spectrum of the cyclohexadienyl radical with the phosphorus atom at the methylene carbon atom[215].

$R_3\dot{P}\dot{C}RMe$ [156], $(HOCH_2)_2\dot{P}H\dot{C}HOH$, and $(HOCH_2)_3\dot{P}\dot{C}HOH$ [157] was interpreted as a result of the spin polarisation of the P–C σ bond; the delocalisation of the spin density at the phosphorus atom due to the $p\pi-d\pi$ interaction is very slight according to some investigators [137, 156]. The same conclusion was reached in other studies [158, 159] on the basis of the ESR spectra of $Ph_3\dot{P}\dot{C}Ph_2$ and $Ph_3\dot{P}\dot{C}(C_6H_4.OMe\text{-}p)_2$. The distribution of spin density over the benzene rings and the carbon atom in these radical-cations and in the diphenylmethyl radical [163] is similar; consequently the phosphorus atom is not involved in conjugation and the splitting by its nucleus is due to spin polarisation.

The radical-cations derived from salts of 1,4-diphosphoniacyclohexa-2,5-diene, which are stable at 20°C, have been investigated [164]; $a_P \simeq 16$ G at −60°C and decreases with increase of temperature, possibly in consequence of a change in the conformation of the radical-cation, leading to a change in the hybridisation of the phosphorus atom.

VII. RADICAL-ANIONS DERIVED FROM PHOSPHORUS COMPOUNDS

1. TETRAATOMIC RADICAL-ANIONS

a. Generation

The first phosphorus-containing radical-anion identified by the ESR spectrum was $\dot{P}O_3^{2-}$ in γ-irradiated $Na_2HPO_3.5H_2O$ and $BaHPO_3.6H_2O$ crystals [7]. This radical-anion was also detected after irradiation with X-rays of crystalline magnesium, strontium, and cadmium phosphites [165], ammonium hydrogen phosphate [166], $(NH_4)_2P_2.O_8$ [167], $(NH_4)_2PO_3F.H_2O$ [168], and $CaCO_3$ with an admixture of phosphite [169]; Schlick et al. [170] studied the ESR spectrum of $\dot{P}O_3^{2-}$ in irradiated $Na_2DP^{17}O_3.5D_2O$ crystals. Morton [171] recorded the ESR spectrum of the HPO_2^- radical-anion in a γ-irradiated ammonium hypophosphite single crystal and Atkins et al. [172] obtained this spectrum for irradiated crystals of sodium and magnesium hypophosphites. Fessenden [173] detected by ESR the FPO_2^- radical-ions in NH_4PF_6 and these were subsequently also found [174] on γ-irradiation of KPO_2F_2. The HPO_2^- and $\dot{P}O_3^{2-}$ radical-ions were obtained in aqueous solutions almost simultaneously by Beckwith [175] and by Norman and coworkers [176] by treating hypophosphorous and phosphorous acids with Fenton's reagent; the latter yields the HPO_3^- radical-ion in an acid medium [175]. Low-temperature irradiation of dimethyl and diethyl phosphites gave, apart from phosphonyl radicals, also the $MeOPO_2^-$ and $EtOPO_2^-$ radical-ions, while only the latter radicals were found in frozen solutions of phosphites in 2-methyltetrahydrofuran [37]. Irradiation of solid phenylphosphinic acid salts with X-rays [177] and their treatment with Fenton's reagent in aqueous solutions [176] yielded the $PhPO_2^-$ radical-anion, while the neutral $Ph\dot{P}(O)OH$ radical was obtained in irradiated phenylphosphinic acid powder [177].

b. Structure

The parameters of the ESR spectra of the simplest phosphorus-containing radical-anions are presented in Table 9. Judging from the values of ρ_P/ρ_S, these radical-anions must be non-planar [178], particularly if the contribution of the 3*d* orbitals of phosphorus to the formation of bonds is considerable (see Section VI). The numerical value of the valence angle in $\dot{P}O_3^{2-}$ depends on the nature of the matrix. With increase of the ρ_P/ρ_S ratio, the overall spin density at the phosphorus atom diminishes; in this respect the $\dot{P}O_3^{2-}$ radical-ion differs from NO_3^{2-}. [179]

A quantum-chemical calculation on $\dot{P}O_3^{2-}$ with a pyramidal structure [168] by the molecular orbital method in Hoffmann's approximation led to a satisfactory agreement between the calculated and experimental splitting constants. After optimising the $\dot{P}O_3^{2-}$ geometry by the unrestricted Hartree–Fock method in terms of the CNDO/2 approximation, Kilcast and Thomson [23] found that the energy minimum corresponds to a planar structure ($\varphi = 120°$, $R_{PO} = 1.69$ Å). According to their data [23], the HPO_2^- and FPO_2^- radical-ions are non-planar. All the calculated *s* spin densities are somewhat higher than the experimental values; it was noted that the *s* spin density at the phosphorus atom increases as the radical-ion becomes flattened, contrary to Walsh's rule [127].

Table 9. ESR parameters of phosphorus-containing radical-anions.

$(PNCl_2)_3^-$		1290		0.354		224

The increase of A_{iso} (^{31}P) and the enhancement of the pyramidal structure of the radical-ion on passing from $\dot{P}O_3^{2-}$ to HPO_3^- has been explained by a decrease of the repulsion between the electronic charges as a result of protonation. However, the qualitative distribution of spin density is not altered either by protonation or by the addition of an alkyl group. The $PhPO_2^-$ radical-anion is undoubtedly non-planar, in contrast to the $PhNO_2^-$ radical-anion. The valence angles in $PhPO_2^-$ are unknown; the *s* spin density at the phosphorus atom increases on protonation of $PhPO_2^-$ and depends on the type of cation in the matrix [177]. As a result of both these effects, the $PhPO_2^-$ radical-anions resemble more closely $\dot{P}O_3^{2-}$ and other tetra-atomic radical-ions.

c. Reactions of XPO_2^- Radical-anions

It follows from the foregoing that the $\dot{P}O_3^{2-}$ and HPO_2^- radical-anions can be regarded as dealkylated phosphonyl radicals. Since the influence of the alkyl groups is relatively slight [37, 38], presumably the chemical properties of

these radical-anions will resemble those of phosphonyl radicals. Indeed they are capable of reducing alkyl bromides, alkyl iodides, bromo- and iodo-substituted carboxylic acids, and diacetyl to alkyl radicals and phenyldiazonium salts to phenyl radicals ($\dot{P}O_3^{2-}$ is the most effective reducing agent[175]) and can also add to the C=C double bond in maleic, acrylic, and methacrylic acids and their anions, and 1,1-dimethylethylene and to the C=N bonds in $CH_2{=}NO_2^-$ and oximes[175,176]. However, the addition proceeds with greater difficulty than that of the $\dot{O}H$ and $\dot{N}H_2$ radicals and only to a carbon atom not bound to a polar group. It follows from the analysis of the ESR spectra of the radical addition products that the spin density is delocalised over the phosphorus atom; free rotation about the P–C bond is hindered; according to Beckwith[175], this can be explained only by the interaction of the unpaired electron with the 3*d* orbitals of phosphorus. The reactions of $PhPO_2^-$ in solution are similar to those $\dot{P}O_3^{2-}$ and HPO_2^-.

When irradiated NaH_2PO_3 is dissolved in aqueous solution of t-butyl nitroxide, $\dot{P}O_3^{2-}$ adds to the nitrogen atom of the N=O bond [175]. A similar reaction takes place between nitrobenzene or *p*-nitrobenzoic acid and $\dot{P}O_3^{2-}$ or HPO_2^-. [176]

2. RADICAL-ANIONS DERIVED FROM PHOSPHINES

The unpaired electron in the radical-anion derived from a phosphorus(III) compound can be stabilised by delocalisation of the π-electron system and can occupy the lowest vacant π orbital. In this case the nature and degree of its delocalisation are related to the degree of involvement of phosphorus in the π-electron interaction.

Arylphosphines are reduced over alkali metals at temperatures between −40° and −80°C to the corresponding radical-anions. However, when this method is used, one has to bear in mind the possibility of their conversion into more stable secondary paramagnetic products. Thus, on reducing triphenylphosphine over potassium, Hanna[180] obtained the phosphyls Ph_2PK, which are also formed when triphenylphosphine reacts with lithium and sodium[181], and not the PPh_3^- radical-ions; as a result, his data[180] concerning the structure of PPh_3^- are erroneous. In the ESR spectra of phosphides a_P = 8.0–8.4 G, regardless of the choice of alkali metals; splitting by the protons in the benzene rings is also observed[181]. The true radical-anions derived from triphenylphosphine, methyldiphenylphosphine, and dimethylphenylphosphine were apparently investigated by Kabachnik and coworkers[182,183], who concluded that the spin density is delocalised over several benzene rings. On reduction of dimethylphenylphosphine over potassium at −90°C, Eliseeva et al. [184] obtained an ESR spectrum with splitting by the ^{31}P nucleus and the benzene ring protons. According to these workers[184], the distribution of spin density corresponds to the vacant orbital of benzene stabilised by an electron-accepting substituent. Gerson et al. [185] showed that the Me_2PPh^- radical-ion is stable over sodium at −40°C and confirmed the electron-accepting properties of the dimethylphosphino-group, although their hyperfine splitting constants differ from those quoted by Eliseeva et al. [184], in particular $a_{H(para)}$ = 8.9 G and a_P = 7.2 G. Since the inductive effect of the dimethylphosphino-group should be positive (electron donating), its electron-accepting properties can be accounted for only by an additional interaction of the π electrons of the benzene ring with 3*d* orbitals of phosphorus. The Me_2PPh^- radical-ion is unstable over potassium[185] and is converted into a secondary radical whose ESR spectrum has been published[184] with an erroneous assignment of the splitting constants; the nature of the secondary radical is not clear. Hnoosh and Zingaro[186] established that the radical-anion derived from tris-(α-naphthyl)phosphine is readily converted in the range between 0° and −65°C into naphthalene radical-anions over sodium and into the phosphyls $(C_{10}H_7)_2PK$ over potassium.

A more reliable method of generating phosphine radical-anions is electrochemical reduction, which can be carried out strictly at the reversible electron transfer stage. The formation of the Me_2PPh^- radical-anion was confirmed by this method in combination with ESR spectra[185]. Triphenylphosphine is also reduced at the cathode to a radical-anion[187–189]; the electrochemical reduction of Ph_2PCl and $PhPCl_2$ immediately leads to the elimination of the Cl^- ion, by-passing the radical-anion stage[187]. According to Santhanam and Bard[188] the Ph_3P^- radical-anion is unstable, readily splits off Ph^-, and is then converted into diphenylphosphine. However, when the reduction potential is controlled within the limits corresponding to the one-electron stage, the Ph_3P^- radical-anions can be generated in amounts sufficient for their detection by ESR [189]. Il'yasov et al. [190] refined the proton splitting constants for the Ph_3P^- radical-anion by deuteriating the phenyl groups and confirmed that the unpaired electron is delocalised over all three benzene rings (for further details, see Section VII, 3).

The electrochemical reduction of the phosphines $p\text{-}XC_6H_4P(C{\equiv}CC_6H_4NO_2\text{-}p)_2$ (X = H, Cl, or NMe_2) in tetrahydrofuran or dimethoxyethane[191] results in the formation of radical-ions where the unpaired electron is localised in the fragment $>PC{\equiv}CC_6H_4NO_2\text{-}p$ (a_N = 7.4–7.8 G; a_P = 0.9–1.3 G). The polarogram of the phosphine resembles that of nitrobenzene in a non-aqueous medium. The presence of powerful electron-accepting groups probably prevents the delocalisation of the unpaired electron. The competitive effect of the electron-accepting group is manifested also in the ESR spectra of ethyl benzoates containing the R_2P group in the *para*- or *meta*-positions[192]. For *para*-substituted radical-anions, a_P = 3.8–5.2 G, which is appreciably lower than a_P for the radical-anion derived from dimethylphenylphosphine[185]; for *meta*-substituted radical-anions, a_P = 1.1–1.3 G and the distribution of spin density in the benzene ring changes little compared with the unsubstituted ethyl benzoate.

3. RADICAL-ANIONS DERIVED FROM PHOSPHORINS AND PHOSPHOLES

The ESR spectrum of the radical-anion derived from TPB shows splitting only due to the ^{31}P nucleus (a_P = 32.4 G) or, in other words, the lowest vacant orbital of TPB is more localised at the phosphorus atom than the highest occupied orbital[150,151,193]. A similar phenomenon has been observed also in the ESR spectra of the radical-anions derived from 1,1-dimethoxy- and 1,1-diphenoxy-TPB (a_P = 31.6 G) [152]. For the ESR spectrum of the TPB radical-trianion, a_P = 4.6 G. [151] Märkl and Merz[154] reported radical-anions derived from 1,1-diaryl-TPB.

Thomson and Kilcast[194] obtained the radical-anions derived from 1-R-2,5-diphenylphospholes: a_P = 23.5 G for R = Me and a_P = 26.5 G for R = Ph. On the basis of these results, and Dimroth's ESR data[152–154] for the phosphorin radical-anions and radical-cations, Thomson and Kilcast[194] attempted to estimate the constant Q^P_{eff} for the σ–π polarisation at the phosphorus atom. The spin density

$\rho\pi(P)$ was calculated by the McLachlan method. Q^P_{eff} = 97.9 G was found from the aP for the phosphorin radical-cations, which is close to the values of Q^P_{eff} obtained from aP for $\dot{P}H_2$, $\dot{P}F_2$, AND $\dot{P}Cl_2$ and from calculations on these radicals by the CNDO/2 method[23]. The values of Q^P_{eff} obtained from the aP for the radical-anions derived from phosphorins and phospholes are 31.7 and 725.4 G respectively. The ^{31}P σ–π interaction constants probably depend strongly on the charge at the phosphorus and adjoining atoms. Thomson and Kilcast[194] attempted to take into account the influence of the adjoining atom in the two-parameter equation $a_P = Q^P_{PP}\rho(P) + Q^P_{CP}\rho(C)$ and found that Q^P_{PP} = 39 G and Q^P_{CP} = 28.6 G.

4. PENTAATOMIC RADICAL-ANIONS

All the radical-anions of this type which have been studied experimentally were obtained by the low-temperature γ-irradiation of solids. The ESR spectra of the $\dot{P}O_4^{2-}$ radical-ion in irradiated phosphates and pyrophosphates have been studied in a number of investigations[127, 195-197]; aP depends on the environment of the radical, as for $\dot{P}O_3^{2-}$. The hypothesis[127] that $\dot{P}O_3$ and not $\dot{P}O_4^{2-}$ is formed in many cases has been confirmed to some extent by a quantum-chemical calculation[23], although its results require serious revision.

The ESR spectrum of a radical which Symons identified[199] as $\dot{P}O_4^{4-}$ was observed for irradiated phenacite [198]; this identification is probably correct[200]. The value of aP for $\dot{P}O_4^{4-}$ is much higher than for $\dot{P}(OR)_4$ radicals[92-94] (Tables 5 and 9). This result is strange from the standpoint of the general rule concerning the increase of aP for $\dot{P}X_4$ with increasing electronegativity of the ligand X, [13, 40] particularly since aP = 860 G for the $(MeO)_3PO^{\cdot-}$ radical-anion, formed[40] in γ-irradiated phosphate together with $Me_2\dot{P}O$, which is less than the value for $\dot{P}(OMe)_4$. The "$\dot{P}O_4^{4-}$ anomaly" has been explained[40] by the influence of the surrounding Be^{2+} cations; it is suggested that aP < 900 G for $\dot{P}O_4^{4-}$ in weaker fields. In the $PO_3F^{\cdot-}$ radical-anion the unpaired electron is highly localised at the oxygen atom[88].

A quantum-chemical calculation[102] for the hypothetical $PH_3O^{\cdot-}$ radical-anion by the CNDO/2 method showed that its equilibrium geometry is almost the same as that of PH_3OH (Table 6), namely trigonal bypyramidal. This result is consistent with the data of Begum and Symons[41] and also of Gillbro and Williams[201] for the ESR spectrum of $POCl_3^{\cdot-}$ radical-anions; in both cases there is splitting by the two equivalent ^{35}Cl nuclei corresponding to the axial positions and a smaller splitting due to the third (equatorial) ^{35}Cl nucleus. The radical-anions have been generated[41] in polycrystalline $POCl_3$, which led to unduly high constants for isotropic splitting by axial ^{35}Cl. A study[201] of the ESR spectra of the radical-anions in irradiated $POCl_3$ single crystals showed that these constants are consistent with data[98] obtained from the ESR spectra of chlorophosphoranyl radicals in solutions. Consequently the chlorine atom in these radicals is fixed in the axial position and there is no pseudorotation. Furthermore, anisotropic splitting by the axial ^{35}Cl ($B_{||}$ = 30 G), corresponding to a spin density of 0.29 in the $3p\sigma$ chlorine orbital, has been observed[201].

According to calculations[102], the distribution of spin density in the $PH_3O^{\cdot-}$ radical-anion differs significantly from that in the neutral $\dot{P}H_3OH$ radical; in particular the s spin density at the phosphorus atom is reduced by an order of magnitude in the radical-anion.

5. THE RADICAL-ANIONS DERIVED FROM PHOSPHINE OXIDES AND PHOSPHATES

Begum and Symons[43] reported that the $Me_3PO^{\cdot-}$ radical-anion, whose aP is fully consistent with the ESR data for $Me_3POBu\text{-}t$ [91] (splitting by methyl protons was not observed[43]), is formed in γ-irradiated trimethylphosphine oxide. This result is inconsistent with the above data obtained by quantum-chemical calculation[102]. It is therefore more likely that Begum and Symons[43] obtained the ESR spectrum of the $Me\dot{P}OH$ [$Me_3\dot{P}OH$? (Ed. of Translation)] radical.

The radical-anions derived from triphenylphosphine oxide[182,183,202], trialkyl phosphine oxides[182,183,203], and alkylarylphosphine oxides[182,183] are formed when these compounds are reduced over an alkali metal in tetrahydrofuran or dimethoxyethane. Il'yasov and coworkers[189,204] showed that, in the electrochemical reduction of triphenylphosphine oxide, triphenylphosphine sulphide, and diethyl β-styrylphosphinate, the first stage is reversible addition of one electron.

The ESR spectra of the radical-anions of all the above compounds generated by this method have been investigated[189,205]. For an unambiguous assignment of the splitting constants in the ESR spectra, a study was also made[190] of the radical-anions $Ph_2(C_6D_5)PO^{\cdot-}$, $Ph(C_6D_5)_2PO^{\cdot-}$, and $(C_6D_5)_3PO^{\cdot-}$. It was established that, as in the triphenylphosphine radical-anion, the unpaired electron is equally delocalised over all three benzene rings and also over the phosphorus atom (aP = 4 G). Such delocalisation cannot be accounted for within the framework of the π-electron model; the unsatisfactory result of the calculation on $Ph_3PO^{\cdot-}$ by the Hückel method confirmed this. Possibly it is dynamic, as in the radical-anions derived from tetraphenylsilane and diethyldiphenylsilane [206], the main feature of such delocalisation being a marked dependence of the rate of electron transfer from one aromatic fragment to another on the counterion solvation conditions[207]. Cowley and Hnoosh[208] studied the $Ph_2(NMe_2)PO^{\cdot-}$ radical-anions generated by reduction over metallic sodium. It follows from the ESR spectra obtained[208] that the spin density is delocalised over the phosphorus atom and one benzene ring; the splitting constants for the $Ph(NH_2)MePO^{\cdot-}$ radical-anion are aP = 8.75 G, aH(para) = aH(ortho) = 3.5 G, $a_{H(Me)}$ = 0.38 G, and a_N = 4.9 G. The π conjugation of the phosphoryl group with the benzene ring probably occurs more readily than with other substituents. Calculation of the spin densities in terms of the π approximation by the McLachlan method gives rise to a satisfactory agreement with experiment. Kabachnik and coworkers [192] generated the m- and p-$R_2P(O)C_6H_4COOEt$ (R = Me, Et, or i-PrNMe$_2$) radical-anions by electrochemical reduction in acetonitrile at –40°C. The ^{31}P splitting in the ESR spectra of the *para*-substituted radical-anions is fairly large (aP ≃ 13 G), increasing somewhat with increase of the bulk of R; slight splitting due to the R protons has also been observed (a = 0.3–0.6 G). The ESR spectra of *meta*-substituted radical-anions are characterised by the absence of splitting due to ^{31}P and the protons in R; other splitting constants differ little from those for the ethyl benzoate radical-anion. The splitting constants for the protons in the *ortho*-position relative to the ethoxycarbonyl group are correlated with the constants $\sigma_{eff} = \sigma_{R(m)} + 0.23\sigma_I$ of the substituents R_2P, $R_2P(O)$, $R_2P(S)$, and simpler groups.

Allen and Bond[209] studied the radical-anions obtained from semiquinone-phosphates derived from benzo- and

naphtho-quinones. a_P = 1.3 G for the p-$OC_6H_4O\dot{P}O_3^{2-}$ radical-anion; after the introduction of four methyl groups, a_P = 17.2 G. Allen and Bond[209] believe that the hyperconjugation model, in which the spin density is transferred directly from the $2p\pi$ orbital of carbon to the 3s orbital of phosphorus, is most suitable for these radical-anions; spin polarisation is less likely. Gulick and Geske[210] generated radical-anions derived from dialkyl p-nitrophenyl and diaryl p-nitrophenyl phosphates by electrochemical reduction and observed in their ESR spectra splitting due to the protons of the p-nitrophenyl group and the ^{14}N and ^{31}P nuclei. The splitting constant a_P = 7–8 G, increasing to 13.6 G for the $(EtO)_2P(O)CH_2C_6H_4NO_2$-$p^{\cdot-}$ radical-anion. They suggested[210] that the transfer of spin density to phosphorus takes place via a hyperconjugation mechanism, although a_P did not change in the range from +25° to −45°C. Gulick[211] interpreted the splittings by the ^{31}P nucleus in the ESR spectra of the radical-anions derived from O-(diphenylphosphoryl)-2,6-di-R-4-nitrophenols in terms of a compound model combining the spin polarisation and hyperconjugation effects. For the $(PhO)_2$.$P(O)SC_6H_4NO_2$-$p^{\cdot-}$ radical-anion, a_P = 24.8 G, either in consequence of direct π conjugation due to the 3d sulphur orbitals or because the PSC valence angle is smaller than the POC angle, which leads to a greater degree of transfer of spin density to phosphorus via the hyperconjugation mechanism. The values of a_N and the potentials $E_{\frac{1}{2}}$ for the radical-anions which he investigated[211], led Gulick to the conclusion that the electronic effects of the $Ph_2P(O)O$ group and the hydrogen atom are approximately the same.

Lassmann et al.[212] established that the splitting constants a_N and a_P for the ESR spectra of the radical-anions derived from diethyl p-nitrophenyl phosphate (paraoxon) and dimethyl p-nitrophenyl phosphate (parathion) are somewhat different. Furthermore, they depend on the anion of the salt used as the supporting electrolyte: a_P is 6.12 G for the parathion radical-anion with NEt_4I and 9.71 G with NEt_4ClO_4. Evidently the radical-anions generated electrochemically form association complexes with the ions of the supporting electrolytes; the spin densities at the phosphoryl group and other polar groups are sensitive to the nature of these complexes.

The $PhP(O)Cl_2^{\cdot-}$ radical-anion, generated by the γ-irradiation of $PhP(O)Cl_2$ at −196°C[216], has a trigonal bipyramidal structure with appreciable localisation of the unpaired electron at the s orbital of phosphorus, as in $POCl_3^{\cdot-}$ (Table 9). When there are two possible ways of adding an electron to the molecule (to the phosphorus atom or the benzene ring), the preferred mode of addition probably depends on the relative electron affinities of the two centres and at low temperatures also on the degree of distortion necessary for the formation of the most stable conformation of the radical-anion[217]. The three-centre σ^* Cl–P–Cl molecular orbital should therefore lie below the π^* molecular orbital of the benzene ring.

6. RADICAL-ANIONS WITH A P = N BOND

The ESR spectra of the $R_3PNC_6H_4NO_2$-$p^{\cdot-}$ radical-anions derived from phosphazo-compounds and generated at the cathode in acetonitrile or dimethylformamide have been investigated[218–220]; the first stage of the electrochemical reduction of these substances is a reversible one-electron process[221]. The splitting constants are $a_{N(NO_2)}$ = 11.0–13.5 G and a_P = 3.5–5.5 G; both constants depend on the electron density of the substituents R. If one of these is R = Ph, a slight (0.2–0.3 G) splitting by the protons of this benzene ring is also observed. The authors[218–220] concluded that the radical-anions from phosphazoarenes contain a π-electron system incorporating the phosphazo-group. The π-electronic structure of the phosphazoarenes and the spin densities were calculated on this hypothesis by the Hückel and McLachlan methods respectively[222]. The calculated energies of the lowest vacant π orbitals are correlated with the potentials $E_{\frac{1}{2}}$ of the phosphazoarenes[221] and the splitting constants found from the calculated spin densities agree very well with experiment. The splitting by the ^{14}N nucleus of the imino-nitrogen does not exceed 0.2 G according to the calculation[222] and is not therefore observed in the ESR spectra[218,219].

The unpaired electron in the $Ph_3PNXC_6H_4NO_2$-$p^{\cdot-}$ (X = S or SO) radical-anions is delocalised only over the p-nitrophenyl residue[218]. Thus the –S– and –SO– bridging groups prevent the inclusion of the phosphazo-group in the π-conjugation system. This system also breaks down in the $(p\text{-}F_3CC_6H_4)_3POC_6H_4NO_2$-$p$ radical-anion, the ESR spectrum of which resembles that of the p-nitroaniline radical-anion[219]; in this case the 3d orbitals of phosphorus are probably involved preferentially in the formation of the P–R bond and not P–N.

Allcock and Birdsall[223] generated the $(PNR_2)_3^{\cdot-}$ radical-anions where R = Ph or OAr, by an electrochemical method in dimethylformamide; under these conditions, $(PNF_2)_3$ and $(PNCl_2)_3$ are not reduced to the radical-anions. It follows from the ESR spectra of the radical-anions obtained by Allcock and Birdsall[223] that the unpaired electron is not delocalised over the phosphazene ring. This conclusion was fully confirmed by Mishra and Symons[224], who obtained the ESR spectrum of $(PNCl_2)_3^{\cdot-}$ on low-temperature γ-irradiation of the phosphonitrilic chloride trimer. It is characterised by an appreciable isotropic splitting by one of the ^{31}P nuclei. Thus the unpaired electron is localised at one phosphorus atom, whose hybridisation probably corresponds to the configuration of a trigonal bipyramid, as in phosphoranyl radicals.

7. THE $PF_5^{\cdot-}$ RADICAL-ANION

Morton[67] observed the isotropic ESR spectrum of a radical containing a phosphorus atom and four equivalent fluorine atoms on irradiation of NH_4PF_6 at about 20°C[67]; the radical was identified as $\dot{P}F_4$. Atkins and Symons[68] observed a similar spectrum on γ-irradiation of KPF_6 and noted that it becomes appreciably broadened at −63°C; at −73°C and below the fluorine atoms become non-equivalent, which is believed to be a consequence of the "freezing" of the pseudorotation in PF_4. Mishra and Symons showed recently[225] that an additional doublet splitting is observed in this spectrum (a = 2.3 G); consequently the paramagnetic species formed is the radical-anion $PF_5^{\cdot-}$ and not $\dot{P}F_4$. This process is more likely also on general grounds. Four fluorine atoms in $PF_5^{\cdot-}$ remain equivalent also at both 20° and −196°C; the broadening of the components of the ESR spectrum observed by Atkins and Symons[68] can be explained by the hindered rotation of the entire radical-anion and not by pseudorotation.

---o0o---

On the whole one may conclude that the free radicals and radical-ions derived from phosphorus compounds constitute a fairly specific class of radical species. Only the properties of phosphinyl radicals resemble those of

aminyl radicals to which the former are formally analogous. The properties of other phosphorus-containing free radicals are determined to a large extent by the characteristics of the nature of the chemical bonds involving phosphorus relative to those of the elements in the Second Period. A detailed study of their properties is undoubtedly important for the development of ideas concerning the stereochemistry and reactivity of phosphorus compounds.

Alkylene Diphosphine Dioxides as Extractants and Complex-forming Agents

T.Ya.Medved', Yu.M.Polikarpov, L.E.Bertina, V.G.Kossykh, K.S.Yudina, and M.I.Kabachnik

Alkylenediphosphine dioxides are a new group of highly effective complex-forming agents capable of binding metal ions to form chelate rings. The review discusses methods for the synthesis of neutral bidentate organophosphorus complex-forming agents based on diphosphine dioxides, their extraction properties, and the possibility of the modification of the structural and steric factors which influence significantly the complex-forming properties of the ligand.
The bibliography includes 133 references.

4. Complex-forming properties 474
5. Dependence of the extraction and complex-forming properties on the structure of the ligands 476

1. INTRODUCTION

One of the characteristic properties of organic compounds of phosphorus is their ability to form complexes with metal ions. The study of these properties of organophosphorus compounds is not only of theoretical interest but also leads to the solution of many important practical problems.

Extensive study of the complex-forming properties of organic derivatives of quinquevalent phosphorus was stimulated by the development of the atomic energy industry which gave rise to a vigorous search for methods whereby complex mixtures of metals could be separated. Compounds containing P=O bonds proved to be highly effective for this purpose. Since then organophosphorus compounds, mainly phosphates, have been widely used in technology as extractants with isolation and concentration of metals.

Further development and improvements in this field have proceeded on lines designed to create more effective complex-forming agents, more selective with respect to individual groups of metal ions, and more universal in their applications. All these problems are now of urgent importance owing to the rapid development of technology and analytical chemistry.

Among the neutral organophosphorus complex-forming agents containing phosphorus(V) which have now been investigated tertiary phosphine oxides exhibit the greatest complex-forming capacity. Their effectiveness greatly exceeds that of phosphates, phosphonates and phosphinates. Although the ability of phosphine oxides to form complexes varies as a function of their structure and the nature of the substituents at the phosphorus atom, the variation do not exceed significantly an order of magnitude.

Fundamentally different possibilities of improving the effectiveness and selectivity of the complex-forming phosphine oxides arise when the chelate-forming effect is used. For this purpose, it is necessary to have substances containing in the molecule at least two and possibly more phosphine oxide groups, when the complex-forming capacity can be enhanced as a result of the formation of rings with the metal ions involving two or several phosphoryl groups.

One of the new trends in the field of organophosphorus complex-forming agents in fact constitutes the synthesis of substances with the structure of polydentate ligands. This group of substances is of interest also because it gives rise to extensive possibilities for the modification of the structural and steric factors which influence significantly the complex-forming properties of the ligands.

In 1968 Kabachnik et al.[1] published a review on the methods of synthesising organophosphorus complexones and their complex-forming properties. This paper is devoted to neutral bidentate organophosphorus complex-forming agents based on alkylenediphosphine dioxides† and consists of two parts: the first discusses the method of synthesising compounds of this class and the second deals with data on their extraction and complex-forming properties; the problems concerning the derivation of a relation between the extraction and complex-properties of polydentate ligands and their structure have been combined in a separate section.

2. METHODS OF SYNTHESIS

a. The Arbuzov Reaction

This classical method of organophosphorus synthesis has been extensively used recently to obtain a wide variety of tertiary alkylenediphosphine dioxides. When a phosphine oxide containing a chloromethyl group is allowed to react with an ester of a secondary phosphinous acid, the dioxide of the tetrasubstituted methylenediphosphine is formed:

$$Ph_2P(O)-CH_2Cl + Ph_2P-OEt \rightarrow Ph_2P(O)-CH_2-PPh_2(O)$$

Tetraphenylbenzylidenediphosphine dioxide was synthesised similarly from α-chlorobenzyldiphenylphosphine oxide and ethyldiphenylphosphinite[4]. Derivatives of tetraphenylmethylenediphosphine with various substituents in

† We shall not consider the esters of alkylenediphosphonic acids, since a special review has been devoted to substances of this class[2].

the *meta*- and *para*-positions in the phenyl group were synthesised in the same way[5]:

$$(XC_6H_4)_2P(O)-CH_2-P(O)(C_6H_4X)_2,$$

where X = CH_3, CH_3O, Cl, Br, or CF_3.

The method of synthesising methylenediphosphine dioxides was extended to polymethylenepolyphosphine polyoxides, i.e. compounds containing several $-P(O)-CH_2-P(O)-$ units in the molecule[6-11]. The oxides of tertiary di(chloromethyl)-phosphine and tri(chloromethyl)-phosphine were introduced into the reaction with phosphorus(III) acid esters. In the first case the reaction proceeds via the mechanism

$$R-P(O)(CH_2Cl)_2 + 2EtOP(R')(R'') \rightarrow R'R''P(O)-CH_2-P(O)(R)-CH_2-P(O)R'R'' .$$

The intermediate products of the incomplete interaction of the initial components, $R'R''P(O)-CH_2-P(O)(R)CH_2Cl$, were also isolated.

The condensation of tri(chloromethyl)phosphine oxide with three ester molecules proceeds similarly:

$$(ClCH_2)_3P=O + 3EtO-P(R')(R') \rightarrow (R'R''PCH_2)_3P=O .$$

Compounds with R = CH_3, C_2H_5, $C_{12}H_{25}$, C_6H_5, C_2H_5O, or C_4H_9O and R′ and R″ = C_4H_9 or C_6H_5 were obtained.

Thus the chloromethyl group at the phosphorus atom, which contains a relatively passive halogen atom, is fairly reactive as regards the isomerisation of phosphorus(III) acids, which can be used successfully for the synthesis of a wide variety of polymethylenepolyphosphine polyoxides.

In the synthesis of ethylenediphosphine oxides one can employ as starting materials the β-chloroethyl esters of dialkyl- or diaryl-phosphinous acids, which on heating give rise to two products of the Arbuzov rearrangement; β-chloroethylphosphine oxide and ethylenediphosphine dioxide[12,13]:

$$R_2P-O-C_2H_4Cl \xrightarrow{t^\circ} R_2P(O)C_2H_4Cl + R_2P(O)C_2H_4P(O)R_2 .$$

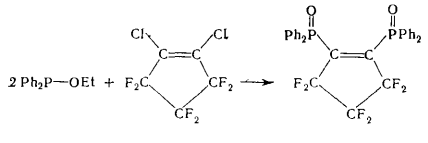
Depending on the conditions, the reaction proceeds preferentially via one pathway or the other. Thus isomerisation in solution promotes the formation of the monoxide and hinders the formation of the diphosphine dioxide. Presumably the β-chloroethyl ester of phosphinous acid initially undergoes intramolecular or intermolecular isomerisation and the resulting β-chloroethylphosphine oxide reacts like an alkyl halide with a second molecule of the β-chloroethyl ester via the mechanism of the Arbuzov rearrangement.

Diphosphine dioxides with ethylene and propylene bridges between the phosphorus atoms have been obtained from phosphinite esters and the corresponding dihalogenoalkanes[14]:

$$2(PhCH_2)_2P-OEt + Br(CH_2)_nBr \rightarrow (PhCH_2)_2P(O)-(CH_2)_n-P(O)(CH_2Ph)_2 .$$

(n = 2 and 3)

The reaction[15]



proceeds similarly.

In the above examples the Arbuzov isomerisation was used to bind two phosphorus-containing residues into the molecules of the alkylenediphosphine dioxide. The latter are also formed in the isomerisation of diphosphinous acid esters. For example, the Arbuzov rearrangement of a 1,4-dialkyl-substituted tetramethylenebis(diphenylphosphinite) in the presence of ethyl iodide leads to the formation of a tetraphenylalkylenediphosphine dioxide:

$$Ph_2-P-O-CHRCH_2CH_2CHR-O-P-Ph_2 \rightarrow Ph_2P(O)-CHRCH_2CH_2CHR-P(O)Ph_2 .$$

When the product of the reaction of ethylene glycol with chlorodiphenylphosphine is distilled, tetraphenylethylenediphosphine dioxide is formed immediately[16]. $Ph_2P(O)CH_2-CHPhOPPh_2$ also rearranges readily[17].

Alkylenediphosphine dioxides are also formed when phosphinamides react with diols with subsequent isomerisation on heating in the presence of catalytic amounts of dibromoethane[18]:

$$2R_2PNR'_2 + HO(CH_2)_nOH \rightarrow R_2P(O)-(CH_2)_n-PR_2(O) ,$$

where R = C_2H_5, C_4H_9, or C_6H_5 and n = 2, 3, 4, or 12.

b. The Michaelis–Bekker Reaction

The use of the magnesium salts of phosphorus(III) acids for the synthesis of alkylenediphosphine oxide was investigated by Kosolapoff[19]. The dioxides of tertiary alkylenediphosphines can be obtained in low yields by the reaction of halogenomagnesium salts of phosphinous acids with alkylenebis(toluene-*p*-sulphonates):[20]

$$2(Ph_2)POMgHal + Tos-O(CH_2)_nO-Tos \rightarrow Ph_2P(O)-(CH_2)_n-PPh_2(O) \quad (n=2, 3).$$

In the synthesis of tetrahexylethylenediphosphine and tetrahexylpropylenediphosphine dioxides Mrochek and Banks modified somewhat the method of isolating the product and increased the yield of the dioxide; or they also obtained tetrahexylbutylenediphosphine dioxide[21].

Tetraphenylmethylenediphosphine dioxide was synthesised by Kosolapoff and Struck[20] by treating halogenomagnesium phosphinite with methylene iodide or chloromethyldiphenylphosphine oxide[20]:

$$2Ph_2POMgCl + CH_2I_2 \rightarrow Ph_2P(O)-CH_2-PPh_2(O) .$$
$$Ph_2POMgCl + ClCH_2PPh_2(O) \rightarrow Ph_2P(O)-CH_2-PPh_2(O) .$$

Strunin et al.[22] and Kabachnik et al.[23] showed that halogenomagnesium salts of phosphinous acids, obtained by the reaction of organomagnesium compounds with dialkyl phosphites, react with alkylene dihalides, yielding alkylenediphosphine dioxides:

$$2R_2POMgX + X-(CH_2)_n-X \rightarrow R_2P(O)-(CH_2)_n-PR_2(O) ,$$

where R = C_6H_5, C_6H_{13}, or C_7H_{15}, X = Cl or Br, and n = 3 or 4.

Hays[24] achieved the alkylation of the halogenomagnesium salt of dimethylphosphinous acid with 1,2-dichlorobutane[24]:

$$2Me_2POMgBr + ClCH_2CHClCH_2Me \rightarrow Me_2P(O)-CH_2-CH(Et)-PMe_2(O) .$$

Tetracyclohexylethylenediphosphine dioxide was obtained by the reaction of sodium dicyclohexylphosphinite with dichloroethane[25].

c. Syntheses using Organometallic Compounds

Alkylenediphosphine dioxides can be obtained by the reaction of alkylenediphosphonic acid tetrachlorides with an excess of a Grignard monoreagent[26-29] or via the reaction of a phosphinic acid chloride with a Grignard direagent[30,31]:

$$Cl_2P(O)(CH_2)_nP(O)Cl_2 + 4RMgX \rightarrow R_2P(O)(CH_2)_nP(O)R_2$$
$$2R_2P(O)Cl + XMg(CH_2)_nMgX \rightarrow R_2P(O)(CH_2)_nP(O)R_2 \quad (n = 1-10)$$

In particular, dioxides with heteroatoms (O, S, and N) in the alkylene bridge between the phosphorus atoms were obtained in this way[26].

Richard and Banks described the synthesis of methylenediphosphine dioxides with symmetric and asymmetric structures from the lithio-derivatives of phosphine oxides and phosphinic acid chlorides[32]:

$$R_2PCH_3 \xrightarrow{BuLi} R_2PCH_2Li \xrightarrow{R_2P(O)Cl} R_2P(O)-CH_2-PR_2$$

Tetraphenylethylenediphosphine dioxide is formed when the molecules of the lithio-derivative of methyldiphenylphosphine oxide are dimerised under the influence of copper(I) chloride in tetrahydrofuran with subsequent treatment of the reaction mixture with oxygen[33]:

$$2(Ph_2)P(O)CH_2Li \xrightarrow{CuCl_2} Ph_2P(O)-CH_2CH_2-P(O)Ph_2$$

d. Syntheses based on Alkali Metal Phosphides

Certain syntheses of alkylenediphosphine dioxides involve the use of alkali metal phosphides, the properties and reactions of which have been extensively studied by Issleib[34]. Their reactions with dihalogenoalkanes can yield alkylenediphosphines, whose oxidation leads to the formation of alkylenediphosphine dioxides[35-37] (for $n = 1$ or 2, the dioxides are formed only from diphenylphosphide; in other cases diphosphyls were obtained[38]):

$$2R_2PM + X(CH_2)_nX \rightarrow R_2P-(CH_2)_n-PR_2 \xrightarrow{O_2} R_2P(O)-(CH_2)_n-P(O)R_2,$$

where R = C_2H_5, C_6H_{11}, or C_6H_5, $n = 1-6$, and M = Na or K.

Primary phosphides react similarly:

$$2RPHNa + Cl(CH_2)_nCl \rightarrow RPH(CH_2)_nPHR$$

The secondary alkylenediphosphines obtained in this way were converted by metallation into dilithioalkylene diphosphides, the interaction of which with alkyl halides followed by oxidation leads to the dioxides of mixed tertiary alkylenediphosphines[39,40]:

$$R_2P-(CH_2)_n-PR_2 \xrightarrow{Li} LiRP-(CH_2)_n-PRLi \xrightarrow{2R'X} R'RP-(CH_2)_n-PRR' \xrightarrow{O_2} R'RP(O)-(CH_2)_n-P(O)RR'$$

e. Cleavage of Phosphonium Salts

The formation of a butylenediphosphine dioxide from a diphosphonium salt on treatment with an excess of sodium butoxide has been described[41]:

$$[Ph_3P(CH_2)_4PPh_3]^{2+} \rightarrow Ph_2P(O)-(CH_2)_4-P(O)Ph_2$$

Petrov et al. synthesised the dioxides of tertiary diphosphines by alkylating dialkyl(aryl)(hydroxymethyl)-phosphines with dihalogenoalkanes and subsequent dehydroxymethylation of the resulting diphosphonium salts with sodium hydroxide and the oxidation of the alkylenediphosphines formed[42]:

$$2R_2PCH_2OH + X(CH_2)_nX \rightarrow [R_2P(CH_2OH)-(CH_2)_n-P(CH_2OH)R_2]^{2+}\,2X^- \xrightarrow{NaOH}$$
$$\rightarrow R_2P-(CH_2)_n-PR_2 \xrightarrow{H_2O_2} R_2P(O)(CH_2)_nP(O)R_2$$

The starting materials used were diheptyl-, dibutyl-, and diphenyl-(hydroxymethyl)phosphines, methylene iodide, and 1,2-dibromoethane; the yields of the alkylenediphosphine dioxides were high.

Horner et al. obtained the dioxides of tetraphenylalkylenediphosphines by heating chlorodiphenylphosphine with $Br(CH_2)_nBr$, where $n = 2$, 3, 4, or 6, or with $ClCH_2C_6H_4.CH_2Cl$ and subsequent hydrolysis of the intermediate alkylenebis(dihalogenophosphoranes).[43]

Similar syntheses was achieved by Tsivunin and Kamai and their coworkers from chlorodiethylphosphine; apart from dibromoalkanes, dichloromethyl ether was introduced into the reaction[44]. Tetramethylmethylenediphosphine dioxide was obtained from chlorodimethylphosphine and dibromomethane with subsequent decomposition by butyl alcohol[45].

Pyrolysis of (2-hydroxyethyl)diphenylphosphine leads to the formation of tetraphenylethylenediphosphine dioxide, probably via an intermediate dimeric diphosphonium base[46]:

$$Ph_2PC_2H_4OH \rightarrow Ph_2P^+(CH_2CH_2)_2P^+Ph_2\,2OH^- \xrightarrow{330^\circ} Ph_2P(O)CH_2CH_2P(O)Ph_2$$

f. Reactions Involving the Addition of Organophosphorus Compounds with a P–H Group to Multiple Bonds

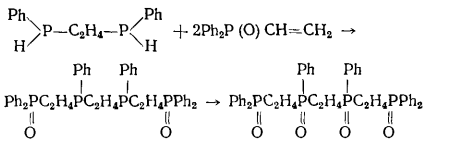
Organophosphorus compounds with a mobile hydrogen atom attached to a multiple bond have been used successfully to synthesise alkylene derivatives with two phosphorus atoms. The addition of diphenylphosphine oxide to diphenylvinylphosphine oxide leads to $Ph_2P(O)C_2H_4P(O)Ph_2$.[47] The reaction with α-chlorovinyldiphenylphosphine oxide proceeds via the following mechanism[4]:

$$Ph_2P(O)-CCl=CH_2 + Ph_2P(O)-H \rightarrow Ph_2P(O)-CHCl-CH_2-PPh_2(O) \xrightarrow{-HCl} Ph_2P(O)-CH=CH-PPh_2(O)$$

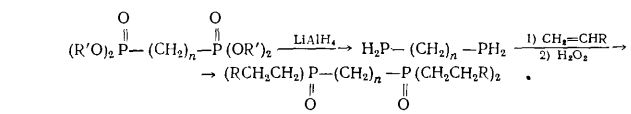
After dehydrochlorination, the *trans*-isomer of diphosphine dioxide is formed in this case (the *cis*-isomer was synthesised from Ph_2PLi and *cis*-dichloroethylene with subsequent oxidation[48]).

Alkylenediphosphines can be used as the bifunctional nucleophilic components in addition to an activated double bond. Hexaphenyltriethylenetetraphosphine tetroxide was

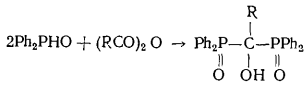
obtained by the reaction of ethylenediphenyldiphosphine with diphenylvinylphosphine oxide and subsequent oxidation[49]:



Maier[50] achieved the synthesis of alkylenediphosphine dioxides reducing alkylenediphosphonate esters to primary alkylenediphosphines with their subsequent addition to olefins and oxidation:



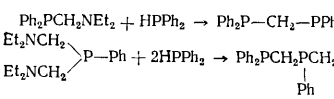
Davidson et al. described the reaction of diphenylphosphine oxide with carboxylic acid anhydrides, which apparently proceeds via a stage involving the addition of phosphine oxide to the C=O bond[51]:



where R = CH_3 or $C_6H_5CH_2CH_2$. The resulting hydroxyalkylidenediphosphine dioxides readily isomerise on heating via a mechanism of the type of the phosphonate–phosphate rearrangement.

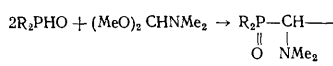
g. Other Methods

An interesting method for the formation of the P–C–P bond system was proposed by Maier on the basis of the reaction of phosphines containing the aminomethyl group with secondary phosphines[52]:



The oxidation of the products leads to the corresponding di- and tri-oxides.

Gross and Costisella achieved the synthesis of the dioxides of amino-substituted methylenediphosphines by the reaction of the acetal or thioacetal of dimethylformamide with secondary phosphine oxides[53–56]:



where R = C_4H_9 or C_6H_5.

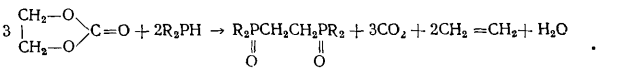
Certain syntheses of the dioxides of tertiary alkylenediphosphines applicable in specific instances have been described.

Tetraphenylbutylenediphosphine dioxide has been obtained by the reductive dimerisation of diphenylvinylphosphine oxide (in aqueous acetonitrile with a platinum anode and a mercury cathode)[57]:

The interaction of malonic ester with two moles of diphenylvinylphosphine oxide proceeds as follows[47]:

Tetraphenylmethylenediphosphine dioxide has been obtained by the alkaline hydrolysis of methylenebis(diphenylphosphine-*N*-phenylimide)[58].

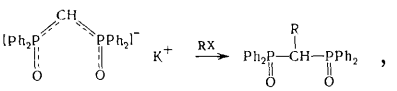
The formation of ethylenediphosphine dioxides has been observed in the reaction of dialkyl- and diaryl-phosphines with cyclic carbonic acid esters[59]:



h. Reactions of Alkylenediphosphine Dioxides

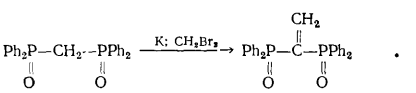
The reactions of diphosphine dioxides leading to changes in the hydrocarbon groups attached to the phosphorus atoms and proceedings without the dissociation of the C–P bonds, i.e. with retention of the initial structure of the tertiary alkylenediphosphine dioxide, are known.

Methylenediphosphine dioxides readily form metal salts on treatment with alkali metals or their hydrides. These salts are highly reactive and are used to obtain various derivatives substituted in the methylene bridge. Alkylation of the potassium salt of tetraphenylmethylenediphosphine dioxide by alkyl halides yielded *C*-alkylated products with substituents in the methylene group[60]:

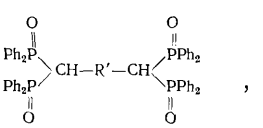


where R = C_2H_5, C_4H_9, C_6H_{13}, $C_{12}H_{25}$, $CH_2{=}CHCH_2$, or $CH{\equiv}CCH_2$.

The analogous reaction of tetraphenylmethylenediphosphine dioxide with methylene bromide leads to vinylidenediphosphine dioxide, which is probably formed as a result of the dehydrobromination of the bromomethyl-substituted dioxide by the initial potassium salt:



In the alkylation of the potassium salt of tetraphenylmethylenediphosphine dioxide by carbon tetrachloride, tetraphenyldichlorovinylidenediphosphine was obtained. The reaction of this salt with 1,6-dibromohexane and *p*-xylylene dibromide yields the corresponding octaphenylalkylenetetraphosphine tetroxides[60]:

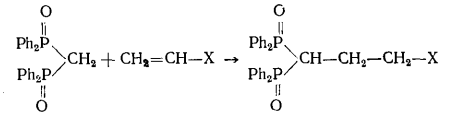


where R′ = $(CH_2)_6$ or n-$CH_2C_6H_4CH_2$.

The reaction with 1,5-dibromopentane under these conditions results in the formation of tetraphenylcyclohexylidenediphosphine dioxide.

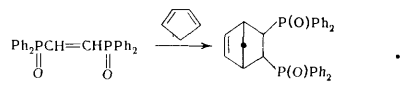
Halogenation of tetraphenylmethylenediphosphine dioxide with bromosuccinimide and thionyl chloride in the presence of azoisobutyronitrile yielded the corresponding monohalogeno-products; when the potassium salt of the dioxide is treated with iodine, the iodo-product is formed[61].

Tetraphenylmethylenediphosphine dioxide undergoes the Michael reaction in the presence of alkaline agents: its addition to ethyl acrylate, diphenylvinylphosphine oxide, and diethyl vinylphosphonate has been achieved[61]:

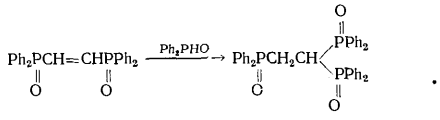


where X = C_2H_5OCO, $(C_6H_5)_2P(O)$, or $(C_2H_5O)_2P(O)$.

The *cis*- and *trans*-isomers of tetraphenylvinylenediphosphine dioxide undergo the Diels–Alder reaction with cyclopentadiene and are converted into the corresponding stereoisomers of norbornenylenediphosphine dioxide[62]:



The addition of diphenylphosphine oxide to phenylvinylenediphosphine dioxide leads to the trioxide of hexaphenyl-1,1,2-ethylenetriphosphine (which is also formed when Ph_2PHO reacts with trichloroethylene in the presence of triethylamine)[4]:



Tetracyclohexylmethylenediphosphine has been obtained by the hydrogenation of tetraphenylmethylenediphosphine dioxide over a platinum catalyst[63].

3. EXTRACTION PROPERTIES

The first reports of studies on polydentate neutral organophosphorus complex-forming agents dealt with tetraalkyl esters of alkylenediphosphonic acid[64]. Although compounds of this type are not in fact considered in this review, it is nevertheless useful to mention briefly certain investigations of their extraction properties, since relations common to alkylenediphosphine dioxides operate here too.

The study of the extraction of zirconium, yttrium, and certain lanthanides by tetra-n-butyl ethylenediphosphonate revealed its high extraction capacity[65]. Similar results were obtained in the extraction of thorium and uranium nitrates[66]. Siddal[67], who studied the properties of tetrabutyl alkylenediphosphonates $(BuO)_2P(O)-(CH_2)_n-P(O).(OBu)_2$, where n = 1, 2, 3, or 4, in the extraction of cerium, promethium, and americium, concluded that the bidentate compounds capable of forming chelates with metals (six- and seven-membered rings) are effective extracting agents.

A series of subsequent studies were devoted to the investigation of the compositions and structures of the complexes in the extraction of various metal salts by alkylenediphosphonate esters[68–73]. A common feature of all the studies quoted above is the conclusion that bidentate organophosphorus extractants have significantly more effective extraction properties (the partition coefficients are higher by a factor of 10–100) [67] than the monodentate extractants.

In the subsequent search for new highly effective neutral extractants, tetraalkyl(aryl)alkylenediphosphine dioxides were of considerable interest. These compounds have been attracting increasing attention: mainly the extraction of uranium from nitrate, chloride, and perchlorate solutions has been studied as well as the extraction of lanthanide and certain other elements. The mechanism of the extraction has been studied simultaneously with the aid of various physicochemical methods.

a. Extraction of Acids and Water

A number of investigations have been made[74–77] of the extraction of acids in which a relation between the extraction capacity of tetra-n-hexylalkylenediphosphine dioxides having the general formula $(C_6H_{13})_2P(O)-(CH_2)_n-P(O).(C_6H_{13})_2$, where n = 1, 2, 3, or 4, and the length of the hydrocarbon bridge between phosphoryl group was discovered.

Mrochek and Banks[75], who studied the extraction of nitric, hydrochloric, and perchloric acids at different concentrations with 0.05 M solutions of tetra-n-hexylalkylenediphosphine dioxides in 1,2-dichlorobenzene, showed that, with increase of the length of the hydrocarbon bridge, the extraction capacity of the dioxides increases in all cases. The degree of extraction of acids decreases in the following sequence as a function of the nature of the anion: $NO_3^- > ClO_4^- > Cl^-$.

The mechanism of the extraction of nitric acid by solutions of tetra-n-hexylmethylenediphosphine dioxide in benzene[76,77] and in carbon tetrachloride with formation of adducts has been studied most thoroughly:

$$H^+ + NO_3^- + S \overset{\bar{K}_1}{\rightleftarrows} HNO_3 \cdot S \ ,$$

$$[HNO_3 \cdot S] + H^+ + NO_3^- \overset{\bar{K}_2}{\rightleftarrows} (HNO_3)_2 \cdot S \ ,$$

where S is the extractant molecule. The effective extraction constants have been determined ($\bar{K}_1$ = 4.9 in CCl_4 and 9.8 in benzene and $\bar{K}_2$ = 0.18 and 0.35 in the two solvents respectively); with increase of the length of the bridge to n = 5, the constants become appreciably greater: $\bar{K}_1$ = 51 and $\bar{K}_2$ = 6.2.[76] However, it has been shown[77] that these equations to not describe the process fully: the constant $\bar{K}_1$ increases with increase of the extractant concentration above 0.05 M and also with decrease of the acid concentration. It has been suggested that this can be accounted for by the formation of solvates $HNO_3.mS$, where $m > 2$.

As for tri-n-butyl phosphate[78,79] and tri-n-butylphosphine oxide[80], in extraction from concentrated solutions the HNO_3 concentration in the organic phase exceeds the value for the stoichiometric composition $(HNO_3)_2.S$. Following Kertes and Platzner[81], the authors explained this by the extraction of undissociated acid.

The extraction of water by solutions of tetra-n-hexyl-, tetra-(2-ethylhexyl)-, and tetra-(3,3-dimethylbutyl)-alkylenediphosphines has been studied in chloroform[82,83] and it has been shown that complexes with water (monohydrates and dihydrates) are formed as a function of the length of the alkylene bridge in the ligand. This process competes with the extraction of salts and acids by the above compounds. Data for the distribution of water, obtained in the study of the infrared and NMR spectra, and the changes in the vapour pressure over the solutions established that, at concentrations of tetra-n-hexylmethylenediphosphine dioxide less than 0.02 M, the monohydrate is formed in the

organic phase. With increase of the extractant concentration in the organic phase, association complexes with a greater number of water molecules are produced.

b. Extraction of Uranium(VI)

The first studies in this field dealt with tetrabutyl methylenediphosphonate and tetrabutylethylene diphosphonate.

The series of studies by Banks and coworkers[74,75,82,84,85] were devoted to the investigation of a number of tetra-n-alkylalkylenediphosphine dioxides having the general formula $(Alk)_2P(O)(CH_2)_nP(O)(Alk)_2$, where $n = 1$, 2, 3, or 4. The n-hexyl, cyclohexyl, and 2-ethylbutyl substituents at the phosphorus atom were investigated. The results of the extraction of uranium(VI) and certain lanthanides from salt solutions in organic acids showed that these compounds are highly effective extractants, superior to the analogous phosphine monoxides.

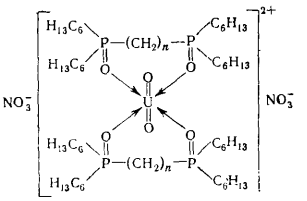
The extraction properties of tetraoctylethylenediphosphine dioxide in relation to uranyl nitrate were investigated by Laskorin and coworkers[86,87], who found that the extraction properties of this reagent depend in a complex manner on the composition of the aqueous phase.

The number of extractant molecules in the complex with uranyl nitrate has been determined[74] on the basis of the relation between the partition coefficients of uranium and the concentration of tetra-n-hexylmethylenediphosphine dioxide (S). It was found that the number is variable and depends on the ratio of the concentrations of the extractant and the salt. Thus, for equilibrium concentrations of the free extractant greatly exceeding the analogous concentration of the salt being extracted, the complex having the composition $UO_2(NO_3)_2.2S$ is formed in the organic phase. Under conditions close to saturation of the extractant, where the equilibrium concentration of the salt in the aqueous phase exceeds the equilibrium concentration of the free extractant, the complex $UO_2(NO_3)_2.S$ exists in the organic phase.

Analogous conclusions were reached in another study[85] where data were obtained, by a method involving the dilution of the extractant, for the compositions of the uranyl nitrate complexes with a number of alkylenediphosphine dioxides in solutions in 1,2-dichlorobenzene. The tetra-n-hexylalkylenediphosphine dioxides $(C_6H_{13})_2P(O)(CH_2)_n.(O)P(C_6H_{13})_2$ with $n = 1$ (DOHM), $n = 2$ (DOHE), $n = 3$ (DOHP), and $n = 4$ (DOHB) were investigated.

Examination of saturation and conductimetric data for solutions of alkylene diphosphine dioxides in 1,2-dichlorobenzene together with their infrared spectra for different ratios of the extractant and uranyl nitrate made it possible to determine the compositions and structures of the complexes extracted[85]. Thus the presence of the monosolvate $UO_2(NO_3)_2.S$ (the absorption band due to the P=O stretching vibrations is at 1136 cm^{-1}) and of the disolvate (the band at 1119 cm^{-1}) has been established for DOHM; similar solvates are also formed with DOHE (the 1124 and 1108 cm^{-1} bands).

The authors concluded that one or two NO_3^- groups in the disolvate with DOHM and DOHE are in the outer coordination sphere of the complex. This is confirmed by the greater intensity of the band due to the double degenerate antisymmetric stretching vibrations of the NO_3^- group (ν_3) at 1350 cm^{-1}, which is characteristic of the NO_3^- anion (D_{3h} symmetry) and by the sharp decrease of the intensity of the bands due to the allowed antisymmetric stretching vibrations at 1481–1520 cm^{-1} (ν_{3b}) and 1253–1290 cm^{-1} (ν_{3a}), which are characteristic of the covalently linked NO_3 group (C_{2v} symmetry)‡. Accordingly the disolvates with DOHM and DOHE have the following structure:

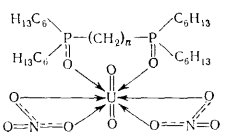


where $n = 1$ or 2.

The above data have been appreciably supplemented by studies on the structure of crystalline complexes of tetra-(2-ethylbutyl)methylenediphosphine (DOEBM) and tetracyclohexylmethylenediphosphine (DOCHM) dioxides with uranyl nitrate and thorium nitrate[84]. According to elemental analysis, the composition of the complexes isolated in the two cases is 1 : 1.

By analogy with the formation of complexes by uranyl nitrate with monodentate neutral organophosphorus compounds and bearing in mind that in the complexes with phosphate the NO_3^- group behaves as a bidentate ligand[88,96,97], the authors concluded that the NO_3 group plays a similar role in the complexes $UO_2(NO_3)_2.DOEBM$ and $UO_2(NO_3)_2.DOCHM$. This is in full agreement with the results of Mrochek et al.[85]

On passing to monosolvates, the nitrate ion anion virtually vanishes; accordingly the following structure has been attributed to the monosolvates $UO_2(NO_3)_2.DOHM$ and $UO_2(NO_3)_2.DOHE$:



where $n = 1$ or 2.

The infrared spectra of the complexes of DOHM and DOHE with uranyl nitrate, which are formed when the two reactants are in equimolar proportions, indicate the absence of water molecules from the coordination sphere of the complexes. In the spectra of the complexes where the ratio of the extractant and uranyl nitrate is 2 : 1 there is a band at 1620 cm^{-1} (O–H deformation vibrations), which indicates the presence of water molecules in their structure.

A very important result of the study of Mrochek et al.[74] is the demonstration of the bidentate coordination of uranyl nitrate to DOEBM and DOCHM on the basis of an investigation of the ^1H NMR spectra of the pure extractants and their complexes with uranyl nitrate. In the NMR spectra of solutions of DOEBM in $CDCl_3$ and of DOCHM in CCl_4 the protons of the methylene bridge give rise to a triplet, which indicates the equivalence of the two phosphorus atoms. When non-equivalent phosphorus atoms are present, as for example, in the di-(n-heptylphosphinyl)methylenephosphonic acid molecule $(n\text{-}C_7H_{15})_2P(O)CH_2(O)P(OH)_2$ the protons of the methylene bridge gave rise to a quartet signal. The fact that in the complexes $UO_2(NO_3)_2.DOEBM$ and $UO_2(NO_3)_2.DOCHM$ the protons of the CH_2 group give

‡ The infrared absorption bands of the NO_3 group under conditions where its covalent or ionic bond predominates in various compounds have been assigned in a number of studies[88–95].

rise to a triplet demonstrates the equivalence of the two phosphorus atoms and hence the bidentate coordination of the phosphoryl group.

The influence of certain electronic and steric factors on the extraction of uranium by tetraarylalkylenediphosphine dioxides has been studied. The results of these investigations are discussed below (see Section 5).

c. Extraction of Other Elements

The extraction of other elements by tetraalkyl(aryl)-alkylenediphosphine dioxides has also been investigated. The results characterise the selective properties of these substances. The qualitative data obtained by Parker and Banks[98] for the extraction of a number of elements from nitric and hydrochloric acids solution by tetra-n-hexylmethylenediphosphine dioxide are presented in the Table.

Characteristics of the extraction of a number of elements from nitric and hydrochloric acid solutions by $[n\text{-}C_6H_{13})P.(O)]_2CH_2$.

Medium	Quantitative extraction	Partial extraction	No extraction
1 M HNO_3	Au^{III}, Bi^{III}, Th, U^{VI}, Zr	Hg^{II}, Fe^{III}, Sm, Y, Mo^{VI}	Al, Ca, Cu, Ga, Pb, Mg, Ni, V, Zn
1 M HCl	Au^{III}, Bi^{III}, Th, U^{VI}, Hg^{II}, Mo^{VI}	Zr, Fe^{III}	Al, Ca, Pb, Zn, Ca, Cu, Fe^{II}, Ni, Sm, V, Y

In the extraction of thorium nitrate by tetraalkylmethylenediphosphine dioxides (S) [98] it was established that, in the presence of an excess of the extractant, complexes having the composition $Th(NO_3)_4.2S$ are formed in the organic phase. When there is a deficiency of the extractant, the complexes $Th(NO_3)_4.S$ are present in the organic phase.

Mrochek and Banks[75] quote comparative data for the extraction of praseodymium, neodymium, samarium, and thulium from nitric, hydrochloric, and perchloric acid solutions by tetrahexylalkylenediphosphine dioxides. After assessing the possibility of the employment of diphosphine dioxides as extractants for the separation of the lanthanides, the authors concluded that their selectivity is insufficient for this purpose.

An extensive study of the extraction properties of many tetraalkylmethylenediphosphine dioxides was carried out by O'Laughlin, Banks, and coworkers. Tetra-(n-hexyl)-methylenediphosphine dioxide proved to be extremely convenient as the stationary phase for the extraction chromatography of various metals, including the lanthanides[99]. A study of the extraction of samarium, thorium, and uranium from nitric acid solutions established that tetraalkylmethylenediphosphine dioxides with straight-chain alkyl groups are better extractants than compounds with branched side chains; compounds with branched side chains are relatively more effective for uranium(VI) than for thorium; the partition coefficients of samarium are much lower than those of thorium and uranyl[100].

The significant difference between the separation factors of lanthanide nitrates, chlorides, and perchlorates for separation with the aid of methylenediphosphine dioxides containing straight-chain and branched-chain alkyl groups (hexyl and 2-ethylhexyl) was explained by steric factors[101].

A detailed study of the separation of the lanthanides, thorium, and uranium with the aid of tetra-(n-hexyl)methylenediphosphine dioxide showed that the degree of separation increases appreciably with increase of the concentration of the nitric and hydrochloric acids[102]. Zirconium was isolated and determined in the presence of a large amount of niobium with the aid of the same dioxide used as the stationary phase[103]. In the extraction of the lanthanides from aqueous solutions of hydrochloric, nitric, and perchloric acids by tetraalkylmethylenediphosphine dioxides in carbon tetrachloride or 1,2-dichlorobenzene solution it was found that, tri- or di-solvates are formed, depending on the extractant concentration[104].

Alkylenediphosphine dioxides having the general formula $R_2P(O)-(CH_2)_n-P(O)R_2$, where $R = C_6H_{13}$ and $n = 1$, 4 or 5, have been used to extract tervalent actinides[105]. A study of the distribution of scandium between a nitric acid solution and a solution of tetraoctylethylenediphosphine dioxide in benzene established that the partition coefficient of scandium is directly proportional to the square of the extractant concentration in the organic phase and inversely proportional to the square of the concentration of hydrogen ions in the aqueous phase[106]. The extraction of cerium with the same extractant was also studied[107] and the same relations were established as in the experiments with scandium. In the extraction of radioactive europium(III) from hydrochloric acid solutions by mixtures of 2-thenoyltrifluoroacetone (S) with $(n\text{-}C_6H_{13})_2P(O)-(CH_2)_n-P(O).(C_6H_{13})_2$ (S') (where $n = 1$, 3, or 4) in cyclohexane adducts having the composition $Eu.S_3.S'$ are formed in the organic cyclohexane phase and synergism is observed[108].

An unusual instance of extraction of the lanthanides by tetraphenylethylenediphosphine dioxide was described recently[109,110]. Praseodymium, europium, and thulium are extracted from the $LiNO_3$–KNO_3 eutectic melt at 160°C. The organic phase is a mixture of biphenyl, *o*-terphenyl, and *m*-terphenyl in which the extractant concentration is 5×10^{-5} M. Two pairs of elements were separated: praseodymium–europium and praseodymium–thulium. In the extraction of americium, curium, and californium under analogous conditions using tetraphenylalkylenediphosphine dioxides $Ph_2P(O)-(CH_2)_n-P(O)Ph_2$, where $n = 2$, 3, or 4, as the extractants lower partition coefficients are observed than for praseodymium, europium, and thulium.

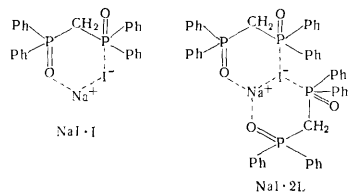
4. COMPLEX-FORMING PROPERTIES

a. Complexes with Alkali Metal Halides

The authors of the present review[111] established that methylenediphosphine dioxides form stable crystalline complexes with alkali metal iodides having the composition $2R_2P(O)CH(R')P(O)R_2.MX$.

Hewerson et al.[112], who oxidised tetraphenylmethylenediphosphine with hydrogen peroxide in acetone in the presence of sodium bromide, isolated the crystalline complex $[(PH_2P(O)CH_2P(O)Ph_2)_3Na]Br.3H_2O$, in which the sodium cation is chelated by three molecules of tetraphenylmethylenediphosphine dioxide with formation of a trigonal prism containing six oxygen atoms.

Yatsimirskii et al.[114] investigated the interaction of alkali metal halides with tetraaryl(alkyl)methylenediphosphine dioxides in non-aqueous solutions. They employed for this purpose conductimetric, spectrophotometric, interferometric, solubility, and other methods. The results obtained in the study of the formation of a sodium iodide complex with tetraphenylmethylenediphosphine dioxide[113] suggested that the entire NaI molecule (ion pair) is involved in the formation of complexes. At this stage of the investigation the hypothesis was put forward that the bond linking the iodide ion to the phosphorus atom can be formed partly as a result of the electrostatic interaction but is mainly due to the overlapping of the orbitals of the ion with the free non-bonding *d* orbitals of phosphorus. The complex formed can be stabilised by the inclusion in its composition of the alkali metal ion. There is then a possibility of the formation of a six-membered ring in which the alkali metal ion interacts electrostatically with the iodide ion and the oxygen atom on which a negative charge is localised. The ring can be built up also on the other side with formation of a condensed complex. The structures of the complexes NaI.L and NaI.2L might have been represented as follows according to this hypothesis:



NaI·I NaI·2L

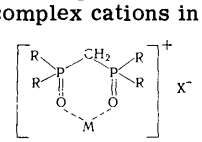
However, further study led to findings conflicting with this hypothesis. Thus, according to ^{31}P NMR data, the two phosphorus atoms are magnetically equivalent, while according to the hypothesis they are non-equivalent. The determination of the real structure of the complexes evidently requires further studies.

To elucidate the influence of the nature of the alkali metal halide on the type of its interaction with phosphine oxides a study has been made of the electrical conductivity of the MX–$Ph_2P(O)CH_2P(O)Ph_2$–acetonitrile system[114], and it has been found that, depending on the nature of the cation and anion in the MX molecule, complex formation can proceed in accordance with one of the following equations:

$$M^+ + X^- + nL \rightleftarrows MX \cdot nL \quad , \qquad (1)$$

$$MX + L \rightleftarrows [ML]^+ + X^- \quad . \qquad (2)$$

The electrically neutral complexes described above arise in the first case and complex cations in the second:



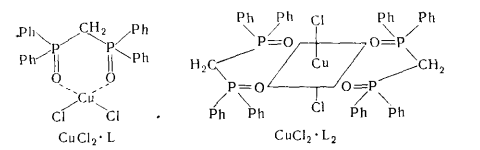
The formation of complexes of the type MX.L or $[ML]^+X^-$ obeys a specific relation: the most favourable conditions for the formation of electrically neutral complexes are created in systems containing a cation with a small radius and a high ionic potential and a large readily polarisable anion. The influence of the structure of phosphine oxides and of the nature of the substituents on the properties of the complexes formed has been studied. A quantitative estimate of the complex-forming properties of phosphine oxides has been made on the basis of the stability constants of their complexes with NaI (the electrically neutral complexes NaI.L) and LiCl {the positively charged complexes $[Li.L]^+$}.[115] The stability of the NaI.L complexes depends significantly on the nature of the substituent at the phosphorus atom. The phenyl group, which can behave both as an electron-donating and an electron-accepting agent, permits the formation of a more stable complex than, for example, the butyl group which behaves as an electron donor only or the butoxy-group which behaves more as an electron acceptor. The complex with an asymmetric dioxide proved to be the most stable.

The interaction of alkali metal halides with tetraalkyl-(aryl)alkylenediphosphine dioxides containing different numbers of methylene groups linking the phosphorus atoms[116], different substituents in the phenyl groups[117], and different substituents in the methylene bridge[118] has also been studied. The results of these investigations are discussed below (see Section 5).

b. Complexes with Copper and Other Metal Salts

The interaction of copper(II) chloride with tetraphenylmethylenediphosphine dioxide $Ph_2P(O)CH_2P(O)Ph_2$ in acetone leads to the formation of the complexes $CuCl_2.L$ and $CuCl_2(Ac)_2$, which can be isolated from solution[119]. At low ligand concentration in solution the product is the complex $[CuCl.L]^+$, while in the presence of an excess of the ligand the complex containing copper(II) chloride and the ligand in the proportions 1 : 2 is formed when the solutions are allowed to stand. The absorption spectrum of the 1 : 1 complex contains a charge-transfer band at 21 000 cm^{-1}; the 1 : 2 (M : L) complex does not exhibit such properties. The stability constant of the complex $[CuCl.L]^+$ was determined from spectrophotometric and conductimetric data.

The structures of the complexes formed can be represented schematically as follows:



$CuCl_2 \cdot L$ $CuCl_2 \cdot L_2$

In the $CuCl_2.L$ complex all four electron-donating atoms (two O atoms and two Cl atoms) are probably located in the same plane. In the $CuCl_2.2L$ complex the four oxygen atoms are probably located in the equatorial plane (the XV plane) and two chloride ions are above and below this plane.

An X-ray diffraction study of the crystalline copper(II) chloride complex with tetraphenylethylenediphosphine dioxide showed that it exhibits a very marked deviation from the ideal tetragonal symmetry[120]. Complexes of tetraphenylethylenediphosphine dioxide with cobalt halides have also been obtained. All the complexes are paramagnetic.

Certain complexes of organic copper(I) compounds (phenylcopper, tolylcopper, and others) with tetraphenylmethylenediphosphine and tetraphenylethylenediphosphine have likewise been isolated and characterised[121].

The interaction of copper(II) chloride with substituted tetraphenylmethylenediphosphines[117] and also the influence of the length of the chain between the phosphoryl groups on the complex-forming properties of alkylenediphosphine dioxides[116] were studied by Sheka, Yatsimirskii et al. The results of these investigations are discussed below (see Section 5).

In addition to the complexes of the copper salts, a study was also made of the formation of complexes with salts of other metals. The formation of stable 1:1 complexes of tin(IV) chloride and bromide with tetraphenylethylenediphosphine and tetraphenylbutylenediphosphine dioxides has been described[122]. Complexes having the following compositions

$MoOBr_3[Ph_2P(O)CH_2CH_2P(O)Ph_2]$,
$MoO_2Br_2[Ph_2P(O)CH_2CH_2P(O)Ph_2]$,
$MoOCl_3[Ph_2P(O)CH_2CH_2P(O)Ph_2]$,
$MoO_2Cl_2[Ph_2P(O)CH_2CH_2P(O)Ph_2]$,
$WO_2Cl_2[Ph_2P(O)CH_2CH_2P(O)Ph_2]$,
$WO_2Br_2[Ph_2P(O)CH_2CH_2P(O)Ph_2]$

have been synthesised by treating tetraphenylethylenediphosphine dioxide and molybdenum or tungsten hexacarbonyls with halogens, isolated, and characterised[123].

The complexes of tetraphenylmethylenediphosphine dioxide (L) with rhenium(I) carbonyl halides have been obtained and investigated: $Re(CO)_3L$, $Re(CO)_3LBr$, and $Re(CO)_3LCl$.[124] The formation of magnesium and calcium halide complexes with tetraphenylmethylenediphosphine dioxide (L) was established by studying the electrical conductivity of and ion transport in solutions of magnesium and calcium iodides and chlorides in acetonitrile. The complexes $[Mg.L]^{2+}$ and $[MgI.L]^+$ are formed with magnesium iodide, while the existence of the complexes $[Ca.L]^{2+}$ and $[CaCl.L_2]^+$ has been observed[125] for calcium chloride.

A spectrophotometric study of neodymium chloride solutions with tetraphenylmethylenediphosphine dioxide in butyl alcohol established that the complexes $NdCl_3.nL$ (n = 1 or 3) and $NdCl_3.nL_2$ (n = 1, 2, or 3) are formed in steps[126].

5. DEPENDENCE OF THE EXTRACTION AND COMPLEX-FORMING PROPERTIES ON THE STRUCTURE OF THE LIGANDS

Although the number of publications dealing with polydentate organophosphorus complex-forming agents has increased recently, problems such as the relation between the structure and stability of the complexes, the relation between structure and selectivity of ligand action, the relation between the stability constants of the complexes and the capacity for complex formation in heterogeneous media, as well as many other aspects have not been studied.

Certain general problems in the field of polydentate neutral organophosphorus complex-forming agents were investigated by the authors of the present review. It was of interest to discover the influence of the electronic effects of the environment of the active centre of the ligand on complex formation and also the role of steric and structural factors.

a. The Electronic Effects of Substituents

The dependence of the extracting capacity of tetraarylmethylenediphosphine dioxides $(RC_6H_4)_2P(O).CH_2P(O).(C_6H_4R)_2$ containing various substituents in the *meta*- and *para*-positions in the benzene rings (CH_3O, CH_3, Cl, Br, CF_3, etc.) was studied in relation to uranyl nitrate[127]. It was established by the method involving dilution of the extractant that the complexes $UO_2(NO_3)_2.3S$ and $UO_2(NO_3)_2.2S$ exist in the organic phase. The effective extraction constants were calculated for uranyl nitrate ($\overline{K}$) and a correlation between $\lg\overline{K}$ on the one hand and $\Sigma\sigma^{ph}$ and $\Sigma\sigma$ was established for the trisolvates. It was also shown that there is a linear relation between the extracting capacity of the dioxides and the pK defining their basicity. The effective extraction constant varies within wide limits: from 0.8×10^{10} (for the p-MeO substituent) to 70 ± 20 (for the p-CF_3 substituent).

The formation of complexes with copper(II) chloride has also been studied for the same series of substitued dioxides[117]. The stepwise stability constants of the complexes $[CuCl.L]^+$ were determined and a correlation was established between these quantities and the σ constants of the substituents and the basicity (pK_a) of the ligands. The stability constants are higher the weaker the electron-accepting properties of the substituents: $\lg\beta_{ML}$ varies from 3.74 (for p-CF_3) to 4.62 (for p-MeO).

Next the complex-forming properties of tetraphenylmethylenediphosphine dioxides with a substituent in the methylene bridge, $Ph_2P(O)-CHR-P(O)Ph_2$, were investigated. It was found that in the case of uranyl nitrate either the trisolvates or disolvates exist in the organic phase. The effective extraction constants were calculated for the trisolvate complexes and, although they were found to vary for dioxides with different substituents in the bridge, they nevertheless remained within the limits of the same order of magnitude. On the other hand, as shown above, for dioxides with substituents in the phenyl groups these values vary in the range of 4–5 orders of magnitude. The formation of complexes of copper(II) chloride was studied on the basis of stability constants calculated from spectrophotometric data. It was shown that the bridge-substituted tetraphenylmethylenediphosphine dioxides (R = Cl, Br, I, C_6H_5, or $C_6H_5CH_2$), without functional groups in the substituents capable of a donor-acceptor interaction with the metals, form complexes of the same type whose stability is determined mainly by the inductive properties of the substituents. On the other hand, in the presence of substituents containing functional groups [R = CH_2CH_2COOH, $CH_2CH_2P(O)Ph_2$, $CH_2CH_2P(O).(OH)_2$, etc.], which may be involved in complex formation, the compositions structures, and stabilities of the complexes formed are altered.

b. Effect of the Length of the Bridge Between the Phosphorus Atoms

The phosphoryl groups in alkylenediphosphine dioxide molecules are electronegative and exert on one another an influence which weakens the complex-forming capacity of the dioxides. An increase of the distance between the phosphoryl groups reduces their mutual influence. On the other hand, the dimensions and stability of the rings of the chelate compounds formed depend on the number of methylene units in the bridge. Allowance for these factors makes it possible to suggest that the length of the alkylene bridge between the phosphoryl groups can have a significant influence on the complex-forming properties of the dioxides.

Mrochek et al. demonstrated the influence of the alkylene bridge on the composition of the complexes formed in the extraction of uranyl nitrate by tetrahexylalkylenediphosphine dioxides[85]:

$$(C_6H_{13})_2P(O)-(CH_2)_n-P(O)(C_6H_{13})_2,$$

where n = 1, 2, 3, or 4. The dioxide with the methylene bridge exhibits the highest extracting capacity in this series[75]. Laskorin et al.[128] found that the maximum partition coefficient in the extraction of uranium from nitric

and hydrochloric acid solutions by di- and poly-oxides is observed for tetraoctylethylenediphosphine dioxide; a further increase of the length of the bridge between the phosphorus atoms leads to a monotonic decrease of the partition coefficients of uranium.

The influence of the number of methylene units between the phosphoryl groups on the complex-forming[116] and acid–base properties[129] of alkylenediphosphine dioxides containing aryl or alkyl substituents at the phosphorus atoms has been studied. The dioxides of two homologous series were investigated as ligands:

$$Ph_2P(O)-(CH_2)_n-P(O)Ph_2,$$

where $n = 1 - 3$, and

$$Bu_2P(O)-(CH_2)_n-P(O)Bu_2,$$

where $n = 1-6$.

The results of potentiometric titration of the dioxides[129] in nitromethane led to the hypothesis that the protonation of the dioxides with methylene and ethylene bridges proceeds via the formation of rings with an intramolecular hydrogen bond involving both phosphoryl groups. In the presence of a larger number of methylene units the ring probably ruptures and the second phosphoryl group is protonated.

The interaction of the same alkylenediphosphine dioxides with alkali metal halides and copper(II) chloride was studied on the basis of the changes in the electrical conductivities of solutions of the salts following the addition of the ligand[116]. As already mentioned, neutral complexes are formed with alkali metal iodides in acetonitrile, while the chlorides give rise to positively charged complexes. Dioxides with a methylene bridge ($n = 1$) have the most marked complex-forming capacity, the interaction with the salts being reduced in parallel with the increase of the ring size as the number of methylene groups between the phosphorus atoms increases. For tetrabutylalkylenediphosphine dioxides with $n = 4$ or 6, an enhancement of the complex-forming effect is observed, probably owing to the rupture of the chelate ring, and the addition of two MX molecules to the dioxide molecule (both phosphoryl groups act independently). For tetraphenylalkylenediphosphine dioxides, an increase of n leads to a sharp weakening of the complex-forming properties.

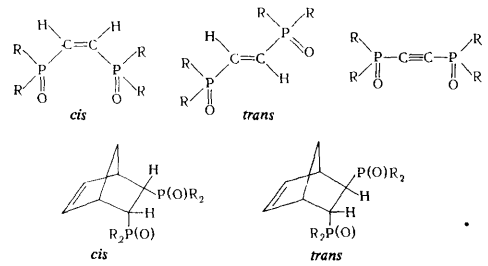
The study of the formation of complexes of copper(II) chloride by spectrophotometric and conductimetric methods showed that tetrabutylmethylenediphosphine and tetrabutylethylenediphosphine dioxides ($n = 1$ or 2) form complexes having the same composition $[CuCl.L]^+$, while for $n = 3$, 4 or 6 ring formation does not occur and the two phosphoryl groups act separately; one cannot rule out the possibility of the formation of polymeric forms of the complexes.

c. Stereochemical Factors

The above data concerning the complex-forming properties of alkylenediphosphine dioxides make it possible in many cases not only to understand but also to predict the nature of the complex formation reaction with particular metals. These considerations apply mainly to the stability of the complexes formed and to the possibility of controlling it largely by varying the electron-donating capacity of the active centre of the ligand.

The problems of the selectivity of the action of the complex-forming agents are a no less interesting and important aspect of the investigation of their properties, since the solution of the problem of selective complex formation is of exceptional significance. However, the principles of creating a complex-forming agent with a high selectivity in relation to the specified metal are still far from being elucidated. Certain studies on these lines were undertaken by the present authors, who began with the hypothesis that the inclusion in the molecule of the complex-forming agent of fragments preventing the free rotation of the individual units and fixing the disposition of the electron-donating atoms would increase the selectivity and efficiency of the complex-forming agent.

This hypothesis was tested by investigating the extraction and complex-forming properties of alkylenediphosphine dioxides with a "rigid" structure, containing a vinylene bridge or a triple bond between the phosphoryl groups: the dioxides of the *cis*- and *trans*-isomers of tetraphenylvinylenediphosphine; tetraphenylethynylenediphosphine dioxide; bicyclic adducts of dioxides containing *cis*- and *trans*-vinylene bridges with cyclopentadiene:



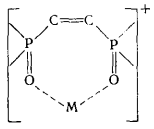
The extraction capacity was studied in relation to nitric acid and uranyl nitrate[130]. It was shown that the partition coefficient of uranyl nitrate is higher by three order of magnitude when the *cis*-isomer of the dioxide with the vinylene bridge is used compared with the dioxide containing an ethylene bridge. Conversely, by fixing the P=O groups in the *trans*-positions, the degree of extraction is reduced to the level characteristic of the corresponding monoxide. The adducts of the *cis*- and *trans*-dioxides with cyclopentadiene behave similarly. The lowest extraction capacity is characteristic of the compound with the ethynylene bridge. The formation of rings is impossible with *trans*-isomers of the dioxide with the ethynylene bridge (the disposition of the atoms in P–C≡C–P is linear). The appreciably enhanced extraction of uranyl nitrate by *cis*-tetraphenylethynylenediphosphine dioxide compared with dioxides containing methylene and ethylene bridges can be attributed to a rigid steric distribution of the phosphorus atoms because, on the one hand, the entropy component of the free energy changes, and, on the other, the distance between the oxygen atom decreases. Possibly it becomes optimal as a result of the formation of rings with uranyl nitrate. Similar results were obtained in a study of the extraction of molybdenum[131].

Thus steric factors have a very significant influence on the extraction properties of the complex-forming agent.

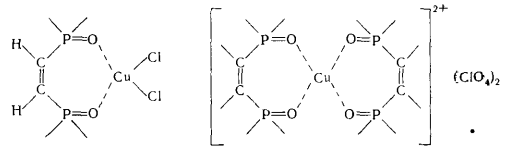
Analogous data were secured in a study of the influence of steric factors on the complex-forming properties of alkylenediphosphine dioxides[132]. The influence of the mutual disposition of the phosphoryl groups in vinylenediphosphine dioxides on the properties of the complexes which they form with certain alkali and transition metal halides was studied. Methylenediphosphine dioxides form electrically neutral cyclic complexes with lithium and sodium iodides as a result of the incorporation in the complex of the ion pair M^+I^-.

The *trans*-isomers of dioxides with a vinylene bridge also form electrically neutral complexes, which shows that the *trans*-disposition of phosphorus atoms apparently makes it possible to form monomeric complexes with the ion pairs M^+I^-.

The interaction of the *cis*-isomer with the same salts results in the formation of positively charged complexes—in this case the cation adds to the oxygen atoms of both phosphoryl groups:

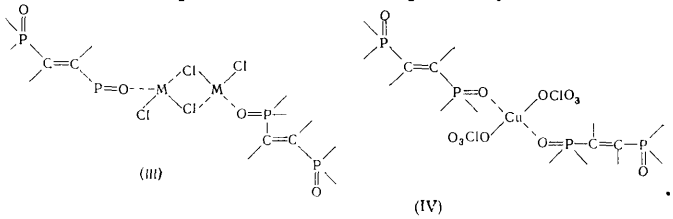


Complexes of the isomeric vinylenediphosphine dioxides have been obtained with cobalt(II) and copper(II) salts. On the basis of reflection and infrared spectroscopic data, structures (I) and (II) were attributed to the crystalline complexes of the *cis*-isomers having the composition $CuLCl_2$ and to the complexes $CuL_2(ClO_4)_2$ respectively:



(I) (II)

Structures (III) and (IV) are most probable for the cobalt(II) and copper(II) complexes with the *trans*-isomers and for the complex $CuL_2(ClO_4)_2$ respectively:



(III) (IV)

Coordination compounds of the dioxides with nickel chloride were obtained by fusing the components at the melting points of the dioxides. The chlorides of the transition metals investigated form 1 : 1 coordination compounds and the perchlorates form 1 : 2 complexes.

The absorption spectra of cobalt complexes show that the absorption band due to the *d*–*d* transition is in the region characteristic of tetrahedral complexes. In the spectra of the copper complexes the band of the *d*–*d* transition is in the near infrared, which suggests that the symmetry of the chromophore in the copper complexes is intermediate between tetrahedral and square planar. At high temperatures the complexes of nickel chloride have spectra characteristic of tetrahedral complexes, while at room temperature the structure of these complexes becomes largely octahedral, which is confirmed both by the spectra and the magnetic moments.

The band due to the vibrations of the free P=O group persists in the infrared spectra of the complexes with the *trans*-isomers of the dioxides and a new band appears, which can be attributed to the vibration of the P=O group bound to the metal. In this case the dioxide behaves as a monodentate ligand, i.e. it combines with the metal via one phosphoryl group. In the spectra of the complexes with the *cis*-isomer the bands due to the vibrations of the P=O group are displaced, which implies that both phosphoryl groups are linked to the metal and the ligand is bidentate.

The Azidoazomethine-Tetrazole Tautomerism

V.Ya.Pochinok, L.F.Avramenko, P.S.Grigorenko, and V.N.Skopenko

The review deals with the literature on the azidoazomethine-tetrazole tautomerism of condensed tetrazoles with a detailed consideration of the influence of the structure of the condensed tetrazoles, the nature of the substituents, solvents, and temperature on the state of the azidoazomethine-tetrazole equilibrium.
The bibliography includes 155 references.

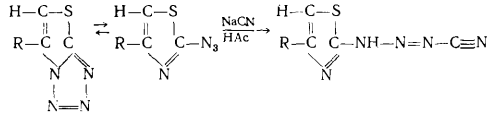
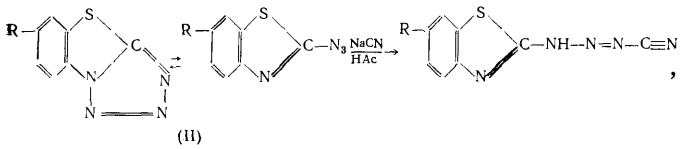
I. INTRODUCTION

A number of studies have been carried out since 1951 on the synthesis and properties of certain condensed tetrazoles[1-24]. The chemistry and fine structure of tetrazolo[5,1-*b*]benzothiazoles and thiazolo[2,3-*e*]tetrazoles were investigated in greatest detail. The studies led to the conclusion that the tetrazole ring condensed with an aromatic heterocycle via the $N_{(1)}-C_{(5)}$ bond is as a rule less stable than 1,5-disubstituted tetrazoles. In many cases it is opened at the $N_{(1)}-N_{(2)}$ bond with formation of the isomeric azidoazomethine derivative. Similar transformations in the series of tetrazolo[5,1-*b*]benzothiazoles and thiazolo[2,3-*e*]tetrazoles frequently occur on heating or dissolution of the substance and following the introduction of electron-accepting substituents into the heterocycle. Therefore, while retaining the properties of 1,5-disubstituted tetrazoles, they enter into reactions characteristic of azides, which was first demonstrated in a number of investigations[1,4,7-10,13,16,18,19,21]. For example, like azides, tetrazolo[5,1-*b*]benzothiazoles and thiazolo[2,3-*e*]-tetrazoles condense with sodium or potassium cyanide to form benzothiazol-2-yl- and thiazol-2-yl-cyanotriazenes respectively[4,19]:



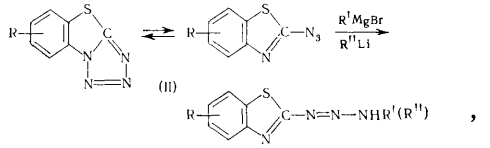
(I)

where R = Me or Ph;



(II)

where R = H, Me, MeO, EtO, F, Cl, or Br. A very interesting relation between condensed tetrazoles and organomagnesium halides and organolithium compounds has been described[1,4,7,13,18,19,21]. It was found that all tetrazolo[5,1-*b*]benzothiazoles, with the exception of the 8-methyl derivative, readily react (like azides) in ether with phenylmagnesium bromide and phenyllithium with formation of phenyl(benzothiazol-2-yl)triazenes:



(II)

where R = H, 6-Me, 6-Cl, 4-Cl, or 6-MeO, R′ = Ph, Bu, Me, or $PhCH_2$, and R″ = Ph or Bu.

8-Methyltetrazolo[5,1-*b*]benzothiazole does not react with phenylmagnesium bromide and phenyllithium. Alkylmagnesium halides and alkyl-lithium compounds are not involved in the formation of aliphatic-aromatic triazenes even on refluxing the reaction mixture in benzene solution. Under these conditions, the initial tetrazoles were isolated in almost quantitative yields[19,21].

On the other hand, 2-azido-4-chlorobenzothiazole, which is isomeric with 8-chlorotetrazolo[5,1-*b*]benzothiazole, forms triazenes with organomagnesium halides regardless of the nature of the organic group[19].

Thiazolo[2,3-*e*]tetrazoles form the corresponding triazenes with phenylmagnesium bromide, phenyl-lithium, and alkylmagnesium halides readily only in the case of the 6-phenyl derivatives[19].

It is interesting that the replacement of the electronegative phenyl group in 6-phenylthiazolo[2,3-*e*]tetrazole by the electropositive methyl group leads to the loss of capacity for the formation of triazenes in the reaction with organometallic compounds.

It has been shown that tetrazolo[5,1-*a*]pyridine does not form triazenes when acted upon by organometallic compounds or sodium and potassium cyanides[19,21]. On the other hand, it has been stated[25] that pyrido[5,1-*a*]tetrazole reacts with triphenylphosphine like azides[18], forming triphenylphosphazo-compounds. The behaviour of tetrazolo[5,1-*b*]benzothiazole and thiazolo[2,3-*e*]tetrazole in relation to phosphines is similar[26].

The reaction of tetrazolo[5,1-*o*]benzothiazoles with 3-methyl-1-phenylpyrazol-5-one and its derivatives has been described[9] and it has been shown that these reactions proceed similarly to the reactions of phenyl azide.

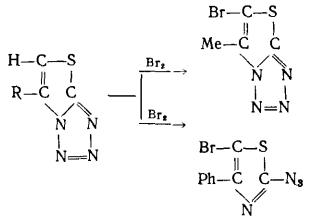
On the other hand, condensed tetrazoles are much more resistant to chemical agents (concentrated acids, oxidising agents) and to light than azides[1,7,10,16,17]. The oxidation of tetrazolo[5,1-*b*]benzothiazole derivatives does not

involve the tetrazole ring. For example, the oxidation of 6-methyltetrazolo[5,1-*b*]benzothiazole leads to the formation of tetrazolo[5,1-*b*]benzothiazole-6-carboxylic acid[10,17].

Dissolution of thiazolo[2,3-*e*]tetrazoles and tetrazolo-[5,1-*b*]benzothiazoles in concentrated inorganic acids leads to the protonation of the tetrazole ring, and, when they are treated with alkylating agents, quaternary tetrazolium salts are formed[14,17].

The isomerisation of 2-azido-4-chlorobenzothiazole to 8-chlorotetrazolo[5,1-*b*]benzothiazole on treatment with sulphuric acid or dimethyl sulphate has been noted[14,17].

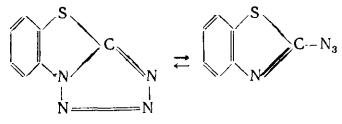
Avramenko, Pochinok, Skopenko, and others[10,17,20,23,24] investigated the halogenation, sulphonation, chlorosulphonation, nitration, and substitution with thiocyanate of thiazolo[2,3-*e*]tetrazoles and tetrazolo[5,1-*b*]benzothiazoles. The halogenation of 6-methylthiazolo[2,3-*e*]tetrazole and its substitution with thiocyanate involve the 5-position of the condensed system and lead to the formation of 5-bromo-6-methyl- and 6-methyl-5-thiocyanato-thiazolo[2,3-*e*]tetrazoles. The corresponding reactions with 6-phenylthiazolo[2,3-*e*]tetrazole proceed similarly at the 5-position. However, the tetrazole ring is opened under the influence of the electronegative phenyl substituent and the reaction products are the isomeric azido-derivatives:



where R = Me or Ph.

The sulphonation, chlorosulphonation, and nitration of 6-phenylthiazolo[2,3-*e*]tetrazole also proceed at the 5-position. The introduction of powerful electron-accepting substituents results in the formation of the isomeric 2-azido-derivatives[17,20,24]. It has been shown[23] that nitration of tetrazolo[5,1-*b*]benzothiazole takes place at the 7-position of the condensed system and the nitration product has the structure of 2-azido-5-nitrobenzothiazole.

In view of the dual nature of the condensed tetrazoles investigated (on the one hand they exhibit the properties of azides and on the other they are much more stable than organic azides and behave like true tetrazoles), Pochinok[2,3] suggested for the first time in 1956 the occurrence of the azidoazomethine–tetrazole tautomerism for condensed tetrazoles:



(II)

It follows from the reactions of various condensed tetrazoles with organometallic compounds, sodium or potassium cyanide, and phosphines that the course of the reaction depends on the state of the azidoazomethine–tetrazole equilibrium, which is influenced by the nature of the substituent in the heterocycle and by the chemical nature of the reagent acting upon the condensed tetrazole.

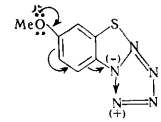
Subsequently the phenomenon of the azidoazomethine–tetrazole tautomerism was demonstrated exactly with the aid of physical research techniques, particularly infrared and NMR spectroscopy.

In 1959 Reynolds et al.[27] and also Boyer and Miller[28] concluded on the basis of spectroscopic studies on condensed tetrazoles that the azidoazomethine–tetrazole tautomerism is possible for some condensed tetrazoles. Infrared spectroscopic data led Boyer and Miller[28] to the hypothesis that tetrazolo[5,1-*b*]benzothiazole is a condensed system in the crystalline state, while in solution it is an equilibrium mixture of the azide and tetrazole forms. In 1961 Sheinker et al.[29] published the results of an infrared spectroscopic study of tetrazolo[5,1-*b*]benzothiazole, which confirmed the earlier conclusions. Furthermore, they observed for the first time that the tetrazolo[5,1-*b*]-benzothiazole ⇌ 2-azidobenzothiazole equilibrium occurs also in the melt[29].

Separate studies on the azidoazomethine–tetrazole tautomerism of tetrazolo[5,1-*b*]benzothiazole, thiazolo[2,3-*e*]tetrazole, and their derivatives were also carried out by infrared spectroscopy[10,11,16,17,20]. The phenomenon of the azidoazomethine–tetrazole tautomerism was likewise observed for other condensed tetrazoles. There are literature data for the azidoazomethine–tetrazole tautomerism of tetrazolopyridine[28,30,31], tetrazolopyrimidines[32-35], tetrazoloquinazoline[36,37], etc.

Condensed tetrazoles have been described in a number of reviews dealing with the chemistry of tetrazoles[38-40]. The reviews by Tisler[41] and Butler[42] on certain aspects of the azidoazomethine–tetrazole tautomerism were published in 1973.

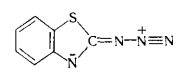
It has been shown[11,14,17,20,33,34] that the state of equilibrium between the azide and tetrazole forms depends on the electron density at the nitrogen atom common to the two rings. In this case the chemical nature of the substituents is of decisive importance. The presence of electron-donating substituents facilitates the closure of the condensed tetrazole ring and increases its stability by enhancement of the electron density at the common nitrogen atom. Electron-accepting substituents stabilise the azido-form:



The study of the azidoazomethine–tetrazole tautomerism has acquired practical importance.

Emulsion-photographic studies have been made[5,12,15,17,22] of tetrazolo[5,1-*b*]benzothiazoles, thiazolo[2,3-*e*]tetrazoles, and certain others. It has been shown that tetrazolo[5,1-*b*]benzothiazole and its derivatives are excellent stabilisers of silver chloride photographic emulsions.

It has been found that the stabilising effect of condensed tetrazoles depends on the state of the azidoazomethine–tetrazole equilibrium. Only those condensed tetrazoles which can give rise to azido-forms with an increased electron density at the heterocyclic nitrogen atom exhibit stabilising properties:



Thus tetrazolopyridine does not stabilise silver chloride emulsions, while 5-nitrotetrazolopyridine is an effective emulsion stabiliser. Infrared spectroscopy of these compounds showed that the former exists only in the tetrazole form in both the crystalline state and in solution. The latter exists in solution as an equilibrium mixture of the azido- and tetrazole forms. For this reason, alkyl

derivatives of thiazolo[2,3-*e*]tetrazole are not stabilisers, while 6-phenylthiazolo[2,3-*e*]tetrazole exhibits a fairly pronounced stabilising effect on the photographic emulsion.

II. METHODS FOR THE INVESTIGATION OF THE AZIDO-AZOMETHINE–TETRAZOLE TAUTOMERISM

The phenomenon of the azidoazomethine–tetrazole tautomerism has been studied in systems where the tetrazole ring is condensed with five- and six-membered aromatic nitrogen-containing heterocycles. The influence of the heterocycle and the electronic nature of its substituents, the polarity of the solvent, the pH of the medium, and temperature on the stability of the condensed tetrazole ring, its isomeric azido-derivative, or the state of the azidoazomethine–tetrazole equilibrium between them has been studied.

The possibility of the annelation of the tetrazole ring to thiazole[4,6,10-12,16,17,20-23,43], 1,2,4-triazole[44,45], thiadiazole[43], tetrazole[46], benzothiazole[1,2,4,6,9-12,14,16,17,19,21,22,24,27-29,47-51], benzoselenazole[27], benzoxazole[27], benzimidazole[26,52], naphtho[2,1-*d*]thiazole[53], naphtho[1,2-*d*]thiazole[53], pyridine[27,28,30,31,47,48,54-64], pyridazine[48,65-77], pyrimidine[27,33-35,47,48,63,69,70,78-87], pyrazine[48,67,79,88], 1,2,4-triazine[47,67,89,90], *s*-tetrazine[91,92], quinoline[93-96], isoquinoline[95], phthalazine[27,77,97,98], quinazoline[36,69-84,85,96,98-110], quinoxaline[96,97,101,111,112], 1,8-naphthyridine[113-122], pyrido[3,4-*d*]pyridazine[72,123,124], pyrido[2,3-*d*]pyridazine[123], 4*H*-pyridazino[6,1-*e*]-1,2,4-triazine[74,75], pyrazino[2,3-*d*]-pyridazine[125], phenanthridine[96,126,127], pyrrolo[1,2-*a*]quinoxaline[129], thieno[3,2-*d*]pyrimidine[129,130], imidazo[1,2-*o*]pyridazine[74,129,131], pyrazolo[1,5-*a*]pyrimidine[132,133], purine[134-137], *s*-triazolo[4,3-*b*]pyridazine[67,71,74,138,139], and *s*-triazolo[4,3-*b*]-*as*-triazine[67,140] has been examined in greatest detail.

The hypothesis of the occurrence of an equilibrium between the azido- and tetrazole forms was put forward on the basis of a study of the chemical properties of these compounds[2]. In certain cases the study of the chemical properties of condensed tetrazoles combined with infrared or NMR spectroscopy can be useful for a quantitative assessment of the equilibrium system. Thus Carboni and coworkers[114,116-118,120] established by a chemical method the proportions of the isomeric 8-azidotetrazolo[1,5-*a*]-1,8-naphthyridines in solutions. The method is based on the different chemical properties of the condensed tetrazole ring and the azido-group. In reduction reactions and in the interaction with nucleophilic agents the azido-group exhibits a higher reactivity. Consequently, in determining the structures and compositions of the products in the reaction mixtures, it is possible to estimate quantitatively the proportions of the isomers in solution.

It is sometimes possible to demonstrate the occurrence of the azidoazomethine–tetrazole equilibrium or even to separate the tautomers by paper and thin-layer chromatography.

In 1959 Boyer and Miller[28] used paper chromatography for the first time in the separation of tetrazolo[5,1-*b*]benzothiazole and 2-azidobenzothiazole and showed that the intensity of the luminescence in the ultraviolet of the two spots on the chromatogram depends on temperature, but no quantitative estimates were made for the equilibrium.

In order to study the azidoazomethine–tetrazole equilibrium and to separate the tautomers in the *s*-tetrazino[2,3-*e*]tetrazole-3-azido-*s*-tetrazine system, Ershov and Postovskii[91] used thin-layer chromatography on alumina.

A detailed study of the phenomenon of the azidoazomethine–tetrazole tautomerism and quantitative estimation of the composition of the equilibrium mixture became possible as a result of the wide-scale application of physical research techniques, primarily infrared and NMR spectroscopy.

The application of infrared spectroscopy is based on the fact that the azido-group has characteristic ν_{as} absorption bands in the range 2100–2200 cm^{-1} and ν_s bands in the range 1100–1350 cm^{-1}. The vibration bands of the tetrazole ring are more difficult to identify and they must be sought at 760, 1212, 1390, 1465, and 1480 cm^{-1}. By measuring the infrared spectra of the compounds in the crystalline state and in solution in polar and non-polar solvents, it is possible to detect the azido- or tetrazole forms of the compounds or both forms simultaneously. Similar measurements at elevated temperatures reveal a change in the intensities of the absorption bands of the azido-group and the tetrazole ring. The heat of the tetrazole–azide transformation can be determined from the temperature variation of the intensities of the absorption bands. It amounts to 4.65 and 0.98 kcal $mole^{-1}$ for the tetrazolo[5,1-*b*]benzothiazoles $\rightleftharpoons$ 2-azidobenzothiazole system in pyridine and dioxan respectively[29,51]. It has been shown that the transformation of the tetrazole into the azide is an endothermic process.

The application of NMR is based on the different effects of the azido-group and the tetrazole ring on the positions of the protons signal in the NMR spectra of the test compounds. These different effects are associated with the greater (in relation to the azido-group) electronegativity of the tetrazole ring. Therefore the proton signals referring to the tetrazole tautomer should occur in the region of lower fields compared with the proton signals due to the azido-tautomers. The nearest protons should be influenced most. The NMR spectra at elevated temperatures reveal an increase of the intensities of the signals of the protons belonging to the azido-form of the compound. This may be regarded as evidence for the validity of the assignment of the proton signals belonging to different tautomeric forms of the compounds.

Quantitative studies of the NMR spectra at different temperatures led to the calculation of the equilibrium constants for various tautomeric systems and to the determination of the heats of the tetrazole–azide transformations in different solutions[33,34,61,72,123,135,136]. These heats for tetrazolo[1,5-*a*]pyridine, tetrazolo[1,5-*a*]pyrimidine, tetrazolo[1,5-*a*]purine, and tetrazolo[5,1-*b*]purine are in the range 2.5–7.0 kcal $mole^{-1}$.

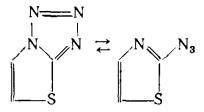
Until recently electronic spectroscopy was not used to investigate the azidoazomethine–tetrazole tautomerism, because the tetrazole ring does not absorb in the ultraviolet and the azido-group gives rise to low-intensity bands at 280 nm. Ershov and Postovskii[91] were the first to employ the ultraviolet spectra to investigate the influence of solvent polarity and to examine the time variation of the tautomeric equilibrium in the *s*-tetrazino[2,3-*e*]tetrazole $\rightleftharpoons$ 3-azido-*s*-tetrazine system. This became possible because the authors separated the tautomers and isolated one of them in a pure form.

III. INFLUENCE OF THE NATURE OF THE NITROGEN-CONTAINING HETEROCYCLE ON THE STABILITY OF CONDENSED TETRAZOLES

The stability of the condensed tetrazole ring is to a large extent determined by the nature of the nitrogen-containing heterocycle to which it is annelated. The

tetrazole ring condensed with saturated heterocycles (trimethylene-[28], tetramethylene-[141,142], and pentamethylene-tetrazoles[142,143], as well as other derivatives[141,144-147], and the nitrogen analogue of trimethylenetetrazole-tetrazoloimidazolidine[28,141]) do not differ in their stability from the 1,5-disubstituted tetrazoles. In the crystalline state and in solution they have cyclic structures.

However, the condensation of the tetrazole ring with a five-membered aromatic heterocycle (thiazole, triazole, tetrazole) leads to a sharp decrease of the stability of the former. The nature and number of heteroatoms in the five-membered heterocycle influence appreciably the stability of the tetrazole ring. Thus in the crystalline state the equilibrium in system (I)

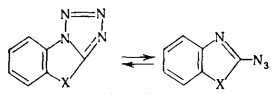


(I)

is almost completely displaced towards thiazolo[2,3-*e*]-tetrazole. However, the tetrazole ring in the latter compound is relatively unstable and tends to be converted into the isomeric azido-form even on dissolution.[20]

It has also been reported that the pyrazole[27], triazole[44], thiadiazole[43], and tetrazole[46] rings destabilise the tetrazole ring condensed to them. For example, 5-azidotetrazole and 5-aryl-3-azido-1,2,4-triazole do not undergo ring closure to the corresponding tetrazoles.

It has been shown[10,11] that tetrazolo[5,1-*b*]benzothiazole (II) is more stable than thiazolo[2,3-*e*]tetrazole (I), as can be seen from the effect of the same solvents on these compounds (see below):

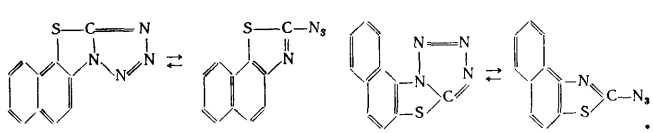


(II-VI)

where X = S (II), Se (III), O (IV), NH (V), and SO_2 (VI).

In systems (II)-(VI) the states of the azidoazomethine-tetrazole equilibrium and the stability of a particular isomeric form depends to a large extent on the electronegativity of the atom X[27]. When X = S or Se, compounds (II) and (III) have the structures of condensed tetrazoles, although they are much less stable than the 1,5-disubstituted tetrazole and exist in solution in equilibrium with the isomeric azido-forms[10,11,16,17,20,27-29]. The replacement of the sulphur atom in the tetrazole (II) by the sulphone group (VI) leads to an increase of the stability of the azido-form and precludes its ring closure[27]. The attempts to obtain tetrazole rings condensed with benzoxazole or benzimidazole rings also did not lead to the desired results. The compounds synthesised had the structures of 2-azido-derivatives of benzoxazole (IV) and benzimidazole (V).

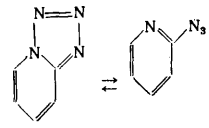
The condensation of the thiazole ring in (I) with the naphthalene ring [systems (VII) and (VIII)] reduces the stability of the corresponding tetrazole forms relative to tetrazolo-[5,1-*b*]benzothiazole (II):



(VII) (VIII)

Even in the crystalline state tetrazolo[1,5-*b*]naphtho-[1',2'-*d*]thiazole (VII) and tetrazolo[1,5-*b*]naphtho[2',1'-*d*]thiazole (VIII) exist in equilibrium with the isomeric azido-derivatives and in the latter case the equilibrium is displaced towards the azido-form. The authors attribute this decrease of stability to the fact that naphthothiazoles have more pronounced electron-accepting properties than benzothiazoles[53].

In the crystalline state tetrazolo[5,1-*a*]pyridine (IX) has a cyclic structure and is not converted into the isomeric azido-derivative in polar and non-polar solvents[27,61,48,63]:

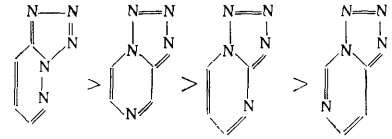


(IX)

However, under severe conditions (in pyrolysis) it can give rise to the reactive azido-form and can enter into reactions characteristic of azides[62,63,47,147].

It follows from a series of studies by Temple and coworkers[33-35], Wentrup[48,70,82], Stanovnik[74,75], and others[65,88] that the replacement of the methine group in the six-membered nitrogen-containing heterocycle by a second electronegative atom (nitrogen) causes some decrease of the stability of the $N_{(1)}-N_{(2)}$ bond in the condensed tetrazole ring. In the crystalline state tetrazolo[1,5-*b*]pyridazine (X)[48,65], tetrazolo[1,5-*a*]pyrazine (XI)[48,70,88], and tetrazolo[1,5-*a*]pyrimidine (XII)[33-35,48] have cyclic structures. Tetrazolo[1,5-*c*]pyrimidine (XII) is in equilibrium with the isomeric 4-azidopyrimidine even in the crystalline state[35]. In polar and non-polar solvents compounds (X)-(XIV) exist in both tautomeric forms, but on heating they behave like azides.

Thus the state of the azidoazomethine-tetrazole equilibrium involving the above heterocycles depends on the relative positions of the two nitrogen atoms in the heterocycle and in compounds (XII) and (XIII) also on the bond of the pyrimidine ring to which the tetrazole ring is attached. These compounds can be arranged in the following sequence in terms of the stability of the condensed tetrazole ring:



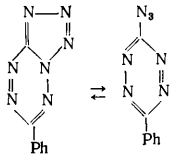
(X) (XI) (XII) (XIII)

This relation is manifested particularly clearly when the influence of temperature and solvent on the state of the azidoazomethine-tetrazole equilibrium is examined.

An increase in the number of nitrogen heteroatoms in the six-membered ring leads to a further destabilisation of the tetrazole ring condensed to it and to an increase of the stability of the azido-form. Ershov and Postovskii[91] carried out calculations for the azido-forms of a number of phenylazines and showed that, with increase of the number of nitrogen atoms in the ring, the π-electron density at the bridgehead nitrogen atom diminishes, which leads to an increase of the energy of the transition to the tetrazole form and to an increase of the stability of the azido-form.

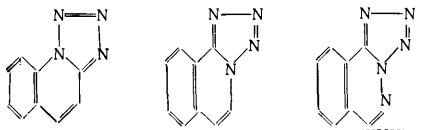
Unsubstituted azidotriazines and azidotetrazines or their isomeric condensed tetrazoles have not been described in the literature. The structures of their derivatives depend on the electronic nature of the substituents and confirm indirectly the calculations of Ershov and Postovskii[91].

Ershov and Postovskii showed that 6-phenyltetrazolo-[5,1-*b*]-*s*-tetrazine (XIV) cannot be isolated in a pure state because of the exceptional ease of its conversion into the azido-form owing to the latter's greater stability[91]:



(XIV)

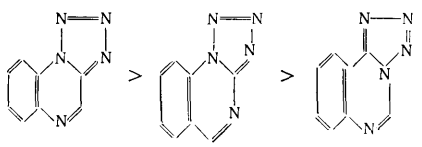
The benzo-analogues of compounds (IX)–(XIII) and (XV)–(XX) contain more stable tetrazole rings. Thus tetrazolo-[1,5-*c*]quinoline (XV) and its analogue tetrazolo[5,1-*a*]isoquinoline (XVI) exist only in the cyclic form[95].



(XV) (XVI) (XVII)

Under severe conditions (380–510°C/10^{-3}–10^{-2} mmHg), they isomerise, like compound (IX), to the corresponding azides. The existence of tetrazolo[1,5-*a*]phthalazine (XVII), but not of its isomeric 1-azidophthalazine, has been reported[27,77,97,98]. Tetrazolo[1,5-*e*]quinazoline (XX) is more stable than the related tetrazolo[1,5-*c*]pyrimidine (XIII). Thus in the crystalline state compound (XX) exists only in the cyclic form[103] and compound (XIII) is present in equilibrium with the azide[35]. Tetrazolo[1,5-*a*]quinoxaline (XVIII) is more stable than tetrazolo[1,5-*a*]pyrazine (XI). This is confirmed by the cyclic structure of compound (XVIII) even in trifluoroacetic acid, in contrast to compound (XI).[101]

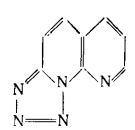
Compounds (XVIII)–(XX) can be arranged in the following sequence in terms of the stability of the condensed tetrazole ring:



(XVIII) (XIX) (XX)

which is analogous to the series (XI) > (XII) > (XIII) discussed above. Thus, in contrast to compound (XVIII), the tetrazoloquinazolines (XIX) and (XX) are converted into the corresponding azides in trifluoroacetic acid[69,101]. The greater stability of tetrazolo[1,5-*a*]quinazolines (XIX) compared with tetrazolo[1,5-*c*]quinazolines (XX) is confirmed by the gradual transformation, observed by Postovskii and coworkers, of certain derivatives of (XX) into the isomeric azido-derivatives in the crystalline state[100,109], which is not observed for compounds of type (XIX).[36]

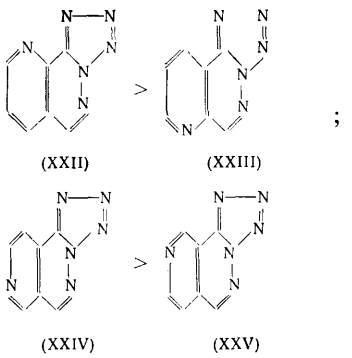
The replacement of the benzene ring in the condensed tetrazoles (XV) and (XVII) by pyridine leads to the somewhat less stable tetrazolo[1,5-*a*]-1,8-naphthyridine (XXI)[114,122]:



(XXI)

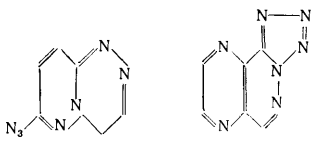
and also to the pyridotetrazolopyridazines (XXII)–(XXV)[72,73,123,124]. The stability of the tetrazoles (XXII)–(XXV) depends on the position of the nitrogen atom in the pyridine ring relative to the condensed tetrazole ring.

This can be inferred indirectly from the ability of 6-azidopyrido[3,2-*d*]tetrazolo[5,1-*b*]pyridazine and 6-azidopyrido[3,4-*d*]tetrazolo[1,5-*b*]pyridazine to isomerise to the thermodynamically more stable 6-azidopyrido[2,3-*d*]-tetrazolo[5,1-*b*]pyridazine and 6-azidopyrido[4,3-*d*]tetrazolo[1,5-*b*]pyridazine respectively[72,123,124]. It follows from these data that compound (XXII) is more stable than compound (XXIII) and compound (XXIV) is more stable than compound (XXV):



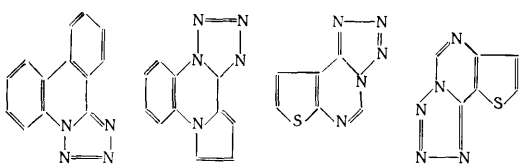
(XXII) (XXIII) (XXIV) (XXV)

It has been shown in a series of studies by Stanovnik and Tisler[74,75] that the condensation of the pyridazine ring to heterocycles containing two nitrogen atoms leads to the formation of the azido-derivative (XXVI) instead of the isomeric condensed tetrazoles. On the other hand, compound (XXVII) exists in the cyclic form:



(XXVI) (XXVII)

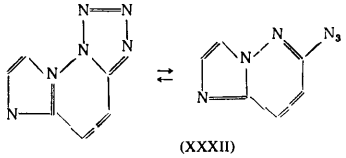
It has been reported[96,126,127] that the condensation of the 9,10-phenanthridine ring with the tetrazole ring leads to the stable tetrazolo[1,5-*b*]-9,10-phenanthridine (XXVIII). Pyrrolo[1,2-*a*]tetrazolo[1,5-*c*]quinoxaline (XXIX) has also been described[87]:



(XXVIII) (XXIX) (XXX) (XXXI)

The systems (XXX) and (XXXI), derived from tetrazolo[1,5-*c*]pyrimidine (XIII) in which the pyrimidine ring is in its turn condensed to a five-membered ring (thiophen) have been described[128,130]. The substances are said to have a cyclic structure in the crystalline state.

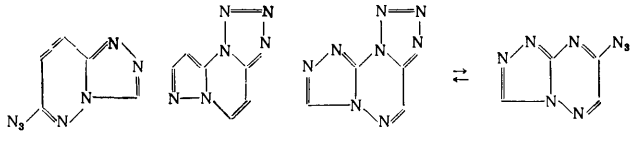
The condensation of tetrazolo[1,5-*c*]pyridazine (X) with a five-membered nitrogen-containing ring (imidazole) leads to the destabilisation of the tetrazole ring in imidazo[1,2-*b*]tetrazolo[5,1-*f*]pyridazine (XXXII):



(XXXII)

It has been stated that even in the crystalline state compound (XXXII) exists in equilibrium with a small amount of the isomeric azido-form[131]. The accumulation of nitrogen atoms in the five-membered ring precludes the closure of the tetrazole ring. 6-Azido-*s*-triazolo[4,3-*b*]-pyridazine (XXXIII), which does not isomerise to the corresponding tetrazole, has been described[67,71,74,138,139].

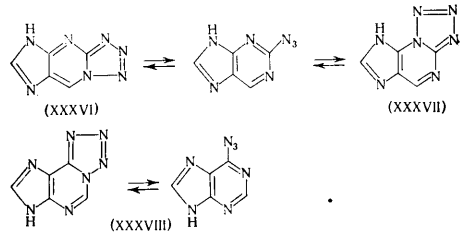
On the other hand, the condensation of tetrazolo[1,5-*c*]-pyrimidine (XIII), which is less stable than compound (X), with the pyrazole ring leads to the formation of the stable pyrazolo[1,5-*a*]tetrazolo[1,5-*c*]pyrimidine (XXXIV), which has only the cyclic structure in the crystalline state[132]:



(XXXIII) (XXXIV) (XXXV)

In the crystalline state the equilibrium in system (XXXV) is fully displaced towards the cyclic form, while in solution there is an equilibrium between both tautomers[67,140].

The condensation of the pyrimidine ring in the tetrazolopyrimidines (XII) and (XIII) with the imidazole ring leads to the formation of the tetrazolopurines (XXXVI), (XXXVII), and (XXXVIII) in which the stability of the tetrazole ring is sharply reduced compared with the related tetrazolopyrimidines:



(XXXVI) (XXXVII)

(XXXVIII)

The studies of Temple and coworkers[134-136] have shown that tetrazolo[5,1-*a*]purine (XXXVIII) exists in the crystalline state in equilibrium with 6-azidopurine, while in the system (XXXVI)–(XXXVII) the equilibrium is almost completely displaced towards 2-azidopurine. However, under certain conditions the azido- and two tetrazole forms can be in equilibrium. These compounds can be arranged in the following sequence in terms of the stability of the tetrazole ring: (XXXVIII) > (XXXVI) > (XXXVII).

IV. INFLUENCE OF SUBSTITUENTS

The electronic nature of the substituent in the nitrogen-containing heterocycle has a considerable influence on the possibility of the formation of the condensed tetrazole ring and its stability and also on the state of the azidoazomethine–tetrazole equilibrium in the system. As a rule, the introduction of powerful electron-donating substituents, which increase the electron density at the nitrogen heteroatom, promotes the formation of condensed tetrazoles in chemical reactions, increases the stability of the condensed tetrazole ring, and shifts the azidoazomethine–tetrazole equilibrium towards the cyclic form. The introduction of powerful electron-accepting substituents, which reduce the electron density at the nitrogen heteroatom, leads to an appreciable decrease of the stability of the condensed tetrazole ring and to a shift of the equilibrium in the tetrazole ⇌ azide system towards the azido-tautomer. A powerful electron acceptor introduced into the nitrogen-containing heterocycle sometimes precludes altogether ring closure by the azido-group via the nitrogen atom and the formation of a condensed tetrazole ring is not observed.

In systems containing a tetrazole ring condensed with five-membered nitrogen-containing heterocycles this phenomenon has been studied in greatest detail for thiazolo[2,3-*e*]tetrazoles (I) and tetrazolo[5,1-*b*]benzothiazoles (II). Thus Pochinok and coworkers[10,14,16,20,23,24] studied the influence of substituents on the possibility of the annelation of the tetrazole ring to the thiazole and benzothiazole rings and the state of equilibrium in systems (I) and (II). It has been shown that electron-donating substituents in the thiazole and benzathiazole rings facilitate the closure of the condensed tetrazole ring and increase its stability. Thus thiazolo[2,3-*e*]tetrazole (I) and its 5-methyl, 6-methyl, 5,6-dimethyl, 6-phenyl, 6-*p*-tolyl, 6-*p*-bromophenyl, 6-*p*-chlorophenyl, 5-bromo-6-methyl, and 6-thiacyanato-derivatives are condensed tetrazoles in the crystalline state. The introduction of the electron-accepting nitro-, sulpho-, chlorosulphonyl, aminosulphonyl, thiacyanato-, or bromo-groups in the 5-position of 6-phenylthiazolo[2,3-*e*]tetrazole (I) decreases appreciably the electron density at the nitrogen atom of the thiazole ring and therefore ring closure by the azido-group via this atom becomes impossible; such derivatives of (I) exist in the azido-form even in the crystalline state. When substituents such as methyl and the bromo-group, methyl and the thiacyanato-group, or the bromo- and thiacyanato-groups are combined in a derivative of (I), the stability of the tetrazole ring also diminishes. However, the presence of the electropositive methyl group in such molecules imparts a certain stability to the tetrazole forms of these compounds in the crystalline state, although in solution (in chloroform, carbon tetrachloride, and acetonitrile) the equilibrium in these systems is almost completely displaced towards the isomeric azides.

Similar relations are observed in systems (II). Tetrazolo[5,1-*b*]benzothiazole and its 6-methyl, 8-methyl, 6-methoxy-, 8-methoxy-, 6-acetamido-, 6-chloro-, 6-bromo-, and 6-fluoro-derivatives are condensed tetrazoles in the crystalline state. The introduction of chlorine in the 4-position of the benzothiazole ring leads to the formation of the isomeric 2-azido-4-chlorobenzothiazole instead of the tetrazole, which is a consequence of the greater influence of the negative inductive effect of the chlorine in the 4-position of the benzothiazole ring compared with the chlorine in the 6-position. The chlorine atom in the 4-position does not give rise to steric hindrance, which might interfere with the formation of the condensed tetrazole, while the analogous compound with the CH_3 group in the 4-position has the cyclic structure.

The introduction of an electron-accepting substituent (the nitro-group) in the 4-, 5-, 6-, and 7-positions of the

benzothiazole ring leads to the existence of stable 2-azido-derivatives even in the crystalline state.

6-Carboxy-derivatives of (II) exist in equilibrium with the azido-form even in the crystalline state, which can be accounted for by the approximately identical electron-accepting properties of the carboxy-group and the tetrazole ring[148,149]. The formation of salts via the carboxy-group results in a decrease of the electron-accepting properties of the substituent and therefore the sodium salt exists as the tetrazole tautomer in the crystalline state.

Boyer and coworkers[28,30] showed that the introduction of hydroxy- and amino-groups into tetrazolo[5,1-*a*]pyridine (IX) does not destabilise the tetrazole ring and the resulting 6- and 8-hydroxy- and 8-amino-derivatives of (IX) have a cyclic structure in both the crystalline state and in solutions (in dimethylformamide, alcohol, and chloroform). The introduction of the electron-accepting nitro-group into the 6-position of compound (IX) reduces the stability of the condensed tetrazole ring, which leads to the formation under certain conditions of an equilibrium system containing both tautomers[28,65,88]. The chlorine atom introduced into the α-position of the pyridine ring acts similarly[61,95]. It has been found that the introduction of chlorine in the 5-position of compound (IX) destabilises the tetrazole form and shifts the equilibrium towards the azide.

It has also been reported[115,117-120,122] that tetrazolo[1,5-*a*]-1,8-naphthyridines (XXI) with electron-donating substituents have only the cyclic structure in the crystalline state with the exception of 8-hydroxy-5-phenyltetrazolo[1,5-*a*]-1,8-naphthyridine[74], which is an azide in the crystalline state. The phenyl substituent decreases the stability of the condensed tetrazole ring in compound (XXI) when it is in the 5-position, evidently because it attracts electrons to itself. This can explain the presence of the $\nu_{as}(N_3)$ band in the infrared spectrum of 8-hydroxy-5-phenyltetrazolo[1,5-*a*]-1,8-naphthyridine in the crystalline state[117] (although under certain conditions the pure tetrazole form can be isolated). On the other hand, when the phenyl substituent is in the 4-position, it stabilises the condensed tetrazole ring as a result of conjugation with the latter.

Similar features were observed in the series of substituted tetrazolo[1,5-*a*]pyrimidines (XII)[33,34,48]. The introduction of two methyl groups, a methyl and a methoxy-group, or a methyl and a methylthio-group into the pyrimidine ring stabilises the condensed tetrazole ring in such systems in relation to the unsubstituted compound (XII).

The introduction of chlorine, which exhibits a stronger negative inductive effect, as a substituent in the 5-position leads to an appreciable destabilisation of the ring compared with the unsubstituted compound (XII). The chloro-derivative of (XII) can be isolated in a pure state when solutions in $CHCl_3$ or CF_3COOH are evaporated and remains metastable for several weeks. However, after prolonged storage it is gradually converted into the more stable tetrazole form. The same process takes place rapidly when compound (XII) is heated above its melting point. Thus both isomers were isolated for the first time in a pure form.

The introduction of the electron-donating amino-group or the methyl group, which exhibits a powerful positive inductive effect, in the 8-position of tetrazolo[1,5-*c*]pyrimidine (XIII) stabilises the tetrazole ring. Thus 5,7,8-trimethyltetrazolo[1,5-*c*]pyrimidine is more stable than the 5,7-dimethyl derivative[14]. 8-Amino-7-chlorotetrazolo-[1,5-*c*]pyrimidine exists in the crystalline state as the tetrazole form. Acylation of the amino-group in the 8-position (with acetic or trifluoroacetic acid) or the introduction of the ethoxymethyleneamino-group in the 8-position leads to the occurrence of the tetrazole $\rightleftharpoons$ azide equilibrium even in the crystalline state, the equilibrium being displaced towards the azido-tautomers[35,86]. When the electron-donating substituent is in the 7-position, its influence on the stability of the tetrazole rings may be various. Thus Postovskii and Smirnova[87] investigated the influence of cycloalkylamino-residues in the pyridine ring on the state of the tetrazole $\rightleftharpoons$ azide equilibrium in system (XIII). It was found that the electron-donating cycloalkylamino-substituents with related structures have different effects on the stabilities of these compounds. When the ring contains morpholine and homopiperidine residues, the compounds exist in the form of azides even in the crystalline state. The pyrrolidino- and piperidino-derivatives are tetrazoles in the crystalline state. This difference between the structures cannot be related to the different basicities of the substituents, since the basicities of homopiperidine, pyrrolidine, and piperidine are approximately of the same order of magnitude. The authors suggested that the observed differences are probably due to the steric effect of the substituents.

It has also been reported[48] that the introduction of two-methoxy-groups into tetrazolo[1,5-*c*]pyrimidine (XIII) in the 5- and 7-positions precludes the formation of the condensed tetrazole ring, which cannot be accounted for by steric hindrance.

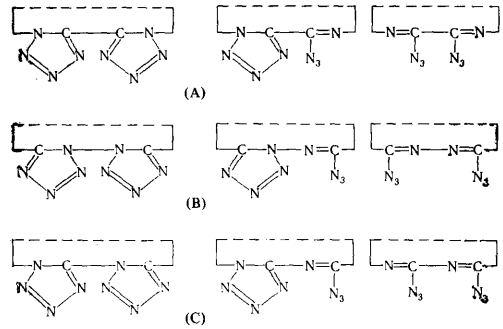
The introduction of the methyl, phenyl, γ-pyridyl, or α-furyl substituents in the 5-position of tetrazolo[1,5-*c*]-quinazoline (XX) does not destabilise the tetrazole form. These compounds have only the cyclic structure in both the crystalline state and in solutions[109]. The introduction of cycloalkylamino-residues into the 5-position of (XX) destabilises the cyclic form and makes possible its conversion into the isomeric azido-form even in the crystalline state after prolonged storage followed by the determination of the azideazomethine–tetrazole equilibrium position[36]. The rate of conversion of the tetrazole into the azide then depends on the basicity of the cycloalkylamino-residue. In contrast to compound (XX), tetrazolo-[1,5-*a*]quinazoline (XIX) with cycloalkylamino-groups in the 5-position has the cyclic structure in the crystalline state[99]. It has been shown[67] that the introduction of two phenyl groups in the 5- and 6-positions of tetrazolo[1,5-*a*]-pyrazine (XI) also leads to the destabilisation of the tetrazole ring.

The introduction of chloro- and methoxy-groups[25] in the 5-positions and cycloalkylamino-groups in the 6-position[68] of tetrazolo[1,5-*b*]pyridazine (X) does not evidently reduce the stability of the condensed tetrazole ring. The authors attribute the appearance of weak bands in the infrared spectrum of cycloalkylaminotetrazolo[1,5-*b*]pyridazine in the range 2100–2200 cm^{-1} to overtones or combination tones of the fundamental vibrations of the heterocycle in the region of the asymmetric vibrations of the azido-group[68].

Temple showed[36] that in purine systems the structure of azidotetrazole derivatives also depends on the presence of electron-donating or electron-accepting substituents. Thus 2-azidopurine exists almost completely in the form of the azide in the crystalline state. The introduction of the electron-donating hydroxy-group in the 6-position of 2-azidopurine leads to the appearance of one of the cyclic forms, which is completely converted into 2-azidopurine after only 30 min even after dissolution in trifluoroacetic acid (TFA)[136]. The amino-group has a similar effect, but in this case the two possible tautomers appear in d_6-DMSO. On the other hand, chlorine in the 2-position of 6-azidopurine appreciably stabilises the azido-form.

In the crystalline state and in solution in dimethyl sulphoxide (DMSO) the compound (XXVII) exists in the form of the azide, in contrast to unsubstituted 6-azidopurine.

Attempts have been made to synthesise compounds containing two condensed tetrazole rings in a single molecule or to condense two such rings with one nitrogen-containing heterocycle in a system of type (A)–(C):

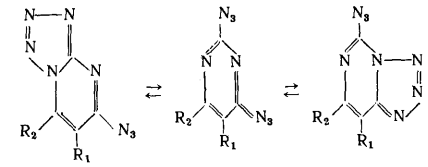


Behringer and Fischer[150] studied non-condensed linear systems of types (A) and (B) and showed that in type (A) systems there is isomerisation to the more stable bistetrazole with the same charge distribution on the nitrogen atoms of the two rings as in the unsubstituted tetrazole. Bistetrazoles of type (B) are as a rule extremely unstable and exist in the form of the isomeric diazides[150,151]. However, it proved possible to isolate 1,1-bis-(5-phenyl)-tetrazole in the crystalline state[150], while in solution the compound is in equilibrium with the isomeric diazide.

Not one case where two tetrazole rings are present in the molecule simultaneously has been described for condensed systems. The attempts to condense the tetrazole ring with another tetrazole ring[46] or two tetrazole rings with pyridazine[65,67,72], pyrimidine[27,48,152–154], tetrazine[92], phthalazine[27,98], quinazoline[72,123], quinoxaline[27,98,103], pyrido[3,2-*d*]pyridazine[72,123], pyrido[4,3-*d*]pyridazine[123], naphthyridine[113,114,117–121], pyrazino[2,3-*c*]pyridazine[125], and purine[136,137] did not lead to the desired results. The reason for this is probably the powerful electron-accepting properties of the tetrazole rings and the consequent decrease of the basicity of the second nitrogen heteroatom. The second azido-group can play the role of a weak electron-donating substituent in such cases.

In most instances compounds of this kind exist as azidotetrazoles in the crystalline state. Azidoazomethine ⇌ tetrazole equilibrium systems arise in solutions and their tautomer content depend on the nature of the heterocycle and the substituents and also on the polarity of the solvent. Sometimes transitions of this kind occur after prolonged storage or heating of the compound.

Thus the structure of diazides was attributed in a number of studies[27,152–154] to 2,4-diazidopyrimidine and its derivatives (6-methyl, 5-methyl, 5,6-dimethyl, 6-phenyl, and 6-furyl) on the basis of an investigation of certain physical and chemical properties. Later studies by Wentrup[48] by NMR showed that at any rate methyl and dimethyl derivatives exist in the crystalline state as tautomeric mixtures of azidotetrazoles (XII, a-c) and (XIII, a-c) in which the more stable (XII, a-c) predominates.

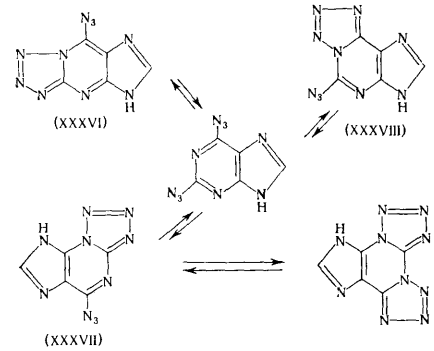


(XII) (XIII)

(a) R_1 = Me, R_2 = H; (b) R_1 = H, R_2 = Me; (c) R_1 = R_2 = Me.

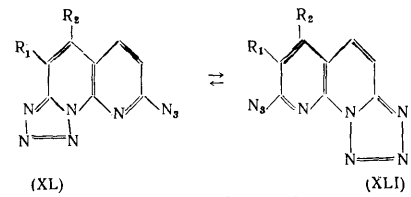
The diazido-forms of the methyl derivatives can be isolated in a pure state only under special conditions; they are metastable at room temperature. At the melting point such diazides are converted into a mixture of the isomeric tetrazoles (XII) and (XIII) which on further heating reforms the diazide. In chloroform solution all three isomers are in tautomeric equilibrium.

Smirnova and Postovskii[137] and Temple et al.[136] showed that, out of the five possible isomeric compounds in the 2,6-diazidopurine system, it is possible to detect 2,6-diazidipurine itself in the crystalline state (and in trifluoroacetic and acetic acids), while in DMSO solution two azidotetrazoles, probably (XXXVI) and (XXXVIII), can be detected in addition to the diazide.



(XXXVI) (XXXVIII) (XXXVII)

The introduction of substituents into the naphthyridine ring of azidotetrazolonaphthyridine leads to the formation of a series of isomeric substituted azidotetrazolonaphthyridines:



(XL) (XLI)

(a) R_1=Me, R_2=H
(b) R_1=H, R_2=Me
(c) R_1=Ph, R_2=H
(d) R_1=H, R_2=Ph

On the basis of a study of chemical properties and infrared spectra, Carboni and coworkers showed that such substances exist in the crystalline state in the form of only one tautomer whose structure was not established. On dissolution, the tautomeric equilibrium (XL) ⇌ (XLI, a-d) arises and the isomer content in such equilibrium is determined by the position of the substituent in the naphthyridine ring relative to the condensed tetrazole ring. When R_1 = Me or Ph, the tetrazole ring is stabilised as a result of conjugation and the isomers (XL, a and c) predominate in the system. When R_2 = Me or Ph, the tetrazole ring condensed with the unsubstituted ring is more stable and the isomers (XLI, b and d) predominate. In the crystalline

state these compounds probably have the structures (XL, a and c) and (XLI, b and d) respectively. Evidence is presented to show that the molecular ions derived from some of these compounds have the ditetrazole structure. Thus pyrolysis of 6-azidotetrazolo[1,5-*b*]pyridazines and 6-azidopyridotetrazolo[1,5-*b*]pyridazines results in the liberation of six nitrogen atoms, which indicates the existence of an intermediate ditetrazole structure[155].

V. INFLUENCE OF SOLVENTS AND TEMPERATURE

The state of the azidoazomethine–tetrazole equilibrium in solutions has been studied in most systems (I, II, VII–XIV, XIX–XXI, XXXVI, XXXVII) using various polar and non-polar solvents: DMSO, d_6-DMSO[33–35,48,61,67,72,86,123,135,136], pyridine[29,33–35,51,87,91,120], acetone, deuterioacetone[33–35,61], dioxan[29,51,87], methanol, deuteriomethanol[33,34,56], dimethylformamide[33,34,67,91,120,131], tetrahydrofuran[67], chloroform, deuteriochloroform[10,16,17,20,29,34,48,51,65,67,68,70,87], carbon tetrachloride[10,16,17,20,29,51,53,87], benzene[29,51,87,91], n-heptane[91], H_2O[70], D_2O[135], NaOD solution[135], acetic acid[114,135,136], TFA[33–35,48,61,65,67,69,101,117,120,135,136], $HF.SbF_5$,[48] and SO_2.[48]

In comparing the action of solvents on various condensed tetrazoles account must be taken in the first place of the stability of the system itself. However, apart from the nature of the annelated nitrogen-containing ring and the electronic structure of its substituents, in solution the stability of the condensed tetrazole ring and of the isomeric azido-derivative or the state of equilibrium between them is in addition greatly influenced by the polarity of the solvent. The dissolution of condensed tetrazoles is frequently but by no means always accompanied by ring opening. On the other hand, a polar solvent sometimes increases the stability of the condensed tetrazole or even promotes the cyclisation of the azide. The constants K_T for the same systems in different solvents are quoted in a review[42]. These data show that a decrease in solvent polarity destabilises the cyclic form and promotes its partial or complete isomerisation to the azide form. When the solvent interacts with the condensed system, for example protonates the second nitrogen atom in tetrazolopolyazines, the azide form is produced.

It has been shown[14,17] that, on dissolution of tetrazolo[5,1-*b*]benzothiazole (II) in concentrated sulphuric acid, TFA, or dimethyl sulphate, the isomeric azido-form is not produced. It is interesting that 2-azido-4-chlorobenzothiazole is converted in the same solvents into the isomeric 8-chlorotetrazolo[5,1-*b*]benzothiazole. In acids this process is accompanied by the protonation of the condensed tetrazole ring and the formation of a tetrazolium salt. With decrease of solvent polarity, compound (II) and its derivatives with electron-donating substituents are partly (in pyridine, acetonitrile, dioxan, and chloroform) or fully (in carbon tetrachloride) converted into the azido-form. The state of tautomeric equilibrium in system (II) depends on the stability of the ring, which is determined by the electronic influence of the substituent and the polarity of the solvent. Thus compound (II) and its derivatives with methyl and methoxy-groups are in equilibrium with the azido-form in acetonitrile, dioxan, pyridine, and chloroform, while in carbon tetrachloride the equilibrium is fully displaced towards the azido-tautomer. The introduction of halogen atoms (F, Cl or Br) into the benzothiazole ring leads to the destabilisation of the tetrazole ring and the consequent full isomerisation to the azide even in acetonitrile[17]. Similar features are observed in the series of thiazolo[2,3-*e*]tetrazoles.

Tetrazolo[5,1-*a*]pyridine (IX) is converted in solutions into the isomeric 2-azidopyridine. However, the introduction in the 6-position of the nitro-group, which destabilises the cyclic system, affects the behaviour of the latter on dissolution. In chloroform, deuteriochloroform, trifluoroacetic acid, and acetone an equilibrium is established between the isomeric azido- and tetrazole forms[28,61,65,88].

The tetrazoloazines (X)–(XIII), which are less stable than compound (IX), exist in solution in polar and non-polar solvents in equilibrium with azides and with decrease of solvent polarity the equilibrium is displaced towards the azido-form. Compound (X), which is the most stable in this series, exists in polar solvents almost completely in the cyclic form[48].

The equilibrium tetrazolo[1,5-*a*]pyrimidine ⇌ 2-azidopyrimidine (XII) is displaced in d_6-DMSO towards the tetrazole tautomer (K_T = 0.07) and with decrease of solvent polarity the content of the azido-form increases with a corresponding increase of the tautomeric equilibrium constant K_T, which is 0.37 in d_6-acetone. In chloroform, which is still less polar, only the azido-form (XII) exists[48].

Owing to the influence of the methyl groups, the stability of the condensed tetrazole ring in the 5,7-dimethyl derivative (XII) is somewhat greater. Therefore only the tetrazole form exists in d_6-DMSO[33,34,48]. With decrease of solvent polarity, there is a similar shift of the equilibrium towards the azide and an increase of K_T, which is 0.12 in d_6-methanol, 0.14 in pyridine, and 0.36 in deuteriochloroform[33,34]. The last value of K_T corresponds to the ratio tetrazole:azide = 1 : 3.[48] When a 6.8% chloroform solution of compound (XII) is diluted to 5.4% with the polar d_6-DMSO, K_T diminishes from 0.36 to 0.1 owing to the increase of the content of the tetrazole form in the system[33,34]. A similar influence of the solvent has been observed also for other substituted tetrazolo[1,5-*a*]pyrimidines[48].

It has also been shown[35,48] that in the tetrazolo[1,5-*c*]-pyrimidine ⇌ 4-azidopyrimidine (XIII) system with electron donating substituents in the pyrimidine ring the tetrazole ring is destabilised to a greater extent in the less polar d_6-acetone, pyridine and deuteriochloroform than in d_6-DMSO. For example, the ratio of the azide form (XIII) and the tetrazole form of the 7-methyl-5-methylthio-derivative is 1 : 16 in deuteriodimethyl sulphoxide and 5 : 1 in deuteriochloroform[48].

Postovskii and coworkers showed that in solutions in alcohol, dimethylformamide (DMF), and benzene 6-phenyltetrazolo[5,1-*c*]tetrazine (XIV) is in equilibrium with the azido-form (4 : 1, 1 : 1 and 2 : 3 respectively).[91] It has also been shown[47,67,90] that, on dissolution in chloroform, tetrahydrofuran, and trifluoroacetic acid, 5,6-diphenyltetrazolo[1,5-*c*]-1,2,4-triazine is in equilibrium with the azido-tautomer.

Temple's studies have shown that, on dissolving 2-azidopurine in d_6-DMSO, a system is produced in which the azido-tautomer is in equilibrium with two tetrazolopurines, (XXXVI) and (XXXVIII), in proportions of 3 : 6 : 1 respectively[94]. Similarly the dissolution of 6-amino-2-azidopurine in DMSO results in a system with the azido-form and the tautomers (XXXVI) and (XXXVIII) in proportions of 1 : 9.5 : 2.

In TFA the majority of tetrazoloazines exist in the azido-form or the latter predominates in the tautomer mixture, despite the fact that TFA can be classified as a polar solvent. This is probably a result of the protonation of the nitrogen atom of the heterocyclic base condensed

with the tetrazole ring or sometimes possibly of the substituent capable of being protonated. The positive charge is delocalised over the entire heterocycle and the electron-donating capacity of the latter, which favours the existence of the tetrazole form, diminishes.

Postovskii and coworkers[27] established that the hydrochloride and picrate of 7-piperidinotetrazolo[1,5-*c*]pyrimidine exist virtually as the azide in the crystalline state, while the base is in the tetrazole form. This example rules out the influence of solvation in this instance on the state of the azideazomethine–tetrazole equilibrium and apparently indicates an effect of protonation.

The studies of Postovskii and coworkers[29,51], Temple and coworkers[33-35,135], Sasaki et al.,[61] and Stanovnik and coworkers[72,123] showed that the transformation of the tetrazole form into the azido-form is an endothermic process and its heat is in the range 1–7 kcal mole^{-1}, a slight increase of temperature displacing the equilibrium towards the azido-form. This is indicated by the increase of the equilibrium constant, the increase of the intensity of the azide band observed in the infrared spectrum, and the decrease of that of the tetrazole bands. Similar features are shown also by the NMR spectra. The study of the pyrolysis of condensed tetrazoles in the gas phase by mass spectroscopy revealed that the first stage in the pyrolytic process is the tautomeric transformation of the tetrazole into the azide[48]. The opening of the tetrazole ring to form the azide with increase of temperature and ring closure to convert the azide into the tetrazole on reducing the temperature to the previous value can occur in both the crystalline state and in solution. The most stable tetrazolo[1,5-*a*]pyridine (IX) and tetrazolo[1,5-*b*]-pyridazine (X) do not isomerise to the corresponding azides on raising the temperature to 140°C.[48]

Postovskii and coworkers[29,51] showed for the first time that in the melt tetrazolo[1,5-*c*]benzothiazole (II) exists in equilibrium with the azido-tautomer. Wentrup[48] noted an interesting transformation of the azide at [above] its melting point into the [solid] tetrazole, which in turn is reconverted into the azide on fusion. On raising the temperature, the labile tautomeric azides, isolated under special conditions[48,133], undergo ring closure to the more stable tetrazole form (in solution or in the crystalline state).

Very low temperatures (obtaining in liquid SO_2) proved to be suitable for the preservation of the labile azido- and tetrazole tautomers[48].

---o0o---

The tetrazole ring condensed with a nitrogen-containing heterocycle is in many instances readily cleaved at the $N_{(1)} - N_{(2)}$ bond with formation of the isomeric azidoazomethine derivative. Such transformations in the series of condensed tetrazoles do not require the expenditure of much energy. Therefore isomerisation frequently occurs on dissolution, heating, and sometimes after prolonged storage of condensed tetrazoles. A tautomeric equilibrium between the cyclic tetrazole and the open-chain azido-forms is frequently established as a result of such transformations and can occur in the crystalline state, in the melt, and in solution. The stability of the condensed tetrazole and the isomeric azido-form or the state of equilibrium between them is determined by the nature of the nitrogen-containing heterocycle with which the tetrazole ring is condensed and by the electronic nature of the substituent in the former, solvent polarity, pH of the medium, and temperature.

Hetarylformazans†

N.P.Bednyagina, I.Ya.Postovskii, A.D.Garnovskii, and O.A.Osipov

The literature data on the synthesis, structure, and properties of formazans containing heteroaromatic substituents (hetarylformazans) have been reviewed and arranged sytematically. Hetarylformazans have been compared with arylformazans in characteristic reactions such as oxidation to tetrazolium salts, alkylation, and conversion into stable verdazyl radicals. Special attention has been devoted to the coordination chemistry of formazan-containing systems and to the consideration of the characteristic features introduced by hetaryl substituents into the structure of the complexes. Various aspects of the practical applications of hetarylformazans and their derivatives (dyes, bioindicators, ligands, analytical reagents) and the prospects for the development of their chemistry have been examined.
The bibliography includes 221 references.

I. INTRODUCTION

Formazans[1-5] are compounds with the characteristic azohydrazone group

The compounds unsubstituted in the 1- and 5-positions and also 1,5-dialkylformazans are so far unknown. The 3-position (the *meso*-position) can contain various substituents (hydrogen, alkyl, aryl, hetaryl, halogens, CN, SH, OH, etc.).

Aromatic formazans—1,5-diphenyl and 1,3,5-triphenyl derivatives—were first described by von Pechmann and Bamberger in 1892.[1,2] However, the chemistry of formazans and the tetrazolium salts obtained from them did not begin to develop vigorously until the 1940s when Kuhn and Jerchel[6] found applications for tetrazolium salts in biochemistry and histology as indicators for oxidation-reduction processes. The successful use of formazans as dyes[3,5], ligands in complex formation reactions[7-12], and analytical reagents[5] played an important role in the development of the chemistry of formazan-containing systems.

While arylformazans have been known since the end of the past century, the first representative of hetarylformazans was described in 1951 by Ludolfy[13], who synthesised a $C_{(3)}$-substituted formazan of the pyridine series by combining a diazonium salt with uracil-4-aldehyde. However, this synthesis constituted merely an episode in a series of studies on the preparation of arylformazan derivatives and a series of systematic studies on heterylformazans was initiated by the investigations of Ried and coworkers[14-18]. These studies were stimulated by the search for blue formazans and new tetrazolium salts which might serve as indicators for the investigation of redox processes in blood[17-21]. Subsequently valuable dyes, analytical reagents, ligands, and other practically important compounds were found among hetarylformazans. All these factors led to a considerable development of the chemistry of hetarylformazan systems. During the last fifteen years (mainly in 1963–1972), more than 200 studies were published on the synthesis, physicochemical properties, structure, complex-forming capacity, and analytical applications of hetarylformazans. This review deals with these studies and includes the literature up to 1974.

† We have given the name hetarylformazans to formazans containing heteroaromatic substituents in the 1-, 5-, or 3-positions in the formazan group.

II. SYNTHESES OF HETARYLFORMAZANS

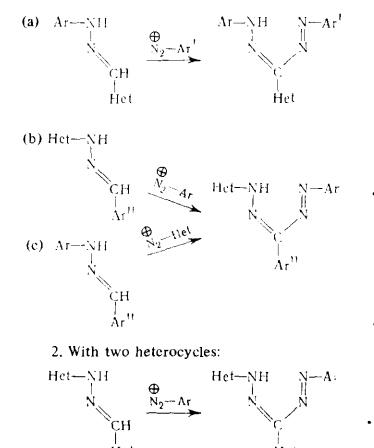
1. The Coupling of Diazo-compounds with Hydrazones (Ried's Method)[1]

The most widely used method for the synthesis of formazans is the coupling of diazonium salts with hydrazones in an alkaline medium[1-5]. Ried developed an amost exhaustive scheme of synthetic pathways for all possible hetarylformazans based on the coupling of aryl- or hetaryl-diozonium salts with various hydrazones (Scheme 1).

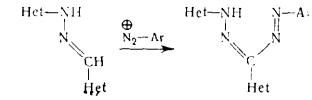
Scheme 1

Ried's syntheses of hetarylformazans

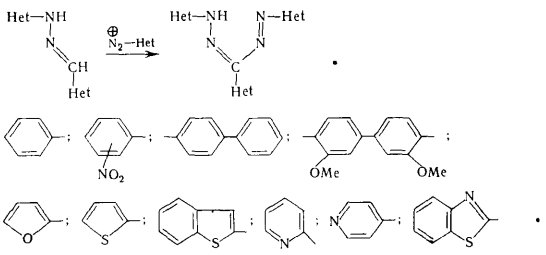
1. With one heterocycle:



2. With two heterocycles:

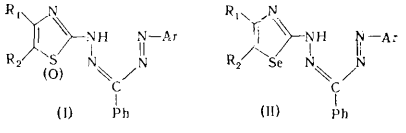


3. With three heterocycles:



The syntheses of formazans containing a heterocycle at the meso-carbon atom, i.e. based on heterocyclic aldehydes (method 1 in Ried's scheme), were developed further. Thus, in order to investigate the biological activity of formazan and tetrazolium salts, Cottrell et al.[22] obtained a group of formazans containing 4-pyridyl, 2-furyl, and 2-phenyl-2,1,3-triazolyl substituents in the *mesc*-position. Pyridine derivatives were synthesised to test them as potential antitubercular agents, since there is some structural similarity between 3-pyridylformazans and 5-pyridyltetrazolium salts on the one hand, and isonicotinic acid hydrazide (isoniazide) on the other.

The syntheses of 1-hetarylformazans developed extensively on the basis of Ried's studies (methods 1b and 2 in Scheme 1). Beyer, Pyl, and coworkers[23-26] described 1-azolylformazans containing thiazole, oxazole (I), and selenazole (II) residues. In their study of the properties of heterocyclic hydrazino-derivatives, they synthesised benzylidenehydrazones and then, via coupling the latter with aryldiazonium salts, they obtained formazans. 1-Thiazolylformazans were also obtained by specific synthesis from thiazolyldiazonium salts and aromatic hydrazones:

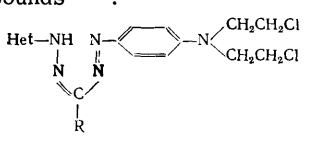


R_1 and R_2 = H, Me, Ph; R_1 = Ph, Me; R_2 = Ph, COOEt

In the study of formazans of this type, the main aim was the preparation of tetrazolium salts suitable for the investigation in enzymohistology.

In order to study the relation between the structure and properties of formazan-containing systems, 1-(1-alkylbenzimadazol-2-yl)-3-methyl-5-phenylformazans with different substituents in the benzene ring[27], 1-benzothiazolyl- and 1-benzoxazolyl-formazans[28-31], and also derivatives containing tetrazole[32-36], triazole[37], or naphthothiazole[38, 39] residues in the 1-position of the formazan group were obtained.

Heterocyclic formazans containing cytotoxic and bis-(β-chloroethylamino)-groups were obtained as potential antitumour compounds[40-41]:

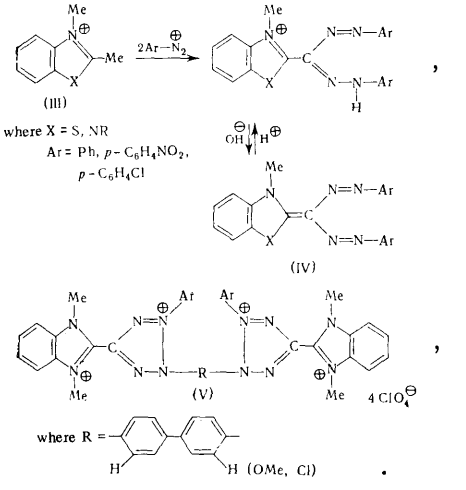


where Het = phenyltetrazolyl, 1-methylbenzimidazol-2-yl, or 1,5,6-trimethylbenzimidazol-2-yl and R = Me or Ph.

To investigate their antibacterial and complex-forming properties, formazans derived from benzimidazole with a sulphamoyl group in the phenyl substituent were synthesised[42]. 1-Benzazolyl-3-methyl-5-phenylformazans containing a sulpho-group in the phenyl residue, introduced to increase the solubility of the compound in water, can be used as analytical reagents[43]. 1-Hetaryl-3,5-diphenylformazans (hetarylthiazoloyl, benzothiazolyl, α-pyridyl, nitropyridyl, and other derivatives) were synthesised and investigated[44-46] as reagents for the determination of a number of metal ions. A series of 1-benzothiazolyl-3,5-diphenylformazans with halogeno-, methyl, and alkoxy-groups as substituents in the 6-position of the heterocyclic ring were synthesised for this purpose[47,48].

2. Azo-coupling with Compounds Containing an Active Methyl Group (the Wahl-Le Bris Method[3])

3-Hetarylformazans can be synthesised not only from aldehydes, but also from heterocycles in which the methyl group has been activated by the quaternisation of the nitrogen atom of the heterocycle[3]. Thus Wahl and Le Bris[49-52] used in the synthesis of 3-benzazolylformazans the quaternary ammonium salts of 2-methylbenzothiazole or 2-methylbenzimidazole (III), which yielded hydrazones (one mole) or "pseudoformazans" (IV) (2 moles) on coupling with diazonium salts. In an acid medium the pseudoformazans exhibited all the properties of formazans, gave rise to deeply coloured chelate complexes with metals, and on oxidation were converted into colourless tetrazolium salts. Bisformazans, obtained by the successive coupling of 1,2-dimethylbenzimidazolium methiodide, initially with phenyldiazonium salts and then with bisdiazobenzidine, had a blue colour and were readily oxidised to colourless bistetrazolium salts (V).[53,54] The authors proposed these salts as histochemical reagents.



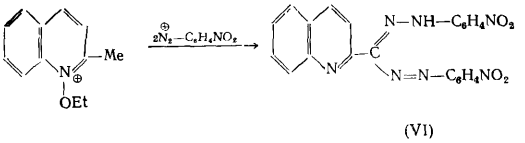
where X = S, NR; Ar = Ph, p-$C_6H_4NO_2$, p-C_6H_4Cl

(IV)

(V)

where R = H (OMe, Cl)

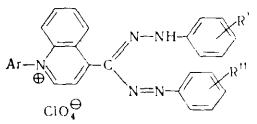
Using the mobility of the hydrogen atoms in the α-methyl groups of the heterocycles (the Porai-Koshits rule), Mishina and Efros[55] obtained a group of 3-hetarylformazans (VI). The quaternary salts of quinaldine or lepidine N-oxide were introduced into the azo-coupling reaction:



(VI)

The ability of the quaternary salts of *N*-oxides to enter into the azo-coupling reaction depends on the structure and basicity of the heterocycle. Thus the quaternary salts of α- and γ-picoline *N*-oxides proved to be incapable of reacting in this way. 9-Methylacridine and its *N*-oxide form only the hydrazone on coupling with diazonitroaniline, while 9-methylphenanthridine is readily converted into 3-phenanthridinylformazan[55].

Pilyugin and coworkers[56-62] synthesised and investigated a series of 3-hetarylformazans (VII). 1-Aryl-lepidinium or arylquinaldinium perchlorates undergo azo-coupling with various diazo-compounds, yielding formazans. On the other hand, the reaction with 1-alkyl-lepidinium salts stops at the hydrazone stage. The structure of the resulting formazans (VII) was demonstrated by the stepwise synthesis of asymmetric formazans (R′ ≠ R″):

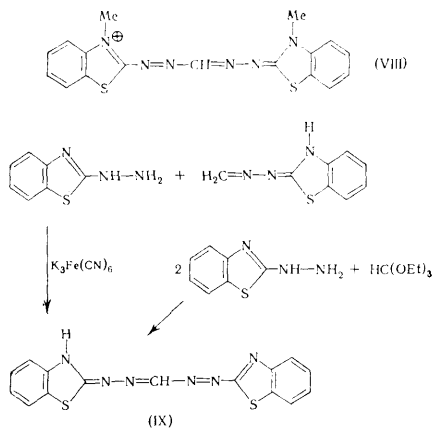


(VII) ,

where R′ and R″ are groups with different electronic effects in the *ortho*-, *meta*-, or *para*-positions.

3. Oxidative Azo-coupling (the Hünig Method[63])

Symmetrical 1,5-dihetarylformazans, which are missing from Ried's scheme, appeared at the beginning of the 1960s. Hünig quotes the synthesis of 1,5-dibenzothiazolylformazan as an example of oxidative azo-coupling. The Hünig reaction is based on the fact that, in an acid medium in the presence of $K_3Fe(CN)_6$ as an oxidant, amidrazone systems (hydrazine derivatives in the hydrazone form) can undergo the electrophilic coupling reaction with azo-components, forming azodyes, or tetraazapentamethine-cyanine dyes (VIII). Numerous studies by Hünig and coworkers, begun in 1957, have been summarised in a review[63]:



In 1963 Hünig[64] obtained the product of the oxidative coupling of 2-hydrazinobenzothiazole and its formaldehyde hydrazone (IX), which was called 1-(benzothiazol-2-yl)-5-(benzothiazolin-2-ylidene)-1,2,4,5-tetraazapenta-1,3-diene. The structure of the compound was demonstrated by a specific synthesis from 2-hydrazinobenzothiazole and orthoformic ester. However, Hünig does not describe studies on the tautomerism and properties of this compound in relation to the properties of formazans and hence its characteristics as a 1,5-dibenzothiazolylformazan.

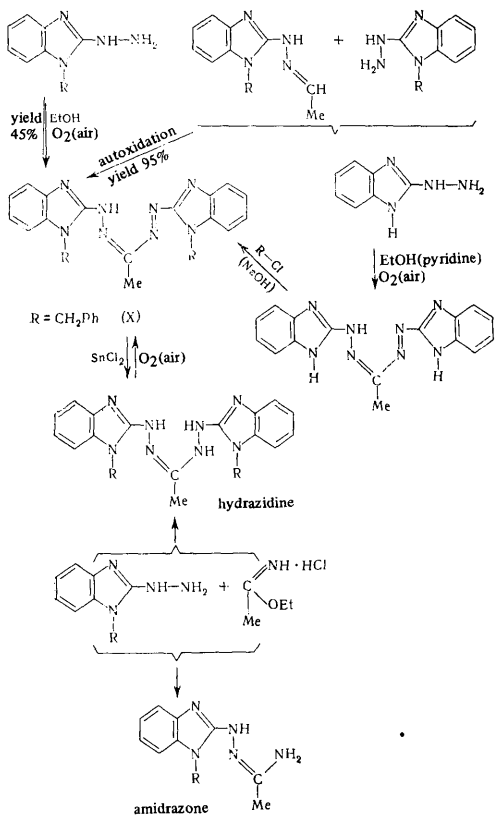
4. Autoxidation of Hetarylhydrazines (the Bednyagina–Postovskii Method[66,70])

Simultaneously with Hünig's studies, the syntheses of 1,5-dibenzimidazoylformazans were described. It was observed in 1960 [65] that alcoholic solutions of 1-alkyl-2-hydrazinobenzimadazoles become dark-violet in air and on standing give rise to large violet crystals of unknown dyes with a green lustre. In the study of the molecular structures of the dyes considerable difficulties arose owing to their ability to form stable solvates with water and alcohol. On varying the 1-alkyl-2-hydrazinobenzimidazoles employed (alkyl = methyl, ethyl, benzyl, or phenyl) and the primary alcohols taken for the autoxidation (methanol, ethanol, and 1-butanol), a series of dyes were obtained. The involvement of the alcohol in the formation of the dye molecule was established and it was shown that the dyes have the structure of the hitherto unknown 1,5-di-(1-alkylbenzymidazol-2-yl)-3-alkylformazans[66]. The autoxidation probably involves several reactions with different mechanisms. Thus oxygen is absorbed rapidly (in the first 30 min) and the colour develops slowly (in 24 h). The rate-limiting stage (the autoxidative coupling) is nucleophilic, since it is catalysed by bases (pyridine) and is inhibited by Lewis acids. Thus, despite its outward similarity to the Hünig reaction, the autoxidation reaction differs significantly from it as regards conditions and mechanism.

The first group of symmetrical 1,5-dibenzimidazolylformazans containing an alkylated or arylated benzimidazole ring was described in 1964.[66,67] 2-Hydrazinobenzimidazole unsubstituted at the nitrogen atom is more acidic and resistant to autoxidation. Formazans based on it can all be obtained by autoxidation in an alcohol–pyridine medium[68]. Formazans unsubstituted at the *meso*-carbon atom have been obtained in two ways to confirm their structure: by autoxidation in methanol and by condensation of hetarylhydrazines with orthoformic ester[66,67]. One of the alkyl-substituted formazans, namely 1,5-di-(1-benzylbenzimidazol-2-yl)-3-methylformazan (X), was obtained by several independent syntheses (Scheme 2), in addition to the autoxidation reaction, which left no doubt about its structure[69,70]. When 1-benzyl-2-hydrazinobenzimidazole was allowed to react with the hydrochloride of acetimidoethyl ether, colourless products—a hydrazidine (in the presence of a deficiency of the iminoether) and an amidrazone (for a 1 : 1 reactant ratio)—were isolated (similarly to the reaction in the series of arylhydrazines[71,72]) in addition to the formazans. It was shown that, the formazan ⇌ hydrazidine oxidation-reduction transitions take place fairly readily.

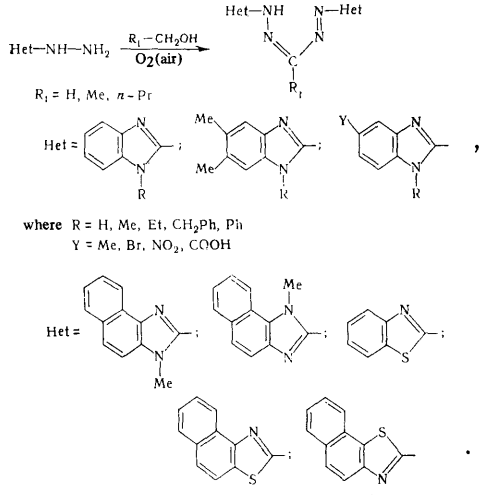
Scheme 2

Syntheses of 1,5-di(1'-benzylbenzimidazol-2'-yl)-3-methylformazan



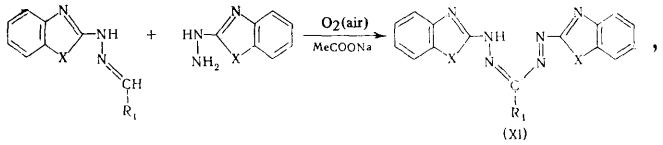
Scheme 3

Synthesis of 1,5-dibenzazolylformazans and 1,5-dinaphthazolylformazans



Other hydrazinobenzazoles or hydrazinonaphthazoles are also capable of spontaneous oxidation and conversion into the corresponding 1,5-dibenzazolylformazans or 1,5-dinaphthazolylformazans (Scheme 3). Thus 2-hydrazinonaphtho[1,2-*d*]imidazole and its 1-methyl- or 3-methyl-substituted derivatives yielded the corresponding 1,5-dinaphthimidazolylformazans in methanol, ethanol, or 1-butanol solutions[73]. 1,5-Di{naphtho[2,1-*d*]thiazolyl}-3-methylformazan was obtained from 2-hydrazinonaphtho-[2,1-*d*]thazole in ethanol[38]. The autoxidation of 2-hydrazinobenzimadazoles substituted in the 5-position proceeds smoothly. 1,5-Di-(1-benzylbenzimazol-2-yl)-3-methylformazans containing methyl, bromo-, methoxy-, nitro-, or carboxy-groups in the benzene rings were obtained in this way[74]. On autoxidation in ethanol, 2-hydrazino-1,5,6-trimethylbenzimidazole or 1-benzyl-2-hydrazino-5,6-dimethylbenzimadazole give rise to beautiful large violet crystals of 1,5-di[1,5,6-trimethylbenzimadazol-2-yl]3-methylformazan or 1,5-di-[1'-benzyl-5,6-dimethyl-benzimadazol-2-yl]-3-methylformazan[75,76].

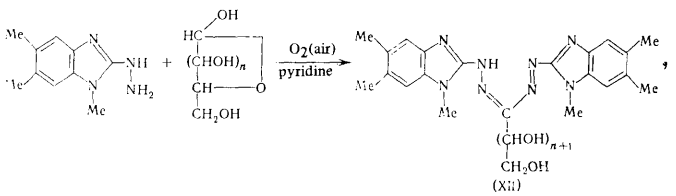
The yields of formazans do not usually exceed 40%. Deeply coloured resins are formed as side products. 1-Alkylbenzimidazoles can be always isolated in 10% yield from the colourless products of the autoxidation of 1-alkyl-2-hydrazinobenzimidazoles. In autoxidation in an alkaline medium (NaOH, pH > 10) nitrogen is evolved and the yield of 1-alkylbenzimidazole rises to 50%. Since 1-alkyl-benzimidazolones were not detected among the side products, the formation of an intermediate diazohydrate appears to be unlikely. It is suggested that 2-benzimidazolyldi-imine and a hydrazone, produced as a result of the oxidation of the alcohol to the aldehyde, are formed as intermediates[70]. The experimental observation that 1-alkyl-2-hydrazinobenzimidazole and its hydrazone with acetaldehyde, taken in equimolecular proportions, give rise to a formazan in a nearly quantitative yield constitutes convincing proof that the autoxidation reaction proceeds via a stage in which a hydrazone is produced. This reaction was extended to other heterocyclic and aromatic hydrazones. A convenient method for the synthesis of 1,5-dibenzalolylformazans (XI) was developed[77]. It consists in the joint autoxidation of 2-hydrazinobenzazoles with their aldehyde-hydrazones in solution in the alcohol corresponding to the aldehyde to which sodium acetate had been added:



where R_1 = H, Me, or n-Pr and X = NH, NMe, NEt, NCH_2Ph, NPh, or S.

In certain cases it is possible to employ a version of the method which involves the joint autoxidation of the hydrazino-derivative and the aldehyde, without the isolation of the intermediate hydrazone, in pyridine solution.

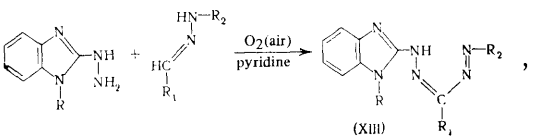
Symmetrical benzimidazolylformazans (XII) containing sugar residues in the 3-position were obtained in this way[78]. The formazans are of interest as structural fragments of vitamin B_{12}:



(XII)

where the sugar is D-ribose, L-arabinose, or glucose.

1-Alkyl-2-hydrazinobenzimidazoles, which undergo autoxidation particularly readily, can undergo autoxidative coupling in pyridine–water solutions with a wide variety of hydrazones, including aromatic hydrazones[79]. Mono-, di-, and tri-hetarylformazans (XIII), including asymmetric formazans, containing various benzazole residues in the 1- and 5-positions (benzimidazole–benzothiazole or benzimidazole–benzoxazole) were obtained in this way:



(XIII)

where R_1 = Me, Ph, or quinoxalin-2-yl and R_2 = Ph, p-$C_6H_4NO_2$, benzothiazol-2-yl, benzoxazol-2-yl, or 1-phenyltetrazol-5-yl.

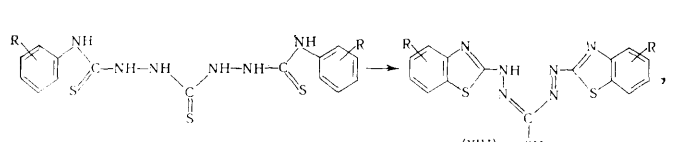
Symmetrical benzazoyl formazans containing the phenyl group in the 3-position were synthesised in the same way[80]. However, autoxidative coupling of 1-benzyl-2-hydrazinobenzimidazole with arylhydrazones of nitroformaldehyde led to the formation of 1-(1-benzylbenzimidazol-2-yl)-5-arylformazans unsubstituted at the *meso*-carbon atom instead of the expected 3-nitroformazans[81].

Thus the syntheses of 1-hetaryl- or 1,5-dihetarylformazans can be based on 2-hydrazinobenzimidazoles, 2-hydrazinobenzothiazoles, or the corresponding naphtho-derivatives, which are all capable of autoxidation. The range of hydrazines capable of autoxidation can probably be extended.

5. Other Methods

Formazans containing non-aromatic heterocycles in the 3-position can be obtained by the introduction of the heterocycle into the finished formazan. Thus, 3-piperidinyl- and 3-morpholinyl-formazans were synthesised from 3-chloro-1,5-diphenylformazan[82] and pyrrolidino-, piperidino-, and morpholino-methyl derivatives were obtained from arylformazans[83] or 1,5-dibenzimidazolylformazans[67] unsubstituted in the *meso*-position.

Pel'kis and coworkers[84,85] obtained 1,5-dibenzothiazol-yl-3-mercaptoformazans (XIV) by the closure of the benzothiazole ring in the almost completed formazan molecule:



(XIV)

where R = H, Me, OEt, or Cl.

The oxidative cyclisation of 1,5-di(phenylthiocarbamoyl) thiocarbonyldihydrazides was carried out in alcoholic alkaline solutions by treatment with potassium hexacyanoferrate(III). The compounds obtained are deeply coloured crystalline substances (λ_{max} = 530–550 nm). They can exist in several tautomeric forms, but on methylation with methyl iodide they give rise to *S*-methyl derivatives. 1,5-Dibenzothiazolyl-3-mercaptoformazan is of interest as the first heterocyclic analogue of dithizone described in the literature.

It follows from the data quoted above that reliable methods have now been developed for the preparation of $N_{(1,5)}$ and $C_{(3)}$-substituted hetarylformazans. Methods involving the coupling of diazo-compounds with hydrazones and the autoxidation of hetarylhydrazines are the most general for the synthesis of hetarylformazans. While the former method is convenient for the preparation of 1(5)-hetaryl- and 1,3-dihetaryl-formazans, the latter can be used to synthesise symmetrical 1,5-dihetarylformazans. At the same time a modification of the second method, making use of the capacity of the readily oxidised hydrazinobenzazoles to undergo oxidative coupling with hydrazones[79], makes it possible to obtain asymmetric formazans, and, what is particularly important, derivatives with various heterocycles in the 1- and 5-positions of the formazan group.

The Wahl–Le Bris and Hünig methods are of limited applicability: the former can be used to prepare $C_{(3)}$-hetaryl-substituted derivatives and the latter is mainly employed for the synthesis of *NN*-dihetaryl-substituted formazans.

Five-membered monoheteraromatic systems (thiophen, furan), six-membered heterocycles (pyridine, quinoline, azines[86,87]), azoles, and their benzo-analogues have been introduced into the formazan group as hetaryl substituents.

III. THE STRUCTURE OF FORMAZANS

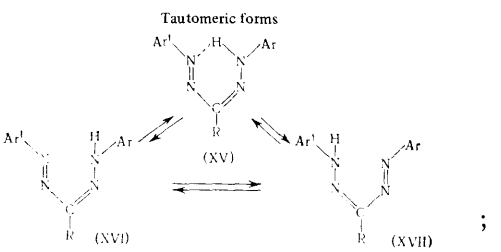
1. Arylformazans

A number of studies have been made on the tautomerism, stereoisomerism, and the state of the hydrogen bond in arylformazans[88–95]. Special studies have been carried out on the infrared spectroscopy of arylformazans[96–106], including a systematic comparative investigation of the infrared spectra of triarylformazans in relation to hydrazones, tetrazolium salts, complexes, and verdazyl radicals[102–104]. The relations between the structure and colour of formazans have been studied[107,108]. Quantum-mechanical calculations on the π-electron systems and the electronic spectra of formazans have been published[109–114].

The isomerism of arylformazans presupposes the existence of three tautomeric (XV–XVII) and four stereoisomeric (XVIII–XXI) forms (*cis-trans* with respect to the N–N bond and *syn-anti* with respect to the C–N bond) (Scheme 4).

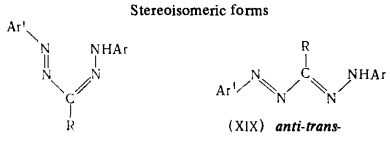
Scheme 4

Tautomeric forms



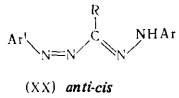
(XV) (XVI) (XVII)

Stereoisomeric forms

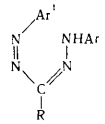


(XVIII) *syn-trans*

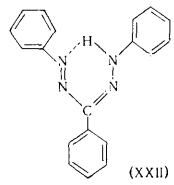
(XIX) *anti-trans-*



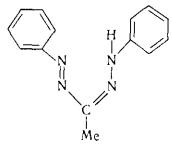
(XX) *anti-cis*
(R = Ph; Me; H)



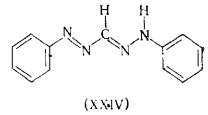
(XXI) *syn-cis*



(XXII)



(XXIII)



(XXIV).

The structure of the formazan chain is influenced significantly by the substituent R in the *meso*-position. The phenyl group usually promotes the fixation of the chelate form. The alkyl substituent (other than t-butyl[115]) weakens the hydrogen bond and leads to the opening of the chelate ring, while hydrogen stabilises the *anti-trans*-structure.

Triphenylformazan has a quasiaromatic chelate ring (XXII) with a strong intramolecular hydrogen bond[88,93,94,116], which is confirmed by the absence of the ν(NH) band in the region 2500–3200 cm^{-1} from the infrared spectra of both crystals and solutions.

The ring is so stable that it is not opened even in alkaline medium although the introduction of a nitro-group in the 1- or 5-position in the phenyl group leads to a weakening of the intramolecular hydrogen bond, which is manifested in a capacity to be converted into the sodium salt[108]. The (XVI) $\rightleftharpoons$ (XVII) tautomerism of such asymmetric formazans has been demonstrated by an isotopic method[117].

3-Methyl-1,5-diphenylformazan has an "open" structure, is more coloured than triphenylformazan [λ_{max} = 430 nm for (XXIII) and 494 nm for (XXII)], its infrared spectrum contains the ν(NH) band (3360 cm^{-1} in chloroform), and it readily forms a sodium salt in solution[2]. According to Zeif et al.[111], it has the *cis-trans*-configuration in solution without an intramolecular hydrogen bond [structure (XXIII)].

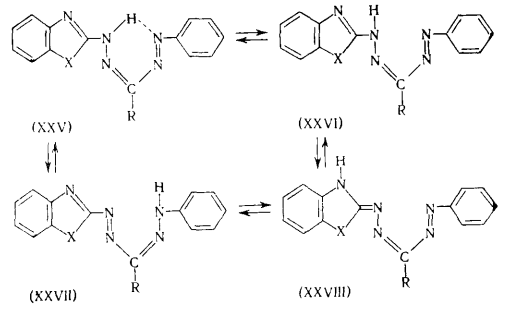
The configuration of the molecule and the nature of the hydrogen bond in diphenylformazan were recently determined by X-ray diffraction[118]. It was found that in the crystalline phase diphenylformazan has an open *anti-trans*-structure with intermolecular hydrogen bonds; according to other data[110,111], diphenylformazan retains the *anti-trans*-structure (XXIV) also in solutions.

Triphenylformazan has the chelate *syn-trans*-structure (XXII) both in solutions and apparently in the crystalline state. This is indicated by the experimental hydrogen bond energies[119] (7 kcal $mole^{-1}$ for triphenylformazan and 2.7 kcal $mole^{-1}$ for diphenylformazan) determined experimentally from the heats of combustion and also from the electronic spectra[111] and the calculation of the energy of the stabilisation of the ring by the hydrogen bond in solution (8.7 kcal $mole^{-1}$).

2. Hetarylformazans

The structure of 1-benzazolylformazans has been studied systematically in the series of hetarylformazans[27-31,108-112,120-122]. The number of possible tautomeric and isomeric forms in the series of hetarylformazans is greater than in the aromatic series. Thus the tautomeric forms (XXV)–(XXVIII) (Scheme 5) are possible for the asymmetric 1-benzazolyl-5-phenylformazans. On the other hand, the number of theoretically possible stereoisomers increases to 16 (on the assumption that the molecule is coplanar). Among these, account has been taken[110,111] of the most probable *syn-trans*- (with or without allowance for the intramolecular hydrogen bond) and linear *anti-trans*-structures.

Scheme 5



(XXV) (XXVI) (XXVII) (XXVIII).

The state of tautomeric equilibrium involving benzazolylformazans depends both on the *meso*-substituent and on the nature of the heterocycle (acidity, basicity, aromaticity) (Table 1).

Table 1. Spectroscopic characteristics and acid pK_a values of 1-benzazolyl-3-R-5-methylformazans.

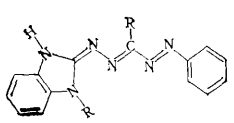
Compound	X	R	ν(NH), cm^{-1} (in CCl_4)	λ_{max}, nm (in n-heptane)	pK_a
(XXIX)	N—$CH_2C_6H_5$	Me	3450	452	12.5
(XXX)	N—$CH_2C_6H_5$	Ph	3445	454	12.1
(XXXI)	S	Ph	absent	492	11.1
(XXXII)	O	Ph	absent	475	11.2
(XXXIII)	S	Me	3450; 3360	445	9.1
(XXXIV)	O	Me	3450; 3370	415	9.7

The ν(NH) bands in the infrared spectra have been assigned on the basis of experimental[109,120] and calculated[110] (Hückel's molecular orbital method) data [correlation between π-electronic charge on the nitrogen atom linked to the proton and the ν(NH) wavenumber]: the high-frequency band (~3450 cm^{-1}) was assigned to the imino-form (XXVIII) and the low-frequency band [~3360 cm^{-1}, coinciding with ν(NH) for 3-methyl-1,5-diphenylformazan] was assigned to the amino-form (XXVI). The ν(C=N) infrared bands, with wavenumbers in the range 1510–1630 cm^{-1} for the chelate forms of formazans and 1555–1580 cm^{-1} for the open-chain forms[103,110,112], are also striking [following Kukushkina et al.[105] these bands were assigned to ν_{as}(–N=C–N)].

The long-wavelength band in the visible spectrum in the range 400–500 cm ($\pi \rightarrow \pi^*$ transition) constitutes a convenient criterion for the comparison of the structures of formazans. In the series of benzazolylformazans the chelate forms (XXXI) and (XXXII) have a deeper colour to the extent of 50–60 nm (Table 1) than the corresponding open-chain forms (XXXIII) and (XXXIV). It has been established[110,111] that in the spectra of formazans with the *anti-trans*-configuration this band exhibits a higher extinction, although it is displaced towards shorter wavelengths compared with the chelate forms.

Calculations (by the Pariser–Parr–Pople method) on the π-electron system of formazans (XXIX)–(XXXIV),[111,112] comparison of the experimental and calculated spectra (the energies and oscillator strengths of various electronic transitions), and the determination of the relations between the reactivity indices, the spectra, and the properties of formazans led to the following conclusions.

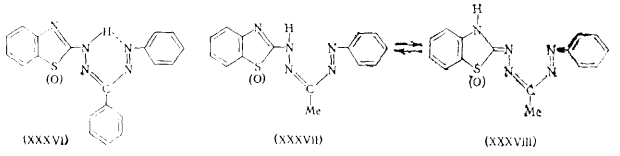
(a) Regardless of the *meso*-substituent, 1-benzimidazolyl-3-methyl(phenyl)-5-phenylformazans (XXIX) and (XXX) have (in heptane, dioxan, and carbon tetrachloride) the open-chain imino-structure and the *anti-trans* chain configuration (XXXV).



(XXXV)

The exceptional behaviour of 1-benzimidazolylformazans (the lack of an effect of the *meso*-substituent on the tautomeric shift) has been explained by the greater basicity of benzimidazole and a tendency towards the transition to imino-systems with an exocyclic double bond.

(b) Benzothiazolyl- and benzoxazolyl-formazans (XXXI)–(XXXIV) exhibit the behaviour discovered in the series of arylformazans, i.e. compounds (XXXI) and (XXXII) with a phenyl substituent in the *meso*-position have a chelate structure, like triphenylformazan. In heptane they assume the *syn-trans*-amino-configuration (XXXVI) with a weak intramolecular hydrogen bond, which dissociates even as a result of the solvating action of solvents [ν(NH) = 3200 cm^{-1} in dioxan]. A *syn-trans*-configuration with a rapid proton transfer and equilibrium between the amino- and imino-forms (XXXVII) $\rightleftharpoons$ (XXXVIII), is characteristic of the formazans (XXXIII) and (XXXIV) with the methyl group in the *meso*-position in heptane or carbon tetrachloride solutions:



(XXXVI) (XXXVII) (XXXVIII)

The changes in acidity[120] are consistent with the above conclusions. As was to be expected, the benzimidazolylformazans (XXIX) and (XXX) have pK_a values of the same order of magnitude (Table 1). In the series of benzothiazolyl- and benzaxolyl-formazans (XXXI)–(XXXIV) the proton mobility depends on the *meso*-substituent. Hydrogen bound in the intramolecular hydrogen bond is less mobile and the chelate formazans (XXXI) and (XXXII) differ from the non-chelate forms (XXXIII) and (XXXIV) by having an acid strength weaker by one–two orders of magnitude (Table 1). The *meso*-substituent has similar effects on the structure of the formazan chain in 5-aryl-1-(1-phenyltetrazolyl)formazans[32,35] and 1-naphthothiazolyl-5-phenylformazans[38,39]

The influence of the nature of the heterocycle on the colour of 1-hetarylformazans is different in the series of "open-chain" and chelate structures[70]. The colour of the "open-chain" 1-benzazolyl-3-methyl-5-phenylformazans (in benzene or heptane) depends on the basicity of the heterocycle, while in chelate formazans the determining factor is the aromaticity of the heterocycle. Formazans with the chelate structure have in general a deeper colour than those with an "open-chain" structure (Tables 1 and 2).

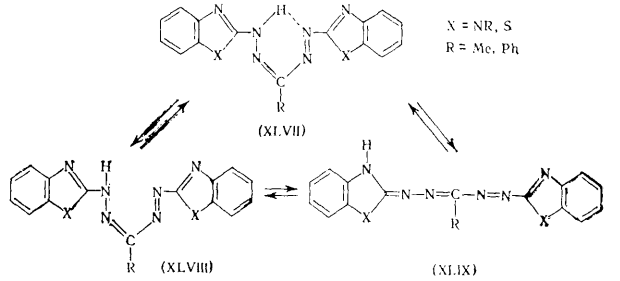
Table 2. Characteristics of 1-benzazolyl-3-R-tolylformazans.

Compound	R	X	Tolyl	M.p., °C	ν(NH), cm^{-1} (in CCl_4)	λ_{max}, nm (in alcohol)
(XXXIX)	Me	NCH_2Ph	*para*	121—124	3445	460
(XL)	Me	NCH_2Ph	*ortho*	85—87	3445	456
(XLI)	Me	S	*para*	136—137	3435; 3340	414
(XLII)	Me	S	*ortho*	81—87	3435; 3340	414
(XLIII)	Me	O	*para*	115—116	3440; 3355	400
(XLIV)	Me	O	*ortho*	80—82	3440; 3355	400
(XLV)	Ph	S	*ortho*	195—198	3425	470
(XLVI)	Ph	O	*ortho*	182—184	3421; 3321	432

The *ortho*-substituent in the benzene ring (methyl[30], halogen[31]) does not affect the structure of the formazan chain in the series of "open-chain" 3-methyl-substituted derivatives. Thus the *ortho*- and *para*-isomers of 1-benzazolyl-3-methyl-5-tolylformazans are spectroscopically indistinguishable (Table 2). However, steric hindrance by the *ortho*-substituent affects the complex-formation reactions[30] or the conversion into tetrazolium salts[31]. In contrast to this, in the series of chelate 3-phenylformazans the steric hindrance of the *ortho*-substituent is clearly manifested in the opening of the chelate ring of (XLV) and (XLVI).[123] The naphthyl residue has an effect similar to that of the *ortho*-tolyl substituent[123].

The introduction of an electron-donating (NMe_2) or an electron-accepting (NO_2) substituent into the *para*-position of the benzene ring has a particularly marked influence on the structure and colour of formazans[124]; a bathochromic effect is observed in both cases.

In the series of symmetrical 1,5-dibenzazolylformazans three tautomeric forms are possible: the chelate form (XLVII) and the "open-chain" amino-form (XLVIII) and imino-form (XLIX):

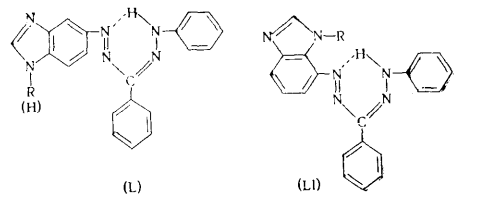


(XLVII) (XLVIII) (XLIX)

Regardless of the substituent in the 3-position (methyl, phenyl), the tautomeric imino-form of 1,5-dibenzimidazolylformazan (XLIX) has been detected in solutions [ν(NH) = 3420 and 3468 cm^{-1} in chloroform].[80] The infrared spectra of benzothiazolylformazans do not contain the ν(NH) band and they probably have the chelate structure (XLVII). Thus in the series of both symmetric and asymmetric

formazans benzothiazolyl derivatives exhibit a greater tendency towards the formation of chelate forms, while benzimidazolyl derivatives tend to form the open-chain imino-forms. The alkyl groups in the benzimidazole ring as well as those at the *meso*-carbon atom of 1,5-dibenzimidazolylformazans do not have a significant influence on the structure and colour of the formazan[66,125]. The mobility of the proton in these formazans is greater than in the asymmetric compounds (pK_a = 9.5–10.5). They are amphoteric and also exhibit a considerable basicity (pK_a = 4–5). The contribution of the imino-form with a cyanine chain is also responsible for the greater dipole moment of 1,5-di-(1-benzylbenzimidazol-2-yl)-3-methylformazan (4.9 D) compared with 1-(benzylbenzimidazol-2-yl)-3-methyl-5-(*p*-tolyl)formazan (2.7 D) or the chelate triphenylformazan (1.73 D).[70,126]

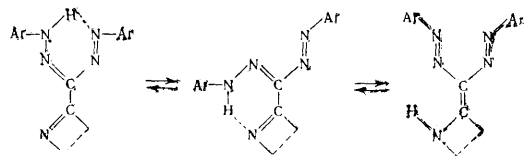
The structure of hetarylformazans in which the benzazole ring is not involved in tautomeric transformations is analogous to that of arylformazan derivatives. 1-(Benzimidazol-5-yl)-3,5-diphenylformazan (L) and 1-(1-benzylbenzimidazol-7-yl)-3,5-diphenylformazan (LI) have a chelate structure like 1,3,5-triphenylformazan (XXII).[127,128]



(L) (LI)

The replacement of the phenyl group in the *meso*-position by the methyl group leads to the opening of the chelate ring. When the benzimidazole ring is unsubstituted, the hydrogen atom attached to the pyrrole nitrogen atom can participate in intermolecular hydrogen bonds (L, R = H) and can form an intramolecular hydrogen bond with a nitrogen atom of the formazan group (LI, R = H).[128]

The tautomerism and isomerism in the series of 3-hetarylformazans has not been studied. Nevertheless in this case too there is a possibility of the existence of a series of tautomeric forms, for example:



The –N=C– fragment can form part of the pyridyl, benzazolyl, or another heterocyclic substituent with a "pyridine" nitrogen atom.

3-Benzothiazolyl-1,5-diphenylformazan does not form a sodium salt and the spectra of its solutions do not contain the ν(NH) band[29,122,129]. The data quoted, although limited, confirm that 3-hetarylformazans do not belong to systems with rapid proton transfer and in all probability give rise to chelate forms.

Thus the structure and tautomerism of hetarylformazans are mainly determined by the mode of fixation and position of the heterocyclic substituent in the formazan ring. 2-Benzazolylformazans are involved in complex tautomeric transformations, in which the state of equilibrium depends not only on the nature of the *meso*-substituent, but also on the nature and properties (basicity, acidity, and aromaticity) of the heterocycle. Similar features should probably be observed also for hetarylformazans, containing azoles and six-membered heteroaromatic systems (pyridines, azines, etc.) as the heterocyclic substituents, while the structure of hetarylformazans derived from five-membered systems with one heteroatom (furan, thiophen, pyrrole, and their benzo-analogues) should be close to those of arylformazans. However, there are virtually no experimental data concerning the tautomerism of these types of hetarylformazans.

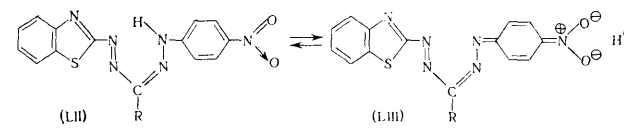
3. Photochromism and Thermochromism

Aryl- and hetaryl-formazans can in many cases isomerise by photoinduction or thermoinduction with proton transfer, which entails a change in the chromophoric system and the colour of the compound. The photochromism of arylformazans has been described by Kuhn and coworkers[89–94]. When a benzene solution of triphenylformazan is illuminated with visible light, the red chelate *syn-trans*-form (XV) (λ_{max} = 495 nm) undergoes reversible isomerisation to the yellow *anti-trans*-form (XIX) (406 nm). The transformation proceeds via the unstable *syn-cis*-form (XXI) and *anti-cis*-form (XX). Negative red-yellow photochromism of this type has also been observed for benzene solutions of compounds (L), which are analogues of triphenylformazan[127].

The photochromism of 1-benzimidazolyl-5-phenylformazans (XXIX) and (XXX), which occurs in chloroform or carbon tetrachloride solutions, is of a different type[120,130]. Here positive red–blue photochromism with a large (up to 200 nm) bathochromic photoinduction effect is observed. The reverse dark transition is difficult, but the initial form can be quantitatively isolated when a more polar solvent is added to the chloroform solution of the blue form. The ease of the reconversion into the initial formazan, the change in the nature of the infrared spectrum of the irradiated form, and steric hindrance by the *ortho*-substituent in the 5-phenyl group suggested[120] that photoinduction is accompanied by intermolecular proton transfer and the formation of dimeric structures.

The photochromism of mercury and zinc dithiozonates, which has been described[131,132], can also be accounted for by a change in the chromophoric system of the ligand (isomerisation and proton transfer). The isomerisation of the formazan chain similarly explains the photochromism of 5-alkyldithizones[133,134].

Substances exhibiting both negative[135,136] and positive[135,137] thermochromism have been found among the benzazolylformazans. The group of 1-benzothiazolyl-5-nitrophenylformazans (LII) has been studied in greater detail:



(LII) (LIII)

λ_{max} = 470–500 nm λ_{max} = 600–610 nm

It has been established that the repeated reversible thermochromic transitions of alcoholic solutions from the initial red form (LII) to the thermally induced blue form are due to dissociation and conversion into the anionic form (LIII), whose spectrum is identical with that of the sodium salt of the formazan. The formazan with R = Me has pK_a = 8.20 and therefore in aqueous and alcoholic solutions (pK_a = 8.15) dissociation proceeds readily as a result of thermoinduction. The formazans with R = Ph

and $CHMe_2$ are less acidic (pK_a = 8.94 and 9.53) and therefore they exhibit thermochromism in buffer solutions at pH values close to the pK_a of the formazans.

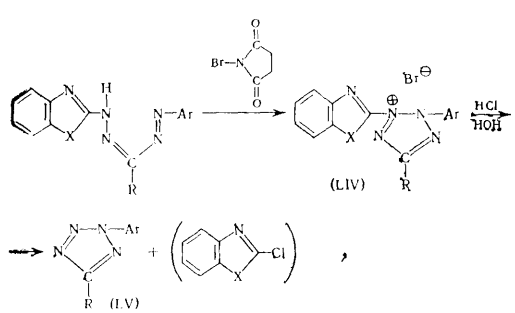
IV. PROPERTIES OF HETARYLFORMAZANS

The characteristic reactions of formazans (reversible oxidation-reduction transitions to tetrazolium salts, alkylation and conversion into verdazyl radicals, and salt and complex formation with metal ions) proceed in a specific manner in the series of hetarylformazans. 1(5)-Hetaryl- and 1,5-dihetaryl-formazans are much more labile and reactive than aryl- or 3-hetarylformazans. 1,5-Dihetarylformazans exhibit a tendency towards transitions to cyanine systems.

1. Oxidation to Tetrazolium Salts

The only method for the preparation of tetrazolium salts is oxidation of formazans. In the series of hetarylformazans the oxidation and formation of tetrazolium salts of 3-hetarylformazans has been most thoroughly investigated[1,6]. Since the stabilities of these formazans and their tetrazolium salts are comparable to those of aromatic compounds, it is possible to employ here the same oxidants, namely mercury(II) oxide, isopentyl nitrite, and lead tetraacetate. A convenient method for the oxidation by nitric acid has been proposed for 3-arylquinaldinium- and 3-aryllepidinium-formazans (VII).[58]

The oxidation-reduction properties of 1-hetarylformazans and their tetrazolium salts have so far been inadequately investigated. Owing to the instability of these formazans in an acid medium, their conversion into tetrazolium salts is carried out by Kuhn's method[138] under the influence of bromosuccinimide. Tetrazolium salts derived from thiazolyl-, oxazolyl-, and selenazolyl-formazans[24,25] and also from 1-benzozolylformazans[29,31,139] were obtained in this way. They differ from aryltetrazolium salts (LIV) by their instability, which becomes more pronounced with increase of the electronegativity of the heterocycle (on going from benzothiazole to benzoxazole). Benzoxazolyltetrazolium bromides have not been isolated at all: they are immediately cleaved with formation of 2,5-disubstituted tetrazoles[29,123] (LV). The more stable benzothiazolyltetrazolium bromides[123] and benzimidazolyltetrazolium bromides[140] are readily cleaved in acid hydrolysis, yielding the same disubstituted tetrazoles and 2-chlorobenzazoles (isolated in the case of benzimidazole[140]):

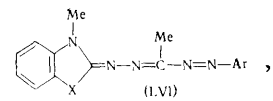


where R = Me of Ph, Ar = Ph or $\alpha(\beta)$-naphthyl, and X = NMe, S, or O.

Symmetrical, 1,5-dibenzimidazolylformazans are readily brominated by bromosuccinimide[139], but instead of tetrazolium salts they probably form bromoamines, which are themselves capable of brominating toluene or acetone.

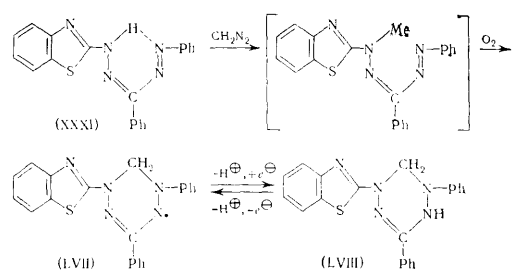
2. Alkylation and Preparation of Verdazyl Radicals

Methylation of 5-aryl-1-benzazolyl-3-methylformazans by methyl iodide in an alcoholic alkaline medium with the aim of investigating the tautomeric shifts and reactivities of asymmetric hetarylformazans led[141,142] to the formation of methyl derivatives (LVI) containing the methyl group in the benzazole ring, i.e. to the fixation of the tautomeric imino-form:



where X = NR, S, or O.

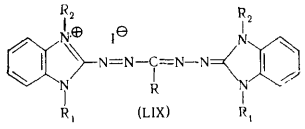
In the light of the studies of Kuhn and coworkers[143,144] and Neugebauer and coworkers[145,146] on the oxidative methylation of triarylformazans and the formation of deeply coloured stable free radicals (verdazyl radicals), the methylation of chelate hetarylformazans is of special interest. However, it was found that in the series of hetarylformazans capable of the amine–imine tautomerism, the possibility of the formation of verdazyl radicals is limited. Thus methylation of compounds (XXXI) and (XXXII) by methyl iodide yielded[142] the methyl derivatives (LVI). Only in the case of compound (XXXI), i.e. the formazan with the most aromatic heterocycle (benzothiazole) was it possible to obtain a crystalline dark-green paramagnetic substance by methylation with a benzene solution of diazomethane and autoxidation in air. Analysis, spectra (ESR and ultraviolet), and properties [capacity for the leuco-base (LVIII) ⇌ verdazyl (LVII) oxidation-reduction transitions] confirmed the structure of the compound as 1-benzothiazolyl-3,5-diphenylverdazyl (LVII):



Presumably, wider possibilities for the synthesis of verdazyl radicals will become apparent also in the series of 3-hetarylformazans or hetarylformazans in which the heterocycle is not involved in tautomerism [compounds (L) and (LI)].

Alkylation of symmetrical 1,5-dibenzimidazolylformazans proceeds in an altogether different manner. When the formazan is acted upon by an alkyl iodide in dimethylformamide, well-crystallised deeply coloured (violet) substances are formed, analysis of which shows them to be the iodides of the alkyl derivatives, while their spectra in

the visible region hardly differ from those of the hydrochlorides of the same formazans. It has been established[141] that these products are tetraazapentamethinecyanines derived from benzimidazole (LIX) and resemble Hünig's azacyanines (VIII):[69]



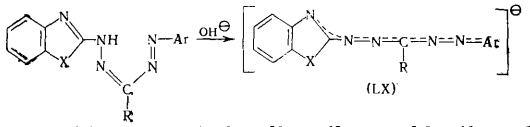
(LIX)

where R = H or Me and R_1 and R_2 = Me, Et, or CH_2Ph.

3. Acid-Base Properties and Capacity for Complex Formation

Benzazolylformazans are much more amphoteric than arylformazans. Their basicity increases owing to the presence of the benzazole ring (the "pyridine" nitrogen atom) and the acidity increases owing to tautomerism.

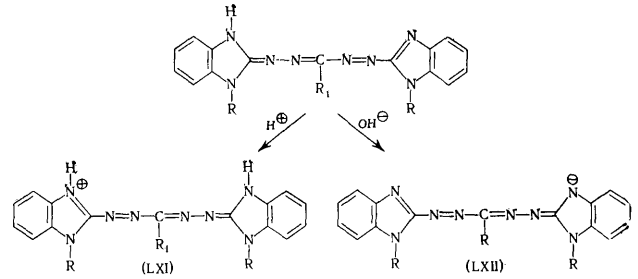
Like arylformazans, asymmetric 1-benzazolylformazans are unstable in acid media, where, after a deepening of the colour (conversion into the cation), the solution undergoes a reversible decolorisation after several minutes (cleavage, oxidation)[70]. Formazans are stable in alkaline media. The conversion into the aryl (LX) is accompanied by a bathochromic shift due to salt formation, which depends on the structure of the formazan. For each formazan, the pH at which the proton is abstracted can be readily determined spectrophotometrically (the most convenient method for the determination of approximate values of pK_a).



(LX)

The colour of the anion is hardly influenced by the substituent R in the *meso*-position. But, since the initial formazans (derived from benzothiazole and benzoxazole) have different colours depending on the *meso*-substituent, the bathochromic effect of the abstraction of a proton from the more deeply coloured chelate formazans (R = Ph) is smaller (50–60 nm), while for the "open-chain" (R = Me) compounds it is greater (100–110 nm). The colour of the anion is determined by the nature of the heterocycle (X = NR, 530–540 nm; X = S, 516–520 nm; X = O, 490–500 nm). The substituents in the benzene rings of the phenyl groups have different effects on the colour of the anion: the sulpho-group (in both *meta*- and *para*-positions) hardly alters the colour[43], while the nitro-group causes a sharp bathochromic shift[124]; the ortho-effect of substituents (methyl, halogen) is not shown[30,31].

The symmetrical 1,5-dibenzimidazolylformazans are stable over a wide pH range. They form well-crystallised salts with both hydrogen halides (monohydrohalides) and with sodium hydroxide (monosodium salts)[147]. The similarity of the absorption spectra in the visible region of the hydrochlorides and sodium salts is striking. When formazans (λ_{max} = 530–540 nm) are converted into salts, a bathochromic shift of the absorption band maximum, an increase in its intensity, and its splitting are observed (570–580 and 600–610 nm for the cation and 560–570 and 600–614 nm for the anion). It has been established[125,147] that these formazans behave in salt formation like cyanine bases and on addition or abstraction of a proton are converted into systems analogous to the onium (cation) or acihalochromic (anion) cyanine dyes. The similarity of the structures of the cation (LXI) and the anion (LXII) is responsible for their identical colour.

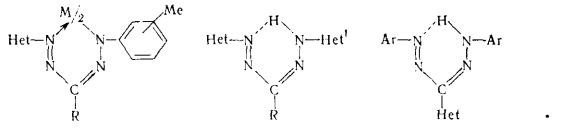


(LXI) (LXII)

The formation of complexes by 1-hetaryl- and 1,5-dihetaryl-formazans with metal ions of the 3-α-series in aqueous organic solutions proceeds just as readily as salt formation. The large bathochromic effect (100–200 nm), high sensitivity, and virtually instantaneous complex formation make these formazans (particularly benzazolylformazans) promising reagents for spectrophotometry. By varying the heterocyclic residues in the formazan molecule or by introducing additional complex-forming groups, it is possible to influence the selectivity of the ligand, the bathochromic shift, and the stability of the complex.

V. COORDINATION COMPOUNDS OF HETARYLFORMAZANS

The capacity for the formation of complexes with metals is virtually the most characteristic property of formazans. The interaction of hetarylformazans with metals leads to the formation of molecular complexes or chelate complexes with an MN_4 coordination unit. The latter has been attracting continued attention not only owing to the specific action of the ligand environment on the stereochemistry of the polyhedra of the complexes but also owing to its exceptional role in biologically important objects[70,148–153].



(LXIII) (LXIV) (LXV)

The molecular complexes $MCl_n.mL$ (n = 2 or 4, m = 1 or 2, L = formazan; M/2 can be also a hydrogen atom) were synthesised by the interaction in the cold between metal chlorides and 1(5)-hetarylformazans in acetone (MX_2) or carbon tetrachloride (MCl_4).[156] At the same time molecular complexes of $C_{(3)}$-hetarylformazans (LXV) with cobalt(II) chloride have been isolated[129] from hot ethanol. This solvent, together with acetone and dimethylformamide, has been widely used to prepare metal chelates[152–155,157–173].

The choice of salts for the synthesis of chelate complexes depends on the complex-forming metal: for copper(II), cobalt(II), and zinc(II), the best result was achieved when chlorides were employed, and for nickel, nitrates were most successful. On the other hand, bearing in mind the continued applications[148,152,153] in the synthesis of different classes of chelate complexes the method based on the interaction of metal acetates in ethanol or methanol, it should be recommended for wide-scale employment also in the synthesis of metal chelates

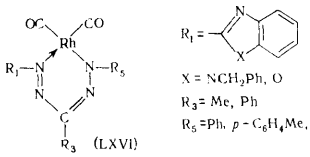
derived from formazans. We see the advantages of this method, which has already been used in a few instances[155,174] in a series of formazan-containing systems and yielded satisfactory results, also in the possibility of avoiding the formation of molecular adducts of the type $M(L-H)_2.nMX_2$, which accompanies the formation of copper chelates[162]. The formation of adducts greatly complicates the isolation of pure $Cu(L-H)_2$ complexes and requires repeated crystallisation of $Cu(L-H)_2.nCuCl_2$ from aqueous pyridine[162]. In this case pyridine apparently play the role not so much of a solvent as of an effective complex-forming agent:

$$Cu(L-H)_2 \cdot n\,CuCl_2 + n\,C_5H_5N \rightarrow Cu(L-H)_2^{+}\,n(C_5H_5N \rightarrow CuCl_2)\ .$$

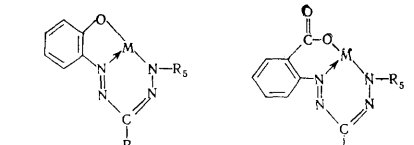
The type of complex (molecular or chelate) depends on the nature of MX_n and the conditions of synthesis.

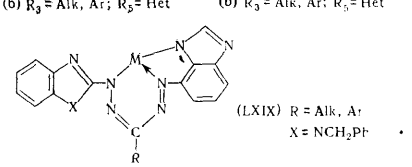
The tetrachlorides of Group IV metals form the molecular complexes $MX_4.L_n$ (n = 1 or 2).[156] Cobalt[129] and zinc[155] dichlorides give rise to complexes of a similar type under mild conditions. Bivalent transition metal and uranyl nitrates and acetates tend to form preferentially metal chelates of the type $M(L-H)_2$ or $M(L-H_2)$. At the same time, depending on the conditions of the synthesis, it is possible in a few instances to obtain complexes of both types indicated above for the same MX_n. Thus zinc chloride forms not only molecular complexes but also chelate complexes (in aqueous acetone or aqueous alcoholic media at pH in excess of 7).[70,155]

Complexes with mixed ligands may occupy a special place among formazan complexes. So far there has been only one report on this subject: dicarbonylhetarylformazanrhodium complexes (LXVI) were synthesised and their infrared absorption spectra were obtained[175].

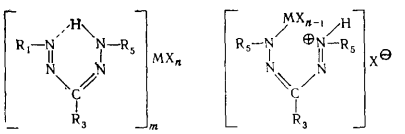


In most cases the molecular complexes have the composition $MX_n.L$ [129,153,155,156] (with the exception of the complexes of tin tetrachloride—$SnCl_4.2L$),[156] while the metal chelates have the composition $M(L-H)_2$.[152–156,162,163,166–168,174,176–178] However, an extremely characteristic feature of hydroxy- and *o*-carboxy-hetarylformazans, like that of 1-(benzimidazol-2-yl)-5-(benzimidazol-4-yl)formazan derivatives, is the formation, together with 2:1 chelate complexes[129,157–160,164,176], of 1:1 metal chelates $(ML-H)_2$ [129,157,164,165,169,172,173] [compounds (LXVII)–(LXIX) respectively].

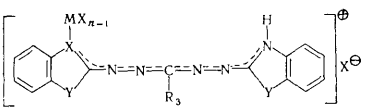




The structure of the molecular complexes was studied mainly by spectroscopic methods[70,153,155,156], while that of metal chelates was investigated in addition by the dipole moment and magnetochemical methods[153,163,166,168,174,177,178]. The compositions $MX_n.L$ and $MX_n.2L$ do not by themselves indicate the nature of the complexes formed, since ionogenic compounds such as the salts (LXXI) or the cyanines (LXXII) can have the same elemental composition as the products (LXX) of the addition of MX_n to formazans[156].



m = 1, 2; n = 2, 4;
M = Ti, Sn, Zn



Y = O, S, NR; M = Ti, Sn, Zn; X = Cl

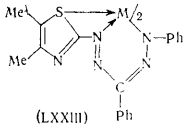
The choice between the above structures in favour of (LXX) [156] for MCl_4 and (LXXII) [155] for $ZnCl_2$ was based on ultraviolet and infrared spectroscopic data and dipole moments. The infrared spectra of $MCl_4.L$ and $MCl_4.2L$ do not contain the absorption bands of the immonium group (NH^+), which would have been expected for the ionic structure of (LXXI). The dipole moments of the compounds (8–10 D) also support molecular complexes of type (LXX).[156] On the other hand, the $ZnCl_2$ complexes with bisazolylformazans have ultraviolet spectra resembling those of the hydrochlorides and sodium salts of the initial formazans (two maxima in close proximity in the spectrum).[155] This factor suggests that the structure of $ZnCl_2.L$ is analogous to that of the cyanine dyes (LIX).[147,155]

Hetarylformazans are ambident systems[179,180], containing several potential electron-donating centres: the nitrogen atoms of the formazans and azole rings and the O and S atoms of the benzothiazole and benzoxazole rings respectively. Therefore in the study of the molecular complexes (LXX) the problem of the location of the coordinate bond in the hetarylformazan system (competitive coordination) was solved[179]. In agreement with the results of quantum-chemical calculations[112], the infrared spectra[156] led to the conclusion that MX_n is coordinated to the $N_{(3)}$ atom of the azole fragment, and, in complexes having the composition $2TiCl_4.L$, to the $N_{(2\ or\ 4)}$ atom of the formazan ring[156].

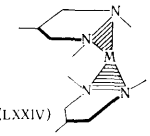
A square planar configuration is most characteristic of the chelate complexes of bivalent metals with the MN_4 coordination unit, to which the metal chelates of hetarylformazans also belong[148,152,181–184]. However, it has been shown for the chelate complexes of hetarylformazans[153,163,166–168,174,177,178] that the metal chelates with an MN_4 coordination unit can also have a non-planar structure: polymeric octahedral in the condensed phase and tetrahedral in solution.

In 1966 two independent investigations[163,174] showed that the nickel chelate complexes of *N*-azolylformazans are paramagnetic, in contrast to the analogous planar metal chelates of the aromatic series[10,88,185], and therefore have non-planar structures. The authors explained in different ways the appearance of paramagnetism in the nickel chelate complexes of formazans of the azole series: three

of the present authors[163] attributed it to a polymeric octahedral configuration of the complexes (MN_6) in the crystalline phase and a tetrahedral configuration (MN_4) in solutions; Pyl and Meyer[174] attributed it to an intramolecular octahedral configuration (LXXIII) containing the MN_4S_2 coordination unit.



(LXXIII)



(LXXIV)

In order to establish how general is the above change in the structure of the MN_4 coordination unit on passing from *N*-aryl to *N*-azolyl complexes in formazans, a study was made of the magnetic and polar properties of a large series of copper, nickel, and cobalt chelates of formazans of the azole series and the following observations were made:

(1) Nickel complexes of *N*-azolylformazans are of the high-spin type in both the crystalline phase and in solution regardless of the structure of the ligand (except for *o*-hydroxy- and carboxy-phenylformazan chelate complexes[164,165]).

(2) The cobalt chelate complexes of hetarylformazans are of the low-spin type, in the condensed phase, while in benzene and carbon tetrachloride solutions they are of the high-spin type.

(3) The copper, nickel, cobalt, and zinc chelate complexes in benzene, dioxan, and carbon tetrachloride solutions have polar structures with dipole moments in the range 1.7–2.5 D.

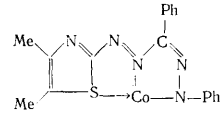
These data made it possible to ascribe a tetrahedral structure to metal chelates of hetarylformazans in solution, in agreement with the results of cryoscopic studies (the existence of the complexes as monomeric species in benzene and dioxan solutions)[153,163,167,177,178]. The polarity of the externally symmetrical (regardless of the type of polyhedron) chelate complexes of *NN*-diazolylformazans merits particular attention[153,167,168,177,178]. The polar model of a tetragonal pyramid with the metal atom above the plane of the metal-containing ring (cf. Garnovskii and coworkers[153,186]) conflicts with magnetochemical data. Therefore the most probable structure of the metal chelates of *NN'*-diazolylformazans, capable of explaining their magnetic and polar properties, we believe to be, by analogy with the complexes of other externally symmetrical *NN'*-disubstituted derivatives[187], the tetrahedral structure (LXXIV) with the metal-containing rings bent along the *N*–*N'* line at an angle α. This hypothesis is also supported by the finding that the nickel complexes of *NN'*-diarylformazans are paramagnetic in solution and have a dipole moment of 1.2 D.[177,178] The results (particularly for bivalent cobalt chelate complexes of hetarylformazans[167]) make it possible to reject the intramolecular octahedral structure (LXXIII) with M–N and M–S bonds.[174]

A polymeric octahedral configuration has been attributed to the metal chelates of formazans of heterocyclic series in the crystalline phase. It is consistent with the results of magnetochemical measurements and the high tendency of azoles to form intermolecular M–N bonds[152,153]. The explanation of the low-spin nature of the cobalt chelate complexes of hetarylformazans involves certain difficulties from this point of view[167,174,177]: their effective magnetic moments are of the order of 1.3–2 Bohr magnetons (B.M.) and can be attributed to the planar model, which is not inconsistent with theoretical and structural‡ considerations[185,188,189], or a spin-paired octahedron, which is comparatively rarely encountered. For this reason, X-ray diffraction data are necessary to reach a final conclusion about the structure of the chelate complexes of hetarylformazans in the crystalline phase. A preliminary report on the problem[190] still does not allow a definite conclusion.

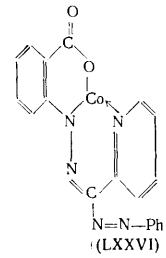
In contrast to the chelate complexes discussed above, the nickel chelates of *N*-(*o*-carboxyphenyl)-*N'* hetarylformazans (LXVIIIb)[164,165] as well as the analogous complexes of *o*-carboxyarylformazans[191–193] are diamagnetic (planar structure). The coordination saturation in complexes of this type [compounds (LXVIIIb)] probably involves the participation of the carbonyl oxygen. However, since there is reason to believe[192] that the chelates (LXVIIIb) have a structure in which the nickel is joined by a double bond, in this case too X-ray diffraction data will prove extremely useful. The metal chelates (LXIX) should probably also be planar[169].

The purely synthetic study by Seyhan[157,161,170–173], who first began to investigate 3-hetarylformazan complexes in 1954, stand alone from the standpoint of modern coordination chemistry. He did not employ any physical research techniques and therefore his structures of the complexes are open to serious objection. This applies particularly to the 2:1 metal chelates, to which the author attributes the structure of 1:1 complexes with an added ligand molecule[158,160,172,173].

In connection with the problem discussed above, the formulae of the cobalt complexes of hetarylformazans proposed by Pearse[194] [structure (LXXV)] and Beffa et al.[195] [structure (LXXVI)] are of very great interest:



(LXXV)



(LXXVI)

Whereas the first structure (LXXV) gives rise to doubts in connection with the possible involvement of the sulphur atom of the thiazole ring in coordination interaction[152,153,179], the second structure (LXXVI) appears to be fully justified.

Thus the introduction of the azole ring induces a preferential tetrahedral coordination of the chelate complexes of the formazan series (compared with the metal chelates of arylformazans) or leads to polymeric octahedral structures. Experimental results have shown[148,152,153,196,197] that both these effects are characteristic not only of metal chelates of the azole series with the MN_4 coordination unit, but also of MN_2O_2 and MN_2S_2.

The properties of the chelate complexes of hetarylformazans have been comparatively little investigated. There are isolated data on their stability[70,154,176] and their infrared spectra[70,122,156,164–166].

The dependence of the ν(C=N) shifts in the spectra of formazans on the structure of the ligand and the nature of the metal is a striking feature of the infrared spectroscopic data[166]. For formazans with the chelate structure, the transition from the chelate with a hydrogen-bond bridge

‡ By analogy with the structure of the nickel complexes of 3-methyl-1-phenyl-5-(*p*-tolyl)formazan[185].

to one of the inner complex type does not entail an appreciable change in the position of the band. On the other hand the ν(C=N) wavenumbers for the metal chelates of formazans with an open-chain structure are significantly reduced compared with the corresponding bands of the non-coordinated formazans[70,166]. The changes in the above infrared bands as a function of the metal are such that the shift $\Delta\nu$(C=N) is a maximum for the cobalt complexes.

In connection with the development of studies on the use of the complexes as ligands[179], the adducts of hetarylformazans with $CuCl_2$,[70,162] MCl_4,[156] and $Zn(OH)_2$[155] are of some interest. The number of MX_n molecules attached to the metal chelate of the hetarylformazan depends mainly on the nature of the metal and the ligand. Thus in the case of $CuCl_2$ it is determined by the number of azole rings[70,162] and in the case of MCl_4 (M = Sn or Ti) by the number of potential electron-donating centres (including the nitrogen atoms of the formazan ring)[153,156,179].

---o0o---

The prospects for the further development of studies in the field of hetarylformazans are determined, apart from their theoretical interest (the problems of complex tautomeric equilibria, photochromic and thermochromic transformations, structure, colour, etc.), by the possibility of using them in various branches of science and engineering. In the introduction and in the description of the methods ofsynthesis, we already mentioned above certain practical applications. Now we shall emphasise particularly the use of tetrazolium salts obtained on the basis of formazans of the heterocyclic series as bioindicators. The tetrazolium salts derived from 1-hetarylformazans, which readily form complexes, are converted by enzymatic reduction into formazans forming deeply coloured complexes with the metal (cobalt) of the enzyme. The use of tetrazolium salts {particularly 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide[23,198]} in histochemistry for the determination of the activities of oxidation-reduction enzymes is based on this reaction[194].

Hetarylformazans and their derivatives are of considerable interest as dyes[3,5]. The azacyanines derived from benzothiazole[63], benzimidazole[141], and indazole[199,200] are dyes resembling the pentamethinecyanine dyes. The deeply coloured inner complexes of formazans containing OH and COOH groups have been patented by the Ciba[201] and Geigy[202,203] Companies as dyes for natural silk. Stable colours on cellulose fibres are produced by the copper complexes of formazans containing dichloropyrimidinyl substituents[204,205]. Hetarylformazans can be of interest as photochromic and thermochromic dyes[130,135] and also as pH indicators[70].

The study of the applications of hetarylformazans in analytical chemistry has been developing rapidly in recent years. Whereas in the series of arylformazans it is necessary to introduce additional groups into the formazan ring for this purpose (the SH group in dithizone[206], the hydroxy- and carboxy-groups in zincon[207], cyanoformazan-II,[208] etc.[5]), among 1-hetarylformazans capable of tautomerism there are extensive possibilities for the selection of effective analytical reagents.

The studies in the field are being carried out mainly by two groups of chemists: Japanese[44,45,209-213] and Soviet[214-220]. Spectrophotometric studies of the formation of bivalent nickel, copper, cobalt, zinc, and cadmium complexes with 1-hetaryl-3,5-diphenylformazans (hetaryl = thiazolyl, benzothiazolyl, selenazolyl, oxazolyl, and pyridyl) were described in reports by the first group. In the studies of the second group of investigators effective analytical reagents for copper, silver, nickel, zinc, lead, mercury, cadmium, and thallium were found among 1-benzazolyl- and 1,5-dibenzimidazolylformazans. The results concerning the application of 3-ethoxycarbonyl-1,5-di(tetrazol-2-yl)formazan as an excellent reagent for the colorimetric determination of copper and nickel[221] are also of interest.

All the foregoing considerations leave no doubt about the necessity for the intensification of research on hetarylformazans and their derivatives (particularly tetrazolium salts, verdazyl radicals, and complex compounds).

Coordination Polymers with Inorganic Main Chains

S.V.Vinogradova and O.V.Vinogradova

A specific set of properties distinguishes coordination polymers with inorganic main chains. The review deals with modern ideas about the structures of these polymers, the possible ways of synthesising them, and a survey of the available data on the properties of metal-containing polymers such as polyphosphinates, polyarsinates, etc.
The bibliography includes 125 references

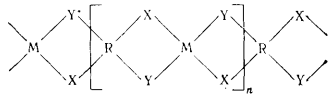
VI. Properties of coordination polymers with inorganic main chains 516

I. INTRODUCTION

Extensive experimental data have now accumulated on the synthesis and properties of polymeric organic derivatives of the elements and inorganic polymers. Polymers of this kind include in particular polyorganosiloxanes which have found numerous practical applications and also polyorganosiloxanes containing other elements, which possess a set of valuable properties [1]. Coordination polymers can also have main chains consisting of inorganic elements only. The available information about the synthesis and properties of coordination polymers has been described in a number of review publications [2-11].

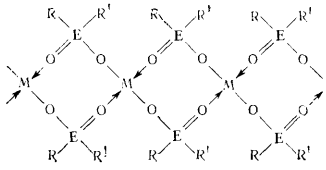
Coordination polymers can be divided into two types on the basis of the structure of the main chain.

1. Polymers with chains consisting of organic derivatives of the elements:



where M is a metal atom with a valence ≥ 2, X = −O−, −S−, =N−, etc., and Y = $>$CO, −N$<$, −N=O, $>$C=S, etc.

2. Polymers with inorganic chains:



where M is a metal atom, E the atom of an acid-forming element, for example phosphorus, arsenic, or sulphur, and R and R′ are organic groups.

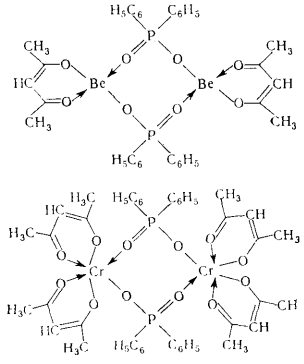
Coordination polymers of the second type, i.e. polymers with inorganic chains, appear to be the most promising. Some of them are fairly thermostable, are capable of flowing under load, and are soluble in the usual organic solvents.

The present review is devoted to coordination polymers with inorganic main chains. Polymers of this type, namely metal polyphosphinates, polyphosphinothioates, and polyarsinates, constitute an unusual group of coordination polymers with the ligands in bridge positions between the metal atoms. The chemistry of bridge coordination polymers has developed mainly during the last decade, although metal derivatives of phosphinic acids were known as early as 1896. [12]

One of the first experimental studies indicating the polymeric nature of the compounds of phosphinic acid with certain metals concerned the viscosity of the product synthesised by Healy and Kennedy [13] by the reaction of di-n-butylphosphinic acid with uranyl acetate, published in 1959. In 1962 Coates and Golightly [14] synthesised cobalt polyphosphinates. The reports of Block and coworkers on the polymeric nature of a number of metal phosphinates were published in the same year [15-18].

II. THE STRUCTURE OF COORDINATION POLYMERS WITH INORGANIC MAIN CHAINS

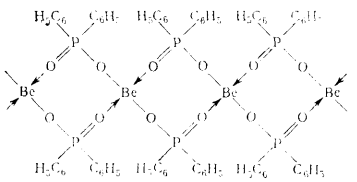
The hypothesis of the bridging properties of phosphinate anions, each of which is linked to two metal atoms, was already put forward in the first reports dealing with the synthesis of polyphosphinates. The bridge type of bond in beryllium and chromium polyphosphinate dimers was demonstrated by Block and coworkers [15,16,18] on the basis of an ebullioscopic determination of their molecular weights, infrared spectroscopic data, and microanalysis.



These dimers were obtained by the interaction of diphenylphosphinic acid with an excess of beryllium acetylacetonate *in vacuo* at 100°C and with an excess of chromium acetylacetonate at 240°C. [15,18] Subsequently the structure of the

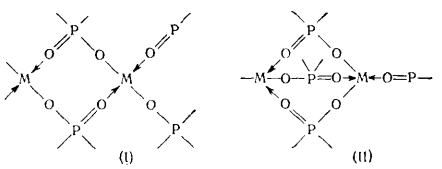
chromium phosphinate dimer was confirmed by an X-ray diffraction study of its single crystals[19]. In these cyclic derivatives the metal atoms are incorporated in the chelate ring with acetylacetone and simultaneously in an eight membered coordination ring with the phosphinate groups[20].

In those cases where diphenylphosphinic acid was introduced into the reaction with beryllium acetylacetonate in a twofold molar excess, the acetylacetonate groups were completely split off and the product was a polycyclic polymer with phosphinate bridges, having the following structure according to the authors[19]:



Block proposed a similar structure also for the polyphosphinates of other metals: cobalt and zinc[16,21-27] and chromium[15,28-34].

Later the Italian investigators Ripamonti, Giancotti, Giordano, and others[35-42] established by X-ray diffraction that certain polyphosphinates of the type MX_2 (M is a bivalent metal and X the phosphinate anion) have a structure different from structure (I) proposed by Block. Their X-ray diffraction study of zinc polydi-n-alkylphosphinates and poly-n-butylphenylphosphinate showed that the chain structure in these crystalline polymers corresponds to structure (II), which includes alternating single and triple bridges:



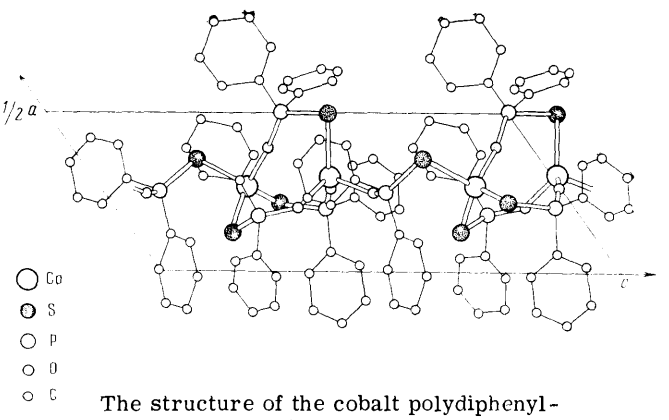
(I) (II)

According to the authors, this structure provides the best explanation of the elastic properties of the amorphous metal polyphosphinates at low temperatures, estimated from the brittleness temperatures[22], since polymeric chains with a type (II) structure should be fairly elastic owing to the possibility of rotation about the P–O and O–M single bridge bonds[35,38,39]. X-Ray diffraction data for cobalt polydi-n-alkylphosphinates[35,38,39] and mixed zinc-containing polymers based on di-n-butyl- and diphenyl-phosphinic acids with the general formula $\{Zn[(C_4H_9)_2PO_2]_{2-2x}[(C_6H_5)_2PO_2]_{2x}\}_n$[39,40] also support structure (II).

Giordano et al.[40] concluded on the basis of an X-ray diffraction study of zinc poly-n-butylphenylphosphinate that the phenyl and n-butyl side groups of the phosphorus atoms in the polymer chain are distributed in a non-ordered fashion.

The influence of the nature of the side groups at the phosphorus atom on the conformation of the polyphosphinate macromolecules has been investigated[37] for mixed beryllium polyphosphinates incorporating di-n-butyl- and diphenyl-phosphinate anions as bridging ligands. It was shown that the skeletal structure of beryllium polydiphenylphosphinate and of mixed polymers with a high content of diphenylphosphinate groups differs from the structure of beryllium polymers in which di-n-butylphosphinate groups predominate. It was found that, depending on the nature of the organic groups, the macromolecule can have a helical or extended conformation, the former being probably characteristic of diphenylphosphinate polymers and the latter of di-n-alkylphosphinate polymers. It is believed that, when a critical content of the more bulky diphenylphosphinate group is reached in the mixed polymer, the extended chain conformation becomes energetically less favourable owing to the appearance of a steric factor, which leads to the generation of a helical structure of the mixed polymers.

X-Ray diffraction was also used by Bruckner et al.[43] to investigate the structure of cobalt polydiphenylphosphinomonothioate (see Figure). The Figure shows that the structure of the monoclinic crystals of this polymer contains two types of cobalt atoms, those of one type being linked to one sulphur atom and three oxygen atoms and those of the other type to three sulphur atoms and one oxygen atom, i.e. the structure is analogous to structure (II) of metal polyphosphinates.



The structure of the cobalt polydiphenylphosphinomonothioate chain.

Thus the distribution of phosphinate groups in the bridge positions between the metal atoms in the polymer chain may be regarded as established for metal polyphosphinates and related polymers. As mentioned above, the structure of the polymer chain of metal-containing polymers based on phosphinic acids can be described in terms of two main structures: (I) and (II), differing in the distribution of the phosphinate groups between the metal atoms. However, one should note that data favouring structure (II) have been obtained only for bivalent metal polyphosphinates with a coordination number of four. Furthermore, they are based on a study of the structure of single crystals grown under special conditions.

The polyphosphinate single crystals were obtained on slow evaporation of the solvent from the polymer solution in water[44] or in a benzene–alcohol mixture[39,40]. Block[45] noted that structure (II) is in principle impossible for certain polyphosphinates, for example for the *trans*-form of chromium polydiphosphinate having the general formula $|Cr(H_2O)(OH)(OPRR'O)_2|_n$.

It follows from the foregoing that it is as yet impossible to reach an unambiguous conclusion about the distribution of the phosphinate bridge groups in the polymers. It is probably also impossible to rule out the possibility of a structure of the polyphosphinates in which the polymer chain includes units of two types corresponding to structures (I) and (II).

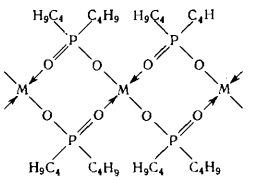
In the treatment below we shall employ the structural formulae of the coordination polymers with inorganic main chains which were proposed by the authors of the studies quoted.

III. SYNTHESIS OF METAL POLYPHOSPHINATES BY THE POLYCOORDINATION REACTION

Metal polyphosphinates have been reviewed by Block[45] and in separate chapters in a number of monographs[46-50]. They can be obtained by the reaction of diorganophosphinic acids with metal salts, by the oxidative decarbonylation of metal carbonyls, by the pyrolysis of complex metal salts with phosphinic acids, and by other methods.

Metal polyphosphinates are usually obtained by the polycoordination of diorganophosphinic acids and various metal-containing compounds: chlorides, acetates, nitrates, acetylacetonates, carbonyls, and organometallic derivatives. The Table shows that the metal polyphosphinates described in the literature differ appreciably in their polymerisation coefficients.

The polycoordination of phosphinic acids with metal salts can be achieved in solution[18,22,23,41,56-58,61,64,65-69,75], in the melt[16,18,51,65,75], and at an interface[16,35,41,44,54]. Thus zinc, cobalt, and manganese polydibutylphosphinates were obtained from the corresponding metal salts and di-n-butylphosphinic acid or its sodium salt by polycoordination in solution and at an interface[41,69]:



where M = Zn, Co, or Mn.

The interaction of phosphinic acids with metal salts is a polycondensation process. The formation of metal-containing coordination polymers by the polycoordination method has a number of characteristic features due to the nature of the M–O bonds arising in this process: ionic–covalent and coordinate.

The polycoordination reactions of phosphinic acids with metal salts proceed readily even at the usual temperatures. However, the ease of formation of coordination compounds

Metal polyphosphinates and their properties.

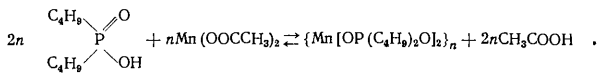
[a] The temperature corresponding to the decrease of the weight of the polymer by 10%.
[b] Intrinsic viscosity. [All the figures in this column appear to be intrinsic viscosities (Ed. of Translation)].

does not always ensure the formation of polymers with high molecular weights, since chain growth is frequently arrested at the stage involving the formation of low-molecular-weight or oligomeric compounds.

In order to find the optimum conditions for the synthesis of various metal polyphosphinates and other coordination polymers with inorganic main chains, Korshak and coworkers [69] investigated the characteristics of this process. They chose for investigation the polycoordination of di-n-butylphosphinic acid with manganese acetate under different conditions. The resulting coordination polymer—manganese polydi-n-butylphosphinate—is comparatively readily soluble in hydrocarbon solvents, which permits the determination of the viscosity of its solutions.

A study was made of the influence on the yield and intrinsic viscosity of the resulting manganese polydi-n-butylphosphinate of factors such as the nature of the reaction medium, the temperature and duration of the reaction, reactant concentration, and reactant ratio. It was found that the acetic acid liberated in the reaction degrades the manganese polydi-n-butylphosphinate formed under the conditions of the synthesis of the coordination polymer; consequently the polycoordination of phosphinic acid with manganese acetate must be regarded as a reversible polycondensation process:



Polymers with the highest molecular weights were obtained in a high-boiling solvent (Dinil) at about 140°C *in vacuo* (30 mmHg) in a stream of an inert gas.

Korshak and coworkers [57,69] showed that the interaction of di-n-butylphosphinic and other phosphinic acids with metal acetates takes place even when a powdered mixture of the two components is ground at room temperature. The amount of acetic acid liberated under these conditions during 10–15 min grinding of the starting materials in a thin layer is 70–80% of theoretical. Owing to the large surface area of the powdered mixture, acetic acid is very rapidly removed from reaction sphere as a result of its volatility. Subsequent treatment of the reaction mass with ethanol leads to the formation of a polymer with a high molecular weight.

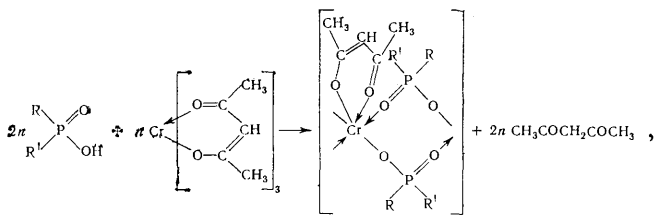
When the reaction is carried out in two stages, in the solid phase and in ethanol, the polymer with the maximum molecular weight is formed from di-n-butylphosphinic acid and manganese acetate taken in various proportions when stoichiometric amounts of the components interact [69], as in the single-stage polycoordination in solution. Thus, as in many other instances of polycondensation, in the formation of a coordination polymer with bridge ligands the rule of the non-equivalence of functional groups operates [101].

Korshak, Vinogradova, and coworkers [57,69,102] synthesised manganese and zinc polyphosphinates based on diphenyl-, dicyclohexyl-, distyryl-, di-n-butyl-, di-n-heptyl-, di-n-octyl-, di-n-nonyl-, and other phosphinic acids by the polycoordination of the acids with metal acetates and acetylacetonates. The molecular weights of manganese polydi-n-octylphosphinate with an intrinsic viscosity $[\eta] = 0.60$ dl g^{-1} (benzene, 50°C, $c = 1$ g dl^{-1}) and zinc polydi-n-butylphosphinate with $[\eta] = 5.45$ dl g^{-1} (benzene, 25°C, $c = 1$ g dl^{-1}), determined ebullioscopically in benzene, proved to be 8000 and 18 000 respectively. The molecular weight of zinc polydi-n-heptylphosphinate with $[\eta] = 18.50$ dl g^{-1} (benzene, 25°C, $c = 1$ g dl^{-1}), determined by the light scattering method in toluene, amounted to 74 000.

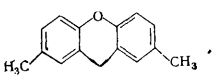
The interaction of phenylmethylphosphinic acid with zinc acetate in ethanol, leading to the formation of zinc polyphenylmethylphosphinate $\{Zn[OP(C_6H_5)(CH_3)O]_2\}_n$ with a molecular weight of 5600 has been described [16,54].

Slota et al. [51] synthesised a number of polymers of beryllium diorganophosphinates by the reaction of stoichiometric amounts of beryllium acetylacetonate with dimethyl-, 1,4-tetramethylene-, phenylmethyl, diphenyl-, and other phosphinic acids. The reaction was carried out in the melt, initially in an inert gas stream at 130°C and then *in vacuo* at 200°C. The resulting beryllium-containing polymers based on phenylmethyl-, di-n-butyl-, and di-n-pentyl-phosphinic acids had molecular weights of 30 000, 50 000, and 26 000 respectively.

Block and coworkers [30–34,78,86] and other investigators [79,87,88,90,103,104] made a detailed study of the synthesis of chromium-containing polyphosphinates. The polymer with tervalent octahedral chromium atoms is formed when a mixture of the monomeric chelate (chromium acetylacetonate) and substituted phosphinic acids is heated in the range 170–250°C in the melt or in a high-boiling solvent in an inert gas atmosphere via the mechanism



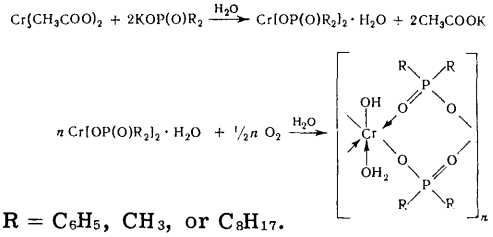
where R = C_6H_5 and R′ = C_6H_5, CH_3, or



The molecular weight of the benzene-soluble fraction of this polymer was about 10 000. [88–91]

The acetylacetonate group present in chromium polydiphenyl phosphinate as an additional chelating ligand can be replaced by another bidentate ligand, for example picolinic acid, as a result of exchange reactions occurring at elevated temperatures [89,91].

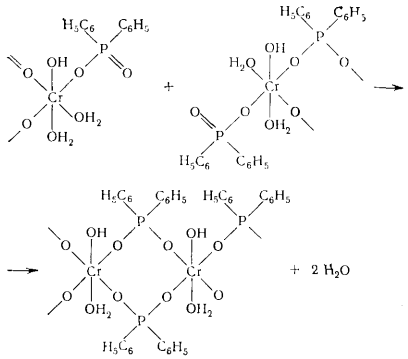
The examination of the structures of chromium polyphosphinates in terms of molecular models [105] showed that, when the dimensions of the additional ligand at the metal atom are greater than those of the acetylacetonate ligand, an appreciable steric hindrance arises in the chain and prevents the formation of high-molecular-weight polymers. For this reason, further studies were directed to the synthesis of chromium polydiphenylphosphinates with small additional ligands at the metal atom, such as water molecules and hydroxy-groups [30,32,78–83], instead of organic bidentate ligands. In particular, Block and coworkers [30,32,34] developed a method for the preparation of a polymer by the oxidation of the chromium(II) phosphinate complex in accordance with the mechanism



where R = C_6H_5, CH_3, or C_8H_{17}.

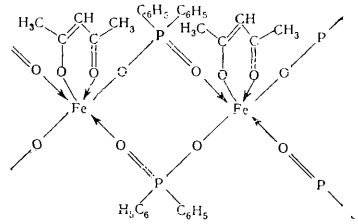
The oxidation of the insoluble intermediate chromium-(II) complex $Cr[OP(C_2H_5)_2O]_2.nH_2O$ was achieved by mixing in air its suspension in a water–tetrahydrofuran (THF) mixture for 12 h. The resulting oligomer with five or six repeating chain units $\{[\eta] = 0.03-0.04$ dl g^{-1} in chloroform$\}$ is readily soluble in benzene, chloroform, THF, and dioxan. On heating solutions of such oligomers in chloroform at 55°C for about 100 h, polymer chains with polymerisation coefficients up to 345 and intrinsic viscosities in chloroform $[\eta] = 0.7-1.0$ dl g^{-1} are formed.

The high-molecular-weight polymer is probably formed as a result of the interaction of the terminal groups of the oligomers with elimination of the water coordinated to the metal, via the mechanism



When other oxidants are used, ligands such as the nitro- and nitroso-groups can be introduced into the polymer chain instead of the hydroxide ion [80]. Additional treatment of the polymer $[Cr(H_2O)(OH)(OPR_2O)_2]_n$ with one mole of phosphinic acid per unit leads to the formation of chromium polytriphosphinates, i.e. in these polymers the additional ligands at the metal atom are the phosphinate anions which function as bridges in the main chain [33,82,85]. After the introduction of the third phosphinate group per chromium atom in the chain, the polymer ceases to be fusible and soluble.

The interaction of iron(III) acetylacetonate with diphenylphosphinic acid in solution, in the melt, or at an interface at 80–108°C led to the formation of iron(III) polydiphenylphosphinate [75]:

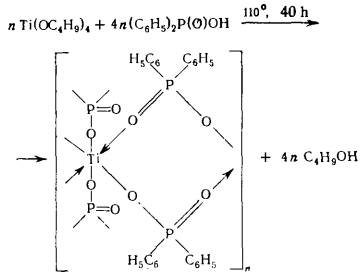


The resulting polymer was divided into four fractions, the first of which consisted of the dimer, the second and third of linear polymers with molecular weights of 4000 and 8800 respectively, and the fourth was insoluble.

Flagg and Schmidt [71,72,74,75,106–108] synthesised coordination polymers with Al–O–P linkages in the main inorganic chain. Aluminium-containing coordination polymers with the general formula $[Al(OPRR'O)_3]_n$ are usually obtained from triethylaluminium or the ether adduct of tetrahydroaluminate and the corresponding phosphinic acids via the mechanism

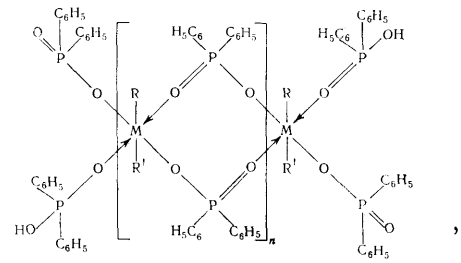
$$3nR_2P(O)OH + nR'_3Al \xrightarrow{THF,\ -70^\circ} \{Al[OPR_2O]_3\}_n + 3nR'H$$

Sutton and Wood [73] described the synthesis of a titanium-containing polymer by the interaction of tetrabutoxytitanate with diphenylphosphinic acid in toluene:



IV. SYNTHESIS BY THE OXIDATIVE DECARBONYLATION OF METAL CARBONYLS

Podall and Japalucci [76,84] proposed the oxidative decarbonylation of metal carbonyls for the synthesis of metal polyphosphinates. As a result of the oxidation-reduction reactions occurring under the influence of ultraviolet irradiation, they obtained polymers with the following tentative structure from chromium hexacarbonyl, iron pentacarbonyl, and diphenylphosphinic acid:



where R = R′ = CO for M = Fe and R = CO and R′ = $-O-\underset{\displaystyle H_5C_6\quad C_6H_5}{\overset{\displaystyle\quad\ \ |}{P}}-O-$ for M = Cr.

Iron polydiphenylphosphinate proved to be insoluble, but fractions soluble in benzene and chloroform were isolated from chromium polydiphenylphosphinate. The minimum molecular weight of these fractions corresponded to the dimer and the maximum molecular weight was 7130.

Iron-containing metal polyphosphinates were obtained from iron nonacarbonyl in a much higher yield than from the pentacarbonyl, the reaction occurring in the absence of ultraviolet irradiation [68]. The corresponding metal-containing polymers were also obtained from manganese, tungsten, and molybdenum carbonyls [66–69].

The study by Korshak, Vinogradova, and coworkers [69] on the oxidative decarbonylation of manganese decacarbonyl with di-n-butylphosphinic acid under different conditions showed that manganese polydi-n-butylphosphinate with the maximum intrinsic viscosity $\{[\eta] = 1.13$ dl g^{-1}, benzene, 70°C, $c = 1$ g $dl^{-1}\}$ was obtained when the process was carried out in benzene under ultraviolet irradiation. The reaction proceeds via the mechanism

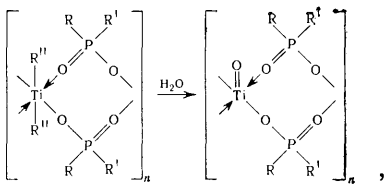
$$4n(C_4H_9)_2\overset{\displaystyle O}{\underset{\displaystyle OH}{P}} + nMn_2(CO)_{10} \xrightarrow{h\nu} \{[(C_4H_9)_2PO_2]_2Mn\}_n + 10nCO + 2nH_2$$

Other Methods for the Synthesis of Polyphosphinates

Dahl and Block [93] described the preparation of a coordination polymer of titanium (with $n = 18$) by the pyrolysis of the complex of titanium tetrachloride with diethyl diphenylphosphinate:

$$n\,TiCl_4 \cdot [OP(C_6H_5)_2OC_2H_5]_2 \xrightarrow{\Delta} \{TiCl_2[OP(C_6H_5)_2O]\}_n + 2nC_2H_5Cl\ .$$

It was shown that titanium polyphosphinates with a higher molecular weight can be obtained by the hydrolysis of dichloro- or dialkoxy- titanium polyphosphinates via the mechanism



where R and R′ = C_6H_5 and R″ = Cl or OC_4H_9.

Synthesis of Mixed Metal Polyphosphinates

The synthesis of mixed metal polyphosphinates by the interaction of two different phosphinic acids with metal-containing compounds under conditions analogous to those in the synthesis of homopolymers has been described [22-24, 38,39,54,56,59,71].

Thus mixed polyphosphinates with molecular weights up to 10 000 were synthesised by the joint polycoordination of two phosphinic acids with zinc, cobalt, and beryllium chlorides, acetates, and acetylacetonates [23,24,37-39,54].

Flagg and Schmidt [71] synthesised a large group of mixed high-molecular-weight aluminium polyphosphinates by the reaction of aluminium hydride or ethoxide with phosphinic acids of different structure in THF solution at −70°C. Thus the aluminium-containing polyphosphinates

$$\{[(C_4H_9)(C_6H_5CH_2)PO_2]_2Al[O_2P(C_8H_{17})_2]\}_n$$

and $\{[(C_4H_9)(C_6H_5CH_2)PO_2]_2Al(O_2P(C_7H_{15})]_2\}_n$

are soluble polymers with anomalously high intrinsic viscosities (up to 37 dl g^{-1}, 25°C, THF) and molecular weights of $(20-78) \times 10^4$.

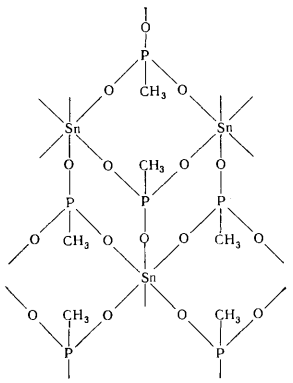
Korshak et al. [88] synthesised chromium-containing mixed polyphosphinates based on diphenyl- and 2,2′-(4,4′-dimethyl-1,1′-oxydiphenyl)-phosphinic acid by polycoordination in the melt at 175−200°C. In contrast to homopolymers, the mixed chromium polyphosphinates based on the above acid are fully soluble in chloroform and have molecular weights up to 10 000.

V. SYNTHESIS OF OTHER COORDINATION POLYMERS WITH INORGANIC MAIN CHAINS

Comparatively few studies dealing with coordination polymers containing bridge ligands other than phosphinate anions have been published. The synthesis of coordination bridge polymers based on phosphinomonothioic and phosphinodithioic acids containing cobalt, manganese, uranyl, and chromium in the inorganic main chain has been described [43,63,104,109-112]. For example, the interaction of diethyl- and diphenyl-phosphinothioic and diethyl- and diphenyl-phosphinodithioic acids with cobalt and uranyl acetates in benzene or ethanol yielded polyphosphinomonothioates and polyphosphinodithioates with molecular weights of 3000−6000. [63]

Callicaris et al. [112] showed that, in contrast to zinc polydiethylphosphinate, zinc diethylphosphinodithioate has a dimeric structure, which led the authors to the conclusion that phosphinodithioic acids are much less capable of forming polymers with metal ions than their phosphinomonothioic and phosphinic analogues.

Owens et al. [113] described a tin-containing polymer based on methylphosphonic acid, which was obtained by the pyrolysis of a tin tetrachloride complex of di-isopropyl methylphosphonate at 140−190°C and had the following structure:



Korshak and coworkers [68,114] achieved the oxidative decarbonylation of the metal carbonyls $M_2(CO)_{10}$, $Fe(CO)_5$, $Fe_2(CO)_9$, $W(CO)_6$, and $Cr(CO)_6$ by toluene-*p*-sulphonic acid. Toluene-*p*-sulphonic acid was also used as the ligand in polycoordination with manganese acetate. The molecular weight of the polymer from manganese acetate and toluene-*p*-sulphonic acid, determined by the light scattering method, proved to be 16 200 and that of the polymer from iron pentacarbonyl and toluene-*p*-sulphonic acid was 7900.

Korshak and coworkers [67,68,115] obtained metal polyarsinates by the reaction of diphenylarsinic acid with iron, chromium, manganese, and tungsten carbonyls and also with manganese and zinc acetates. The tungsten polyarsinate contained residual carbonyl groups and the degree of its polymerisation was 3-4. [115]

Metal polyarsinates, some of which proved soluble in water, were synthesised by the polycoordination of di-n-alkylarsinic acids with zinc acetate and chromium nitrate in solution [86,116].

VI. PROPERTIES OF COORDINATION POLYMERS WITH INORGANIC MAIN CHAINS

Metal polyphosphinates are usually powdered substances. Some of them have a characteristic colour (for example cobalt polyphosphinates are pale-blue and chromium polyphosphinates are green). The Table shows that certain metal phosphinates exhibit a high thermal stability. For example beryllium polydimethyl- and polydibutylphosphinates have melting points of 465° and 452°C respectively [51]. Polyphosphinates based on acids with aromatic substituents at the phosphorus atom are as a rule infusible, but cobalt polymethylphenylphosphinate and also certain mixed polyphosphinates whose chain contains the anions of both aromatic and aliphatic phosphinic acids are capable of passing to a fluid state [23,24,51].

X-Ray diffraction studies on metal phosphinates showed that they usually have a crystalline structure [11,22,24-33,35-44,58].

Crystalline polyphosphinates can be converted into an amorphous form by rapid cooling of the polymer melts. A characteristic feature of bivalent metal (zinc and cobalt) polydialkylphosphinates in the amorphous form is their high frost resistance. For example, amorphous zinc polydi-n-butylphosphinate with a molecular weight of about 10000, obtained by rapid cooling of the polymer melt (150°C), had a brittleness temperature of −40°C.[22] Mixed bivalent metal polyphosphinates have even lower brittleness temperatures. Thus zinc polyphosphinate based on di-n-butyl- and di-n-octyl-phosphinic acids remained elastic down to −100°C.[22,54]

Amorphous metal homopolyphosphinates crystallise slowly at room temperature, but certain mixed coordination polymers in the amorphous form do not show a tendency towards crystallisation at the usual temperatures[22].

Giancotti, Giordano, and coworkers[38] explained the high elasticity of mixed polymers by the disordered distribution of their alkyl side groups at the phosphorus atom on the basis of X-ray diffraction and differential thermographic studies.

Giancotti et al.[42] observed solid-phase transitions between two crystalline forms of zinc polyphosphinates between −13° and 77°C. They showed that above the transition temperature, i.e. in the β-form, the carbon chains of the aliphatic substituents at the phosphorus atom are flexible and capable of twisting; they are more ordered in the α-form.

Bivalent metal polyphosphinates with aliphatic substituents at the phosphorus atom are completely or partly soluble in organic solvents[22,24,38,51,57,69]. Homopolyphosphinates with aromatic substituents are largely insoluble[23,51,65].

Korshak, Krukovskii, and coworkers showed[56] that the solubility of mixed zinc polyphosphinates based on di-n-butylphosphinic acid, which also contain the residues of diphenyl-, distyryl-, and 2,2′-(4,4′-dimethyl-1,1′-oxydiphenyl)-phosphinic acids, increases with increase of the content of dibutylphosphinate groups in the polymer.

Mixed bivalent metal polyphosphinates based on phosphinic acids containing only aliphatic alkyl substituents at the phosphorus atom showed the highest solubility[22,38].

The available literature data on the behaviour of metal polyphosphinates in solution are difficult to compare, since they refer to polyphosphinates containing in the chain metal atoms of different valence. Furthermore, different experimental techniques were used in the investigations.

Thus the viscosity of solutions of chromium polydiphosphinate $\{Cr(H_2O)(OH)[OP(C_6H_5)_2O]_2\}_n$ in chloroform was found to increase with time; after keeping the polymer in chloroform at 55°C for several days, the intrinsic viscosity increased from 0.03−0.04 to 1.0 dl g^{-1}.[32,34]

Slota et al. observed a decrease of the molecular weights of beryllium-containing polyphosphinates with time in different solvents[53,55].

Examination of the relations quoted in a number of studies between the intrinsic viscosities of metal polyphosphinate solutions and polymer concentration shows that they are not linear. The intrinsic viscosities of solutions of many polymers increase sharply with increase of the concentration[22,23,44,56], which has been attributed[56] to the instability of metal polyphosphinates in solution.

The explanation of such concentration variation of the intrinsic viscosities of metal polyphosphinates by the aggregation of the molecules of the coordination polymer as a result of hydrogen bonding[55] is apparently invalid in the light of the results of Kuchen and Hertel[110], who showed that the concentration variation (in benzene) of the molecular weight of cobalt polydiethylphosphinothioate is the same at 37°, 45°, and 60°C. This suggests that the bond strengths in the association complexes are much higher than those of hydrogen bonds.

Korshak et al. showed[57] that 0.5−1% solutions of metal polyphosphinates in benzene and toluene are stable over a period of time. However, measurements of the intrinsic viscosities of manganese and zinc polyphosphinate solutions in benzene and toluene at different concentrations revealed a sharp decrease of the intrinsic viscosity with dilution of the solution. The anomalously low intrinsic viscosities of dilute manganese and zinc polyphosphinate solutions indicate the degradation of the macromolecules in solutions at low concentrations.

Indeed measurements of the molecular weight of manganese polydi-n-octylphosphinate in benzene by the ebullioscopic method and of zinc polydi-n-heptylphosphinate in the same solvent by sedimentation in an ultracentrifuge showed that the molecular weights of these polymers decrease sharply in both cases with decrease of the concentration of the solutions.

It has been shown for metal polydialkylphosphinates that the degradation of bivalent metal polyphosphinates in organic solvents is reversible and takes place almost instantaneously when the solution is diluted even at room temperature.

Delman et al.[117] demonstrated the high polydispersity of chromium polyphosphinates determined by the gel-chromatographic method.

In certain studies attempts were made to prepare films from coordination polymers[22,51,54,64,80,82,87]. However, non-plasticised films prepared from melts or solutions of homopolyphosphinates are brittle[82]. Their elasticity can be improved by the introduction of 20−60% of a plasticiser relative to the weight of the polymer. Thus a film containing 30% of the "Aroclor 1254" plasticiser and having a tensile strength of 133 kgf cm^{-2} was obtained from a polymer based on bivalent chromium acetate and diphenylphosphinic acid (molecular weight about 10000).[30]

American investigators[82,86,87] described the preparation of moulded articles, transparent films, and fibres from a chromium-containing polytriphosphinate obtained by the cross-linking of linear polymers of the type $\{Cr(H_2O)(OH)[OPRR'O]_2\}_n$ with low-molecular-weight cross-linking agents, which consisted of acid having the general formula R′R″P(O)OH.

Mixed polymer films are very elastic. A thin film, which did not change its size up to 100°C and remained flexible on cooling down to −100°C, was obtained from a mixed zinc polymer based on di-n-butyl- and di-n-octylphosphinic acids (molecular weight 10000) by pressing at about 150°C.[22,54]

The thermal stabilities of coordination polymers with inorganic main chains were estimated from thermogravimetric data. It was found that they depend both on the nature of the metal entering into the coordination centre and on the structure of the ligand forming the bridge group. Thus various metal polydiphenylphosphinates can be arranged in the following series in terms of the temperatures corresponding to 10% increase of their weight in an inert atmosphere (at a heating rate of 5 deg min^{-1}):

$$Mn(580°) < (Zn(520°) > W(510°) > Fe(453°) > Mo(425°) > Cr(390°)[67,102].$$

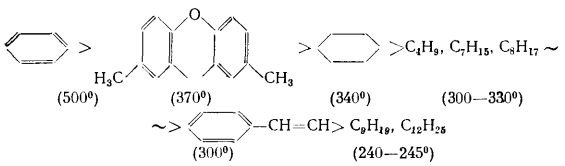
When the given ligand is replaced by a diphenylarsinic acid residue, the thermal stability of the corresponding coordination polymers falls and the relative stability series of the metals changes:

$$Cr\,(390^0) > Fe\,(380^0) > Mo\,(360^0) > W\,(320^0) > Mn\,(240^0)\ ^{67}.$$

Polymers based on toluene-*p*-sulphonic acid exhibit the highest thermal stability. Thus manganese polysulphonate does not begin to decompose in an inert atmosphere until 520°C and its weight decrease by 10% at 600°C.[67,114]

According to thermogravimetric data (heating rate 4.5 deg min^{-1}), the weight of coordination polymers based on phosphinic acids with aliphatic substituents at the phosphorus atom begins to decrease in air at a temperature as low as 160–230°C.[57,69,102]

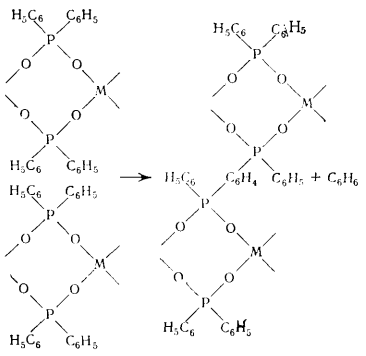
It has been established that manganese polyphosphinates form the following sequence of substituents at the phosphorus atom as a function of the temperature (indicated in brackets) corresponding to the 10% decrease in the weight of the polymer in air at a heating rate of 4.5 deg min^{-1}:



Among the bivalent metal polyphosphinates described, cobalt polydiphenylphosphinate proved to have the highest thermal stability: its weight begins to decrease in an inert atmosphere at 485°C.[24]

Investigations have shown[23,24,51,63] that the alkyl or aryl groups at the phosphorus atom are the first to be split off in the thermal degradation of bivalent metal polyphosphinates.

Only benzene has been detected in the volatile decomposition products of zinc polydiphenylphosphinate at 500°C; it is probably liberated via the mechanism[24]



Golgotui and Rosca[63] noted that the most stable bonds in metal polyphosphinates are the O–M and O–P linkages in the inorganic main chain of the macromolecules, which persist in the solid decomposition products characterised as $M(PO_3)_2$ or $MO.P_2O_5$. According to Saraceno and Block[32], chromium polyphosphinates with the structure $\{Cr(H_2O)(OH)[OP(C_6H_5)_2O]_2\}_n$ begin to lose weight at about 375°C in dry nitrogen, at 355°C in air, and at 335°C in moist oxygen. The authors attribute the initial decrease of the weight of the polymers at 370–420°C to the elimination of the residual acetate groups from the polymer and not to its true decomposition.

Comparison of the temperatures corresponding to the onset of weight loss by chromium polydiphosphinate (296 to 300°C), obtained from chromium acetylacetonate and diphenylphosphinic acid, and chromium acetylacetonate itself (approximately 250°C)[118] led Block et al.[15] to the conclusion that the side ligand at the chromium atom (acetylacetone) is the first to be split off on heat treatment.

The study of beryllium[51], chromium[32], zinc[23], and manganese[102] polyphosphinates subjected to a prolonged heat treatment under isothermal conditions revealed a fairly high thermal stability. Thus, on heating in air at 440°C for 20 h, zinc polydiphenylphosphinate lost only about 2.8% of its weight[23].

The literature data available at present therefore permit the conclusion that the thermal decomposition of metal polyphosphinates does not involve the inorganic main chain in the initial stage and proceeds as a result of the elimination of the organic substituents at the phosphorus atom or the additional ligands linked to the metal atom.

When the oxygen atom is replaced by sulphur in the phosphinate group, the thermal stability of the polymers diminishes. This can be traced on the basis of the results of the thermogravimetric analysis of cobalt-containing coordination polymers based on diethylphosphinic, diethylphosphinothioic, and diethylphosphinodithioic acids[63]. These polymers can be arranged in the following series in terms of the temperatures corresponding to the onset of their weight loss in air:

$$\underset{(285^0)}{\{Co[(C_2H_5)_2PO_2]_2\}_n} > \underset{(195^0)}{\{Co[(C_2H_5)_2POS]_2\}_n} > \underset{(185^0)}{\{Co[(C_2H_5)_2PS_2]_2\}_n}$$

The chemical stability of metal polyphosphinates has been very little studied. It has been shown that pyridine has a degrading effect on zinc polydi-n-butylphosphinate[56] The dissolution of cobalt polydiphenylphosphinate in pyridine is accompanied by the formation of adducts in which the phosphinate : pyridine ratio is 1 : 1.[18]

Slota et al.[53] studied the degrading influence of water on beryllium-containing polyphosphinates and suggested that the bonds formed by the residues of the phosphonic acid, present as an admixture in the initial phosphinic acid, are unstable with respect to hydrolysis.

Under the influence of concentrated inorganic acids and bases, bivalent metal polyphosphinates decompose with the liberation of the corresponding phosphinic acids even at room temperature. Acetic acid degrades polymers to a much smaller extent. Manganese polyphosphinates with aliphatic substituents and zinc polyphosphinate resist the action of water[102].

Rose and Block[23] noted the stability of zinc polyphosphinates with respect to radiation.

The resistance of metal polyphosphinates to the action of water together with their high thermal stability and heat resistance constitutes an important factor, which provides a basis for the development of various materials from them. However, there is so far very little information about the practical applications of bridge coordination polymers. It is contained mainly in the patent literature. In particular, it has been noted that polyphosphinates can be used as protective coatings[119]. Titanium and chromium polyphosphinates as components of coatings impart antistatic properties to organic plastics[120]. The study of the influence of metal polyphosphinates on the polymerisation of aminoalkyl acrylates showed that metal polyphosphinates are responsible for the formation of gel-like structures in the monomer at low concentrations (of the order of several per cent). It has been shown that the

introduction of small amounts of polyphosphinates into the initial monomeric composition gives rise to a structural viscosity, which is reflected in the supermolecular structure and improves the physicomechanical properties of the coatings based on the polymers [59,121].

Certain chromium triphosphinate polymers can be used as thickening agents for silicones which enables them to be used at elevated pressures [120,122].

According to an American patent [123], chromium polyphosphinate additives are used as photostabilisers and thermostabilisers for poly(vinyl chloride) and its copolymers. Chromium polymethylphenylphosphinate is a satisfactory stabiliser of the viscosity of greases and hydraulic liquids based on phosphate esters (for example, tricresyl phosphate) [124]. Heat resistant (up to 300°C) metal polyphosphinates manufactured in the USA are recommended as coatings, composition for the formation of hermetic seals, and adhesives [125].

Dissociation of Positive Molecular Ions

A.A.Perov, S.E.Kupriyanov, and R.V.Manvelyan

The dissociation of accelerated positive molecular ions on collision with atoms and molecules (impact dissociation) is considered. Various experimental methods for the investigation of such dissociation are compared. The mechanisms of the impact dissociation of molecular ions are examined in relation to the simplest diatomic ions. Attention is concentrated on the impact dissociation of polyatomic ions. The scope of this in the determination of the structures and energetics of excited ions is discussed.
The bibliography includes 120 references.

I. INTRODUCTION

The study of the structures and excitation energies of ions yields much information about the structure and state of the initial neutral molecule; furthermore, it has additional interest, since ions arise and are involved in various processes and information about their structures and excitation energies can be used to characterise such processes.

The structures and excitation energies of ions can be studied by mass-spectroscopy using different procedures, in particular it is possible to investigate their spontaneous dissociation or their dissociation under the influence of various agents, i.e. induced or impact dissociation. The spontaneous dissociation of molecular ions is already used in mass-spectrometry to determine the mechanisms of the dissociation of the initial ion, to determine the structure of the ion, to classify the transition states leading to a specific reaction, and to obtain analytical information about mixtures. Impact dissociation reactions of molecular ions can yield more information about the ion and the initial molecule than spontaneous dissociation, particularly because they can occur with any ion and via numerous channels. The impact dissociation of ions can be achieved by the same procedures as the ionisation of molecules, i.e. as a result of the collision of electrons and protons, but with ions and not molecules. This excites the initial ions (they can actually be ionised further) and causes their dissociation, yielding their fragmentation spectra, which can be called the mass spectra of the ions by analogy with the mass spectra of molecules. The mass spectra of both positive and negative ions can be studied in this way. However, the study of the dissociation of ions under the influence of electrons and photons is only just beginning and so far only the first experiments have been carried out with the simplest ions.

This is due to considerable technical difficulties in studies of this kind, although there is no doubt that this procedure will yield more accurate answers to many questions concerning the structures and the energy states of ions and the mechanisms of their dissociation of accelerated ions by collisions with atoms and molecules.

In experiments designed to investigate impact dissociation one measures the total dissociation cross-sections, the relative probabilities of the formation of various fragments (dissociation spectra), and the angular and energy distributions of the dissociation products. Many characteristics of impact dissociation have been observed and investigated; these yield conclusions concerning the structures and excitation energies of the initial ions and also concerning the mechanisms of their decomposition.

The present review is devoted mainly to studies on the dissociation of polyatomic ions and its aim is not to cover the majority of investigations in this field. The fundamental characteristics of impact dissociation were discovered by the present authors on the basis of experiments carried out mainly at the Karpov Physicochemical Institute. The dissociation of diatomic molecular ions is considered only in order to examine the mechanisms of impact dissociation. The entire vast experimental and theoretical data on the dissociation of the simplest molecular ions evidently merit separate consideration.

II. EXPERIMENTAL METHODS FOR THE INVESTIGATION OF THE DISSOCIATION OF IONS

There are several groups of investigators of the dissociation of ions, who are using the usual analytical mass-spectrometers without any significant modification, i.e. in approximately the same way as in the work of Aston[1], who first observed the dissociation of H_2^+ ions on collision with the molecules of the residual gases. However, it is already clear that, by employing the usual mass-spectrometers with a single analyser, it is possible to obtain only very limited information about the dissociation processes of molecular ions. For this reason, in order to study in detail the ion dissociation reactions and hence obtain information about their mechanisms and about the structures and excitation energies of the ions and of the initial molecules, it is necessary to apply a modified mass-spectrometric technique, which involves at least two analysers and a collision chamber.

In a sector mass-spectrometer with a single magnetic analyser dissociation is usually observed in the region where there is no magnetic field between the outlet slit of the ion source and the magnet and it can occur both as a result of collisions with the molecules of residual gases and spontaneously. The fragment ions then give diffuse peaks in the collector, the so called Aston bands or "fractional" peaks, the positions of which on the mass scale are defined by the formula

$$m^* = \frac{m_f^2 q_i}{m_i q_f^2}, \qquad (1)$$

where m^* is the apparent mass of the fragment ion, m_f and q_f are the true mass and charge of the fragment ion, and m_i and q_i are the mass and charge of the initial ion. This formula was obtained on the assumption that the velocity of the ion does not change significantly on decomposition. This is in fact found to be the case in the experiments. If the charge does not change either in the decomposition of the initial singly-charged ion, Eqn. (1) simplifies to

$$m^* = \frac{m_f^2}{m_i}. \qquad (2)$$

On the other hand, if the ion decomposes in the ion source during the acceleration process, the apparent mass of the fragment ion is defined by the formula[2]

$$m^* = \left(\frac{m_f^2 q_i}{m_i q_f^2} \cdot \frac{V_1}{V}\right) + \left(1 - \frac{V_1}{V}\right)\frac{m_f}{q_f}, \qquad (3)$$

where V_1 is the potential difference corresponding to the distance traversed by the metastable ion before the decomposition point and V is the total accelerating potential difference.

The use of a mass-spectrometer with a single magnetic analyser to investigate ion dissociation suffers from the disadvantages that, in the region between the ion source and the magnetic analyser, all the ions emerging from the ion source can dissociate. As a result, the peaks corresponding to different dissociation processes can be superimposed. In particular, this hinders the observation of spontaneous and impact dissociation in the ionisation of polyatomic molecules. The absence of a localised gas target (collision chamber) hinders the determination of the collision cross-sections. The technique for the investigation of the dissociation of the simplest ions in a usual mass-spectrometer has been described[3].

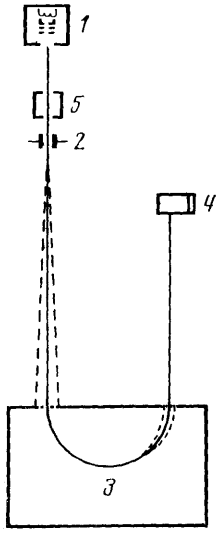

Figure 1. Schematic illustration of a mass-spectrometer: 1) ion source; 2) electrostatic deflector; 3) magnetic analyser; 4) ion detector; 5) collision chamber.

Thus mass-spectrometers with a single magnetic analyser are at present used mainly to investigate the dissociation of the simplest diatomic and triatomic molecular ions. Modified designs of such apparatus have been used by Los[4] and Durup et al.[5] Fig. 1 presents a schematic illustration of Los's apparatus. In contrast to the usual mass-spectrometers, it incorporates a collision

chamber *5*. The presence of narrow collimators at the outlet from the collision chamber makes it possible to achieve a high angular resolution (10^{-3} rad). The analysing magnet has an inhomogeneous field, which results in a high resolving power with respect to energy ($\sim 10^{-4}$).

The disadvantages of single mass-spectrometers are eliminated in apparatus with two magnetic analysers (double mass-spectrometers), which were used for the first time to investigate the impact dissociation of the simplest diatomic and triatomic ions by Ioffe[6-9] at the Leningrad Physicotechnical Institute.

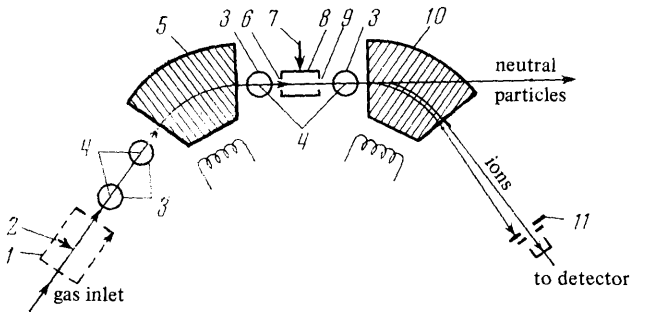

Figure 2. Schematic illustration of a double mass-spectrometer: 1) ion source; 2) electron beam; 3) diffusion pumps; 4) electronic valves of the ionisation manometer; 5) mass-monochromator; 6) inlet slit S_1 of the collision chamber; 7) admission of target gas; 8) collision chamber; 9) outlet slit S_2 of the collision chamber; 10) mass analyser; 11) the slit S_3 before the ion collector.

Studies on the dissociation of polyatomic ions using double mass-spectrometers have begun at the Karpov Physicochemical Institute[10-12]; a schematic diagram of one of these instruments is presented in Fig. 2. The first magnetic analyser (mass-monochromator) isolates the beam of the ions being investigated and directs them to the collision chamber which has controllable inlet and outlet slits S_1 and S_2. Beyond the chamber, there is a second magnetic analyser (the mass-analyser) which analyses the spectrum of the fragments arising as a result of impact or spontaneous dissociation. The width of the slit S_3 before the collector varies in the range 0–16 mm. The differential evacuation of the mass-spectrometer is achieved by four diffusion pumps, which give a pumping rate of 100 litre s^{-1}. The ion source consists of a gas source with ionisation of the molecules by an electron beam with a controllable energy. The accelerating potential varies from 2 to 5 kV. Furthermore, there is a possibility of a further acceleration of the ions up to 100 keV. On a double mass-spectrometer, it is possible to investigate both the spontaneous dissociation of the metastable ions and the dissociation resulting from single collisions of the accelerated ions with the molecules of the gas admitted to the collision chamber up to a pressure of 10^{-4} torr, measured with the aid of a calibrated ionisation manometer or a McLeod gauge.

The total dissociation cross-section of the ions σ is calculated from the formula

$$\sigma = \frac{I^* kT}{Ipl}, \qquad (4)$$

where I^* is the current due to the secondary fragment ions, I the current due to the initial ions, p the gas pressure in the collision chamber, l the effective length of the collision chamber†, k the Boltzmann constant, and T the absolute temperature of the gas in the chamber.

For single collisions I^*/I varies linearly with pressure and the dissociation cross-section is characterised by the slope of the linear plot of I^*/I against p. Fig. 3 illustrates relations of this kind for a number of dissociation processes of ions derived from ethylene. Extrapolation of the I^*/I–p straight lines to zero pressure yields intercepts on the ordinate axis, which characterise the contribution of spontaneous decompositions to the given dissociation process.

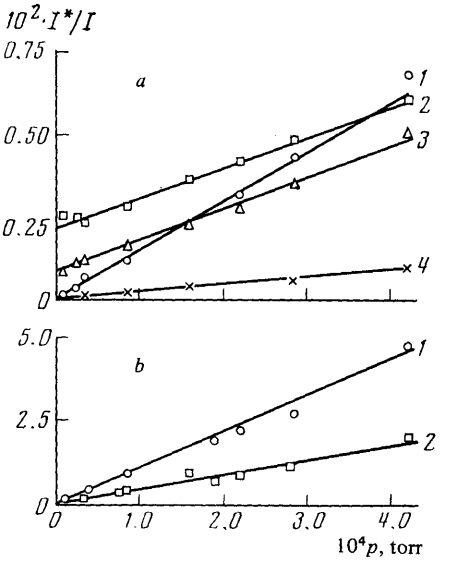

Figure 3. Variation of the relative ionic currents (I^*/I) with gas pressure p (measured using an LM-2 gauge) in the collision chamber. *a*: 1) $C_2H_4^{2+} \rightarrow C_2H_4^+$; 2) $C_2H_4^{2+} \rightarrow C_2H_3^+ + H^+$; 3) $C_2H_4^{2+} \rightarrow C_2H_2^+ + H_2^+$; 4) $C_2H_4^{2+} \rightarrow C_2H^+$; *b*: 1) $CH_2^+ \rightarrow CH^+ + H$; 2) $CH_2^+ \rightarrow C^+$.

To determine the true extent of spontaneous decomposition, it is always necessary to investigate the relation between the ratio I^*/I and the pressure in the region where it occurs, as has been done in studies on a double mass-spectrometer. In certain other investigations the pressure was not measured directly in the region where ions are decomposed but measurements were made of parameters such as the pressure in the system for supplying the ion source with gas[16] or of the current due to the initial ions[17], which is proportional to the gas pressure in the ion source. A situation may arise where the pressure in the region where ions decompose varies only slightly

† It is as a rule greater than the geometrical length of the collision chamber. The methods for its calculation have been described[13,14] and in the study of Menendes et al.[15] the collision region was isolated by an electric field.

when the pressure in the filling system is altered (for example with a high pumping rate in this region and when it is remote from the source) and is close to the background (residual) pressure. Then, when dissociation occurs on collision with the molecules of the background gas, the ratio I^*/I will vary only slightly as a function of the pressure measured in this way, creating the impression that it is apparently independent of pressure. One cannot rule out the possibility that such a situation arose under the conditions used by Wankenne and Momigny[17]. Extrapolation of this relation to zero pressure (in the measurement of p by the above methods) leads to an incorrect determination of the contribution by the spontaneous decomposition of the metastable ions. For this reason, the pressure must be measured directly in the region where decomposition is observed.

For a more complete understanding of the impact dissociation process, it is necessary to carry out investigations for different kinetic energies of the initial ions, particularly in the region of threshold energies, which permits the determination of the dissociation and excitation energies of the ions. A number of instruments have been constructed[18-20] for the investigation of dissociation under the conditions of low energies.

Double-focussing mass-spectrometers have been used recently to study ion dissociation. In such instruments there are three regions in which it is possible to observe the dissociation of metastable ions[21]. The first region is between the inlet slit of the ion source and the inlet to the electrostatic analyser. The second region is between the electrostatic and magnetic analysers and the third region is located in the accelerating section of the ion source. In the study of spontaneous decompositions in the first region the defocussing method is used. The double-focussing mass-spectrometer transmits only ions with a narrow range of kinetic energies. Ions formed on spontaneous decomposition possess only part of the energy of the initial ion. To detect the metastable ion in the reaction $m_0^+ \rightarrow m_1^+$, it is necessary to increase the ratio of the accelerating potential V to the potential on the plates of the electrostatic analyser E by the factor m_0/m_1, i.e. the mass-spectrometer must be defocussed in relation to the initial ion[22]. This can be done by scanning the accelerating potential from its usual value corresponding to a constant potential E using a magnetic field tuned for the transmission of the ion with the mass m_1. The spectrum of all the ions generated on spontaneous decomposition by the ions with the mass m_1 can be obtained in this way.

In another method[23-25] the peaks corresponding to the decomposition of the metastable ions are observed by decreasing the potential applied to the electrostatic analyser by the factor m_1/m_0 and by tuning the magnetic field for the transmission of the "apparent mass" $m^* = m_1^2/m_0$. The advantage of this method over the first procedure is that, in carrying out quantitative measurements, the intensities of different metastable transitions can be more effectively compared under the same conditions in the ion source, in particular at a constant accelerating potential.

The technique for the investigation of spontaneous dissociation in a double-focussing mass-spectrometer having the Nier–Jones geometry, with scanning of the potential applied to the electrostatic condenser, has been described in relation to the decomposition of the ions formed from the toluene molecule[26]. The sensitivity achieved in recording the ions generated on decomposition amounted to $(1 - 2) \times 10^{-6}$ of the intensity of the initial ion, i.e. about 10^{-4}%.

McLafferty and coworkers[27] used a mass-spectrometer with the reverse geometry. Here the ion source in the double-focussing instrument was located in the place of the detector and the detector was in the place of the ion source. Spontaneous decompositions are recorded in the region between the magnetic and electrostatic analysers. This method has certain advantages compared with the other two procedures described above. The scanning of the potential applied to the electrostatic condenser yields the entire spectrum of the fragment ions obtained from the given initial ion. Ion dissociation on collision is now also beginning to be investigated on apparatus with double-focussing having both normal and reverse geometry[28].

In the study of ion dissociation the measurement of the angular and energy distributions of the dissociation products is important. To measure the angular distributions of ions in double mass-spectrometers, it must be possible to move the second analyser relative to the axis passing through the centre of the collision chamber, as for example in the apparatus illustrated in Fig. 2. Another method has been used in studies[4,5] where a deflecting collimator was mounted at the outlet from the collision chamber and was able to scan the ion beam via a narrow collimator.

The energy distribution is measured with the aid of magnetic[4,5] or electrostatic analysers. A method for the energy spectroscopy of ions using a double-focussing mass-spectrometer, which makes it possible to record the changes in the energy of the fragment, equal to 10^{-4} eV in the centre of mass system for a dissociating ion, has been reported[29]. A novel apparatus using a 127° electrostatic analyser and a quadrupole mass-analyser, which were positioned beyond the collision chamber, has been used to measure the angular and energy distributions of the dissociation products of certain diatomic ions[30]. The nature of the energy distribution of the dissociation products is important, since the efficiency of the recording of the fragment ions depends on it. When it is necessary to measure the total dissociation cross-section, all the fragment ions formed in the collision chamber should be recorded in the collector. This is most important also for the comparison of the intensities of different metastable transitions. Incomplete recording of the protons has been the cause of an error in the measurement of the total dissociation cross-section of the H_2^+ ions in certain early investigations, discussed in a number of communications[13,14,31].

In the measurement of the total dissociation cross-sections of simple diatomic and triatomic ions, where there is no need for a high resolution, the slit before the ion collector must be as wide as possible. Sometimes it must also be made wide in the study of the dissociation of polyatomic ions[32]. This is difficult to achieve in analytical mass-spectrometers. For a narrow slit, it is necessary to measure the distribution of the peak intensity by scanning the magnetic field and the total current must be found by integrating this distribution. In double-focussing apparatus this procedure is more complicated, since it is necessary to scan the electric and magnetic fields[33]. Quantitative analysis of metastable transitions involving polyatomic ions may be experimentally difficult, requiring the use of a computer, as was done by Coutant and McLafferty[34].

In concluding this section, we shall consider briefly a method for the investigation of ion dissociation under the influence of electron and photon impact. The dissociation in collisions with electrons is studied by the method of ion and electron beams intersecting at right angles. To

reduce the signal arising due to the impact dissociation of the initial ions in collisions with the molecules of the background gas, the pressure in the region of the intersection of the beams is less than 10^{-9} torr. Furthermore, a technique involving modulation of the peaks is employed to isolate the required signal. Measurements have been made of the dissociation cross-sections of H_2^+, O_2^+, N_2^+, and D_2^+ for electron energies in the range 10–1500 eV.[35]

Using the emission from a ruby laser to investigate the photodissociation of H_2^+ ions[36], the energy spectrum of the protons was found to depend on the plane of the polarisation of the light and vibrational structure was observed, reflecting the populations of the vibrational levels of the initial H_2^+ ions. Thus the study of the photodissociation of molecular ions by means of laser light with simultaneous analysis of the dissociation products with respect to kinetic energies may prove to be promising in the sense of creating a desirable method for determining the excitation energies of molecular ions obtained in different processes. Still greater possibilities arise when tunable lasers are used.

III. DISSOCIATIVE COLLISIONS OF DIATOMIC IONS

The studies on the impact dissociation of diatomic ions carried out up to 1970 have been reviewed in a book[37] and two articles[38,39]. The aim of this section is to describe the fundamental mechanisms of the impact dissociation of accelerated ions with illustrations by examples taken mainly from the recent studies in this field.

The impact dissociation of a diatomic ion proceeds via the mechanism

$$AB^+ + M \begin{cases} \longrightarrow A^+ + B + M \\ \longrightarrow B^+ + A + M \end{cases}, \qquad (5)$$

where all the species on the right-hand side can also be formed in excited states and, for high kinetic energies, in ionised states.

The dissociation mechanisms have been classified by Durup[38], the classification having been somewhat modified by Los[4]. Four mechanisms can be put forward for the impact dissociation of molecular ions: (1) electronic transitions to unbound states of the molecular ion or to bound states above the dissociation limit; (2) vibrational-rotational transitions to a continuum without a change in the electronic state of the ion AB^+ (adiabatic mechanism); (3) dissociation via the formation of an intermediate complex (AB^+M), which decompose into $A^+ + B + M$ or into $B^+ + A + M$, which occurs when the energies of the relative motion are of the order of magnitude of the bond energy of the AB^+ ion; (4) predissociation caused by the collision.

The contribution of each mechanism to the total dissociation cross-section depends to a large extent on the kinetic energy E_0 of the AB^+ ion and also on its excitation. Since ion dissociation has been studied over an extremely wide range of values of E_0 (from several electron-volts to tens of MeV for H_2^+ ions), it is possible to estimate the approximate limits of the region of E_0 within which a particular mechanism predominates. Electronic transitions predominate over a wide range of energies from hundreds of electron-volts to the maximum values achieved experimentally. Vibrational transitions are probably important for energies in the range 10–100 eV. Finally, induced predissociation has been observed for energies in the range $\sim 10^3$–10^4 eV.

There is an unambiguous relation between the distribution of the dissociation products in the centre of mass coordinates based on the AB^+ ion and the form of the distribution in terms of the laboratory coordinate system, or, using the mass-spectrometric terminology, the shape of the peak in the ion collector. We may note that, in order to obtain the true energy distribution in the centre of mass coordinates on transformation from the distribution in terms of the laboratory coordinate system, account must be taken of the apparatus function of the instrument[5,40]. The relation between the shape of the peak and the energy distribution of the dissociation products for double-focussing mass-spectrometers has been considered[41,42]. There is a simple relation between the energy in the centre of mass system and the energy E_A of the fragment ion in terms of the laboratory system. For convenience we shall assume that the masses of the species A and B involved in reaction (5) are $m_A = m_B = m$. If the velocity of the fragment in the centre of mass system is u, then

$$E_A = \frac{m(v_0 + u)^2}{2} = \frac{mv_0^2}{2} + mv_0 u\cos\varphi + \frac{mu^2}{2} = \frac{E_0}{2} + \frac{W}{2} + mv_0 u\cos\varphi, \qquad (6)$$

where v_0 is the velocity of the AB^+ ion, φ the angle at which the A^+ ion is ejected in the (A, B) centre of mass system, W the kinetic energy of the dissociation products in the (A, B) centre of mass system, and E_0 the kinetic energy of the initial AB^+ ion. The quantity $\frac{1}{2}W + mv_0 u\cos\varphi = \Delta E$ is the additional kinetic energy acquired by the A^+ ion in the laboratory system of coordinates.

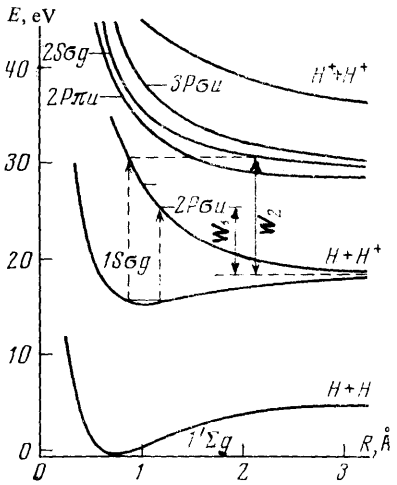

Figure 4. Potential energy curves for H_2^+ ions.

We shall consider this in relation to the dissociation of H_2^+ ions, the potential energy curves for which are shown in Fig. 4. In the electronic transition from a particular vibrational level in the ground state $1s\sigma_g$ to the nearest unbound state $2p\sigma_u$ in the centre of mass system a kinetic energy in the range from W_1 to W_2 is liberated, since for $E_0 \simeq 10^3$ eV and above the collision time is much shorter than the vibration period of the nuclei and the Franck–Condon principle is maintained in the electronic transition.

The limits W_1 and W_2 are determined by the initial vibrational level of the H_2^+ ion. In the measurement of the energy distributions use is made of narrow outlet collimators, which isolate the fragment ions emerging in the centre of mass system at angles close to $\varphi = 0°$ and 180°. Then, in accordance with Eqn. (6), two energies are observed in terms of the laboratory system for each energy of the fragment in the $\frac{1}{2}W$ centre of mass system (and the corresponding velocity u):

$$E_1 = \frac{E_0}{2} + mv_0u + \frac{1}{2}W;$$

$$E_1' = \frac{E_0}{2} - mv_0u + \frac{1}{2}W.$$

Thus in the laboratory coordinate system an energy distribution with two symmetrical maxima will be observed. The maxima will be diffuse owing to the contributions of different W acquired by the dissociation products of the AB^+ ions in a particular initial vibrational state and in consequence of a distribution with respect to vibrational states in the beam of the initial H_2^+ ions. Since in reality the outlet slits of the instruments have a finite width and transmit a proportion of the ions with a transverse velocity component u, the form of the distribution changes, since the number of ions detected increases for $\Delta E \simeq 0$ [the values of W in Eqn. (6) can be neglected, since $W \ll E_0$].

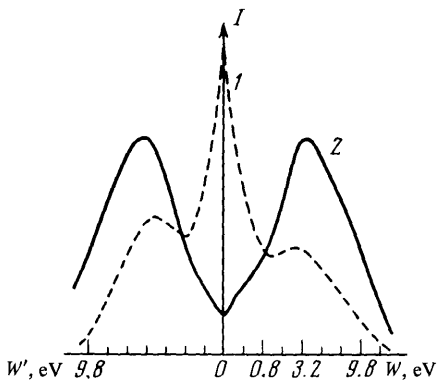

Figure 5. The energy spectrum of H^+ ions in the centre of mass system on impact dissociation of H_2^+: 1) without allowance for the apparatus function; 2) with allowance for the apparatus function.

Therefore a sharp peak appears at the centre of the distribution (Fig. 5). Transitions for which $W \simeq 0$ make a definite contribution to this maximum; these are vibrational transitions to the continuum of the $1s\sigma_g$ state adjoining the dissociation limit. The contribution of the vibrational transitions increases with increase of the atomic number of the target[38,40]. Some workers believe that electronic transitions to the $2p\sigma_u$ state from high vibrational levels of the ground state make a significant contribution to the formation of the central peak[43]. The possibility of dissociation via the excited state $2p\pi_u$, which has a low-slope potential curve, is also assumed. A shift of the central peak towards lower energies has been observed in experiments with different targets, particularly when the excitation energy of the target is small[38,44]. The position of the central peak is determined by the quantity $E_0/2 - E^*/2$, where E^* is the energy consumed in the dissociation process (the excitation energy of the particles involved in the collision).

The angular distributions of the protons in the dissociation of accelerated H_2^+ ions have been studied both theoretically and experimentally. A calculation carried out for different internuclear distances R (i.e. for different vibrational levels) has shown that, for low values of R, protons move apart preferentially parallel to the axis of the beam. For large values of R, dissociation with the orientation of the internuclear axis at right angles to the axis of the beam is more likely. The simultaneous excitation of the target can markedly alter the distribution and can lead to various anomalies[43,45-48].

The cross-section for the dissociation of H_2^+ ions due to electronic transitions has been estimated theoretically by various investigators in terms of the Born approximation[49-56]. Despite the fact that this is a high-energy approximation, it has been used successfully for energies in the range 1–100 keV. The contribution of the vibrational mechanism to the total dissociation cross-section has also been estimated[57]. For this purpose, the classical momentum approximation was employed[58]. For an energy of H_2^+ ions of 3 keV and collisions with hydrogen atoms, the cross-section for the vibrational dissociation is approximately 10% of the experimental value. Calculations have been made for vibrational transitions due to polarisation forces in terms of a modified Born approximation[59].

Table 1. The dissociation cross-sections Σ of H_2^+ ions obtained from different molecules.

Initial molecule	H_2	CH_4	C_2H_4	C_4H_{10}	$C_{12}H_{24}$	GeH_4	SiH_4
$10^{16} \cdot \Sigma$, cm^2	1.06[65]	2.5[66]	1.4[65]	1.7[65]	1.4[65]	2.1[67]	1.7[67]

The dissociation cross-section of H_2^+ ions depends on vibrational excitation. Experiments confirming this fact have been carried out by different groups of investigators[60-64]. H_2^+ ions were obtained not only by the ionisation of H_2 molecules by electrons of different energies but also in the dissociative ionisation of various hydrogen-containing molecules[65-67]. Table 1 lists the experimental dissociation cross-sections of H_2^+ ions obtained from different molecules. The energy of the H_2^+ ions was 3.8 keV and the target was neon. Evidently the most excited H_2^+ ions are formed in the dissociative ionisation of methane molecules by electrons (E_e = 120 eV).

The interpretation of experiments on the dissociation of N_2^+ is less unambiguous than in the case of H_2^+ owing to the more complicated electronic structure[69-72]. A marked dependence of the impact dissociation cross-section of N_2^+ ions on the energy of the electrons ionising the nitrogen molecules has been observed in a number of studies[73-75]. This result suggests an appreciable proportion of excited N_2^+ ions in the beam. Among these may be not only vibrationally excited but also electronically excited ions. The N_2^+ ions formed by the ionisation of HN_3 molecules are appreciably excited[76]. The most probable process in the dissociation of N_2^+ ions for energies in the region of about

10^3 eV is an electronic transition to a section of the $D^2\Pi_g$ potential curve above the dissociation limit and predissociation in the $C^2\Sigma_u^+$ state[77,78].

Heteronuclear ions dissociate via the same mechanisms as homonuclear ions. However, there are certain characteristic features owing to the presence of a permanent dipole moment in heteronuclear ions[59]. The dissociation of the heteronuclear ions HeH^+,[79-81] HD^+,[82,83] CO^+, and NO^+ [72] has been studied.

IV. METASTABLE IONS

In mass-spectrometry metastable ions are excited ions whose lifetime with respect to decomposition and emission is of the order of 10^{-6}–10^{-5} s. This is determined by the residence time of the ions in the ion source after their formation as a result of the ionisation of the molecules by electrons and by the time taken to traverse the path from the field-free region of the mass-spectrometer to the point where the metastable ion decomposes. The observed slow decompositions of the ions may be due to different causes. Firstly, as a result of the ionisation of the molecule, the ion can be formed in excited electronic states, which have longer lifetimes with respect to emission and emit with transition to an unbound state or to a section of a bound state above the dissociation limit. Secondly, the ion may be in an excited state which has a barrier; in this case the dissociation proceeds via the tunnel effect. Calculations of the permeability of the barrier carried out by the usual equations have shown that, for example, for a barrier height of 1 eV and widths of 0.15 and 0.25 Å, the lifetimes of N_2^{2+} and NO^{2+} are found to be respectively $\sim 10^{-7}$ and 10^{-6} s.[16] Calculations for the spontaneous decomposition of $C_2H_4^{2+}$ and CO^{2+} ions have shown that their lifetimes are of the order of $\sim 10^{-5}$ and 10^{-4} s respectively.

The third possible mechanism involves slow predissociation in the excited state of the ion. Predissociation usually takes place during a period which is much shorter than the lifetime with respect to emission. When not all the selection rules are obeyed, predissociation is then slow[84]. Thus the metastable ion will be observed when the predissociation time is of the order of magnitude of the lifetime with respect to emission, which in turn should be $>10^{-7}$ s.

The rate of predissociation in the mass-spectra of polyatomic molecules, is calculated using the quasiequilibrium theory of mass-spectra, the latest review of which has been written by one of its originators[85]. This theory presupposes that the processes leading to the formation of the mass-spectra consist of a series of consecutive and competing reactions, the rates of which can be calculated on the basis of the theory of absolute reaction rates.

The general expression for the rate constant for a unimolecular reaction is[85]:

$$k(E) = \frac{S}{h}[N^*(E-\varepsilon_0)/\rho(E)],$$

where S is the symmetry factor equal to the number of identical reaction paths (with the same activation energy and activated complex), h Planck constant, $N^*(E-\epsilon_0)$ the number of states of the activated complex with energy $\leq E-\epsilon_0$, $\rho(E)$ the density of the states of the initial ion with a total energy E, and ϵ_0 the activation energy.

The quasiequilibrium theory predicts that the rate constant should be a monotonically increasing function of the internal energy. Considering the molecular ion as an assembly of N harmonic oscillators (N is the number of internal degrees of freedom of the molecular ions) and assuming for simplicity that the frequencies of all the oscillators are identical, we obtain a simple expression for the decomposition rate constant:

$$k(E) = \nu\left(1-\frac{\varepsilon_0}{E}\right)^{N-1},$$

where ν is the frequency factor.

Table 2. C–H bond dissociation energies E_{C-H}.

Ion	$C_3H_8^+$	$C_3H_7^+$	$C_3H_6^+$	$C_3H_5^+$	$C_3H_4^+$	$C_3H_3^+$
E_{C-H}, kcal mole^{-1}	8	92	49	102	44	150

Ions with a large excitation energy E have large decomposition rate constants and decompose in the ion source. Weakly excited ions have $k \simeq 10^6$ s^{-1} and decompose after emerging from the ion source into the field-free region of the analyser, forming "metastable peaks". Since metastable ions are weakly excited, the energy of the process should play a significant role in their dissociation. In particular, one may expect appreciable differences in the spontaneous decomposition of alkane ions with even and odd numbers of hydrogen atoms. Table 2 presents the dissociation energies of the C–H bonds for ions with three carbon atoms[85] and Table 3 lists the intensities of the spontaneous decompositions for the corresponding ions obtained from propane molecules.

Table 3. The intensities of the spontaneous decompositions (% relative to the intensity of the initial ions).

Decomposition process	I^*/I, %	Decomposition process	I^*/I, %
$C_3H_8^+ \rightarrow C_3H_7^+ + H$	1.5	$C_3H_6^+ \rightarrow C_3H_5^+ + H$	0.1
$C_3H_7^+ \rightarrow C_3H_5^+ + H_2$	0.1	$C_3H_5^+ \rightarrow C_3H_3^+ + H_2$	2.0

The last Table shows that the spontaneous decomposition of ions with an even number of hydrogen atoms proceeds with loss of one hydrogen atom in accordance with the low activation energies for this process listed in Table 2. The spontaneous decomposition of ions with an odd number of hydrogen atoms involves the loss of two hydrogen atoms in the form of a molecule, since the activation energy for this process is reduced owing to the formation of a bond between the two hydrogen atoms abstracted.

The significant influence of the energy relations on the dissociation process frequently leads to the decomposition of the metastable ions via pathways other than simple bond dissociation. In particular, many rearranged ions are formed, since the decomposition reactions with the rearrangement of these atoms have small activation energies. This process has been discussed in detail in a monograph[88]. The decomposition of the molecular ion derived from benzoic acid labelled with deuterium in the

carboxy-group may be quoted as an example of the interchange of the positions of the atoms involved in the decomposition of metastable ions. In this case the loss of the OH group is twice as likely as the loss of OD, while for the decomposition in the ionisation chamber during periods comparable to the time required for the rotation of the carboxy-group the loss of OD groups predominates greatly over the loss of OH groups[89].

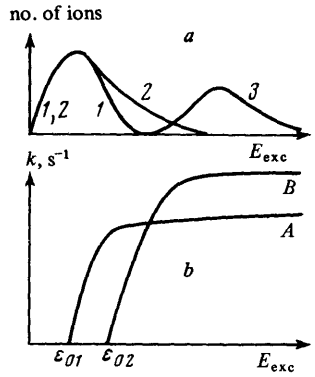

Figure 6. Impact activation of the direct bond dissociation reaction[91].

The contribution of decomposition reactions with rearrangement is greater by 2–3 orders of magnitude compared with simple bond dissociation reactions for metastable ions than for the ions decomposing in the ionisation chamber[90]. The rearrangement reactions hinder the determination of the structure of the metastable ions and their contribution may be reduced by the impact activation of the direct bond dissociation reactions. This idea is illustrated schematically in Fig. 6. Fig. 6*a* shows the distribution of ions with respect to the excitation energy E_{exc} in the ion source at the instant of their formation (curve *2*). Curve *1* describes the distribution with respect to excitation energy of the metastable ions which do not have sufficient time to dissociate in the ion source and decompose in the field-free region. Curve *A* in Fig. 6*b* represents the hypothetical dependence of the decompositon rate constant for rearrangement reactions on the excitation energy E_{exc}. Curve *B* illustrates the analogous relation for the simple bond dissociation rate constant. Curve *A* is below curve *B* for high values of E_{exc}, because the rearrangement reactions have lower frequency factors than the direct bond dissociation reactions. On the other hand, the activation energy $\epsilon_{01} < \epsilon_{02}$. The Figure shows that metastable ions, which have low excitation energies, decompose mainly via rearrangement reactions. In order to reduce their contribution, it is necessary to increase the excitation energy of the metastable ion, i.e. to shift the distribution defined by curve *1* to the position characterised by curve *3*. This is achieved by the collision of the metastable ion with a neutral particle in the region of ion drift. It has been shown[91] for the molecular ions $C_6H_5CD_3^+$ and $C_6D_5CH_3^+$, which decompose with abstraction of H or D atoms, that the contribution of the decomposition with a rearrangement of H and D atoms in impact activation is smaller by a factor of 5 compared with the spontaneous decomposition of the ions.

In the mass-spectra of polyatomic molecules the fraction of metastable ions can be fairly high. It has been shown[32] that in the mass-spectrum of n-octane, 26% of the molecular ions $C_8H_{18}^+$ undergo a metastable transition leading to the formation of the ions $C_6H_{13}^+$. Many instances of the spontaneous decomposition of molecular and fragment ions in the mass-spectra of n-octane, n-hexane, benzene, n-butane, isobutane, and other compounds have been investigated[32,57] with the aid of a double mass-spectrometer. Certain aspects of the spontaneous decomposition of polyatomic ions have been elucidated in a review[92].

We shall also consider the spontaneous decompositions of doubly-charged ions and certain simple singly-charged ions. As in the study of the decomposition of other metastable ions, valuable information is obtained here by studying the energy spectra of the dissociation products.

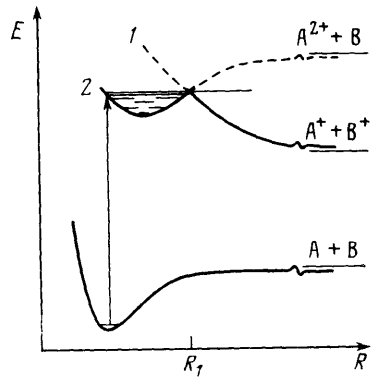

Figure 7. Hypothetical potential energy curves for a doubly-charged ion.

In the decomposition of doubly-charged ions the kinetic energy of the fragments in the centre of mass system is high (several electron-volts) and the peak has a characteristic shape with two vertices and an intervening minimum[93]. The depth of the minimum depends on the width of the collimating slits and the distance between the vertices defines the most probable kinetic energy of the fragments in the centre of mass system. The distance between the charged fragments in the doubly-charged ion can be inferred from this kinetic energy. Fig. 7 presents schematic potential curves for a neutral diatomic molecule and its doubly-charged ion. For large interatomic distances R, the potential energy of the system of ions A^+ and B^+ varies in accordance with the Coulomb law: namely as e^2/R. The overall energy of A^{2+} and B tends to a limit, which lies above the sum of the ionisation potentials of A and B, since the double-ionisation potential of A is greater than the sum of the ionisation potentials of A and B. For a certain value of R_1, the total energies of states *1* and *2* are equal. At this point the states leading to the formation of $A^+ + B^+$ and to $A^{2+} + B$ intersect, provided that they have different symmetries[84]. For the same symmetry and spin, the levels do not intersect, which leads to the formation of a barrier in one of the states. If the AB^{2+} ion is formed in a vibrationally excited state

close to the top of the barrier, then rapid predissociation takes place since the corresponding selection rules are fulfilled[84]. When the AB^{2+} ion is formed in the lower vibrational levels, it is almost stable, since the probability of passing through the barrier decreases sharply with increase of its width and height. The lifetimes characteristic of metastable ions ($\lesssim 10^{-5}$ s) will be observed in a small region of excitation energies of the AB^{2+} ion, located several tens of electron-volts below the top of the barrier. The energy of the A^+ and B^+ fragments in the centre of mass system will thus characterise the position of the top of the barrier.

For the doubly-charged ions N_2^{2+}, O_2^{2+}, I_2^{2+}, Br_2^{2+}, IBr^{2+}, and ICl^2, the kinetic energies of the fragments and the position of the top of the barrier have been determined[94]. The kinetic energy of the fragments from CO^{2+} has been found to be [57,95,96] 5.5– 6 eV, which corresponds to R = 2.6 Å. Metastable decompositions have been observed also for the CO_2^{2+} and N_2O^{2+} ions[96], the $C_2H_4^{2+}$, $C_2H_3^{2+}$, and $C_2H_2^{2+}$ ions[57,97], and for the doubly-charged ions derived from aromatic hydrocarbons (benzene, naphthalene, and biphenyl derivatives)[98]. The ion decomposition reaction $C_6H_6^{2+} \rightarrow CH_3^+ + C_5H_3^+$ results in the liberation of 2.8 eV of energy, which corresponds to a charge separation in the ion of 5.14 Å.[99]

Metastable ions were observed recently for the diatomic single-charged ions N_2^+ and NO^+ [16,17,100,101] and HS^+ ions[102]. The predissociated states were not identified exactly and much work is still required here.

V. IMPACT DISSOCIATION OF POLYATOMIC IONS

Systematic studies have been made on a double mass-spectrometer (Fig. 2) of the dissociation of a series of polyatomic ions on collision with various targets[57]. The total cross-sections for dissociation via different channels (reaching values of about 4×10^{-15} cm^2 for certain ions), their dependence on the excitation energy of the initial ion and its origin, and the dependence of the cross-sections on the kinetic energy of the ions and the type of target have been determined. Such data have been obtained for the ions[10–14,32,57] CH_4^+, CD_4^+, CH_5^+, CD_5^+, $C_2H_4^+$, $C_2H_4^{2+}$, $C_3H_8^+$, $C_4H_{10}^+$, $C_6H_6^+$, $C_7H_{16}^+$, $C_8H_{18}^+$, and many others[57]. Comparison of the mass-spectra of molecules in dissociative ionisation by electrons with the dissociation spectra of the corresponding ions obtained on collision between the accelerated molecular ions and neutral particles is also of interest.

1. Dependence of the Total Dissociation Cross-Sections and the Dissociation Spectra on the Dissociation Energy of the Ions and the Type of Target

Table 4 presents the dissociation spectra of ions from methane obtained when they collide with different atoms and molecules[10,12,57]. The kinetic energy of the ions was 2530 eV and the energy of the electrons in the ion source was 70 eV.

The Table shows that the dissociation spectra depend only slightly on the mass and the structure of the neutral target particle‡. However, the absolute values of the cross-sections differ markedly. For example, the cross-section for the process $CH_4^+ \rightarrow CH_3^+ + H$ on collision of CH_4^+ ions with air molecules is 7×10^{-16} cm^2, while on collision with hydrogen it amounts to only 2.5×10^{-16} cm^2. Similar results were obtained for the dissociation of ions from ethylene in collisions with air molecules and neon atoms[103].

‡Only collision with helium leads to more extensive dissociation.

Table 4. The relative intensities of the products of the dissociation of methane ions on collision with the target atoms and molecules.

Process		Target						
		He	Ne	Ar	H_2	n-C_4H_{10}	n-C_5H_{12}	CH_4
CH_4^+	$\rightarrow CH_3^+$	100	100	100	100	100	100	100
	$\rightarrow CH_2^+$	53	44	49	50	34	35	39
	$\rightarrow CH^+$	17	9	11	11	9	10	9
	$\rightarrow C^+$	6	3	4	4	3	3	3

The cross-sections for the individual processes depend to a large extent on the energy consumed in the process. Table 4 shows that the cross-sections decrease appreciably with increase of the number of hydrogen atoms lost, which also requires greater energy expenditure. However, for high energies of the ions, the cross-sections for the individual processes approach one another[13]. This may be associated with the increase of the excitation energy received by the ion in the collision and also with the increase of the contribution to the dissociation cross-section by processes involving the loss ("abstraction") of an electron, which results in the simultaneous dissociation of several bonds in the case of methane.

Table 5. The dissociation cross-sections ($10^{16}\sigma$, cm^2) of CD_5^+ ions on collision with air molecules and neon atoms.

Decompositon process		ϵ_0, eV	Neon	Air
CD_5^+	$\rightarrow CD_4^+ + D$	4.4	0.13	0.28
	$\rightarrow CD_3^+ + D_2$	1.3	1.1	2.0
	$\rightarrow CD_2^+ + D_2 + D$	6.5	0.3	0.56
	$\rightarrow CD^+ + 2D_2$	5.5	0.08	0.18

Total cross-section Σ			1.64	3.06

A dependence of the cross-section on the energy ϵ_0 consumed in the given dissociation process has been observed for all the processes studied with the kinetic energies of the initial ions in the region of several keV. Table 5 illustrates this fact for the CD_5^+ ions obtained in the ion source by an ion–molecule reaction.

It is interesting to note[57] that the total dissociation cross-section of CD_5^+ ions is smaller almost by a factor of two than for CD_4^+ ions. On the basis of the relation between the dissociation cross-section and the process energetics, this can be accounted for by the greater stability of the CD_5^+ ion compared with the CD_4^+ ion. The greater stability of CD_5^+ may be due to the structure of its electron shell, which is isoelectronic with that of the neon

atom, and the low internal excitation energy, which, as will be seen from the description below, greatly influences the total dissociation cross-section. Other examples of this kind can be found in studies on the dissociation of ions produced from propane as a result of collision with neon atoms. Table 6 lists the cross-section for the formation of dissociation products with three, two, and one carbon atoms and the total dissociation cross-sections Σ of certain ions from propane with a kinetic energy of 2.8 keV.[57,105]

Table 6. The overall dissociation cross-sections of the ions formed from propane ($10^{16}\sigma$, cm^2).

Dissociation products	Initial ions							
	$C_3H_8^+$	$C_3H_7^+$	$C_3H_6^+$	$C_3H_5^+$	$C_3H_4^+$	$C_3H_3^+$	$C_3H_2^+$	C_3H^+
$C_3H_n^+$	6.2	5.3	7.6	5.7	7.5	4.2	3.9	2.1
$C_2H_m^+$	13.6	3.1	1.8	0.7	0.4	0.3	0.4	0.4
CH_k^+	0.5	0.4	0.3	—	—	—	—	0.6
Σ	20.3	8.8	9.7	6.4	7.9	4.5	4.3	3.1

Evidently, with decrease of the number of hydrogen atoms in the initial ion, the cross-section for dissociation with rupture of the C–C bond decreases rapidly, becoming constant starting with the $C_3H_4^+$ ion. This behaviour reflects the fact that, with decrease of the number of hydrogen atoms in the ions, the C–C bond is stabilised up to the formation of a double bond in the $C_3H_4^+$ ion. The structure of the $C_3H_8^+$ ion is particularly unstable owing to the greatly weakened C–C bond. The abstraction of a single hydrogen atom leads to a sharp alteration of the structure and the formation of the protonated cyclopropane ring in the $C_3H_7^+$ ion, which is stable. Ions with a smaller number of hydrogen atoms probably retain this carbon skeleton with a gradual increase in the strength of the C–C bonds in the ring. The variation of the total dissociation cross-sections of these ions reflects the variation of the overall cross-sections for the abstraction of hydrogen atoms, which are somewhat greater for ions with an even number of hydrogen atoms (an odd number of electrons), Such variation of the cross-sections with abstraction of hydrogen atoms is characteristic of the ions in the mass-spectra of saturated hydrocarbons and implies that the strength of the C–H bonds varies depending on whether the number of hydrogen atoms in the ion is even or odd.

Spontaneous decomposition processes, superimposed on impact dissociation, have been observed for polyatomic ions[32,106]. As a rule, a high cross-section for dissociation on collision corresponds to an intense spontaneous decomposition of the ions, which is related to the influence of the initial excitation energy of the dissociation cross-section. Many characteristics of the impact dissociation of the ions in the mass-spectrum of n-butane and other molecules have been examined[57,107].

The total cross-sections for the dissociation, with the rupture of C–C bonds, of the molecular ions from saturated hydrocarbons are additive, i.e. the cross-section is proportional to the number of CH_2 groups in the initial ion[32,57]; the data in Table 7 illustrates this finding.

2. Comparison of the Impact Dissociation Spectra of Ions with the Mass Spectra of Molecules Obtained on Electron Impact

Comparison of the dissociation spectra of ions with their mass spectra obtained on electron impact is of great interest. Such a comparison is presented in Tables 8 and 9 for the $C_3H_8^+$ and $C_3H_3N^+$ ions and the corresponding molecules[57,103].

Table 7*. Total dissociation cross-sections Σ (Kupriyanov[57]).

Initial ion	$C_3H_{10}^+$	$C_3H_{14}^+$	$C_4H_{10}^+$	$C_4H_8^+$
$10^{15}\cdot\Sigma$ (calc.), cm^2	4.0	3.0	2.0	1.5
$10^{15}\cdot\Sigma$ (expt.), cm^2	$4.3^{\pm 3}$	$3.0^{\pm 3}$	$2.3^{\pm 6}$	$1.4^{\pm 7}$

*In the calculation of Σ it was assumed that the contribution to the total decomposition cross-section by one CH_2 group in the molecular ion is 5×10^{-16} cm^2.

The mass-spectra of the molecules were obtained for an electron energy of 70 eV. The energy of the accelerated ions was 3.5 keV and the dissociation occurred on collision with air molecules.

Table 8. Comparison of the mass-spectrum ($I_{m.s.}$) of propane and the impact dissociation spectrum (I_{im}) of the propane ion (the relative intensities of the fragment ions are quoted).

Ions	$C_3H_7^+$	$C_3H_6^+$	$C_3H_5^+$	$C_3H_4^+$	$C_3H_3^+$	$C_3H_2^+$	C_3H^+
$I_{m.s.}$	8.7	3.9	7.4	1.5	23.0	23.5	13.5
I_{im}	17.4	2.8	5.4	1.2	22.8	23.5	16.7

Table 9. Comparison of the mass-spectrum of C_3H_2N molecules ($I_{m.s.}$) and the impact dissociation spectrum (I_{im}) of $C_3H_2N^+$ ions (the relative intensities of the initial and fragment ions are quoted).

Ions	$C_3H_2N^+$	C_3HN^+	C_3N^+	C_3N^+ $C_3H_3^+$	C_3H^+	$C_3H_3^+$ CNH+	$C_3H_2^+$ CN+	C_3H^+
$I_{m.s.}$	29.5	12.6	3.2	2.6	1.7	7.1	39.4	3.9
I_{im}	36.0	12.2	1.3	3.4	1.4	6.3	36.2	3.2

A comparison of the impact dissociation spectra with the electron impact mass-spectra has also been made for a whole series of other molecular ions (derived from methane, ammonia, water, ethylene, n-octane, n-hexane, benzene, etc.). A significant similarity between the impact dissociation spectra of the ions with an energy of about 3–4 keV and the mass-spectra of the corresponding molecules follows from the data in Tables 8–10 and the

results published by Kupriyanov[57]. A similar phenomenon was noted also by other investigators[28]. Table 10 presents a section of the dissociation spectrum of benzene ions $C_6H_6^+$ and the corresponding section of the mass-spectrum of benzene itself[108]. The mass-spectrum was recorded for an electron energy of 70 eV. The kinetic energy of the $C_6H_6^+$ ions was 8 keV.

Table 10. Comparison of the mass-spectrum ($I_{m.s.}$) of benzene and the impact dissociation spectrum (I_{im}) of benzene ions (the relative intensities of the fragment ions are quoted).

m/e	68	67	66	65	64	63	62	61	55	54	50	40	39
$I_{m.s.}$	43	100	67	46	51	45	25	13	11	18	57	90	92
I_{im}	44	100	57	45	46	36	21	8	11	20	67	117	86

The similarity of the dissociation spectra and the mass-spectra has been noted in the literature for a whole series of other aromatic compounds. It has been shown[57] that the impact dissociation spectra of the $C_3H_6^+$ and $C_4H_8^+$ ions obtained by the ionisation of various molecules are not only close to one another, as can be seen from the data in Table 11, but they also resemble the mass-spectra of the corresponding C_3H_6 and C_4H_8 molecules.

Table 11*. Comparison of the mass-spectra of molecules and the impact dissociation spectra of ions obtained from different compounds.

Process	Dissociation spectra: Initial molecule C_3H_6	C_4H_{10}	C_6H_{14}	Mass-spectra: a	C_3H_6	b
$C_3H_6^+ \rightarrow C_2H_m^+$	85	83	78	81		76
$C_3H_6^+ \rightarrow CH_k^+$	15	17	22	19		24

Process	Initial molecule C_4H_{10}	C_6H_{14}	C_8H_{18}	c	C_4H_8	d
$C_4H_8^+ \rightarrow C_3H_n^+$	69	54	50	60		58
$C_4H_8^+ \rightarrow C_2H_m^+$	29	43	46	38		40
$C_4H_8^+ \rightarrow CH_k^+$	2	3	4	2		2

* The overall intensities were assumed to be 100.
a) Propene; *b*) cyclopropane; *c*) *cis*-but-2-ene; *d*) *trans*-but-2-ene; energy of the ions 3 keV; target—neon.

Such similarity of the mass-spectra of the ions suggests that in both cases, i.e. in impact dissociation of the ion and in the ionisation of the corresponding molecule by electrons, approximately identical excited ions are produced[109]; the mechanism of their dissociation is also the same.

The similarity of the mass-spectra has likewise been noted in other ion-formation processes, particularly in charge-transfer processes[110,111]. This problem has been examined in detail[112]. In all these instances the energy of the ions does not exceed several keV. For higher kinetic energies of the ions (about 20 keV and above), an appreciable difference is observed between the dissociation spectra of the ions and the mass-spectra of the corresponding molecules. This has been demonstrated for the dissociation of CH_4^+ ions[13,57,103], $C_2H_4^+$ ions,[103] and a number of other ions[13,57]. In these cases, the collisions of the ions with atoms and molecules lead to strong excitation of the ions, as a result of which they dissociate with abstraction of many hydrogen atoms (in the case of CH_4^+ ions) with the same probability as the dissociation involving the abstraction of a single hydrogen atom[13,57,103]. Therefore one should note that an increase of electron energy up to 12 keV does not lead to an intense decomposition of CH_4 molecules under electron impact of the kind observed for the dissociation of CH_4^+ ions on collision with heavy particles in the range of energies of the order of tens of kiloelectron-volts[114].

3. Characteristics of the Ion Dissociation Spectra

Table 12 shows that for each energy there are identical regions in the dissociation spectra of the initial ions containing different numbers of hydrogen atoms. This phenomenon, which we called the "inclusion" of the dissociation spectra of ions[114,115], occurs also for NH_3^+ and NH_2^+ ions[13] as well as certain other ions[57].

Table 12. Parameters of the dissociation spectra of various ions derived from methane for several (four) collision energies (the cross-section for the formation of the C^+ ion was assumed to be 1.0).

Dissociation products	Initial ions: CH_4^+	CH_3^+	CH_2^+	CH_4^+	CH_3^+	CH_2^+
	E_0=1350 eV (Ref.12)			E_0=3000 eV (Ref.12)		
CH_2^+	21	20	—	11	12	—
CH^+	4	5	4	3	4	3
C^+	1.0	1.0	1.0	1.0	1.0	1.0
	E_0=30 keV (Ref.13)			E_0=90 keV (Ref.13)		
CH_2^+	1.9	2.0	—	1.2	1.3	—
CH^+	1.3	1.3	1.3	1.0	1.0	1.0
C^+	1.0	1.0	1.0	1.0	1.0	1.0

Table 13 shows that the phenomenon of "inclusion" of the dissociation spectra is observed for the majority of processes. Thus the situation arises in which the dissociation spectra of ions containing a larger number of hydrogen atoms include the dissociation spectra of ions with a smaller number of hydrogen atoms.

The "inclusion" of spectra makes it possible to infer from the known mass-spectra of molecules obtained on electron impact the mass-spectra of radicals, which are as a rule unknown. In fact, since the spectra for dissociation on collision with molecules and the mass-spectra of molecules under electron impact are similar, presumably the phenomenon of "inclusion" will be observed also for neutral molecules. Table 14 presents the mass-spectra of methane and the radicals CH_3, CH_2, and CH calculated[57,115] from the methane mass-spectrum (b) and

determined experimentally[116] (a). Column c presents the parameters of the mass-spectra calculated from the mass-spectrum for CH_3 radicals.

Table 13. Parameters of the dissociation spectra of the ions obtained from propane (the cross-section for the formation of the CH_3^+ ion was taken to be 1.0).

Dissociation products	Initial ions					
	$C_3H_8^+$	$C_3H_7^+$	$C_3H_6^+$	$C_3H_5^+$	$C_3H_4^+$	$C_3H_3^+$
$C_3H_6^+$	5.2	5.9	—	—	—	—
$C_3H_5^+$	12.8	22.0	10.6	—	—	—
$C_3H_4^+$	2.4	2.3	3.9	0.7	—	—
$C_3H_3^+$	10.5	11.1	10.6	10.5	7.1	—
$C_3H_2^+$	1.9	1.8	2.0	1.9	2.0	1.3
C_3H^+	1.0	1.0	1.0	1.0	1.0	1.0

Table 14 shows that the mass-spectra of CH_3 radicals determined experimentally[116] and calculated[57,115] from the methane mass-spectrum agree satisfactorily. There are no experimental data for the mass-spectra of CH_2 and CH radicals. However, their calculated mass-spectra also agree with the dissociation spectra of CH_3^+ and CH_2^+ ions as well as the dissociation spectra of CH_4^+ and CH_3^+ ions. Therefore one may suppose that the experimental mass-spectra of the radicals are close to those whose parameters are listed in Table 14. Further experimental studies are necessary in order to extend this rule to the mass-spectra of other radicals.

Table 14. Parameters of the mass-spectra of methane and certain radicals (the relative cross-sections are expressed in arbitrary units).

Ions formed	Species ionised						
	CH_4	CH_3		CH_2		CH	
		a	*b*	*b*	*c*	*b*	*c*
CH_3^+	31	28	31	—	—	—	—
CH_2^+	6	9	6	6	9	—	—
CH^+	3	3	3	3	3	3	3
C^+	1	1	1	1	1	1	1

4. Dependence of the Ion Dissociation Cross-sections and Spectra on the Electron Energy and the Origin of the Ions

The impact dissociation cross-sections of polyatomic ions as well as those of diatomic ions increase with increase of the electron energy until the attainment of constant values. Fig. 8 illustrates the variation of the dissociation cross-section with electron energy in the ion source for $C_2H_3^+$ ions, which decompose via different channels[114]. The ion energy was 2.8 keV. The corresponding relations for other ions derived from ethylene and methane have also been examined[57,117].

Markedly different impact dissociation cross-sections were obtained for the dissociation of diatomic ions of different origins[65,76], which suggests an appreciable difference between the distributions with respect to excited states for identical ions from different molecules (see Section III). For polyatomic ions, the dissociation cross-sections of identical ions of different origins differ from one another to a lesser extent[10,118]. For example the dissociation cross-sections of the CH_3^+ ions obtained from CH_4 and n-butane are similar[10] and this is also true of the $C_2H_4^+$ ions obtained from C_2H_4, C_3H_8, and n-C_4H_{10}.[118] It is noteworthy that the internal excitation energy in a polyatomic ion can affect not only the total dissociation cross-section, as in a diatomic ion, but also the dissociation spectrum. It is seen from Fig. 8 that the total dissociation cross-section varies mainly as a result of the increase of the cross-section for dissociation processes with a low activation energy. The internal excitation energy has only a slight influence on the cross-sections for dissociation processes with a high activation energy. In order to achieve such processes, the initial ion must be strongly excited on collision and, in conformity with the considerations put forward in Section IV and the discussion of Fig. 6, such a highly excited ion will decompose mainly as a result of simple bond dissociation.

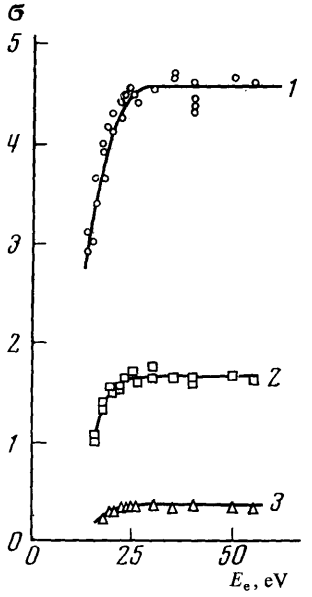

Figure 8. Effect of the electron energy E_e on the relative impact dissociation cross-sections of $C_2H_3^+$ ions: 1) $C_2H_3^+ \rightarrow C_2H_2^+$; 2) $C_2H_3^+ \rightarrow C_2H^+$; 3) $C_2H_3^+ \rightarrow C_2^+$.

Thus the relative yield of the fragments whose formation requires high energies will not depend markedly on the initial excitation energy but will be determined mainly by the structure of the initial ion. The differences between the dissociation spectra in the region of such fragments for identical ions of different origins indicate differences between the structures of these ions. This conclusion has been reached[119] on the basis of an analysis of the dissociation spectra of the $C_6H_7^+$ ions from cyclohexa-1,4-diene and methylcyclohexa-1,4-diene.

---o0o---

Much less can be said about the specific mechanisms of the impact dissociation of accelerated polyatomic ions than about the dissociation of diatomic ions owing to the insufficiency of detailed information about the decomposition of polyatomic ions, which can be obtained from the angular and energy distributions of the fragments. In the general case the dissociation process can be divided into two stages. Initially, at the instant of collision between the accelerated ion and the target particle, the electronic and vibrational degrees of freedom of the ion are excited. The order of magnitude of the collision time τ is defined by the relation $\tau = \sqrt{\Sigma}/v_0$, where Σ is the total dissociation cross-section.

For the energies of the initial ions $E_0 \simeq 10^3$ eV, τ is approximately 10^{-15}–10^{-16} s. On the other hand, the time of the most rapid dissociation is 10^{-13} s. Therefore in the second stage the isolated molecular ion excited by collision decomposes in accordance with the quasiequilibrium theory of mass-spectra.

The principal experimental characteristics of the impact dissociation of polyatomic ions can be briefly generalised by the following postulates:

1. The dissociation spectra of polyatomic ions depends only slightly on the nature of the neutral target. They are determined by the structure and energy of the excited ions and also by their kinetic energy.
2. The dissociation spectrum is independent of the electron energy in the ion source for $E_e \geqslant 30$ eV. The excitation of the initial molecular ion greatly affects dissociation processes with a low activation energy and only weakly influences dissociation processes with a high activation energy.
3. The total dissociation cross-section depends on the ion dissociation energy. The more stable the given structure the smaller the total dissociation cross-section of the given ion, other conditions being equal.
4. For many ions derived from saturated hydrocarbons, the total cross-section is an additive function of the number of CH_2 groups in the ion.
5. The impact dissociation spectra of the ions and the mass-spectra of the corresponding molecules under electron impact are similar under certain conditions.
6. Similar dissociation spectra have been obtained for many ions differing from one another only in the number of hydrogen atoms (the "inclusion" of the spectra).
7. The decomposition of ions via different channels proceeds with similar probabilities for higher kinetic energies of the ions.

On the basis of these empirical characteristics, it is possible to reach conclusions, admittedly so far qualitative, about the differences or similarities between the structures of ions of identical composition obtained in different ionisation processes. Examples of this kind for the $C_3H_6^+$ ions from cyclopropane and propene and the $C_4H_{10}^+$ ions from n-butane and isobutane can be found in Kupriyanov's thesis[57] and those for the $C_3H_7^+$ ions from different compounds are quoted by Haddon and McLafferty[120]. Table 15 compares the dissociation spectra of the molecular ions from n-butane and isobutane[57].

Evidently these spectra differ markedly for both spontaneous and impact dissociation. This suggests that the structures and excitation energies of the $C_4H_{10}^+$ ions obtained by the ionisation of n-butane and isobutane molecules are different. It is noteworthy that further investigation and accumulation of experimental data are necessary to refine the characteristics of the impact and spontaneous dissociation of polyatomic ions. In particular, the problem of the individual influence of the excitation energy and structure of the ions on their total dissociation cross-section and dissociation spectrum is of interest. The results available at present suggest that the excitation energy probably affects the total dissociation cross-section to a greater extent, while the structure has a greater influence on the dissociation spectrum of the ions. Under real experimental conditions, the beam of the initial ions may contain ions with different structures and excitation energies and the observed differences in the impact dissociation pattern of such ions reflect the differences in the distribution of the initial ions with respect to structure and excitation energy. More careful experiments with allowance for the above factor are needed to solve this problem. In this sense mass-spectrometric study of the photodissociation of ions formed by the photoionisation of molecules with simultaneous analysis of the dissociation products with respect to the angle at which they are ejected and the kinetic energies is promising.

Table 15*. Parameters of the dissociation spectra of the ions obtained from n-butane and isobutane (relative cross-sections).

Decomposition process	n-Butane		Isobutane	
	a	*b*	*a*	*b*
$C_4H_{10}^+ \rightarrow C_3H_7^+$	0.9	9.5	0.1	6.3
$C_4H_{10}^+ \rightarrow C_3H_6^+$	0.9	2.4	0.9	7.5
$C_4H_{10}^+ \rightarrow C_3H_5^+$	0	1.3	0	2.0

* *a*) Spontaneous decomposition spectrum; *b*) impact dissociation spectrum for an ion energy of 3.0 keV; target—air.

The study of spontaneous, induced, and impact dissociation of ions may be called, by analogy with the mass-spectrometry of molecules, the mass-spectrometry of ions if one understands by this the employment of mass-spectrometric techniques for the measurement of the masses and intensities of the ions formed and for the analysis of the structures and excitation energies of the ions obtained in different processes and from different compounds. Thus mass-spectrometry of ions is a new method for the analysis of their structures and excitation energies. It can be used to measure the mass-spectra of ions (by a procedure similar to the measurement of the mass-spectra of molecules), the ionisation potentials and dissociation energies of ions, and other characteristics.

Effect of An Electric Field on the Thermal Decomposition of Solids

A.A.Kabanov and E.M.Zingel'

Studies on the thermal decomposition of solids subjected to the influence of an electric field (EF) are analysed and the effect of the electric field on the rate of decomposition is considered. Attention is drawn to the likely usefulness of the electric field in the study and control of the rates of the thermal decomposition of solids.
The bibliography includes 182 references.

I. INTRODUCTION

Advances in solid state chemistry (SSC) depend in many ways[1] on the extent of which the theory and experimental techniques of solid state physics (SSP) have been applied to it. The principal difficulty here is associated with the specific features of the problems in solid state physics and chemistry, which require not only a systematic treatment but also an analysis of the achievements of physics in relation to problems in solid state chemistry. This review is devoted to a partial solution of this problem: the analysis and systematic treatment of the scope of the applications of the electric field (EF) as a research technique and a method for controlling the rate of the thermal decomposition of solids. We neglect the magnetic component of alternating electric fields, since it is too small to influence significantly the physicochemical processes in solids.

II. EXAMPLES OF THE EFFECT OF AN ELECTRIC FIELD ON THE DECOMPOSITION OF SOLIDS

The paper of Bel'kevich and Osinovik[2] is apparently the first publication concerning a study of the thermal decomposition of solids in an electric field. The authors investigated by a volumetric method the thermal decomposition of silver oxalate *in vacuo* in the temperature range 105 to 120°C. The specimens were prepared by pressing and were clamped between metallic electrodes. Although the strength of the steady electric field was low (of the order of 3–4 V cm^{-1}) a clear effect of the field on the decomposition process was observed. In the absence of the field the specimens did not explode after attaining the maximum rate of decomposition in the given temperature range, while in the presence of the field an explosion generally occurred. The authors believe that the explosion is not associated with the electric breakdown of the specimens at the instant of the mutual approach of the silver particles, although this does appear to be most likely. The present authors also investigated[3,4] the thermal decomposition of silver oxalate in a constant 80 V cm^{-1} electric field. Three series of experiments were performed: decomposition in the absence of a field; decomposition in a steady field, and decomposition in a periodically applied field. The specimens were heated continuously at a rate of 0.5 deg min^{-1} to 90°C in a vaccum of 10^{-3}–10^{-4} torr. The cell was then disconnected from the pumps, heating was continued, and the amount of carbon dioxide formed before the detonation of the specimen was measured. During the decomposition in the absence of a field, the specimens exploded at 143°C, in a periodically applied field the detonation occurred at 130°C, and in a constant field it occurred at 122°C. Thus the field accelerated the attainment of the maximum rate of thermal decomposition of the specimen at which silver oxalate exploded. Simple calculation of the heat of decomposition rules out the explanation of the observed phenomenon as due to the heating of the specimen by the current.

Bowden and coworkers[5,6] investigated the behaviour of silver azide single crystals between -100° and 50°C in steady and alternating electric fields. At room temperature in a steady electric field weaker than 250 V cm^{-1} the crystals clamped between silver electrodes did not explode, while in higher fields detonation was observed. Before the detonation the resistance of the specimens fell sharply to 10^4 Ω and the crystals exploded approximately 45 s afterwards. The field strength necessary for the explosion of silver azide increased appreciably with decrease of temperature. Thus, whereas at 50°C 19 V was needed for explosion, at -45°C 125 V was already required and at -100°C more than 400 V had to be applied. Calculations showed that approximately 10^{15} electrons per second entered the crystals before detonation and that this was sufficient to heat them to the detonation temperature. It was established that the decrease of the resistence of the crystals before detonation is not caused by the formation of silver dendrites penetrating the crystal. It was suggested that the decrease of the resistance and the detonation of silver azide are due to the injection of electrons from the electrodes in the presence of an electric field. It was also stated[6] that similar results were obtained by Evans and Yoffe for copper azide, and by Berthold for silver acetylide. Subsequently Savel'ev and coworkers[7–9] established that a steady electric field accelerates the thermal decomposition of silver, lead, and barium azides and of silver oxalate. Studies of the effect of the electric field on the rate of thermal decomposition of azides confirmed the conclusion reached earlier using the method of homophase additives. The electric field influenced only the induction period in the decomposition of silver oxalate.

Sukhushin et al.[10] investigated the behaviour of lead, silver, and thallium azides in a strong steady and a pulsed electric field. The azides were found to decompose in the electric field with formation of gaseous and solid products, which was explained by a discrete development of electron avalanches and their chemical effect. Related results were obtained in a study[11] where an unexpected phenomenon,

hindering the investigation of the ferroelectric properties of potassium nitrate in a constant electric field, was observed: after the application of a 1 kV cm^{-1} electric field, a 1 V e.m.f. appeared between the platinum electrodes, which slowly decreased with time and did not disappear even after the specimens had been short-circuited. It was suggested that the phenomenon is caused by the partial decomposition of potassium nitrate in the electric field into potassium ions, nitrogen dioxide, and molecular oxygen with formation of an electrochemical battery. Kabanov and Zharova[12] studied the thermal decomposition of $KMnO_4$ at 220°C in a constant 250 V cm^{-1} electric field and in the absence of a field. The electric field was applied periodically (for 15 s at 5 min intervals) throughout the entire decomposition period. The maximum rate of decomposition of $KMnO_4$ was reached at 54% decomposition in the absence of a field and at 64% decomposition of the preparation under the influence of the electric field. The rate of decomposition of $KMnO_4$ was influenced by the electric field in different ways during different periods. During the first 25 min, the electric field did not affect the rate of decomposition at all, but afterwards the thermal decomposition was accelerated. In the range between 50 and 70 min from the start of the decomposition the electric field stabilised the rate. In the absence of the field there was a smooth increase of the rate of decomposition up to the maximum.

The studies examined above indicate the possibility of a marked influence of the electric field on the decomposition of solids. A common disadvantage of the published investigations is their superficiality, the main aim being to establish merely that an electric field affects the rate of thermal decomposition and yet they permit the conclusion that this rate can be controlled with the aid of the electric field. To develop further and extend studies of this kind, it is necessary to analyse the possible ways in which the electric field influences the rate of thermal decomposition and a systematic treatment of the achievements of solid state physics in this field with an indication of the scope of their applications to solid state chemistry is needed.

III. WAYS IN WHICH AN ELECTRIC FIELD INFLUENCES THE RATE OF DECOMPOSITION OF SOLIDS

The rate of thermal decomposition of solids is greatly influenced[13,14] by point and linear defects and also by the composition of the atmosphere. On the other hand, they give rise to many physical and physicochemical phenomena, which constitutes the basis for considering the ways of which the electric field influences the rate of thermal decomposition solids.

1. Properties of Crystals Grown in an Electric Field

The structure and habit of crystals play[13] a major role in the kinetics of their thermal decomposition. Therefore, by altering the conditions governing the formation of the crystals, it is possible to alter the rate of their thermal decomposition. The study of the influence of the electric and magnetic fields on various physicochemical properties of growing crystals is receiving increasing attention[15–17], since this method of controlling the properties of crystals is more convenient than the method based on the introduction of impurities during crystallisation. It has been established that the electric field has a significant influence on the formation of crystal nuclei and on crystallisation kinetics. Although the problem has been little studied, it is possible to distinguish three possible ways in which the electric field influences the formation of crystals: 1. By the alteration of the properties of water[18–21] (in growing crystals from aqueous solutions) under the influence of a variable electric field in combination with its magnetic component. 2. By the effect of the electric field on the habit and structure of the crystals formed[22–35]. 3. By the electric field[20] initiating a chemical reaction between the solvent and solute, which leads to the entrainment of various impurities by the growing crystals.

The contactless method of applying an electric field to solutions (via glass, air, etc.) is more popular[21,23] than the contact method. It yields more reproducible properties of the grown crystals. When an electric field is applied to the test substances, various types of polarisation arise in the prenuclear groups of atoms: electronic, ionic, and dipole-orientation. The orientation of polar molecules in the field does not occur instantaneously, which promotes the formation of crystals with polar species. In an electric field the number of crystallisation centres initially increases rapidly and then the growth slows down and finally stops completely, reaching saturation. The orienting effect of the electric field frequently entails structural changes in the solvent, which makes it more difficult to understand the mechanism of the influence of the field on the crystallisation process. The nature of the changes in the rate of formation of crystallisation centres under the influence of a variable field depends on temperature[23].

Melent'ev and Kozlovskii[24] studied the effect of an electric field on the crystallisation of lead sulphide from the gas phase. Lead sulphide was vaporised at 850–900°C and, after precipitation on a quartz support, crystallised in a steady electric field. A 2–3 kV cm^{-1} field influences significantly the habit and properties of the growing crystals. For example, Mohs' hardness of the crystals is appreciably lower for specimens grown in the absence of a field; this is associated with the influence of the electric field on dislocation density. Steady and alternating electric fields in supercooled betol, salol, and piperine melts lower[25] the temperature of the onset of crystallisation. The rate of migration of the layers in spiral-laminar crystal growth[26,27] from the gas phase can increase in a steady electric field, which affects the density of the dislocations produced. A change in the structure and catalytic properties of Cu_2O formed in an electric field at 1040°C was observed by Stadnik and Kuznetsov[28], who explained it by the formation of an interstitial solid solution with an excess of copper ions or oxygen.

The influence of an electric field on the crystallisation of amorphous selenium has been observed[29–35] and a number of interesting facts have been established. Thus Geller et al.[29] noted that electric fields up to 10 kV cm^{-1} at mains frequency increase the number of spherolites at 50 to 90°C in selenium specimens with an admixture of bromine and accelerate their growth due to the polarising effect of the electric field on selenium molecules. In a 180 to 360 V cm^{-1} steady electric field the rate of crystallisation of selenium usually[30,31] increases and in higher fields begins to decrease. The growth of spherolites[32,33] under the influence of the electric field takes place usually (but not always) along the lines of force of the field, since the direction of growth depends on the material of the support. On a mica support preferential growth of spherolites in opposition to the lines of force of the electric field is observed, while on a carbon support the growth takes place along the lines of force. A similar result was obtained by Odobescu[34], who investigated the influence of a constant electric field on the kinetics of the crystallisation of selenium from the amorphous and liquid states in the temperature range 150–190°C. He established that the rate of crystallisation of selenium depends

on the direction of the electric field, which exhibits an orienting effect and facilitates the crystallisation process. Bolotova et al.[35] observed the effect of the exposure of liquid selenium to an electric field on its subsequent crystallisation. On cooling in air melts which were not in an electric field, crystals of selenium were not observed.

2. Effect of an Electric Field on Electronic and Ionic Processes

The thermal decomposition of solids is accompanied by different[1,13,14,36,37] electronic processes: the excitation of ions with formation of excitons, polarons, or free electrons and the migration of the local excitation of the crystal with charge transfer, or with energy transfer alone, or with recombination of the excited electrons, which can lead to luminescence in self-activating systems[38]. Apart from luminescence, the above processes give rise also to other physical phenomena: a change in the electronic and hole conductivity[1,12–14,36,37–39], a change in the concentration of the colour centres[13,14], and a change in magnetic properties[40]. Chemical transformations of the initial substances involving the dissociation of old and the formation of new chemical bonds take place simultaneously with physical processes, which implies[41] a redistribution of charges, the transition of electrons from one state to another, or quantum-mechanical resonance.

A common method for altering the concentration of free electrons in the surface region of crystals is that of heterophase additives, the influence of which is explained[42,43] by the transfer of electrons into the substance with a higher work function. We believe[44] that at least two other evident possibilities have been neglected here; chemical interaction of the additive with the substance undergoing decomposition and the influence of the solid decomposition products of the initial substance on the catalytic activity of the additive. As in the method of heterophase additives, the electric field alters the concentration of free electrons in the surface region without changing the structure of the solids. We shall analyse examples of the influence of the electric field on various physical phenomena, which depend on point (in the given case electronic) defects. (The influence of the field on luminescence will be analysed separately).

A strong electric field can alter the state of solids[40] from antiferromagnetic to ferromagnetic by generating conduction electrons. This method is better than the introduction of impurities (homophase additives), since it does not distort the crystal lattice, does not alter the chemical composition of the substance and the nature of the distribution of electron density, and finally makes it possible to control readily and reversibly the concentration of conductivity electrons. The electric field can cause the dissociation of excitons with a large radius, as a result of which the exciton absorption bands are broadened. For example, Thomas and Hopfield[45] observed that the absorption lines corresponding to large-radius excitons in the spectrum of cadmium sulphide are broadened and merge in a field as low as 500 V cm^{-1}. Gross and Zakharchenya[46] observed a similar effect in copper(I) oxide, but in a field of 9 kV cm^{-1}. The difference in field strengths is consistent with the dimensions of the excitons: the exciton radius in copper(I) oxide is smaller by a factor of 2 than the radius of the analogous excitons (on the basis of the absorption spectrum) in cadmium sulphide and their bonding energy is higher by a factor of approximately 4. Consequently, the ionisation of excitons in copper(I) oxide requires an approximately 8 times higher field than in cadmium sulphide. The experimental data are qualitatively consistent with this rough estimate.

Kucherov et al.[47] and Lyashenko[48] established that the electrical conductivity of cadmium sulphide[47] and antimony sulphide[48] increases with time when an electric field is applied. This has been explained by the diffusion of the impurities and of the adsorbed gases in the direction of the field of which diminishes the concentration of the capture centres for free electrons and holes. Subsequently Cox and Tredgold[49] and also Kunin et al.[50] observed a change in the electrical conductivity and colour of $SrTiO_3$ single crystals in an electric field at an elevated temperature. During the first 1–2 min, the electrical conductivity diminished by an order of magnitude and then reached a value higher than at the beginning. It is suggested that the initial decrease of conductivity is caused by ionic polarisation and the subsequent increase is due to the increase of the concentration of V-type colour centres, formed under the influence of the electric field and altering the colour of the crystals. A sharp change in electrical conductivity during the application of the electric field (electric ageing) has been observed also for rutile single crystals[51] at 300°C, which has been attributed to the formation of new donor centres (defects) in the crystal lattice and a transition from p-type conductivity to n-type conductivity.

It has been established[52–54] that the potential barrier $\Delta\varphi$ (the difference between the electron work functions) of the metal–dielectric couple can be decreased with the aid of the electric field not only as a result of the Schottky effect but also owing to the penetration of the electrodes by the external electric field. Then, for low strengths E of the external electric field the condition $\Delta\varphi \propto \sqrt{E}$ holds and at high field strengths we have $\Delta\varphi \propto E$. The effect observed by the authors may predominate over the Schottky effect in high electric fields. It is useful to know this phenomenon in the study of the thermal decomposition of substances with a high-resistance additive in electric fields. The effect[55] observed in β-carotene and selenium is no less interesting. A transverse constant electric field superimposed on a longitudinal constant electric field causes periodic oscillations in solids at very low frequencies. The period of the observed current oscillations is influenced significantly by the strength of the transverse field, the intensity and length of the monochromatic light, the temperature of the specimen, and the composition of the atmosphere. The authors put forward two interesting hypotheses to account for the phenomenon.
1. In certain regions of semiconductors and probability of the localisation of charge carriers (electrons and holes) may increase with increase of the field strength and local unstable regions with a variable resistance may appear.
2. The cause of the observed current oscillations may be the formation of bulk-phase charges. The external field then disturbs locally the equilibrium current carrier density.

On the other hand, the application of a pulsed electric field and of illumination by flashes of ultraviolet light to a silver bromide photographic emulsion[56] induces physicochemical processes associated with the generation of a symmetry in the photoproducts and a decrease of the lifetime of the light-generated electrons. The intensity of these processes depends on the strength and duration of the application of the electric field.

In a strong electric field the long-wavelength limit of the intrinsic optical absorption of semiconductors (λ_g) must shift[57,58] towards longer wavelengths (the Franz–Keldysh effect). This can be explained by a definite probability of the migration of electrons from the valence band to the forbidden levels by a tunnel mechanism under the influence of the electric field. In other words, in a strong electric field the interaction of electrons with photons having a large

momentum can generate electron-hole pairs owing to the transition of some of the valence electrons to forbidden energy levels. In consequence of this process, electrons appear in the semiconductor above the valence band and their excitation to the conduction band requires a lower photon energy than for the electrons in the valence band. For this reason, a shift of λ_g towards lower energies is observed. By definition λ_g corresponds to the minimum energy of photons required for the excitation of electrons from the valence band to the conduction band of the crystal. The shift of λ_g for the semiconductor is observed also from absorption spectra and reflection spectra in constant and alternating fields. Seraphin and Bottka[59] proposed an analytical method for the interpretation of the electro-reflectance effect in semiconductors. The Franz–Keldysh theory has been extended to the majority of the field-induced changes in absorption and reflection spectra. The authors showed that the shift of λ_g in the field is not always towards longer wavelengths but only when the edge of the absorption (or reflection) band is parabolic. When the edge of the main band is saddle-shaped, the shift of λ_g is towards shorter light wavelengths. In degenerate semiconductors[60] (a high concentration of free charge carriers is characteristic of these) the electric field can shift λ_g much more owing to the "heating" of the charge carriers than at a concentration of carriers far from degeneracy. This additional shift of λ_g under the conditions of the field in degenerate semiconductors is called[61] the Burnstein shift. For example, in InSb for $n = 10^{19}$ cm^{-3} and 300 K the shift of λ_g is 0.50 eV via the Burnstein mechanism and 0.18 eV for a non-degenerate state.

The Franz-Keldysh effect has been frequently confirmed experimentally[62–66] for both atomic semiconductors (germanium and silicon) and for more complex substances with polar bonds: sulphides, selenides, tellurides, arsenides, and other typical semiconductors. For example, Moss[62] and Kireev et al.[63] measured the shift of the absorption edge in GaAs, CdS, and CdTe spectra by a 5 kV cm^{-1} electric field. The authors indicate a satisfactory agreement between the calculated and experimental shifts of λ_g. A difference was observed between the results for films and single crystals. There has been an interesting study by Dneprovskii et al.[64], who observed a shift of the absorption band in the spectra of mixed crystals of CdS_xCdSe_{1-x} semiconductors at liquid nitrogen temperature in electrostatic fields up to 30 kV cm^{-1}. The shift of λ_g for $CdS_{0.5}CdSe_{0.5}$ amounts to 30 Å in a somewhat weaker electric field than for $CdS_{0.7}CdSe_{0.3}$ crystals, which the authors attribute to a steeper absorption spectrum of the specimen. The most complete study of the shift of the intrinsic absorption band of a ZnTe single crystal in 60 kV cm^{-1} electric fields was that of Strel'tsov and Freidin[65]. The shift of λ_g is 0.004 eV. The effective mass of charge carriers $m^* = 0.16m_0$ was calculated from the shift, the result being in good agreement with the data obtained in other investigations. The shift of the absorption edge towards longer wavelengths leads to a change[66] of the absorption coefficient of PbI_2 single crystals in a 2.85×10^5 V cm^{-1} variable electric field, which is probably the result of the influence of the field on the transitions of excitons to the ground state.

One cannot rule out the possibility that the Franz–Keldysh effect also operates in non-classical semiconductors, which may be investigated in solid state chemistry. The determination[67,68] of the effective mass of free electrons and holes from the Franz–Keldysh effect is most important and promising: the energy of the shift of the long-wavelength absorption limit λ_g is inversely proportional to the reduced effective mass of charge carriers. It is also possible to obtain information about the structure of the valence levels and the levels of the conduction band involved in the electronic transitions. Knowing the effective mass of the majority charge carriers, it is possible to calculate[69,70] (using additional data for the thermo-e.m.f. and electrical conductivity) the concentration and mobility of the free charge carriers, which are needed to analyse the electronic processes in the thermal decomposition of solids. In a field of the order of 10^5 V cm^{-1} the minimum shift (in terms of energy) for semiconductors amounts to hundredths of an electron-volt[67], greatly exceeding the possible Stark effect[71], which also shifts λ_g. The method for the determination of the effective mass of charge carriers with the aid of the Franz–Keldysh effect is much simpler and no less accurate than the method of cyclotron resonance[72], which is the classical procedure.

While chemical bonds are redistributed by electronic processes, ionic processes are responsible for the transfer and redistribution of mass in the decomposition of solids. The ionic processes underlying[13,14] the formation and growth of the nuclei of the new phase are much slower than the electronic processes and for this reason they often constitute the rate-limiting stages in the thermal decomposition of solids. Naturally, the electric field, influencing the diffusion coefficient and mobility of ions, will influence also the thermal decomposition of solids. We shall analyse examples of this effect.

Geguzin and Solunskii[73] observed an effect of a constant 100 V cm^{-1} electric field on the kinetics of the development of diffusional porosity in alkali metal halide crystals at 650° C. It was suggested that the electric field, influencing the directed diffusion of charged vacancies, influences also the pore-formation process. Together with this phenomenon, the constant electric field can affect the phase composition of solid solutions. Thus Freimanis et al.[74] established that in ceramic specimens of barium niobate there exist two ferroelectric phases with orthorhombic and tetragonal symmetry. A 20–90 kV cm^{-1} electric field gives rise to phase transitions between the orthorhombic and tetragonal symmetry or conversely, depending on the orientation of the crystals. The magnitude of the effect depends on the field strength and the energy state of the specimens. The influence of the heat treatment of the specimens on electrical ageing has been studied by Harwood[75] for rutile. He established that the greatest changes in electrical conductivity occur when the field is applied along the *c* axis regardless of the direction in which the crystals are grown. It was suggested that the impairment of the dielectric properties of rutile as electrical ageing progresses is due to the drift of certain ions under the influence of the applied electric field. This experiment is important for the investigation of the anisotropy of the thermal decomposition of ionic crystals. The problem of the effect of the electric field on the alloying process is no less urgent in practice. Pavlienko et al.[76] observed that the rate of alloying of silicon by boron from the gas phase depends on the electric field, which causes an additional ionisation of boron at high temperatures in the gap between the electrodes and, when a positive potential is applied to the electrode, causes an accelerated diffusion of boron to silicon. The tracer atom technique makes it possible to investigate the rate of self-diffusion of various ions on the natural cleavage surfaces of single crystals in an electric field. Thus, it has been shown[77] that a field oriented along the surface of an NaCl single crystal can alter the rate of self-diffusion of sodium and chloride ions. On the other hand, a field oriented at right angles to the surface can influence the amount of the

"pumping away" of these ions, diffusing on the surface, into the bulk of the crystal.

The thermal decomposition of certain ionic salts, for example permanganates[78,79], is accompanied by intense cracking and atomisation of the crystals. The results of a study by Kononov et al.[80], who investigated the dust carried away from a fluidised bed furnace in the presence of an electric field in the working space of a reactor, are of interest for the investigation of the decomposition of such substances, with and without additives, in an electric field. The field reduced the amount of dust removed by a factor of 3–5 and caused the coagulation of dust particles whose size was between 40 and 80 μm.

The effect of the electric field on the physicochemical properties of silver bromide under illumination has been studied[81-83]. Although the aim was to investigate photolysis, the observation that the field influences ionic processes is useful also for the investigation of such processes in thermal decomposition. For example, Klein and Matejec[81] studied the formation and growth of silver nuclei on silver halide microcrystals (grains). When the silver halide grain is irradiated in a strong stationary field (of the order of 10 kV cm^{-1}) by ultraviolet light pulses lasting 10^{-2}–10^{-3} s, it is possible to accumulate photoelectrons on the anodic side and interstitial ions on the cathodic side, without the complete disappearance of these charge carriers in the remaining parts of the grain. As a result, better conditions are created on both the cathodic and anodic sides of the grain for the formation of nuclei compared with the rest of the grain. The formation of negative centres on pulsed illumination of a photographic emulsion based on silver bromide under the conditions of a pulsed electric field has been observed by Hamilton and Bready[82], who proposed a method for calculating the cationic conductivity. At room temperature the calculation yielded a conductivity differing only by an order of magnitude from the experimental value for silver bromide single crystals. The bulk-phase diffusion of cationic vacancies, arising in the photochemical decomposition, was also observed for the single crystals[83]. A semi-transparent metallic layer was deposited on the one side of the single crystal and a continuous silver layer, obtained by evaporation *in vacuo*, was deposited on the other side. The light intensity decreased by a factor e at a depth of 1.5 μm, but, owing to the electric field, a dark reaction took place on the other side of the single crystal, which resulted in a gradual increase of transparency of the silver layer and its final disappearance. This study was apparently the first in which the bulk-phase diffusion of cationic vacancies was observed experimentally. The problem of the diffusion of ions in an electric field is no less important. Thus, Arnikar and Chaure[84] studied the influence of γ-radiation and of the electric field on the diffusion of the tracer ions $^{45}Ca^{2+}$, $^{90}Sr^{2+}$, and $^{133}Ba^{2+}$ through calcite. The application of a 27–100 V cm^{-1} electric field increased the diffusion coefficients of all three ions in the direction of the field as well as in the opposite direction. This effect was explained by an increase in the probability of the diffusional jumps of the ions in the electric field. The authors' studies are of fundamental importance, since an increase of the rate of diffusion had not been observed previously in similar experiments[85,86] and an impression had been created that the electric field cannot influence the diffusion coefficients of ions.

All these observations are valuable and interesting for the development of a method for electrophysical studies on the thermal decomposition of solids in an electric field.

3. Influence of the Electric Field on Dislocations

The influence of dislocations on the rate of thermal decomposition of solids is well known[13,87,88]. The decomposition of solids usually begins from the surface at the point of emergence of dislocations and extends throughout the bulk of the substance. It is therefore necessary to know the influence of the external field on the behaviour of dislocations in solids. Sproull[89] investigated elastic deformation effects, arising as a result of the application of an electric field, in lithium fluoride crystals bent at 220°C. He established that the dislocations in lithium fluoride are charged and can migrate over distances which are not susceptible to measurement, and that a considerable proportion of the mechanical strain is electrostatic in nature. The migration of the dislocations caused by the electric field in lithium fluoride crystals reaches a maximum in the course of a fraction of a second. The excess of dislocations of the same sign in cubic NaCl type crystals can actually disturb the symmetry and can make the crystal anisotropic, which is extremely interesting for the investigation of the electrophysical properties and decomposition of crystals. The migration of dislocations under the influence of a steady electric field of up to 15 kV cm^{-1} leads to a decrease in the optical transmission by sodium chloride[90] at a wavelength of 220 nm. A strong electric field also intensifies the absorption of light in this optical region. The migration of charged dislocations in an 8 kV cm^{-1} electric field has been observed by following the migration of etching figures under the microscope in studies by Zagoruiko[91] and Shvidkovskii et al.[92] The minimum field in which the migration of dislocations was observed was found to have a strength of 2 kV cm^{-1}. It was suggested that the migration of dislocations is caused by electrostriction, by the direct action of electrical forces on the charged dislocation, or by the joint influence of both factors. Using a similar technique, Zuev and Turchinovich[93] studied the migration of dislocations in lithium fluoride crystals under the conditions of a constant electric field. The authors suggest that the electric field lowers the potential barrier to the thermal liberation of dislocations from fixation centres. The influence of the electric field on the structural changes in such solids has been studied by Trap and Stevels[94]. The authors observed in certain chalcogenide glasses a transition to two states with different electrical conductivities when the electric field was altered. The conductivities of these states can differ by many orders of magnitude (up to 7). The transition of the glasses from one state to the other took place in a period of about 10^{-6} s. Since the conductivities of solids are related solely to the concentration of charges and their mobility, it is easily understood that the electric field alters sharply in this case the conditions governing the occurrence of ionic and electronic processes.

4. Influence of the Electric Field on Luminescence

The initial stage in the thermal decomposition of solids may be accompanied by luminescence[38]. Despite the great possibilities which arise from the application of luminescence measurements, this method has not so far been used in the experimental techniques of solid state chemistry. We are not aware of any study of the thermal decomposition of solids employing the luminescence phenomenon. In investigations of the photolysis of solids there are examples of the use of luminescence measurement which are of interest also for the study of thermal decomposition. For example, Belous and Chibisov[95] used luminescence measurements to

study the photolysis of silver chloride. They established that, depending on their size, the silver nuclei can serve as traps for both electrons and holes. The hole traps are usually aggregates consisting of several atoms with pre-colloidal and colloidal degrees of dispersion. The thermal decomposition may be accompanied by luminescence in the following cases: 1. The thermal excitation of complex anions of self-activated[38,96] inorganic compounds, which usually contain transition metals with a partly filled 3*d* orbital. 2. The thermal decomposition of substances with homophase additives, which can serve as luminescence centres. 3. The thermal decomposition of substances in different gases, whose absorption may be accompanied by luminescence[97].

In view of the likely usefulness of luminescence measurements in the study of the mechanism of thermal decomposition, it is desirable to analyse the ways in which the electric field influences the luminescence process in solids. The electric field can be a source of a specific type of luminescence of solids — electroluminescence. Electroluminescence is observed when steady and alternating electric fields of several kV cm^{-1} are applied. The brightness of the glow then depends on the field strength, the field frequency, and the duration of application of the field. It is particularly characteristic of alternating electric fields. A few crystalline phosphors are capable of electroluminescence, but the mechanism of the generation of the glow has been by no means fully studied. Afanas'eva and Mikho[98] observed the electroluminescence of a microcrystalline alumina powder using a transparent electrode. The brightness of the luminescence is related exponentially to the exciting potential, which agrees well with the concept of an inhomogeneous distribution of the field in the specimen. The threshold potential for the occurrence of the electroluminescence of ZnCdS discs was reduced[99] when the specimens were irradiated with light in the spectral region corresponding to the excitation of the intrinsic or impurity photoconduction. In this way a relation was established between the electroluminescence and photoconductivity of the specimens. Electroluminescence was observed also in powdered tantalum pentoxide[100] on excitation by potential Π-pulses lasting 2×10^{-3}–3×10^{-2} s. The hypothesis of an inhomogeneous distribution of the electric field in the specimens made it possible to explain the shape of the curves describing the development of the luminescence. The electroluminescence of cadmium selenide single crystals, arising on excitation by variable 5–25 kV cm^{-1} electric fields, was studied by Ivanchenko[101]. The electric field caused appreciable heating of the crystals and the electroluminescence was observed at a high temperature. It was noted that the free electrons generated in the electric field and to some extent thermal electrons pass from the conduction zone to ionised acceptor levels. Assuming that the luminescence is excited by the electrons displaced by the field, Henich[102] and Curevich[103] proposed a mechanism of the electroluminescence of ZnS with an admixture of copper and chlorine. The holes formed in this process are localised at the luminescence centres and the electrons are displaced from the excitation region and are captured by traps.

Apart from initiating electroluminescence, the electric field can also influence[104–109] the intensity of other types of luminescence: thermoluminescence photoluminescence, and radioluminescence. For example, this has been established for Cu_2O, ZnS, and alkali metal halide crystals with additives. Thus Peka[104,105] observed an effect of constant electric fields up to 10^6 V cm^{-1} on the photoluminescence of copper(I) oxide. The magnitude of the effect depended on the treatment of the surface, the strength and sign of the electric field, the surrounding gas, and the wavelength of the light exciting the luminescence. The author explains this dependence by a change in the conditions governing the annihilation of excitons with the depth of screening on the Cu_2O surface. Busca et al.[106] determined the temperature variation of the effect of the electric field on the thermoluminescence of ZnS with copper additives. It is suggested that the electric field influences the capture of electrons by recombination centres, which consist of copper atoms, and this alters the intensity of the thermoluminescence. The influence of the electric field on the X-ray luminescence of phosphors based on KI–Tl at low excitation intensities is contradictory[107]. At the instant of application of the field the glow is quenched, but after a time it is intensified. This complex behaviour of the luminescence is difficult to interpret, although the most likely mechanism of the increase of the luminescence intensity is a reduction by the electric field of the radiationless recombinations outside the luminescence centres. The results obtained by Denks[108] for alkali metal iodides activated by thallium are close to those of Pologrudov and Penzina[107], but in this case the electric field resulted merely in an instantaneous decrease in the intensity of the thallium luminescence without a subsequent increase in intensity. The influence of the electric field on radioluminescence and thermoluminescence has been studied most completely by Volkov et al.[109] in alkali metal halide scintillators. Both positive and negative effects of electric fields up to 50 kV cm^{-1} were observed. Various experimental findings enabled the authors to conclude that the effect of the electric field on radioluminescence and thermoluminescence reduces to a redistribution of the probabilities of radiative and radiationless processes. It follows from the studies quoted above that the most likely mechanism of the influence of the electric field on the intensity of the luminescence of solids is a shift of the cloud of quasifree electrons in the electric field, which reduces their concentration in the glowing region of the crystalline phosphor and diminishes the number of radiative recombinations. The influence of the electric field on luminescence can be used to study the recombination of electrons on the surface of crystals.

The possibility that an electric field quenches the photoluminescence, thermoluminescence, and radioluminescence of zinc sulphide with admixtures of copper and chlorine and also of alkali metal halide crystals has been studied[110–115]. Thus Vereshchagin et al.[110] observed the quenching of the luminescence of ZnS powder with an admixture of copper in constant and pulsed fields of the same polarity. The variable electric field led to a brief change in the brightness of the photoluminescence. Several possible mechanisms have been proposed for the quenching of photoluminescence: (1) in the region of electroluminescence the electric field accelerates free electrons: (2) weak electric fields cause the migration of holes, liberated from the emission centres by heat or light, to quenching centres; (3) strong electric fields ionise the luminescence centres.

The quenching by the electric field of the photoluminescence of a powdered ZnS phosphor with an admixture of chlorine[111] occurs differently with light corresponding to different spectral bands. It is suggested that the luminescence bands are caused by various luminescence centres differing from one another in their energy structure. The mechanism of the quenching of the photoluminescence is believed to involve the thermoelectric saturation of the luminescence centres by electrons ionised on photoexcitation. However, a similar mechanism can lead to an increased intensity of the photoluminescence due to the electric field when the electronic levels of the activator in the crystalline phosphor are above the middle of the forbidden gap. Andrianov and

Bogacheva[112] reviewed studies on the effect of the electric field on the thermoluminescence of activated zinc sulphide and noted three possible mechanisms for the quenching of the luminescence: (1) the field accelerates free electrons and holes; (2) the field displaces the charges to sites of radiationless transitions; (3) the field alters the potential barrier to the thermal liberation of the electrons and holes localised after excitation.

Denks et al.[113] and Grigor'ev et al.[114] applied the mechanism of the quenching of the ZnS luminescence in an electric field to alkali metal halide scintillators with an admixture of thallium, where a 10^5 V cm^{-1} electric field weakened the photoscintillation by 25%. The quenching of the luminescence of alkali metal halide crystalline phosphors by the electric field is of a general type and the authors believe it to be related to the separating effect of the field, which prevents the recombination of electrons and holes. An example of the quenching of the thermoluminescence of alkali metal halide crystals doped with thallium and indium by a 50 kV cm^{-1} electric field is provided by the study of Grigor'ev et al.[115] The field intensified the thermoluminescence after prolonged application and quenched it after brief application. The observed intensification of the thermoluminescence was attributed by the authors to the decrease in the potential barrier to the autolocalised holes.

5. Phase Transition in the Electric Field

Phase transitions are usually accompanied[116,117] by anomalies in the temperature dependence of the rate of decomposition and conductivity under the conditions for investigating the mechanism of the thermal decomposition of the material. To develop electrophysical methods[1] for the investigation of the thermal decomposition of solids, it is necessary to know how the electric field affects their phase transitions.

A semiconductor–metal phase transition has been observed in a number of transition metal oxides, such as vanadium oxides, and has been explained by the instability of the electronic excitation system[118–120]. Owing to the intense electron-phonon interaction, the crystal lattice of the oxide is then rearranged. Andreev et al.[121] observed a sharp jump in the conductivity of V_2O_5 (an increase by 5 orders of magnitude) in a 10^4 V cm^{-1} field, which indicated the appearance of metallic conduction. The electric field shifts the temperature of the phase transition. The thermal effect and the Poole effect do not then play a significant role. It has been suggested that the increase of conductivity is caused by the decrease of the width of the forbidden gap due to the piezoelectric effect, which is the main cause of the semiconductor–metal phase transition. Valiev et al.[122] observed a similar phase transition under the influence of the electric field in another crystalline vanadium oxide (VO_2) at $T < T_c$ (T_c is the temperature of the VO_2 phase transition). The authors attribute the phase transition to a change in the lattice parameters in the electric field (the reverse piezoelectric effect). The influence of the electric field on the ferroelectric phase transition in barium metatitanate has been studied[123] and a change in the phase transition temperature in the electric field has been demonstrated. The same problem was investigated by Zarembskaya et al.[124] in a study of the influence of a constant electric field on the temperature of the phase transition in triglycine fluoroberyllate. The ferroelectric phase transition was recorded on the basis of a maximum in the dielectric constant measured at a frequency of 1 kHz in the temperature range 40–90°C. The application of the electric field decreased the dielectric constant of triglycine fluoroberyllate and shifted the ferroelectric phase transition to higher temperatures.

6. Adsorption in the Electric Field

The thermal decomposition of solids is frequently carried out in different vapours and gases: for example, in water vapour[125,126], in ammonia vapour[127], in oxygen[128], and in carbon dioxide[129]. Such studies are performed either to establish an effect of different components of the atmosphere on the decompositon kinetics, or to investigate the autocatalytic influence of the gaseous decomposition products of the initial substance, or to investigate the electronic stages of the decomposition process. In view of this and also bearing in mind the development of electrophysical methods[1] for the investigation of the thermal decomposition of solids, it is necessary to formulate clearly the specific influence of the electric field on the adsorption of gases.

The Fermi level can be regarded[130] as the regulator of the chemisorption properties of the semiconductor surface. The position of the Fermi level fixes the concentration of the electron and hole gas on the semiconductor surface. The surface and bulk phase of the semiconductor have a common Fermi level at equilibrium. The chemisorption of gases entails the charging[130,131] of the semiconductor surface, which causes the bending of the energy bands at the surface. This alters the position of the Fermi level in the energy spectrum of the crystal on the surface compared with the bulk phase. Factors which shift the Fermi level in the bulk of the crystal (which corresponds to a change in conductivity) shift it also on the surface, altering the catalytic activity of the semiconductor. However, under certain conditions[130] the position of the Fermi level on the crystal surface is independent of its position in the bulk phase (the case of a quasi-isolated surface).

Vol'kenshtein and coworkers[130,132–134] predicted theoretically the possible changes in the electronic properties of the surfaces of semiconductors under the influence of the electric field. If a semiconductor plate is placed between the plates of a planar air condenser, then a positive charge will be induced on one side of the semiconductor and a negative charge on the other. The semiconductor as a whole remains electrically neutral, but the adsorption capacity of its sides is altered. Vol'kenshtein's theoretical predictions have been frequently confirmed experimentally. For example, Stadnik and coworkers[135–140] demonstrated the influence of a constant electric field on the rate of liberation of various products of heterogeneous catalytic reactions, one of the stages of which is adsorption. For instance, studies have been made on the oxidation of the propane–butane mixture in the presence of platinum with formation of peroxides, aldehydes, and acids, the oxidation of methanol to formaldehyde on zinc oxide and a zinc oxide (60%)–copper(II) oxide (40%) mixture, the oxidation of various alcohols on silver, and the oxidation of sulphur dioxide to the trioxide on a platinum catalyst. The field can influence only the electronic stages of heterogeneous catalytic reactions and therefore its influence on the rate of reaction leads to the converse conclusion that electronic processes take place and play a significant role in the given heterogenous process. In the examples quoted the catalysts are metals. This does not contradict the previous conclusions reached for semiconductors, since the catalytic activity of metals is due to the presence of a very thin layer of oxides, which are semiconductors[130,141].

The gas–solid interaction, which frequently accompanies thermal decomposition, gives rise to the adsorption phenomenon. The adsorption of gases alters[142] various electrophysical parameters of the surface of solids, primarily their conductivity. A decrease of the concentration of charge carriers as a result of chemisorption at the points of contact between the particles in "sintered" specimens can give rise[131] to "blocking" layers due to the migration of the gas along the pores. These layers cause a particularly marked change in the conductivity of semiconductors. The adsorbed gas species can themselves behave as electron donors and acceptors if they react with the solid. The activation energy for chemisorption on semiconductors is in most cases considerable. The adsorbed gas molecules charge the semiconductor surface[130] and a potential difference, the value of which can be very high, is established between the surface and the bulk phase. For example, in the chemisorption of oxygen on zinc oxide[131] a 10^6 V cm^{-1} field is established between the surface and the bulk phase. The impurity ions can diffuse into the bulk phase under the influence of the electric field. The surface potential can be altered by the field effect and adsorption methods. Under certain conditions, both effects can operate simultaneously. Thus in very high fields and in measurements in a high vacuum the adsorption—desorption equilibrium can be displaced by the electric field, i.e. electroadsorption and electrodesorption is possible. In measurements in a vacuum of the order of 10^{-5}–10^{-6} torr, for a field strength less than 10^6 V cm^{-1}, the electroadsorption effect does not influence the field effect[142]. Unfortunately the electrodesorption effect has so far been studied only on classical semiconductors.

Flitner[143] investigated the effect of the field on germanium under the condition of the adsorption of oxygen, ozone, and water vapour. He established that ozone increases the number of fast states. Slow energy states arise on the surface of germanium in the adsorption of oxygen. A moist atmosphere influences the fast states, but does not alter the charge of the slow states. The author believes that this indicates the formation of germanium oxide on the germanium surface. Lyashenko and coworkers[144,145] observed the influence of the electric field on the desorption of gases from a germanium film. The resistance of the film increased following the desorption of gases. It is interesting that an increase of gas pressure in the system was observed only after the first application of the electric field. When the desorbed gas is evacuated, a repeated application of the field within the same limits does not alter the gas pressure. However, after the readsorption of the gas the electrodesorption process is again observed. The change of pressure in the system and of the resistance of germanium are due to the same cause—the change in the surface charge of the semiconductor. The gas contained hydrogen, hydrocarbons (oil from the pump), nitrogen, and nitric oxide. Mainly nitrogen was electrodesorbed. In the case of a negative potential on germanium this phenomenon was not observed. The external field reduced the negative charge on the surface of germanium, which led to the desorption of the gas. The electrodesorption effect was not observed on germanium films with a thickness greater than the screening radius. The studies by Mikheeva and Keier[146–148], who investigated the influence of a constant transverse electric field on the chemisorption properties of *n*-type germanium in relation to methanol and oxygen, constitute a logical continuation of studies on the adsorption capacity of germanium in the electric field. The field, leading to an increase in the surface potential, which is positive on germanium, and to an upward bending of the bands), resulted in the appearance of charged chemisorbed methanol species. In the absence of the field under these conditions (at 27°C and a pressure of 10^{-2} torr) methanol was not adsorbed. It was established that a transverse electric field disturbs the electronic equilibrium between the surface and bulk-phase bands. After the application of this field, the equilibrium between the surface and the bulk phase was restored in 1.5 to 2.0 h. When a field is applied, there is a possibility of side effects associated with the ionisation, polarisation, and orientation of the molecules in the gas phase. Therefore measurements must be made at a pressure of the order of 10^{-2}–10^{-3} torr. It was also established that the change in the adsorption properties of germanium in the electric field is caused by the change in the position of the Fermi level and the filling of the surface energy levels with electrons. The influence of the field on the adsorption of oxygen was observed only following the application of a negative potential to germanium, which decreases the electron work function. By measuring the relaxation of the conductivity of germanium when the field was switched on and off *in vacuo* and in an atmosphere of oxygen, it was shown that oxygen does not form new acceptor centres and that adsorption takes place on the existing surface acceptor centres. It was suggested that the active adsorption centres on germanium are slow donor states for methanol and slow acceptor states for the adsorption of oxygen. It was concluded that the adsorption properties of semiconductors are determined by the chemical state of the surface and the presence of active adsorption centres. Similar studies on the effect of a steady electric field on the adsorption of CO_2 were carried out by Ivankiv and coworkers[149,150] using thin tellurium films. Electrodes (silver, aquadag) for the measurement of the resistance were located along the edges of the film and a field electrode was placed on the other side of the support. Simultaneously measurements were made of the CO_2 pressure, and of the film resistance. The experiment on the electrodesorption of CO_2 from the tellurium film was performed in a vacuum of 5×10^{-9} torr in a 10^5 V cm^{-1} field. Under these conditions, with a positive potential on the semiconductor, CO_2 was electrodesorbed. At a negative potential a slight adsorption of CO_2 was observed on the film. The same workers[151,152] investigated the adsorption of oxygen and water vapour in an electric field on epitaxial β-HgS films with *n*-type conductivity. The adsorption was investigated on the basis of the changes in film conductivity. The application of a positive potential to the film increased the degree of adsorption of donor molecule and decreased the degree of adsorption of acceptor molecules, while at a negative potential the opposite effect was observed. The removal of the field restored the conductivity of the previous value owing to intense chemisorption on certain sections of the film. It was concluded that the chemisorption of oxygen on mercury sulphide is enhanced following the application of the electric field.

The conductivity of potassium permanganate single crystals has been investigated in water and ethanol vapours[153]. Single crystals, clamped between graphite electrodes, were alternately placed in desiccators [sic] containing water or alcohol and in a desiccator with phosphorus pentoxide. A 100 V cm^{-1} electrostatic field acted constantly or was applied periodically (at the instant of measurement of the conductivity). As potassium permanganate was made moist under the conditions of a briefly applied field, its conductivity steadily increased, tending to saturation. On the other hand in a steady field the conductivity passed through a maximum after the first moistening process. Due to the repeated drying and treatment of the crystals in water

and ethanol vapours, residual effects appeared in the changes of the conductivity of the single crystals, which were accounted for by the influence of the field on the chemisorption of the polar vapours.

7. The Change in the Properties of the Surfaces of Solids under the Influence of the Electric Field.

Since the thermal decomposition of solids begins as a rule from the surface[13,14], the state of the surface plays a major role in the development of the decomposition process. There is usually a complete system of discrete and continuously distributed energy levels on the surface of crystals[142,154–159], which may have different origins. These may be Tamm levels, arising on the surface as the result of the termination of the crystal lattice, and also energy levels associated with impurities or due to surface defects in the crystal lattice. Finally surface levels may be associated with the adsorption of molecules from the surrounding gas. The local energy levels on the surface and the associated surface charge lead to the bending of the energy bands near the surface, which is reflected in a significant change of the electron field work function and photoelectric and other properties. Often the state of the surface largely determines the course of the physical processes associated with the bulk phase of the crystal. Thus the surface levels can behave as recombination centres and can influence the lifetime of the non-equilibrium charge carriers in the specimen. Owing to the presence of the potential "well" near the semiconductor surface, the migration of the charge carriers in the surface region differs significantly from their migration in the bulk phase. This leads to a change in the mobility of the carriers owing to the additional scattering of the electrons and holes on the surfaces. The change in the energy state of the surface is attributed to a change in a particular surface parameter of the substance—the surface potential φ_S. This quantity can be determined as the difference between the potential energy of the electrons in the bulk phase and on the surface of the crystal. There are many experimental methods for the measurement of the surface potential, the most convenient of which is the field effect method.

The field effect is characteristic of semiconducting substances and consists in a change of the conductivity of the semiconductor following the application of a potential difference at right angles to its surface (and to the direction of the current). The field effect was first observed on copper(I) oxide by Schockley and Pearson[154]. It can be interpreted as follows. If one assembles a condenser one plate of which consists of the specimen and the other of a metal, using an intervening layer of an insulator with a high dielectric constant, and an electric field is applied to the condenser, then a space charge is created near the semiconductor surface, neutralising the charge on the metallic plate. Thus Lashkarev and Lyashenko[155] continued the study of the field effect on copper(I) oxide and defined rigorously the semiconductor surface as a layer with a thickness equal to the free path of the charge carriers. The surface charge constitutes an obstacle to the imposition of an external electric field on the semiconductor. If a negative potential is applied to the metallic plate of the condenser, the semiconductor plate becomes positively charged. This charge is localised in the bulk phase and on the surface of the semiconductor and the neutrality of the latter is disturbed, the energy bands being bent upwards relative to the Fermi level. The decrease of the degree of filling of the surface level by electrons (which corresponds to an upward bending of the bands) leads to the appearance of an additional surface charge, i.e. to the screening of the external field. As a result of the field effect, the electron work function of thin layers of copper(I) oxide is greater than that of thick layers by 0.13–0.15 eV. Thus a considerable proportion of the charge induced by the electric field is captured[142,155–157] by the surface states and the bulk phase of the semiconductor is electrically neutral. If the metallic plate is positively charged, a negative charge is induced on the surface of the semiconductor and the surface region of the bulk phase of the conductor is positively charged. The thickness of the layer screening the external charge in the semiconductor is inversely proportional to the square root of the equilibrium concentration of its charge carriers outside the limits of the space charge. The bulk-phase charge carriers near the surface contribute to the conductivity of the specimen, in contrast to the stationary carriers in the surface energy levels[158]. By measuring the resistance of the specimen along the surface layer for different electric field strengths, it is possible to determine the change in conductivity associated with the applied field. To increase the accuracy of the measurements, the specimen should be made fairly thin, so that the change in the surface resistance constitutes an appreciable proportion of the total resistance of the specimen. The field effect can be investigated[158] in steady and alternating fields at frequencies up to 10^8 Hz. In an alternating field the degree of screening of the surface from the bulk phase is reduced at higher frequencies, and it becomes constant from 10^3 Hz up to 10^7 Hz. The thickness of the charged region near the surface of semiconductors is usually[159] of the order of 10^{-4}–10^{-6} cm and the mobility of the charge carriers in this layer depends on the thickness of the semiconductor. When the field effect method is used to measure the surface potential, the density of the surface states does not change, in contrast to the absorption method. When a transverse electric field is switched on, an induced charge is initially created at the surface and then equilibrium is established between the conduction band, the valence band, and the fast surface states with a time constant of 10^{-7}–10^{-4} s, as a result of diffusion, capture, and recombination. After this, an equilibrium degree of filling of slow surface states is established during a period from several seconds to 1 h. Ultimately the concentration of surface levels remains unchanged during the measurements and only the degree of their filling is altered. A continuous variation of the surface potential within fairly wide limits up to the minimum in the surface conductivity of the crystal can be readily achieved by the field effect method.

The type of surface conductivity and the relation between the degree of bending of the bands and the applied potential can be determined, the charge in the region near the surface can be discovered, and the mechanism of the surface recombination of charge carriers can be investigated by measuring the field effect under steady-state conditions[142,160–166]. Finally the field effect method makes it possible to determine whether or not the energy spectrum of the surface levels is continuous or discrete and their concentrations and energy positions can be determined. The study of the kinetics of the field effect (non-steady-state case) makes it possible to calculate the relaxation time of the surface levels and to elucidate the mechanism of the exchange of charge carriers between the bands in the bulk phase and the surface energy levels. A theory of the field effect has been devised for band semiconductors, but, as shown by Sandomirskii and Pyasta[160], it is applicable also to

polaron semiconductors with jump conductivity. In particular potassium permanganate, a classical system in solid state chemistry, is a polaron semiconductor[37]. The field effect has been observed[166] also in organic semiconductors. Thus Petrova and Rozenshtein[166] observed the field effect in a number of organic semiconductor films obtained by vacuum sublimation. The authors determined the sign of the conductivity of the test substances and observed the enrichment and depletion of the specimens in charge carriers under the influence of the electric field. It was concluded that slow states are characteristic of organic semiconductors. Consequently the type of chemical bond in solids does not play a decisive role in the manifestation of the field effect.

Measurement of the field effect using an alternating current yields information about the time characteristics of the surface traps, which measurements with a direct current fail to do. Whereas the field effects measured using a direct current are frequently masked by slow states, with an alternating current they are clearly manifested. Mathematical treatment of the frequency characteristics of the field effect yields quantitative data on the distribution of surface states with different time constants. Frolov et al.[167], who studied the influence of the thickness of silicon oxide on the field effect in silicon, observed a correlation between the thickness of the surface oxide layer and the concentration of surface electronic states in etched silicon specimens. It was shown that the nature of the fast surface states is determined by the structural defects at the semiconductor–oxide boundary. By studying the relation between the surface conductivity of silicon and the strength of a variable transverse field, Einspruch[168] showed that, under the experimental conditions, most of the charge induced by the field is captures by surface layers. Esaki et al.[169] studied the influence of the field effect on the conductivity of the contact layer in germanium–gallium arsenide heterojunctions. The mobilities found in the contact layer proved to be constant for fields in the range 2×10^4–5×10^5 V cm^{-1}. This case permits a simple investigation of the surface conductivity of semiconductors. The field effect in a high-resistance zinc oxide powder mixed with a silicone resin[170] showed that its magnitude and time constant in such specimens depend more on the associated charges than on the free charges, in contrast to low-resistance semiconductors. The rate of recombination of free electrons and the concentration of electron traps were calculated from the change in photoconductivity as a function of the transverse electric field.

Using the classical method[171] for the investigation of the field effect on zinc oxide single crystals, it was established that the surface potential of zinc oxide is negative and the specific conductance of the specimen increases rapidly with increase of the applied potential. It has been suggested that there are acceptor oxygen levels on the surface of zinc oxide to which electrons are withdrawn from the region of the bulk phase near the surface under the influence of the field. As a result, the layer of the bulk phase near the surface is depleted in electrons and their concentration on the surface increases. At a high concentration the acceptor levels on the surface of the ZnO crystals may be split off[172] as a band, which leads to an increase in the surface conductivity with increasing electric field strength. The bulk-phase specific conductance of the specimen then diminishes. For anisotropic semiconductor crystals[173], the relation between the transverse and longitudinal alternating currents is linear. This makes it possible to control the current in anisotropic semiconductors.

A steady influence of a constant electric field on surfaces has been established in a number of studies.[174–176] Thus Costa and Murphy[174] observed a persistent internal polarisation of a sulphur single crystal due to the operation of the electric field, the removal of which requires the application of external energy. It was established that the relation between this energy and the decrease of the polarisation is exponential. In amorphous selenium the phenomenon of residual polarisation, which decays exponentially as a function of time, was observed by Nasledov and Malyshev[175]. The mechanism of this phenomenon has not so far been elucidated, although it has been stated that the electrons get "stuck" within or on the surface of selenium. CdS single crystals placed between the plates of a charged condenser are quasineutral[176]. However, owing to the inhomogeneous bulk-phase conductivity of CdS, the charges are polarised and the polarisation may persist for a long time. It is suggested that in a strong electric field there is an injection of electrons at the cathode and not a limitation of the space charge.

The problem of the preparation of specimens for thermal decomposition is no less urgent. Ziman[177] reviewed studies on methods for the elimination of solid impurity particles from surfaces by the application of a high steady electric field. The initial specimen is earthed and exposed to the field via an air gap. The material of the field electrode does not affect the degree of purification of the dust-covered surface of solids. It is suggested that the dust particles are removed as a result of their becoming charged in the electric field. An electrical interaction then arises between the particles and the electrode, which tends to abstract the particles from the support.

In studies on the electrophysical properties of semiconductors and dielectrics attempts are made to carry out measurements in the region where Ohm's law holds. This is done to eliminate side effects: contact resistances and the Poole effect. However, it is not always possible to avoid the side effects and it is necessary to formulate clearly the influence of the field on these effects. The Poole effect[178,179] can be observed only for high-resistance substances in fields of 10^3–10^4 V cm^{-1}. The electrical breakdown of a layer of dielectric thicker than 10^{-5} cm occurs in fields of $(1–5) \times 10^6$ V cm^{-1}, which increase with decrease of the thickness. As the field increases, there is a rise in the concentration of charge carriers and not an increase of mobility[179]. Injection of charge carriers from the electrodes is one of the causes of the Poole effect, consisting in a rapid increase of the current with potential, which follows from Ohm's law. The knowledge of the relation between the field effect and the properties of the point contact is no less important in experimental studies. Nesmelova[180] stated that near the point contact the electric field has both normal and tangential components in relation to the surface. The presence of the normal component leads to the bending of the energy bands, similarly to the field effect, and hence to a change in the conductivity of the specimen. Then the dependence of the conductivity of the specimen on the applied potential should be minimal. Guerci and coworkers[181,182] observed the influence of a steady transverse electric field on the lag of the photocurrent in CdS crystals behind the instant when light is switched on. This lag was proportional to the electric field applied at right angles. They suggested that the transverse field disturbed the ohmicity of the contact and consequently reduced the current through a cadmium sulphide crystal. The same field induced oscillations in the photocurrent within the specimen, which made it possible to separate the surface and bulk-phase components of the photoconductivity.

Thus the study of the field effect yields important information about the electronic processes on the surfaces of solids, which can be used to understand the influence of the field on the development of the decomposition process.

* * *

The examples analysed leave no doubt about the great but hitherto incompletely utilised scope of the electric field as the foundation of a method for the investigation of the mechanism of thermal decomposition and as a procedure for stimulating the thermal decomposition of solids. Electrophysical studies of the thermal decomposition of solids constitute an effective means of comprehending the essential physical nature of the elementary stages in the decomposition reactions and the mechanisms of the electronic and ionic processes whereby the initial substance is converted into the reaction products. These problems constitute the corner stone of solid state chemistry.

Alkylation and Arylation of Unsaturated Compounds with the Aid of Transition Metal Complexes

L.G.Volkova, I.Ya.Levitin, and M.E.Vol'pin

Methods for the alkylation and arylation of unsaturated compounds with the aid of Group VIII metal complexes are examined and both the preparative aspects and the mechanism of the reactions involving the introduction of various organic groups into olefins are discussed.
The bibliography includes 77 references.

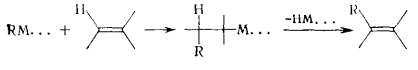
III. Alkylation and arylation of olefins by organic halogeno-derivatives in the presence of Group VIII metal compounds 557
IV. Arylation of olefins by aromatic compounds in the presence of transition metal salts 558

I. INTRODUCTION

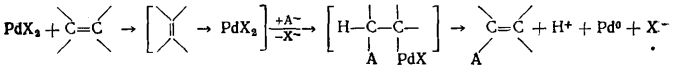
In the chemistry of olefins reactions occurring under the influence of transition metal compounds have been acquiring increasing importance. Important industrial processes such as polymerisation of olefins at low temperatures and pressures, direct oxidation of propene to acrolein, the oxidation of propene and ammonia to acrylonitrile, the oxidation of olefins in the presence of vanadium salts with formation of carbonyl compounds and vinyl esters of carboxylic acids, and the hydroformylation and disproportionation of olefins were introduced in the course of the last two decades.

Significant advances have also been achieved in the development of methods for the consecutive growth of the carbon chain in unsaturated compounds. The classical Meerwein reaction[1]—the arylation of olefins by diazonium salts in the presence of copper compounds—is of limited importance, since it makes it possible to introduce only an aromatic residue into the unsaturated molecule. The use of Group VIII metal complexes has given rise to good prospects for the introduction of organic groups into olefins. Their application is based on the capacity of certain organometallic σ derivatives of these elements, particularly those of palladium, to add to the double bond and on the instability of the addition products with respect to β-elimination:



Although the oligomerisation, disproportionation, and hydroformylation of olefins should be formally included in the type of processes under consideration, we shall not discuss them here, since an extensive literature has been devoted to each of these reactions. The oligomerisation and cyclooligomerisation reactions[2] are particularly characteristic of compounds with the C≡C triple bond in the presence of Group VIII metal complexes, while the growth of the carbon chain in acetylene derivatives is achieved more readily by the methods which have been thoroughly developed in organic chemistry. For this reason, attention will be concentrated in the present review on the introduction of alkyl and aryl groups into compounds with a C=C double bond, which is of preparative interest.

The interaction of olefins with transition metal complexes is known to involve in many instances the ready formation of π complexes. As a result of the changes in the electronic structure of the unsaturated ligand, the reactivity of the double bond in many π complexes in relation to nucleophilic reagents increases compared with the free olefin. Nucleophilic addition to π complexes has been comparatively thoroughly investigated in the chemistry of palladium. If there are no factors favouring the stabilisation of metal–carbon σ bond in the resulting compound (for example the influence of other ligands or of chelate formation), the hydride is eliminated and the overall process reduces to the substitution of the vinyl hydrogen:

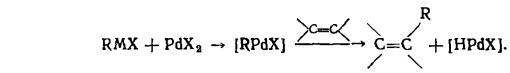


The mechanism of such reactions has been thoroughly studied by Moiseev in the oxidation of olefins by palladium(II) compounds[3]. It was shown that the intermediates in this reaction are labile organopalladium σ compounds obtained as a result of a rearrangement of the palladium complex containing the olefin, joined by a π bond, and a solvent molecule[4-6]. These fundamental stages are apparently characteristic of the majority of the reactions discussed in the present review.

II. ALKYLATION AND ARYLATION OF OLEFINS BY ORGANIC TRANSITION METAL σ DERIVATIVES OBTAINED BY DOUBLE DECOMPOSITION REACTIONS BETWEEN GROUP VIII METAL SALTS AND ORGANOMETALLIC COMPOUNDS

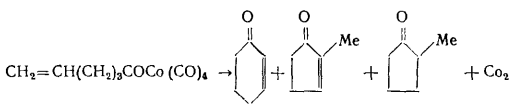
The possibility, in principle, of the formation of labile organopalladium σ complexes in double decomposition reactions of organomercury compounds with palladium salts was demonstrated by Moiseev in 1960[4]. Ways of employing such complexes in organic syntheses were discovered in 1968 by Heck[7]. He succeeded in synthesising a wide range of alkylated and arylated olefins by

allowing the olefin to react jointly with a transition metal salt and an organic derivative of a non-transition metal[7-12]:



It is noteworthy that, even before these investigations by Heck, instances were known where the interaction of alkyl σ complexes of transition metals with olefins resulted in the formation of a new carbon–carbon bond, namely the addition of methylmanganese pentacarbonyl to tetrafluoroethylene with formation of a new organometallic complex[13]:

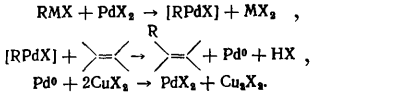
and the cyclisation of the organic ligand of hex-5-enoylcobalt tetracarbonyl, which resulted in a mixture of cyclohexenone, 2-methylcyclopentenone, and 2-methylcyclopentanone[14]:



A characteristic feature of the new stage in the wide-scale application of transition metal compounds for the alkylation and arylation of olefins was the use of stable organometallic compounds of non-transition metals as the source of organic groups. Heck and other investigators showed[7,15-20] that such donors or organic groups may be derivatives of lithium, magnesium, thallium, mercury, tin, and lead. However, these organometallic compounds are either sensitive to air and moisture (organolithium and organomagnesium compounds) or are highly toxic (organic derivatives of mercury, tin, thallium, and lead), so that their use in many cases involves significant difficulties. The recently discovered possibility of using organosilicon compounds—alkyl- and aryl-silanes, which are stable, non-toxic, and relatively readily available—as sources of alkyl and aryl groups in these reactions[21,22] is therefore of interest. Symmetrical organic derivatives Ar_2E, where E = P, As, Sb, or Bi, can also be used for arylation[23,24]. It has been shown that stable alkyl and aryl σ complexes of cobalt, rhodium, and iron with chelating ligands RM(Chel), where R = Me, Ph, or $PhCH_2$ and Chel = bis(dimethylglyoximate), bis(salicylidenato)ethylenediamine, and corrin and phthalocyanine ligands[25,27].

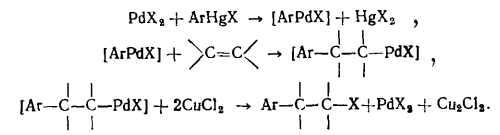
In most cases the above reactions occur at room temperature in various polar solvents, such as methanol, acetonitrile, acetic acid, and tetrahydrofuran and lead to the formation of substituted olefins in yields which are nearly quantitative in many cases. In arylation with the aid of compounds of Group VA elements more severe conditions are required (refluxing in an acetic acid–dioxan mixture)[24], probably in order to suppress the coordination of palladium to these compounds via a heteroatom.

The most active "transferring" agents for organic groups in these reactions are palladium compounds, the rhodium, ruthenium, and nickel complexes being less active[7]. Upon reaction, the transition metals acquire the zero oxidation state. The use of suitable reoxidising agents, such as copper(II) chloride, and iron and mercury salts, permits their regeneration and thus makes the reaction catalytic[7]:



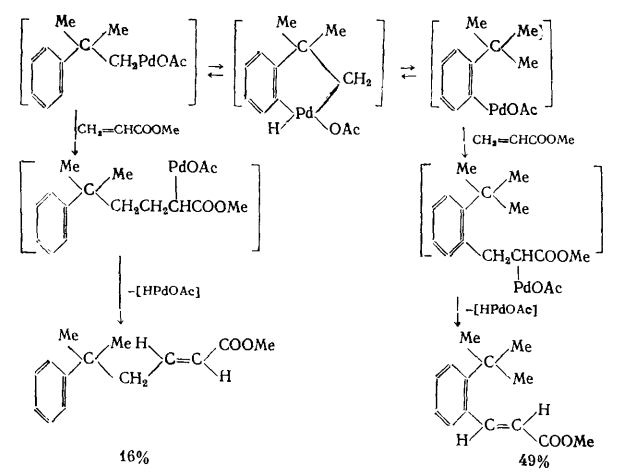
Copper(II) chloride can be regenerated from copper(I) chloride with the aid of atmospheric oxygen and hydrogen chloride.

In those cases where the concentration of the copper salt in solution exceeds 0.5 M halogeno-derivatives are also formed and the halogenoethylation reaction can become the main one[10]. For example, the reaction of phenylmercury chloride with ethylene in the presence of catalytic amounts of $PdCl_2$ and $CuCl_2$ at a concentration of 2 M results in the formation of phenylethyl chloride in 76% yield:

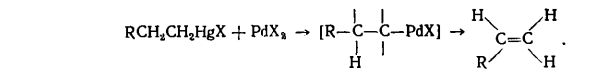


This reaction is itself also very useful for synthetic organic chemistry, because there is no other way of adding, in a single stage, a 2-halogenoethyl group to an olefin.

Alkylation of unsaturated compounds by organopalladium σ complexes makes it possible to introduce into olefins alkyl groups without a β-hydrogen atom, such as the methyl, carboxyalkyl[7], benzyl, and neopentyl[28] groups. From the standpoint of synthesis, the transfer of the neopentyl group as a method for the introduction of a quaternary carbon atom into an unsaturated molecule is of special interest. The transfer of another group fully substituted in the β-position—2-methyl-2-phenylpropyl—is accompanied by an interesting rearrangement, probably in the stage involving the formation of the organopalladium σ compound, so that the normal product is accompanied by an olefin with the *o*-(t-butyl)-phenyl substituent at the double bond:

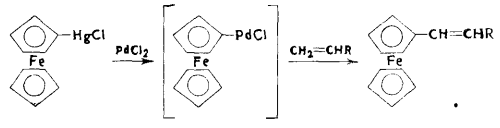


The attempts to transfer groups containing hydrogen in the β-position were unsuccessful: the olefin corresponding to β-elimination from the alkyl group was obtained instead of the alkylated products[7]:



Like alkyl groups without β-hydrogen, aryl groups with various substituents can be introduced into unsaturated molecules with the aid of transition metals[7]. Under these conditions, powerful electron-donating groups such as the methoxy-, hydroxy-, and diethylamino-groups in the *ortho*- and *para*-positions, lower the yield of the arylated olefins; substituents with a marked capacity for coordination to metals, for example the amino-group, hinder still more the reaction or preclude it altogether.

Subsequently arylation by a non-benzenoid aromatic system was achieved—the ferrocenyl residue was introduced into olefins[29]:

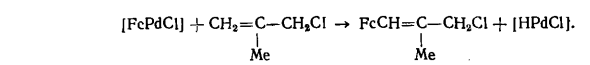


The nature of the olefin also plays a significant role in the above reaction. In particular the arylation of olefins with the normal structure and a short chain proceeds more readily and with higher yields. The relative rates of arylation decrease in the following sequence[7]:

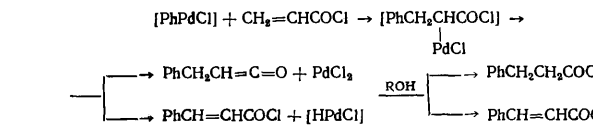
$$\underset{14\,000}{CH_2{=}CH_2} > \underset{970}{CH_2{=}CHCOOMe} > \underset{220}{MeCH{=}CH_2} > \underset{42}{PhCH{=}CH_2} > \underset{1}{MeCPh{=}CH_2}.$$

The arylation of olefins with functional groups has also been achieved. If a complex containing in the β-position relative to the metal a group tending to form an anion is formed in the interaction between the substituted olefin and the organopalladium compound, the decomposition of this complex can proceed with elimination of the corresponding anion instead of the hydride. For example, in the arylation of allyl halides the intermediate organopalladium compound decomposes exclusively with the elimination of the chloride ion[9]:

Aryl groups with various substituents (the nitro-group and ether and aldehyde groups) were introduced in this way into the allyl position. On the other hand, when the ferrocenyl group is introduced into allyl chloride, palladium hydride is split off and not the chloride[27]:

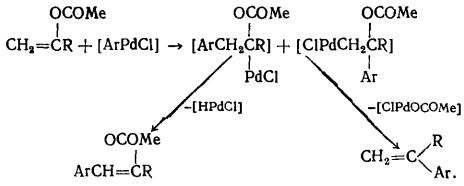


Arylation of the chlorides of αβ-unsaturated acids in the presence of $PdCl_2$ led to the formation of a mixture of various products[30]:

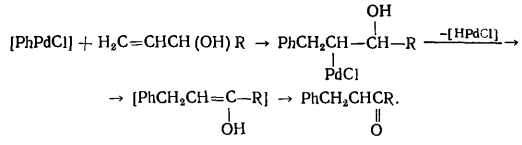


Depending on the pathway in the decomposition of the organopalladium complex, with elimination of $PdCl_2$ or [HPdCl], esters of β-phenylpropionic or substituted cinnamic acids are formed in the subsequent alcoholysis. However, the yields of both are low, of the order of 10 to 16%, so that the reaction in this form has no preparative interest.

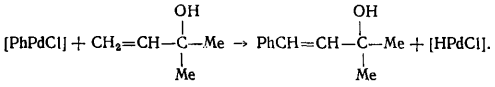
The reaction of enol ethers and esters with arylpalladium salts, obtained *in situ*, gives rise to various products, depending on the mode of addition of the organopalladium compound (see p. 556) and on the nature of the species eliminated[10]:



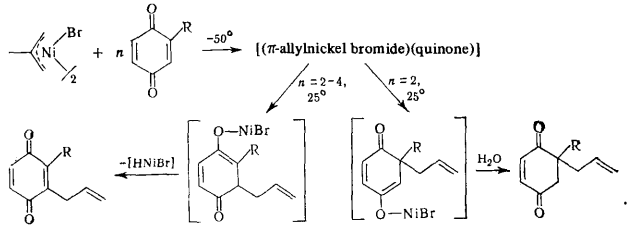
In certain cases the arylation reactions of substituted olefins are accompanied by rearrangements. For example, phenylation of primary or secondary allyl alcohols leads to 3-aryl-substituted aldehydes and ketones, probably via the corresponding enols[8]:



Tertiary ally alcohols react normally:



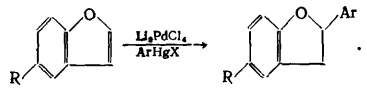
Examples of the introduction of substituents into benzo- and naphtho-quinones with the aid of Group VIII metal complexes are now known. The reaction of π-allylnickel bromides with *p*-quinones, discovered by Hegedus et al.[31], which makes it possible to introduce an allyl substituent into the quinones, is of great interest. The synthesis is carried out in polar solvents, [tetrahydrofuran (THF), dimethylformamide (DMF)] in two stages. Mixed allyl–quinone π complexes of nickel are formed at a low temperature (−50°C), while the second stage takes place at room temperature. In particular, coenzyme Q_1 and 1-plastoquinone were obtained by this method in 40 and 30% yields respectively. The authors represent this reaction by the following general scheme:



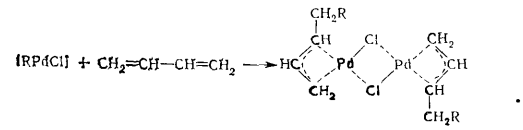
Thus the reaction with a monosubstituted *p*-benzoquinone results in the formation of a mixture of isomeric allylquinones and, for a comparatively small quinone: nickel complex reactant ratio cyclohexenedione derivatives are also formed. In the first two stages 1,4-addition probably takes place. However, the third stage suggested by the authors—the elimination of the hydride—appears unlikely; the oxidation of the cyclohexadienone derivative by an excess of the initial quinone is more probable.

Kim et al. [32] found that *p*-quinones can be methylated by methylpalladium complexes obtained *in situ* from a palladium salt and a methylcobalt chelate. In the methylation of *p*-benzoquinone the yield is very low (4%); but in the case of 1,4-naphthoquinone it is much higher (30–40%). The palladium salt can be replaced by a nickel salt, although the yield is then appreciably reduced.

The unsaturated systems capable of being arylated include certain heterocyclic compounds [33]. The interaction of benzofuran with intermediate arylpalladium chloride leads to the formation of 2-arylbenzofuran derivatives:

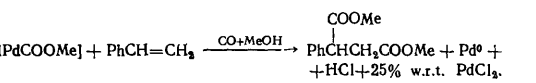


Conjugated dienes such as butadiene and cyclohexa-1,3-diene react with alkyl-, aryl-, and ferrocenyl-palladium compounds obtained *in situ*, with formation of stable allyl π complexes [12, 34]:

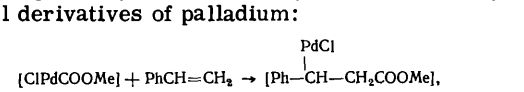


Methyl 5-ferrocenylsorbate was obtained directly from methyl sorbate and ferrocenylpalladium chloride, evidently also via an allyl π intermediate.

Reactions involving the insertion of simple molecules, particularly CO, in the palladium–carbon bond in the intermediate organopalladium σ compounds give rise to extensive synthetic possibilities. We shall quote several examples of reactions of this kind. Thus Heck discovered the reaction involving the addition of two methoxycarbonyl groups to multiple bonds [35]. When olefinic and acetylenic hydrocarbons are acted upon by methoxycarbonyl derivatives of palladium [obtained directly from $PdCl_2$, methanol, and CO or by the double decomposition reaction of palladium(II) with the corresponding organomercury compound], dialkoxycarbonyl derivatives are formed:

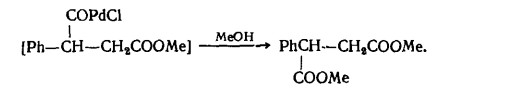


The olefin probably reacts initially with the methoxycarbonyl derivatives of palladium:

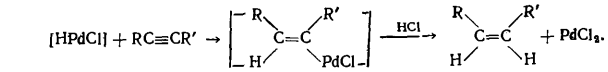


and then a CO molecule is inserted in the new palladium–carbon bond:

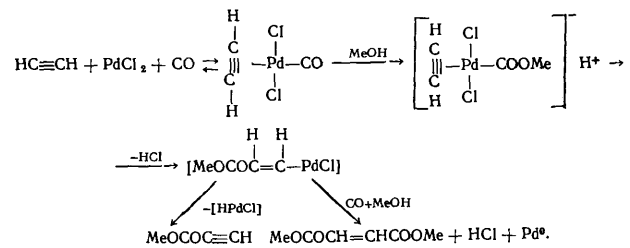
after this, the organometallic compound undergoes alcoholysis:



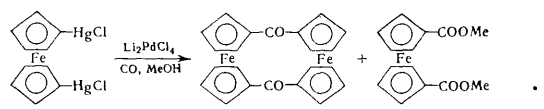
In the reactions with acetylene the yields of the products exceed the stoichiometric values (up to 200%), which can be accounted for by the regeneration of the palladium(II) compound as a result of the oxidation of zero-valent palladium by acetylene:



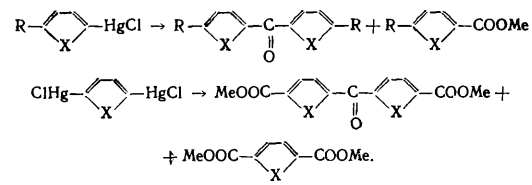
Overall, the reaction with acetylenes can be represented as follows:



The carbonylation of 1,1′-bis(chloromercury)ferrocene with the aid of a palladium salt in methanol at 70°C and a CO pressure of 50 atm led to the synthesis of 1,1-ferrocenophane-1,12-dione [36]:



The carbonylation of organomercury derivatives of the furan and thiophen series was achieved by means of the same scheme [37]:

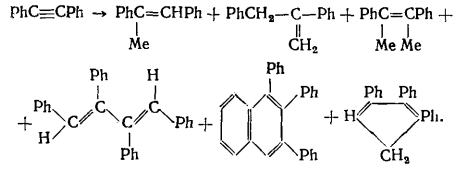


Generalising the reactions discussed in the present section, in which olefins are alkylated and arylated by organic σ derivatives of transition metals, obtained by double decomposition reactions of organic derivatives of non-transition metals with Group VIII metal salts, one may conclude that this procedure has great possibilities for the synthesis of a wide variety of derivatives of unsaturated compounds.

In all the reactions examined the intermediate formation of transition metal σ complexes is postulated, but these complexes cannot be isolated in view of their high kinetic lability. There exists only indirect evidence for their formation. In particular, in a study of the alkylation of olefins by organic derivatives of chelate complexes of cobalt in the presence of palladium compounds it was possible to isolate bis-π-allylpalladium chloride, formed as a result of the double decomposition reaction between the allyl derivative of the cobalt chelate and palladium(II). [26] Presumably the allyl π complex is formed on rearrangement of the intermediate π-allylpalladium chloride.

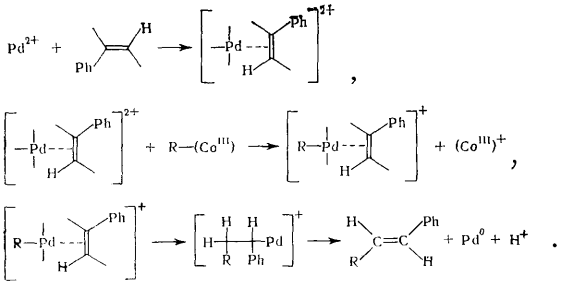
The reaction of the methyl σ complex of rhodium $MeRh(PPh_3)_3$ with diphenylacetylene can serve as an example of the alkylation of an unsaturated compound by a more stable organic σ derivative of a transition metal.

It results in the formation of the same products as in the alkylation of tolane by MeMgBr in the presence of $RhBr_3 \cdot 3H_2O$, $Rh(PPh_3)_3Br$, or $(PhCN)_2Pd$ [15,16]:



The main product is α-methylstilbene, with the additional formation of isomerisation, dimethylation hydrogenation, and cyclisation products.

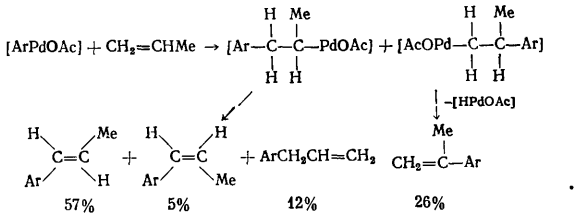
The mechanism of the intermediate formation of organopalladium σ compounds, has been studied in relation to the interaction of palladium complexes with organic derivatives of chelate Group VIII metal complexes of olefins, where this stage is apparently rate-limiting[38]. It was shown that the dealkylation of methylcobalamine by lithium chloropalladate in the presence of styrene proceeds approximately fifty times faster than in its absence. Evidently the stage involving the transfer of the organic ligand from cobalt to palladium precedes the formation of the π complex of palladium with the olefin. The next stage is apparently the exchange proper of the organic group between the organometallic compound and the olefinic π complex of palladium, the influence of the olefinic ligand in the π complex promoting the labilisation of the Pd–Cl bond in the *trans*-position relative to it:



The observed electronic effects in the reactions considered correspond to the usual rules governing electrophilic substitution at a metal atom.

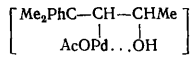
Later a study was published in which the kinetics of the transfer of the methyl group from methylcobalamine to palladium(II) were investigated in the absence of any organic substrate[39]. The reaction products were aquocobalamine, metallic palladium, and methyl chloride. In discussing the reaction mechanism, the authors also suggest the intermediate formation of a methylpalladium σ complex as a result of electrophilic attack by Pd^{2+} on the carbon atom linked to cobalt.

In studies of the arylation and alkoxycarbonylation of olefins by organopalladium compounds factors on which the mode of addition of the organic group to the olefin depends were determined[40,41]. It was found that in the main the reaction mechanism is determined by steric factors, namely the large organic group adds preferentially to the less substituted carbon atom involved in the double bond and palladium therefore adds to the more substituted carbon atom. When the steric and electronic factors act in the same direction, the reaction becomes fairly selective. For example, in the methylation of styrene by "methylpalladium acetate" 95% of trans-β-methylstyrene, about 3% of the *cis*-isomer, and only 2% of α-methylstyrene is obtained. In the arylation of propene the steric and electronic factors act in opposition. The principal mode of substitution is in this case determined by steric effects:

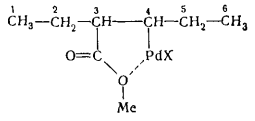


However, the ratio of the yields of products shows that the electronic effects are nevertheless manifested quite distinctly.

In cases where there is a possibility of the formation of a chelate intermediate, this implies a significant influence on the mode of the reactions under consideration. This effect is observed in the arylation reactions of allyl alcohols which we have already discussed[8]. The addition of the phenyl group to such alcohols takes place preferentially at the terminal carbon atom involved in the double bond of the alcohol. This cannot be accounted for either by electronic or steric effects. The mode of addition is in this case probably determined by the possibility of the formation of the four-membered ring

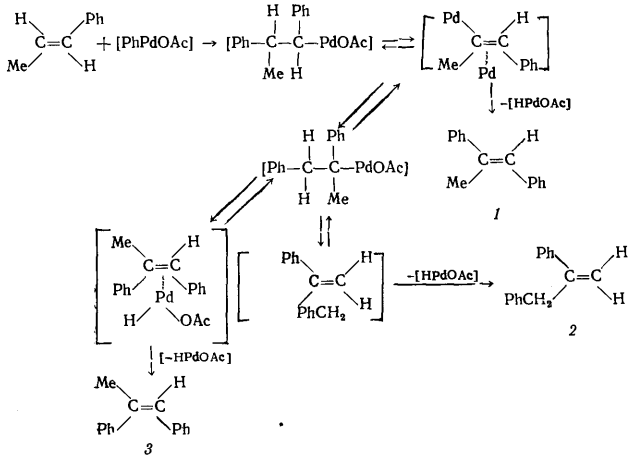


in the intermediate organopalladium compound. The same effect is manifested in the methoxycarbonylation of cyclic olefins and olefins with an inner double bond, leading to preferential substitution in the allyl position. For example, in the methoxycarbonylation of *trans*-hex-3-ene the following chelate intermediate may be formed:



Evidently the *cis*-elimination of the hydride from the 3-position in this complex cannot occur.

Identification of the products obtained in the reaction of "phenylpalladium acetate" with *trans*-1-phenylprop-1-ene yielded information about the stereochemistry of the reaction:

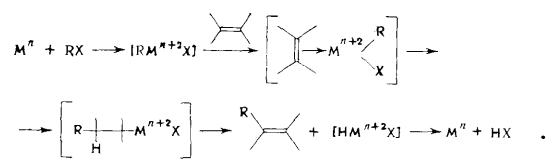


The reaction results in the formation of a mixture of olefins with a nearly quantitative overall yield. The principal product is *trans*-1,2-diphenylprop-1-ene (*1*) (98% yield) with the additional formation of 2,3-diphenylprop-1-ene (*2*) (0.5% yield) and only traces of *cis*-1,2-diphenylprop-1-ene (*3*). The formation of the *trans*-isomer corresponds to the mechanism involving the *cis*-addition of [PhPdOAc] to propenylbenzene with the *cis*-elimination of [HPdOAc]. The preferential formation of *trans*-1,2-diphenylprop-1-ene might be accounted for also with the aid of the *trans*-addition–*trans*-elimination mechanism. However, this appears unlikely[3,40,41], since the reaction should then proceed intermolecularly and not in the inner coordination sphere of palladium.

The selectivity of the substitution of the vinyl hydrogen atom in olefins is significantly influenced by the nature of the anion in the initial palladium complex. The selectivity increases on replacement of the chloride ion by the acetate ion[40,42,43]. It was established that the use of chlorides induces the isomerisation of olefins (both the migration of the double bond and *cis–trans* isomerisation). This can probably be explained by the greater stability of the complex [HPdCl] compared with [HPdOAc]. There is probably sufficient time for the hydride complex [HPdCl] to add several times to the double bond and to be split off before its decomposition into zero-valent palladium and HX. Such partial reversibility of the elimination of the hydride leads to a decrease of selectivity, namely to an increase of the yield of the thermodynamically more stable isomer.

III. ALKYLATION AND ARYLATION OF OLEFINS BY ORGANIC HALOGENO-DERIVATIVES IN THE PRESENCE OF GROUP VIII METAL COMPOUNDS

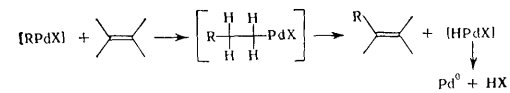
The studies carried out in recent years have shown that not only organometallic compounds but also purely organic reagents, in particular organic halogeno-derivatives, can serve as donors of the alkyl and aryl groups in olefin substitution reactions carried out with the aid of transition metal compounds. The possibility, in principle, of achieving such reactions is based on the ability of metals in a low oxidation state to enter into oxidative addition reactions and on the ability of the resulting complex to interact with the olefin:



Catalytic reactions involving the substitution of the vinyl hydrogen atom of olefins by aryl, benzyl, and styryl halides with the aid of palladium have now been achieved[44–46]. These reactions are carried out in methanol[44,45] or without a solvent[46] at 100°C and atmospheric pressure. The active catalysts are zero-valent palladium and palladium(II) salts. In the latter case the reaction probably begins with the reduction of palladium(II) to zero-valent palladium under the influence of the olefin or methanol. This is followed by the oxidative addition of the organic halogeno-derivative to the zero-valent palladium. The observed reaction rate is determined by the rate of this stage. The reactivity of aryl halides varies in the sequence PhI > PhBr ≫ PhCl, which corresponds to the change in the bond energy between carbon and halogen. The interaction results in the formation of an organopalladium σ complex:

$$Pd^0 + RX \rightarrow [RPd^{II}X].$$

The subsequent interaction of this complex with the olefin leads to the formation of a substituted olefin and the unstable palladium hydride:



The zero-valent palladium is involved in the next reaction cycle.

The accumulation of HX in the reaction medium has an inhibiting effect on the reaction. The point is that the σ complex [RPdX] is unstable in relation to the action of acids; it can be split into RH and PdX_2. Furthermore, an acid medium promotes the hydrogenation of olefins. For this reason, various bases are used to bind HX: potassium acetate and benzoate, pyridine, triethylamine[44,45], and tri-n-butylamine[46].

These reactions are applicable to various substituted olefins containing nitro-, methoxy-, and methoxycarbonyl groups. In the case of olefins containing a methylene group next to the double bond the yields of the reaction products are relatively low[46]. This can be explained by the formation of allyl π complexes of such olefins with the catalysts.

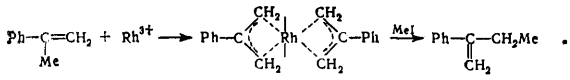
Despite their advantages over arylation, benzylation, and styrylation by organometallic derivatives these reactions also suffer from certain limitations, namely the reaction products are usually a mixture of geometrical isomers, the isomerisation taking place intramolecularly, possibly via a π complex of palladium hydride with the olefin. This is supported by the finding that none of the initial olefins isomerises under the reaction conditions. Since the reaction proceeds at an elevated temperature, the migration of the double bond becomes appreciable. Furthermore, one cannot employ in the reaction starting materials sensitive to the action of bases. This probably explains the failure of the attempts to alkylate olefins by alkyl halides under these conditions.

Olefins were successfuly methylated by methyl iodide in another system using rhodium compounds[47]. The methylation of styrene, linear terminal olefins, and cyclohexene was achieved under the joint action of methyl iodide or chloride or tetramethylammonium iodide and rhodium trichloride in the presence of a reducing agent. The reducing agents used are primary and secondary alcohols and also bivalent tin. Weak bases such as DMF and acetronitrile are used to bind HX in this reaction. Reactions are carried out at 100–160°C using an excess of the olefin. The methylated olefins are formed in stoichiometric yields.

The active species in the reaction is probably a complex of rhodium(I), which is involved in the oxidative addition of MeI. However, this complex is unstable and is partly converted into zero-valent rhodium under the reaction conditions, which was found to be incapable of transferring the organic group to the olefin. This factor complicates the catalytic process.

Together with monomethylated olefins, the formation of small amounts of doubly methylated olefins has been observed in a number of instances. This can be explained

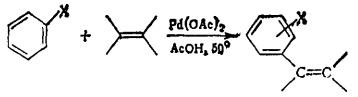
by the subsequent methylation of the allyl π complex of rhodium with the monosubstituted olefin:



IV. ARYLATION OF OLEFINS BY AROMATIC COMPOUNDS IN THE PRESENCE OF TRANSITION METAL SALTS

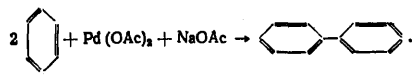
The communications of Fujiwara and coworkers [42, 48, 49] concerning the reactions of olefins with benzene derivatives in the presence of palladium(II) salts, which appeared in 1967, initiated a whole series of investigations on the synthesis of substituted olefins using a wide variety of aromatic compounds as arylating agents.

The interaction of benzene derivatives, an olefin, and palladium acetate results in the formation of aryl-substituted olefins [42, 48, 47]:



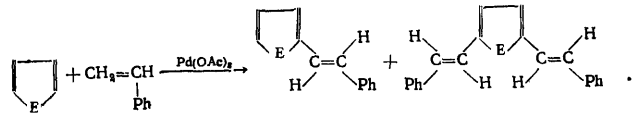
The reactions are carried out with equivalent amounts of the olefin and palladium(II) acetate in a large excess of the aromatic compound in the presence of acetic acid. The reaction does not proceed without the acid. The yield of the arylation products varies from 10 to 90% and metallic palladium is produced. When silver and copper acetates are added to the reaction mixture [50] or the reaction is performed under oxygen pressure [51, 52], it can be made catalytic as a result of the regeneration of palladium(II).

It is noteworthy that the arylation of olefins is accompanied by the dimerisation of the aromatic radicals. The addition of nucleophilic reagents causes the reaction to be of the preformation type and permits its employment for the synthesis of biaryl derivatives [52-61]:



Intramolecular aromatic substitution can also be achieved with the acid of palladium(II). [62] Thus the reaction of the olefins $PhR_2C-CH=CH_2$ (R = Ph or Me) with palladium(II) acetate in acetic acid at 80°C results in the formation of the corresponding 1,1-disubstituted indenes:

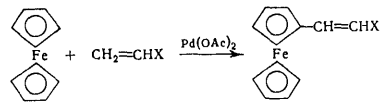
Together with benzene derivatives, other compounds with aromatic properties such as heterocycles [33, 63] and ferrocene [64-66] proved to be active arylating agents. It has been shown that furan, thiophen, selenophen, *N*-methylpyrrole, and *trans*-2-styrylfuran arylate olefins with high yields, disubstituted derivatives being formed together with monoarylated derivatives:



E = O, S, Se.

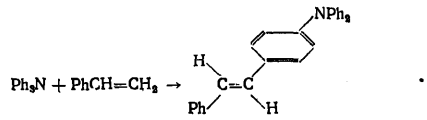
The authors believe that the reaction proceeds in two stages: monosubstituted products are formed in the first stage and further alkenylation takes place in the second stage. This is not observed in the reaction of benzenoid aromatic compounds with olefins [48]. Substitution in heterocycles takes place mainly at the 2- and 5-positions, which corresponds to the usual orientation in electrophilic substitution in heterocycles of this kind.

Ferrocene reacts with various olefins in the presence of palladium(II) acetate with formation of alkenylferrocenes [64-66]. The reactivity of olefins increases appreciably under the influence of electron-donating groups:



(X = Ph, CN, COOMe, CHO)

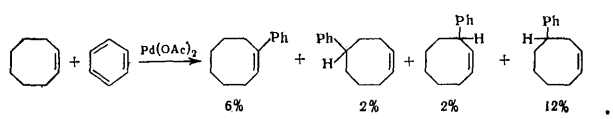
The arylation of olefins by triarylamines is an interesting example of the formation of compounds with functional groups as substituents [24]. The reaction with styrene gives rise to *trans*-*p*-diphenylaminostilbene:



Thus there is a significant difference between the behaviour of Ar_3N as an arylating agent and Ar_3E, where E = P, As, Sb, or Bi; in the presence of the latter stilbenes without a heteroatom are formed (see p. 553). Evidently this difference is due to the greater strength of the C–N bond than the bond between carbon and other Group VA elements.

The aryl group adds to asymmetric olefins preferentially at the least substituted carbon atom involved in the double bond, probably because of the steric hindrance of the substituents [67].

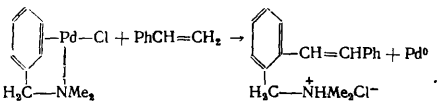
In contrast to acyclic olefins, cycloolefins give rise to a mixture of isomeric arylation products [68]:



The initial stage in the arylation of olefins is probably the formation of an organopalladium σ compound as a result of the direct combination of palladium with a benzene ring [43]:

$$PdX_2 + ArH \rightleftarrows [ArPdX] + HX$$

This is supported by Tsuji's data[69] concerning the formation of an arylated product in the reaction of the stable aryl σ complex between palladium and styrene:



The nature of the substituents in the aromatic system has a significant influence on the mode of substitution in the benzene ring. Electron-donating groups, for example alkyl groups, direct the substituents to the *o*- and *p*-positions, while electron-accepting groups (the nitro-group) are *m*-directing; chlorobenzene gives rise to a mixture of isomeric products with a high content of each isomer[70]. Hence the nature of the substituent hardly affects the reactivity of the aromatic compound.

On the other hand, the presence of polar groups in the olefin has a marked influence on the yields of the arylated products[71]. The reactivity of olefins decreases in the sequence

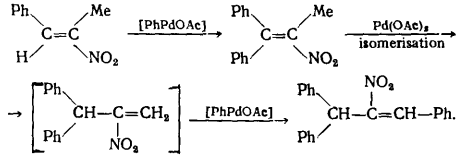
$$PhCH{=}CH_2 > NCCH{=}CH_2 > AcOCH{=}CH_2 > EtOCH{=}CH_2.$$

In arylation with heterocyclic aromatic compounds the inhibiting effect of electron-donating substituents in the olefin is also observed[31].

The reactivity of nitroolefins varies as follows[72]:

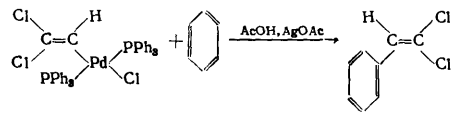
$$PhCH{=}CHNO_2 > CPhCH{=}CPhNO_2 > Ph_2C{=}CHNO_2.$$

It is noteworthy that the phenylation of β-methyl-β-nitrostyrene does not stop at the monoarylated product stage but leads to an olefin with two additional aryl groups[73];

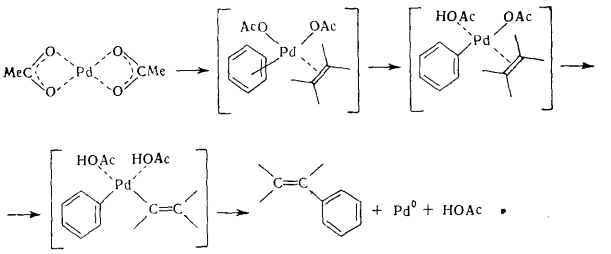


The absence of a substituent effect in the aromatic system on the rate of phenylation shows that the stage involving the formation of the aryl palladium σ complex is probably not rate-limiting. On the other hand, the marked influence of the substituents in the olefin suggests that the slow stage is the interaction of the olefin with palladium. However, the problem of the rate-limiting stage remains controversial. Thus the formation of an arylpalladium σ complex is believed[74] to be the rate-determining stage. This assertion is based on a study of the isotope effect in the arylation of olefins by deuteriobenzene in the presence of palladium(II) acetate.

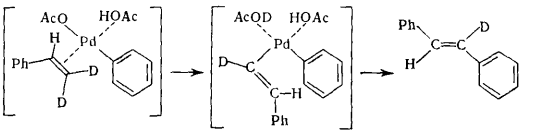
It has been suggested[71] that alkenylpalladium σ complexes take part in the arylation of unsaturated systems together with arylpalladium σ complexes. This is confirmed by the reaction of a stable vinylpalladium σ complex with benzene or toluene, which leads to the formation of an arylated olefin[75]:



Thus the mechanism of the reactions considered can be represented as follows[71]:



Indeed the study of the arylation of olefins in the presence of palladium using isotopes showed that, in contrast to the oxidation of olefins, there is no hydride shift in this reaction[76,77].



A similar study showed that the arylation of olefins by heterocyclic aromatic compounds also takes place without a hydride shift[33]. On the other hand, the mechanism of the substitution of unsaturated compounds with ferrocene includes a hydride shift stage[66].

The methods for the alkylation and arylation of olefins described above have been available for only a few years but they are nevertheless already of considerable preparative interest. Furthermore, the study of these reactions yields interesting information about the role of the formation of organometallic π and σ compounds in homogeneous catalysis.

Ethereal Electrolytes for Aluminium Plating

A.Levinskas

The review deals in detail with ethereal electrolytes widely used at the present time for the formation of high-quality aluminium coatings and mandrels at room temperature. The most important postulates of the theory of electrode processes in ethereal media are discussed on the basis of the latest classification of ethereal electrolytes. The industrial applications of electrolytic aluminium-plating processes and prospects for their further development are briefly enumerated. The bibliography includes 106 references.

I. INTRODUCTION

Aluminium electroplating yields coatings and electroforming mandrels having a wide variety of physicomechanical properties and at the same time capable of meeting the complex requirements demanded of such coatings by modern instrument engineering, electrical engineering, radio electronics, space technology, and optics. The applications of ethereal electrolytes operated at room temperature are the most promising. In the last decade they have been used in a number of technological processes and industrial technological developments. The experience gained in the employment of ethereal electrolytes enriched the electroplating technology by fundamentally new procedures for electrodeposition in hermetically sealed electrolysers. Furthermore the group of ethereal electrolytes for aluminium platings is the object of current electrochemical studies. Numerous data on the compositions and chemical, electrolytic, and physicochemical properties of ethereal electrolytes and on the characteristic features of electrocrystallisation involving non-aqueous media have now accumulated. All these data refer, in Bockris's terminology[1], to the ionics and electronics of non-aqueous solutions and liquid phases, i.e. important branches of modern electrochemistry.

The review deals systematically with all the known ethereal electrolytes for aluminium plating and describes the most important results of their electrochemical study.

II. ETHEREAL AMINE AND ETHEREAL HYDRIDE ELECTROLYTES

One of the early studies on ethereal electrolytes for aluminium plating was the development of the ethereal amine baths by Doumas and Murphy[2,3]. The general composition of ethereal amine electrolytes may be characterised by the following proportions of the initial components used to prepare the electrolyte: anhydrous aluminium chloride (on average 10–45 mole %), an alkylamine including up to three alkyl groups and up to twelve carbon atoms in the molecule (20–40 mole %), and an aliphatic ether incorporating up to six carbon atoms (30–80 mole %). The electrolytes are prepared by adding, with stirring, the ethereal aluminium halide solution to the cooled amine diluted with the ether. According to the authors, refined electrolytic aluminium is deposited over a wide range of cathodic current densities (up to 0.130–0.140 A cm^{-2} inclusive), but preliminary treatment with a current is necessary. The working temperature of the ethereal amine baths is mainly 20–30°C. The gas used to produce the hermetic seal is dry nitrogen or argon. Best results were obtained for electrolysis in electrolytes prepared using the following components: n-butylamine, ethylhexylamine, and diethyl, dipropyl, and butyl ethyl ether or tetrahydrofuran.

Brenner frequently noted the unsatisfactory reproducibility of the composition of ethereal amine electrolyte. Menzies and Salt[4] subsequently showed that the reproducibility is fully ensured only when chemically pure components and anodes of specially pure aluminium are employed. The authors improved the technology of the preparation of ethereal amine baths before use and the procedures for their employment, as a result of which high-quality elastic aluminium deposits were obtained with thicknesses up to 1–2 mm with an average current yield of 78–80%. Consequently ethereal amine electrolytes are suitable both for electroplating and galvanoplastics.

The development of an NBS (U.S. National Bureau of Standards) process by Brenner, based on his ethereal hydride bath, has had a considerable influence on the development of research into ethereal electrolytes for aluminium plating[5–9]. The composition of the ethereal hydride electrolyte, expressed in terms of the concentrations of the initial components was as follows: 1–4 M anhydrous aluminium chloride, 0.5–1.0 M lithium hydride or 0.1–0.4 lithium tetrahydroaluminate, and absolute diethyl ether. The electrolyte was made by mixing the components in different ways, but in all cases the optimum conditions for the Wiberg–Schlesinger reaction must be maintained[10].

The ethereal hydride electrolyte has excellent electroplating properties. The aluminium deposit contains only traces of heavy metals. A deposit 20–25μm thick is continuous, cryptocrystalline, and elastic. These qualities as well as the 100% current yield of aluminium are maintained at different rates of electrocrystallisation up to values of the order of 0.10–0.15 A cm^{-2} inclusive.

Galvanoplastic layers up to 2–5 mm thick can also be obtained using the NBS electrolyte. Special electroforming procedures make it possible to vary the actual thickness of the mandrel. The NBS ethereal hydride electrolyte is usually hermetically sealed under dry nitrogen or argon. The exposure of its surface to air during the replacement of the electrode rods must be reduced to a minimum. When the requirements of an effective hermetic seal, regular filtration, adjustment, and periodic replacement of the spent anolyte are observed, continuous operation of the bath around room temperature is possible for 15–18 months. Brenner proposed also other ethereal hydride electrolytes, the components of which are sodium or potassium hydride, fused aluminium bromide, butyl ethyl, dibutyl, and diphenyl ethers, anisole, phenetole, etc.[11] However, cathodic deposits of the highest quality and the highest operating efficiency of the baths were achieved only in the NBS process.

The successful development of the ethereal hydride electrolyte for aluminium plating enabled Brenner to turn subsequently to the study of the possibilities of the preparation of analogous hydride systems. Thus they obtained titanium–aluminium, titanium–zirconium, beryllium–boron, magnesium–zirconium, magnesium–titanium, and magnesium–beryllium alloys from an ethereal hydride–tetrahydroborate electrolyte and beryllium–aluminium and magnesium–aluminium alloys from an ethereal hydride electrolyte[12–14]. Subsequently the method for the preparation of the beryllium–aluminium alloy was improved by Lui and Guidotti[15]. It is noteworthy that all cathodic deposits of the above alloys are formed in the form of a powder or strained coatings. Therefore the method of their electrodeposition is of extremely great theoretical value.

Certain electroplating problems of the NBS process have been examined also in studies by other investigators. A microscope study of the structure and properties of the aluminium deposit as a function of its thickness and the nature of the cathode material was carried out by Elze et al.[16] The changes in the morphology, texture characteristics, and microhardness of the deposits after a prolonged operation of the bath (up to 1200 Ah) were studied with the aid of an electron microscope by Addison et al.[17] The high purity of the aluminium deposit obtained from an ethereal hydride electrolyte was confirmed spectroscopically and by X-ray diffraction in studies of Hayashi and Ishida[18,19], while Takahashi and Nomura improved the conditions for the attainment of optimal electrolysis conditions[20].

The need for the improvement of the operating conditions of ethereal hydride baths led to the creation of the so called modified ethereal hydride electrolytes for aluminium plating. McGraw[21] and subsequently Smith and McGraw[22] proposed an "involatile" hydride electrolyte with an ignition point increased to 85–90°C (the Lovet electrolyte). Compared with the ethereal hydride NBS electrolyte, the Lovet electrolyte contains only a very small proportion of diethyl ether in a free state. The presence of alane complexes in the Lovet concentrate requires very careful protection of the latter from atmospheric carbon dioxide. A disadvantage of the Lovet electrolyte is a somewhat reduced conductivity $(0.7–0.8) \times 10^{-3}\ \Omega^{-1}\text{cm}^{-1}$, so that an increased potential is needed. Subsequently special ionising additives were selected and synthesised. The most effective is 2-ethoxyethyltrimethylammonium chloride, the addition of which to the Lovet electrolyte increases its conductivity to $(0.1–0.2) \times 10^{-1}\ \Omega^{-1}\ \text{cm}^{-1}$. A variant of the modified Lovet hydride electrolyte (the Etmac electrolyte) with an enhanced conductivity was proposed by McGraw and improved by Beach and coworkers[23,24]. The aluminium deposit obtained in the Etmac electrolyte is less elastic and its microhardness is almost twice as high as the average microhardness of electrolytic aluminium.

A group of modified ethereal hydride electrolytes with a more complex composition was developed by Japanese investigators—Ishibashi, Hanamura, Yoshio, Kurata, and others[25–32]. The composition of the electrolytes was based on the optimum ratio of the volume fractions of the ether (tetrahydrofuran or its derivatives—2,3-dichlorotetrahydrofuran, 3-chloro-2-methyltetrahydrofuran, 3-bromotetrahydrofuran, 2-methyltetrahydrofuran, and 2,2-dimethyltetrahydrofuran) and the hydrocarbon (benzene, chlorobenzene, toluene, xylene, dichlorobenzene, and chlorotoluene). For example, in one of the variants the set of components of the modified electrolyte contained 58 vol.% of tetrahydrofuran, 42 vol.% of the hydrocarbon, 0.7–1.0 M aluminium chloride, and 0.2–0.7 M lithium tetrahydroaluminate. The cathodic current density was 0.01–0.05 A cm^{-2}, the experiments were performed at room temperature, the thickness of the coating was up to 0.1 mm, and the purity of the deposit was 99.999 wt.%. The role of the hydrocarbon additive consists in increasing the conductivity. Diethyl, dipropyl, diisopropyl, or dibutyl ethers can be used as other additives and poly(vinyl chloride) or 1,2-dichloroethane can be used as brightening agents. Bright coatings can be obtained in some cases by anodising in the same electrolyte.

The above studies dealt mainly with the solution of problems concerning the composition, preparation, stability, and efficiency of the ethereal electrolytes, the optimal conditions for electrolysis and the principles governing the formation of hermetic seals and adjustment of the baths were established, and the physicomechanical and morphological properties of the aluminium deposits were investigated. Systematic studies on the theory and kinetics of the electrode processes were not made, apart from several investigations on specific problems.

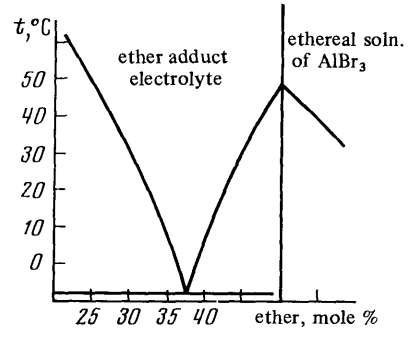

Figure 1. Phase diagram for the aluminium bromide–diethyl ether system.

Connor and Brenner[11] and Clay et al.[33] accumulated extensive factual data on the conductivities of ethereal aluminium halide solutions and an ethereal hydride electrolyte, established the component ratios corresponding to maximum conductivity in the total volume and in the catholyte or anolyte, and investigated the transport of the

hydride component. Using the component ratios thus determined (the ratios of lithium hydride and aluminium halide), the authors put forward suggestions concerning the type of ions promoting the electrocrystallisation of the aluminium deposit. On the basis of a similar correlation between conductivity and composition, Ishibashi and Yoshio[26] attempted to account for the nature of the ionisation of the electrolyte modified with tetrahydrofuran. As mentioned correctly at one time by Kessler et al.,[34] such determinations of the type of ionisation ($Li^+AlH_4^-$, $Li^+AlH_2Cl_2^-$, $Li^+AlHCl_3^-$, etc.) are made without due allowance for the properties of the alane complexes and the nature of the chemical composition and structure of the phases of the ethereal electrolytes.

Individual Tafel relations, obtained in narrow ranges of cathodic current densities, are quoted in reports by Hayashi and Ishida[18,19] and Takahashi and Nomura[20].

III. A NEW CLASSIFICATION OF ETHEREAL ELECTROLYTES

Systematic studies on ethereal electrolytes using a wide variety of electrochemical techniques are being made in our laboratory[35,36]. The objects of the studies are the principal groups of electrolytes: the NBS ethereal hydride electrolyte, the Lovet ethereal hydride electrolyte, ethereal amine electrolytes, and also the etherate, ethereal ammonia, and ethereal dative electrolytes which we proposed. The similarity of their chemical and electrochemical properties is due to the similar proportions of the ingredients in all the groups enumerated.

The etherate of an aluminium halide (chloride or bromide) solvated by the ether constitutes the structural and electrolytical basis of all the phases of the ethereal electrolytes. Diethyl ether is not the only one which can serve, in principle, as the main component of the molecular complex, but it is the most readily available ether, is most convenient to handle, and at the same time ensures the most satisfactory electroplating parameters.

The degrees of solvation of the etherate are various. With an increase in the ether content, a usually slight excess of the so called free ether, which exists in all ethereal electrolytes with the exception of the etherate electrolytes, arises relative to the ether involved in solvation[37].

The next ingredient important for the preparation of ethereal electrolytes (with the exception of those of the etherate type) is a substance (or a set of substances) binding vigorously protons, which are weakly solvated by the ether. This ingredient consists of (a) certain organic bases with high acid dissociation constants, which largely exhibit an n-donor (dative) activity—pyrrolidine, hexamethyleneimine, piperidine, ethylaminocyclohexane, morpholine, N-methylmorpholine, benzimidazole, and indole (ethereal dative electrolytes[38]) and n-butylamine, diethylamine, and triethylamine (ethereal amine electrolytes[39]), (b) ammonia (an ethereal ammonia electrolyte[40]), and (c) the hydride mixture (HM), i.e. the set of products of Wiberg–Schlesinger reaction (alane complexes)[41-48] obtained under the conditions of the preparation of ethereal hydride electrolytes (NBS, Lovet, and Etmac electrolytes[49-53]).

The combination of the above ingredients is important for the attainment of the optimal operating conditions in ethereal electrolytes.

IV. FUNDAMENTALS OF THE THEORY OF ELECTRODE PROCESSES IN AN ETHERATE MEDIUM

Aluminium halide-ether is a 1 : 1 molecular adduct of the highly acidic vacant-orbital acid AlX_3 and diethyl ether as the n-donor: $AlCl_3.(C_2H_5)_2O$.ether and $AlBr_3.(C_2H_5)_2O$. .ether ("ether" is the part of the ether involved in solvation). Compared with other bases, diethyl ether exhibits one of the most intense dative interactions in relation to AlX_3.

The thermochemical characteristics are as follows; the heats of formation of the molecular complexes (in the crystalline state) are ΔH_f(cryst.) = −18.6 ± 0.2 kcal mole^{-1} for $AlCl_3.(C_2H_5)_2O$ and ΔH_f(cryst.) = −23.2 ± 0.2 kcal mole^{-1} for $AlBr_3.(C_2H_5)_2O$; the heat of formation of $AlCl_3.(C_2H_5)_2O$ is ΔH_f = −247.91 ± 0.95 kcal mole^{-1} and the heat of formation of the $AlCl_3$ acceptor itself is ΔH_f = −170.77 ± 0.25 kcal mole^{-1}.[54-58]

The high stability of aluminium halide-ether has been confirmed by studies on the physicochemical phase diagrams for the binary[59] and ternary[60,61] systems and also spectroscopically[62]. Thus the characteristics of the electrode processes in ethereal electrolytes should be determined essentially by the electrolytic properties and the nature of the ionisation of the etherate, while the effect of the remaining ingredients is indirect. According to a thermochemical calculation and infrared spectrophotometric and Raman spectroscopic data for the crystalline state and infrared spectrophotometric and ^1H NMR data for the solutions[34,62-66], the type of ionisation of the etherate (and certain related molecular complexes) is determined by the thermodynamically favourable stable tetrahedral structure of AlX_4^- and the competitive interaction of the Al–O and Al–X bonds (dative bonds):

$$AlI_3 \cdot \text{ether} + AlI_4^- . \qquad (1)$$

Allowance for the dimerisation of aluminium halide in melts and solutions leads to a similar scheme:

$$Al_2I_6 \cdot \text{ether} + Al_2I_7^- . \qquad (2)$$

The etherate electrolytes (the region of melts to the left of the dystectic above the liquidus line on the phase diagram for the aluminium bromide-diethyl ether[67]) is the structurally simplest electrochemical system among ethereal electrolytes. The dystectic (Fig. 1) corresponds to the equimolar composition of the complex $AlBr_3.(C_2H_5)_2O$. The specificity of the composition of etherate electrolytes consists in a complete absence of n-donor additives and free ether; the molecules of the etherate are subject to the ionising action of homopolar aluminium bromide dimers[68,69]. It is noteworthy that the region to the right of the dystectic corresponds to the ethereal solution of aluminium bromide (the etherate in an excess of free ether)–the initial mixture for the preparation of all remaining ethereal electrolytes.

When ionisation of types (1) and (2) occurs in the etherate electrolyte, the stages involving the electrodeposition of aluminium in the presence of Al_2Br_6 as the active acceptor are as follows: reduction of the complex cation with liberation of the unstable Br^- ions and free ether molecules; addition of Br^- to Al_2Br_6 with formation of the particularly stable $AlBr_4^-$ structure; addition of ether to Al_2Br_6; transfer of $AlBr_4^-$ from the cathodic region; transfer of $AlBr_n.\text{ether}^{(2/n)+}$ ions (n = 1 or 2) to the cathode. This results in a redistribution of the substance in the electrolyte (in the presence of a membrane between the catholyte and anolyte)—ether is transferred by the solvated cations to the catholyte. The transfer of

ether decreases the density of the catholyte (the isothermal transition to the left of the dystectic implies an increase in the density of the melts—Fig. 1). The coefficients of the variation of the density of the working electrolyte with time are $\Delta\rho = -0.025$ g cm^{-3} per ampere-hour (catholyte) and $\Delta\rho = 0.021$ g cm^{-3} per ampere-hour (anolyte). The stages involving the addition of the decomposition products of the complex cation to Al_2Br_6, unhindered by steric effects, are more distinctive on increase of temperature and on increase of the content of the free acceptor. Such a change in the conditions governing the reduction of the cation reduces the aluminium overvoltage, which is clearly indicated by the constant-resistance polythermal cathodic polarisation plots (Fig. 2). The decrease in the content of the Al_2Br_6 acceptor should somewhat increase the contribution of the diffusion-dependent rate-limitation of the cathodic process, since the enrichment of the surface layer of the electrode in ether at the instant of the reduction of the cation becomes more distinct under these conditions. The effective activation energy for the cathodic process diminishes correspondingly (Table 1).

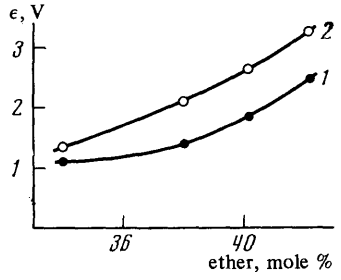

Figure 2. An example of constant-resistance polythermal cathodic polarisation plots for a liquid gallium electrode: 1) electrolyte specific conductance $\kappa = 2.0 \times 10^{-3}\ \Omega^{-1}\text{cm}^{-1}$; 2) electrolyte specific conductance $1.5 \times 10^{-3}\ \Omega^{-1}\text{cm}^{-1}$; $i_C = 0.02$ A cm^{-2}; temperature range 25–50°C.

Table 1. The effective activation energies for the cathodic process (kcal mole^{-1}).

ϵ, V	Ether, mol %				ϵ, V	Ether, mole %			
	41	38	36	32		41	38	36	32
2.00	5.6	7.1	7.8	8.0	2.95	4.8	5.7	6.2	6.9
2.48	5.5	5.8	6.4	7.1	3.43	4.5	5.1	5.3	6.4

The ether molecules arising at the cathode surface interact in a complex manner with the electrolyte. After the enrichment of the electrode surface in ether, the latter adds to Al_2Br_6 or to cations the inner sphere of which may contain several molecules of the base. The interaction with the cations begins to predominate when the concentration of the Al_2Br_6 acceptor in the electrolyte falls. The capture of ether molecules by the inner sphere of the cation increases structural strain. Consequently the reduction of such a cation is facilitated and the rate of the process increases at a constant potential. This conclusion has been confirmed experimentally (Fig.3): the hysteresis polarisation branch as a rule lies above the forward branch, since the cations acquire an additional activity in the region of the reversal of the potential scan. Fig. 3 illustrates the increase of the current by the section *ao* or *cd* ($\Delta i_C > 0$). Δi_C increases with temperature ($\Delta i_C/\Delta t = -0.00023$ A cm^{-2}) and with increase of the Al_2Br_6 concentration in the electrolyte (Table 2).

	ϵ = 3.25 V	ϵ = 3.50 V
40	0.54	0.47
36	0.47	0.40
31	0.33	0.22

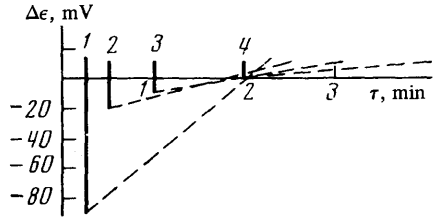

Figure 4. Variation of the probe cell potential after switching off the current pulse: 1) after the first (15 s) pulse; 2) after the second (30 s) pulse; 3) after the third (1 min) pulse; 4) after the fourth (2 min) pulse; continuous lines—variation of Δϵ at the instant of switching off the current pulse; dashed lines—return to the initial potential; copper cathode; $i_C = 0.02$ A cm^{-2}; electrolyte—38 mole % of ether; $t = 20$°C.

The inner sphere of the cation contains together with ether up to two electron-donating Br^- ions, which, having been liberated in the overall electrode reaction and having reacted with the acceptor molecule, stimulate the anodic flux of $AlBr_4^-$ (or $Al_2Br_7^-$) ions. At the instant when the

cathodic current pulse is switched off the increase of the surface $AlBr_4^-$ concentration is manifested by a negative shift of the potential of the platinum probe. In view of the occurrence of the slow reaction between the added free Br_2 and Al_2Br_6, the effect is weaker in subsequent current pulses (Fig. 4).[70,71]

The weak supporting electrolyte in ethereal electrolytes limits the anodic polarisation curve to a single horizontal section located directly beyond the Flade potential (Fig. 5). A passivating film, which is at the same time soluble in the electrolyte is formed along section *bcd*. When this film is observed visually, the anolyte is at the same time seen to be coloured brown. The changes in the electron surface can be compared with the following mechanism for the oxidation of the $AlBr_4^-$ (or $Al_2Br_7^-$) anion:

$$AlBr_4^- - e = AlBr_{3(film)} + \frac{1}{2}Br_2. \qquad (3)$$

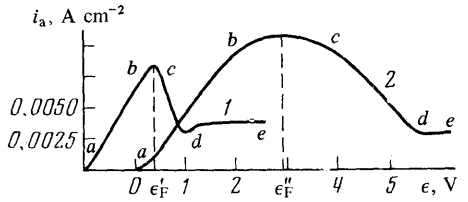

Figure 5. Anodic polarisation curves for aluminium (curve *1*) and platinum (curve *2*) electrodes in an etherate electrolyte.

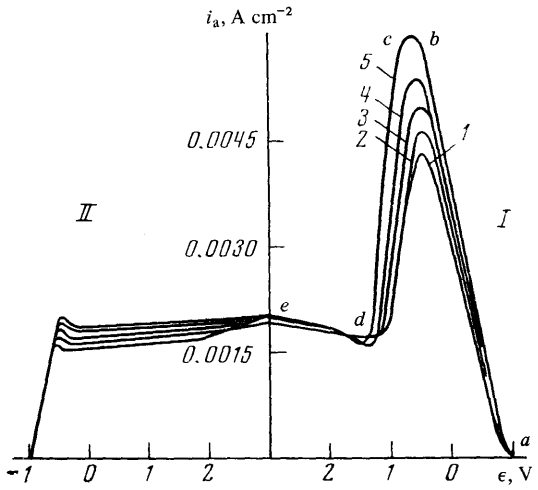

Figure 6. Anodic polarisation curves for an aluminium electrode; electrolyte—31 mole % of ether; scan—2.0 V min^{-1}; t = 25°C: I) forward branch; II) hysteresis branch; rate of rotation of disc electrode (rev. min^{-1}): 1) 400; 2) 800; 3) 1200; 4) 1600; 5) 2000.

Since Br_2 interacts vigorously with aluminium, the colour of the anolyte at the aluminium anode is weaker than at the platinum anode. Owing to the additional Br–Al bonds, the film on the surface of the soluble electrode is more stable, [the passivation maximum is sharper, there are no maxima on the hysteresis branches, and the shape of the polarisation curves changes only slightly when the rate of stirring is altered (Fig. 6)].

Mechanism (3) has been confirmed by studies on the physicochemical properties of the passivating film and on the colour of the surface layer at the anode.

Together with the characteristic absorption wavelength of the Al–O bond (460 nm), the absorption spectrum of the electrolyte (Fig. 7, curve *1*) usually shows a band corresponding to the Br_2–Al_2Br_6 bond (560 nm). The absorption intensity at 560 nm clearly increases following the addition of bromine to the anolyte. A similar increase of the intensity of the absorption band at 560 nm is observed also under the conditions when the electrolyte becomes brown on passivation of the anode (Fig. 7, curve *4*).

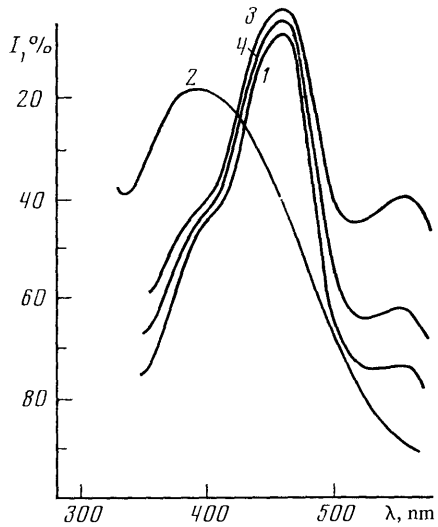

Figure 7. The spectrum of an etherate electrolyte (anolyte): 1) spectrum of electrolyte; 2) spectrum of bromine; 3) spectrum of electrolyte with added bromine; 4) spectrum under the conditions of the brown colour of the electrolyte during the passivation of the anode.

The solubility of the film in ethereal electrolytes of different compositions varies in the same way as the solubility of pure aluminium bromide (Fig. 8). The film dissolves faster in media with a reduced concentration of the free acceptor (Fig. 9). The *bcde* section of the anodic polarisation curve (Figs. 5 and 6) shifts similarly on increase of temperature (0.001–0.004 A cm^{-2} for Δt = 10 degC) or of the rate of stirring. The dissolution of the passivating film in the anolyte (30–32 mole % of ether; volume 30–40 ml) increases its crystallisation temperature on average by 4–5 degC, corresponding to a quantity of electricity of 0.30–0.35 Ah, i.e. displaces the phase equilibrium in the anolyte to the left along the liquidus line (Fig. 1); the same is observed when aluminium bromide is added.

Mechanism (3) for a soluble anode in etherate electrolytes must be supplemented by the indirect dissolution stage

$$\frac{3}{2}Br_2 + Al_{(anode)} = AlBr_{3(film)}. \quad (4)$$

The occurrence of indirect dissolution, which is in general characteristic of the oxidation of anions of the $AlBr_4^-$ type, rules out conditions for the occurrence of disproportionation reactions. At potentials more negative than ϵ_F (Fig. 9) the current yield of the metal in the region of the active electrode surface is almost independent of the rate of stirring (Table 3)[72-74].

rev min^{-1}	η_a, %	rev min^{-1}	η_a, %
—	93.5	1000	101.3
600	98.1	1500	106.8

The NBS ethereal hydride electrolyte is structurally most complex among other ethereal electrolytes, since in this case the aluminium halide-ether medium contains the components of the hydride mixture (HM). The composition of the hydride mixture in the range of the initial molar component ratios usually adopted for the electrolyte, $A = LiH : AlCl_3 = 1.40 : 0.25$, varies within fairly narrow limits. If the set of alane complexes is expressed by the molar ratios of the initial monomers $AlHCl_2$, AlH_2Cl, and $LiAlCl_4$ and account is taken of their interaction with the etherate (the mole of the etherate refers by convention to one mole of the monomer), then the typical proportions of the components of the hydride mixture in the etherate medium are readily obtained on the basis of the results of elemental chemical analysis (Fig. 10). The wavenumbers of the absorption bands in the spectra of the electrolyte (534, 492, and 1900 cm^{-1}) correspond to the vibrations of the Al–O, Al–Cl (in $AlCl_2^-$), and Al–H bonds.

The volume of free ether and the ether involved in solvation in the electrolyte is always limited by the total solvating capacity of the etherate medium. For $A > 1.4$ or on direct decrease of the concentration of the etherate (to less than 1 M in terms of anhydrous aluminium chloride) over the ethereal hydride phase, it is possible for an ethereal layer to appear. The separation into layers occurs also following direct dilution of the electrolyte with the ether. The ethereal layer disappears under the influence of the addition of an ethereal solution of aluminium chloride or under the conditions where $A < 1.4$.

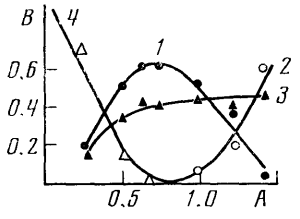

Figure 10. Relative amounts of the components of the hydride mixture in aluminium chloride-ether; A—molar component ratio $LiH : AlCl_3$; mole fraction B (not including the ether): 1) of $AlHCl_2.AlCl_3.(C_2H_5)_2O$.ether; 2) $AlH_2Cl.AlCl_3.(C_2H_5)_2O$.ether; 3) $LiAlCl_4$; 4) $AlCl_3.(C_2H_5)_2O$.ether.

According to the studies of Arkhipov and Mikheeva[47] and Kohler[75], the following mechanism of the ionisation of the hydride mixture is most likely:

$$\begin{aligned} 2AlHCl_2 \cdot AlH_2Cl \cdot ether &\rightarrow Al_2Cl_5 \cdot ether^+ + AlH_4^- \\ Al_2Cl_5 \cdot ether^+ &\rightarrow AlCl_2 \cdot ether^+ + AlCl_3 \cdot ether \\ &\quad \downarrow +AlCl_3 \cdot ether \\ &\quad AlCl_2^+ \cdot ether + AlCl_4^-. \end{aligned} \quad (5)$$

Anions of the AlH_4^- type are oxidised at insoluble anodes[76] and there is no direct involvement of the hydride mixture in the cathodic process. The potentials corresponding to the deposition of aluminium in ethereal hydride electrolytes and in an ethereal solution of aluminium chloride differ on average by 1–1.5 V, but, on smooth increase (decrease) of the hydride mixture concentration, the limiting current densities with respect to hydride ions are not observed at all (Fig. 11), regardless of the nature of the cathode. The electrodeposition is accompanied by the simultaneous liberation of hydrogen, which has no direct bearing on the current yield of aluminium, the latter being always 100%. This side effect can be accounted for by the

spontaneous decomposition (which is in general slight) of the alane complexes arising under the catalytic influence of the freshly formed surface of the aluminium deposit [78-80].

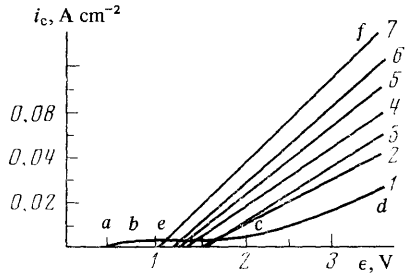

Figure 11. Variation of the cathodic polarisation of an aluminium electrode with increasing content of the hydride mixture in an etherate medium (2 M aluminium chloride, initial volume of electrolyte 30 ml); volume of added hydride mixture (ml): 1) 0; 2) 1; 3) 3; 4) 6; 5) 9; 6) 12; 7) 15; scan—0.8 V min^{-1}; reference electrode—Al(Ag). [77]

The nature of the complex cations of the etherate responsible for the electrodeposition of aluminium and ionisation mechanisms of types (1) and (2) for ethereal hydride electrolytes are to some extent confirmed also by the characteristics of the transport process (electrolyser with a glass membrane, aluminium anode).

Table 4. The transport of ether in the Lovet ethereal hydride electrolyte (i_c = 0.02 A cm^{-2}; volume of electrolyte 50 ml).

t, °C	V_{free}, ml*		V_{int}		Al deposit on cathode		N
	cathode (Cu)	anode (Al)	ml	mole	g	g-atom	
70	3.8	2.2	1.6	0.01533	0.1788	0.00666	2.3
80	3.7	2.7	1.0	0.00958	0.1126	0.00417	2.3
80	4.2	3.0	1.2	0.01150	0.1350	0.00500	2.3

* V_{free} is the volume of free ether collected from the electrode surface and V_{int} is the volume from the inner sphere of the cations.

When an anolyte with labelled chlorine ($H^{36}Cl$) and a non-radioactive catholyte are used at the beginning of electrolysis, the subsequent distribution of radioactivity in the working ethereal hydride bath makes it possible to establish the relation between the diffusion and migration of ions. The migration of $AlCl_4^{*-}$ to the anolyte under the influence of the current in the absence of the Cl^- ligand in the complex cation [81] should in all cases inhibit the diffusional equalisation of the radioactivities of the catholyte and anolyte over a period of time. On the other hand, in the presence of the Cl^- ligand, the effect of the current is varied. According to the Hittorf calculation, in a medium with an equal or greater mobility of $AlCl_4^-$ relative to that of the cation the transport of Cl^{*-} anions to the catholyte is inhibited by migration and for a higher mobility of $AlCl_2.ether^+$ the transport of Cl^{*-} (and hence the equalisation of the radioactivities in the course of time) is accelerated. The acceleration of the equalisation of radioactivities by current in the NBS ethereal hydride electrolyte is observed when the molar ratio A is reduced to values of the order of 0.1–0.2 (Fig. 12). There is apparently an appreciable simultaneous increase in the mobility of the $Al_2.ether^+$ cation.

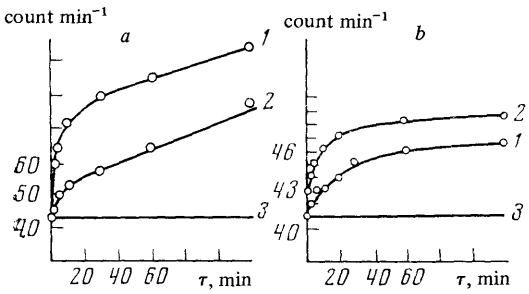

Figure 12. Increase of the radioactivity of the catholyte: *a*) A = LiH : $AlCl_3$ = 0.8; *b*) A = 0.2; 1) diffusion through a membrane (in the absence of a current); 2) superposition of migration (electrolysis); 3) supporting electrolyte; I = 40 mA; electrolyte volume 50 ml.

It follows from mechanisms (1) and (2) that the cation of the etherate is more solvated than the anion with a blocked aluminium atom. Furthermore, at the instant of the reduction of the cation the ether passes from the inner sphere to the free state. The distillation and trapping (by liquid nitrogen traps) of the ether at the instant of the reduction of the cations and the oxidation of the anions of the etherate on the electrode surface are most effective in the Lovet ethereal hydride electrolyte.

The absence of free ether in the Lovet electrolyte makes it possible to determine clearly the difference between the volumes of the ether trapped from the cathode and anode (Table 4). Since the current yield of aluminium at the cathode is 100% regardless of i_c, the ratio of this difference (in moles) to the number of gram-atoms of the aluminium deposit N expresses the number of ether molecules entering into the inner sphere of the cation as the second ligand. The value obtained N = 2.3 is somewhat too high owing to the impossibility of allowing exactly and separately for the total number of ether molecules constituting the solvation shells of the cation and anion, but, according to the results of a study of the transport process, the most probable composition of the cation is undoubtedly $AlCl_2.2(C_2H_5)_2O^+$. The result of the calculation agrees fully with the thermochemical and structural characteristics of aluminium chloride-ether.

In the remaining ethereal electrolytes (ethereal amine [39], ethereal ammonia [40], and ethereal dative [38] electrolytes) the ingredient which binds the solvated protons exhibits a marked chemical individuality. Such ingredients are either organic bases (in ethereal amine and ethereal dative electrolytes; their approximate composition is 1–3 M aluminium chloride or bromide, 5–20 mole% of the base relative to the etherate, and diethyl ether) or ammonia (in the ethereal ammonia electrolyte with the

composition 1–4 M aluminium chloride, 17–30 mole % of ammonia, and diethyl ether) which vigorously bind the protons of the ionised Wiberg-Brown complex[82-84] H. .ether$^+$.AlX_4^-—the product of the interaction of hydrogen halide with the complex cation of aluminium halide–ether. The reaction reduces to the formation of the stable AlX_4^- structure and protons weakly solvated by ether. Therefore the Wiberg-Brown complex is always present in preparations of an ethereal solution of aluminium chloride or bromide.

The distribution of the organic base (and ammonia) in the ethereal electrolyte as a whole is regulated by the equilibria

$$H.ether^+ + base = H.base^+ + ether, \quad (6)$$

$$AlX_3.ether + base = AlX_3.base + ether. \quad (7)$$

In view of the considerable excess of free ether, the low solubility of the type AlX_3.base complexes in the ethereal medium (according to analytical and spectrophotometric data and the results of studies of the electrolytic properties of the systems under consideration), equilibrium (7) is to a large extent displaced to the left[85-88]. Consequently the base is bound by the ethereal aluminium halide solution mainly as a result of the rightward shift of equilibrium (6). This is indicated by the distinct decrease of i_{lim} for the H.ether$^+$ ions (Fig. 13) following the addition of the base. The converging series of values of i_{lim} reflects the existence of equilibrium (6) and its rightward shift.

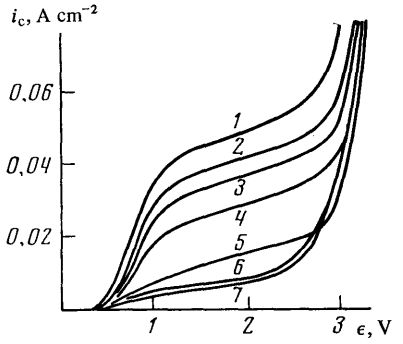

Figure 13. Effect of added base in an ethereal solution of aluminium chloride on i_{lim} for the solvated protons H.ether$^+$; amount of base (hexamethyleneimine, mole %): 1) 0.00; 2) 0.25; 3) 1.00; 4) 1.60; 5) 2.40; 6) 4.00; 7) 6.10.

The Lewis acidity in relation to protons in the bulk of the ethereal electrolyte and in the diffusion layer of the cathode under the conditions of a current can be expressed by the residual concentration of the free H.ether$^+$ ions. The optimum conditions for the electrocrystallisation of aluminium arise only in the absence or at a vanishingly low concentration of the H.ether$^+$ ions, i.e. for a high Lewis basicity of the medium. Otherwise the process is complicated by the presence of the electroorganic component, catalysed by the solvated H.ether$^+$ protons in the presence of free ether molecules (a dark dispersed powder is deposited on the cathode). Etherate electrolytes in which there is no free ether at all constitute an exception. Therefore in etherate electrolytes H.ether$^+$ ions do not exhibit a catalytic activity and a high quality crystalline aluminium deposit is obtained in the presence of even large concentrations of the Wiberg–Brown complexes[89]. A high basicity is always readily generated in ethereal hydride electrolytes owing to the decomposition of the Wiberg–Brown complex by the compounds constituting the hydride mixture [a complete rightward shift of equilibrium (6)][51,79].

The remaining electrolytes [with an incomplete rightward shift of equilibrium (6)] are distinguished by a more complex mechanism for the attainment of a high Lewis basicity. A high quality deposit arises on the cathode only after a preliminary passage of a current (4.0–4.8 Ah per litre of solution), i.e. after an additional decrease of the residual concentration of the H.ether$^+$ ions owing to the electrolytic liberation of hydrogen. In consequence of the low rate of interaction of the complex H.base$^+$ and ether, a steady-state distribution of the components of equilibrium (6), close to the distribution which obtains when the equilibrium is completely displaced to the right, arises under the influence of the current.

When a current is passed through ethereal electrolytes, there are a number of features which reflect directly the changes in electrocrystallisation conditions. The values of i_{lim} for H.ether$^+$ ions on the cathodic polarisation curves fall to zero only as a result of the current (Fig. 14); curve 4 in the same Figure reflects the variation of i with ϵ under the optimal electrodeposition conditions.

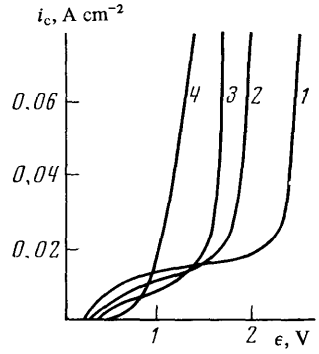

Figure 14. Variation of cathodic polarisation during the passage of a current through the ethereal electrolyte (base—hexamethyleneimine): 1)–3) decrease of the residual concentration of H.ether$^+$ ions (dispersed deposit); 4) electrodeposition under the conditions of high basicity (dense crystalline deposit); galvanostatic conditions; reference electrode—Al(Ag).

The increase of basicity on passage of a current can be expressed quantitatively as an increase of conductivity (Fig. 15) or as a negative shift of the platinum probe potential reversible with respect to H.ether$^+$. The considerable decrease in conductivity can be explained by the weakness of the H$^+$–ether bond ($pK_a = -3.59$) relative to the H$^+$–base bond ($pK_a = 7.3–12.3$)[38]. The reversibility of the probe electrode potential relative to H.ether$^+$ is a result of the saturation of the electrolyte by cathodic hydrogen.

In the presence of Lewis bases and ammonia, potentials of the probe cell in the range between −0.3 and −0.6 V (the probe potential is negative) correspond to optimal electrocrystallisation (a dense crystalline deposit). In the absence of bases (a dispersed deposit is formed regardless of the amount of electricity passed through the system) the potential is limited to 0.0–0.2 V (the probe potential is positive). In ethereal hydride electrolytes the very presence of the hydride mixture alters the cell potential to between −0.9 and −1.1 V, as a result of which the necessity for exposure to a current is eliminated.

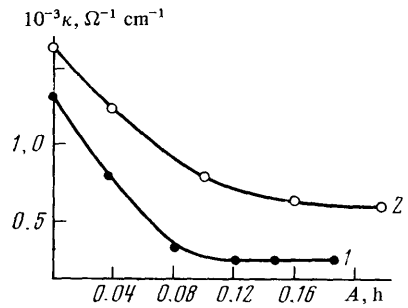

Figure 15. Variation of the conductivity of the ethereal electrolyte during the passage of a current: 1) base—piperidine; 2) base—hexamethyleneimine.

The elimination of the electroorganic component of the electrodeposition process (transition from a dispersed deposit to a dense crystalline deposit) in general increases the purity of the coating. However, under optimal electrocrystallisation conditions in ethereal ammonia and ethereal dative electrolytes, side processes persist at elevated current densities ($i_C > 0.005$–0.010 A cm^{-2}): there is a weak evolution of hydrogen owing to equilibrium (6) and possibly an additional electroorganic reaction. For this reason, in the given group of electrolytes the current yield of aluminium in certain cases does not exceed 75–80% following an increase of i_C and the morphology of the deposit may be complicated by local spheroidal formations[90–92].

The significant characteristics of electrode polarisation in ethereal electrolytes are high exchange current densities [$(2.0–5.0) \times 10^{-4}$ A cm^{-2} in etherate electrolytes and 1.6×10^{-3}–4.3×10^{-4} A cm^{-2} in ethereal hydride electrolytes] and high temperature coefficients of the overvoltage (which usually exceed by an order of magnitude the analogous values in an aqueous medium) 0.01–0.03 V deg^{-1}, as a result of which the kinetics of the reduction of the etherate cations when $i_C < 0.01$ A cm^{-2} depend on the superposition of limitations due to the reaction (in etherate electrolytes), crystallisation, and diffusion (in the NBS ethereal hydride electrolyte; in this case the Faraday impedance can be represented by the equivalent circuits for the transition, diffusion, and crystallisation–see Fig. 16). In the range $i_C = 0.10$–0.40 A cm^{-2} diffusion-dependent limitations fully predominate (ethereal hydride and ethereal ammonia electrolytes). Since free dilution of the etherate phase by ether is ruled out, the properties of the limiting current density of the diffusion overvoltage (the dependence of i_{lim} on the molarity of the etherate, the content of the hydride mixture and organic bases, temperature, rate of stirring, etc.) can be investigated exclusively by a pulse technique. The transition time for strong current pulses can be determined only when a rigorous correspondence between the true and induced currents i_C is maintained (< 0.40 A cm^{-2}). For this purpose, the treatment of the test electrode must ensure the homogeneity of the surface and inhibition of the growth of crystal nuclei during the pulse (galvanostatic switching on)[51,71,80,90,93].

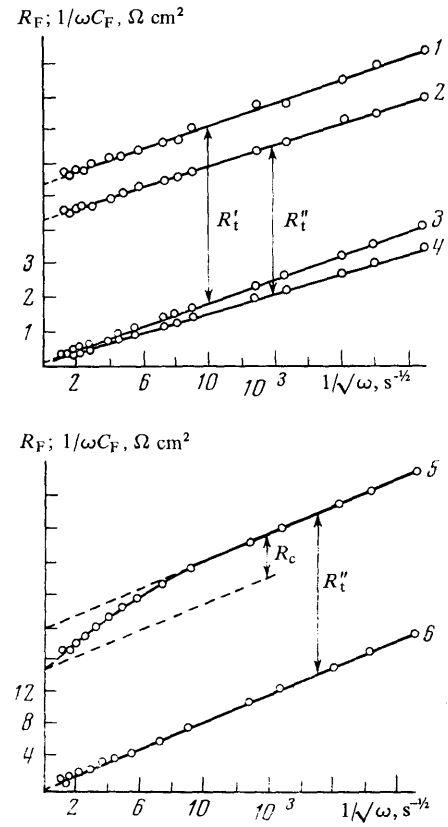

Figure 16. Components of the Faraday impedance; aluminium electrode: 1) R_F; 3) $1/\omega C_F$; Al(Hg) electrode: 2) R_F; 4) $1/\omega C_F$; Al(Hg) electrode: 5) R_F; 6) $1/\omega C_F$; measurements in aluminium bromide–ether.

V. THE OVERVOLTAGE OF HYDRIDE HYDROGEN

The behaviour of soluble and insoluble anodes in all ethereal electrolytes is determined by the oxidation of the AlX_4^- anions from the etherate with the exception of hydride media where the anodic process is complicated by the involvement of the AlH_4^- ($Al_2H_7^-$) ions[75,76,80,81]. In the case of an insoluble electrode AlH_4^- ions are oxidised under conditions corresponding to the first section of the anodic polarisation curve ($i_C \leq 0.01$ A cm^{-2}, $\epsilon \leq 1.5$ V). Consequently the above ranges of the i_C and ϵ values are convenient for the measurement of the overvoltage of hydride hydrogen.

The concept of electrolytic desorption proposed by Heyrovsky is justified by the nature of the protons $H.aq^+$ solvated by water. Hence the hypothesis that the potentials of the spent and anodically polarised electrode in the ethereal hydride electrolyte depend on the Volmer–Tafel mechanism is quite natural. After replacing $H.aq^+$ by $H.hydr.^-$, the mechanism becomes

$$\begin{aligned} H^- &\rightleftharpoons H + e, \\ H + H &= H_2. \end{aligned} \qquad (8)$$

Thus examination of the hydride hydrogen overvoltage could also permit the solution of the problem of the relation between the successive discharge and recombination stages. Calculation of the overvoltage from the Tafel relations or the equations of the Kheifets pulse technique leads to large numerical values of the exchange current density (Table 5) and the coefficient b and to extremely small transition coefficients α (Table 6).

Table 5. The exchange current densities at the hydride hydrogen overvoltage ($-\lg i_0^*$).

Electrode	Temperature, °C				Electrode	Temperature, °C			
	10–12	15–18	24–25	30		10–12	15–18	24–25	30
Ag	3.4	3.2	2.9	2.8	Sn	—	3.6	2.8	2.5
Ni	—	6.0	5.8	5.7	Pb	5.0	4.5	—	3.2
Zn	—	4.5	3.5	3.2	Pt	5.5	5.3	5.0	4.7

Table 6. The coefficients b and α for hydride hydrogen (t = 20°C).

Electrode	b, V	α	Electrode	b, V	α	Electrode	b, V	α
Ag	0.56	0.105	Zn	0.28	0.210	Pb	0.22	0.267
Ni	0.55	0.107	Sn	0.39	0.150	Pt	0.38	0.155

Table 7. A series of Tafel coefficients a at the hydride hydrogen overvoltage.

Electrode	a, V	Electrode	a, V	Electrode	a, V
Pb	0.9	Sn	1.3	Pt	2.0
Zn	1.1	Ag	1.7	Ni	3.4

In terms of the values of b, the Tafel relations for hydride hydrogen express the overvoltage of the transition, i.e. the kinetics of the oxidation of the AlH_4^- ($Al_2H_7^-$) ions are determined by the discharge reaction and not the recombination reaction. Furthermore, the possible influence of the spontaneous decomposition reactions of the hydride mixture on the oxidation of hydride hydrogen reduces the probability of a mixed mechanism for overvoltage of the type under consideration.

The low values of the coefficient α indicate a high activation energy for the reverse Volmer reaction [Eqn. (8)], which is equivalent to hindrance characteristic of the formation of structures deformed by hydride hydrogen. For the hydride hydrogen overvoltage, the sequence of the activation energies for the forward Volmer reaction differs appreciably from the classical sequence, usually represented by a series of increasing Tafel coefficients a (Table 7)[94,95].

VI. INDUSTRIAL APPLICATIONS OF ETHEREAL ELECTROLYTES

The aluminium deposits coating the surfaces of various metals at room temperature in ethereal electrolytes are obtained in the form of dense, homogeneous plate of high purity[8,11,16,18,26,50]. The usual technical procedures (stirring, adjustment of the position of the rods, regulation of the electrolyte stream, periodic filtration, employment of certain additives) make it possible to vary the thickness of such coatings from several micrometers to 2–3 mm, while ensuring at the same time the necessary uniformity. The advantages of electrolytic aluminium (small weight, high thermal conductivity, electrical conductivity, and reflectivity, effective anticorrosion properties, low melting point, only slight deterioration in the properties of the coated metal under the conditions of heat treatment, and low cost) compared with zinc, tin, cadmium, gold, and titanium–silver coatings have greatly increased interest in the aluminium-plating process in ethereal electrolytes in the field of both modern electroplating technique and in galvanoplastics. Mainly ethereal hydrides (NBS, Lovet, and Etmac) electrolytes have been recommended for electroplating baths in technological and industrial-technological processes.

The most important stages in electroplating processes are the choice of the surface to be coated (usually steel, copper, nickel, Kovar, titanium, and silicon), the search for a technique to be used in the preparation of the surface for aluminium plating giving a reliable adhesion of the coating, and the design of a hermetically sealed bath and electrode rods (in an atmosphere of dry nitrogen or argon). Various workers have often used the so called aliphatic acid treatment of the surface, originally proposed by Schickner[96,97]. Before being immersed in the ethereal hydride bath, the metal surface is uniformly coated by a crystalline layer of aliphatic acid (oleic, linolenic, etc.) or by a layer of salicylic, benzoic, pyrogallic, phenylacetic, or heptafluorobutyric acid[11]. The onset of the aluminium electrodeposition process (the switching on of the working current) is synchronised with the dissolution of the layer of acid in the electrolyte. The aliphatic acid treatment requires expensive reagents and must be performed with exceptional precision. The maximum adhesion of the coatings is achieved by selecting the appropriate acid and the appropriate duration of the individual operations in the treatment in relation to various aluminium-plated metals. An easier and universal method of preparing the surface for aluminium plating involves chemical or anodic etching of iron, steel, Kovar, nickel, and copper in hydrochloric acid[53,75], phosphate, nitric acid, and hydrogen peroxide[98–100] solutions, which prevent saturation with hydrogen.

Industrial-technological aluminium plating of constructional titanium rods (NBS ethereal hydride electrolytes) was achieved by Hess and Betz[101]. Aluminium plating at room temperature is hardly reflected in the mechanical properties of the rods. An appreciable corrosion resistance of the components was achieved. The authors note that different variants of their technology

can be used for the aluminium plating of titanium components of more complex shape, certain parts of laboratory and workshop furniture, and also individual units in microelectronics (including, for example, the local aluminium plating of locating frames).

Electroforming techniques for aluminium have found extensive applications (NBS, Lovet, and Etmac ethereal hydride electrolytes). Buschow and Esola[102] and Schmidt and Hess[103] developed a process and designed a manufacturing set up for the construction of high-quality light aluminium reflectors for the concentration of solar energy (18 and 76 cm in diameter). Aluminium layers are grown at room temperature on nickel and silver templets with mirror-bright surfaces. The improvement in the design of the ethereal hydride bath hermetically sealed under argon and nitrogen is noteworthy; the authors increased the volume of the bath to 700–800 litres. The construction of aluminium reflectors was developed in processes used in the manufacture of telescopic reflectors, non-magnetic optical systems, light and precision mirrors, and optical systems for cosmic space apparatus.

Another trend in the development of techniques for electrolytic aluminium plating using ethereal electrolytes involves the electroforming of layers with fillers. The technique of the preparation of matrix composites (with boron rods, silicon carbide, beryllium, steel, and graphite fibres as fillers), which are light, very hard, and at the same time elastic, to be used in the construction of components of cosmic space apparatus, has been proposed and successfully introduced by Hanson et al.[104] and Withers and Abrams[105]. Electroforming techniques for aluminium have considerable advantages over other methods for the preparation of matrix composites, since electrodeposition in the range of room temperatures hardly influences the properties of the fillers themselves, which makes it possible to increase sharply the set of physicomechanical properties of the composites themselves and at the same time achieve an exceptionally high strength to weight ratio for such composites.

A new stimulus to further improvement of the manufacture of solar batteries arose from the technology of the deposition of aluminium layers (NBS ethereal hydride electrolyte) on the surface of silicon sections proposed by Lui and Yasui[106]. Aluminium terminals simplify the construction and parallel connection of aluminium sections compared with the earlier technology in which a titanium–silver alloy was used.

Manufacturing–technological processes involving the electrodeposition of aluminium from ethereal electrolytes at room temperature have greatly increased practical and theoretical interest in this field of electrochemistry.

Reactions of Oxo-derivatives of Furan with Hydrogen Peroxide and Peroxy-acids

V.G.Kul'nevich and L.A.Badovskaya

The reactions of furan oxo-compounds with hydrogen peroxide and with peroxy-acids are surveyed, different views on the reaction mechanism are discussed, and modern concepts are explained. Possible practical applications of the process are shown. Comparison with the oxidation of aromatic compounds under similar conditions indicates several specific features of the process in the furan series. The bibliography contains 160 items.

I. INTRODUCTION

The oxidation of oxo-derivatives of furan by hydrogen peroxide and peroxy-acids yields such valuable products as furancarboxylic, oxo, and dibasic acids, lactones [1-14], peroxides of carbonyl compounds of the furan series, furyl formate, its homologues, and derivatives, and also unsaturated lactones [6,8,15-18]. However, by no means all potentialities of this process have been realised. The reaction is extremely sensitive to the nature of the solvent used, the temperature, and the proportions, concentration, and structure of the reactants. This enables its direction to be controlled, and provides ready methods for obtaining new compounds [8,17,18].

II. DEVELOPMENT OF IDEAS ON THE REACTION OF FURAN OXO-COMPOUNDS WITH HYDROGEN PEROXIDE AND PEROXY-ACIDS

The prospect of utilising the reactions of furan oxo-compounds with hydrogen peroxide has been established only during recent decades. For a long time investigators were unable to isolate any products other than maleic and succinic acids [3,7,9,19-23] because of the absence of systematic work, although these acids are formed as a result of fundamental changes in more valuable oxo-acids and lactones [4,5].

The reaction of 2-furaldehyde with 3% hydrogen peroxide in the presence of iron(II) sulphate was first accomplished in 1899 by Cross et al. [19], who postulated the formation of hydroxo-2-furaldehyde and hydroxyfuran-2-carboxylic acid. Neither they nor subsequent investigators were able to isolate these products, and later an error in identifying the latter was demonstrated. The mechanism of the reaction was not considered. Succinic, maleic, and fumaric acids have since been isolated (in 20-50%, 10-40%, and 2-25% yields respectively) from the oxidation of 2-furaldehyde by hydrogen peroxide in water [1,3,9,20-23]. Several workers have reported the formation of formylacrylic acid, either detected qualitatively or isolated as the unpurified product in yields up to 25%. [1,23] Formic acid was formed in all cases. Pyromucic acid could be obtained only when furaldehyde was oxidised with hydrogen peroxide in pyridine [2,24].

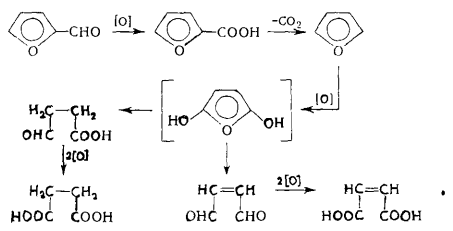
Very little information is available on the oxidation of furan oxo-compounds by peroxy-acids. The action of Caro's acid on 2-furaldehyde yields succinic and formic acids [25]. Oxidation by aliphatic and aromatic peroxy-acids gives a mixture of maleic, formic, formylacrylic, and succinic acids in proportions varying with the conditions [7,26,27]. Hydroxy-lactones may also be formed [26]. Marked resinification accompanies oxidation by peroxy-acids. In isolated cases succinic acid is not detected when 2-furaldehyde is oxidised by peracetic acid, but only formylacrylic, maleic, and fumaric acids [28]. A similar result has been obtained in the oxidation of 2-acetylfuran. A mixture of γ-oxovaleric and 4-oxopent-2-enoic acids is formed by the oxidation of 5-methylfuran-2-al by peracetic acid [28]. Furancarboxylic acids were not found among the oxidation products from carbonyl derivatives with peroxy-acids, but aldehydes gave the theoretical yield of formic acid, and ketones similarly formed acetic acid.

Some authors consider that the initial attack by hydrogen peroxide on 2-furaldehyde takes place at the furan ring [1,19,29], and others at the aldehyde group [22,23]. Salchinkin [22] supposes that the oxidant is active oxygen formed from hydrogen peroxide, which oxidises the furaldehyde at the carbonyl group to pyromucic acid, and the latter then undergoes decarboxylation to furan. Conversion of this product into the hypothetical furandiol is followed by the formation of malealdehyde and succinaldehyde, and finally maleic and succinic acids (Scheme 1). Only these acids were isolated among the products included in Scheme 1. No other evidence was given.

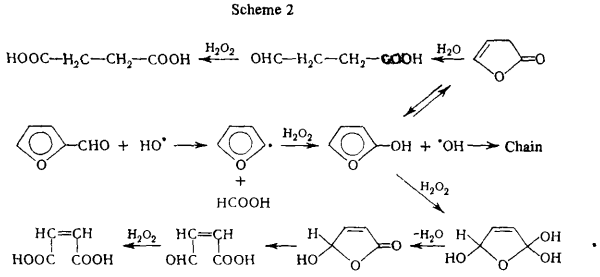
An alternative mechanism also involving the carbonyl group as the reactive centre entails oxidation by the hydroxyl radical (Scheme 2) [23]. Pyatnitskii and Lapkova suppose [23] that the reaction passes by a homolytic chain

mechanism through furanol and its tautomeric form (crotonolactone), which are converted into the β-formyl acids and then oxidised to maleic and succinic acids. The only evidence given in support of this scheme comprises isolation of the dibasic acids and the qualitative detection of 4-oxobut-2-enoic acid.

Scheme 1

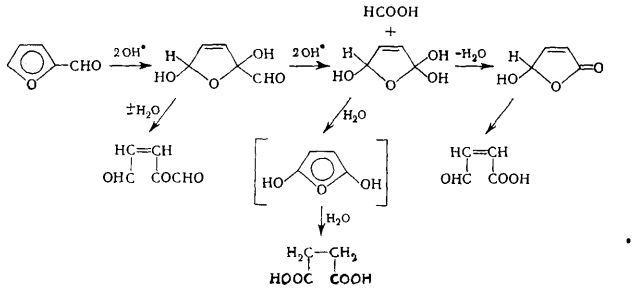


Scheme 2



Clauson-Kaas and Fakstorp[29] regard the interaction of 2-furaldehyde with hydrogen peroxide in alcoholic solution containing added osmium tetroxide as starting at the diene system of the furan ring, without indicating whether the mechanism is homolytic or heterolytic (Scheme 3). The mechanism suggested by Kallay[1] differs only in preliminary protonation of the heterocycle at the oxygen atom followed by ring opening and subsequent cyclisation. This assumes that the radical reactions of hydroxylation of the ring are coupled with the ionic reactions of its opening.

Scheme 3



No detailed consideration has been given to the mechanism of the oxidation of furaldehyde by peroxy-acids. It was suggested[26] that opening of the furan ring begins with formation of an unstable oxide involving one of the double bonds, while formic acid is obtained as a result of detachment of the aldehyde group; no information was given on the structure of the oxide or the mechanism of the process.

No proofs were given of the reliability of the mechanisms suggested for the oxidation of furaldehyde by hydrogen peroxide and peroxy-acids. They are inconsistent with modern views on the reactions of carbonyl compounds with these reagents, and do not take into account the formation and transformation of organic peroxy-compounds[30-32]. Nor are the schemes consistent with available information on the structure and reactivity of furan oxo-compounds and hydrogen peroxide; the mechanism is not related to the structural features of the reactants or the reaction conditions.

Discussion of the mechanism of the reactions between furan oxo-compounds and hydrogen peroxide or peroxy-acids cannot be based on any close analogy with corresponding reactions of aliphatic and aromatic aldehydes: the structure and the properties of furan systems are so specific that special consideration must be given even to whether the peroxide attacks the carbonyl group or the ring.

III. STRUCTURAL PECULIARITIES AND REACTIVITY OF FURAN OXO-COMPOUNDS AND HYDROGEN PEROXIDE

The reactions of 2-furaldehyde are often divided into aldehydic, diene, and ethereal.

The series of compounds—furan, 2-furaldehyde, and benzaldehyde—differ significantly in structure and properties. Thus no analogy is observed in the diene properties of furan and furaldehyde. Furan reacts with active dienophiles, whereas furaldehyde and other derivatives containing electron-accepting substituents (pyromucic acid, nitrofuran, etc.) do not react at all as dienes[33-38]. Furaldehyde itself is able to act as a dienophile[39]. Products of addition at the diene system of furaldehyde could not be isolated from the reactions of it and its derivatives with molecular oxygen even with active initiation by light[40-42,59].

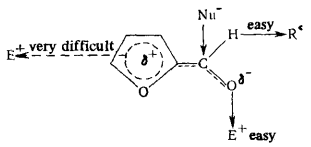
These facts are fully consistent with the view that oxygen adds only to those 1,3-dienes having enhanced electron density at the site of addition[43]. In furaldehyde, its homologues, and isomeric ketones the furan ring is conjugated with the carbonyl group, with displacement of electron density towards the latter. This is indicated by numerous data on the dipole moments[44,45], ultraviolet[6,46], infrared[6,47,48], proton magnetic resonance[48-50], and Raman[51] spectra, as well as the molecular exaltation. The infrared spectra show that the carbonyl group in furaldehyde lies in the plane of the ring owing to conjugation with the latter. The vector of the dipole moment is directed towards the carbonyl group with $\mu = 3.61$ D. The degree of conjugation between the π-bonds of the furan ring and the carbonyl group is clearly demonstrated by a comparison of the ultraviolet spectra of 2-furaldehyde and fur-2′-ylacetaldehyde, in which the carbonyl group is not conjugated with the ring ($\lambda_{max} = 277$ and 220 nm respectively). Calculation of the π-electron density shows considerable diminution in the ring and enhancement on the carbonyl oxygen in furaldehyde[52,53]. These facts are evidence of marked impoverishment of the electron density of the heterocycle and enrichment of the π-bond of the carbonyl group. This in turn strengthens the participation of p-electrons of the oxygen heteroatom in conjugation with the π-electrons of the ring. Hence the furan ring is more strongly aromatic in furaldehyde than in furan itself. This feature of the electronic structure of the furaldehyde molecule eliminates reactions involving the cyclic diene bonds, even with hydrogen peroxide. Thus Scheme 3 and

similar mechanisms[1,29] are inconsistent with modern views on the structure and properties of 2-furaldehyde.

Protolytic or hydrolytic cleavage of the furan ring by rupture of the C–O–C bond may be expected in systems containing hydrogen peroxide and especially its aqueous solutions. With regard to the acidophobic nature of furan compounds it is supposed that the cyclic oxygen atom forms a dative bond with the proton (oxonium ion) by means of the lone pair of electrons not involved in conjugation, which breaks down, and the ring is cleaved[54-56]. On the other hand, a vast amount of experimental work has been published indicating that electrophilic reagents do not attack the heteroatom but a cyclic carbon atom to form α-substituted furan derivatives[57]. The electron density on the cyclic oxygen atom is already low in the furan molecule, still lower in furaldehyde[52,53], and interaction with a proton cannot be ensured. The protonation of aromatic ethers involves the disruption of $p-\pi$ conjugation (E_{conj} = 8–12 kcal mole^{-1}), and occurs only if the energy of the resulting dative bond exceeds the conjugation energy[58]. Oxonisation is difficult with diphenyl ether, and is impossible at the heterocyclic oxygen atom in furaldehyde: this oxygen already possesses an oxonium character, and the energy of conjugation is very high.

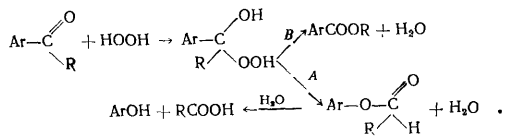
It has been proved experimentally that furaldehyde undergoes protonation not at the cyclic oxygen atom but throughout the conjugated system with formation of π-complexes[59,60]. This is consistent with the supposed π-functionality of the furan ring in complex formation[61]. In furaldehyde the end of the conjugated system having enhanced electron density is the aldehydic oxygen atom, to which a proton attaches in the limiting case. The protonation of furaldehyde by acids is accompanied by a strong bathochromic shift of the ultraviolet bands. Experiments suggest that electrophilic, nucleophilic, and radical reactions involve predominantly the aldehyde function, owing to the distribution of electron density in furaldehyde. Reaction will be favoured energetically if a stable transition state is established, in which the conjugation of the ring is preserved. The aldehydic carbon–hydrogen bond is less stable than a similar bond in the furan ring (70 and 103 kcal mole^{-1} respectively). Thus the direction of reactions in furaldehyde can be represented by Scheme 4, where R· is a free radical, E^+ an electrophilic species, and Nu^- a nucleophilic species. This scheme has been confirmed experimentally in the reduction[62] and the acetalation[63] of furan oxo-compounds. There are no grounds for supposing that reactions with hydrogen peroxide and with peroxy-acids will constitute exceptions.

Scheme 4



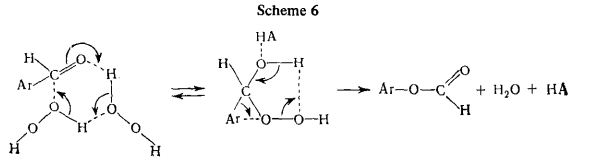
It does not follow that the reaction of furan oxo-compounds with these reagents will be analogous to that of the corresponding benzene derivatives, which also begins at the carbonyl group. Furaldehyde is more polar and more easily polarised than is benzaldehyde, as shown by the higher dipole moment and dielectric constant of the former. Experiment suggests that the π-electron system of the furan ring is more mobile than that of the benzene ring[44,46,64], which can be attributed to the presence of two oxygen atoms: the heterocyclic oxygen is a donor, and the carbonyl oxygen an acceptor, of electrons. As a result, the electron density and also the basicity of the ring are lower, while those of the carbonyl group are higher, than in benzaldehyde. On the other hand, furyl is more electronegative than is phenyl: the dissociation constant of pyromucic acid is 76.2×10^{-5}, tenfold that of benzoic acid (6.3×10^{-5}), which can be attributed to the weak aromaticity of furyl and its definite unsaturation. A significant difference in reactivity towards hydrogen peroxide and peroxy-acids should be observed between oxo-compounds derived from furan and benzene respectively. On the other hand, there are no grounds for supposing that these differences will be apparent in the direction of the early stages of interaction with the carbonyl group: only differences in reaction velocity are to be expected here.

Scheme 5



The oxidation of oxo-derivatives of benzene by hydrogen peroxide can be represented[30-32,65-69] by Scheme 5: hydrogen peroxide adds at the carbonyl group to give a hydroxy-hydroperoxide[67,69], whose formation in the aromatic and aliphatic series has been demonstrated by isolation or spectroscopically[70-73]. The resulting peroxide undergoes an intramolecular Baeyer–Villiger rearrangement[74], which is substantially accelerated by acids. In the case of benzaldehyde the rearrangement leads either to an ester (hydroxyphenyl formate) or to benzoic acid. Rearrangements of this type are widespread. Discussion of the mechanism of the formation and rearrangement of peroxides in the oxidation of aromatic and aliphatic oxo-compounds by hydrogen peroxide and peroxy-acids has considered as intermediate stages heterolysis[30,66,67,75-78], homolysis[79-81], or activated complexes[67,75-78]. A mechanism involving the molecular formation and rearrangement of hydroxy-hydroperoxides has the most convincing theoretical and experimental support[31,82-84]. Reactions of this type (Scheme 6) involve a continuous transition from the initial to the final state without formation of kinetically independent ions or radicals. This is due to the wave properties of electrons, the high polarity and the polarisability of bonds in oxo-compounds and peroxides, and the far greater instability of activated bonds in transition complexes in comparison with ordinary bonds[85-91].

Scheme 6



Transition states are usually regarded as stable five- or six-membered cyclic complexes [31]. An important part in these processes is played by acids, which largely polarise carbonyl and peroxide bonds, thereby promoting the formation and transformation of the transition complexes [31]. Arguments in support of molecular mechanisms do not exclude the probability of complete ionisation, adequate reasons for which have been given for the stage of peroxide formation [75], and this probability is increased by the effect of strong acids and bases.

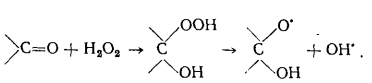
Irrespective of whether the hydroxy-hydroperoxide undergoes rearrangement by an ionic or by a molecular mechanism, it involves migration of one of the groups (Ar or R in Scheme 5) to the peroxide oxygen atom of diminished electron density. Migration of a hydrogen atom or the group R yields benzoic acid or its ester (Scheme 5*B*); that of aryl residues yields phenyl esters (Scheme 5*A*), which are then hydrolysed to phenols and acids. The relative migratory power of the groups varies in the sequence [30,68]

$$HOC_6H_4 > MeC_6H_4 > H > Ph > ClC_6H_4 > NO_2C_6H_4 > Me\ .$$

Similar data are not available for furan derivatives.

The main product of the oxidation of benzaldehyde is benzoic acid, in conformity with the greater ease of displacement of hydrogen than of phenyl. The simultaneous formation of small quantities of phenol and formic acid indicates the significance of the migration of phenyl. Electron-accepting substituents strongly impede such migration, and oxidation goes solely towards formation of benzoic acids. Electron donors, on the other hand, facilitate the formation of phenyl formates, and oxidation occurs very readily [30]. These results, as well as investigations using an oxygen isotope [92], have shown the untenability of the mechanism [93] of direct hydroxylation of the benzene ring by hydroxyl radicals. In the oxidation of salicylaldehyde by hydrogen peroxide the carbonyl group is the reactive centre, and a molecular activated complex is formed in which the *o*-phenoxy-group can easily migrate to an oxygen atom. As a result, the main oxidation product is catechol [92], whereas 3,5-di-t-butylbenzaldehyde yields the corresponding dialkylphenol and formic acid [94].

It is quite important to discuss the possible modes of breakdown of hydrogen peroxide in considering the mechanism of the oxidation of oxo-compounds. Some authors suppose that oxidation is effected by the cation HO^+ formed from hydrogen peroxide [95,96], but this is not supported by isotopic investigations [97–100]. The existence of an independent species HO^+ is improbable [101]. According to Denisov [102] ketones promote the homolysis of hydrogen peroxide:



It has been suggested [103] that radicals are formed in oxidations catalysed by certain strong acids in anhydrous medium:

$$H_2O_2 + H^+ \rightleftarrows H_3O_2^+ \xrightarrow{H_2O_2} H_3O^+ + HO^{\cdot} + HO_2^{\cdot}\ .$$

These processes are regarded as an exception to the general rule.

Oxo-compounds of low polarity in non-polar solvents, or in their absence under conditions of thermolysis, photolysis, or radical initiation, are able to react with hydrogen peroxide also by a homolytic mechanism [101]. In polar media (water, alcohols, organic acids, etc.), however, the mechanism is heterolytic [101,104]. Such a path is energetically more favourable, since solvation of the polar hydrogen peroxide molecule (μ = 2.13 D and ϵ = 73.1) [101,105] and its decomposition products greatly diminishes the energy of rupture of the bonds. Aqueous solutions of hydrogen peroxide have an acid reaction [101,105,106]:

$$H_2O_2 + H_2O \rightleftarrows H_3O^+ + HO_2^-.$$

Acid dissociation predominates over other types of breakdown [106] and increases with rise in temperature and increase in the hydrogen peroxide concentration of the solutions up to 80%. This compound also undergoes autoprotolysis:

$$H_2O_2 + H_2O_2 \rightleftarrows H_3O_2^+ + HO_2^-.$$

The degree of dissociation of hydrogen peroxide is determined by the nature of the solvent, the acidity of the medium, and the basicity of the substrate.

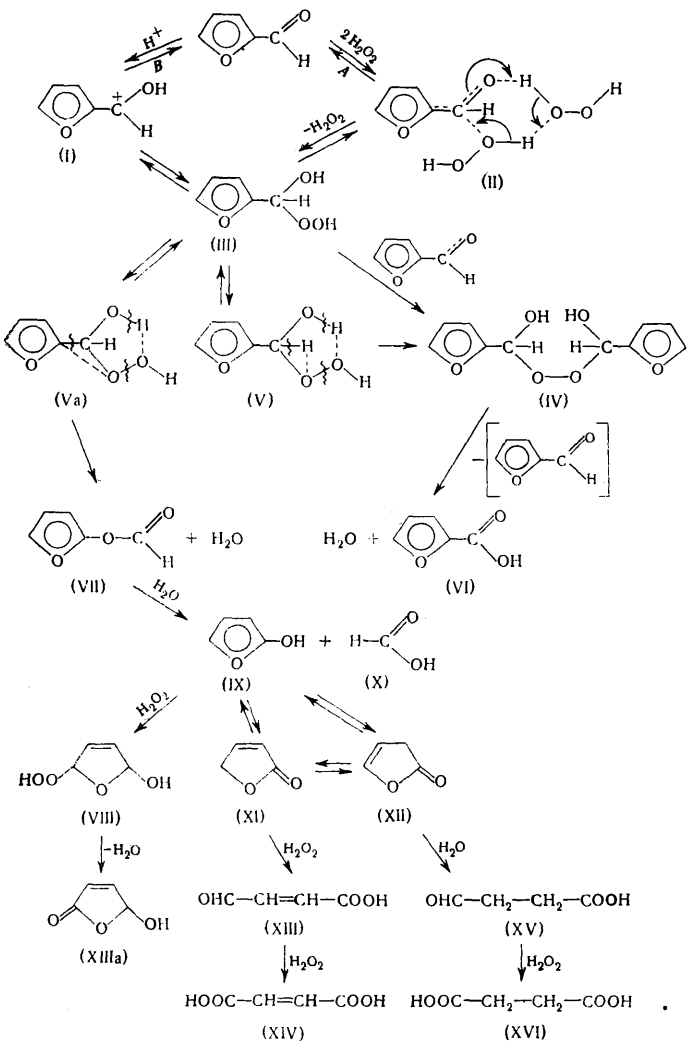
The high polarity and the polarisability of aromatic and especially furan oxo-compounds, their basicity due to the carbonyl group, the polar media used, and the relatively low temperatures—all these factors show that the reactions with hydrogen peroxide and peroxy-acids take place by a heterolytic or molecular mechanism. Either the hydrogen peroxide anion HOO^- or the molecule as a whole can act as nucleophilic reagent at the carbonyl group; it is also the proton donor.

Thus published experimental and theoretical results on the structure and properties of oxo-derivatives of furan and hydrogen peroxide, as well as the reactions of the latter and of peroxy-acids with aromatic oxo-compounds, show that Schemes 1–3 have no basis in fact. They and similar schemes cannot be used to describe the mechanism of the reactions of 2-furaldehyde and other furan oxo-compounds with these reagents. They are inconsistent with the structure and properties of furan aldehydes and ketones and of hydrogen peroxide, disregard the vast amount of experimental information on the peroxide oxidation of benzaldehyde and its derivatives, and do not provide for the formation of intermediate peroxy-compounds. Other concepts have therefore been advanced, and confirmed experimentally, to explain the mechanism of the oxidation of furan oxo-compounds by hydrogen peroxide and peroxy-acids.

IV. CURRENT IDEAS ON THE MECHANISM OF OXIDATION OF FURAN OXO-COMPOUNDS BY HYDROGEN PEROXIDE AND PEROXY-ACIDS

The special features of the reactivity of furan oxo-compounds and hydrogen peroxide and the reactions of aromatic carbonyl compounds with this reagent and peroxy-acids are taken into account in Scheme 7. The oxidation of the furan derivatives is regarded as a consecutive reaction having an ionic–molecular mechanism [4,5,120,126]. Here the carbonyl group is attacked initially either by a hydrogen peroxide molecule (reaction *A*) or by a proton (*B*). The predominance of *A* or *B* is determined by the structure of the carbonyl compound and by the reaction conditions. An intermediate linear or cyclic complex (II) is quite probably formed by reaction *A*, and the protonated species (I) by reaction *B*. The common result of the first stage is formation of the α-hydroxy-hydroperoxide (III), which may be converted, perhaps via the complex (V), either into the furyl ester (VII) or into the $\alpha\alpha'$-dihydroxy-peroxide (IV) depending on the structure and the reaction conditions. The corresponding furancarboxylic acid (VI) might be formed from (III) or

Scheme 7



from (IV). These stages show an analogy with the mechanism of the corresponding reactions in the benzene series (Scheme 5).

Significant differences in reaction velocity and proportions of products can be expected between furan and benzene derivatives, because of the greater mobility of the π-electron system of the furan ring. The rate of rearrangement of the peroxide (III) into the ester (VII) should be far greater with furaldehyde than with benzaldehyde. Furthermore, the rearrangement is stimulated in the furan series by hydrolysis of the ester to furanol (IX) and formic acid (X). The reverse reaction is improbable in this case, since the products of hydrolysis—(IX), (XI), and (XII)—are converted irreversibly into acids—4-oxobut-2-enoic (XIII), maleic (XIV), γ-oxobutyric (XV), and succinic (XVI). In the case of benzaldehyde, its derivatives, and its homologues, compounds containing stable aromatic rings are formed at all stages, and reactions involving cleavage of the ring are not observed (Scheme 5).

The oxidation of furan oxo-compounds is accompanied by substantial variation in the stability of the heterocyclic ring in the initial and intermediate products (IX): its stability undergoes a marked decrease after removal of the electronegative carbonyl group. The intermediate furanol (IX), in which the stability of the ring should be significantly lower than in furan itself, can readily undergo transformation involving the diene system and with cleavage of the ring. This is consistent with its ready oxidation via the peroxide (VIII) to formylacrylic acid (XIIIa) and the tautomerisation into the lactones (XI) and (XII) of but-2- and -3-enoic acids. The oxidative and hydrolytic changes undergone by the lactones and the furanol yield 4-oxobut-2-enoic (XIII—XIIIa) and γ-oxobutyric (XV) acids, which are converted by excess of hydrogen peroxide into succinic, maleic, and fumaric acids. The mechanism of the changes undergone by furanol and its tautomeric forms will not be considered here.

1. Role of Complex Formation

Various factors can influence the redistribution of electron density in oxo-derivatives of furan; these produce significant changes in their reactivity. Thus the self-association of 2-furaldehyde and association in its binary systems with the solvent and with hydrogen peroxide cause significant polarisation of the carbonyl group and affect its reactions with this reagent and with peroxyacids. The tendency of furaldehyde to associate[108] is such that its molecules are associated even in benzene[109], although the interaction is then weaker than for ordinary hydrogen bonds. It is not associated in dilute (<0.02 M) solutions. The tendency of furaldehyde to associate is indicated by its abnormally high boiling point in comparison with furan and its great solubility in water, as well as by significant differences in the ultraviolet and infrared spectra in various solvents[60,107,110]. Its self-association and its association with the solvent have been confirmed cryoscopically[112-115]. Weak hydrogen bonds are formed with acetic acid, and stronger bonds with stronger acids[115,116]. Complex formation between furaldehyde and pyromucic acid has been detected polarographically[5]. With sulphuric acid furaldehyde and its derivatives form complexes, which are completely converted into the initial aldehydes when the solutions are diluted[5]. No common view is held on the structure of the complexes. There is no doubt, however, that interaction in furaldehyde–solvent systems does not involve the ring but the carbonyl group. This is indicated by the constancy of the $\nu C:C$ band of the furan ring (1565 cm^{-1}) and the variation in the $\nu C:O$ band in the infrared spectra of furaldehyde obtained in various solvents[107]. Comparison of the infrared spectra of furaldehyde and its solutions in non-polar and in polar solvents shows (Table 1) a change in the structure of the doublet at 1660–1690 cm^{-1} representing vibrations of the carbonyl group involved in hydrogen bonding.

Considerable shifts in the $\nu C:O$ bands are also observed when water and hydrogen peroxide are dissolved in furaldehyde, indicating considerable association in the binary systems. These observations have also been confirmed by cryoscopic measurements: when increasing quantities of hydrogen peroxide are added to a solution of furaldehyde in benzene, the freezing-point depression diminishes, indicating the bonding of furaldehyde molecules by hydrogen peroxide molecules and their removal from solution as complexes[8,117]. Association is more marked with hydrogen peroxide than with water; this is confirmed by the greater solubility, exceeding that in water by a factor of ~3.5.[4]

The strong association in the furaldehyde–hydrogen peroxide system shown by the above facts is consistent with the assumed formation of the intermediate complex (II) (Scheme 7) governed energetically by the stability of the resulting ring. Although the structure of the complex is open to discussion, the fact of its formation is indisputable. Polarisation of the carbonyl group by the hydrogen peroxide molecule must be taken into account in connection with the mechanism of the oxidation of furan oxo-compounds, and by the acid molecule or the proton in acid catalysis [cation (I) in Scheme 7]. Subsequent stages of the reaction will be facilitated significantly by such activation of the molecule.

Table 1. Dependence of stretching frequencies $\nu_{C:O}$ of 2-furaldehyde[107] on nature of solvent.

No.	Solvent	c, M	$\nu_{C:O}$, cm^{-1} [a]

[b] Water and hydrogen peroxide in furaldehyde.

2. Role of Peroxy-compounds

The formation of peroxy-compounds was not even mentioned in the early papers on the oxidation of carbonyl derivatives of furan by hydrogen peroxide and peroxy-acids (Schemes 1–3). Various organic peroxides have since been detected among the products of the oxidation of furan aldehydes and ketones by hydrogen peroxide in the experimental verification of Scheme 7.[118,125] Originally only the total organic peroxides could be determined quantitatively, and the composition qualitatively[118,120-123].

For a long time it proved impossible to isolate the intermediate peroxy-compounds as individual species because of their tendency to detonate. They were stable in solution, but detonated on concentration (cf. the properties of the "active" and "inactive" forms of acyl hydroperoxides[126-130]). By the use of highly concentrated hydrogen peroxide under special conditions it has proved possible to prepare α-hydroperoxyfurfuryl alcohol (III)[18,126,131] and its ring-substituted nitro-derivative[16], which was stable unlike (III) but resembling other peroxides having electronegative substituents[119]. The synthetic compound (III) was identical with one of the peroxides detected among the oxidation products[120,126]. In the active period of oxidation in water the only intermediate peroxy-product is (III). The oxidation of furaldehyde in water involves intermediate formation of this peroxide. Formic, oxo, and furancarboxylic acids accumulate only after it has been transformed. During oxidation in anhydrous media (III) is accompanied by (IV), which predominates when the reaction is conducted in an alcohol[126].

The peroxide (III) is extremely unstable both in aqueous solution and in the crystalline state, decomposing with the formation of furaldehyde, hydrogen peroxide, the peroxide (IV), formylacrylic, maleic, formic, and pyromucic acids, and non-acidic products. The corresponding peroxide from nitrofuraldehyde is quite stable at +5°C, but when heated in water undergoes quantitative conversion into nitrofuran-2-carboxylic acid[18]. In aqueous solution this acid is accompanied by nitrofuranal and hydrogen peroxide. The formation of furaldehyde, its nitro-derivative, and hydrogen peroxide among the products from these hydroxy-hydroperoxides results from their dissociation into a furaldehyde and hydrogen peroxide. This process takes place both during the reaction and when samples of the oxidation products are diluted with water[8]. All the remaining products formed from (III) result from its conversion into (IV), (VI), and (VII). Conversion into furyl formate (VII) is assumed to involve a sextet rearrangement of the Baeyer–Villiger–Criegee–Waters type. Furancarboxylic acid can be formed not only from (III) but also by breakdown of the dihydroxy-peroxide (IV).[126,131] The direction of the rearrangement for furan hydroxy-hydroperoxides is determined by the structure. Electron-accepting substituents cause marked weakening of the π-donor properties of the furan ring, and its migration to the peroxide oxygen atom depleted in electrons becomes impossible. Hydrogen is then more mobile, and the hydroxy-hydroperoxide rearranges to the corresponding furancarboxylic acid (VI), perhaps via (V). Peroxides of furaldehyde itself, its homologues, and derivatives having electron-donating substituents rearrange preferentially into furyl formate (VII).

It is noteworthy that furancarboxylic esters are not detected among the oxidation products of acetylfuran and its derivatives[125]. Independently of the substituents in the furan ring, it obviously migrates in preference to the methyl group during the rearrangement, and furyl acetates are formed. A similar phenomenon has been observed among ketones of the benzene series[30,65,132]. Very small quantities of three further peroxides besides (III) and (IV) have been detected qualitatively in the aqueous oxidation products at the later stages of oxidation[8]. They have been regarded as formed from intermediate products—(IX), (XI)–(XIII), and (XV)—and could not be isolated or prepared in individual form.

Furoyl peroxide and hydroperoxide are not formed in the oxidation of oxo-derivatives of furan by hydrogen peroxide and peroxy-acids. Their presence could easily have been detected from their intense absorption maxima at 262 and 240 nm respectively[119,133], as well as by chromatography[119]. When furaldehyde is oxidised by hydrogen peroxide in water the products do not absorb in the range 240 to 265 nm; in anhydrous media a band is observed at 243 nm, which is due to pyromucic acid[17,126], formed only after breakdown of the organic peroxides.

In order to assess the mechanism of the action of hydrogen peroxide on oxo-derivatives of furan it is important to determine the kinetics of the stage in which peroxides are formed. Oxidation in water cannot be arrested at this stage [120,122,123]. Because water is present, the process goes so far as the formation of acids (Scheme 7), whose accumulation catalyses both the formation and the transformation of the peroxy-compounds, and the final content of organic peroxides is only 0.5–1 g-equiv. litre^{-1}. The kinetic curves representing their accumulation and conversion pass through three maxima. A similar pattern is observed in the oxidation by aqueous hydrogen peroxide of several furan aldehydes [120,124] (methylfuranal, 2-furaldehyde, and its amino- and halogeno-derivatives) and ketones [125] (acetylfuran and its derivatives).

In the absence of acids oxidation in anhydrous solvents ceases at the stage of formation of peroxy-compounds [111,120,126]. The rate constant for the consumption of furaldehyde corresponds to that for accumulation of the organic peroxide [120]. Oxidation in alcohol is a third-order reaction—of the first order with respect to furaldehyde and of the second order with respect to hydrogen peroxide [126]—which is consistent with formation of the hydroxy-hydroperoxide via the complex (II) involving three molecules. If formation of the peroxide is controlled by conversion of the transition complex, the overall process should be described by a third-order equation, as is the case. In the presence of acids the reaction is first order with respect to hydrogen peroxide, which confirms the catalytic role of hydrogen peroxide in the absence of acids.

The above results on the composition and reactions of the intermediate hydroxy-hydroperoxides in the action of hydrogen peroxide on furan oxo-compounds support Scheme 7. However, they still cannot indicate whether conversion of the oxo-compounds into peroxides takes place by a homolytic, heterolytic, or molecular mechanism.

Neither the changes undergone by furaldehyde and hydrogen peroxide nor the accumulation and transformation of organic peroxides and acids in this reaction are influenced by molecular oxygen [134]: the processes are identical in its presence and after it has been completely removed. Breakdown of the organic peroxides is not accompanied by the evolution of oxygen. These facts indicate that, as in most radical oxidations, molecular oxygen plays no part in the oxidation of furaldehyde and its derivatives by hydrogen peroxide. The formation of peroxy-acids and diacyl peroxides characteristic of radical processes is not observed [135,136]. In the autoxidation of furaldehyde, in which radical reactions predominate in the early stages, the initial products of the action of molecular oxygen are furoyl hydroperoxide and difuroyl peroxide [135,137], which are not formed in the oxidation of furaldehyde by hydrogen peroxide [4,126], as mentioned above.

The reacion is accelerated neither by ultraviolet nor by ultrasonic irradiation [4,123,140]. If the formation and transformation of the organic peroxides occurred homolytically, exposure would produce a marked change in its rate [136,138], but some specific effect on the direction of the process merely occurs. This ultraviolet irradiation increases the yield of 4-oxobut-2-enoic acid, and fumaric acid appears [4,123]. Treatment with ultrasonic vibrations results in considerable quantities of malic acid among the oxidation products [14,139,140], as a consequence of ultrasonic initiation of the breakdown of hydrogen peroxide and water with the formation of hydroxyl species [138]. If formation of the peroxide (III) had involved hydroxyl radicals or hydroxide ions, ultrasonic exposure should have intensified the process significantly, but this is not observed.

It is evident that neither molecular oxygen nor hydroxyl species are involved in the formation of (III). The oxidant giving the hydroxy-hydroperoxide must thus be the hydrogen peroxide molecule or ion H_2O_2 or OOH^- (Scheme 7). As the process exhibits no clear sign of a homolytic chain reaction, it cannot be regarded as a radical reaction. Furthermore, a heterolytic or molecular mechanism is suggested by many factors—those mentioned above together with the action of acids and water, the influence of the nature of the solvent, and the electronic effects of substituents in the furan ring.

In the oxidation of furan aldehydes and ketones by hydrogen peroxide the conversion of starting materials and intermediates becomes more intense as acids accumulate in the reaction mixture [4,6,122,123]. Neutralisation of the acids among the oxidation products slows the process down. The oxidation of oxo-derivatives of furan by hydrogen peroxide is evidently catalysed by the acids formed.

The addition of mineral and organic acids to the reaction mixture increases the rate of formation of peroxy-compounds, as can be assessed from the consumption of furaldehyde or acetylfuran. Acids also have a significant influence on the rate of subsequent stages (Scheme 7), as well as on the direction of the process [1,4,141]. Additions of formic, acetic, maleic, succinic, and sulphuric acids [4,6] all increase the consumption of furaldehyde or acetylfuran and hydrogen peroxide, and shorten or completely eliminate the induction period. The catalytic effect of the acid is greater the higher its dissociation constant:

sulphuric > maleic > formic > succinic.

The effect is greatest in the initial stages of the reaction. Such a strong effect of acids on the rate shows that the oxidation of furaldehyde and acetylfuran by hydrogen peroxide is ionic or molecular in character. Further evidence in support of this conclusion is the significant dependence of the rate and the direction of oxidation on the nature of the solvent [2,4,17,107,120,126,141,142].

The oxidation of furan oxo-compounds by hydrogen peroxide in anhydrous media or with a small water content differs significantly from oxidation in water: in the former case the reaction almost stops at the stage of formation of peroxides, and little or no acid is formed. As compared with water, alcohols, and organic acids, protophilic solvents (dioxan, oxolan, pyridine, ethers) slow down markedly the formation of hydroxy-hydroperoxides. Solvents having pronounced protogenic properties (formic and acetic acids) cause strong formation and transformation of (III) (Scheme 7). Initially reaction in alcohols is more intense than in water, after which it slows down. Small quantities of water have a peculiar effect: comparison of the consumption of furaldehyde and the accumulation of peroxides on oxidation in water and in aqueous ether shows that the presence of up to 5% of water in the reaction mixture accelerates the reaction in the initial period; higher water contents retard the process [142] (cf. Table 2).

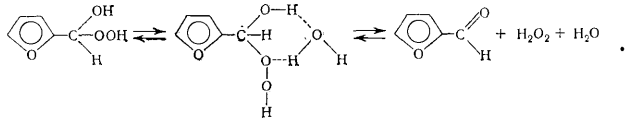
The action of water in the initial stage (Scheme 7) may be to affect either formation of the complex of furaldehyde with $2H_2O_2$ or the dissociation of (III) into furaldehyde and hydrogen peroxide. A high content of water in the oxidation products results in formation of a monohydrate of furaldehyde [107]. Competition in complex formation with furaldehyde between water and hydrogen peroxide molecules delays formation of a peroxide. A similar effect is possible in the presence of excess of water, because the dissociation of (III) into furaldehyde and hydrogen peroxide

is accelerated (Scheme 8). Small quantities of water activate the oxidation of furaldehyde by hydrogen peroxide, mainly by accelerating further transformations of the hydroperoxide (III).

Table 2. Effect of quantity of water on consumption of furaldehyde (Fu) on oxidation with 50% hydrogen peroxide (Fu : H_2O_2 = 1 : 2.2 at 22°C).

Solvent	10^4k_1, min^{-1}
Water	≈0.00
Ether + 0.80% H_2O	21.4
Ether + 1.40% H_2O	34.6
Ether + 3.60% H_2O	59.8

Scheme 8



The nature of the solvent governs not only the rate but also the direction of the process. It has been shown above that the $\alpha\alpha'$-dihydroxy-peroxide (IV) is formed together with (III) in anhydrous and aqueous organic media. The nature of the conversion products of the peroxides varies in anhydrous media: thus the yield of the furancarboxylic acid (VI) is ~50% in alcohols, but only 2% in water[4,120,126]. This reaction is influenced by the polarity and the protophilic or protogenic character of the medium. Such a considerable solvent effect may be expected for ionic or molecular reactions[143]. The influence of solvents on radical reactions would be opposite to that found, since solvents capable of forming hydrogen bonds or π-complexes with radicals terminate the kinetic chain and lower the rate of oxidation[129,144,145]. In the present case alcohols and organic acids, which readily form hydrogen bonds, accelerate the oxidation of furan oxo-compounds by hydrogen peroxide.

A molecular or ionic mechanism is indicated not only by the above experimental results but also by the electronic effect of substituents in the furan ring on the rate and direction of the reaction. The effect on the rate has been assessed[120,124-126] by oxidising a series of aldehydes and ketones with a substituent—methyl, chloro, bromo, iodo, dialkylamino, hydroxymethyl, nitro—at position 5 in the furan ring. This series has the same reactive centre—the carbonyl group—and a variable 5-substituent. Conducting the reactions in a solvent containing a small quantity of water and at a relatively low temperature (30 to 40°C) enabled the process to be arrested at the stage of peroxide formation. The quantitative results given below relate to this particular stage. Its direction and mechanism were unaffected by the choice of solvent: in all cases the hydroxy-hydroperoxide (III) was formed with the substituent at position 5 in the heterocycle. Electron-donating substituents (methyl, dialkylamino) tend to increase the oxidation rate constant, whereas electron-accepting substituents (nitro, hydroxymethyl) tend to diminish the rate (Table 3). In contrast to methyl, hydroxymethyl retards oxidation[4]. Hydroxymethylfuraldehyde is oxidised rather more slowly than furaldehyde itself ($\tau_{1/2}$ = 63 and 55 min).

Table 3. Rate constants for the oxidation of 5-substituted furaldehydes[120] (aldehyde : H_2O_2 = 1 : 10 at 40°C) and acetylfurans[6] (ketone : H_2O_2 = 1 : 50 at 30°C) in aqueous dioxan.

5-Substituent	Aldehydes			Ketones

The oxidation of halogenated furan oxo-compounds follows a curious course in aqueous dioxan. That of ketones by hydrogen peroxide is accelerated by all the halogens examined at position 5 of the furan ring, with chlorine more effective than bromine, and iodine the least effective. Oxidation of the aldehydes is accelerated by chlorine, but somewhat retarded by bromine and iodine. All the halogens accelerate the oxidation of furaldehyde in anhydrous media[126]. The reason is that, during the reaction, the positive conjugation effect of the halogens becomes stronger in comparison with their negative inductive effect. This is already observed in the parent substance as a result of the strong acceptor properties of the carbonyl group. The ultraviolet and infrared spectra of substituted furan oxo-compounds provide convincing support[6]. Under the influence of the polarised carbonyl group the positive conjugation effect of the halogen increases many times during the reaction. Similar phenomena are observed in the electrophilic substitution of halogenated benzenes[143]. The greatest positive conjugation effect is found[146] with chlorine, and diminishes in the sequence Cl > Br > I; it is explained by the most favourable overlap of electrons in the 3p shell of chlorine with 2p electrons of carbon.

It is remarkable that this effect of halogens has not been observed among acetophenones: the rates of oxidation of p-chloro- and p-bromo-acetophenones by peroxy-acids are lower than those of acetophenone[147]. This shows that the transmissibility of electronic effects through the benzene ring differs from their transmissibility through the heterocyclic furan system: the π-electrons of furan are more mobile. A complete analogy cannot, of course, exist in the oxidation of benzene and furan carbonyl compounds by hydrogen peroxide and peroxy-acids.

The positive conjugation effect of halogens is more strongly developed in substituted acetylfurans than in furaldehyde and its derivatives, owing to the greater interaction of p-electrons of the halogens with those of the furan ring in ketones. The π-electron density of the furan ring is less displaced by the ketone group, being a weaker acceptor than the aldehyde group, and better conditions are created for interaction of electrons of chlorine and the ring. On the other hand, more intense polarisation of the carbonyl group is required during reaction with ketones

than with aldehydes, which tends to strengthen the positive effect of halogens. The difference in degree of conjugation of halogens in furan aldehydes and ketones develops mainly in the reactive state, since the infrared spectra indicate no special difference in the static state [6]. The effects of substituents are more strongly developed in the oxidation of furan aldehydes by hydrogen peroxide in aprotic solvents of low polarity (dioxan, oxolan), and are extremely slight in alcohol [126].

Migration of electrons towards the reactive centre—the carbonyl group—evidently governs the rate of oxidation of furan oxo-compounds by hydrogen peroxide. Hence the formation of (III) is a result of electrophilic attack, which apparently consists in protonation of the carbonyl group. Conjugation of π-electrons of the ring and the group diminishes the δ^+ charge on the carbonyl carbon, so that nucleophilic attack by such a weak nucleophile as hydrogen peroxide requires preliminary polarisation of the carbonyl by a proton. Hydrogen peroxide and the solvents used (water and alcohols) are extremely weak acids, which is responsible for the slowness of the electrophilic stage [143]. If the acidity of the solvent is closely similar to that of hydrogen peroxide, the solvent may act as protogenic substance, as in the oxidation of furaldehyde by hydrogen peroxide in water [142]. In less acidic media hydrogen peroxide acts as the acid [126].

The rate of oxidation is affected not only by substitution at the 5-position in the furan ring but also by change in the character of the side-chain containing the carbonyl group. Furylacrylaldehyde is oxidised very easily, but oxidation begins at the unsaturated side-chain, and the primary reaction products are furaldehyde and oxalic acid. The furaldehyde then undergoes conversion by the usual scheme [4]. This example clearly demonstrates that the oxidation of furan oxo-compounds containing electron-accepting substituents does not start at the furan ring, and that the ring is more stable than the double bond in the side-chain. Acetylfuran is oxidised considerably more slowly than is furaldehyde [125]: thus with 50% hydrogen peroxide at 60°C and the reactants in the proportions 1 : 2.5 furaldehyde is oxidised more rapidly than acetylfuran by a factor of 20 (the respective half-conversion times are 23 and 450 min). Substitution of the aldehydic hydrogen by methyl produces no great change in the distribution of electron density in the furan ring, as is indicated by the close similarity of the ultraviolet and infrared spectra of acetylfuran and furaldehyde [6,148]. The infrared spectra reveal no difference in position or intensity of the absorption bands due to stretching and deformation vibrations of the furan rings in aldehyde and ketone; appreciable differences are shown only by bands due to the carbonyl group.

The introduction of alkyl substituents increases the electron density on the carbonyl group and should thereby improve its sensitivity to electrophilic attack. This is accompanied by a diminution in the tendency of the carbonyl carbon to interact with nucleophilic reagents, owing both to electronic and to steric factors. The stage of hydroxy-hydroperoxide formation is limited by electrophilic attack with both aldehydes and ketones (Table 3). The unexpected sharp decrease in rate of oxidation with acetylfuran compared with furaldehyde can be explained if the formation of (III) is regarded as a termolecular reaction. The plausibility of this hypothesis has been demonstrated for furaldehyde [126]. The nucleophilic stage may be slower with ketones, resulting in a fall in the overall rate of oxidation. The electronic effects of substituents in the furan ring, like other factors, suggest an ionic or a molecular mechanism of the formation and transformation of hydroxy-hydroperoxides in the oxidation of furan oxo-compounds by hydrogen peroxide.

3. Furyl Formate and its Conversion Products

Furyl formate and the homologous acetate are intermediates in the oxidation of furaldehyde and acetylfuran by hydrogen peroxide (Scheme 7). They have been isolated individually, which convincingly proves the suggested rearrangement of the hydroxy-hydroperoxide (III) into (VII).

Formation of these compounds when furan oxo-compounds were treated with hydrogen peroxide and peroxy-acids had previously been ignored (Schemes 1–3), and no attempts had been made to isolate them from the oxidation products. Furyl formate (VII) was first isolated from the products of the oxidation of furaldehyde by hydrogen peroxide when they were evaporated down or at the start of vigorous reaction [15]. Furyl formate is comparatively easily hydrolysed to formic acid (X), the butenolides (XI) and (XII), and 4-oxobutyric acid (XV), and oxidised to 4-oxobut-2-enoic acid (XIII). [8,15] Accumulation and transformation of these products are observed in the oxidation of furaldehyde by hydrogen peroxide, which has been investigated quantitively [4,8,126]. The rate of accumulation of formic acid when furaldehyde is oxidised in water [120] clearly shows that intense formation of the acid ensues after considerable quantities of furaldehyde have been consumed. This is fully consistent with the characteristics of the consecutive reaction represented in Scheme 7.

The furanol (IX) formed by the hydrolysis of (VII) is too unstable to be detected among the oxidation products [54]. For this reason furanol has not yet been prepared in any other way. However, its stable tautomers—the butenolides (XI) and (XII)—have been isolated in large quantities [8,57]. Products of the extensive transformation of furanol—4-oxobutyric and 4-oxobut-2-enoic acids—are formed in this reaction [1,10,12,126]. Accumulation of the aldehydic acids suffers a delay, the maximum occurring only after 2 h, when the furaldehyde is almost completely exhausted. The oxo-acids formed undergo vigorous oxidation to succinic and maleic acids (XVI) and (XIV), which have been isolated from the oxidation products [1,3,14,17]. The same acids are formed when furaldehyde is oxidised by peroxy acids [26,28], which indicates the same mechanism of oxidation as with hydrogen peroxide.

Furyl acetate could not be isolated from the products of the oxidation of acetylfuran by hydrogen peroxide, because it is oxidised much more rapidly than the initial ketone [149]. However, its formation and transformation during the reaction have been demonstrated qualitatively [149–154]. The processes occurring in the oxidation of acetylfuran are analogous to the hydrolytic and oxidative changes undergone by furyl formate (VII) and shown in Scheme 7, except that hydrolysis of furyl acetate yields acetic acid. These results show that rearrangement of the peroxide (III) into (VII) does actually take place.

Formation and transformation of the peroxides have been most fully studied in the complicated consecutive reaction of furan oxo-compounds with hydrogen peroxide. The occurrence of the remaining stages has been proved by the products, but their mechanism has not been investigated in detail. This is due to the peculiarities of the reaction: when oxidation occurs in water, individual stages cannot be isolated, nor can autocatalysis by the resulting acids be taken into account; in anhydrous media

the reaction effectively ceases at the stage of peroxide formation. The rate of conversion of (III) could not be estimated because of the accumulation of other peroxides. In view of the properties of (III), however, the process can be regarded as fairly rapid [18]. It is strongly exothermic [155].

Thus the regularities found in the reaction and the intermediate and final products identified permit Scheme 7 to be accepted as soundly based both theoretically and experimentally for the oxidation of furan oxo-compounds by hydrogen peroxide. It is very useful to estimate the activation parameters of the reaction in order to interpret its mechanism.

V. ACTIVATION CHARACTERISTICS OF THE PROCESS

The thermal effects of individual stages and of the overall oxidation of furaldehyde by hydrogen peroxide have been found by calculating the energies of formation of the products on the basis of approximate additivity [120,156,157]. The conjugation energy of furaldehyde and other furan compounds has been taken into account at the stage of their transformation [48,53]. The method used is arbitrary, since it allows for neither the complete interaction of atoms in the molecules nor the effects of the medium. However, the results are useful for estimating the thermal effects.

Table 4 shows that the oxidation of furaldehyde by hydrogen peroxide is exothermic, which has been confirmed experimentally [3,123]. The greatest quantity of heat is evolved during the conversion of peroxy-compounds [155], which is consistent with the results in Table 4 (stages *2*, *5*, and *8*). Calculation of the thermal effects shows the largest consumption of energy at stages *3*, *4*, and *6*. However, the experimental conditions require the significant corrections to be made to these results. Excess of water in the oxidation products, catalysis by the accumulating acids, and conversion of the reaction products in the later stages (*4*–*8*) promote ready hydrolysis of furyl formate when the process is conducted in water. This explains the low yields when furyl formate is isolated. The limiting stage in processes *1*–*8* is most probably formation of the hydroxy-hydroperoxide (stage *1*).

Table 4. Energies of formation of molecules and heats of oxidation of furaldehyde by hydrogen peroxide.

	water	alcohol	
Apparent activation energy E, kcal mole^{-1}	11.4	20.5	21.9
Pre-exponential factor A at 60°C, s^{-1}	$8.5 \cdot 10^{-5}$	$7.4 \cdot 10^{11}$	$5.1 \cdot 10^{11}$
Free energy of activation $\Delta G^{\neq}$ at 60°C, kcal mole^{-1}	24.7	24.7	25.7
Enthalpy of activation $\Delta H^{\neq}$ at 60°C, kcal mole^{-1}	10.7	19.8	21.2
Entropy of activation $\Delta S^{\neq}$ at 60°C, cal deg^{-1} mole^{-1}	−41.3	−14.6	−13.7

The experimental activation parameters of such complicated reactions as the oxidation of furan oxo-compounds by hydrogen peroxide (Table 5) apply in effect to the limiting stage of the process. As shown above, in water this is the stage of conversion of the carbonyl compound into a hydroxy-hydroperoxide. Oxidation in an anhydrous medium ceases at the first stage. The comparatively low activation energies are consistent with thermochemical calculations (Table 4) and the observed exothermic character of the process. The high activation energy for acetylfuran in comparison with furaldehyde corresponds to the above features of its oxidation. The lower activation energy of oxidation in water than in alcohol is consistent with the above role of water in the reaction. The experimental enthalpies of activation are closely similar to those calculated for the first stage in Scheme 7 (Table 4).

The low values of the pre-exponential factor (according to collision theory $A \simeq 10^{13}$ s^{-1}) suggest that the molecules are in contact and that the transition state is polar. The considerable degree of order of the transition state with loss of its rotational and translational degrees of freedom, as well as its polarity, is confirmed by the negative entropy of activation, which is possible in a system having a cyclic activated complex [159].

The autocatalytic character of the process is confirmed by the low entropy of activation [160]. The conclusion that, when oxidation takes place in water, the active stage is catalysed by acids accumulating during the reaction is supported by the identity of the activation energies for the oxidation of acetylfuran with and without acid catalysis [6], as well as by the lower activation energy in water than in alcohol (Table 5). Like the other experimental results cited, the activation parameters indicate that the action of hydrogen peroxide on furan oxo-compounds involves a transition complex and is autocatalytic.

Thus the investigations surveyed above indicate that the mechanism of the reaction of furan oxo-compounds with hydrogen peroxide and peroxy-acids represented by Scheme 7 is soundly based both experimentally and theoretically. The regularities elucidated in its occurrence and the effects of various factors permit this complicated consecutive and parallel process to be controlled with the aim of obtaining the most important products [1-18].

Dextran and Its Derivatives

A.D.Virnik, K.P.Khomyakov, and I.F.Skokova

The Review covers the physicochemical properties of dextran, the preparation of various types of derivatives, and the study of their properties and possible fields of application. Consideration is given also to the preparation of dextranates of alkali and alkaline-earth metals, complexes of dextran with multivalent metals, oxidation products of dextran and their derivatives, deoxy-derivatives, esters and ethers, dextran derivatives having a three-dimensional cross-linked structure, graft copolymers, and derivatives containing chemically attached medicinals. The production of many of the above derivatives is shown to extend considerably the possible applications of dextran. A list of 335 references is included.

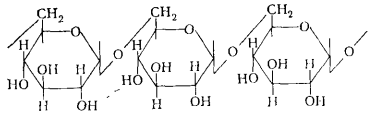
I. INTRODUCTION

"Dextran" is the group name for polysaccharides, obtainable by microbiological synthesis, whose main molecular chain consists of anhydro-D-glucopyranose units linked predominantly by α-1,6-glycosidic bonds



The macromolecules of various dextran preparations may contain also various quantities of α-1,2-, α-1,3-, and α-1,4-glycosidic bonds, by means of which side-chains are usually attached to the main chain. Dextrans have been obtained whose molecules are almost entirely unbranched, while the monomer units are 95% linked by α-1,6-glycosidic bonds.

Dextran is obtained from cultures of the micro-organisms—*Leuconostoc mesenteroides*, *Leuconostoc dextranicum*, *Streptobacterium dextranicum*, etc.—in a medium containing sucrose or other carbohydrates in which anhydro-D-glucopyranose units are present, including a dextran of low molecular weight. The product of microbiological synthesis is termed "native dextran".

Many strains of the above micro-organisms exist, and produce dextrans differing in structure and properties, i.e. in molecular weight, degree of branching of the macromolecules, relative contents of particular types of glycosidic links, solubility, optical activity, and physiological action. The molecular weight of native dextran is usually lowered by acid hydrolysis, generally with simultaneous decrease in the degree of branching of the macromolecules.

The polysaccharide dextran has become widely known because aqueous solutions of certain preparations of molecular weight $(35-70) \times 10^3$ and low degree of branching are effective substitutes for blood plasma. The advantage of dextran over carbon-chain polymers also employed for this purpose (polyvinylpyrrolidone, polyvinyl alcohol) consists in its gradual hydrolysis by enzymes in the organism. This eliminates the danger that the polymer will accumulate in organs of the macro-organism. A very important use of dextran is as starting material for the production of Sephadexes, which are widely employed in gel chromatography. Dextran and its derivatives are finding increasing applications for other purposes.

The microbiological synthesis, structure, biological properties, and application of the polysaccharide in medicine have been described in detail in reviews and monographs[1-13]. However, no systematic surveys have been made of the physicochemical properties of dextran and the preparation and properties of its derivatives. The present Review covers work published mainly during the past decade.

II. PHYSICOCHEMICAL PROPERTIES OF DEXTRAN AND ITS APPLICATION

Native dextran is a polymer of high molecular weight (reaching 10^7-10^8) and high polydispersity ($M_w/M_n = 10^2-10^3$).[14] Information on the determination of the molecular weight of native dextran will be found in Refs. 15 and 16.

The molecular weight of native dextran can be reduced by acid hydrolysis[17,18], enzymic depolymerisation[19], alcoholysis[20], thermal degradation[21], treatment with hydrogen peroxide[22], γ-irradiation[23-26], ultraviolet and X-ray irradiation[27,28], and the action of ultrasonic vibrations[29]. Under industrial conditions acid hydrolysis is used for this purpose. The nature of the acid—hydrochloric, perchloric, nitric, sulphuric, or orthophosphoric—has little effect on the quantitative proportions of the hydrolysis products[17]. Hydrolysis followed by fractionation enables the ratio M_w/M_n to be reduced to 1.2-1.5. Acid hydrolysis results also in a diminished degree of branching of the

dextran macromolecules, owing to the relatively high stability of the α-1,6-glycosidic bond to acid hydrolysis. A systematic investigation has been made by electron spin resonance of the nature of the radicals formed when dextran is exposed to ultraviolet radiation, X-rays, and γ-rays, and of the kinetics of their accumulation and destruction[24,25,27].

Partly hydrolysed dextran can be fractionated and its polydispersity determined by fractional precipitation from solution on addition of an oxidising agent[30,31], gel permeation using Sephadexes[32-35] and other gels[36-39], filtration through microporous membranes[40], and turbidimetric titration[41]. It dissolves in water, formamide, and dimethyl sulphoxide; various alcohols and acetone do not dissolve dextran, but precipitate it from solution.

Many physicochemical researches have been aimed at establishing a relation between the properties and the structure of dextran preparations. The infrared absorption band at 794 cm^{-1}, due to the presence of α-1,3-glycosidic links in the macromolecules, varies in intensity in the spectra of dextrans formed by different micro-organisms[42]. Measurement of the intensity has been used to determine the content of this type of glycosidic link in various dextran preparations[43]. The conformation of the monomer unit of carbohydrates has a significant influence on the infrared spectrum in the range 700–1000 cm^{-1}. Investigation of this region in the spectrum of dextran and its derivatives[44] led to the suggestion that the most probable conformation of the anhydro-D-glucopyranose units in dextran macromolecules is $C1$. Nuclear magnetic resonance and Raman spectra have been determined for dextran[45-47].

Thermogravimetric investigation of the structure of dextran[48,49] reveals endothermic peaks in the range 130–310°C on the thermograms of all the dextran preparations investigated. The peak in the region of 200°C is typical of dextrans containing mainly α-1,6-glycosidic links; the thermograms of dextrans containing a considerable quantity of α-1,3-glycosidic links included a peak near 245°C.

The structure of dextran macromolecules also influences the sorption of water vapour by the polymer[50,51]. The quantity of water sorbed by specimens in which the α-1,6-glycosidic links were accompanied by a considerable number of α-1,3- and α-1,4-bonds increased monotonically with increase in the relative water vapour pressure. With preparations having a high content of α-1,6-glycosidic links the quantity of sorbed water increased with the vapour pressure to 75–85%, after which it decreased. This phenomenon was attributed to crystallisation of the dextran. Preparations whose macromolecules are only slightly branched, with the branches consisting mainly of one or two anhydro-D-glucopyranose units, are evidently able to crystallise. Study of such a preparation[52] by means of an original method for determining the lengths of side-chains established that approximately 40% of the branches contained one glucose residue, 45% contained two residues, and only 15% had a longer chain. Examination of eight different preparations by X-ray diffraction established[53] that all the dextran polymers were amorphous.

During recent years investigations have been made[54,55] on several physicochemical properties of dextran produced in the USSR, obtained by the partial acid hydrolysis of native dextran formed by the strain *Leuconostoc mesenteroides* SF-4 (molecular weight 55 000). X-Ray diffraction and thermomechanical examination have shown that spray-dried dextran is amorphous (glass point 140°C, flow point 180°C), but is able to crystallise when certain temperature–time heat-treatment schedules are used (with relatively slow cooling from 190 to 20°C or with slow heating), and also on treatment with liquids in which it swells (water, formamide)[55]. The possibility of converting dextran into states of rubberlike elasticity and viscous flow is the first observation of these phenomena in polysaccharides. The crystallisation of dextran on heat-treatment and when treated with water or formamide results in the appearance of new absorption bands in the infrared spectrum and in selective increase in the relative intensity of individual bands, which can be explained by the predominance of certain types of rotational isomers that favour crystallisation. The heat of interaction of amorphous dextran with water is 29.5 cal g^{-1}, and the "water surface" calculated from the water-vapour sorption isotherm is 228 m^2 g^{-1}.[54]

Many studies have been made of dextran solutions, an important physical characteristic of which is their optical activity, which depends on the structure of the macromolecules—the content of α-1,3-glycosidic bonds—and on the nature of the solvent[58]. The value of $[\alpha]_D$ for aqueous solutions of various dextran preparations varies from +199° to +235°. Extrapolation to zero content of such bonds gives 194.6°.[56,57] The optical activity of dextran solutions is unaffected by the presence of α-1,4-glycosidic bonds[56,57]. The influence of the solvent on $[\alpha]_D$ has been investigated[58]. Study of the optical rotation of dextran in cuprammonium solution indicates that the monomer units in the dextran macromolecules have the $C1$ conformation[59]. Similar conclusions were reached[60] from an n.m.r. study of a solution of dextran in dimethyl sulphoxide.

Several investigations have been made recently of the interaction of dextran macromolecules with the solvent. The macromolecules of several preparations of native dextrans form structural association complexes with the solvent[61]. The possibility of such association was examined in terms of the helical structure of native dextran stabilised by intramolecular hydrogen bonds and of the character of the hydrogen bonds formed in solution. The form of the macromolecules and the viscosity of aqueous solutions are affected by the presence of other substances: the asymmetry of the macromolecules of native dextran is greater in aqueous solutions of urea and glucose and in concentrated salt solutions than in water, but is less in aqueous methanol[15].

Study of the rheological properties of aqueous solutions of dextran (M_W = 120 000) over a wide concentration range revealed a sharp change at concentrations of 40–43%.[62] This was attributed to the structure of the hydration sheath of the macromolecules: an abrupt change in viscosity occurs when the composition corresponds to the formation of $1\frac{1}{2}$ layers of water molecules around each dextran macromolecule. Nuclear magnetic resonance has been used to study the interaction of water with dissolved dextran macromolecules[63], and electron microscopy to determine the size and configuration of the macromolecular aggregates in solution[64].

Viscosimetry has certain limitations as a method for determining the molecular weight of dextran. The constants K and α in the formula $[\eta] = KM^{\alpha}$ are different for dextran preparations differing in degree of branching or in the proportions of the various types of glycosidic bonds in the macromolecules. Examination of various dextran preparations by light scattering established[65] that, when 15–20 α-1,6-glycosidic bonds are present per glycosidic bond of a different type, the molecular weight of the dextran can be calculated by means of the formula $[\eta] = 0.00218M^{0.43}$; with greater branching of the macromolecules, when the ratio becomes 2–3, the coefficients K and

α are respectively 0.0044 and 0.34. Soviet dextran (polyglucin) preparations conform to the expression $[\eta] = 0.000966M^{0.5}$ over the range of molecular weights 40 000–100 000.[66]

The intrinsic viscosity of aqueous solutions of hydrolysed dextran is increased by the addition of potassium thiocyanate and calcium chloride, but diminished by lithium and potassium chlorides[67]. It depends also on the solution pH.[68] The variation in viscosity is attributed to variation in the character and number of intramolecular hydrogen bonds. The relation between the degree of branching of the macromolecules of dextrans and other natural polymers and the viscosity of their solutions has been studied[69,70]. The effects of the nature of the solvent (water, formamide, aqueous methanol, and aqueous dimethylformamide), the molecular weight of the dextran (M_n = 4100–32 000), and the temperature on the intrinsic viscosity of the solutions have been investigated[71]. Various aspects of the use of viscosimetry to determine the molecular weight of dextran have also been discussed[72–76].

Several papers have also appeared during recent years on the conformational transitions of dextran macromolecules in solution[77], the determination of virial coefficients[72,78], increments of the refractive indices of aqueous solutions of dextran[79], the heat and entropy of mixing of dextran with water over a wide concentration range[78], and the study of osmotic pressure and the scattering of light in aqueous solutions[72,78,80–82].

Applications of Dextran

As mentioned above, dextran is widely used to prepare most effective plasma substitutes for application in shock and the loss of blood; these are manufactured in various countries under the names polyglucin, dextran, Macrodex, Expandex, Intradex, and Dextraven[7]. The use of dextran for the production of Sephadexes is discussed in Section VIII. Other uses of dextran have also been reported—for preparing various forms of medicines (tablets, capsules for pharmaceutical preparations, eye-drops)[83–85], in the foodstuffs industry[86], in drilling, and in the production of cosmetic agents[87]—and the production of fibres from dextran has been patented. As mentioned above, dextran is hydrolysed by enzymes in the organism[88–92], so that considerable interest attaches to obtaining from dextran fibres or other articles (e.g. pins for joining bones in fractures) for use in surgery, when they would be gradually absorbed in the organism.

III. DEXTRANATES OF ALKALI AND ALKALINE-EARTH METALS AND COMPLEXES OF DEXTRAN WITH MULTIVALENT METALS

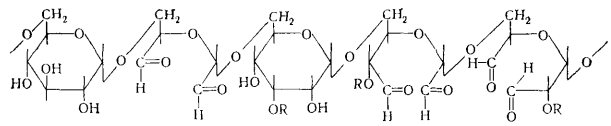
With alkali and alkaline-earth metals dextran forms alkoxides termed "dextranates". Sodium dextranate is produced when dextran is treated with a solution of sodium in liquid ammonia[93,94]; calcium dextranate, containing up to 20% of calcium, can be obtained according to a patent[95] from dextran and a calcium alkoxide of a lower alcohol. Dextranates are used as intermediates in the preparation of other dextran derivatives, e.g. its graft copolymers[94] and ethers[93].

Complex compounds of dextran have been described with Cuoxene $[Cu(NH_2CH_2CH_2NH_2)_2](OH)_2$ and Cadoxene $[Cd(NH_2CH_2CH_2NH_2)_3](OH)_2$.[96] The scientific and patent literature contains reports of the formation of compounds of dextran (probably complex) with hydroxides of several multivalent metals—calcium(II), bismuth(III), lead(II), cerium(III), lanthanum(III), chromium(III), aluminium(III), copper(II), cobalt(II)[97–99], and also iron(III)[100–108]—the exact structure of most of which has not been established. They are generally obtained by reaction between dextran and salts of the metals in an alkaline medium (sometimes in the presence of other compounds of low molecular weight, in particular those possessing complexing properties). In some cases dextran is pretreated with a reductant (e.g. sodium tetrahydroborate) or an oxidant (hydrogen peroxide). The largest number of patents and scientific papers deal with the preparation and study of the compound of dextran with iron(III) hydroxide, which is used for the treatment of anaemia in veterinary practice and is produced in several countries. Information is available also on the biological properties of compounds of dextran with hydroxides of other multivalent metals[97,99].

IV. PREPARATION OF OXIDATION PRODUCTS AND THEIR DERIVATIVES

The main lines of development of this branch of the chemistry of dextran during the past decade have been the use of additional oxidants to obtain carbonyl-containing derivatives and the preparation of several new derivatives from oxidation products of dextran.

Complete oxidation with periodic acid has long been used, together with other methods, to study the structure of dextran macromolecules. Investigation of the influence of the conditions of oxidation on the content of formyl groups in the water-soluble reaction product (which can provisionally be named "dialdehydodextran" by analogy with "dialdehydocellulose") showed[109] a high rate of reaction in a homogeneous medium (oxidation was complete in 25 min in the presence of 1 mole of periodic acid per monomer unit). The structure of the product of the partial oxidation of dextran by periodic acid can be represented by



Since the 1740-cm^{-1} band in the infrared spectrum of this polymer is very weak[110], however, it may be concluded that most of the aldehyde groups are not in the free state but probably involved in the formation of acetal, hemiacetal, and hemialdol[110] bonds or are present in the hydrated form. Study of the stability in an alkaline medium (pH $\geq$ 10) of dextran oxidised with periodic acid shows that hydrolysis of the glycosidic links is then accompanied by the Cannizzaro reaction with the formation from two formyl groups of one carboxy- and one hydroxy-group[111,112].

The oxidation of dextran by lead tetra-acetate in dimethyl sulphoxide, which also yields dialdehydodextran, is more rapid than oxidation by sodium periodate in aqueous solution[113]. Oxidation with a mixture of dimethyl sulphoxide and acetic anhydride gives a polymer containing keto-groups[114,115]. Under these conditions oxidation involves mainly hydroxy-groups at position 3 in the monomer unit of dextran[114]. A side-product of oxidation with dimethyl sulphoxide and acetic anhydride is the methylthiomethyl ether of dextran. The aqueous solubility of preparations from this dextran derivative depends both on the degree of

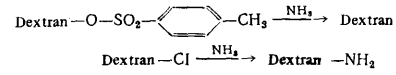
oxidation and on their sulphur content[115]. Water-soluble keto-derivatives can be obtained by oxidising dextran with chlorobenzotriazole[115]. In contrast to dialdehydodextran, the above keto-derivatives are quite resistant to alkaline hydrolysis (pH 9.5 at 20°C).[115]

Dialdehydodextran has been used to prepare derivatives containing carboxy- and amino-groups, the former by oxidation with sodium chlorite[109] and the latter by treatment with liquid ammonia in the presence of Raney nickel under pressure[116]. Degradation accompanying the action of aqueous ammonia on dialdehydodextran at high temperatures leads to the formation of imidazole and 4-methylimidazole[117].

The above dextran derivatives containing formyl, carboxyl, and keto-groups have been used to prepare derivatives containing chemically attached medicinal compounds (isonicotinohydrazide, novocaine, sulphanilamide, serotonin, morphine, Promedol, and various antibiotics)[118-124]. The infrared spectra of several of these compounds have been published[110,115,121]. Intraperitoneal injection of dialdehydodextran enhances the resistance of mice to infection with pathogenic strains of *Escherichia coli* [125, 126].

V. DEOXY-DERIVATIVES OF DEXTRAN

Study of the preparation of deoxy-derivatives of dextran containing halogen, thiol, and amino-groups has begun during recent years. Deoxyiodo-derivatives have been obtained[115] by nucleophilic substitution when dextran is treated with methyltriphenoxyphosphonium iodide and when sodium iodide acts on dextran toluene-*p*-sulphonate or nitrate. The fact that deoxyiododextran having a degree of substitution of 0.71 can be obtained from dextran toluene-*p*-sulphonate shows the possibility of replacing by halogen toluene-*p*-sulphonyloxy-groups attached to secondary carbon atoms in the anhydro-D-glucopyranose monomer unit. A water-soluble chlorodeoxydextran has been prepared by treating dextran with thionyl chloride in dimethylformamide[115,127]. Aminodeoxy-derivatives have been obtained[115,127] by nucleophilic substitution:



A deoxymercapto-derivative of dextran has been obtained by pyrolysis of the product of the oxidation of dextran xanthate with sodium nitrite followed by treatment of the resulting polymer with alkali[128].

VI. DEXTRAN ESTERS

Development of this branch of the chemistry of dextran in recent years has been characterised by the study of new methods for preparing already known esters, the elaboration of methods for obtaining new types of esters (including those containing residues of natural compounds—α-amino-acids and heterocyclic bases present in ribonucleic and deoxyribonucleic acids), and investigation of the properties and possible fields of application of dextran esters.

Esters with Inorganic Acids

The most fully studied ester is dextran sulphate, usually obtained by treating dextran with chlorosulphuric acid in absolute pyridine. Sulphur trioxide, sulphuryl chloride, oleum, concentrated sulphuric acid, and piperidine-*N*-sulphonic acid can also be used[129-134]. The reaction can be conducted in dimethylformamide, formamide, methylpyridine, dioxan, or dimethyl sulphoxide. Treatment of dextran with piperidine-*N*-sulphonic acid dissolved in dimethyl sulphoxide enables a uniformly substituted dextran sulphate to be obtained without significant fall in the degree of polymerisation[133]. The distribution of sulphate groups in the dextran sulphate macromolecule obtained in a heterogeneous system is non-uniform[135].

Alkaline saponification of dextran sulphate followed by complete acid hydrolysis of the product yields not only glucose but also altrose, mannose, and gulose[135,136]. Formation of such monomer units in the polysaccharide macromolecules is due to change in the configuration of the hydroxy-groups accompanying cleavage in an acid medium of the α-oxide rings formed by saponification of the sulphate groups.

Measurement of the viscosity of dextran sulphate solutions of different ionic strengths indicates that the macromolecules are highly flexible[137]. The interaction of dextran sulphate with various inorganic cations and organic cations of low molecular weight has been studied[138-142].

The ability of dextran sulphate to form compounds with various biopolymers enables it to be used to separate, isolate, and purify proteins, nucleic acids, lipoproteins, and viruses[143], and is also the reason for various aspects of its biological activity. Much work has been done on the possibility of using dextran sulphate as a blood anticoagulant. Despite the pronounced effect obtained with a dextran sulphate of high molecular weight, however, the strong toxic action on the organism has prevented its practical application.

During recent years, however, interest has been renewed in the preparation of less toxic forms of dextran sulphate, and in the study of its possible application as a blood anticoagulant[133, 144, 145] and for other purposes in biology, biochemistry, and medicine. The results obtained from investigation of the medicobiological properties of dextran sulphate are summarised below. Dextran sulphate intensifies the antiviral activity of interferon in experiments *in vitro*[146,147], and itself possesses antiviral activity *in vitro*[148-150], but was inactive in experimental influenzal infections of white mice[148,151]. Dextran sulphate inhibits the activity of proteinases[152,153] and lipoprotein lipase[154], when its molecular weight has a significant influence on the degree of inhibition. It is therefore suggested[152] that dextran sulphate can be used to treat gastric ulcers. Products of its reaction with aluminium salts have been patented for this purpose[155,156]. Dextran sulphate possesses antilipaemic activity[130,133], and inhibits the template activity of deoxyribonucleic acids[157] and the respiratory activity of the mitochondria of rat liver cells in a medium of low ionic strength[158]. In the latter case it was assumed that the sulphate prevents the entry of nucleotides into the mitochondria. In experiments on mice spleen cells dextran sulphate inhibited the formation of antibodies on the injection of sheep erythrocytes[159]. It has been proposed also for the preparation of polymeric medicinals[160] and of photographic films[161].

According to the patent literature dextran phosphates can be prepared by the action of phosphoryl chloride in pyridine followed by treatment of the product with caustic soda or directly in the presence of the alkali. They have recently been obtained by treating dextran with a mixture of polyphosphoric acid and a trialkylamine[162]. Dextran phosphates form complexes with lipoproteins[163], and can

be used to obtain polymeric medicinals and photographic materials[164].

Studies have been made on the effect of the reaction conditions on the composition of nitric esters formed by the nitration of dextran with concentrated nitric acid and various nitrating mixtures[55,165-167]. Nitration with a mixture of 64% of nitric acid, 26% of orthophosphoric acid, and 10% of phosphorus pentoxide produces no decreases in the degree of polymerisation of dextran[168]. Highly substituted dextran nitrates are soluble in acetone, dimethylformamide, cyclohexanone, and oxolan. The infrared spectra over the range 700–1000 cm^{-1} indicate that the monomer units of dextran nitrate macromolecules have the same conformation ($C1$) as those of dextran itself[55,167]. Dextran trinitrate is an amorphous polymer[55], which absorbs water vapour[54]. Dextran xanthates have been obtained[169] and proposed for use in fibre production and the finishing of paper and textiles. Dextran methyl xanthate has been prepared and subjected to pyrolysis at 160°C.[170]

Esters with Organic Acids

Detailed investigations on the acetylation of dextran with various acetylating mixtures have yielded dextran acetates having degrees of substitution up to 3.0[55,167,171-173]. The rate of acetylation depends significantly on the conditions of preliminary activation of the dextran: a sharp increase in rate was observed after preliminary activation by reprecipitation from water into glacial acetic acid[55,167]. The infrared spectrum over the range 1270–1420 cm^{-1} of dextran activated in this way differs markedly from those of non-activated dextran and of dextran activated by treatment with glacial acetic acid[55,167].

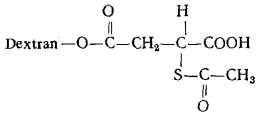
Investigation of the distribution of substituents in partly substituted dextran acetates has shown that acetylation of dextran with acetic anhydride in the presence of sodium acetate gives a product in which the 2-, 3-, and 4-hydroxyls are approximately equally reactive, whereas the 2-hydroxy-groups are most reactive in the product obtained with acetic anhydride in an equimolecular mixture of formamide and pyridine[172]. Since the infrared spectrum of dextran triacetate at 700–1000 cm^{-1} is identical with that of dextran, the monomer units in the corresponding macromolecules can be assumed to have the same conformation ($C1$). Only one solvent—symmetrical tetrachloroethane—is at present known for the triacetates of various dextran preparations[167,171,173,174]. The formula $[\eta] = 10^{-3}M^{0.5}$ has been proposed[171] for the viscosimetric determination of the molecular weight of dextran triacetate in this solvent.

Thermomechanical examination and X-ray diffraction indicate that dextran triacetate is a crystalline polymer (melting point 210°C).[55] The crystalline structure was improved by heating in tetrachloroethane and evaporating off the solvent. The heats of interaction of dextran triacetate with water and with dimethylformamide are respectively 3.0 and −9.4 cal g^{-1}, while the "water surface" calculated from the water-vapour sorption isotherm is 45 $m^2 g^{-1}$.[54]

Esters of dextran with aromatic carboxylic acids (benzoic, acetylsalicylic, cinnamic, nitrobenzoic) have been prepared by treating the polysaccharide with the acid chlorides in absolute pyridine[175] and by nucleophilic substitution of dextran nitrate by the action of the sodium salts in aqueous dimethylformamide[176]. The latter reaction has an S_N2 mechanism. Dextran phenyl diphenylcarbamate is obtained by the action of phenyl isocyanate on dextran[177]. The succinate, maleate, and phthalate, which are able to form complexes, have been obtained by the action of the acid anhydrides in formamide and pyridine[178,179]. Treatment of dextran maleate with sodium hydrogen sulphite yields an ester containing both carboxylate and sulphonate groups:

$$\text{Dextran}\!-\!OCOCH\!=\!CH\!-\!COOH + NaHSO_3 \rightarrow \text{Dextran}\!-\!OCOCH_2\!-\!\underset{\displaystyle SO_3Na}{\underset{|}{CH}}\!-\!COOH .$$

Dextran reacts with S-acetylthiosuccinic anhydride to give the corresponding ester[180]:

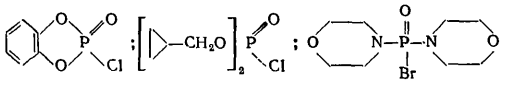


A systematic investigation has been made of the preparation of dextran esters of N-substituted α-amino-acids and the possibility of obtaining from them derivatives of dextran containing a free amino-group[181-188]. The esters were obtained by the action of the acids in the presence of NN'-dicyclohexylcarbodi-imide[181,182] by a method providing for the formation of mixed anhydrides[183-185] (these are formed when the amino-acids are treated with ethyl chloroformate, phosphoryl chloride, toluene-p-sulphonyl chloride, or benzenesulphonyl chloride in the presence of an organic base), by treating dextran with imidazolides of N-protonated α-amino-acids (obtained by the reaction of trifluoroacetates or hydrochlorides of the α-amino-acids with thionyl- or carbonyl-bi-imidazolyl)[186,187], and also by transesterification of p-nitrophenyl esters of the N-substituted α-amino-acids with dextran in dimethyl sulphoxide in the presence of excess of imidazole[188].

Of the various groups used to protect the amino-group in the acids nitrophenylsulphonyl is the most easily removed, by treatment with thiophenol in a mixture of dimethyl sulphoxide and pyridine or in the sodium thiosulphate–potassium iodide system in aqueous solution[183]. When dextran is treated with N-protonated imidazolides of α-amino-acids, poly(amino-acid) residues are added to the macromolecule[186]. Adenine, thymine, and uracil residues are introduced into the macromolecule by treating dextran with the carboxymethylated bases in the presence of dicyclohexylcarbodi-imide[189]; the resulting dextran esters form compounds with polynucleotides.

Toluene-p-sulphonic and methanesulphonic esters of various polysaccharides are widely used as intermediates for preparing derivatives of the polysaccharides by nucleophilic substitution. Considerable interest therefore attaches to the recent preparation of the dextran esters from the acid chlorides[115,190]. A similar scheme has been used to prepare the 5-dimethylaminonaphthalene-1-sulphonic ester (which is fluorescent)[191] and the p-iodobenzenesulphonic ester[192]. The latter has been proposed for preparing tissues of various animal organs for electron microscopy.

Phosphorus-containing esters can be obtained[193] by treating dextran with compounds of the type



A compound which may be used to detect specific immunoglobulin receptors on the surface of tumour cells is obtained by the action of fluorescein isothiocyanate on dextran[194]. A water-soluble ester is obtained from dextran and a chlorotriazine reactive blue dye (Dextran Blue

2000), which can be used to determine the dead space in column gel permeation, to check that the column is correctly packed, and as substrate in estimating the activity of enzymes that hydrolyse dextran[195-202]. Dextran coloured with a reactive orange dye has been suggested for use in thin-layer gel permeation[203,204].

VII. DEXTRAN ETHERS

The main lines of development at present are the preparation of ethers containing various reactive functional groups, elaboration of new methods for preparing already known ethers, determination of the distribution of alkyl groups at carbon atoms in the anhydro-D-glucopyranose unit, and study of the properties and possible fields of application of dextran ethers.

The completely substituted methyl ether of dextran had been obtained earlier by repeatedly treating sodium dextranate with methyl iodide or dextran with dimethyl sulphate or methyl iodide in the presence of alkali. This ether has now been obtained[205] by treating dextran acetate, which is soluble in acetone, first with dimethyl sulphate and then with methyl iodide in the presence of silver oxide. A single-stage preparation of the completely substituted methyl ether involves treating dextran in dimethyl sulphoxide with methyl iodide in the presence of the methylsulphonylmethyl carbanion in an atmosphere of nitrogen[206].

In the methylation of dextran with dimethyl sulphate in a homogeneous medium the relative rate constants for the hydroxyls at positions 2–4 are 8 : 1 : 3.5.[207] The probable reason is that the 2-hydroxyl, in the α-position to the glycosidic link and arranged equatorially in the monomer unit of dextran, is more acidic than the hydroxyls at positions 3 and 4. The 3-hydroxyl shows the lowest reactivity also in the methylation of dextran with methyl iodide[55]. Infrared spectra have been published for methyl ethers of dextran of different degrees of substitution[167]. An ethyl ether has been obtained by treating dextran dissolved in 10% caustic soda with ethyl bromide[55,167].

Dextran ethers containing hydroxyalkyl groups—2-hydroxyethyl, 2-hydroxypropyl, 2-hydroxybutyl—can be obtained, according to the patent literature, by the action of compounds containing α-oxide rings or 1,2-halogenohydrin groups on dextran in alkaline medium. Reaction between dextran and epoxides may yield not only the ether but also graft copolymers by interaction of the epoxides with the hydroxy-groups in the alkyls:

$$\text{Dextran}-O-CH_2-CH_2OH + n\,CH_2-CH_2 \rightarrow \text{Dextran}-O(CH_2CH_2O)_n-CH_2CH_2OH\ .$$

The distribution of alkyl groups in a 2-hydroxyethyl ether obtained by the action of oxiran on dextran dissolved in 0.25% caustic soda has recently been examined[208]. Analysis by gas–liquid chromatography with reference samples of the products of the acid hydrolysis of the ether shows that the alkyls are distributed among positions 2–4 in the proportions 5.8 : 1 : 3.

Preparation of the water-soluble 3-chloro-2-hydroxypropyl ether by treating dextran with epichlorohydrin in the presence of zinc tetrafluoroborate[209]

$$\text{Dextran}-OH + CH_2-CH-CH_2Cl \xrightarrow{Zn(BF_4)_2} \text{Dextran}-O-CH_2-CH(OH)-CH_2Cl$$

is of considerable interest as a method of introducing reactive chlorohydrin groups into the macromolecule. This ether is the starting material for the preparation of other dextran ethers[210-212] and polymeric medicinals[115,119,121,123,124]. A dextran derivative labelled with radioactive iodine can be obtained by first treating dextran with allyl bromide and then iodinating the resulting allyl ether with radioactive iodine[213,214].

Cyanoethyl and carbamoylethyl ethers of various degrees of substitution have been prepared by nucleophilic addition to dextran of acrylonitrile and acrylamide in the presence of caustic soda[167,168,210,211,215]:

$$\text{Dextran}-OH + CH_2=CH-CN \rightarrow \text{Dextran}-O-CH_2-CH_2-CN$$

$$\text{Dextran}-OH + CH_2=CH-C(=O)-NH_2 \rightarrow \text{Dextran}-O-CH_2-CH_2-C(=O)-NH_2\ .$$

Investigation of cyanoethyl ethers of low degrees of substitution has established that cyanoethylation of one of the secondary hydroxyls in a monomer unit of dextran diminishes the rate of cyanoethylation of the other secondary hydroxyls in that unit[55,167]. In the initial stage acrylonitrile reacts mainly with the 2- and 4-hydroxyls[55]. A cyanoethyl ether of degree of substitution 3.0 is crystalline (melting point 80°C)[55], and its crystal structure is improved by heating it in dimethylformamide and then evaporating off the solvent. Data have been published on the sorption of water vapour and the heats of interaction with water and with dimethylformamide for this ether[54], and infrared spectra for cyanoethyl ethers of dextran having various degrees of substitution[167,216].

A trityl ether can be prepared[168,217] by treating dextran with chlorotriphenylmethane in the presence of pyridine:

$$\text{Dextran}-OH + ClC(C_6H_5)_3 \rightarrow \text{Dextran}-O-C(C_6H_5)_3\ .$$

An ether has been prepared also with oxan-2-ol[218]. The addition of D-mannose and D-xylose to dextran has been reported[219].

Dextran Ethers containing Ionogenic, Complexing, or Electron-exchange Groups

Increasing interest has been taken during recent years in the preparation, properties, and fields of application of dextran ethers containing ionogenic, complexing, or electron-exchange groups. A considerable number of scientific papers and patents have been published on the preparation and application of the carboxymethyl ether[220-222], obtained by treating dextran with sodium chloroacetate in the presence of caustic soda:

$$\text{Dextran}-OH + ClCH_2COONa \xrightarrow{NaOH} \text{Dextran}-OCH_2COONa\ .$$

The patent literature describes the application in veterinary practice of compounds (probably complex) formed in an alkaline medium between dextran carboxymethyl ether and iron hydroxide (for the treatment of anaemia), as well as cobalt and copper hydroxides. The product obtained from the ether with a basic aluminium salt has been proposed for the treatment of ulcers. The ether can be used also for the preparation of polymeric medicinals[115,119,120,123,124], the production of long acting forms of medicines (tablets), X-ray contrast media, cosmetic preparations, paints and varnishes, and in the foodstuffs industry[9,223,224]. Various methods for preparing derivatives of dextran carboxymethyl ether containing α-amino-acid residues have been studied in detail[225-228].

In the presence of caustic soda dextran reacts with the sultone of 3-hydroxypropanesulphonic acid, chloromethylphosphonic acid, and thi-iran to give the water-soluble

sulphopropyl, dihydroxyphosphinylmethyl, and mercaptoethyl ethers[209,210,229]:

$$\text{Dextran}-OCH_2CH_2CH_2SO_3Na, \quad \text{Dextran}-OCH_2PO(ONa)_2,$$
$$\text{Dextran}-OCH_2CH_2-SNa$$

The first of these ethers is a strong polyelectrolyte; the second and third ethers possess respectively complexing and electron-exchange properties. The infrared spectra have been published[230]. The sulphopropyl ether exhibits anticoagulant activity, and has been used to obtain polymeric medicinals[115,119-124,231].

Several new water-soluble dextran derivatives containing various ionogenic, complexing, and electron-exchange groups have been prepared[115,121,168,210-212,232] by the action on the 3-chloro-2-hydroxypropyl ether of ammonia, aliphatic amines, aliphatic and aromatic amino-carboxylic acids, hydrazine, sodium sulphide, and other compounds according to the general scheme

$$\text{Dextran}-OCH_2-\underset{\underset{OH}{|}}{CH}-CH_2Cl \xrightarrow{HX} \text{Dextran}-OCH_2-\underset{\underset{OH}{|}}{CH}-CH_2X + HCl$$

where X is a molecular residue of one of the above monomeric agents. Water-soluble dextran ethers containing thiocarbamoyl and amidrazone groups, which possess complexing properties, have been prepared[168,213] from the cyanoethyl ether:

$$\text{Dextran}-OCH_2-CH_2CN \xrightarrow{H_2S} \text{Dextran}-OCH_2-CH_2C(=NH)SH$$
$$\text{Dextran}-OCH_2-CH_2CN \xrightarrow{H_2NNH_2} \text{Dextran}-OCH_2-CH_2C(=NH)NH-NH_2 .$$

The infrared spectra of these ethers have been published[219]. The above dextran derivatives, containing various complexing groups and prepared from the 3-chloro-2-hydroxypropyl and cyanoethyl ethers, form water-soluble complexes with several bivalent metals—copper, cobalt, nickel, and mercury—whose stability constants have been given in Ref. 168.

Treatment of dextran in alkaline medium with 1-diethylamino-2,3-epoxypropane and 1-chloro-2-diethylaminoethane yields[233,234] the 3-diethylamino-2-hydroxypropyl and diethylaminoethyl ethers

$$\text{Dextran}-O-CH_2-\underset{\underset{OH}{|}}{CH}-CH_2-N(C_2H_5)_2, \quad \text{Dextran}-O-CH_2CH_2-N(C_2H_5)_2 .$$

The diethylaminoethyl ether has been quaternised with benzyl chloride[235]. Dextran ethers containing primary and tertiary aliphatic amino-groups have been investigated by potentiometric titration[121,236-238]. Viscosity measurements on solutions of carboxymethyl, diethylaminoethyl, and quaternised diethylaminoethyl ethers of dextran at various ionic strengths[137] suggest that the ether macromolecules are very flexible. A water-soluble ether containing aromatic amino-groups has been prepared[210] by treating dextran in alkaline medium with the sulphuric ester of 2-(3-amino-4-methoxyphenylsulphonyl)ethanol:

$$\text{Dextran}-OH + NaO_3SOCH_2-CH_2-O_2S-C_6H_3(NH_2)(OCH_3) \xrightarrow{Na_2CO_3}$$
$$\rightarrow \text{Dextran}-OH + CH_2=CH-SO_2-C_6H_3(NH_2)(OCH_3) \xrightarrow{NaOH}$$
$$\rightarrow \text{Dextran}-OCH_2CH_2SO_2-C_6H_3(NH_2)(OCH_3) .$$

The resulting 2-(3-amino-4-methoxyphenylsulphonyl)ethyl ether was used for the preparation of graft copolymers of dextran[214,239,240]. Dextran reacts also with chlorotrialkyl(aryl)silanes and hexa-alkyldisilazanes[241].

Several workers have shown that the diethylaminoethyl ether of dextran enhances interferon formation and antiviral activity caused by the introduction of polynucleotides into animals or into a cellular culture[242-244]. Pretreatment of the cells (before introduction of polynucleotides) with the diethylaminoethyl ether also increases viral resistance. The 3-diethylamino-2-hydroxypropyl ether of dextran possesses similar properties[245]. Nevertheless, the diethylaminoethyl ether increases the infective activity of viruses[246-249]. The reasons for these phenomena are firstly that this dextran ether protects nucleic acids and polynucleotides (by forming compounds with them) from the degrading action of nucleases and secondly that it promotes penetration of polynucleotides and nucleic acids into the cells by reacting with the cell membrane[242,246,248-250]. However, it has been stated[251,252] that dextran diethylaminoethyl ether is also able to suppress the growth of viruses.

VIII. DERIVATIVES WITH A THREE-DIMENSIONAL CROSS-LINKED STRUCTURE

Derivatives of dextran having a three-dimensional cross-linked structure, known under the general name Sephadexes, are obtained by treatment with epichlorohydrin in an alkaline medium[253-256]. Intermolecular bonds are formed by the reactions

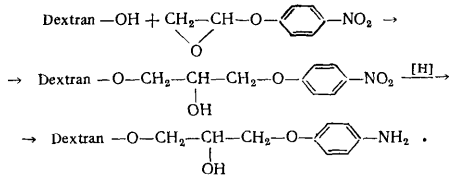
$$\text{Dextran}-OH + CH_2-\underset{\underset{O}{\diagdown\diagup}}{CH}-CH_2-Cl \xrightarrow{NaOH}$$
$$\rightarrow \text{Dextran}-O-CH_2-\underset{\underset{OH}{|}}{CH}-CH_2-O-\text{Dextran} .$$

Sephadexes of different degrees of cross-linking, differing in gel pore size and in ability to swell in water, are obtained by varying the reactant concentrations and also the molecular weight of the dextran. Several brands of Sephadex G are marketed at the present time, and are widely used in gel permeation in aqueous media for preparative and analytical purposes[257-260]. Other cross-linking agents suitable for application to dextran are glycidyl tetramethylene ether[261] and 1,2 : 3,4-diepoxybutane[256]. Cross-linked dextran derivatives can be used in perfumery and cosmetics[262].

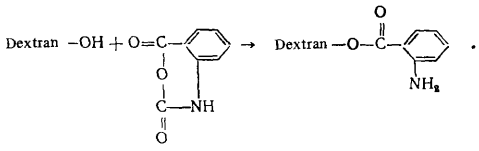
Alkylation or acylation of the hydroxy-groups of the dextran macromolecules in Sephadexes yields derivatives which swell well in organic solvents while retaining the ability to fractionate substances according to molecular dimensions. The hydroxyls of the dextran can be blocked by subjecting Sephadexes to acetylation[263,264], benzoylation[265], methylation[266], or treatment with aliphatic isocyanates[267] or aliphatic α-oxides[268]. Thus Sephadex LH-20 is Sephadex G-25 treated with an aliphatic epoxide.

Cross-linked dextran derivatives have been obtained containing aminoethyl[269], sulphoethyl[270] and sulphopropyl, carboxymethyl[270,271], diethylaminoethyl[270,272], and quaternary ammonium groups[273]; the last four are marketed under the respective names SP, CM, DEAE, and QAE Sephadexes[274]. These Sephadexes possess ion-exchange properties and are widely used for the separation of biologically active substances such as proteins, hormones, nucleic acids, etc.

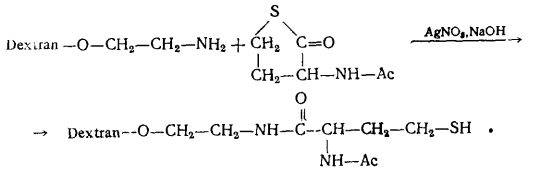
Cross-linked dextran ethers containing aromatic amino-groups have been prepared in three ways. Firstly, treatment of a cross-linked dextran derivative with 1,2-epoxy-1-*p*-nitrophenoxypropane is followed by reduction of the nitro-groups to amino[275,276]:



The second method consists in reaction between a cross-linked dextran derivative and the sulphuric ester of 2-(3-amino-4-methoxyphenylsulphonyl)ethanol[277]. Thirdly, carbon dioxide is evolved when dextran is treated with *N*-carboxyanthranilic anhydride[278]:



A derivative containing isothiocyanato-groups was obtained by treating a cross-linked 3-*p*-aminophenoxy-2-hydroxypropyl ether of dextran with thiocarbonyl chloride[275]. These polymers, containing isothiocyanato- or aromatic amino-groups, are used to prepare insoluble derivatives of enzymes and antibodies. A cross-linked dextran derivative containing mercapto-groups was prepared[269] by the reactions



This polymer can be used to prevent the oxidation of compounds containing thiol groups[279,280].

A cross-linked dextran derivative containing an organomercury residue (which can be used to isolate proteins containing thiol groups) has been obtained[281] by alkylating dextran with 1-allyloxy-2,3-epoxypropane and then treating with mercury acetate. Patents and scientific papers[282-284] have reported the preparation of cross-linked dextran derivatives possessing complexing properties. An insoluble cross-linked dextran derivative coloured with a reactive dye can be used as substrate in studying the activity of enzymes that hydrolyse dextran[261]. The rate of oxidation of Sephadexes by periodic acid is not much lower than the rate of oxidation of dextran in solution[285].

IX. PREPARATION OF GRAFT COPOLYMERS OF DEXTRAN

Graft copolymers of dextran have been obtained with carbon-chain polymers, starch, polypeptides, and biologically active proteins (enzymes, antigens, and hormones). Detailed investigations of the preparation of graft copolymers with polyacrylic acid and with poly-2-methyl-5-vinylpyridine used as initiators redox systems in which the oxidants were cerium(IV) or vanadium(V) compounds and the reductants respectively dextran or its 2-(3-amino-4-methoxyphenylsulphonyl)ethyl ether[214,239,240]. These methods of preparation enabled the length of the grafted chain to be controlled, and water-soluble graft copolymers of dextran with polyacrylic acid or with poly-2-methyl-5-vinylpyridine containing up to 30–40% of the grafted polymer to be obtained without accompanying formation of a carbon-chain homopolymer.

These methods are characterised by high reaction velocities, the formation of comparatively short grafted chains, and a high degree of involvement of macromolecules of the 2-(3-amino-4-methoxyphenylsulphonyl)ethyl ether of dextran (up to 70% in the grafting of polyacrylic acid), which are explained by the occurrence of copolymerisation in a homogeneous medium. Cerium(IV) compounds have been used to initiate the graft copolymerisation of comparatively short polyacrylamide chains with dextran[286]. A graft copolymer of dextran and poly(methyl methacrylate) has recently been synthesised by anionic polymerisation involving treatment of a dextranate with methyl methacrylate in the presence of dimethyl sulphoxide[287]. A graft copolymer of dextran and polytyrosine is obtained by treating the aminoethyl ether of dextran with the anhydride of *N*-carboxy-L-tyrosine[288]. Graft copolymers of dextran and polypeptides have been obtained also by treating sodium dextranate with anhydrides of other *N*-carboxy-*α*-amino-acids[184], by reaction between the carboxymethyl ether of dextran and a peptide in the presence of dicyclohexylcarbodi-imide, and by acylating dextran with a succinyloligopeptide in the presence of dicyclohexylcarbodi-imide[289].

The starting material in the preparation of a graft copolymer with starch is a cyclic carbonate obtained by treating dextran with chloroform, whose ester groups react with starch[290]. The addition of insulin to dextran pretreated with cyanogen bromide is of great interest[291,292]. The activity of the relatively non-toxic water-soluble product is closely similar to that of the original insulin both *in vitro* and *in vivo*; its immunochemical activity is less than that of free insulin, but the lipoglycaemic action is stronger and more prolonged. A graft copolymer of dextran and insulin (when injected in smaller doses than the original insulin) induced the formation of several enzymes in the liver of animals suffering from diabetes. Yet other workers state[293] that the biological activity of the insulin derivative obtained in this way is considerably below that of the initial insulin.

During recent years increasing interest has been aroused by the preparation of insoluble derivatives of biologically active proteins (enzymes, antigens, antibodies), which can be used as specific catalysts, immunosorbents, or sorbents for affinity chromatography[294-298]. Starting materials used for the addition of enzymes have been cross-linked dextran derivatives containing carboxyl[299], diethylaminoethyl[300,301], or isothiocyanate[275,276] groups or aromatic amino-groups[302,303], as well as Sephadexes treated with phenyl isocyanate[304] or cyanogen bromide[305-310]. In these insoluble derivatives the enzyme macromolecules are attached to the dextran macromolecules by ionic[300,301] or covalent[275,276,302-310] bonds.

Interesting results have been obtained[309] showing that the activity of trypsin added to Sephadex pretreated with cyanogen bromide is 15–35% of that of the original enzyme; but if the dextran in this compound is subjected to enzymic hydrolysis with dextran glucosidase, the activity of the resulting water-soluble trypsin derivative is 60–100% of the original. This technique can probably be widely used

in the future to analyse the reasons for the decrease in activity of enzymes attached to insoluble dextran derivatives. A graft copolymer of cross-linked dextran and trypsin can be used[310] to isolate the ovomucoid glycoprotein by affinity chromatography. The properties of nucleases can be improved by addition to soluble dextran derivatives[311].

Table 1. Reactions used to obtain medicinal polymers based on dextran and its derivatives. (D = dextran macromolecule; M = residue of medicinal molecule; DCCD = dicyclohexyldi-imide).

1. $D{-}OH + C(=O)(OH){-}M \rightarrow D{-}O{-}C(=O){-}M$[121,322];

2. $D{-}OH + Cl{-}C(=O){-}M \rightarrow D{-}O{-}C(=O){-}M$[9,175,323,324];

3. $D{-}OH + HOOC{-}M \xrightarrow{DCCD} D{-}O{-}C(=O){-}M$[289];

4. $D{-}COOH + H_2N{-}M \rightarrow D{-}COO^{-}(H_3\overset{+}{N}{-}M)$[116,121];

5. $D{-}OSO_3Na + HCl \cdot H_2N{-}M \rightarrow D{-}OSO_3^{-}(H_3\overset{+}{N}{-}M)$[160,325–328];

6. $D{-}OCH_2CH_2CH_2SO_3H + H_2N{-}M - D{-}OCH_2CH_2CH_2SO_3^{-}(H_3\overset{+}{N}{-}M)$[115,119–121,123,124,231];

7.* $D{-}O{-}CH_2CH_2SO_3H + H_2N{-}M \rightarrow D{-}O{-}CH_2CH_2SO_3^{-}(H_3\overset{+}{N}{-}M)$[329];

8. $D{-}OCH_2COOH + H_2N{-}M \rightarrow D{-}O{-}CH_2COO^{-}(H_3\overset{+}{N}{-}M)$[115,119–121,123,124];

9. $D{-}O{-}CH_2{-}CH(OH){-}CH_2{-}\overset{+}{N}(C_2H_5)_3 + HOOC{-}M \rightarrow$

$\rightarrow D{-}O{-}CH_2{-}CH(OH){-}CH_2{-}\overset{+}{N}(C_2H_5)_2(\bar{O}\bar{O}C{-}M)$[115,123,124];

10*. $D{-}O{-}CH_2CH_2{-}N(C_2H_5)_2 + HO_3S{-}M \rightarrow$

$\rightarrow D{-}O{-}CH_2{-}CH_2{-}\overset{+}{N}(C_2H_5)_2(O_3\bar{S}{-}M)$[330];

11. $D{-}O{-}CH_2{-}C(=O){-}O{-}C(=O){-}O{-}C_2H_5 + H_2N{-}M \rightarrow D{-}O{-}CH_2{-}C(=O){-}NH{-}M$[120,121]

12. $D{-}O{-}CH_2{-}COOH + H_2N{-}M \xrightarrow{DCCD} D{-}O{-}CH_2{-}C(=O){-}NH{-}M$[288];

13. $D{-}O{-}CH_2{-}CH(OH){-}CH_2Cl + H_2N{-}M \rightarrow D{-}OCH_2{-}CH(OH){-}CH_2{-}NH{-}M$[115,119,121,123,124]

14. $D{-}O{-}CH_2{-}CH(OH){-}CH_2{-}NH{-}C_2H_4{-}OH + H_2CO + H_2N{-}C(=O){-}M \rightarrow$

$\rightarrow D{-}O{-}CH_2{-}CH(OH){-}CH_2{-}N(CH_2{-}NH{-}C(=O){-}M){-}C_2H_4OH$[115,123,124];

15. $D{-}Cl + H_2N{-}M \rightarrow D{-}NH{-}M$[115];

16. $D{-}NH_2 + H_2CO + H_2N{-}C(=O){-}M \rightarrow D{-}NH{-}CH_2{-}NH{-}C(=O){-}M$[218];

17. $D{-}C(H)=O + H_2N{-}M \rightarrow D{-}C(H)=N{-}M$[115,118–124,231,232];

18. $D{>}C=O + H_2N{-}M \rightarrow D{>}C=N{-}M$[115];

19. $D{-}OR{-}C_6H_4{-}CH(=O) + H_2N{-}M \rightarrow D{-}O{-}R{-}C_6H_4{-}CH=N{-}M$[116].

* Dextran derivatives having a three-dimensional cross-linked structure are used in reactions 7 and 10.

When an animal is immunised by the hypodermic, intramuscular, or intraperitoneal injection of an insoluble graft copolymer of cross-linked dextran and an antigen, the synthesis of antibodies in the organism lasts longer than on immunisation with a soluble antigen[312,313]. A repeat immunisation with a soluble antigen of an animal previously injected with the above graft copolymer caused extraordinarily intense production of antibodies, in numbers exceeding by factors of 10–20 those formed if the first immunisation had been made with a soluble antigen. This work established that the injected insoluble graft copolymer of dextran and antigen is gradually absorbed, probably by the action of dextran glucosidase present in the animal organism.

X. DERIVATIVES CONTAINING ATTACHED MEDICINALS

During the past decade the achievements of the chemistry of macromolecular compounds have been used ever more frequently and widely in the solution of medical problems[314–321]. An urgent line of research is the synthesis of polymeric medicinals by attaching drugs of low molecular weight to water-soluble or -insoluble polymers.

Table 2. Brief summary of effects achieved by the attachment of medicinals of low molecular weight to dextran.

Reaction	Dextran derivative	Medicinal	Effect	Ref.
1	Dextran	pelentan	water solubility	121, 322
2	Dextran	aspirin	less toxic	175
2	Dextran	nicotinic acid	prolongation	9
3	Dextran	oligopeptide analogue of eledoisin	prolongation	289
5	Sulphate	streptomycin, neomycin	prolongation, increased concn. in lymphatic system	160, 325
5	Sulphate	mitomycin	increased antitumour activity	326
6	Sulphopropyl ether	cystamine	prolongation, more effective	121, 231
7	Cross-linked sulphoethyl ether	papaverine, codeine	better taste, less toxic	329
8	Carboxymethyl ether	Tubazid	prolongation	119, 121
8	Carboxymethyl ether	kanamycin	prolongation	115
11	Carboxymethyl ether	serotonin	less toxic	120, 121
12	Carboxymethyl ether	peptide analogue of eledoisin	prolongation	289
17	Dialdehydo	kanamycin	prolongation	115
17	Dialdehydo	Tubazid	prolongation, less toxic	119, 121, 122
17	Dialdehydo	serotonin	prolongation, less toxic	120, 121
17	Dialdehydo	4-methylthiosemi-carbazide	antitumour activity	331
17*	Dextran	tetracycline	prolongation	333, 334
17*	Dextran	thyrocalcitoin hormone	prolongation	335

* Probably complex compounds.

The purpose is to improve the properties of the drugs—to prolong their action and enhance their activity, lower the toxicity, change the distribution in the organism, improve solubility, and increase stability to the action of enzyme systems in the organism that tend to destroy them.

In the preparation of polymeric medicinals for introduction into the organism, especially by injection, it is necessary to take into account the ability of the polymer to be assimilated in the organism and to be isolated from

the latter after fulfilling its functions. From this point of view the use of dextran for the production of physiologically active polymers is of considerable interest, as it is gradually hydrolysed by enzymes in the organism, which eliminates the danger of accumulation of the polymer in the tissues of various organs. The gradual enzymic cleavage of dextran in the organism may not permit the action of drugs to be prolonged to the extent achieved by the use of synthetic carbon-chain polymers, which are not broken down in the organism, but in many cases this is not required: it is sufficient to increase the period of action of the medicinals to a few hours or days. Table 1 lists the reactions used to obtain medicinal polymers based on dextran. Table 2 summarises the information in the scientific literature on the effects achieved by the chemical attachment of drugs of low molecular weight to derivatives of dextran.

Several workers have shown that the nature of the chemical bond between the dextran derivative and the attached medicinal has a significant influence on the biological properties of the resulting medicinal polymer, e.g. on the antibacterial activity of polymeric derivatives of isonicotinohydrazide[119,121] and antibiotics (kanamycin, ampicillin, tetracyclines)[115,123,124], and on the toxicity of polymeric derivatives of serotonin[120,121]. Available experimental results show that attachment to dextran and its derivatives can be regarded as a method for improving the properties of medicinal drugs.

Mass Spectrometry of Chromen-2-ones (Coumarins) and of Furo- and Pyrano-chromenones

N.S.Vul'fson and L.S.Golovkina

Mass-spectrometric results for the coumarins, furocoumarins, and pyranocoumarins are summarised. The characteristic elimination of carbonyl groups characteristic of coumarin itself can be traced also in the spectra of substituted (halogenated, hydroxylated, methoxylated, carbonylated, *O*- and *C*-alkylated, and *O*- and *C*-acylated) coumarins, but the nature of the substituent has a decisive influence on the way in which derivatives break down, and in many cases elimination of carbonyl groups takes place only after partial or complete elimination of the substituent. With bicoumarins elimination of carbonyl groups is observed in the later stages of decomposition or not at all. The regularities reported for coumarins are found also with furo- and pyrano-coumarins. Differences in the spectra of positional isomers are usually apparent only in differences in the peak intensities of the characteristic ions. There is a list of 59 references.

I. INTRODUCTION

We began the mass-spectrometric investigation of natural chromen-2-ones (coumarin, umbelliferone, herniarin, and osthol) in 1963.[1] Independently, but a little later (1964), the same chromenones were studied by Barnes and Occolowitz[2]. The largely identical results obtained in the two investigations showed that, because of the specificity of the breakdown of chromen-2-ones on electron bombardment and the characteristic influence of the number, nature, and position of substituents on this process, mass spectrometry is an extremely promising method in this case as with other classes of naturally occurring compounds. This promise has been fully confirmed by the further accumulation of experimental information. The number of mass-spectrometric investigations on chromenones and their derivatives, including furo- and pyrano-chromenones, has now become very considerable, which has led us to attempt in this Review to systematise and summarise the accumulated results.

II. CHROMEN-2-ONE AND ITS HALOGENO-DERIVATIVES

The spectrum of chromen-2-one itself (I) is very simple (Fig. 1*a*), containing only five peaks—one due to the molecular ion having $m/e = 146$, peaks due to the repeated elimination of 28 amu (atomic mass units) ($m/e = 118$ and 90) and the loss of 29 amu at the second stage (or the detachment of 1 amu after the second elimination of 28 amu) ($m/e = 89$), and a fifth peak with $m/e = 63$, caused by breakdown of the aromatic ring and devoid of diagnostic significance.

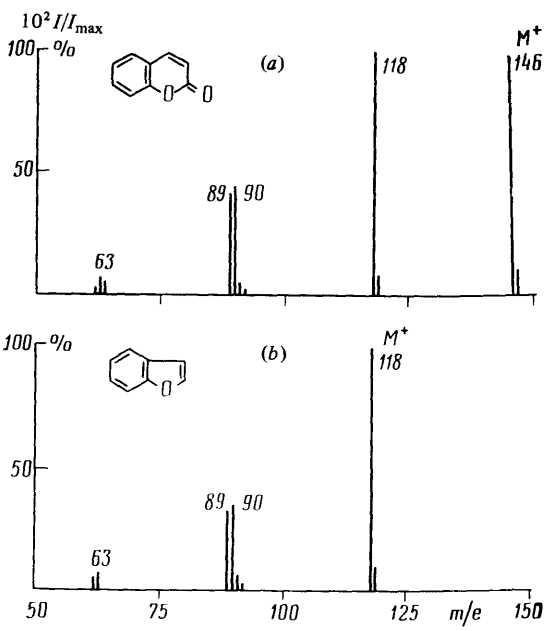

Figure 1. Mass spectra of: *a*) chromen-2-one; *b*) benzofuran.

It was reasonable to suppose that the first stage of decomposition involved elimination of the lactonic carbonyl, although the possibility of elimination of an ethylene molecule involving the 3- and 4-carbon atoms with migration

of two hydrogen atoms from the charged fragment could not be completely excluded. The first hypothesis is unambiguously supported by Zakharov's observations[3] of shifts of 1 amu to 119 and 91 (m/e) respectively in the peaks due to the ions $[M - 28]^+$ and $[M - 2 \times 28]^+$ in the mass spectra of the 3- and 4- deutero-analogues of chromen-2-one (Table 1). Similarly, double elimination of 28 amu occurs in the spectra of 3-chloro-, 4-chloro-, and 3,4-dichlorochromen-2-ones. Only in the spectrum of 3-bromochromen-2-one is this sequence changed: a molecule of carbon monoxide is eliminated first, then the bromine atom, and after this another carbon monoxide molecule.

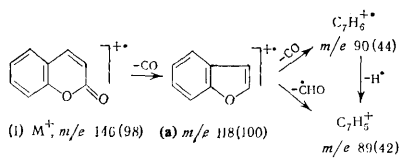
Table 1. Peaks (m/e) of main ions in the mass spectra of chromen-2-one and its deutero- and halogeno-derivatives (values of $100I/I_{max}$ given in parentheses, where I_{max} is the maximum intensity in the spectrum).

Chromenone derivative	M+	M—CO	M—2CO	M—Hal	M—Hal—CO	M—2CO—Hal
Chromen-2-one (I)	146 (98)	118 (100)	90 (44)	—	—	—
3-Deutero	147 (86)	119 (100)	91 (75)	—	—	—
4-Deutero	147 (88)	119 (100)	91 (41)	—	—	—
3-Chloro	180 (75) / 182	152 (43) / 154	124 (18) / 126	145 (8)	117 (6)	89 (100)
4-Chloro	180 (99) / 182	152 (44) / 154	124 (15) / 126	145 (10)	117 (10)	89 (100)
3,4-Dichloro	214 (83) / 216	186 (47) / 188	158 (23) / 160	—	—	123 (100) / 125
3-Bromo	224 (74) / 226	196 (22) / 198	—	145 (40)	117 (8)	89 (100)

A second mode of decomposition is also evident in the spectra of all the halogenated chromen-2-ones: elimination of the halogen atom from the molecular ion is followed by double elimination of carbonyl (Table 1).

In order to ascertain the possible structure of the $[M - CO]^+$ ion both the Reviewers[1] and the Australian workers[2] compared the mass spectra of chromen-2-one and benzofuran (*a* and *b* in Fig. 1), and concluded from their identity, beginning with the 118 peak ($[M - 28]^+$ for chromenone and the peak due to the molecular ion of benzofuran), that the molecular ion of chromenone, on losing a carbonyl group, is converted into a benzofuran ion (a), which in turn loses the second carbonyl group and then a hydrogen atom or else a formyl group at once (Scheme 1).

Scheme 1



The structure of the 118 ion has since been discussed many times, with arguments both for[4] and against[5-8] the benzofuran structure. The latter view was based on the difference between the appearance potential of the 118 ion on breakdown of the molecular ion of chromenone and the ionisation potential of benzofuran. In the Reviewers' opinion a more convincing argument is the similarity in the spectra of these two compounds, not only in the m/e values but also in the intensities of corresponding peaks (*a* and *b* in Fig. 1). However, this question has not been finally settled.

The spectrum of the corresponding dihydro-derivative—chroman-2-one, melilitol (II)—is very similar to that of the chromenone[2]: it too is characterised by successive double elimination of 28 amu with subsequent loss of a hydrogen atom (or elimination of 29 amu together at the second stage). In this case, however, elimination of an ethylene molecule instead of a carbonyl group is more probable at the first stage, since with (II) this process does not require the migration of two hydrogen atoms from the charged fragment.

The mass spectra of substituted chromenones reflect their specific characteristics resulting from the nature, number, and positions of substituents, as has already been partly shown by the halogeno-derivatives.

III. HYDROXYCHROMEN-2-ONES

The mass spectra of the hydroxychromenones, e.g. umbelliferone (III), are distinguished merely by an increase in the number of carbonyl groups ejected[1,2] (Scheme 2). As with coumarin itself, elimination of 28 amu at the second stage is accompanied by removal of 29 amu (formyl or carbonyl plus hydrogen). In contrast to the unsubstituted chromenone, later eliminations of a carbonyl group drop sharply in intensity (Table 2).

Scheme 2

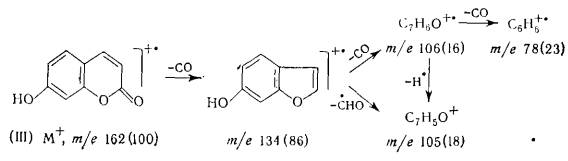


Table 2. Values of m/e and $100I/I_{max}$ for peaks due to ions involved in elimination of carbonyl groups in the mass spectra of hydroxychromen-2-ones.

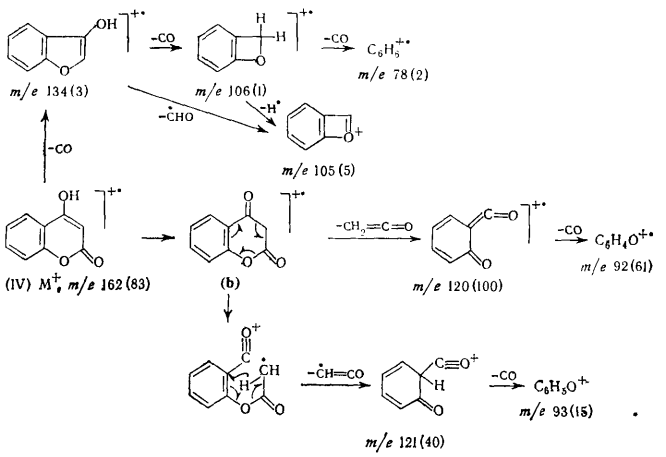
Derivative	M+	M—CO	M—2CO	M—2CO—H	M—3CO	M—4CO
4-Hydroxy (IV)	162 (86)	134 (3)	106 (1)	105 (5)	78 (3)	—
6-Hydroxy	162 (100)	134 (69)	106 (6)	105 (5)	78 (18)	—
7-Hydroxy (umbelliferone, III)	162 (100)	134 (86)	106 (16)	105 (18)	78 (20)	—
6,7-Dihydroxy (aesculetin)	178 (100)	150 (75)	122 (3)	121 (3)	94 (8)	66 (6)

The appearance potential of the 134 ion $[M - 28]^+$ for umbelliferone (10.6 eV) is closer to that of the corresponding ion for the chromenone (11.6 eV) than that of the same ion in the case of phenol (12.3 eV), which indicates elimination of the lactonic carbonyl at the first stage of decomposition[2].

The Reviewers have observed a significant difference between the breakdown of 4-hydroxychromenone (IV) and that of other hydroxychromenones. Decomposition involves mainly elimination of 42 amu from the molecular

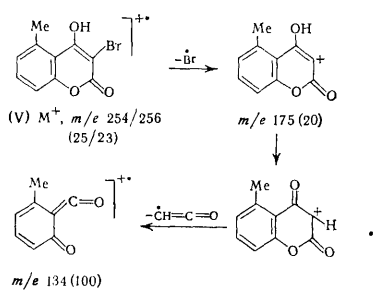
ion (the 120 peak at m/e is the most intense in the spectrum) followed by elimination of carbonyl (92 peak) (Scheme 3). Although the successive elimination of three carbonyl groups can be traced in the spectrum of the 4-hydroxy-derivative (Table 2), this process takes place to only a slight extent.

Scheme 3



On electron bombardment the molecular ion of 4-hydroxychromenone probably undergoes tautomerisation into the ion of chroman-2,4-dione (b), which then decomposes by a retrodiene reaction with elimination of a keten molecule and formation of a radical-ion having $m/e = 120$, or with removal of a keten radical and formation of an ion having $m/e = 121$. Analogous elimination of a keten molecule is evident in the mass spectrum of the monocyclic analogue of 4-hydroxychromenone—triacetic acid.

Scheme 4

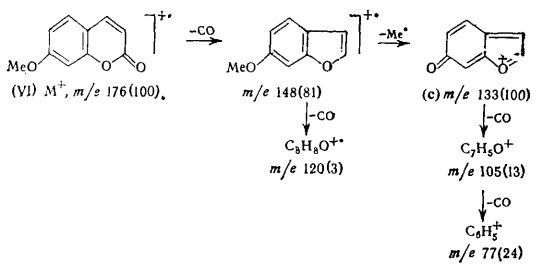


According to Johnson and Pelter[9] 3-aryl-4-hydroxychromenones also eliminate an arylketen molecule or radical on electron bombardment. With 3-bromo-4-hydroxy-5-methylchromenone (V),[10] as with the halogenated chromenones described above, the bromine atom is eliminated first, and a keten radical is subsequently eliminated after tautomeric ketonisation of the 175 ion (Scheme 4).

IV. METHOXYCHROMEN-2-ONES

The mass spectra are greatly affected by methylation of the hydroxyl in hydroxychromen-2-ones[1,2]. Although elimination of a carbonyl group is still the first stage in decomposition of the molecular ion of the methyl ether of umbelliferone—herniarin (VI)—elimination of the methyl group with formation of a 133 ion (Scheme 5, ion c), evidently stabilised by a quinonoid structure, predominates at the second stage. After this another carbonyl group is eliminated. It must be emphasised that neither methyl nor methoxyl is eliminated from the molecular ion in the case of herniarin (Table 3).[1,2,11]

Scheme 5



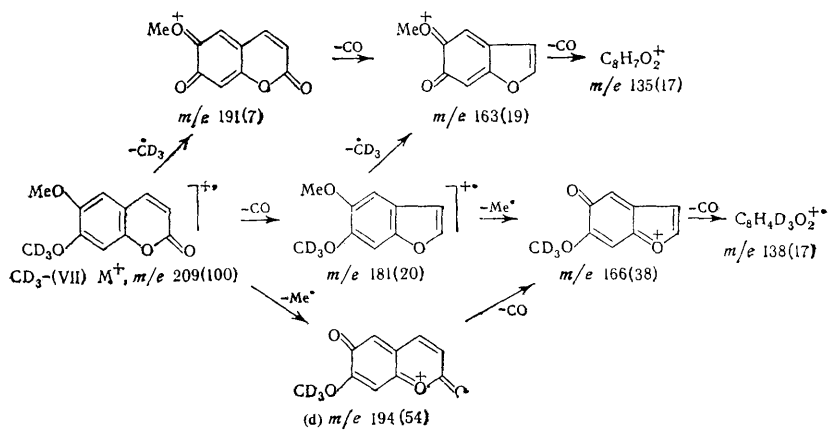
The Reviewers have observed a similar pattern in the mass spectrum of 7-hydroxy-6-methoxychromen-2-one (scopoletin), and the Australian workers[2] in that of 6,7-dimethoxychromen-2-one (scoparin) (VII). However, a significant feature of the behaviour of these compounds under electron bombardment is elimination of a methyl group from the molecular ion together with the first elimination of a carbonyl group, the peak of the $[M - CH_3]^+$ ion being more intense than that of the $[M - CO]^+$ ion. The sequence of subsequent eliminations in this mode of decomposition is included in Table 3.

Table 3. Values of m/e and $100I/I_{max}$ for peaks due to main ions in the mass spectra of methoxychromen-2-ones.

Derivative	M+	M—Me	M—CO	M—2CO	M—CO—Me M—Me—CO	M—CO—Me—CO M—Me—2CO	M—CO—Me—2CO M—Me—3CO	M—CO—Me—3CO M—Me—4CO
7-Methoxy (herniarin, VI)	176 (100)	—	148 (81)	120 (3)	133 (100)	105 (13)	77 (14)	—
7-Hydroxy-6-methoxy (scopoletin)	192 (100)	177 (43)	164 (22)	—	149 (37)	121 (14)	93 (1)	65 (4)
6,7-Dimethoxy- (scoparin, VII)	206 (100)	191 (30)	178 (20)	—	163 (30)	135 (19)	107 (20)	79 (6)

Shapiro and Djerassi[12] compared the spectra of (VII) and its 7-trideuteromethyl analogue and showed that formation of the $[M - CH_3]^+$ ion involves elimination of the methyl group predominantly from the 6-methoxyl with formation of a *p*-quinonoid 194 ion (ion (d) in Scheme 6). This observation is fully consistent with the absence of the $[M - CH_3]^+$ peak in the spectrum of herniarin and its presence in that of scopoletin. In contradistinction to this, loss of a methyl group by the $[M - CH]^+$ ion occurs with equal probability from either the 6- or the 7-methoxyl in scoparin, as is indicated by the fact that the peaks of the resulting 163 and 166 ions have approximately the same intensities as the 135 and 138 peaks in the spectrum of the 7-trideuteromethyl analogue of scoparin (Fig. 2). As with *o*-dimethoxybenzene, elimination of a formaldehyde molecule from the methoxyl is not observed here[11].

Scheme 6



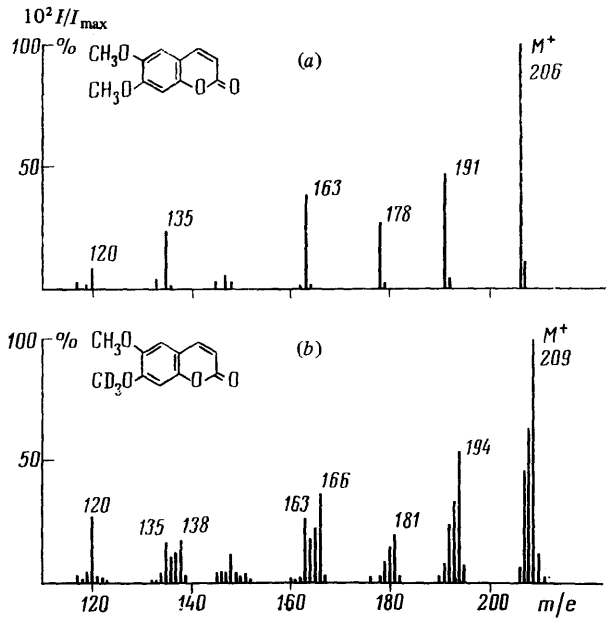


Figure 2. Mass spectra of: *a*) scoparin; *b*) 7-trideuteromethylscoparin.

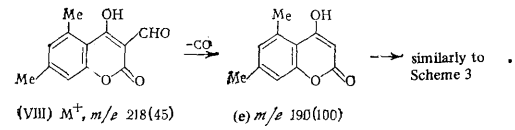
The fragmentation paths are little affected by introduction of a methyl group at any of the carbon atoms[10] or of a 4-phenyl group in the chromenone molecule or its hydroxy- or methoxy-derivatives[13-15]. Introduction of an ethyl group, however, leads to elimination of a methyl group, which is favoured by the possibility of formation of a tropylium ion[10].

V. 3-CARBONYL-CONTAINING CHROMEN-2-ONE DERIVATIVES

Aldehydes

The only aldehyde derivative whose mass spectrum has been reported—3-formyl-4-hydroxy-5,7-dimethylchromen-2-one (VIII) [10]—undergoes elimination of a carbonyl group with formation of the 190 ion (e) (Scheme 7) (whose peak is the most intense in the spectrum), having the structure 4-hydroxy-5,7-dimethylchromenone. Subsequent breakdown of the ion is analogous to that described for 4-hydroxychromenone (Scheme 3).

Scheme 7



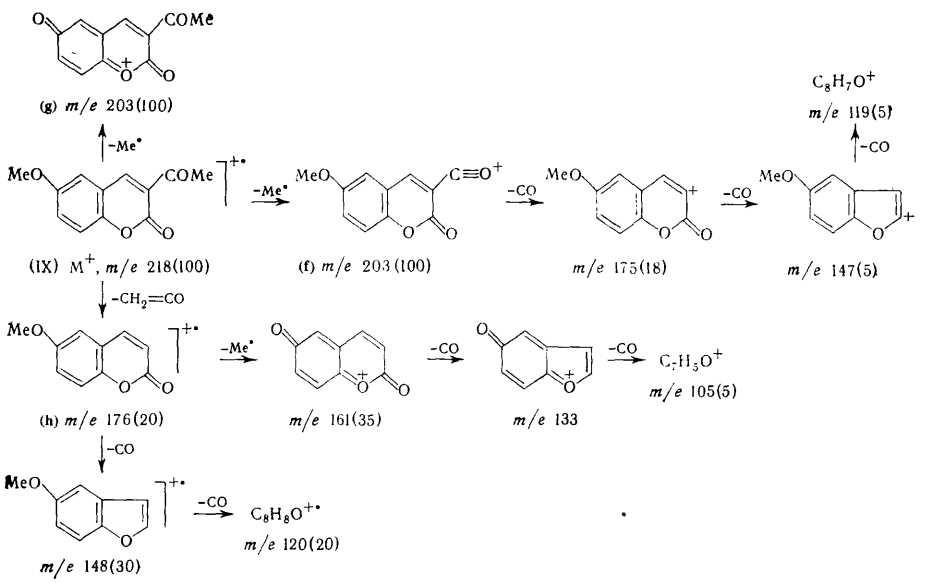
Ketones

The most intense peaks in the mass spectrum of 3-acetyl-6-methoxychromen-2-one (IX) [10] are due to the molecular ion and to the 203 ion $[M - CH_3]^+$. Formation of the latter is due to the equal probability of loss of methyl from the acetyl group (Scheme 8, ion f) and from the 6-methoxy-group (ion g). This is followed by the repeated loss of carbonyl groups. The molecular ion of the ketone (IX) can break down also by elimination of a keten molecule with formation of the 176 ion (h), which then either loses successively a methyl group and two molecules of carbon monoxide or else eliminates the two molecules (Scheme 8).

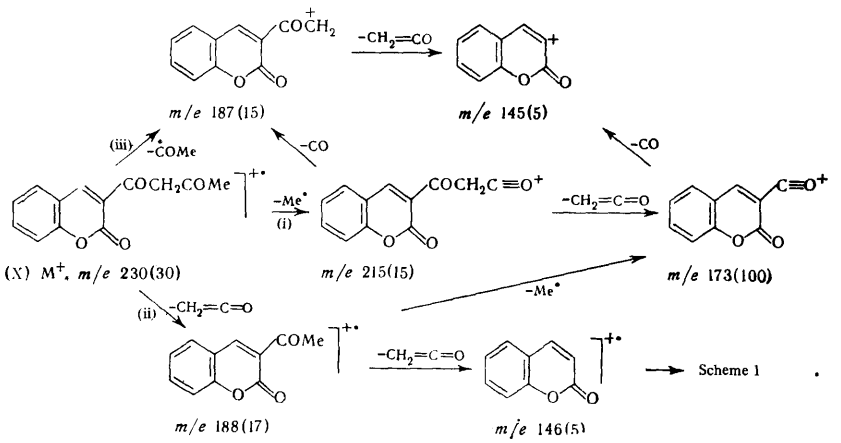
3-Acetoacetylchromen-2-one (X) can break down in three ways[10] (Scheme 9): (i) successive loss of a methyl group, a keten molecule, and a carbonyl group involves formation of a 145 ion analogous to the 175 ion formed from the ketone (IX) (Scheme 8); (ii) preliminary elimination of a keten molecule entails formation of an ion identical with the molecular ion of 3-acetylchromen-2-one, which then loses either another keten molecule or a methyl group followed by carbonyl; or (iii) preliminary elimination of an acetyl group and then a keten molecule yields an ion with $m/e = 145$.

Introduction of 4-hydroxyl and 6-methyl into the 3-acetoacetylchromenone has no significant effect on breakdown of the molecular ion under electron bombardment[10]. Only after elimination of the acetoacetyl group does decomposition characteristic of 4-hydroxychromenone begin.

Scheme 8



Scheme 9

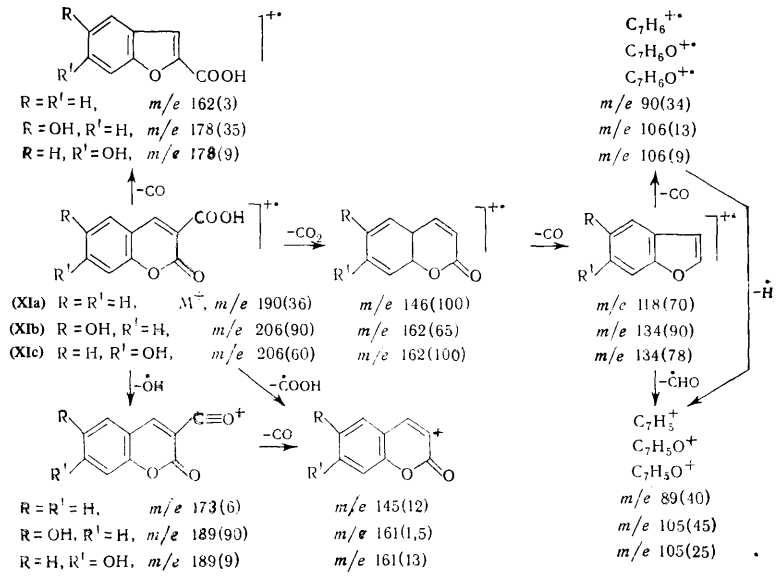


Acids and their Esters

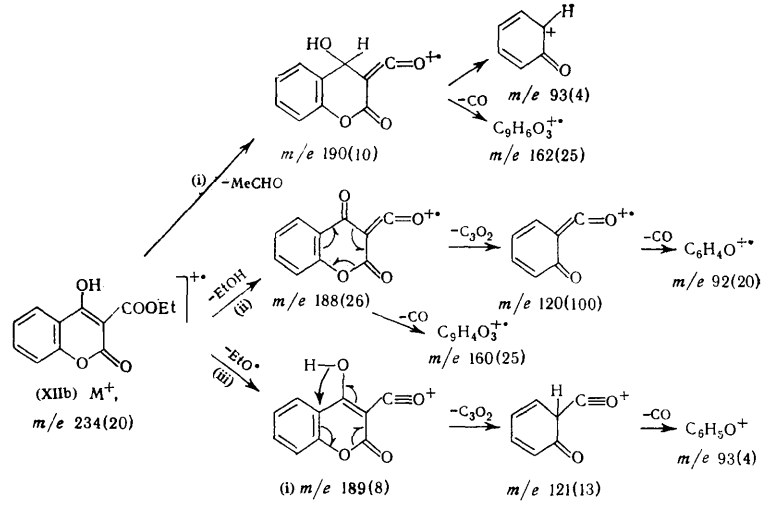
The Reviewers have found three independent modes of decomposition for 2-oxochromen-3-carboxylic acid (XIa) and its 6- and 7-hydroxy-derivatives (XIb) and (XIc) (Scheme 10). The first of these (traditional for coumarins), involving successive elimination of a carbonyl group, is strongly repressed. The second begins with elimination of a carboxyl as OH–CO and COOH (the peak due to the $[M - OH]^+$ ion is extraordinarily intense (90%) in the spectrum of the 6-hydroxy-derivative (XIb)). This is accompanied by very slight removal of formic acid to give the ion $[M - HCOOH]^+$. The third and main mode of breakdown of the oxochromencarboxylic acid entails detachment of a molecule of carbon dioxide, probably via a four-membered transition state. The $[M - CO_2]^+$ ion, which has the structure of the corresponding chromenone, breaks down further with successive elimination of carbonyl groups (elimination of a formyl group again accompanies elimination of a carbonyl group).

The pattern of fragmentation is still more complicated when the carboxyl has been esterified, as a consequence of breakdown of the alkoxycarbonyl group. Johnstone et al.[10] reported the mass spectra of methyl (XIIa) and ethyl (XIIb) 4-hydroxy-2-oxochromen-3-carboxylates, and of the 8-methyl (XIII) and 5,7-dimethyl (XIV) derivatives of (XIIa). Esters that were unsubstituted in the aromatic ring—(XIIa) and (XIIb)—could decompose in three independent ways (Scheme 11): (i) initial elimination of an aldehyde molecule is followed by cleavage of the heterocyclic ring and migration of a hydrogen atom to the charged particle or loss of a carbonyl group; (ii) initial elimination of an alcohol molecule from the alkoxycarbonyl group is followed by rupture of the heterocyclic ring (due to elimination of a carbon suboxide molecule) and then elimination of a carbonyl group or by immediate elimination of carbonyl from position 2 or 4; and (iii) initial detachment of alkoxyl gives the ion (i), which then loses a carbon suboxide molecule and a carbonyl group in succession.

Scheme 10



Scheme 11



The Reviewers suppose that the latter two routes may result from initial tautomeric ketonisation of the molecular ion followed by elimination of an alcohol molecule or alkoxyl and then a retrodiene decomposition, accompanied in (iii) by migration of a hydrogen atom to the charged particle (see Scheme 3).

Methylation of the aromatic ring in the ester (XIIa)—to give (XIII) and (XIV)—has no significant effect on the modes of decomposition of their molecular ions under electron bombardment, and is apparent merely in a decrease in intensity of peaks due to ions of type (i).

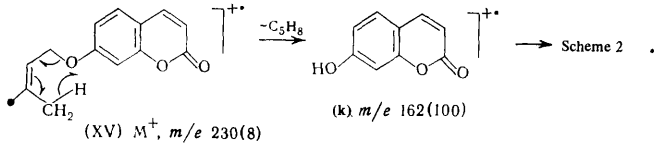
Introduction of an *O*- or a *C*-alkyl or -cycloalkyl substituent with a large number of carbon atoms into the chromenone molecule complicates appreciably the pattern of fragmentation of the molecular ion, since processes involving rupture of bonds in these substituents begin to play a significant part. Direct loss of a carbonyl group by the molecular ion becomes less characteristic, and often this process becomes apparent only in the later stages of decomposition.

VI. *O*-ALKYLATED CHROMEN-2-ONES

Naturally occurring chromenones, which usually contain an isopentenyl or a still longer isoprenoid residue attached to the ring through oxygen, are characterised by extreme ease of decomposition under electron bombardment. As a consequence, peaks in the range of high mass numbers are usually weak in their mass spectra. Thus according to Bohlmann et al.[16] 7-isopentenyloxychromen-2-one (XV) first loses the side-chain as a result of rupture of the carbon–oxygen bond with migration of a hydrogen atom to the charged particle. The 162 ion (k) thus formed

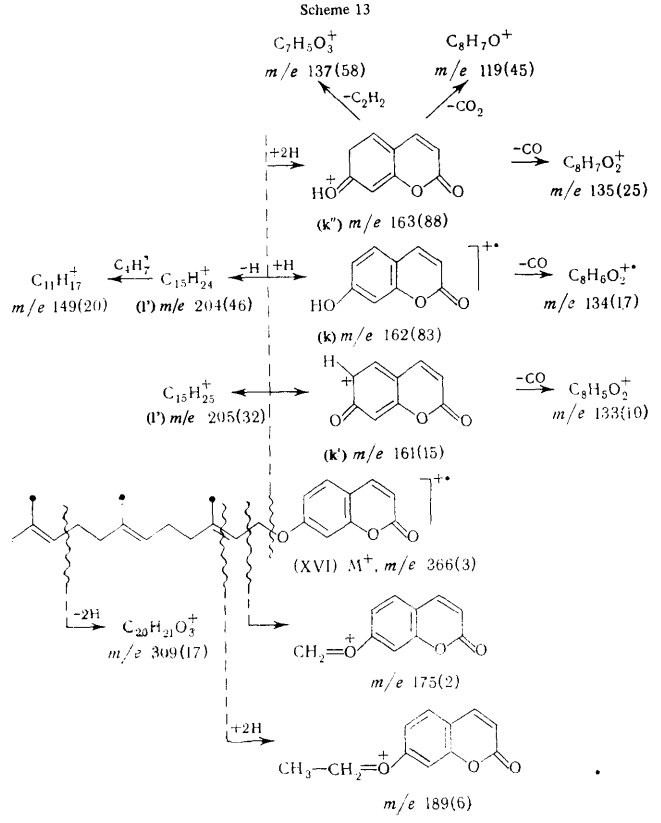
(Scheme 12) is identical with the molecular ion of umbelliferone (III), and subsequently breaks down as described above (Scheme 2 and Table 2).

Scheme 12



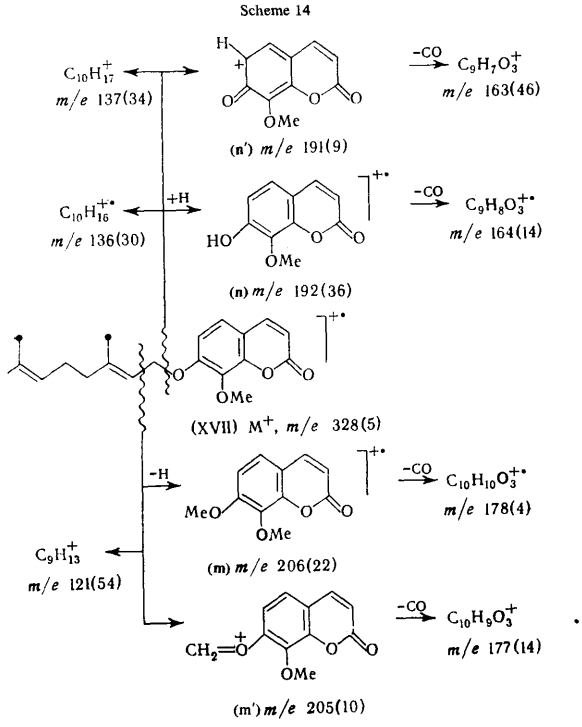
The Reviewers have found a similar situation in the mass spectrum of umbelliprenin (XVI). Cleavage of the side-chain at the carbon–oxygen bond with migration of a hydrogen atom to the charged fragment gives the 162 ion (k), accompanied by the 161 and 163 ions (k′) and (k″) formed respectively by simple rupture of the carbon–oxygen bond and by such rupture with migration of two hydrogen atoms to the charged particle. Localisation of the charge on the side-chain residue yields the 204 and 205 ions (l) and (l′) (Scheme 13).

Scheme 13

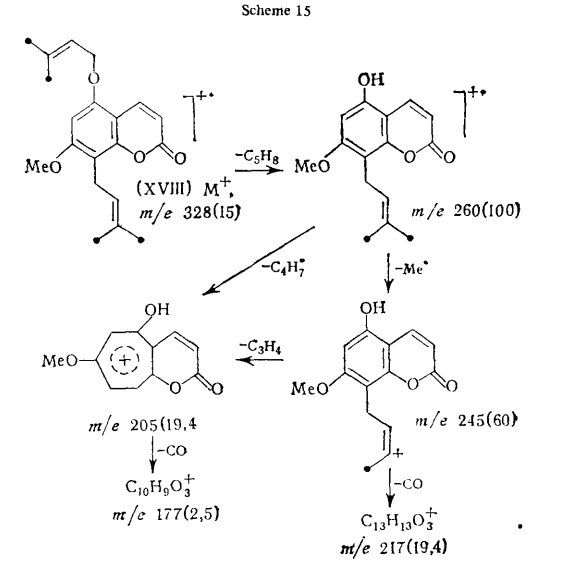


It must be borne in mind, however, that a long side-chain may break into fractions as a result of cleavage of allyl bonds. Nor can the possibility of migration of double bonds along the carbon chain be excluded. This is probably responsible for the peaks due to 309, 267, and 254 ions (17%, 2%, and 4%) in the spectrum of umbelliprenin. A 175 ion (2%) is formed by simple cleavage of the α-carbon–carbon bond, and corresponds to a deprotonated form of the molecular ion of herniarin. The ion (k) and the accompanying ions (k′) and (k″) then eliminate carbonyl groups in stages.

Scheme 14

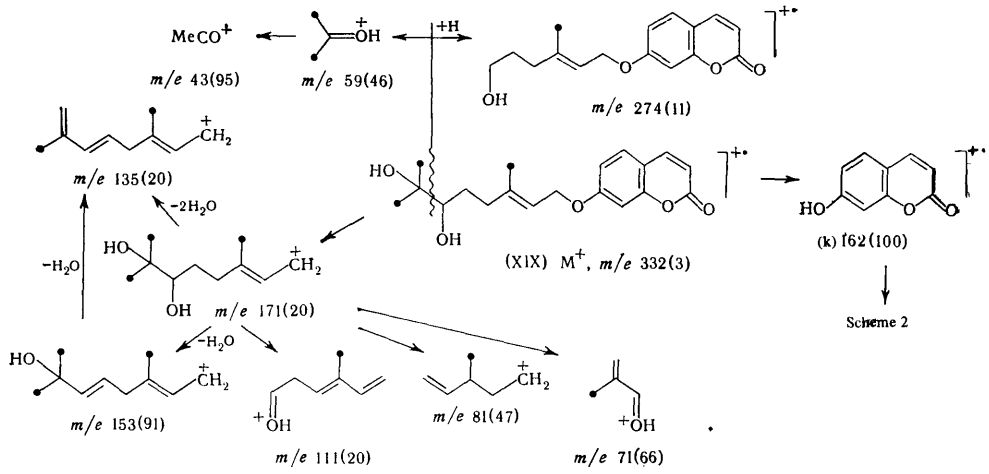


Scheme 15



In contrast to the above, according to Barnes and Occolowitz[2] collinin—7-geranyloxy-8-methoxychromen-2-one (XVII)—undergoes α-cleavage of the carbon chain with migration of a hydrogen atom to the charged fragment and formation of a 206 ion (m) identical with the molecular ion of 7,8-dimethoxychromen-2-one (Scheme 14). This ion is accompanied by a 205 ion (m′) formed by simple

Scheme 16

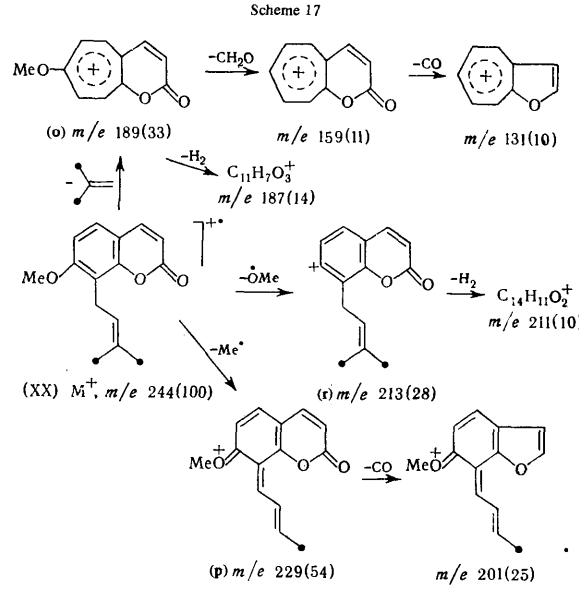


α-cleavage. With collinin the above rupture of the carbon–oxygen bond also occurs, with the formation of ions 192 and 191 (n and n'), the former identical with the molecular ion of 7-hydroxy-8-methoxychromen-2-one, and the latter with its deprotonated form. Rupture of the same bonds but with localisation of the charges on the aliphatic chain yields ions having m/e = 121, 136, and 137.

Loss of an isopentenyl substituent with migration of a hydrogen atom to oxygen has been observed also by Seshadri and Vishwapaul[17] in the mass spectrum of sesibiricin—8-isopentenyl-5-isopententyloxy-7-methoxychromen-2-one (XVIII) (Scheme 15)—isolated from *Sesili sibiricum*. Subsequent breakdown of the 260 ion is governed by the presence of the *C*-isopentenyl residue (Section VII).

Decomposition of the more complicated 7-(6,7-dihydroxy-3,7-dimethyloct-2-enyloxy)chromen-2-one (XIX) follows a similar pattern[18]. Besides rupture of the carbon–oxygen bond with migration of a hydrogen atom to the charged fragment with formation of the ion (k) (Scheme 16), the presence of an α-diol group in the side-chain stimulates formation of ions having m/e = 274, 171, 153, 135, 111, 81, 71, 59, and 53.

Scheme 17



VII. *C*-ALKYLATED CHROMEN-2-ONES

When an isopentenyl residue is directly attached to the chromenone ring system, as e.g. in osthol[1,2]—8-isopentenyl-7-methoxychromen-2-one (XX)—part of the side-chain is lost as an isobutenyl radical with formation of a tropylium ion (o) having m/e = 189 (Scheme 17), which then loses a molecule of formaldehyde from the methoxy-group (similarly to anisole[19] and methoxy-quinones[20,21]) and a carbonyl group. Successive elimination of carbonyl groups takes place only after loss of a terminal methyl from the molecular ion, i.e. from a 229 ion. Elimination of only methoxyl from the molecular ion, which has not been observed in the above cases, is evidently due to the proximity of the unsaturated isopentenyl residue. A 213 ion (r) is thus formed, which then loses a molecule of hydrogen.

Fragmentation of the isomeric suberosin—6-isopentenyl-7-methoxychromen-2-one (XXI)—is in principle very similar to that of osthol[22,23]. The difference in the position of the isopentenyl residue is reflected, however, in a fairly considerable change in intensity of several peaks, especially those due to breakdown of the side-chain (Table 4).

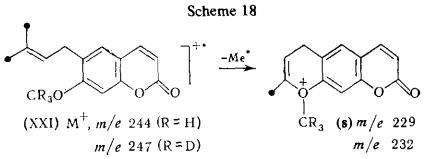
Table 4. Values of m/e and $100I/I_{max}$ for the peaks due to the main ions in the mass spectra of osthol and suberosin.

Compound	M+	M—Me	M—CH_2O	M—MeO	M—C_4H_7	M—C_5H_9
Osthol (XX)	244 (100)	229 (54)	214 (5)	213 (28)	189 (33)	176 (7)
Suberosin (XXI)	244 (97)	229 (100)	214 (3)	213 (4)	189 (13)	176 (5)

Compound	M—C_5H_9	M—Me—CO	M—C_4H_7—H_2	M—C_4H_7—CH_2O	M—C_4H_7—CH_2O—CO
Osthol (XX)	175 (8)	201 (25)	187 (14)	159 (11)	131 (10)
Suberosin (XXI)	175 (4)	201 (3)	187 (3)	159 (4)	131 (3)

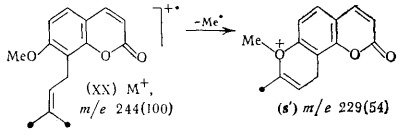
From the mass spectrum of the trideuteromethyl analogue of suberosin, in which the 229 peak of the $[M - 15]^+$ ion is almost completely (98%) displaced to 232, MacLeod confirmed experimentally[23] that methyl is eliminated from the side-chain. He assigned the cyclic structure (s) (Scheme 18) to this ion. For the rest his results are consistent with the scheme of decomposition of osthol (Scheme 17).

Scheme 18



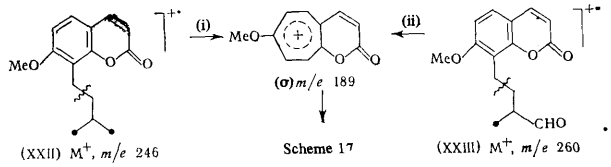
It cannot be excluded that the $[M - 15]^+$ ion from osthol also has an angular cyclic structure (s') (Scheme 19). The molecular ion of the recently reported 8-isopentenyl-5,7-dimethoxychromen-2-one decomposes similarly to osthol and suberosin on electron bombardment[24].

Scheme 19



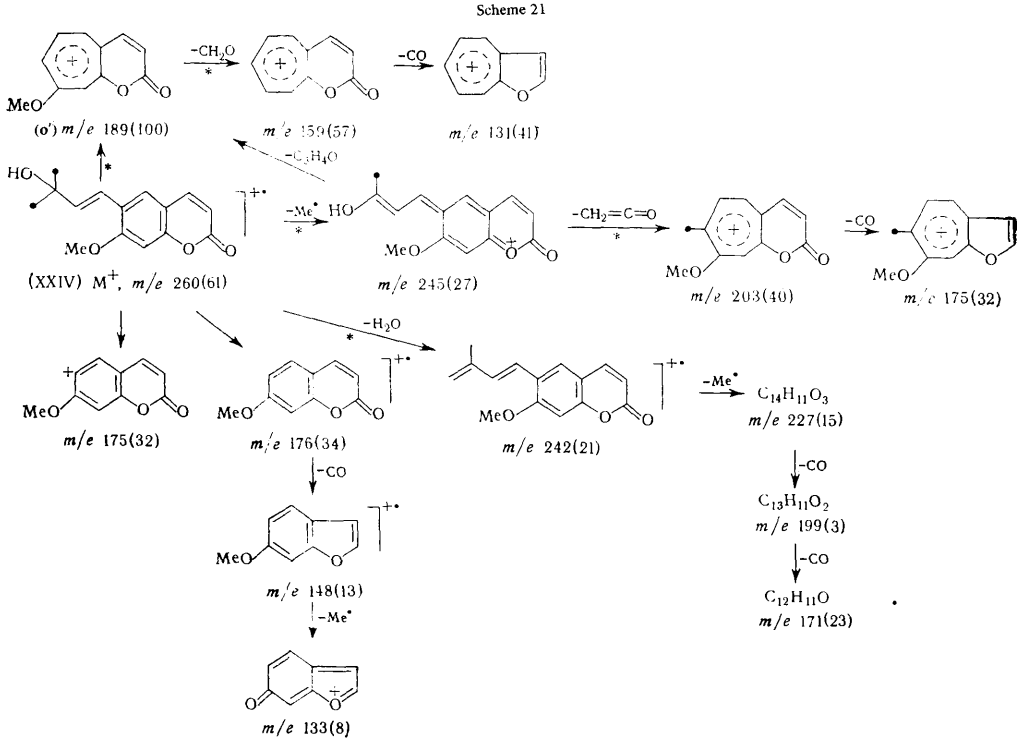
The peak due to the $[M - CH_3]^+$ ion is of negligible intensity in the spectrum of dihydro-osthol (XXII),[2] owing to the saturated character of the side-chain, and is completely absent from the spectrum of dihydrosuberosin[23], which can be attributed to the impossibility of stabilising the charge by a conjugated system of double bonds. Elimination of methoxyl as formaldehyde is also absent. The main mode of decomposition of dihydro-osthol[2] and dihydrosuberosin[23] is elimination of the side-chain by rupture of the benzylic carbon–carbon bond with formation of the tropylium ion (o) having $m/e = 189$ (Scheme 20i). Similar decomposition with formation of the ion (o) is evident also in the mass spectrum of 8-3'-formylbutyl-7-methoxychromen-2-one (XXIII)[25] (Scheme 20ii). It is curious that the $[M - CH_3]^+$ ion is not formed even in this case.

Scheme 20



Hydroxylation or epoxidation of the side-chain causes additional decomposition in the side-chain, as has been shown above for the derivative (XIX) (Scheme 16). Thus Australian workers have shown[22] that the molecular ion of suberenol—6-(3-hydroxy-3-methylbut-1-enyl)-7-methoxychromen-2-one (XXIV)—breaks down along three main paths (Scheme 21). (i) Elimination of a methyl group from the side-chain is followed by detachment of C_3H_4O and migration of a hydrogen atom to the charged fragment. The resulting tropylium ion (o') having $m/e = 189$ (whose peak is the strongest in the spectrum) can also be obtained directly from the molecular ion in a single-stage process analogous to that described above. The ion (o') loses further the methoxy-group as formaldehyde, and then a carbonyl group; the 245 ion $[M - CH_3]^+$ also loses a keten molecule, being converted into a 203 ion and subsequently eliminating a carbonyl group. (ii) Loss of the whole side-chain results from simple rupture of the carbon–oxygen bond (175 ion) or with migration of a hydrogen atom to the charged fragment

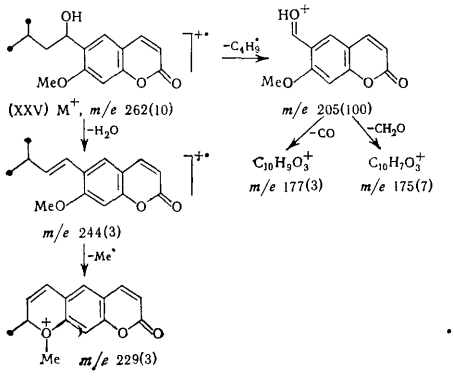
Scheme 21



through a six-membered transition state (176 ion). The 175 peak may be composite, with its second component arising from elimination of a carbonyl group from the 203 ion. The 176 ion then loses carbonyl and methyl. (iii) Loss of a water molecule by the molecular ion leads to formation of a 242 ion, from which one methyl and two carbonyl groups are then split off (the methyl probably from the side-chain). The mass spectrum of suberenol (XXIV) given by MacLeod[23] differs from the above merely in a considerably less intense peak due to the ion (o').

The mass spectrum of 6-(1-hydroxy-3-methylbutyl)-7-methoxychromen-2-one—tetrahydrogeijerin (XXV)—is very meagre[23]. The most intense peak is due to the 205 ion $[M - C_4H_9]^+$ ion (Scheme 22), which then loses a formaldehyde molecule or a carbonyl group. Another mode of decomposition of the molecular ion involves detachment of a water molecule followed by a methyl group. All the peaks due to these ions, including the molecular ion, are weak.

Scheme 22



In contrast, the mass spectrum of 6-(2,3-dihydroxy-3-methylbutyl)-7-methoxychromen-2-one—dihydrodihydroxysuberenol (XXVI) [23]—like that of the α-glycol (XIX) described earlier (Scheme 16), contains a considerable number of peaks due to ions formed by the rupture of bonds in the side-chain. The modes of decomposition indicated in Scheme 23 are supported by the mass spectra of the trideuteromethyl and 2-deuteroxyl analogues, as well as by the presence of many metastable peaks in the spectra.

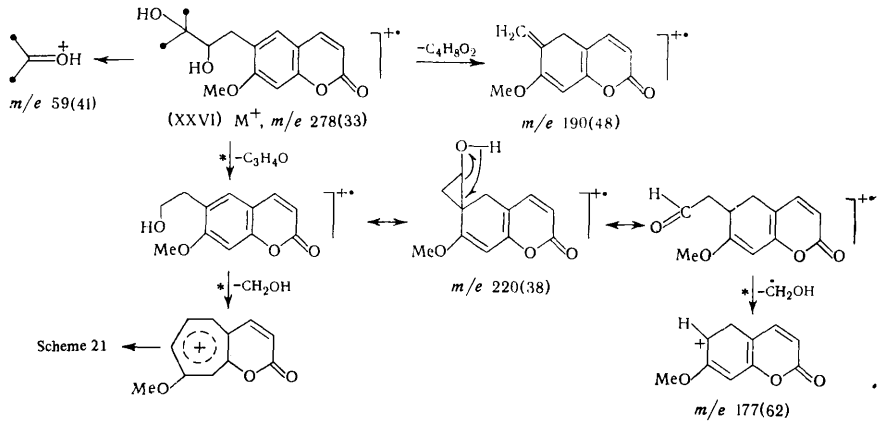
The same compound was isolated by Abyshev et al.[26] from *Prangos ulopteria* D.C. and termed *ulopterol*. Its mass spectrum corresponds essentially to Scheme 23. The spectrum of the isomeric 8-(2,3-dihydroxy-3-methylbutyl)-7-methoxychromen-2-one—merancin hydrate (XXVII)—is described in the same paper. The spectra of the isomers are very similar, differing mainly in the relative intensities of peaks due to individual ions. The chief difference is that the most intense peak in the spectrum of ulopterol is due to the 220 ion, whereas in the spectrum of merancin hydrate the 177 peak is the strongest.

According to Chakraborty et al.[27] the molecular ion of 8-(2,3-dihydroxy-3-methylbutyl)-5,7-dimethoxychromen-2-one—mexoticin (XXVIII), isolated from *Murraya exotica* L.—breaks down somewhat differently. In this case the most characteristic process is loss of the whole side-chain at position 8 with migration of a hydrogen atom to the charged fragment and formation of a 206 ion isomeric with ion (m) (Scheme 14). Rupture of the benzyl bond gives the tropylium ion (o") at 219 (Scheme 24), but simultaneous migration of a hydrogen atom to the charged fragment gives a 220 ion. The above cleavage of the α-glycolic carbon–carbon bond also occurs, with the appearance in the spectrum of peaks due to ions at 249 (t) and 59.

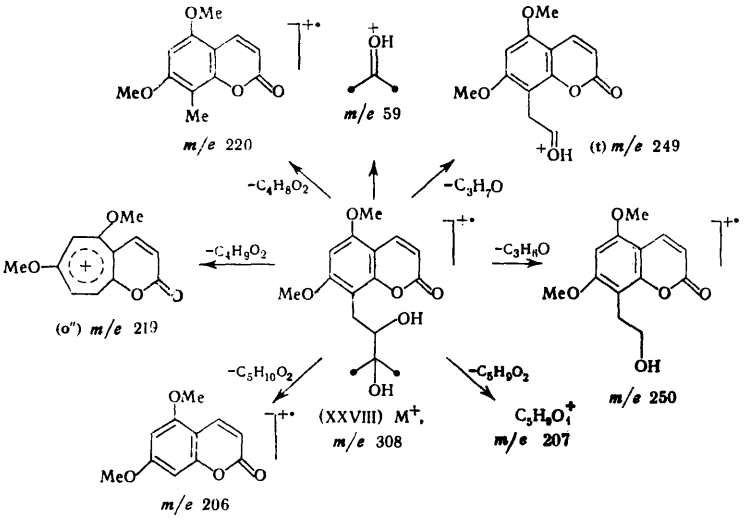
A formally similar but essentially different pattern is observed in the mass spectra of the monoacetates of ulepterol (XXIX) [26] and of merancin hydrate (XXX), [28] the latter isolated from *Prangos ferulacene* L. Decomposition can take place in two ways (Scheme 25) on electron bombardment: (i) elimination of a molecule of acetic acid from the molecular ion with formation of a 260 ion—respectively identical and isomeric with the molecular ion of suberenol—which breaks down further according to Scheme 17 or 21; or (ii) rupture of the α-glycolic carbon–carbon bond accompanied by elimination of a keten molecule, leading to the formation of ions 59 and 219. As in previous cases, the mass spectra of positional isomers (6- or 8-substituted) differ only in the relative intensities of peaks due to individual ions: for example, the most intense peak in the spectrum of (XXIX) is due to the 189 ion, but the most intense in the spectrum of (XXX) is at 219. Acetylation of the second hydroxyl in merancin hydrate has no significant effect on the decomposition of the diacetate on electron bombardment[28].

The mass spectrum of 6-(2,3-epoxy-3-methylbutyl)-7-methoxychromen-2-one—epoxysuberosin (XXXI) [23]—represents a still more complicated process, involving

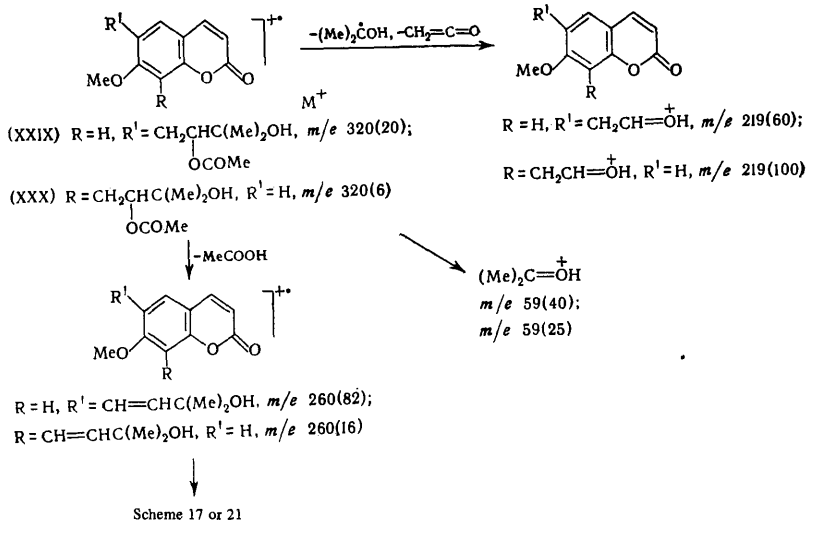
Scheme 23



Scheme 24



Scheme 25

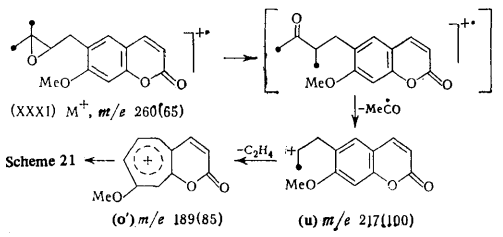


Scheme 17 or 21

a pinacolinic type of rearrangement in the side-chain of the molecular ion followed by ejection of an acetyl group and formation of the 217 ion (u) (Scheme 26). The latter ion then eliminates a molecule of ethylene and is converted into the tropylium ion (o') (189), which decomposes further in conformity with Scheme 21. This route is confirmed by the mass spectrum of the trideuteromethyl analogue and by the presence of many metastable peaks.

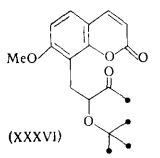
MacLeod's results[23] for the high-resolution mass spectrum of 7-methoxy-6-(3-methyl-2-oxobutyl)chromen-2-one (XXXII) (Scheme 32) and the absence of the elimination of a C_3H_7 radical (43 amu) from the molecular ion indicate that the epoxide ring does not undergo direct cleavage. They are inconsistent with Bohlmann and Rode's studies[29] of the mass spectra of 8-(2,3-epoxy-3-methylbutyl)-5,7-dimethoxychromen-2-one (XXXIII) and 8-(2,3-epoxy-3-methylbutyl)-7-isopentenyloxy-5-methoxychromen-2-one (XXXIV), both isolated from *Libanotis buchtormenis*. The latter workers regard elimination of 43 amu from the molecular ions of these two compounds as involving preliminary cleavage of the epoxide ring and formation of an ion of type (v) (at 247 and 301 respectively) (Scheme 27). Furthermore, Bohlmann and Rode[29] consider formation of the tropylium ion (o"), whose peak at 219 is the strongest in the spectrum of (XXXIII), to result from a single-stage elimination of the side-chain by cleavage of the benzylic carbon–carbon bond. Another discrepancy must be noted between the two sets of results. Bohlmann and Rode find in the spectrum of (XXXIII) quite clear evidence of the elimination from the molecular ion of an acetone molecule followed by formaldehyde (peaks at 232 and 202), whereas peaks due to the corresponding ions are almost completely absent from the spectrum of (XXXI).[23] The spectrum of (XXXIV), moreover, reveals elimination of the isopentenyl residue with migration of a hydrogen atom to the charged fragment and formation of the 7-dimethyl analogue of the molecular ion of (XXXIII), which then decomposes similarly to the latter.

Scheme 26



A rearrangement similar to that described by MacLeod for the epoxide (XXXI) has been examined by Kutney et al.[30] for 6-(1,2-epoxy-3-methylbut-3-enyl)-7-methoxychromen-2-one (XXXV), whose molecular ion eliminates a formyl radical. The $[M - CHO]^+$ ion, whose peak at 229 is the most intense in the spectrum, then loses either methyl to form a 214 ion or C_3H_4 with conversion into the ion (o') (Scheme 28). However, it is also possible that this last ion (o') is obtained as a result of fission of the epoxy-group to give a keto-form of the molecular ion, which is supported by the fairly intense peak due to the 69 ion.

Besides the above chromenones containing isoprenoid side-chains Abyshev et al.[31] described an optically inactive chromenone $C_{18}H_{22}O_5$, which they had isolated from *Prangos ferulaceae* L. and termed *pranferin*. On the basis of its chemical reactions and ultraviolet, infrared, and nuclear magnetic resonance spectra they regarded this compound (XXXVI) as 8-(2-t-butoxy-3-oxobutyl)-7-methoxychromen-2-one

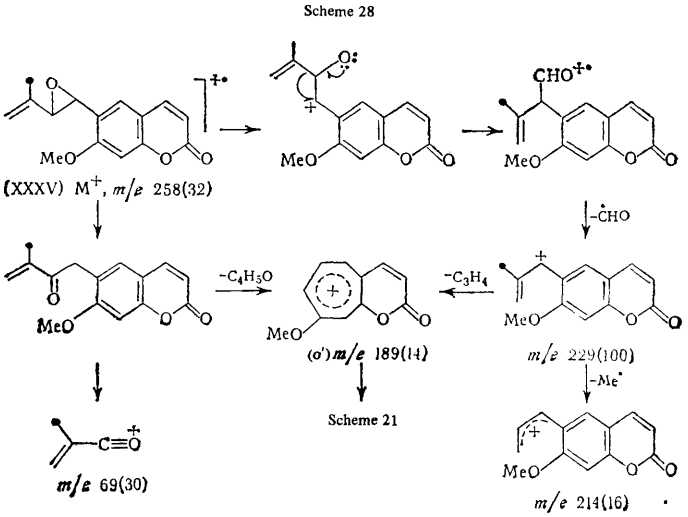


The authors state that this structure agrees well with the mass spectrum, which they do not analyse in detail. However, the one- and two-stage elimination of acetic acid from the $[M - 15]^+$ ion, clearly traceable in the spectrum, completely contradicts the proposed structure for the side-chain at position 8, although the presence of a fairly intense peak due to a 189 ion confirms that pranferin is a 7-methoxychromen-2-one derivative. Furthermore, the proposed[31] formula (XXXVI) contains an asymmetric carbon atom, which is inconsistent with the stated absence of optical activity, whereas other chromenones isolated by these workers from the same plant and containing an analogous

$$-CH_2-\underset{|}{CH}-O-$$

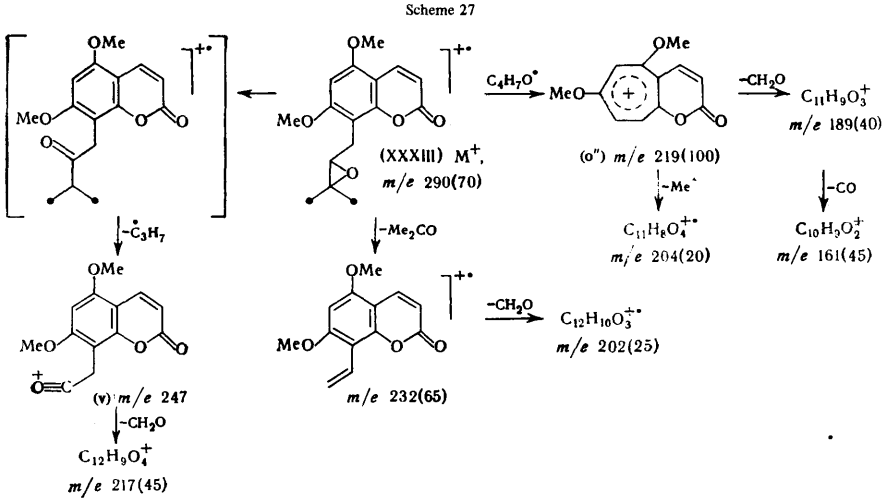
group are optically active[28].

Scheme 28

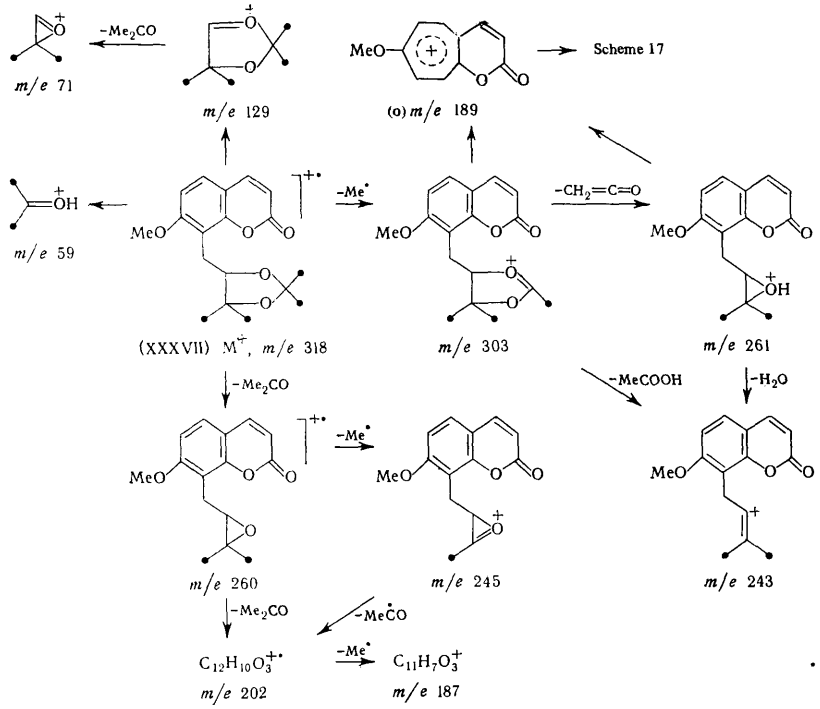


Nikonov and Saidzhadzhiev[32] analysed the n.m.r. data given by Abyshev et al.[31], and concluded that pranferin is an acetonide of merancin hydrate (XXXVII), which was confirmed by synthesis from osthol via the corresponding epoxide and merancin hydrate. The published mass spectrum of pranferin[31] agrees well with formula (XXXVII) (Scheme 29).

Scheme 27

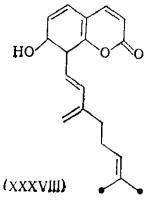


Scheme 29



VIII. CHROMEN-2-ONES CONTAINING CYCLOALKYL SUBSTITUENTS

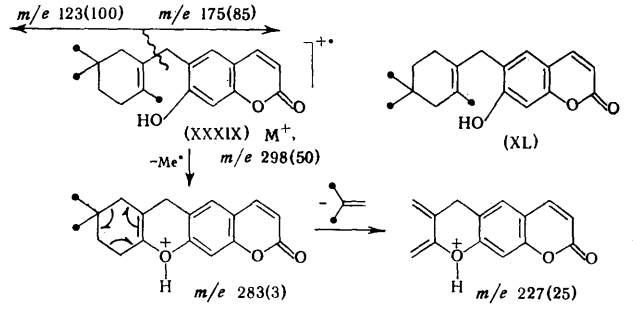
The first representative of this type of chromenone whose mass spectrum has been reported is peucenol (peumorisine), isolated from the roots of *Peucedanum morisonii* Bes. The Reviewers originally assigned to it the structure 8-(7-methyl-3-methylenocta-1,6-dienyl)-7-hydroxychromen-2-one[33]



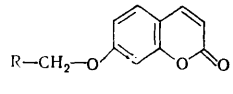
(XXXVIII) ,

but this formula was not confirmed by subsequent study of the n.m.r. spectrum. Examination of the n.m.r. and mass spectra of peucenol suggested a cyclic structure, either (XXXIX) or (XL) [34] (Scheme 30), both consistent with biogenetic considerations. Perel'son later showed unambiguously, on the basis of the nuclear magnetic double resonance spectrum, that peucenol has the structure (XXXIX), in good agreement with the mass spectrum: detachment of the carbocyclic substituent by rupture of the benzylic bond yields 175 and 176 ions of tropylium type (by simple rupture and by rupture with migration of a hydrogen atom to the charged fragment). If the charge resulting from this process is localised on the other part of the molecule, a 123 ion is formed. The peaks at 283 and 227 are due to loss by the molecular ion of a methyl group (probably that adjacent to the double bond of the cyclohexene ring) followed by retrodiene decomposition in the cyclohexene ring with ejection of isobutene.

Scheme 30

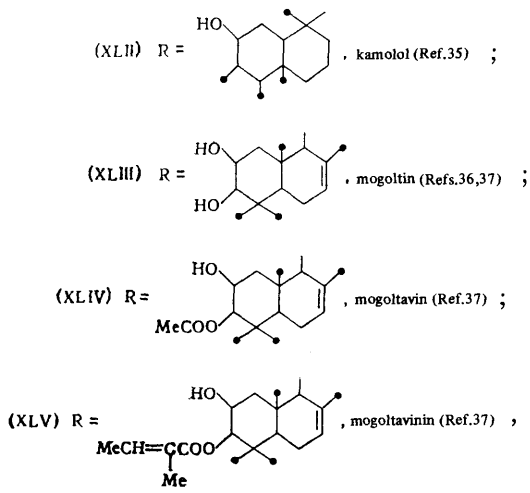


During recent years mass spectra have been reported for the umbelliferone derivatives (XLI)-(XLV) isolated from *Ferula peninervis*[35] and *Peucedanum mogeltovicum* Korov[36,37], in which the phenolic hydroxyl has been alkylated with sesquiterpenoid bicyclic residues. The mass spectra of all these compounds



(XLI)† R =  , kamolone (Ref.35) ,

† From biogenetic considerations Paknikar and Kirtany[59] have recently assigned to the sesquiterpenoid substituent of kamolone the structure decahydro-1,2,4a,5-tetramethyl-6-oxonaphthylmethylene.

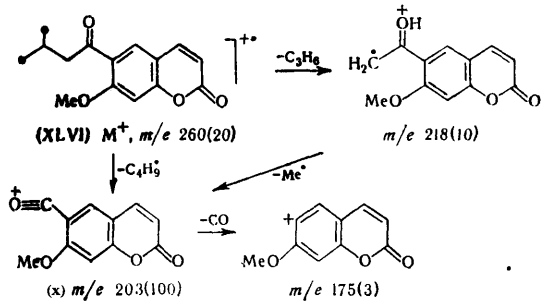


indicate rupture of a carbon–oxygen bond and the α-carbon–carbon bond in the side-chain, both alone and accompanied by migration of hydrogen atoms. The charge is localised on either moiety, chromenone or sesquiterpenoid. The spectra, of course, contain many peaks due to ions formed by further breakdown of the sesquiterpenoid ions, but information on the structure of this part of the molecules is obtained mainly from an analysis of the n.m.r. spectra.

IX. CHROMEN-2-ONES CONTAINING A KETO-GROUP IN THE SIDE-CHAIN

Study by MacLeod[23] of the mass spectra of two isomeric ketones—7-methoxy-6-(3-methyl-1-oxobutyl)chromen-2-one geijerin (XLVI) and 7-methoxy-6-(3-methyl-2-oxobutyl)chromen-2-one (isogeijerin) (XXXII)—and their deuterated analogues showed that the route of decomposition of the molecular ions is significantly influenced by the position of the keto-group in the side-chain.

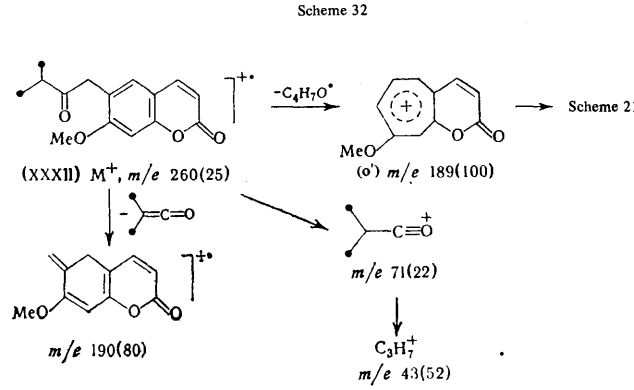
Scheme 31



The most intense peak in the mass spectrum of geijerin is due to the 203 ion (**x**), which may be formed in a single stage by elimination of an isobutyl radical or in two stages by the successive elimination of a propene molecule and a methyl group (Scheme 31).

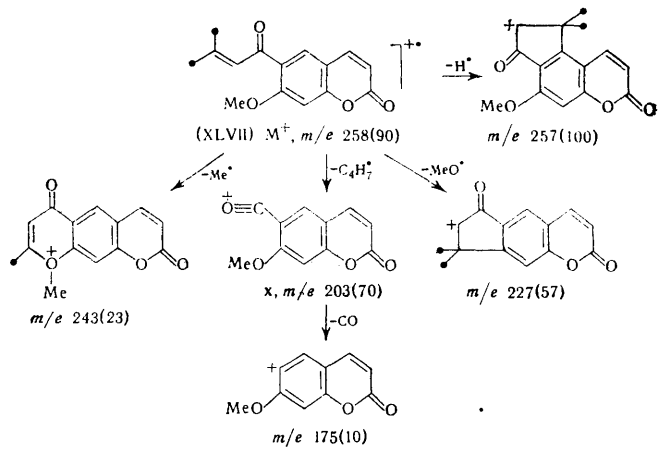
In the mass spectrum of isogeijerin, however, the strongest peak is due to the tropylium ion (**o'**) at 189, and is accompanied by a very intense peak due to a 190 ion (Scheme 32).

Scheme 32



The spectrum of 7-methoxy-6-(3-methyl-1-oxobut-2-enyl)chromen-2-one—dehydrogeijerin (XLVII)—is considerably more complicated[23] than those of the above saturated ketones. The peak due to the molecular ion is very strong, while the most intense peak is due to the ion $[M - 1]^+$, to which a tricyclic structure was assigned (Scheme 33). The molecular ion readily loses a methyl group to give a 243 ion, a methoxy-group to form a 227 ion (owing to the presence of an unsaturated substituent in the *ortho*-position), and a C_4H_7 radical to form the 203 ion (**x**).

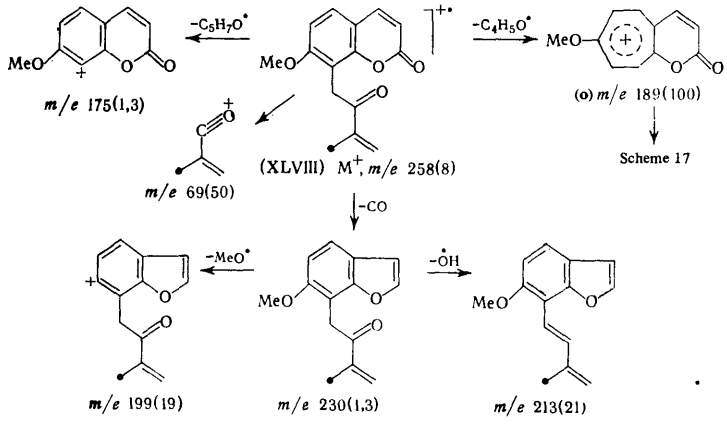
Scheme 33



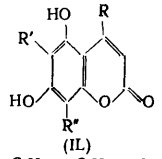
Another chromenone containing a keto-group in an unsaturated side-chain—7-methoxy-8-(3-methyl-2-oxobut-3-enyl)chromen-2-one (XLVIII), isolated from *Murraya exotica* L.—has been described by Subba Rao et al.[38] Its decomposition on electron bombardment (Scheme 34) differs significantly from that described above (Scheme 31) for the ketone (XLVI). Formation of the 189 ion (**o**) and a 69 ion, the latter produced by localisation of the charge on the side-chain residue, is accompanied by elimination from the molecular ion of a carbonyl group (230 ion) followed by elimination of methoxyl (199 ion) or of a hydroxyl resulting from enolisation (213 ion).

This type of compound includes a large group of 4-alkyl and 4-phenyl-5,7-dihydroxychromen-2-ones containing isopentenyl and various *C*-acyl radicals in the aromatic

Scheme 34



ring, isolated from *Mammea americana* L.[13,39] and from *M. africana*,[14,40] which can be represented by the general formula



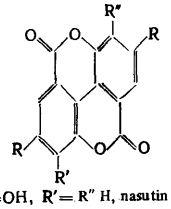
(IL)

R=H, *n*-C_3H_7, *n*-C_4H_9, s-C_4H_9, *n*-C_5H_{11} or C_6H_5.
R′=H, $Me_2C{=}CHCH_2$, iso-C_5H_7CO, iso-C_4H_9CO or s-C_4H_9CO.
R″=H, $Me_2C{=}CHCH_2$, *n*-C_5H_7CO, iso-C_4H_9CO or s-C_4H_9CO.

The decomposition of these compounds conforms in principle to the above rules, but interpretation of the mass spectra is greatly complicated by the presence of many diverse substituents, each of which makes its own contribution.

X. BICHROMENONES

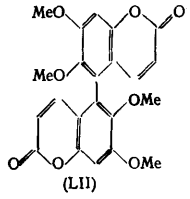
The mass spectra of the dimethyl ether (L) of nasutin A—a metabolite of termites—and the 3,3′,4-trimethyl ether (LI) of ellagic acid[41]



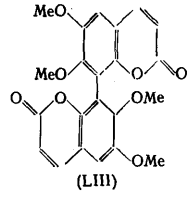
R=OH, R′= R″ H, nasutin A;
(L), R=OMe, R′=R″=H;
R=R′=R″=OH, ellagic acid;
(LI), R=R′=OMe, R″=OH,

are characterised by maximum intensities of the peaks due to the molecular ions (in the case of (L) the $[M-14]^+$ ion is present) and the detachment of methyl and methoxyl groups. Elimination of a carbonyl group is not observed.

The mass spectrum of euphorbetin—the tetramethyl ether of 6,6′,7,7′-tetrahydroxy-5,5′- or -8,8′-bichromenyl-2,2′-dione (LII) or (LIII)



(LII)



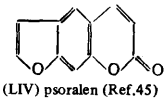
(LIII)

isolated from *Euphorbia lathyris* L.[42], is also characterised by preliminary elimination of methyl and methoxyl groups from the molecular ion. Elimination of a carbonyl group is observed only in the later stages of breakdown, and rupture of the bond between the chromen ring systems does not take place.

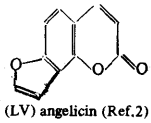
XI. FUROCHROMEN-2-ONES

The above regularities in the decomposition of chromenones under electron bombardment are largely applicable also to the more complicated furo- and pyranochromenones. The account of these will therefore be less detailed.

Unsubstituted furochromen-2-ones—the linear psoralen (LIV)[3] and the angular angelicin (LV)[2]



(LIV) psoralen (Ref.45)

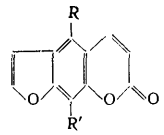


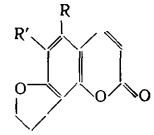
(LV) angelicin (Ref.2)

lose three carbonyl groups in succession. It is difficult to make a quantitative assessment of the results obtained by various workers with different apparatus under different experimental conditions, but a striking difference is evident in the intensities of certain peaks in the spectra of these compounds (Table 5).

The presence in the furochromenone molecule of one methoxy-group--bergapten (LVI),[2,43] xanthotoxin (LVII),[2]

isobergapten (LVIII) [44]—or of two methoxy-groups—isopimpinellin (LIX) [2,43,44] and pimpinellin (LX) [43,44]





(LVI) R = OMe, R′ = H, bergapten (Refs.2,43)
(LVII), R = H, R′ = OMe, xanthotoxin (Ref.2),
(LIX), R = R′ = OMe, isopimpinellin (Refs.2,43,44).

(LVIII), R = OMe, R′ = H, isobergapten (Ref.44),
(LX), R = R′ = OMe, pimpinellin (Ref.44),

leads to competitive elimination of a methyl group in the early stages, and this dominates the mass spectra of the latter pair of compounds. The spectra of isomers differ in the relative intensities of characteristic peaks (Tables 6 and 7).

Table 5. Values of m/e and $100I/I_{max}$ for peaks due to the main ions in the mass spectra of psoralen and angelicin.

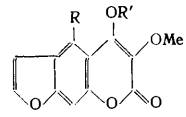
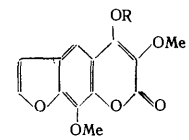
Analogous decomposition is undergone by the molecular ions of furochromen-2-ones from *Halfordia kendack* and *H. skleroxyla*, [45] containing substituents at other positions in the chromenone ring system—halkendin (LXI), norhalkendin (LXII), halfordin (LXIII), norhalfordin (LXIV), halfordinin (LXV), isohalfordin (LXVI), and norisohalfordin (LXVII)

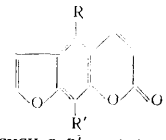




(LXI), R = H, R′ = Me, halkendin;
(LXII), R = R′ = H, norhalkendin;
(LXIII), R = OMe, R′ = Me, halfordin;
(LXIV), R = OMe, R′ = H, norhalfordin;
(LXV), R = OMe, R′ = $OCMe_2CH=CH_2$, halfordinin (Ref.45).

(LXVI), R = Me, isohalfordin;
(LXVII), R = H, norisohalfordin (Ref.45);

When the aromatic ring of the furochromenone contains more complicated substituents—isopentenyl groups (isoimperatorin (LXVIII), [43,46] imperatorin (LXIX) [43]), their epoxides (oxypeucedanin (LXX), prangenin (LXXI), [43] the epoxide of the methyl ether of alloimperatorin (LXXII) [30]), and others (gosferol (LXXIII), isolated from *Prangos ferrulaceae* Lindl, and its acetate (LXXIV), [47] the ethyl ether of oxypeucedanin hydrate (LXXV), [48] and also a furochromenone containing a formyl group in a long isoprenoid chain (LXXVI) isolated from grapefruit[25])



(LXVIII), R = $Me_2C=CHCH_2O$, R′ = H, isoimperatorin (Refs.43,46);
(LXIX), R = H, R′ = $Me_2C=CHCH_2O$, imperatorin (Ref.43);
(LXX), R =  , R′ = H, oxypeucedanin (Ref.43);
(LXXI), R = H, R′ =  , prangenin (Ref.43);
(LXXII), R =  , R′ = OMe, methyl ether of epoxyalloimperatorin (Ref.30);
(LXXIII), R = $MeC(=CH_2)CH(OH)CH_2O$, R′ = H, gosferol (Ref.47);
(LXXIV), R = $MeC(:CH_2)CH(OAc)CH_2O$, R′ = H, gosferol acetate;
(LXXV), R = $Me_2C(OEt)CH(OH)CH_2O$, R′ = H, ethyl ether (Ref.48) of oxypeucedanin hydrate;
(LXXVI), R = $Me_2(CHO)CH_2CH_2C(Me)=CHCH_2O$, R′ = H (Ref.25).

the mass spectra exhibit peaks due to ions formed in the types of decompositions considered above for the corresponding substituted chromenones.

Table 8. Values of m/e, (intensities, % on total ion current), and ratios of intensities of peaks due to characteristic ions in the mass spectra of certain furochromenone derivatives[43].

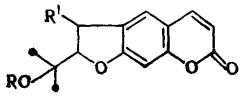
* Detachment of the side-chain and a hydrogen atom.
** Detachment of part of the side-chain.

A difference in the position of a substituent (5 or 9) is apparent only in a change in the relative intensities of the peaks due to certain ions, as can be seen from the isomers (LXVIII)–(LXXI) (Table 8). The ratio of the intensity of the peak due to the molecular ion to that of the peaks due to ionic fragments is evidently larger with the

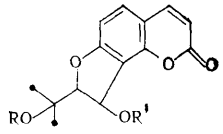
5-substituted derivatives, which will probably be useful for diagnostic purposes.

Mass spectra have been reported for mono- and di-hydroxylated linear and angular dihydrofurochromen-2-ones—marmesin (LXXVII) and its acetate (LXXVIII), angelate (deltoin) (LXXIX), senecionate (prantschimgin) (LXXX), and ω-methylthiocrotonate (seseliflorin) (LXXXI),[49] smyrniorin (LXXXII)[50,51] and its methanolysis product (LXXXIIa),[51] smyrnioridin (LXXXIII)[50,51]



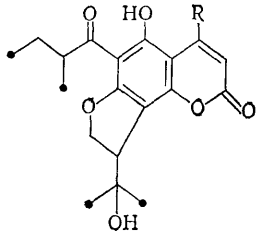
(LXXVII) R = R′ = H, marmesin;
(LXXVIII) R = MeCO, R′ = H, marmesin acetate;
(LXXIX) R = MeCH = CH(Me)CO-*trans*, R′ = H, deltoin;
(LXXX) R = Me_2C = CHCO, R′ = H, prantschimgin;
(LXXXI) R = MeSCH = CHCO, R′ = H, seseliflorin (Ref.49);
(LXXXII) R = MeCO, R′ = MeCOO, smyrniorin (Refs.50,51);
(LXXXIIa) R = MeCO, R′ = MeO, methanolysis product of smyrniorin (Ref.51);
(LXXXIII) R = MeCO, R′ = MeCH = CH(Me)COO-*trans*, smyrnioridin (Refs.50,51);

peucenidin (LXXXIV),[50] athamantin (LXXXV), and libanotin (LXXXVI)[51]



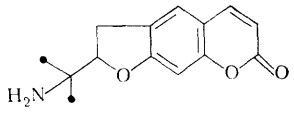
(LXXXIV) R = Me_2C = CHCO, R′ = Me, peucenidin (Ref.50);
(LXXXV) R = R′ = Me_2CHCH_2CO, athamantin (Ref.51);
(LXXXVI) R = MeCO, R′ = MeCH = C(Me)CO-*trans*, libanotin (Ref.51).

Analogous angular furochromenones



(LXXXVII) R = Ph[40];
(LXXXVIII) R = Pr[40]

isolated from *Mammea africana* G. Don are biogenetically related to the polysubstituted chromenones described in Section IX and encountered in the same plants. A mass spectrum has been reported also for the alkaloid prangosine



(LXXXIX) prangosine (Ref.52).

isolated from *Prangos pabularia* Lindl, which is a derivative of psoralen, containing a 1-amino-1-methylethyl group in the furan ring.

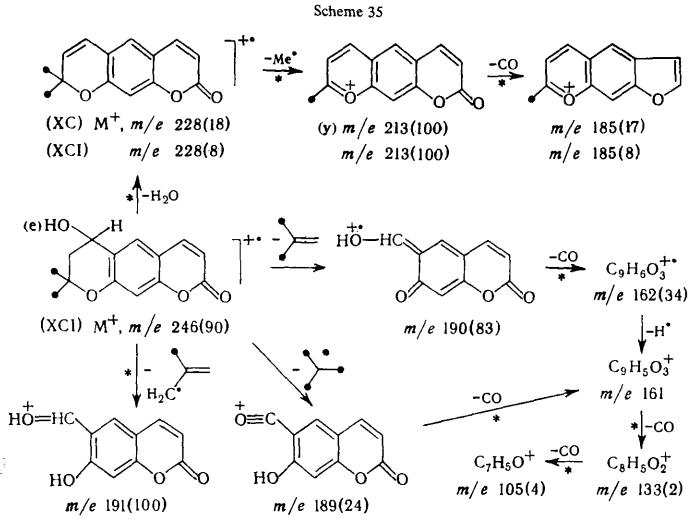
Compounds (LXXVII)–(LXXVI) undergo elimination of an acyl radical and an acid molecule (an acetyl residue is often removed as keten), and a methyl group is eliminated in the later stages of decomposition. Compound (LXXXVII) eliminates (i) a carbonyl group, an isopropoxy-group, a C_4H_9 radical from the 6-acyl substituent, and then a water molecule or (ii) an isopropoxy-group with part of the dihydrofuran ring. Only the latter type of decomposition occurs with (LXXXVIII).

Prangosine on electron bombardment eliminates a methyl group or an ammonia molecule, being converted in the latter case into an isopropenylfurochromen-2-one ion, which then loses successively a carbonyl group, a methyl group, and two more carbonyl groups.

XII. PYRANOCHROMEN-2-ONES

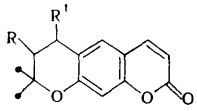
The mass spectrum of the simplest linear pyranochromen-2-one—xanthyletin (XC)[53]—indicates elimination of a methyl group to form the completely aromatised 213 ion (y) (Scheme 35), which then loses a carbonyl group.

Scheme 35



The pattern of decomposition of the molecular ion is considerably complicated when a 6-hydroxyl is introduced into dihydroxanthyletin to give (XCI).[53] Dehydration yielding an ion identical with the molecular ion of (XC) is accompanied by a retrodiene decomposition yielding a 190 ion together with migration of a hydrogen atom to or from the charged fragment (191 or 189 ion). These latter ions then eliminate a carbonyl group (Scheme 35). The corresponding ketone (XCII) decomposes similarly (Scheme 36).[53]

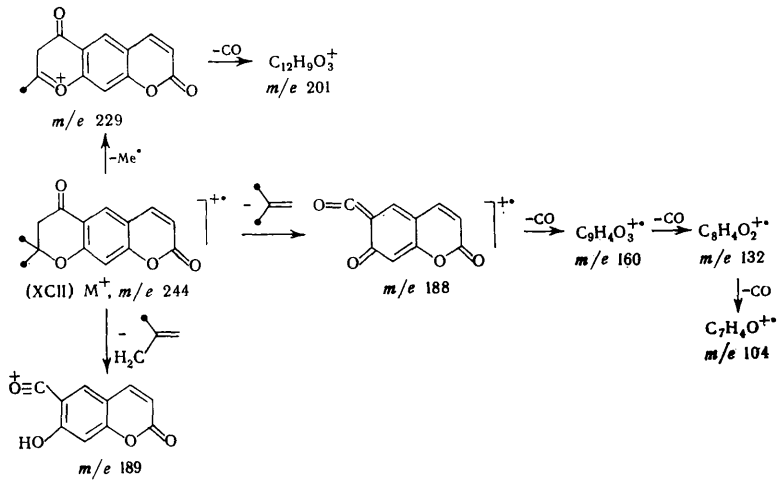
Mass spectra have been described also for the isomeric (with XCI) alcohol—agasyllol (XCIII)—its acetate (XCIV) and angelate—agasyllin (XCV)[54]—and the diacyldihydropyranochromen-2-one—andelin (XCVI)[55]



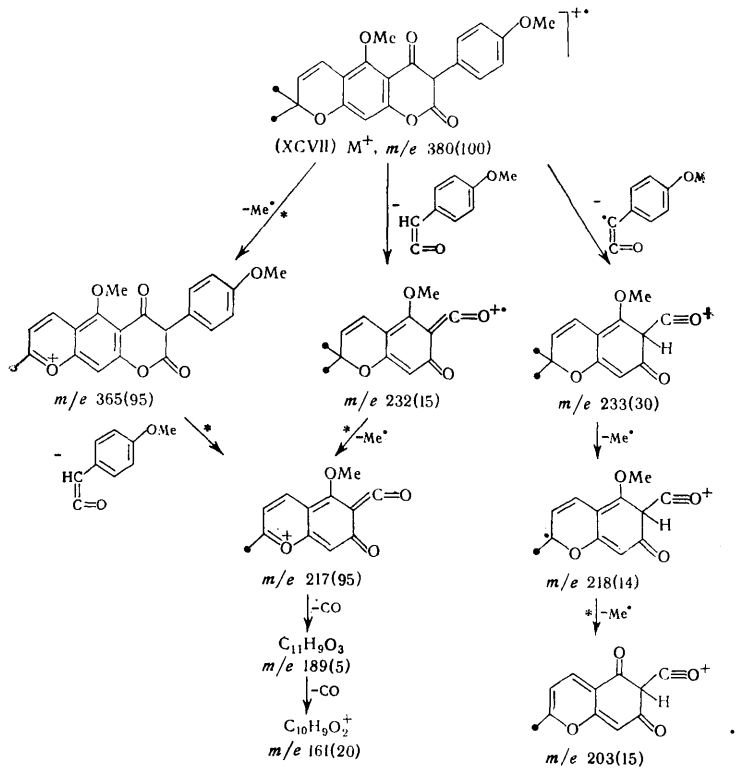
(XCIII) R = R′ = H, agasyllol;
(XCIV) R = MeCO, R′ = H, agasyllol acetate;
(XCV) R = MeCH = CH(Me)CO-*trans*, R′ = H, agasyllin (Ref.54);
(XCVI) R = Me_2C = CHCO, R′ = MeCH = C(Me)CO-*trans*, andelin (Ref.55).

Decomposition of the molecular ion of agasyllol is analogous to that described for (XCI), but breakdown of its acyl derivatives resembles that of acyl derivatives of furochromenones: i.e. the acid molecule or radical is split off. Elimination of a methyl group plays an important

Scheme 36



Scheme 37



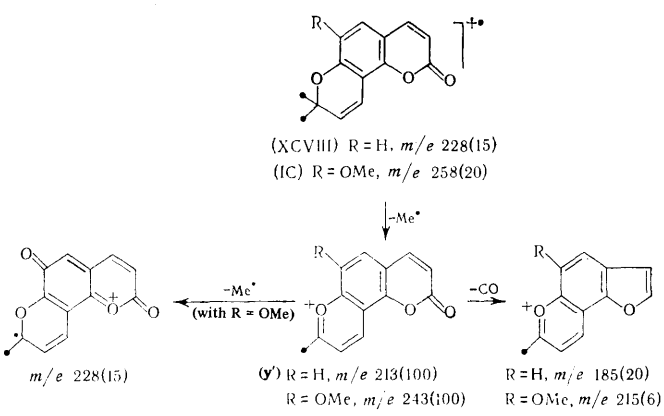
part, since, in combination with the detachment of an acid molecule, it leads to aromatisation of the pyran ring.

A more complicated example of a linear pyranochromenone is robustic acid, isolated from *Derris robusta*, which contains a 3-phenyl group (XCVII).[9,56] The breakdown of its molecular ion on electron bombardment is indicated in Scheme 37.

Angular pyranochromenones are considerably more widely distributed in Nature, so that mass spectra has been reported for an appreciably larger number of these compounds. The mass spectrum of the simplest angular pyranochromenone—seselin (XCVIII) [2]—is analogous to that of xanthyletin (XC). Elimination of a methyl group from the molecular ion yields the completely aromatised 213 ion (y'), which then loses a carbonyl group (Scheme 38). The spectrum of 6-methoxyseselin—brayelin (IC) [2]—differs from that of (XCVIII) only in the elimination of another methyl group in the second stage of decomposition, with formation of a quinonoid 228 ion (Scheme 38).

Mass spectra have been reported for dihydroseselin (C), a hydroxy-derivative (xanthogallol) (CI), and its acetate (CII), angelate (xanthogalin) (CIII),[54] senecionate[29]

Scheme 38



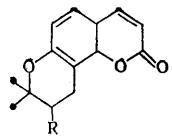
(XCVIII) R = H, *m/e* 228(15)
(IC) R = OMe, *m/e* 258(20)

m/e 228(15)

(γ') R = H, *m/e* 213(100)
R = OMe, *m/e* 243(100)

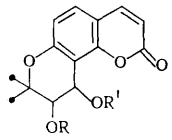
R = H, *m/e* 185(20)
R = OMe, *m/e* 215(6)

(buchtarmin) (CIV),[54] and isovalerate (CV),[29] as well as lomatin angelate (selenidin) (CVI)[57]



(C) R = H, dihydroseselin;
(CI) R = OH, xanthogallol;
(CII) R = MeCOO, xanthogallol acetate;
(CIII) R = MeCH = C(Me)COO-*trans*, xanthogalin (Ref.54);
(CIV) R = Me_2C = CHCOO, buchtarmin (Refs.29,54);
(CV) R = Me_2CHCH_2COO, xanthogallol isovalerate (Ref.29);
(CVI) R = MeCH = C(Me)COO-*trans*, selenidin (Ref.57).

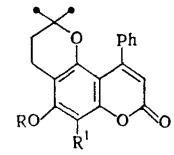
The dihydroxy-derivatives of (C) include the diol itself (kellactone) (CVII) and its diacetate (CVIII),[55] methylkellactone (CIX),[16,55] pterixin (CX),[16,55,58] its methanolysis product (CXI),[58] epoxypterixin (CXII),[58] and dihydropterixin (CXIII),[55] visnadin (CXIV), dihydrosamidin (CXV), anomalin (CXVI),[55] its monoepoxide (CXVII), and its diepoxide (CXVIII),[58] floroselin (CXIX), and its methanolysis product (CXX)[55]



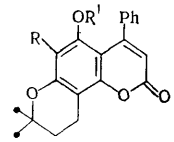
(CVII) R = R' = H, kellactone;
(CVIII) R = R' = MeCO, kellactone diacetate (Ref.55);
(CIX) R = H, R' = Me, methylkellactone (Refs.16,55);
(CX) R = MeCO, R' = MeCH = C(Me)CO-*trans*, pterixin (Refs.16,55,58);
(CXI) R = Me, R' = MeCH = C(Me)CO-*trans*, methanolysis product of pterixin;
(CXII) R = MeCO, R' = MeCH–C(MeCO, epoxypterixin (Ref.58)
O
(CXIII) R = MeCO, R' = $MeCH_2CH(Me)CO$, dihydropterixin;
(CXIV) R = MeCH = C(Me)CO-*trans*, R' = MeCO, visnadin;
(CXV) R = Me_2CHCH_2CO, R' = MeCO, dihydrosamidin;
(CXVI) R = R' = MeCH = C(Me)CO-*trans*, anomalin (Ref.55);
(CXVII) R = MeCH = C(Me)CO-*trans*,
R' = MeCH—C(Me)CO;
O
(CXVIII) R = R' = MeCH—C(Me)CO (Ref.58);
O
(CXIX) R = MeCH = C(Me)CO-*trans*,
R' = MeSCH = CHCO, floroselin;
(CXX) R = MeCH = C(Me)CO-*trans*,
R' = Me, methanolysis of floroselin (Ref.55).

On the whole all the above compounds undergo the same types of decomposition on electron bombardment as do linear pyranochromenones.

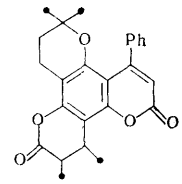
Mass spectra have been described also for several 4-phenylpyranochromen-2-ones with a different mode of fusion of the rings[15]



(CXXI) R = Me, R' = H;
(CXXII) R = Me, R' = MeCH = C(Me)CO-*trans*;
(CXXIII) R = MeCO, R' = $MeCH_2CH(Me)CO$ (Ref.15),



(CXXIV) R = H, R' = Me;
(CXXV) R = Me_2CHCH_2CO, R' = H (Ref.15),



(CXXVI)

as well as polyfunctional angular pyranochromenones isolated from *Mammea americana* L.[13] and *M. africana* G. Don.[40] Molecular ions of these compounds break down on electron bombardment similarly to the furochromenones and linear pyranochromenones described above.

Another type of angular pyranochromenone, in which the two pyran rings are fused together—4-methylpyrano-[5,6-*c*]chromen-2,5-dione (CXXVII)—was described by Johnstone et al.[10] Its mass spectrum represents a four-stage elimination of carbonyl groups and includes a metastable peak, indicating that the second and third carbonyls may be eliminated in a single stage. Such an observation is not unique, and has been reported in particular for monocyclic 2-pyrones. This simultaneous elimination of two carbonyl groups suggests that they may be contiguous. Measurement of the ionisation and appearance potentials at each stage, together with a study of the mass spectrum of the 5-carbon-13 analogue, made it possible to assess the sequence in which the carbonyl groups were ejected.

In order to elucidate the structure of the 200 ion $[M - CO]^+$ the mass spectrum of this pyranochromenone was compared with that of a similarly fused furochromenone. Although the spectra were qualitatively and quantitatively almost identical in the region of 200 and below, it was considered that these two 200 ions differed in structure, since the appearance potential of one differed appreciably from the ionisation potential of the other. An open-chain structure was therefore assigned to the 200 ion $[M - CO]^+$ in the case of the pyranochromenone (CXXVII). As has been stated earlier in connection with chromen-2-one itself, the Reviewers regard this conclusion as questionable.

Finally it must be emphasised that this Review makes no claim to exhaustive coverage of published information,

but nevertheless the Reviewers hope that it will show quite clearly the possibilities and limitations of mass spectrometry for determining the structure of naturally occurring chromen-2-ones, furochromenones, and pyranochromenones.

Stabilisation of the Surface Potential and Determination of the Activities of Individual Ions in Solution

Yu.F.Rybkin (deceased)

The problem of the determination of the thermodynamic characteristics of individual ions, the Galvani potentials, and the liquid junction potentials by a method based on the stabilisation of the surface potentials of electrolyte solutions is examined. The results of experiments on the applications of surface-active agents (aliphatic carboxylic acids, alcohols and amines) as stabilisers of the surface potentials are discussed. The scope and limitations of the method are indicated. The bibliography includes 85 references.

I. INTRODUCTION

The problem of determining the thermodynamic characteristics of individual ions and their variation with the composition of the medium still remains controversial in the physical chemistry of electrolyte solutions. The development of ideas in this field has been notably influenced by Guggenheim [1,2], who formulated the following principle: "the electrical potential difference between two points in different media can never be measured and has not yet been defined in terms of physical realities. It is therefore a conception which has no physical significance"[2]. From this point of view, the Galvani potential between the electrode and the electrolyte solution, the liquid junction potential (diffusion potential), and the potential difference between the gas phase (or vacuum) and a condensed phase (the surface or χ-potential) are not susceptible to experimental determination and lack physical significance. The above potential differences are functionally related to the activities and other thermodynamic characteristics of individual ions in solution (see, for example, Izmailov [3]). Thus the latter cannot be measured either and lack physical significance. Furthermore, according to Guggenheim there is no need for their determination, since the thermodynamic state of an electrolyte solution can be described in terms of the thermodynamic characteristics of the electrolyte as a whole or electrically neutral combinations of the charged components of the solution, which are susceptible to experimental determination.

Up to the present time, the majority of investigators have not shared Guggenheim's radical view, although the thesis that the thermodynamic characteristics of individual ions are not susceptible to the determination within the framework of rigorous thermodynamics appears to be generally accepted. The possibility, in principle, of measuring the potentials of individual electrodes was demonstrated in recent studies [4,5], although it has still not proved possible to develop experimental methods based on these ideas. The greatest progress has been achieved in the development of methods for the estimation of the thermodynamic characteristics of individual ions based on

different kinds of non-thermodynamic assumptions. The results obtained by these methods are discussed in a number of monographs [3,6,7] and reviews [8-10]. The available methods based on non-thermodynamic assumptions have been classified in the review by Popovych [8], who divides them into two categories. The first includes methods based on the estimation of the liquid junction potentials (Bjerrum and Larsson [11], Oiwa [12] and Parker and coworkers [13]) and the second includes methods involving correlations between the dimensions of ions and molecules and their solvation energies (Pleskov's normal cell method [14], Strehlow's ferrocene–ferricinium electrode method [15], Izmailov's extrapolation methods [16,17], Grunwald's standard electrolyte method [18], de Ligny's method [19], and others). Furthermore, Popovych considers in a separate category methods based on the estimation of Galvani potentials. The usefulness of these methods for the solution of the problem under discussion has been frequently noted [20]. This review deals with the problem of using the method based on the stabilisation of the χ-potentials of electrolyte solutions for the estimation of the activities of individual ions and the solvent effects for such ions and also to determine the Galvani potentials and liquid junction potentials.

II. PRINCIPLES OF THE SURFACE POTENTIAL STABILISATION METHOD

1. Calculation of the Thermodynamic Characteristics of Individual Ions from the Real Potentials of Ions and the Surface Potentials of Solvents

The principle of the calculation of the thermodynamic characteristics of individual ions in solution using the χ-potentials of the solvent was formulated after the development of the concept of the real potential† (real solvation energy) of ions α_i (Frumkin [22], Lange and Mishchenko [23]). According to Lange and Mishchenko [23], the real potential of ions α_i is related to their chemical potential (chemical solvation energy) μ_i as follows:

$$\alpha_i = \mu_i + z_i F\chi, \tag{1}$$

where z_i is the ionic charge and F the Faraday. The potentials α_i can be calculated directly from experimental data [24-27]. For ions in aqueous solutions, the most reliable data have been obtained by Randles [27], who estimates the error in the α_i for cations as ±0.5 kcal g-ion^{-1} and for anions as ±1 kcal g-ion^{-1}. The χ-potentials of solvents, which are defined as potential differences between points in different media, are inaccessible to direct measurements. Theoretical calculation of this quantity for water leads to an improbably high result [28]. Estimates of χ_{H_2O} based on non-thermodynamic assumptions have been frequently made [25,26,29-34]. The values of χ_{H_2O} obtained vary from −0.5 to 1.0 V. The low accuracy of the α_i and the uncertainty in χ for water and other solvents vitiate at present the attempts to obtain accurate values of $\lg \gamma_i^\circ$ (the so-called medium effects) or other corresponding thermodynamic characteristics of individual ions in terms of the absolute values of α_i.

†In defining the concepts of the electrochemical, real, and chemical potentials of ions, we follow the terminology employed by Parsons [21].

2. Non-thermodynamic Assumption of a Constant Surface Potential

It is easier to estimate the medium effects and the activities of individual ions in terms of the changes in the real and χ-potentials. Eqn. (1) can be transformed as follows:

$$\Delta\alpha_i = \Delta\mu_i + z_i F\,\Delta\chi, \tag{2}$$

where $\Delta\alpha_i$ is the change in the real potential of the ith ion and $\Delta\chi$ the change in surface potential on passing from one solution to another. It follows from Eqn. (2) that, when the surface potentials of solutions are stabilised (i.e. when $\Delta\chi = 0$), the values of $\Delta\alpha_i$ determined experimentally are equal to the corresponding changes in the chemical potential of ions of type i. Measurements of $\Delta\alpha_i$ on passing from one solvent to another have recently become common [36-41]. The experimental determination of $\Delta\alpha_i$ is based on the following factors. The real potential α_i is related to the electrochemical potential $\bar{\mu}_i$ by the familiar expression

$$\bar{\mu}_i = \alpha_i + z_i F\psi, \tag{3}$$

where ψ is the external potential of the phase. If two conducting phases whose interface is permeable only to charged species of type i are brought into electrical contact, the electrochemical potentials of such species in these phases become equal:

$$\bar{\mu}_i^{(1)} = \bar{\mu}_i^{(2)}\ . \tag{4}$$

Using Eqn. (3), one can write

$$\alpha_i^{(1)} + z_i F\psi^{(1)} = \alpha_i^{(2)} + z_i F\psi^{(2)}, \tag{5}$$

or

$$\Delta\psi = \psi^{(1)} - \psi^{(2)} = (\alpha_i^{(2)} - \alpha_i^{(1)})/z_i F = \Delta\alpha_i/z_i F, \tag{6}$$

where $\Delta\psi$ is the difference between the external potentials or the Volta potential difference arising between phases (1) and (2) as a result of the contact between them. Rabinovich [42] showed that more correctly the potential $\Delta\epsilon$, compensating $\Delta\psi$, is proportional to $\Delta\alpha_i$, rather than $\Delta\psi$ itself, since at the instant of compensation the phases are subjected to the same potential relative to earth and therefore there is no need for the assumption that the real potential is independent of the charge of the phase (Bridgman's hypothesis [43]). Henceforth, we shall call $\Delta\epsilon$ the "compensating potential"‡. Consequently, one can write

$$\Delta\varepsilon = \Delta\alpha_i/z_i F. \tag{7}$$

The interfaces between electrolyte solutions are permeable to both cations and anions. Nevertheless, systems permeable to ions of only one type can be produced by means of reversible ion-selective electrodes. We shall consider the specific instance of solutions of a strong acid HA for which it is necessary to determine the thermodynamic state of H^+ ions. Isolated HA solutions in which two reversible hydrogen electrodes are immersed and which are joined by a metallic conductor constitute a system permeable to H^+ ions only (Fig. 1*a*). One of the HA solutions will be regarded as the standard and the

‡The condenser and ionisation methods as well as flow methods are equally suitable for the measurement of $\Delta\epsilon$. Kenrick's method [44] has been widely used hitherto for the determination of $\Delta\alpha_i$. The technique of the measurements has been described in detail [45].

other as the test solution. As a result of contacts via the hydrogen electrodes, the previously electrically neutral HA solutions are charged relative to one another and a Volta potential difference arises between their free surfaces. The contact charging of solution is due to the fact that, by virtue of the difference between their compositions, the electrochemical potentials of the H^+ ions in them are different too. By virtue of the equilibrium $H^+ + e \rightleftharpoons \frac{1}{2}H_2$ between the solution and the electrodes, the electrochemical potentials $\bar{\mu}_e$ of the electrons in the solid phase of the electrodes should also be different. Contact between the hydrogen electrodes leads to the equalisation of the $\bar{\mu}_e$, which shifts the equilibrium $H^+ + e \rightleftharpoons \frac{1}{2}H_2$. As a result, a number of H^+ ions disappear from the HA solution where their activity is higher and an equal number appear in the solution where their activity is lower. The compensating potential $\Delta\epsilon$ which shifts the equilibrium in the system so that the Volta potential difference $\Delta\psi$ between the solutions becomes zero can be selected by means of a potentiometer included in the circuit between the hydrogen electrodes (Fig. 1*b*). For the given specific case, Eqn. (7) becomes

$$\Delta\varepsilon = [\alpha_{H^+}(m) - \alpha_{H^+}(m_{st})]/F, \qquad (8)$$

where $\alpha_{H^+}(m)$ and $\alpha_{H^+}(m_{st})$ are the real potentials of H^+ ions in the test and standard solutions respectively. The electrochemical system illustrated in Fig. 1*a* is usually represented symbolically as follows:

$$\mathrm{Pt(H_2)}\,|\,\mathrm{HA},\ m_2\,|\,\mathrm{air}\,|\,\mathrm{HA},\ m_{st}\,|\,\mathrm{Pt(H_2)}. \qquad (A)$$

In contrast to the usual galvanic cells, such systems will be called Voltaic cells.

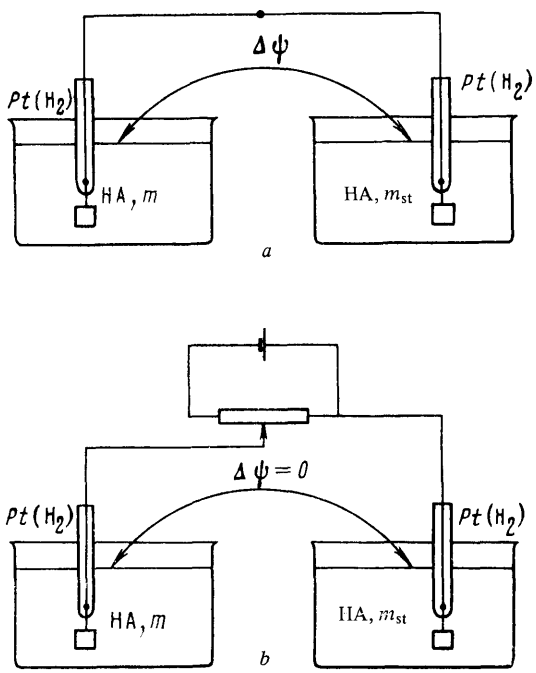

Figure 1. Schematic illustration of the electrochemical system used to investigate the Volta effect on joining together two electrolyte solutions via ion-selective electrodes: *a*) contact charging of the solutions; *b*) compensation of the Volta potential difference produced using a potentiometer to generate a compensating potential.

According to Eqns. (2) and (7), the compensating potential of the voltaic cell (A) is proportional to the difference between the chemical potentials of H^+ ions in the test and standard solutions when the difference between the potentials jumps at the interfaces *2* and *3* in the cell is zero ($\Delta\chi = 0$). This condition holds when the solutions being compared are fairly dilute or when their surface potentials are artificially stabilised. With the aid of the voltaic cell (A), it is in essence possible to determine $\mu_{H^+} - \mu^\circ_{H^+}$ to within the unknown value of $F\Delta\chi$.

The assumption that $F\Delta\chi$ is zero implies the non-thermodynamic assumption of the equality of the surface potentials of the solutions being compared. In practice, it is more convenient to employ, instead of a voltaic cell of type (A), a voltaic cell of the following type:

$$\mathrm{Pt(H_2)}\,|\,\mathrm{HA},\ m\,|\,\mathrm{air}\,|\,\text{standard solution}\,|\,\text{reference electrode}, \qquad (A')$$

the $\Delta\epsilon$ values for which can be readily converted into the $\Delta\epsilon$ value for a cell of type (A) by a computational procedure.

On the basis of the non-thermodynamic assumption of equal surface potentials, a voltaic cell of type (A) essentially permits an experimental determination of the dependence of the Galvani potentials of the individual electrodes on the composition of the electrolyte solution. A similar relation for the liquid junction potentials permits a determination for voltaic cells of the type

$$\mathrm{Hg}\,|\,\mathrm{Hg_2Cl_2}\,|\,\text{saturated KCl solution}\,|\,\mathrm{HA},\ m\,|\,\mathrm{air}\,|\,\text{standard solution}\,|\,\text{reference electrode}. \qquad (B)$$

Indeed if the potential jump at the interface between the HA solution and air does not vary with the composition of the solution, the change $\Delta\epsilon$ for a voltaic cell of type (B) is due exclusively to the change in the liquid junction potential ΔE_j at the interface between the HA solution and the saturated KCl solution.

3. The Concepts of the "Real" Ionic Activity and the "Real" Acidity of the Medium

For further exposition, it is important to consider the concepts of the "real" ionic acitivity in solution[46] and the "real" acidity of the medium[47]. The activities of individual ions in solution a_i as well as the activities of the electrically neutral components are usually defined by the equation

$$\mu_i = \mu_i^\circ + RT\ln a_i = \mu_i^\circ + RT\ln m_i\gamma_i, \qquad (9)$$

where μ_i° is the chemical potential of ions of type i in the standard state, γ_i their chemical activity coefficient in the test solution, and m_i their molality. However, a physical interpretation of Eqn. (9) is difficult, because it is impossible to imagine a real transfer of the charged solution component from the standard state to the test solution without crossing the interface. Rabinovich et al.[46] suggested that the thermodynamic activities of ions in solution be defined by the equation

$$a_i = a_i^\circ + RT\ln a_i^r = a_i^\circ + RT\ln m_i\gamma_i^r, \qquad (10)$$

where m_i, a_i^r, and γ_i^r are the molality, real activity, and real activity coefficient of species of type i respectively. In the special case of H^+ ions the quantity $-\ln a^r_{H^+} = pa^r_H$ will be called the real acidity of the solution (medium). The following real physical process corresponds to Eqn. (10): the transfer of one gramme-ion of charged species of type i from the electrically neutral test phase to the standard phase (Fig. 2). The ions pass from the test

phase to a point in the gas phase (or *in vacuo*) at an infinite distance from the test phase, crossing the boundary between the test phase and air; in this process they overcome the energy barrier due to the electrical double layer at this boundary, which is characterised by the χ-potential of the phase. In such a transition it is necessary to expend work equal to the real solvation energy of species of types i in the test phase. Next the ions pass from the gas phase to the standard phase, also crossing (this time in the opposite direction) the corresponding interface. This transition involves a gain in work equal to the real solvation energy of species of type i in the standard phase. Thus the quantities a_i^r and γ_i^r are measures of the change in the real solvation energy (real potential) of the charged species on passing from the standard state to the test solution. If the transfer process proceeds under the conditions of equal surface potentials of the phases ($\Delta\chi = 0$), then, according to Eqns. (2) and (9), the real activity and activity coefficient are equal to the corresponding chemical quantities.

We shall employ the same formal treatment for the real activities and activity coefficients of ions as for the mean ionic activities and activity coefficients of electrolytes. The overall real activity coefficient γ_i^r becomes unity only at infinite dilution in aqueous solution. For the test solvent, γ_i^r tends to a limiting value $\gamma_i^{r\circ}$ when $m_i \to 0$. We shall call this value the real solvent activity coefficient. The activity coefficients γ_i^r and $\gamma_i^{r\circ}$ are linked by the relation

$$\gamma_i^r = \gamma_i^{r*}\gamma_i^{r\circ}. \qquad (11)$$

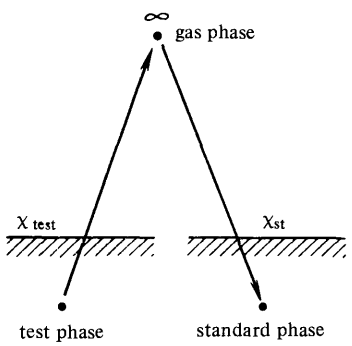

Figure 2. Schematic illustration of the transfer of the charged component of the electrolyte solution from the test phase to the standard phase via the gas phase.

The coefficient γ_i^{r*}, which we shall call the real concentration activity coefficient, becomes unity at infinite dilution in the given solvent. Finally, the product of the real activity coefficients of the electrolyte ions is equal to the square of the mean ionic activity coefficient:

$$\gamma_+^r\gamma_-^r = \gamma_\pm^2. \qquad (12)$$

The activity coefficients $\gamma_\pm$, $\gamma_\pm^*$, and $\gamma_\pm^\circ$ are usually called the overall, salt, and solvent effects of the medium respectively. However, this terminology is inapplicable to real activity coefficients, since their numerical values, obtained from experimental data, depend not only on the state of the ions in the bulk of the solution but also on the electrical states of the surfaces of the solutions being compared. Only when the experiment is carried out under the conditions of equal χ-potentials of the solutions being compared can the real activity coefficients be interpreted as medium effects for the individual ions.

III. DISCUSSION OF EXPERIMENTAL RESULTS OBTAINED BY THE SURFACE POTENTIAL STABILISATION METHOD

The stabilisation of the χ-potential by surface-active substances was observed[48] for HCl solutions. The authors determined the real activity coefficients of H^+ and Cl^- ions in aqueous and aqueous alcoholic HCl solutions by measuring the compensating potentials of the voltaic cell

$$Ag \mid AgCl \mid HCl, m \mid air \mid KCl, m_{st} \mid AgCl \mid Ag,$$

and the electrical potentials of the galvanic cells

$$Pt(H_2) \mid HCl, m \mid AgCl \mid Ag.$$

It was found that the values of $\gamma_{H^+}^{r*}$ and $\gamma_{Cl^-}^{r*}$, which differ sharply from one another and from the $\gamma_\pm^*$ in pure HCl solutions, approach one another and almost coincide with the $\gamma_\pm^*$ for solutions to which 1% of n-pentyl alcohol has been added (Table 1). This was given the following explanation, which subsequent studies showed to be inaccurate. Molecules of n-pentyl alcohol, which have a higher adsorption potential at the solution–air interface, displace the ions and undissociated HCl molecules from the surface layer of the solution, as a result of which the electrical properties of the surfaces of the HCl solutions become the same for different compositions.

Table 1. The real activity coefficients of H^+ and Cl^- ions in pure aqueous HCl solutions (*a*) and in HCl solutions containing 1% of n-pentyl alcohol (*b*) at 25°C.

HCl, M	*a*		*b*		*a*

0.01	0.82	0.99	0.90	0.94	0.90
0.02	0.79	0.98	0.87	0.92	0.88
0.05	0.74	0.94	0.82	0.88	0.83
0.10	0.70	0.89	0.78	0.86	0.80
0.20	0.71	0.82	0.73	0.85	0.77
0.50	0.98	0.59	0.72	0.85	0.76

The observed stabilisation of the χ-potentials of aqueous HCl solutions was then used[49] to determine the acidity of the medium in the HCl–H_2O system over the complete range of compositions. Voltaic cells of type (A′) were used for the measurements. The HCl–H_2O mixtures investigated were saturated with surface-active alcohols and aliphatic acids. The authors observed that the experimental real acidities pa_H^r of the solutions stabilised by heptyl and nonyl alcohols agreed with the corresponding Hammett acidity functions H_0,[50] while the pa_H^r for pure HCl solutions differed sharply from the H_0 (Table 2). Table 2 shows that significant discrepancies between pa_H^r and H_0 for solutions with heptyl alcohol are observed for concentrations of 12 M and above and for solutions saturated with n-nonyl alcohol for concentrations of 14 M and above. The mutual approach of the

values of pa_H^r and H_0 was explained by the complete equalisation of the χ-potentials of the HCl solutions when the latter were saturated with a surface-active agent, whose molecules displaced the electrolyte (HCl) from the surface layer. The agreement between the acidities of the medium obtained by fundamentally different methods is itself remarkable if one recalls that more than 10 different indicator acidity scales[51] are known at present for the H_2SO_4–H_2O, $HClO_4$–H_2O, and HCl–H_2O systems, which do not agree. This provides some justification for the interpretation of both the pa_H^r and H_0 values for HCl solutions as the protic activities of the medium pa_H.

Table 2. Comparison of the acidity functions for HCl–H_2O solutions on the basis of the results of Rybkin and Shevchenko[49].

*According to the results of Vinnik et al.[50]

The study of the stabilisation of the χ-potentials of solutions of strong inorganic acids was continued in another investigation[52], where the χ-potential shifts for the HCl solutions at different concentrations under the influence of surface-active alcohols were determined with the aid of a voltaic cell of type (B). Figs. 3 and 4 and Table 3 illustrate the results of this study in relation to the χ-potential shifts due to the adsorption of n-heptyl and n-perfluoroheptyl alcohols. Whereas the χ-potential shift on passing from pure 0.1 M HCl solution to the corresponding HCl solution saturated with n-heptyl alcohol is about 300 mV, the shift for the 15 M HCl solution is about 550 mV.

This was explained[52] by the fact that in concentrated HCl solutions the formation of a monolayer of the surface-active alcohol at the solution–air interface is accompanied by the disruption of the double layer due to the adsorption of HCl. Another explanation is also possible. The monolayer of the surface-active molecules screens the adsorption layer formed by the HCl dipoles, as a result of which the latter does not influence the external potential of the solution. Therefore, when HCl solutions are saturated with a surface-active alcohol, their χ-potentials are determined only by the monolayer of the surface-active molecules, regardless of the HCl concentration, and are therefore the same for all HCl solutions. Since the adsorption of n-heptyl alcohol and of HCl shift the χ-potential of water in opposite directions, these effects are combined and the overall shift of the χ-potentials of concentrated HCl solutions is large.

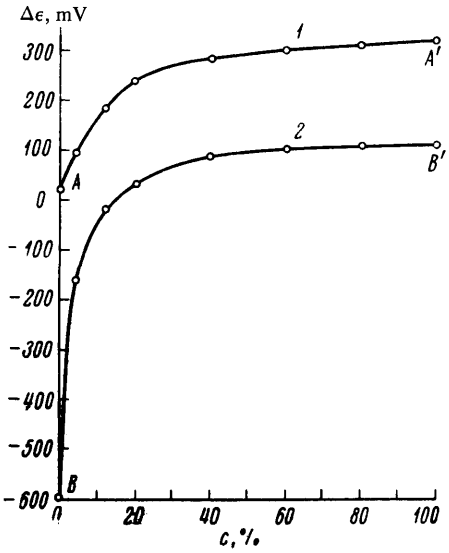

Figure 3. The adsorption shift of the χ-potentials of HCl solutions following their saturation with n-heptyl alcohol [1) 0.32 M HCl; 2) 16.42 M HCl]. The concentration c of the surface-active agent, expressed as a percentage relative to its concentration in the saturated solution, is plotted as abscissa.

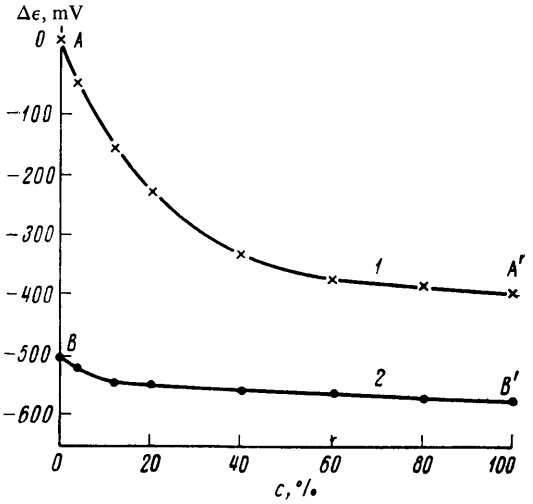

Figure 4. Adsorption shift of the χ-potentials of HCl solutions following their saturation with n-perfluoroheptyl alcohol [1) 0.3 M HCl; 2) 14.7 M HCl]. The concentration c of the surface-active agent, expressed as a percentage relative to its concentration in the saturated solution, is plotted as abscissa.

In conformity with the foregoing considerations, the lengths of the $A'B'$ sections in Figs. 3 and 4 can be interpreted as representing the change in the compensating potential of a cell of type (B) caused exclusively by the change in the liquid junction potential ΔE_j at the interfaces between the test solutions and the saturated KCl

solution as the HCl concentration is varied. The lengths of the *AB* sections in these figures reflect the changes in $\Delta\epsilon$ for a cell of type (B) caused both by the shift of the χ-potential of water following the adsorption of HCl at the solution–air interface and by ΔE_j as the HCl concentration is varied. If it is assumed that the ΔE_j are independent of the presence of the surface-active agent in the HCl solutions, it is easy to calculate the change in the adsorption potential of hydrochloric acid ΔE_{HCl} at the solution–air interface with change in the HCl concentration. The adsorption potential of HCl (ΔE_{HCl}) is understood as the component of $\Delta\epsilon$ for a voltaic cell of type (B) due to the adsorption of HCl alone at the solution–air interface. The numerical values of ΔE_{HCl} are equal to the lengths of the *AB* and *A'B'* sections and are listed in Table 3.

*Averaged for solns. stabilised with n-heptyl, n-perfluoroheptyl and isopentyl alcohols.

**The positive sign ΔE_j, ΔE_{HA}, and $\Delta\epsilon$ implies that the reference electrode in a cell of type (B), immersed in the standard solution, becomes more positive owing to these potential shifts relative to the calomel electrode in the test solution.

***Referred to the compensating potential of a cell of type (B) for pure 0.01 M HCl solution.

The curves in Fig. 4 represent the χ-potential shifts for HCl solutions under the influence of n-perfluoroheptyl alcohol, which displaces the potential of water in the same direction as that of HCl. Therefore, the overall shift of the χ-potential diminishes with increase of HCl concentration and it may happen that in concentrated HCl solutions the surface activity of n-perfluoroheptyl alcohol is reduced. It is interesting that, when n-heptyl and n-perfluoroheptyl alcohols are used, similar values of ΔE_j and ΔE_{HCl} are obtained. Figs. 3 and 4 also show that the "tail" sections of the curves relating $\Delta\epsilon$ to the concentration of the surface-active agent are almost parallel.

When the variation of ΔE_{HCl} with the concentration of the surface-active agent is determined, it is found that, at a relative concentration of n-heptyl alcohol of 4%, the adsorption potential ΔE_{HCl} is already close to zero.

Thus, at comparatively low concentrations of the surface-active agent, the electrical properties of the surfaces of the solutions already approach those of the surface of the solution saturated with the surface-active alcohol. As before[49], the values of pa_H^r found from the observed ΔE_j and the experimental data for the cells with transport

$$Pt(H_2)\,|\,HCl,\ m\,|\,\text{sat. KCl soln.}\,|\,\text{reference electrode}\ \S$$

proved to be extremely close to the corresponding acidity functions H_0.[53]

The results of experiments on the stabilisation of the χ-potentials of concentrated HBr and $HClO_4$ solutions have been published[54]. Calculation of pa_H^r for HBr solutions from experimental data for cells of types (B) and (B') on the assumption that the surface-active agent (n-heptyl alcohol) causes the complete equalisation of the χ-potentials of the HBr solutions leads to values which differ appreciably from the corresponding acidity functions H_0 [55] (Table 4). This result can be explained by the fact that n-heptyl alcohol only partially stabilises the χ-potentials of HBr solutions. The monolayer of n-heptyl alcohol molecules, screening the adsorption layer of HBr dipoles, cannot constitute an obstacle to the electrostatic field generated by the Br^- ions which have undergone specific adsorption at the solution–air interface.

Table 4. The acidity functions pa_H^r and H_0, the adsorption potentials ΔE_{HA} and ΔE_{A^-}, the changes in the liquid junction potential ΔE_j in cell (B), and the compensating potentials $\Delta\epsilon$ in cell (B) for $HBr–H_2O$ solutions at 25°C.

16	9.34	5.47	—	—	229	—	—	415

Accordingly, the χ-potential shift can be expressed as a function of HBr concentration in the form of a sum of the changes of two components: the adsorption potential due to the adsorbed undissociated HBr molecules (ΔE_{HBr}) and the adsorption potential due to the specifically adsorbed Br^- ions (ΔE_{Br^-}). The values of ΔE_{Br^-} can be estimated approximately from the χ-potential shift for water[56] under the influence of metal bromides, obtained with the aid of a voltaic cell of the type

$$Hg\,|\,Hg_2Cl_2\,|\,\text{sat. KCl. soln.}\,|\,MBr\,|\,\text{air}\,|\,\text{reference soln.}\,|\,\text{reference electrode.}\ \S$$

§Cell (B')? (Ed. of Translation).

Although the estimate of ΔE_{Br^-} for HBr solutions involves at least two gross assumptions (namely that the degrees of dissociation of HBr and metal bromides MBr are the same in equimolar solutions and that the liquid junction potentials in the above voltaic cell does not vary with MBr concentration), allowance for ΔE_{Br^-} in the calculation of pa_H^r from experimental data leads to satisfactory agreement between pa_H^r and the values of H_0, as can be seen from the data in Table 4. The results obtained for $HClO_4$ solutions were exactly the same (Table 5).

Table 5. The acidity functions pa_H^r and H_0, the adsorption potentials ΔE_{HA} and ΔE_{A^-}, the changes in the liquid junction potential ΔE_j in cell (B), and the compensating potentials $\Delta\epsilon$ in cell (B) for $HClO_4$–H_2O solutions at 25°C.

Commenting on the results described[52,54], the following factors should be noted. The complete stabilisation of the χ-potential by non-ionogenic surface-active substances (particularly aliphatic alcohols) can be achieved only when there is no specific adsorption of the charged solution components and charged monolayers are not formed on the free solution surface. The question of the stabilisation of the surface potentials of solutions on the free surfaces of which charged species are specifically adsorbed remains open and its further investigation is extremely desirable. Furthermore, the changes $\Delta\epsilon$ for voltaic cells of type (B) as the acid concentration is varied can be divided into three components corresponding to the changes in the liquid junction potential ΔE_j, the adsorption potential ΔE_{HA} due to the molecular adsorption of acids and the adsorption potential ΔE_{A^-} due to the specific adsorption of the acid anions.

The results[52,54] yielded new information about the structure of the surfaces of solutions of strong inorganic acids. To explain the anomalously high adsorption shift of the χ-potential caused by strong acids, Randles suggested that H_3O^+ ions in the surface layer are preferentially oriented with the three H atoms directed towards the liquid phase. He believes that the other possible explanation, involving the preferential orientation of the ion pairs or undissociated acid molecules near the surface is unlikely, since $HClO_4$ and HI cause the greatest shifts of the χ-potential, while the dipole moments of these acids are smaller than that of HCl. The results presented in Tables 3, 4 and 5 show that, although $\Delta\epsilon$ for a cell of type (B) does decrease in the sequence $HClO_4 > HBr > HCl$, the quantity ΔE_{HA} increases in this sequence, which agrees with the increase in the dipole moments of the molecules on passing from HBr to HCl (the dipole moments of $HClO_4$ molecules are not available). Thus the experimental results support the hypothesis of the preferential orientation of the undissociated acid molecules in the surface layer.

The fact that the adsorption potentials of acids can be divided into molecular and ionic components (ΔE_{HA} and ΔE_{A^-}) using experimental data (on the basis of the non-thermodynamic assumption of the equality of the surface potentials of the stabilised solutions) suggests that the surface layers of solutions of strong acids consist of two sublayers. The upper sublayer adjoining the gas phase contains undissociated acid molecules with a preferential orientation of the dipoles such that the negative poles point towards the gas phase. These molecules may be hydrated. Ion pairs separated by solvent molecules are located in the lower sublayer with the same orientation of the dipoles. The monolayer of molecules of the surface-active agent on the solution–air interface screens the field generated by the acid and solvent dipoles in the upper sublayer. However, this sublayer does not constitute an obstacle to the electrostatic field generated by the ion pairs.

Table 6. The acidity functions pH, pa_H^r, and H_-, the adsorption potentials, the liquid junction potentials in cell (B), and the compensating potentials $\Delta\epsilon$ in cell (B) for NH_3–H_2O and N_2H_4–H_2O solutions at 25°C.

The stabilisation of the surface potentials of concentrated NH_3 and N_2H_4 solutions has been investigated[58,59] by the method used by Rybkin and Karpenko[52]. The surface-active agents employed were isopentyl and hexyl alcohols, hexylamine, and 1,1,3-tetramethylbutylamine. The use of these agents leads to similar values of ΔE_j and pa_H^r (Table 6). ΔE_j for NH_3–H_2O solutions does not vary greatly (only by 35 mV on passing from dilute solutions to 12 M NH_3 solution). Therefore, the real acidities of these media differ little from the pH. There are no literature values of the acidity functions H_0 or H_- for NH_3–H_2O solutions, which precludes a comparison of the results of the electrometric and indicator methods for the measurement of the acidity of the medium.

The ΔE_j for N_2H_4–H_2O solutions are negative at low concentrations, but their sign changes at concentrations above 10 M. As in NH_3–H_2O solutions, ΔE_j does not reach high values (about 25 mV in the 20 M solution), as a result of which the values of pa_H^r and pH are similar. However, they differ somewhat from the H_-.[60] The authors do not give a preference for any one of these acidity scales. Nevertheless, bearing in mind the results of Rybkin and Karpenko[54], the following remarks may be made. NH_3 and N_2H_4 solutions are extremely convenient for applying the method based on the stabilisation of the surface potential, since the ionisation of ammonia and hydrazine in the bulk of the solution and hence in the surface layer is insignificant. Because of this, it is extremely likely that the surface potentials of these solutions are completely equalised when they are saturated by surface-active agents. It also permits the assertion that the pa_H^r scale reflects most satisfactorily the concentration dependence of the acidity of the medium for the NH_3–H_2O and N_2H_4–H_2O systems.

The study of the stabilisation of the surface potentials of concentrated lithium, sodium, and potassium hydroxide solutions[59] yielded less clear-cut results owing to experimental difficulties caused by the salting-out of the surface-active substances in concentrated solutions of alkalis and by the poor wetting of the glass by the solutions saturated with the surface-active agent. Nevertheless, experiment showed that the shift of the χ-potential following the addition of the surface-active agents to the solutions of alkalis decreases in absolute magnitude with increased concentration of alkali. This indicates the stabilisation of the surface potentials of these solutions and presumably the stabilisation is fairly satisfactory, since OH^- ions show a smaller tendency towards specific adsorption at the solution–air interface compared with other ions. Furthermore, the adsorption of OH^- ions should be compensated to some extent by the specific adsorption of the cations. Comparison of the pa_H^r and pH scales with the known values of H_- [61–65] for concentrated lithium, sodium, and potassium hydroxide solutions (Table 7) shows that the indicator method yields unduly high values of the basicity of the medium. However, the insufficiency of experimental acidity data and the experimental difficulties in the study of the stabilisation of the χ-potentials of these media make it so far impossible to give preference to any of the acidity scales mentioned above.

The stabilisation of the χ-potential of the HCOOH–H_2O system has been studied[66,67] by means of a voltaic cell of type (A′). Caproic and oenanthic acids were used as surface-active agents, because the employment of alcohols is undesirable owing to the possible formation of esters. Like the NH_3 and N_2H_4 solutions, HCOOH–H_2O mixtures are suitable for the application of the surface potential stabilisation method, since HCOOH is a moderately strong acid and therefore the specific adsorption of anions in the surface layer should be significant. A constant amount of added caproic and oenanthic acids (0.1 and 0.03 mole % respectively) stabilises the χ-potentials of the HCOOH–H_2O mixtures, as shown by the markedly different acidity functions pa_H^r obtained for the pure HCOOH–H_2O mixtures and for the same mixtures containing the surface-active agent (Table 8). Table 8 also lists the acidity functions H_0 [68] and the pH. The results in Table 8 show that the pa_H^r differ sharply from the corresponding values of the other functions, indicating a higher acidity of the medium than that given by the other functions.

Table 8. The acidity functions pa_H^r, pH, and H_0, the compensating potentials in cell (B), the adsorption potentials of formic acid, and the liquid junction potentials in cell (B) for HCOOH–H_2O solutions at 25°C.

*Interpolated from literature data[68].

The following comments may be made concerning Table 8. The known values[69] of the adsorption shift of the χ-potentials of water caused by aliphatic carboxylic acids (ranging from formic to caproic) are listed without correction for the change in the liquid junction potential in a cell of type (B). These data create the impression of an anomalous behaviour of formic acid, the addition of which

to water causes a negative shift of the χ-potential [negative values of $\Delta\epsilon$ for a cell of type (B) in Table 8], while the addition of the remaining acids of the same homologous series leads to a corresponding shift in the opposite direction. The results[66,67] compiled in Table 8 show that the adsorption behaviour of formic acid at the solution–air interface is not anomalous: the corresponding function ΔE_{HA} assumes positive values, reaching almost 330 mV, which is extremely close to the corresponding values of this function for butyric, valeric, and caproic acids (349, 355, and 340 mV respectively)[69]. The negative values of $\Delta\epsilon$ for a voltaic cell of type (B) are caused by the fact that the liquid junction potential in this cell shifts faster than ΔE_{HA} and in the opposite direction, reaching a value of about 400 mV for concentrated formic acid.

It is striking that, in the range of compositions from 0 to 35 mole % HCOOH, there is a sharp variation of both ΔE_j and the acidity of the medium. For this reason, in a cell of type (B′) the concentration variation of the potential of the hydrogen electrode, due to the changes in the acidity of the medium, is partly compensated by the corresponding variation of ΔE_j. As a result, measurements using cells of type (B′) lead to low pH values, which incorrectly reflect the acidity of the HCOOH–H_2O solutions. Low Hammett acidity functions H_0 have also been observed for such solutions[68], but the reason for this has not been established accurately. They are probably caused by the specific interaction of the indicator base, used for the measurement of H_0, with formic acid, of the type observed by Kolthoff and coworkers[70].

Table 9. The acidity functions pa_H^r and pH, the adsorption potentials of acetic acid, and the changes in the compensating potential and the liquid junction potential in cell (B) for 0.01 M HCl solutions in CH_3COOH–H_2O mixtures at 25°C.

*Found by extrapolation.

The stabilisation of the χ-potentials of 0.01 M HCl solutions in acetic acid–water mixtures has been studied[71]. The results are compiled in Table 9. The values for 100% acetic acid were obtained by extrapolation. The surface-active agent (caproic acid) stabilises the surface potentials of the solutions (at least at low acetic acid concentrations), as shown by the markedly different values of pa_H^r for the pure solutions and the solutions stabilised by caproic acid. The function ΔE_{HA} for acetic acid assumes positive values, reaching approximately 320 mV, which is a little less than the corresponding values for formic[66,67], butyric, valeric, and caproic acids[69].

As for HCOOH–H_2O mixtures, a fairly sharp variation of the acidity of the medium and of the liquid junction potential in a cell of type (B) at low acetic acid concentrations (up to 10 mole %) is characteristic of CH_3COOH–H_2O mixtures and these two effects again partly cancel out, as a result of which the pH of these solutions, determined with the aid of cells of type (B′), varies more slowly with solvent composition than pa_H^r. According to Schwarzenbach and Stensby[72], H_0 varies even more slowly. At high acetic acid concentrations, pH overtakes pa_H^r. This may be associated with the unusual dependence of the liquid junction potential on solvent composition, the potential shifting towards negative values at low acetic acid concentrations, reaching a minimum of 10–15 mole% of acetic acid and then slowly shifting towards positive values at high concentrations. This behaviour of ΔE_j appears strange and may be associated with an experimental error. This is suggested also by the finding that the ΔE_{HA} function for acetic acid does not reach values characteristic of caproic and other carboxylic acids and the ΔE_{HA}–composition curve for the CH_3COOH–H_2O mixtures passes through a maximum. At high acetic acid concentration the introduction of caproic acid into the solutions probably does not adequately stabilise the surface potential. The problem of the stabilisation of the χ-potential in the CH_3COOH–H_2O system requires further study.

Table 10. The compensating and liquid junction potentials in cell (B), the adsorption potentials of CH_3OH, and the $\lg \gamma^{\circ r}_{H^+}$ for hydrogen ions in dilute HCl solutions in CH_3OH–H_2O mixtures at 25°C.

The assumed constancy of the surface potential has been used to determine the medium effects of H^+ ions on passing from water to methanol[73]; the surface potentials of dilute HCl solutions in aqueous alcoholic solvents were stabilised by heptyl alcohol. The results are illustrated in Table 10. As regards certain features, they resemble the results for HCOOH–H_2O and CH_3COOH–H_2O mixtures. In particular, at low methanol concentrations in the solvent both the acidity of the medium (pa_H^r) and the liquid junction potential vary sharply. Therefore, in a cell of type (B′) the shift of the hydrogen electrode potential due to the change in the acidity of the medium is overlapped by the corresponding more marked shift of ΔE_j, as a result of which the pH values measured with the aid of this cell yield incorrect information about the acidity of the aqueous alcoholic HCl solutions. In contrast to the

behaviour of the HCOOH–H_2O and CH_3COOH–H_2O mixtures, small amounts of added organic solvent do not increase but actually decrease the acidity of the medium and the liquid junction potential shifts towards positive values rather than to negative values.

The above features and also the results discussed previously for the HCl–H_2O, $HClO_4$–H_2O, HBr–H_3O, NH_3–H_2O, and N_2H_4–H_2O systems suggest that there is at least a qualitative correlation between the variation of the acidity of the medium and the corresponding variation of the liquid junction potential: an increase of acidity is accompanied by a shift of the liquid junction potential towards negative values, while a decrease of acidity corresponds to a positive shift of ΔE_j. In other words, with decreased basicity of the medium, the tendency of H^+ ions to cross the test solution–saturated KCl solution interface is weaker than for ions of the opposite sign. However, a quantitative correlation cannot be observed. It is appropriate to mention here that the idea of a relation between the acid–base interactions in solutions and the anomalous mechanism of charge transfer by H^+ ions has already been suggested in the literature [74]. Continuing the analysis of the results of experiments on the stabilisation of the χ-potentials of aqueous alcoholic HCl solutions, mention must be made of the fact that there is a qualitative agreement between the results obtained from the analysis of the dependence of the functions $\lg \gamma^{\circ r}_{H^+}$, $\lg \gamma^{\hat{r}}_{H^+}$, and H_0 on the composition of the aqueous alcoholic solvent [8,55]. The sharp decrease of the acidity of the medium following the addition of small amounts of methanol to water is consistent with the changes in the other volume properties of electrolytes in alcohol–water mixtures and with the changes in the volume properties of the mixtures themselves, which can be explained by the stabilisation of the water structure in the presence of alcohol molecules [75,76].

It is known that the addition of inorganic salts to water usually leads to an increase in the surface tension of the solutions formed, as a result of which the surface layers of such solutions are depleted in the electrolyte. According to the calculations of a number of investigators [77,78], the thickness of the surface layer free from the electrolyte ranges from 3 to 5 Å for dilute aqueous solutions of strong electrolytes. This suggests that the surface potentials of electrolyte solutions, whose ions exhibit a weak tendency towards specific adsorption at the solution–air interface, do not differ significantly from the surface potential of pure water. This is valid also for fairly dilute solutions of weak electrolyte, which are not very active at the solution–air interface. If this is true, the voltaic cells of type (A) or (A′) can be used to compare the activities of individual ions (in particular the medium acidities) in such solutions or to estimate ΔE_j without introducing into the test solutions surface-active agents in order to stabilise the surface potential. Direct evidence for the weak influence of electrolytes on the surface potentials of solutions has been published [79–81]. The acidities of standard buffer solutions have been compared without the stabilisation of the potentials [82] and it has been shown that the values of pa^r_H obtained using a voltaic cell of type (A) do not differ from the corresponding values of pa_H (to within 0.02). A standard hydrogen phthalate buffer solution was an exception for reasons which are not altogether clear; according to the results of Kamienski et al [83] both potassium hydrogen phthalate and phthalic acid are surface-active.

The acidities of dilute HCl solution and standard buffer solutions have been compared in the presence of high concentrations of neutral salts [84,85]. The main result of these studies is that the values of pa^r_H and pH agree over fairly wide ranges of the concentrations of the supporting salt. Thus pH and pa^r_H for 0.01 M HCl solution agree up to LiCl, NaCl, and KCl concentrations of 3.5, 3.0, and 1.5 M respectively. The discrepancies between pH and pa^r_H at higher concentrations of the neutral salts can be naturally accounted for by a shift of the χ-potential of the solution due to the appearance of electrolyte ions in the surface layer. Then anions, which are less hydrated, are on average distributed closer to the solution–air interface than cations. A definite inference can be drawn about the diffusion potential at the interfaces between concentrated salt solutions and the saturated KCl solution. The agreement between pH and pa^r_H over a fairly wide range of concentrations of the neutral salts suggests that the diffusion potential varies little with salt concentration and the measurements of the pH of salt solutions in cells with transport are fairly reliable. One should not expect an appreciable effect of acidity on ΔE_j in concentrated salt solutions, of the kind observed in the systems discussed above, since charge transfer across the liquid junction is effected by the salt ions and not H^+ ions.

In conclusion the following remarks may be made. The technique involving the stabilisation of the surface potentials of solutions makes it possible to obtain information about the thermodynamic characteristics of individual ions and liquid junction potentials, which are in good agreement with data found by other non-thermodynamic methods. In many cases this makes it possible to obtain completely new data (for example, for the HCOOH–H_2O, CH_3COOH–H_2O, NH_3–H_2O, and N_2H_4–H_2O systems), which had been hitherto outside the scope of other methods. The technique involving the stabilisation of the χ-potentials of solutions yields fairly accurate values of the adsorption potentials of a number of substances (for example, HCl, HBr, $HClO_4$, HCOOH, CH_3COOH, CH_3OH, NH_3, and N_2H_4) at the solution–air interface, which until now could not be achieved owing to the miscibility of these substances with water and owing to the influence of the liquid junction potentials. The knowledge of the adsorption potentials makes it possible to set up a scale of χ-potentials for a number of solvents and media (adopting as the zero point for the readings the χ-potential of water, the absolute value of which is not yet known reliably): CH_3OH (280–290 mV); HCOOH (320–330 mV); CH_3COOH (320–350 mV); 20 mole % HCl–H_2O (about −350 mV); 25 mole % HBr–H_2O (about −210 mV); 10 mole % $HClO_4$–H_2O (about −115 mV); 10 mole % NH_3–H_2O (about 290 mV); 18 mole % N_2H_4–H_2O (about 330 mV). The χ-potential scale may prove useful in the derivation of information about the chemical potentials of individual ions on the basis of the experimental values of the real potentials of these ions.

The Oxygen Dimers, Clusters, and Cluster Ions in the Gas Phase

N.P.Lipikhin

The formation, thermodynamic properties, and chemical reactions of neutral and charged oxygen clusters of the type O_{2n} ($n \geqslant 2$), (O_4^- and $O_4^+ - O_{18}^+$) as well as oxygen clusters with other molecules (N_2, N_2O, SO_2, H_2O, CO_2, NO, and CO) are examined.
The bibliography includes 49 references.

I. INTRODUCTION

In a mass-spectrometric study of oxygen which had passed through an ozoniser Grundland[1] observed in 1953 weak currents due to ions with masses of 48 and 64 and attributed them to the presence in the ozonised oxygen of ozone (O_3) and "oxozone" (O_4) molecules. He was apparently the first to attempt the detection in oxygen at normal temperatures and pressures of polymeric oxygen molecules as well as oxygen ions with large masses.

Although Grundland's data were subsequently disproved in a number of studies[2-4], the presence of dimeric molecules O_2-O_2 in oxygen under normal conditions and the formation of clusters on adiabatic expansion of the gas has been recently demonstrated mass-spectrometrically and spectroscopically.

Improvements in technique of mass-spectrometric and certain other physical research methods for reactions in gases made it possible to investigate the thermodynamics and kinetics of the formation of positive and negative oxygen cluster ions $O_{2n}^{\pm}$ and also heteromolecular oxygen cluster ions $O_{2n}^{\pm}X_kY_lZ_m$ incorporating neutral molecules X, Y, and Z such as H_2O, CO_2, and NO.

It has been shown mass-spectrometrically[5,6] that these ions are very reactive. One of the causes of this is their capacity to form a relatively long-lived ion-molecule (molecules) complex, i.e. a cluster ion. The reaction time proved to be sufficient for bond rearrangement[7]. For example, the complex $O_2^-.H_2O$, formed as an intermediate in the reduction of oxygen by low-energy electrons, plays an important role in the chemistry of the ionosphere. Other oxygen cluster ions are also characteristic of the chemistry of the low-temperature plasma and of the radiation chemistry of gases.

The bond in the $AB^{\pm}$ cluster ion is mainly due to the polarisation of the molecule A under the influence of the ion $B^{\pm}$; the bond energy is given to a first approximation by the equation $V_n = -\alpha e^2/2r^4$, where α is the polarisability of the molecule A, r the distance between the centres of A and $B^{\pm}$, and e the electronic charge.

Comparison with experimental values of bond energies and other parameters of oxygen cluster ions, which have now been calculated by quantum-mechanical and statistical physical methods, yields valuable data for the theory of the chemical bond. The knowledge of the chemistry of oxygen cluster ions may be useful in the development of ways of synthesising new potential sources of oxygen which are valuable in practice.

II. THE O_4 MOLECULE, OXYGEN CLUSTERS

The existence of O_4 molecules is due to weak intermolecular interactions. The bond strength in such molecules is hundreds of times smaller than in the usual chemical compounds, for example the O_2-O_2 bond energy has been estimated as 460 cal $mole^{-1}$.[8]

The interaction of oxygen molecules in the gas phase leads to three types of binary species: collision pairs, metastable dimers, and bound dimers[9]. The collision pair is a pair of molecules in the gas phase subjected to appreciable mutual attraction (the molecules are usually separated by a distance of 5-10 Å during the collision) and having a kinetic energy greater than the height of the potential barrier on the intermolecular potential. The lifetime of the molecules of this type has been estimated as 10^{-13} s under the usual conditions.

When a so-called "triple" collision occurs and the third species acquires part of the kinetic energy of the other two colliding molecules, the metastable dimer—the O_2-O_2 molecule with energy greater than its dissociation energy but smaller than the maximum on the potential curve—may be formed. The lifetime of the metastable dimer has been estimated as $10^{-11}-10^{-16}$ s. The triple collision can result also in the formation of the bound dimer—a stable molecule with energy below the dissociation energy of the O_2-O_2 bond.

Metastable dimers can decompose spontaneously as a result of the tunnel effect. Since the rotational energy of the dimer in the gas phase at normal temperatures is comparable to the depth of the well on the potential energy curve for the dimer, the concentrations of the bound and metastable dimers are approximately equal.

The O_2 molecule does not have a dipole moment and therefore does not absorb in the infrared. On contact with another molecule, its quadrupole moment generates a dipole moment in its neighbour, which modulates the vibrational and rotational frequencies of the molecule, so that absorption in the infrared becomes possible. In other words, the pair of colliding oxygen molecules

absorbs due to transitions which are forbidden in the absence of the collision. The bands of such absorption should be broad and diffuse owing to the short lifetime of the colliding pair. On the other hand, the bound dimer should give rise to narrow absorption bands in consequence of its relatively long lifetime.

There are numerous spectroscopic data showing that at room temperature oxygen contains only collision pairs[10,11,12]. The infrared spectra of solutions of oxygen in liquid nitrogen show a broad shoulder on the vibrational absorption band induced by collisions, which vanishes on dilution; this phenomenon can be attributed to the presence of the dimer[13].

However, the infrared absorption spectrum of solid oxygen does not support the conclusion that individual $(O_2)_2$ molecules exist[14]. An X-ray diffraction study of solid oxygen also ruled out the presence of dimeric species[15]. In 1971 Long and Ewing[16] obtained the infrared absorption spectrum of gaseous oxygen (Fig. 1) at 87 K and a pressure of 559 torr for an optical path length of 152 m. A diffuse doublet with the centre at 1591.2 cm^{-1} was observed. The doublet had components with a width $\Delta\nu_{1/2} \simeq 7$ cm^{-1} and with centres at 1586.1 and 1596.6 cm^{-1}. These data confirm the presence of bound dimers in gaseous oxygen, which naturally exist also at other temperatures.

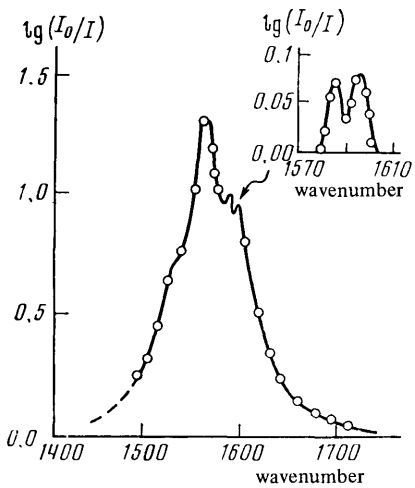

Figure 1. The infrared spectrum of gaseous oxygen induced by collisions.

The energy of formation of $(O_2)_2$ observed in the above study is 830 cal $mole^{-1}$, in good agreement with the value calculated by Stogrin and Hirschfelder[17]. The lifetime of the absorbing species is linked to the width of the corresponding line by the relation $\tau = (2\pi c\Delta\nu_{1/2})^{-1}$. The lifetime of the oxygen dimer, estimated from the doublet width $\Delta\nu \simeq 7$ cm^{-1}, is 10^{-12} s. This shows that the absorbing O_4 species must be regarded as the bound dimer. The actual lifetime of the dimer is somewhat greater than the above value, since the doublet contains a number of unresolved lines.

In 1966 Leckenby and Robbins[18] demonstrated mass-spectrometrically for the first time the presence of dimers in gaseous oxygen at the usual temperature and pressure. The oxygen dimers were detected with the aid of a mass-spectrometer of special design, in which oxygen was admitted into an ion source of the open type through an aperture in a 1 μm foil, the ion accelerating and ion focussing plates having been replaced by grids to increase the pumping rate. The concentration of the $(O_2)_2$ dimers in oxygen at a pressure of 100 torr and 300 K amounted to about 5×10^{-7}.

Previously Leckenby et al.[19] detected mass-spectrometrically dimers, trimers, and heavier clusters in a number of gases, including oxygen, during supersonic adiabatic flow of the gas from a reservoir (of gas pressures up to 40 atm) into a high vacuum maintained by a powerful pump. They found that the variation in the concentration of clusters with the reservoir temperature and pressure is approximately the same for each of the gases investigated; the differences are determined by the critical temperature T_c and pressure p_c and the ratio of the specific heats $C_p/C_V = \gamma$ for the given gas. It was noted that, for gases with similar critical constants T_c and p_c but with different values of γ, the maximum concentration of the polymer is observed at different pressures in the reservoir. Thus in argon ($T_c = -122°C$, $p_c = 48$ atm, $\gamma = 1.66$) the maximum concentration of clusters is reached at a reservoir pressure of 20 atm (at about $\sim 20°C$), while in oxygen ($T_c = -119°C$, $p_c = 50$ atm, $\gamma = 1.40$) it is reached at a pressure in excess of 50 atm. It was also established that gases with high values of γ show a greater tendency towards the formation of clusters.

On the other hand, for gases with similar values of γ the tendency towards polymerisation is determined by the critical constants. Oxygen ($T_c = -119°C$, $p_c = 50$ atm, $\gamma = 1.40$) exhibits a greater tendency towards the formation of clusters than nitrogen ($T_c = -147°C$, $p_c = 33.5$ atm, and $\gamma = 1.40$). In experiments with compressed air the formation of the dimers $(N_2)_2$, N_2O_2, and $(O_2)_2$ in the proportions 1 : 0.3 : 1.6 was observed. The concentration of clusters increases rapidly with increase of gas pressure in the reservoir, reaches a distinct maximum, falls, and then increases again.

Green and Milne[20] also observed the formation of oxygen cluster molecules during the supersonic flow of oxygen under analogous conditions. In 1972 Golomb and Good[21] demonstrated mass-spectrometrically the formation of dimers, trimers, and oligomeric clusters (up to molecules with a mass of 600) in the supersonic adiabatic flow of a number of gases into a vacuum. The maximum concentration of the oxygen dimer was observed at an O_2 pressure in the reservoir-source of 200 torr and a temperature of 400 K.

The clusters thus detected have come to be regarded as condensation "embryos" in the supercooled gas. This view is supported by the finding that gases with high values of T_c, p_c, and γ, i. e. with a considerable tendency towards condensation, show a greater tendency towards the formation of clusters.

Thus the existence of the oxygen dimers (O_2) in the gas under the usual conditions and also of clusters with a high molecular weight in the stream during the supersonic adiabatic flow of the gas must now be regarded as firmly established.

III. OXYGEN CLUSTER IONS

A considerable proportion of studies on the equilibria and rates of formation and decomposition of negative cluster ions were made using instruments consisting of a

combination of a drift tube and a mass-spectrometer[22-25]. A potential difference is applied between two electrodes in a tube 2.5 cm in diameter; these define the drift region (usually 2.5–3 cm long). The primary negative ions are formed by electron impact at the beginning of the drift tube[26]. The electron source is a heated filament or a photocathode. The ions pass from the drift tube to the mass analyser through an aperture of small diameter (25–250 μm) in the centre of the anode. Such devices sometimes operate under pulsed conditions, the ions and electrons being admitted into the drift space in pulses lasting between 1 and 20 μs, which amount to about 1% of the drift time[27,28].

Another type of instrument used in the study of reactions of oxygen cluster ions, in particular positive ions, is the high-pressure mass-spectrometer. Positive ions are obtained by a pulsed electron beam with energies up to 4 keV. The ions drift from the field-free space in the ion source to the inlet aperture in the mass analyser. At pressures up to 10 torr the reaction time reaches some hundreds of microseconds[29]. The use of such a device with pulsed operation for the study of reactions in the absence of a field was first described by Tal'roze and Frankevich[30]. The duration of the electron pulse was usually 10 μs, the time during which the inlet to the mass analyser is open also being 10 μs; the period between the pulses (2 ms) is sufficiently long for the ion current due to the preceding pluse to disappear completely.

The instrument makes it possible to record the time variation of the current due to each ion investigated. In continuous-operation devices the ion–molecule reaction takes place in a field where ions have a kinetic energy exceeding by 1–3 orders of magnitude the thermal energy corresponding to the temperature of the walls of the ionisation chamber. The reaction velocities obtained in such apparatus must be extrapolated to zero field. Such extrapolation involves errors, since the variation of the reaction rate with field strength is not always simple. Pulsed operation devices make it possible to avoid these complications.

A series of studies were made on equilibria involving positive cluster ions of oxygen in low-pressure mass-spectrometers using tritium as the source of ionising radiation[31]. In such apparatus the reaction time is about 1 ms and the time resolution achieved by the amplifier is better than 1 μs.

Reactions involving the formation of heteromolecular oxygen cluster ions and the exchange reactions of the neutral molecule in the cluster were studied using flow apparatus in a stream of carrier gas (helium, argon, etc.). Such flow apparatus makes it possible to investigate the reactions at temperatures from 80 to 600 K and pressures up to 10 torr. Oxygen is ionised by electron impact in the ion source located at the beginning of the tube through which the stream of gas is flowing. The reaction products are detected with a quadrupole mass analyser.

IV. THE O_4^- ION

The early attempts to detect the O_4^- ion in oxygen at 300 K and a pressure in the range 0.6–3 torr using a drift tube[32-34] were unsuccessful, although in analogous experiments at 77.4 and 87.6 K Voshall et al.[35] detected the O_4^- ion and estimated its dissociation energy as 0.06 ± 0.006 eV (1.4 ± 0.2 kcal mole^{-1}) from the temperature variation of the equilibrium constant for the formation and decomposition of O_4^-. On the basis of their results, the authors[35] concluded that the O_4^- ion cannot be detected in the drift tube above 195 K. However, theoretically it was to be expected that the O_4^- ion should be approximately as stable as the O_4^+ ion investigated previously ($\Delta H = -9.6$ kcal mole^{-1}).[36]

Using a high-pressure mass-spectrometer and titanium tritide as a 2 c source of ionising radiation, Conway and Nesbitt[37] detected the O_4^- ion and determined the equilibrium constant for the reaction $O_2^- + O_2 \rightleftharpoons O_4^-$ at temperatures from 273.2 to 352.8 K and oxygen pressures of 6.9 and 12 torr. The equilibrium constants (K, torr^{-1}) for the formation of O_4^- are listed below

T, °K	6 torr	9 torr	12 torr	K_{av}
273.2	9.46 *	10.6 *	10.7	10.3
293.0	1.58	1.55	1.61	1.58
313.4	0.323	0.344	0.335	0.334
333.0	0.102	0.106	0.102	0.103
352.8	0.0323	0.0341	0.0368	0.0344

* Determined for a flow reaction.

ΔH°_{298} for the formation of O_4^-, calculated from the above equilibrium constants, is −13.55 ± 0.16 kcal mole^{-1} (0.59 eV).

Using an improved drift tube, McKnight and Sawina[28] obtained curves relating the relative concentrations of O_4^- and O_2^- ions to drift time in oxygen at 310 K and pressures from 0.5 to 4 torr and found that the equilibrium constant for the formation of O_4^- is 0.5 torr^{-1} (1.6×10^{-17} cm^3), which virtually agrees with the above data of Conway and Nesbitt[37]. McKnight and Sawina[28] measured for the first time the rate of the termolecular reaction involving the formation of O_4^-:

$$O_2^- + 2O_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} O_4^- + O_2 \ .$$

The rate constant k_1 for this reaction is 3×10^{-31} cm^6 mol.$^{-2}$ s^{-1} at 310 K. The rate constant for the reverse reaction was found from the rate constant for the forward reaction and the equilibrium constant: $k_2 = 2 \times 10^{-14}$ cm^3 mol.$^{-1}$ s^{-1}.

Pack and Phelps[38] studied recently the reactions of negative oxygen ions on apparatus consisting of a combination of a drift tube and a quadrupole mass analyser and found that the rate constants for the forward and reverse reactions in the formation of the O_4^- ion are $k_1 = 4 \times 10^{-31}$ cm^6 mol.$^{-2}$ s^{-1} and $k_2 = 2.7 \times 10^{-14}$ cm^3 mol.$^{-1}$ s^{-1} respectively, which agrees well with McKnight and Sawina's data[28]. Thus the reaction of O_2^- with O_2 is fairly rapid, the system reaching equilibrium with a time constant of 1 ms at an oxygen pressure of 1 torr.

The detection of O_4^- ions with the aid of the mass-spectrometer is difficult, since their content at equilibrium is smaller by a factor of 2 than that of O_2^- ions at 310 K and 1 torr and the time constant for equilibration increases with decrease of pressure. In the presence of traces of CO_2 the O_4^- ion is converted into CO_4^- as a result of the reaction $O_4^- + CO_2 \xrightarrow{k} CO_4^- + O_2$ ($k = 4.3 \times 10^{-10}$ cm^3 mol.$^{-1}$ s^{-1}), which masks still further the O_4^- ion (at a CO_2 partial pressure of 10^{-5} torr the time constant for this reaction is 10 ms).[39]

Lecuiller et al.[40] detected the O_4^- ion in the zone of the corona discharge between the surface of an aqueous $FeSO_4$ solution and a negatively charged knife edge (2–30 kV) together with the negative oxygen ions O^-, O_2^-, and O_3^-; they found that the relative concentrations of O_3^- and O_4^- ions depend greatly on the discharge current (0–70 μA). O_4^- ions should be present in the atmosphere, since at a height of 40 km they are formed as a result of the reaction between O_2^- and O_2 with a time constant less than 10 ms;

the presence of CO_2 and H_2O in the troposphere promotes the conversion of O_4^- into water and carbon dioxide clusters followed by their reactions[28].

It is of interest to compare the rates of formation of O_4^- and O_4^+. Durden et al.[29] found that the rate constant for the formation of O_4^+ is 2.8×10^{-30} cm^6 s^{-1} at 298 K and also determined the dissociation energy of the O_4^+ ion as 0.4 eV, while, as stated above, the dissociation energy of the O_4^- ions is 0.58 eV.[37] Thus the rate of formation of the negative cluster ion is smaller by an order of magnitude than the rate of formation of the positive ion, although the bond energy in the negative ion is greater than in the positive ion. Apparently it does not necessarily follow that the higher the bond energy the higher the rate of formation of the cluster ion. The properties of the O_4^- ion investigated show that the ion plays a major role in systems involving negative oxygen ions, for example in the reactions of electrons in the lower layers of the atmosphere.

V. THE O_4^+–O_{18}^+ OXYGEN CLUSTER IONS

In 1964 Yang and Conway[36] determined the equilibrium constant for the reaction $O_2^+ + 2O_2 \rightleftharpoons O_4^+ + O_2$ at temperatures from 239 K to 344 K and oxygen pressures from 1 to 9 torr with the aid of a high-pressure mass-spectrometer and titanium tritide as a 400 mc source of ionising radiation in oxygen. These data are presented in Table 1.

Table 1. The equilibrium constants (K, torr^{-1}) for the reaction $O_2^+ + O_2 \rightleftharpoons O_4^+$.

The familiar relation

$$\Delta F_{T_2} - \langle \Delta C_p \rangle_{av} \left(\Delta T - T_2 \ln \frac{T_2}{T_1} \right) = \Delta F^\circ_{T_1} - \Delta S^\circ_{T_1} \Delta T, \qquad (1)$$

where $\Delta F^\circ_{T_1}$ is the Gibbs free energy of reaction under standard conditions linked to the equilibrium constant K (Table 1) by the relation $\Delta F^\circ_{T_1} = -RT_1 \ln 760 \times K$ and $\langle Cp \rangle_{av} = 2.8$ cal mole^{-1} deg^{-1} is the average change in heat capacity in the above temperature range, was used to determine the thermodynamic characteristics of the reaction. The estimate was based on the assumption that O_4^+ is a rigid linear complex with a distance of 3.0 Å between the centres of O_2 and O_2^+; it was also assumed that the distance between the centres of the atoms in O_2^+ is equal to the corresponding distance in O_2; $\Delta S^\circ_{T_1}$ is the standard entropy of reaction at a temperature T_1. Graphical solution of Eqn. (1) gave $\Delta S^\circ_{293} = -20$ e.u. and $\Delta F^\circ_{293} = -3.56$ kcal mole^{-1}. Hence $\Delta H^\circ_{293} = -9.60$ kcal mole^{-1} (0.416 eV).

In 1965 Conway and Yang[41] estimated mass-spectrometrically the equilibrium constants for the formation of positive homomolecular oxygen cluster ions ($O_{2n}^+ + O_2 = O_{2n+2}^+$ with $n = 2$–5) at a low temperature (Fig. 2).

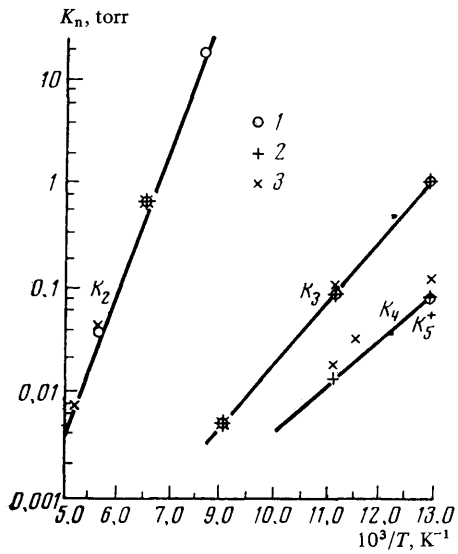

Figure 2. Temperature variation of the equilibrium constants K_n of reactions of the type $O_{2n}^+ + O_2 = O_{2n+2}^+$; oxygen pressure (torr): 1) 1; 2) 2; 3) 4.

In 1970 Conway and Janik[42] repeated the previous study and refined the results for the O_4^+–O_{18}^+ cluster ions, using a somewhat improved research technique. Table 2 lists the observed equilibrium constants for the formation of the cluster ions by the reaction $O_2 + O_{2n}^+ \rightleftharpoons O_{2n+2}^+$.

Table 2. The equilibrium constants K_n for the reactions $O_{2n}^+ + O_2 \rightleftharpoons O_{2n+2}^+$.

n	T, °K	p_{O_2}, torr				Multiplier
		1,55	3,09	6,15	9,14	
3	77.3	1.07	1.10	1.18	1.26	·100
3	90.1	1.03	1.02	1.06	1.16	·10^{-1}
4	77.3	8.02	8.21	9.37	10.78	·10^{-2}
4	90.1	—	0.79	1.03	1.31	·10^{-2}
5	77.3	4.50	4.47	5.21	5.95	·10^{-2}
5	90.1	—	—	8.48	9.30	·10^{-3}
6	77.3	—	—	2.77	3.30	·10^{-2}
7	77.3	—	—	1.90	2.40	·10^{-2}
8	77.3	—	—	—	1.70	·10^{-2}

The standard enthalpies and entropies of formation of the cluster ions by the reaction $O_2 + O_{2n}^+ = O_{2n+2}^+$ and the corresponding bond energies were calculated from the observed low-temperature equilibrium constants (77–90 K) and the models adopted for the ions (Table 3).

Conway[43] calculated the energies of the O_4^+ and O_4^- ions (together with N_4^+) by a somewhat modified MO-SCF method for structures with C_2 symmetry as a function of the angles $\theta = \theta'$ and the distance R between the interacting species (Fig. 3). The equilibrium dissociation energies D_3 for the equilibrium distances R_e and angles θ_e are listed below:

Ion	D_e, kcal mole^{-1}	R_e, Å	θ_e, deg	D(expt.), kcal mole^{-1}
O_4^+	11.66	2.03	—67	10,8
O_4^-	8.49	2.08	—71	13,6
N_4^+	34.7	2.04	0	11,5

Table 3. Thermodynamic characteristics of the reactions $O_2 + O_{2n}^+ = O_{2n+2}^+$.

n	ΔS, e.u.	ΔH°, kcal mole^{-1}	$D_0(O_2-O_2^+)$	$D_e(O_2-O_2^+)$*

* $D_e(O_2 - O_2^+)$ is the dissociation energy corresponding to the minimum in the potential energy curve.

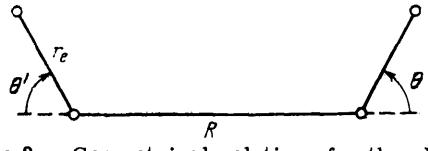

Figure 3. Geometrical relations for the planar ion–molecule complex.

Durden et al.[29] also determined the rate constants for the formation of the O_4^+ ion and its dissociation energy using a high-pressure mass-spectrometer with a pulsed electron beam having an energy of 4 keV as the source of ionising radiation. They succeeded in following the decrease of the concentration of O_2^+ ions and the increase of the concentration of O_4^+ ions in oxygen after the electron pulse (at an oxygen pressure of 3–4 torr) before the equilibrium concentrations of these ions were reached. Equilibrium was attained 60 μs after the pulse at 298 K and after 20–30 μs at 341 K. The rates of formation of O_4^+ were also determined in other investigations[29,44,46,47] and in a study by Joung and Falconer[45]. Using the mass-spectrometric method for the study of reactions in a stream of carrier gas (helium), Adams et al.[46] investigated at 200 K and an overall pressure of 1.767 torr the equilibrium in the following reaction involving a cluster ion:

$$O_2^+ + O_2 + He \rightleftarrows O_4^+ + He \ .$$

The rate constants for the formation and decomposition of the O_4^+ ion are listed in Table 4.

It is interesting to note that the rate constant for the formation of the cluster ion O_4^+, equal to 2.8×10^{-30} cm^6 mol.$^{-2}$ s^{-1}, is almost a factor of 30 smaller than the rate constant for the corresponding reaction of nitrogen[29] ($N_2^+ + 2N_2 \rightarrow N_4^+ + N_2$), which is 8.57×10^{-29} cm^6 mol.$^{-2}$ s^{-1}.

Table 4. The rate constants for the formation (k_1) and decomposition (k_2) of the O_4^+ ion.

Reaction	°K	k_1, cm^6 mol.$^{-2}$ s^{-1}	k_2, cm^3 mol.$^{-1}$ s^{-1}	Refs.
$O_2^+ + 2O_2 \underset{k_2}{\overset{k_1}{\rightleftarrows}} O_4^+ + O_2$	298	$2.8 \cdot 10^{-30}$	$2.8 \cdot 10^{-13}$	29
»	298	$2.4 \cdot 10^{-30}$	—	44
»	298	$1.5 \cdot 10^{-30}$	—	45
$O_2^+ + O_2 + He \underset{k_2}{\overset{k_1}{\rightleftarrows}} O_4^+ + He$	200	$2.45 \cdot 10^{-30}$	$3 \cdot 10^{-17}$	46,47
	200	$2 \cdot 10^{-31}$	$1 \cdot 10^{-14}$	48

VI. REACTIONS OF HETEROMOLECULAR OXYGEN CLUSTER IONS

Adams et al.[46] measured the rate constants for trimolecular reactions involving the association of O_2^+ with H_2, N_2, O_2, CO_2, NO_2, and SO_2 in a stream of helium as the carrier gas and the third body at temperatures below 300 K, which proceed via the general mechanism

$$A^\pm + B + M \rightarrow A^\pm B + M \ .$$

The rates of association of O_2 with N_2, O_2, and CO_2 at 200 K were also measured.

Since the bond energy and the rate constant for the termolecular reaction vary in the same sense (in agreement with theoretical concepts), the authors[46] found that the molecules can be arranged in the following sequence in order of increasing energy of the bond with the O_2^+ ion: $H_2 < N_2 < O_2 < N_2O < SO_2 < H_2O$. For O_2^-, the stability of the ionic clusters increases in the sequence $N_2 < O_2 < H_2O < CO_2 < NO$. The rates of formation of cluster ions such as $O_2^+.N_2.N_2$, $O_2^+.O_2.N_2$, etc. were also estimated.

Reactions of another type involving the formation of heteromolecular ionic clusters in a stream which have been investigated are the bimolecular exchange reactions of the neutral molecule in the cluster:

$$A^\pm \cdot B + C \rightarrow A^\pm \cdot C + B \ ,$$

where A = O_4^-, O_2^+, O_2^-, or O^- and B and C = O_2, N_2, N_2O, SO_2, H_2O, CO_2, NO, or CO. The rate constants for these reactions were measured at 80, 200, and 300 K. In certain cases the exchange reactions of the neutral molecule in the cluster ion are only weakly exothermic, so that the reverse reaction takes place; it is then possible to estimate the free energies of these reactions (from the equilibrium constants). Since the entropy changes in these reactions should be small, their free energies $\Delta F^\circ = -RT \ln K$ are close to the enthalpies of reaction ΔH. The latter values are approximately equal to the differences between the bond energies of the initial molecules and the resulting cluster ion. This has been confirmed to some extent by data for the equilibrium in the reaction $O_2^- \cdot O_2 + CO_2 \rightleftharpoons O_2^- \cdot CO_2 + O_2$.

It was found that the free energy of this reaction, and hence the approximate difference ΔD between the association energies of $O_2^-.CO_2$ and $O_2^-.O_2$, is 0.26 eV. Pack and Phelps[49] found that the energy of the dissociation of the $O_2^-.CO_2$ ion into O_2^- and CO_2 is 0.8 ± 0.08 eV. On the basis of this value and the value of 0.59 eV obtained by Conway and Nesbitt[37] for the $O_2^- - O_2$ bond energy, we find ΔD = 0.21 eV. Within the limits of experimental error, this agrees with the above value of 0.26 eV.

The data presented for the chemistry of oxygen cluster ions show that much experimental information has already been accumulated in this field and that theoretical studies are being made in order to refine the ideas concerning the nature of the interaction forces in these ions; the results of the two lines of research supplement one another. Evidently in the future research in this field will develop vigorously in connection with the growing interest in the chemistry of the ionosphere, the radiation chemistry of gases, etc.

The Structures and Reactivities of *Closo*- and *Nido*-carboranes

V.I.Stanko, V.A.Brattsev, and S.P.Knyazev

The structures, methods of synthesis, and chemical properties of *closo*- and *nido*-carboranes are discussed and certain general features of the chemical reactions of carboranes are indicated.
The bibliography includes 228 references.

I. INTRODUCTION

Among organic derivatives of the elements, the class of organoboron compounds (carboranes)—compounds having the structure of regular polyhedra or their fragments [1] and consisting of boron and carbon atoms or the atoms of other elements†—shows very great promise.

The most complete compilation of data on the chemistry of carboranes has been published in Grimes' monograph [2] (up to 1970) and in Williams' review [3] (up to 1968). Lipscomb's monograph [4] deals with problems of the theory of the structures and chemical bonding in boron hydrides and carboranes. The latest advances in the chemistry of carboranes have been described systematically in annual reviews [5-8]. Furthermore, individual stages in the development of this field of chemistry were dealt with in a number of early reviews [9-15]. Certain special problems of the chemistry of carboranes are considered in other publications [16-25].

Bearing in mind the considerable interest shown by many investigators in modern problems of the chemistry of organic derivatives of the elements, in particular in the chemistry of carboranes, which is developing vigorously, we thought it useful to supplement and to attempt to survey the available literature data. The main aim of the present review is a consideration of the general characteristics of the chemical reactions of *closo*-, *nido*-, and *arachno*-carboranes, the methods of synthesis, structures, and chemical properties of each representative of these classes of compounds being quoted for reference and illustration.

According to Williams [3], the first information about the existence of carboranes was obtained by Landesman in 1953, who detected by mass-spectrometry ions derived from compounds having the compositions $C_2B_3H_x$, $C_2B_4H_y$, and $C_2B_5H_z$ amongst the pyrolysis products of a mixture of diborane and acetylene, their overall yield with respect to the amount of diborane which reacted being less than 1%. Later, Keilin obtained the same mixture (in a yield of about 2%) from pentaborane(9) and acetylene in an electric discharge. The lower limit to the number of hydrogen atoms, $C_2B_4H_{y\geq 6}$ and $C_2B_5H_{z\geq 7}$, was established on the basis of mass-spectrometric data and it was concluded that the compounds have a closed structure. In 1956 Good repeated this investigation and isolated compounds having the compositions $C_2B_3H_5$, $C_2B_4H_6$, and $C_2B_5H_7$. According to mass-spectrometric, ^{11}B NMR, and ^1H NMR data, the only possible structure for $C_2B_5H_5$ proved to be that of a trigonal bipyramid. Octahedral and pentagonal bipyramidal structures were proposed respectively for $C_2B_4H_6$ and $C_2B_5H_7$. These data were published at the beginning of the 1960s. [26,27] Good and Williams suggested that the compounds obtained be called carboranes. Subsequently, this name was extended also to other compounds whose molecules consist of closed polyhedra or their fragments and contain boron and carbon atoms.

Reports of the synthesis of yet another representative of the family of carboranes—$C_2B_{10}H_{12}$ and its *C*-derivatives obtained from decaborane(14) ($B_{10}H_{14}$) or its complexes with Lewis bases ($B_{10}H_{12}L_2$) and compounds of the acetylene series—were published in 1962-1963. Thermal isomerisation (450-500°C) of the 1,2-isomer yielded the 1,7-isomer [28] and at a higher temperature also the 1,12-isomer of carborane(12). [29]

Carboranes with 9,8,7, and 6 boron atoms in the polyhedron were obtained by the degradation of 1,2- and 1,7-$C_2B_{10}H_{12}$. [30-32] The compound $Me_2C_2B_6H_6$ was isolated by Williams and Gerhart from the products of the reaction of hexaborane(10) with dimethylacetylene [33]. Thus systematic studies yielded all the representatives of the homologous series of *closo*-carboranes having the general formula $C_2B_nH_{n+2}$. *closo*-Carboranes containing one and three carbon atoms in the molecule have now been also synthesised.

Reports of the synthesis of a representative of *nido*-carboranes ($C_2B_4H_8$), i.e. carboranes with an open structure, appeared at the beginning of the 1960s. [34] *nido*-Carboranes containing up to four carbon atoms in the molecule are now known.

$C_2B_7H_{13}$, the first representative of *arachno*-carboranes, was reported in 1966. [35] The second *arachno*-carborane ($C_2B_8H_{14}$) became known comparatively recently [36].

† Compounds containing in the molecule nitrogen, phosphorus, arsenic, sulphur, germanium, silicon, etc. atoms as well as transition metal atoms have been obtained. In the present review the chemistry of heteroboranes, heterocarboranes, metalloboranes, and metallocarboranes is not considered, but the general features of the chemistry of carboranes can be extended also to these classes of compounds.

II. CLASSIFICATION AND NOMENCLATURE. THE NATURE OF BONDING IN CARBORANES

In accordance with Williams' suggestion [1], carboranes are classified as follows: *closo*-carboranes $C_0-_2B_nH_{n+2}$, *nido*-carboranes $C_0-_4B_nH_{n+4}$, and *arachno*-carboranes $C_0-_6B_nH_{n+6}$; the case with C_0 corresponds to boron hydride (boranes).

1. Nomenclature

According to the recommendations by the Commission on Nomenclature of the American Chemical Society [37], the names of these compounds are devised in accordance with the following rules: initially the location of the carbon atoms in the molecule is indicated, then the number of carbon atoms is stated, and a prefix is added characterising the type of structure (*closo*- or *nido*-); next follows a Greek numeral corresponding to the total number of atoms in the molecule and the ending borane is added; finally the number of hydrogen atoms is indicated in brackets.

For anions, the method of forming the name is on the whole the same, but the number of hydrogen atoms is stated at the beginning, the ending borane is replaced by borate, and the charge of the anion is indicated in brackets. For example, the compound 1,10-$C_2B_8H_{10}$ is called 1,10-dicarba-*closo*-decaborane(10), 7,8-$C_2B_9H_{13}$ is 7,8-dicarba-*nido*-undecaborane(13), and 7,8-$C_2B_9H_{12}^-$ is dodecahydro-7,8-dicarba-*nido*-undecaborate(1-).

The fundamental principles of the numbering of atoms in boron hydride and carborane molecules are as follows. In *closo*-carboranes atoms located in planes perpendicular to the highest-order symmetry axis are numbered clockwise in succession starting with the topmost atom. For *nido*-carboranes, one employs their planar projection and the structure is considered from the side opposite to that of the open face. The numbering is also clockwise and begins with the atoms closest to the centre of the projection. The numbering must be such that carbon atoms and those of other elements have the minimum numbers (Fig. 1)

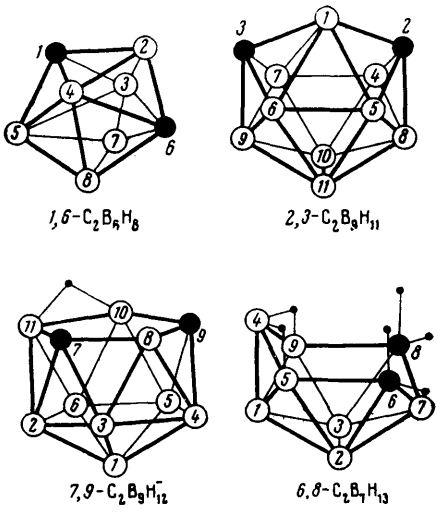

Figure 1.

2. Isoelectronic Series

In the chemistry of carboranes it is convenient to distinguish isoelectronic series [3], i.e. series of compounds whose molecules have the same geometrical and electronic structures, differing from one another in the CH/BH^- or CH/BH_2 ratios of the numbers of different units, BH^- or BH_2 being equivalent to the CH structural unit. As an example, one may quote the series B_6H_{10}, CB_5H_9, $C_2B_4H_8$, $C_3B_3H_7$, $C_4B_2H_6$ or B_6H_8‡, CB_5H_7, and $C_2B_4H_6$ (Figs. 2 and 3).

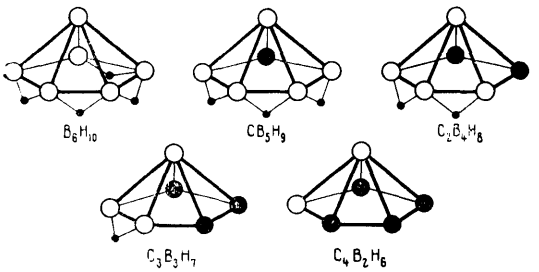

Figure 2.

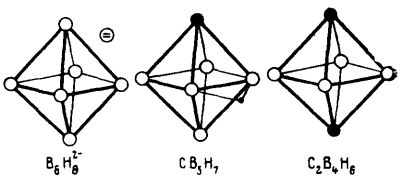

Figure 3.

For *closo*-compounds, the CH/BH^- series can be represented as follows in a general form: $B_{n+2}H_{n+2}^{2-}$, $CB_{n+1}H_{n+2}^-$, and $C_2B_nH_{n+2}$. If this electronic series is extended by yet another CH unit, we obtain the family $C_3B_{n-1}H_{n+2}^+$. A compound of this type must have a positive charge (+1), but the abstraction of a proton should make the molecule neutral as a whole ($C_3B_{n-1}H_{n+1}$). A compound of this type has been obtained ($C_3B_5H_7$); [39] it belongs to the isoelectronic series $C_3B_5H_8^+$, $C_2B_6H_8$, ($CB_7H_8^-$), and $B_8H_8^{2-}$ (Fig. 4).

The following series may be quoted as an example of a CH/BH^- isoelectronic series of compounds with an open structure: $C_2B_8H_{12}$§, CB_9H_{12}¶, and $B_{10}H_{12}^{2-}$ (Fig. 5).

---

‡ B_6H_8 has not been obtained, but $B_6H_6^{2-}$ does exist. Formally, protonation of the latter should yield B_6H_8, analogously to the reaction $B_{10}H_{10}^{2-} + 2H^{2+} \rightarrow B_{10}H_{12}$. [38]

§ Obtained for the isomer $C_2B_8H_{12}$. [40,41]

¶ A C-$\overset{+}{N}R_3$-substituted derivative of this carborane ($R_3NCB_9H_{11}$) has been obtained; the molecule is neutral as a result of the presence of the cationic fragment $R_3\overset{+}{N}$. [35]

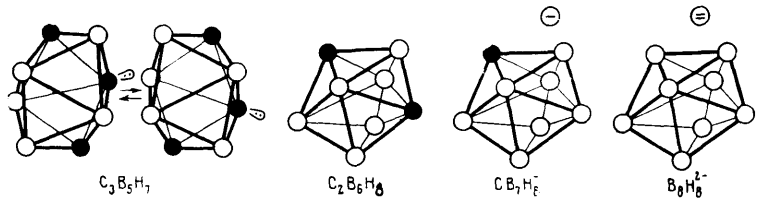

Figure 4.

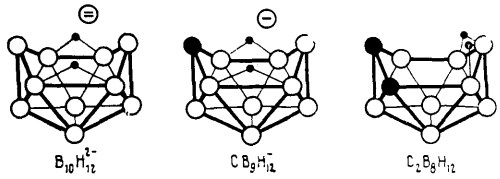

Figure 5.

The above isoelectronic series can be significantly extended by employing the atoms of other elements as the structural units of the polyhedral molecules, such as those of aluminium, gallium, zinc, germanium, tin, lead, nitrogen, phosphorus, sulphur, arsenic, and others.

Since the isoelectronic compounds have corresponding structures, it follows that carbon and other atoms are involved in the formation of the system of bonding orbitals in the same way as boron atoms, i.e. all the principles governing the formation of chemical bonds proposed for boron hydrides[4] apply to them. When transition metal atoms are considered as structural units, account must be taken of the specific character of their bonds with the carborane ligand. Transition metal complexes with carborane ligands have been examined in detail in Hawthorne's reviews[19,21-23].

3. The Three-centre Bond and the Influence of the Carbon Atom on Electron Distribution in Carboranes

The characteristics of the structure and chemical bonding in boron hydrides and carboranes have been explained by postulating the formation of a two-electron chemical bond between three atoms (a three-centre bond). In the non-excited state there are two electrons in the three-centre bonding orbital. In boron hydride and carborane molecules all the atomic orbitals of each atom are involved in the formation of a chemical bond and all the resulting bonding orbitals are filled with electrons. Three different types of three-centre bonds can be formed: the central B–B–B bond, the open B–B–B bond, and the open B–H–B bond.

In the central B–B–B bond each atom provides one hybridised atomic orbital, and the orbitals overlap in such a way that the maximum electron density is in the centre of the triangle (Fig. 6*a*). In the open B–B–B bond the central atom provides a *p* orbital and the other two supply hybridised atomic orbitals, their overlapping being of the type shown in Fig. 6*b*. In the open B–H–B bond the central hydrogen atom provides the *s* orbital for the formation of the bond and the two boron atoms provide their hybridised atomic orbitals (Fig. 6*c*). In case *a* 2/3 of an electron formally corresponds to each atom forming the three-centre bond, and in cases *b* and *c* there is one electron per central atom, while the other two atoms each have half an electron. The principles governing the calculation and description of the bonding in boron hydrides and carboranes have been described in detail in Lipscomb's monograph[4].

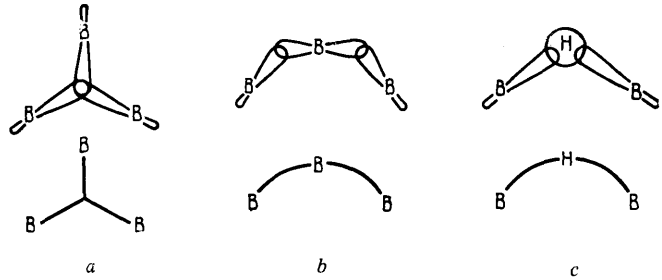

Figure 6.

When highly symmetrical $B_nH_n^{2-}$ anions and certain carboranes were considered, it proved convenient to describe these structures on the hypothesis that molecular orbitals delocalised over the entire molecule are present[43-46].

Using the Edmiston–Ruedenberg method, Lipscomb and coworkers recently determined the degree of localisation of the orbitals for a series of carboranes and introduced the concept of fractional three-centre bonds, i.e. essentially of specifically delocalised three-centre bonds embracing more than three atoms of the molecule[47-51]. It was shown that the valence structures of boron hydrides can be described without resorting to open three-centre B–B–B bonds[50,52]. For example, Fig. 7 illustrates the valence structure of decaborane[53], used until 1971 and proposed by Laws et al.[51] On the other hand, valence structures involving open three-centre B–C–B bonds were suggested for some of the carboranes investigated[50].

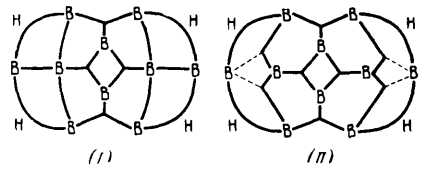

Figure 7.

Fig. 8 presents the valence structure proposed recently for the compounds 1,2-$C_2B_4H_6$,[50] 1,6-$C_2B_4H_6$,[50] 2,3-$C_2B_4H_8$,[49] and 2,4-$C_2B_5H_7$.[47,48]

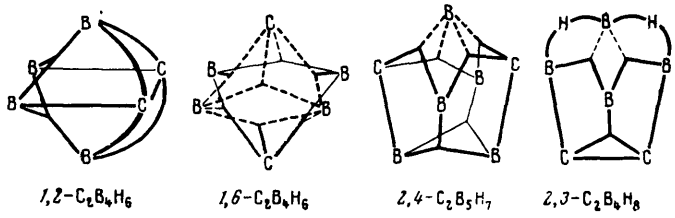

Figure 8.

Having surveyed the available data, Lipscomb and coworkers[50] formulated several additional conclusions the essential features of which are as follows:

(1) there exist unique valence structures for many boranes and carboranes (B_2H_6, B_4H_{10}, B_5H_{11}, B_6H_{10}, 1,2-$C_2B_4H_6$, 2,4-$C_2B_5H_7$, 2,3-$C_2B_4H_8$, etc.);

(2) the concept of fractional three-centre bonds can be successfully applied to certain boron hydrides and carboranes;

(3) for the description of boron hydrides, it is not obligatory to resort to the concept of the open B–B–B three-centre bond;

(4) in contrast to boron hydrides, the employment of the concept of the open three-centre bond in order to describe the valence structure is useful for only some carboranes.

Since the carbon atoms in carboranes are involved in the formation of three-centre and two-centre bonds, like boron atoms, and bearing in mind that the charge of the carbon nucleus is greater by unity than that of the boron nucleus, the appearance of an excess positive charge on the carbon atoms (at least in relation to the boron atoms equivalent in the structural sense) may be expected. The polyhedral species $B_nH_n^{2-}$ have a 2- charge and in a symmetrical structure, for example the icosahedral structure, the charge is distributed uniformly among all the boron atoms. The replacement of two BH structural units by two CH units leads to a molecule which is neutral as a whole. Two "superfluous" electrons remain (in $B_nH_n^{2-}$), but, instead of being localised, are distributed over the entire molecule. As a result, the carbon atoms bear a considerable positive charge.

Certain chemical properties of carboranes and of the functional groups linked to carbon atoms are due to the excess positive charge on the carbon atoms. This is manifested by the acidity of the hydrogen atoms in the C–H bonds, by the cleavage of the C–C and C–element bonds with substituents in certain functional derivatives of carboranes, by the ^{13}C NMR spectra, and by other physicochemical properties. This factor can also account for the electron-accepting effect of the corresponding carboranyl group in the carboranes investigated.

The presence of a positive charge on the carbon atom leads to the "withdrawal" of the electron densities from the neighbouring boron atoms, and these atoms of the carborane nucleus are in fact involved in nucleophilic reactions, while electrophilic reactions involve the boron atoms most remote from carbon[44,45].

The general ideas concerning the chemical reactions and their possible mechanisms are discussed in Section VI.

III. THE SYNTHESIS, STRUCTURE, AND PROPERTIES OF *CLOSO*-CARBORANES

Dicarba-*closo*-pentaborane(5) ($C_2B_3H_5$)

Of the three possible isomers of the first representative of *closo*-carboranes, two are known—1,2- and 1,5-$C_2B_3H_5$ (Fig. 9). According to a molecular orbital calculation, the thermodynamic stability of the $C_2B_3H_5$ carborane isomers decreases in the sequence 1,5->1,2->2,3-.[53] Among these isomers, 1,5-$C_2B_3H_5$ is the most readily available and has been most thoroughly investigated. For example, 1,2-$C_2B_3H_5$ was obtained by Grimes[54,55] in the form of the *CB*-dimethyl derivative in a mixture with other carboranes by the reaction of acetylene and diborane in an electric discharge. The structure with the methyl groups in the 2- and 3-positions has been proposed for this compound on the basis of ^{11}B NMR, ^1H NMR, infrared and mass-spectrometric data.

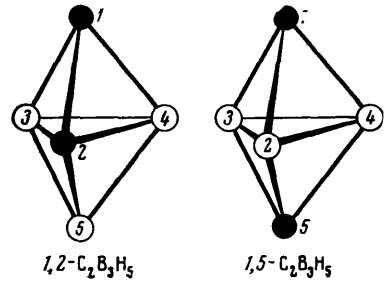

Figure 9.

The 1,5-$C_2B_3H_5$ isomer was detected in the pyrolysis products of a mixture of acetylene and diborane[3]. It is also formed, in a mixture with other carboranes, by the reaction of pentaborane(9) with acetylene in an electric discharge[26]. Methods have been developed for the synthesis of the lowest carboranes in high yields[56–58]. The interaction of pentaborane(9) and acetylene in a stream at 500–600°C using hydrogen as the carrier gas leads to a 70% yield of a mixture of the lower carboranes containing about 40% of 1,5-$C_2B_3H_5$.[56] Pyrolysis of 2,3-$C_2B_4H_8$ at 450–460°C for 10 s gives a 100% yield (25–30% conversion) of a mixture of the same carboranes containing 40% of 1,5-$C_2B_3H_5$.[57,58] The structure of the carborane was established on the basis of ^{11}B NMR, ^1H NMR, infrared and mass-spectrometric data[26]. The exact molecular structure of 1,5-$C_2B_3H_5$ was determined by electron diffraction[59].

1,5-$C_2B_3H_5$ is resistant to the action of air, water, carbon dioxide, and acetone at room temperature. Also at room temperature, the carborane mixed with B_2D_6 exchanges the hydrogen atoms linked to boron for deuterium[26]. The chemical stability of this compound can be explained by its high electronic symmetry. The breakdown of the symmetry following the introduction of polar substituents results in a decrease of stability[60]. For example, the adduct of 1,5-$C_2B_3H_5$ with triethylamine and the product of the halogenation of the carborane are stable only at a low temperature (−78°C). With increase of temperature, the compounds decompose. On the other

hand, derivatives of the carborane with non-polar substituents are stable. When, 1,5-$C_2B_3H_5$ is heated to 350°C in sealed tubes for 9 h, it dimerises with formation of a B–B bond between two $(C_2B_3H_4)_2$ bipyramids. The formation of a small amount of the trimer $C_2B_3H_4(C_2B_3H_3)C_2B_3H_4$ has also been suggested. The reaction of 1,5-$C_2B_3H_5$ with methylacetylene leads to an interesting result. *B*-(*cis*-prop-1-enyl)-1,5-dicarba-*closo*-pentaborane ($C_2B_3H_4$.C_3H_5)—the product of the addition of the *closo*-carborane to the acetylene derivative—is formed in 20% yield after 24 h at 165°C.[60] At 300°C, 1,5-$C_2B_3H_5$ interacts with diborane to form 3,6-$C_2B_6H_{10}$ in a yield less than 5%.[61]

Monocarba-*closo*-hexaborane(7) (CB_5H_7)

This compound is obtained in the decomposition of 1-methylpentaborane(9) in an electric discharge[62]. Another method of synthesis involves the pyrolysis of alkylpentaboranes(9).[63] According to ^{11}B NMR, ^1H NMR, and infrared spectroscopic data, CB_5H_7 has an octahedral structure (Fig. 10). It is of interest to note that the bridging hydrogen atom is not localised between two boron atoms, but executes tautomeric transitions with $\Delta G = 14$ and 12 kcal mole^{-1} for CB_5H_7 and $CH_3CB_5H_6$ respectively[63]. This is reflected in the ^{11}B NMR spectra, which contain three doublets with 1 : 2 : 2 intensity ratios at −30°C, while at 110°C the spectrum consists of two doublets with a 1 : 4 intensity ratio in consequence of the rapid transitions of the bridging hydrogen atom between the boron atoms in the 2-, 3-, 4-, and 5-positions, i.e. the boron atoms in these positions are indistinguishable by the above method. It is suggested that the tautomeric transitions take place via a transition state with a bridging hydrogen atom between the boron atoms in the 3- and 6-positions[63]. When acted upon by bases, the CB_5H_7 molecule splits off the bridging hydrogen atom with formation of the anion $CB_5H_6^-$.[64]

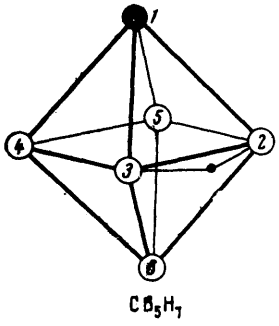

Figure 10.

Dicarba-*closo*-hexaborane(6) ($C_2B_4H_6$)

Both possible isomers of dicarba-*closo*-hexaborane with the carbon atoms in the 1,2- and 1,6-positions have been obtained (Fig.11). It is formed in a mixture with other carboranes by the reaction of acetylene with pentaborane in an electric discharge[65]. The analogous interaction of acetylene with diborane leads to a mixture of products containing 1,6-$C_2B_4H_6$.[54,55] The best method for the synthesis of a mixture of $C_2B_4H_6$ isomers on a preparative scale involves the decomposition of $C_2B_4H_8$ by ultraviolet radiation[66]. The yields of the 1,2- and 1,6-isomers in this reaction reach 15 and 20% respectively, with the simultaneous formation of 15% of 1,5-$C_2B_3H_5$. 1,2-$C_2B_4H_6$ is formed in a low yield (3–5%) in the pyrolysis of $C_2B_4H_8$ at 450°C in the course of 0.5 s; the yield of the 1,6-isomer in this reaction is about 20%.[57]

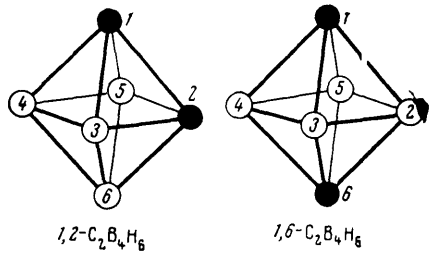

Figure 11.

An octahedral structure has been proposed for 1,2- and 1,6-$C_2B_4H_6$ on the basis of NMR, infrared spectroscopic, and mass-spectrometric data (Fig. 11).[27] The exact molecular structure of 1,6-$C_2B_4H_6$ in the gas phase was determined by electron diffraction[59,67]. The 1,2-$C_2B_4H_6$ [68] and 2-Cl-1,6-$C_2B_4H_5$ [69] structures were investigated by microwave spectroscopy. The results led the authors[69] to the conclusion that there is no additional interaction between the chlorine atom and the carborane nucleus, i.e. the contribution of B–Cl π bonding in 2-Cl-1,6-$C_2B_4H_5$ is almost zero.

The 1,6-isomer is thermodynamically more stable than the 1,2-isomer by 15 kcal mole^{-1} [70,71] and at 250°C the latter is converted quantitatively into 1,6-$C_2B_4H_6$.[72] Certain chemical properties of only one of the isomers (1,6-$C_2B_4H_6$) have been studied. The carborane is stable at room temperature in air and does not react with water or acetylene; it exchanges with B_2D_6 the hydrogen atoms bound to boron[27]. The reaction of 1,6-$C_2B_4H_6$ with a threefold excess of trimethylamine at room temperature in the course of eleven days leads to the formation of 5-Me_3N^+.$(2,4\text{-}C_2B_4H_6)^-$. The base introduces an additional electron pair into the nucleus of the *closo*-carborane and converts it into a *nido*-carborane derivative 2,4-$C_2B_4H_8$.[73] The dilithio-derivative $LiCB_4H_4CLi$ is formed slowly by the reaction 1,6-$C_2B_4H_6$ with BuLi in ether at room temperature; the dilithio-derivative reacts with MeI to form a *CC*-dimethyl derivative and treatment with one equivalent of MeI and then with bromine yields $MeCB_4H_4CBr$. The interaction with electrophilic agents proceeds via the boron atoms. Thus bromination in the presence of $AlBr_3$ gives rise to 2-Br-1,6-$C_2B_4H_5$,[74] while iodination in the presence of Al_2I_6 leads to the formation of 2-I-1,6-$C_2B_4H_5$.[75] Iodocarborane reacts with trimethylamine to form the quaternary ammonium salt $[Me_3N^+C_2B_4H_5]I^-$, which suggests the mobility of the I atom in the B–I bond.

Treatment of 1,6-$C_2B_4H_6$ with sodionaphthalene followed by the addition of $CoCl_2$ and NaC_5H_5 and oxidation with air led to a mixture of products, from which 1,7,2,4-$(CoC_5H_5)_2$.$C_2B_3H_5$ was isolated in 3% yield[76]. This complex is formally a derivative of the tetra-anion $C_2B_3H_5^{4-}$.

Dicarba-*closo*-heptaborane(7) ($C_2B_5H_7$)

In this case four isomers are possible of which only two (2,3- and 2,4-$C_2B_5H_7$) have been obtained (Fig. 12). The 2,3-isomer has been isolated in a yield of about 1.5% as the *CC*-dimethyl derivative from a mixture with other carboranes formed by the reaction of B_8H_{12} with dimethylacetylene. The structure of the compound has been determined by NMR and infrared spectroscopy[40].

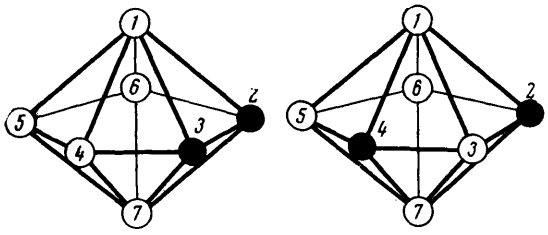

Figure 12.

The 2,4-$C_2B_5H_7$ isomer is more readily available and has been studied in greater detail. It was obtained for the first time by the reaction of B_5H_9 with acetylene in an electric discharge[26,27]. It is formed in 40% yield on pyrolysis of $C_2B_4H_8$ at 450°C for 10 s. Pyrolysis for 8 h above 300°C leads to a single volatile reaction product—2,4-$C_2B_5H_7$, in a yield reaching 38%.[57,58,77] This carborane is also formed together with other products from a mixture of diborane and acetylene in an electric discharge[54,55]. A structure has been proposed for 2,4-$C_2B_5H_7$ on the basis of NMR, infrared and mass-spectrometric data[77]. Subsequently the pentagonal bipyramidal structure was confirmed by microwave spectroscopy[78]. The study of the vibrational spectra of 2,4-$C_2B_5H_7$ and two other lower carboranes (1,5-$C_2B_3H_5$ and 1,6-$C_2B_4H_6$) led to the assignment of all the line frequencies, to the determination of the integral line intensities, and to the calculation of the polarisation constants[79].

The 2,4-$C_2B_5H_7$ isomer reacts with BuLi in ether to form the dilithio-derivative. *C*-Methyl, *CC*-dimethyl, *C*-bromo-, and *C*-trimethylsilyl derivatives of 2,4-$C_2B_5H_7$ were obtained from the lithio-derivatives. When the carborane is treated with alcoholic alkali, it undergoes total degradation[80]. Electrophilic reactions involve the boron atom in the 5-position. For example, bromination in the presence of $AlBr_3$ leads to 5-Br-2,4-$C_2B_5H_7$ [80] and chlorination yields 5-Cl-2,4-$C_2B_5H_7$.[81] A mixture of all the isomers (1-, 3-, and 5-$ClC_2B_5H_6$) is formed under the conditions of radical chlorination.

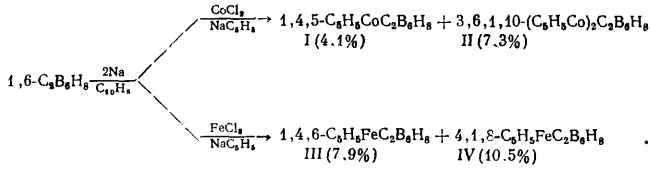
The hydrogen atoms linked to $B_{(3)}$, $B_{(5)}$, and $B_{(6)}$ are involved in isotope exchange with B_2D_6 at room temperature, and on heating to 100°C the hydrogen atoms at $B_{(1)}$ and $B_{(7)}$ are also exchanged[82].

When a solution of 2,4-$C_2B_5H_7$ in tetrahydrofuran (THF) is treated with sodionaphthalene and then with $CoCl_2$ and NaC_5H_5 and oxidised by air, a mixture of compounds is formed, eight of which have been isolated[83]. Two of these are derivatives of the dianion $C_2B_5H_7^{2-}$ and the tetraanion $C_2B_5H_7^{4-}$. In addition there are the mononuclear and dinuclear complexes $(C_5H_5)Co(C_2B_4H_6)$, $[(C_5H_5)Co]_2(C_2B_4H_6)$, $(C_5H_5)Co(C_2B_6H_8)$, and $[(C_5H_5)Co]_2(C_2B_6H_8)$, which are the products of the disproportionation of the polyhedral carborane ligand $C_2B_5H_7$. The mechanism of the disproportionation reaction has not been established.

Treatment of the reaction mixture obtained by reducing $C_2B_5H_7$ with $FeCl_2$ and NaC_5H_5 followed by oxidation leads to the preferential formation of 5-[(2)-2,4-$C_2B_5H_6$]-1,2,4-$C_5H_5Fe^{III}C_2B_4H_5$ and a small amount of 1,2,4-$C_5H_5Fe^{II}HC_2B_4H_6$ and 5-R-1,2,4-$C_5H_5Fe^{III}C_2B_4H_5$, where R = $C_{10}H_7H$ (traces). It is interesting to note that analogous iron complexes with a carborane ligand are formed directly from 2,4-$C_2B_5H_7$ and $Fe(CO)_5$ when they are heated in the gas phase. 1,2,4-$(CO)_3Fe^{III}C_2B_4H_6$ and 5,1,7-$(CO)_3Fe^{III}C_2B_5H_7$ were isolated[84].

Dicarba-*closo*-octaborane(8) ($C_2B_6H_8$)

Six structural isomers are possible. However, only the 1,6-$C_2B_6H_8$ isomer has so far been obtained. It was first isolated in a yield of about 12% as the *CC*-dimethyl derivative by the reaction of hexaborane(10) with dimethylacetylene[33]. The authors proposed a dodecahedral structure (Fig. 13) as the most likely. Hawthorne and coworkers synthesised this isomer in a mixture with other carboranes by the pyrolysis of $C_2B_7H_{13}$; the yield of 1,6-$C_2B_6H_8$ reaches 30%.[31,32,85] A method of synthesis based on the pyrolysis of $C_2B_5H_7$ in the presence of B_2H_6 has also been proposed[86]. The cleavage of 1,6-$C_2B_6H_8$ by Me_4NBH_4 on heating in diglyme with subsequent treatment by dry HCl leads to a mixture of the monocarba-*nido*-boranes CB_5H_9, 1-$MeCB_5H_8$, and 3-$MeCB_5H_8$.[87] The reduction of 1,6-$C_2B_6H_8$ with sodionaphthalene in THF followed by treatment with transition metal salts and NaC_5H_5 led to a series of transition metal π complexes with the carborane ligands C_2B_6:[88]



The reaction constants for the carboranyl group have been determined using *C*-(fluorophenyl)derivatives of 1,6-dicarba-*closo*-octaborane: $\sigma_i = +0.08$ and $\sigma_R^\circ = -0.02$.[89]

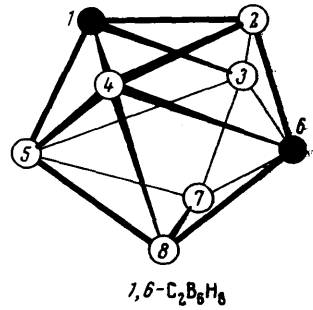


Figure 13.

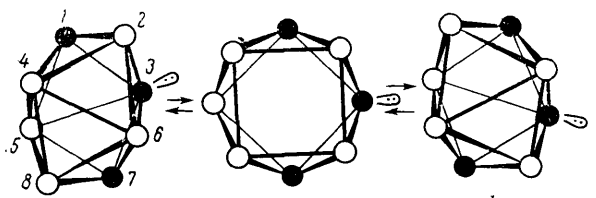
Tricarba-*closo*-octaborane(7) ($C_3B_5H_7$)

$C_3B_5H_7$ is rightly regarded as one of the most interesting and unusual carboranes and is an example of tricarba-*closo*-boranes—compounds which, according to the isoelectronic principle, should be either positively charged or should exist in the form of neutral molecules with an overal zero charge as a result of the abstraction of a single proton from the carbon atom. Two carbon atoms differ from the third, at which there is a free electron pair.

The carborane $C_3B_5H_7$ was obtained by the pyrolysis of μ-SiH_3- or 4-SiH_3-2,3-$C_2B_4H_7$ in 15–20% yields [39]. According to ^{11}B NMR and ^1H NMR data, rapid transitions between structures *a* and *b* (Fig. 14) and time-averaged NMR spectra are observed. Thus the ^{11}B NMR spectrum contains three doublets with the intensity ratios 2 : 2 : 1 and the ^1H NMR spectrum contains three quartets due to the protons bound to boron and the signal due to the proton in the C–H bond with the relative intensity ratio 5 : 2. $C_3B_5H_7$ is stable in air and withstands heating to 250°C. On heating to 450°C, partial degradation takes place quantitatively, and 2,4-$C_2B_5H_7$ is formed. The fate of the carbon atom split off was not determined.



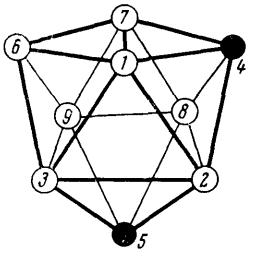
1,3,7-$C_3B_5H_7$

Figure 14.

Dicarba-*closo*-nonaborane(9) ($C_2B_7H_9$)

Six isomers are possible, but the only one known is 4,5-$C_2B_7H_9$ (Fig. 15), which is obtained by the pyrolysis of $C_2B_7H_{13}$ in a yield of about 7% [32,85] together with other carboranes. The yield of $C_2B_7H_9$ increases in the pyrolysis of the sodium salt of $C_2B_7H_{13}$. [85] 4,5-$C_2B_7H_9$ is also formed in a yield of 30% as a result of the slow reaction of 1,6-$C_2B_6H_8$ with B_2H_6 at room temperature [90]. The structure of the compound, proposed on the basis of infrared spectroscopic and NMR data [32,85], has been confirmed by the X-ray diffraction analysis of 4,5-$Me_2C_2B_7H_7$. [91]

As expected, electrophilic substitution of 4,5-$C_2B_7H_9$ involves the boron atom in the 6-position, it being most remote from the carbon atoms. 6-Me, 6-Et-, and 6-Br-4,5-$C_2B_7H_8$ have been obtained. The product of exhaustive bromination at 100°C is the tetrabromo-derivative [92] and not the pentabromide. The reduction of 4,5-$C_2B_7H_9$ by sodium in THF followed by treatment with $CoCl_2$ and NaC_5H_5 and oxidation by air leads to the formation of the three complexes 2,3,10-$C_5H_5CoC_2B_7H_9$ (I), 4,1,8-$C_5H_5CoC_2B_6H_8$ (II), and 1,2,3,6-$(C_5H_5Co)_2C_2B_8H_{10}$ (III). Compound (II) is the cobalt analogue of the iron–carborane complex 4,1,8-$C_5H_5FeC_2B_6H_8$. The complexes (I) and (III) are derivatives of the dianion $C_2B_7H_9^{2-}$ and the tetra-anion $C_2B_8H_{10}^{4-}$. $\sigma_i = 0.09$ and $\sigma_R^\circ = -0.05$ for the 4,4,5-$C_2B_7H_8$ group were determined using *C*-(fluorophenyl) derivatives. The authors believe that σ_R° for this group is higher than the corresponding constant for other carboranes [89].



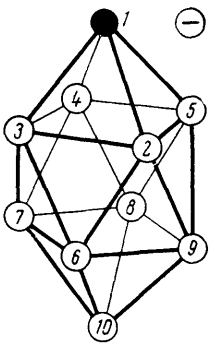
4,5-$C_2B_7H_9$

Figure 15.

Decahydromonocarba-*closo*-decaborate (1-) ($CB_9H_{10}^-$)

Two isomers are possible. One of them, 1-$CB_9H_{10}^-$ (Fig. 16), was obtained by the following reaction [93,42]:

$$Na_2B_{10}H_{13}CN \xrightarrow{2H^+} CB_{10}H_{12}NH_3 \xrightarrow[NaOH,\ H_2O]{Me_2SO_4} CB_{10}H_{12}NMe_2 \xrightarrow[Na,\ THF]{} CB_{10}H_{13}^- + 2\text{-}CB_{10}H_{11}^- \xrightarrow{310^\circ} 1\text{-}CB_9H_{10}^- + CB_{11}H_{12}^-.$$



1-$CB_9H_{10}^-$

Figure 16.

The electrochemical oxidation of $Et_4N^+CB_9H_{10}^-$ in acetonitrile involves dimerisation with formation of $(Et_4N^+)_2B_{18}C_2H_{18}^{2-}$. According to ^{11}B NMR data, the compound has a dimeric structure with a σ bond between the boron atoms in the 10- and 10′-positions [94]. Chlorination of $CB_9H_{10}^-$ in aqueous solution at room temperature yields $CB_9H_5Cl_5^-$. According to ^{11}B NMR data, the chlorination involves boron atoms remote from carbon. The chlorination of the dimer with formation of the *B*-octachloro-derivative proceeds similarly [94].

Dicarba-*closo*-decaborane(10) ($C_2B_8H_{10}$)

Of the seven possible isomers, three have been obtained: 1,2-, 1,6-, and 1,10-$C_2B_8H_{10}$ (Fig. 17). The 1,2-isomer can be synthesised in a nearly quantitative yield by the pyrolysis of 5,6-$C_2B_8H_{12}$ [95] or its sodium salt at 120–200°C *in vacuo*.[96] 1,2-$C_2B_8H_{10}$ is also one of the products of the thermal decomposition of $C_2B_7H_{11}$.[40] The structure of the carborane was established by infrared spectroscopy and NMR.[95,96] Among chemical properties, its capacity for involvement in oxidation and reduction reactions is noteworthy. When it is treated with sodium in THF, a dianion is formed and protonation of the latter gives 5,6-$C_2B_8H_{12}$ in 30% yield[96]:

$$1,2\text{-}C_2B_8H_{10} \xrightarrow{2e} (C_2B_8H_{10})^{2-} \xrightarrow{2H^+} 5,6\text{-}C_2B_8H_{12}.$$

The 1,6-$C_2B_8H_{10}$ isomer is formed on pyrolysis of $C_2B_7H_{13}$. When this reaction is carried out in the presence of diborane, the yield of 1,6-$C_2B_8H_{10}$ increases to 41%. About 8% of 1,7-$C_2B_{10}H_{12}$ is formed similarly. Other carboranes were not isolated[32,85]. When B_2H_6 is allowed to react with sodium salt of $C_2B_7H_{12}^-$ and $C_2B_7H_{13}$ in an ethereal solution, the yield of the isomer reaches 75–80%.[97]

Rapid pyrolysis of 5,6-$C_2B_8H_{12}$ at 500°C *in vacuo* gives a mixture of the two isomers 1,6-$C_2B_8H_{10}$ and 1,10-$C_2B_8H_{10}$.[96] Structures were proposed for 1,6- and 1,10-$C_2B_8H_{10}$ on the basis of infrared spectroscopic and NMR data[32,85] and have been confirmed by X-ray diffraction of 1,6-Me_2-1,6-$C_2B_8H_8$.[98] Among the three isomers of *closo*-$C_2B_8H_{10}$, the 1,10-isomer is the most stable. The 1,2- and 1,6-isomers are wholly converted into the 1,10-isomer on heating to 300°C. Among chemical properties, mention should be made of the fairly high acidity of the C–H protons, which are readily split off under the influence of strong bases (pK_a = 27.3 for the 1,10 isomer[99]). Interaction of 1,6- and 1,10-$C_2B_8H_{10}$ with BuLi results in the formation of the dilithio-derivative, from which various *C*-substituted carboranes were obtained[100–102]. Treatment of 1,6-$C_2B_8H_{10}$ with aqueous-alcoholic alkali leads to partial degradation of the carborane with elimination of the boron atom in the 2-position and the formation of $C_2B_7H_{12}^-$. The reaction with piperidine proceeds similarly.

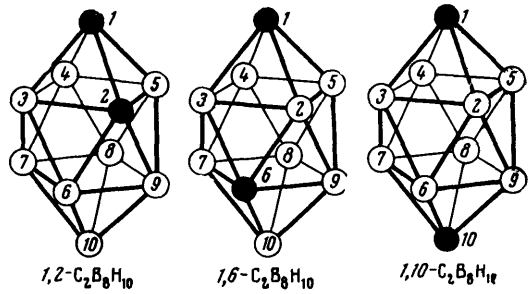


Figure 17.

Under the influence of acids, the 1,6-isomer decomposes to boric acid, and the reaction of 1,6-$C_2B_8H_{10}$ with diborane yields 1,7-$C_2B_{10}H_{12}$. The 1,10-$C_2B_8H_{10}$ isomer is resistant to the action of both acids and alkalis. Photochemical chlorination of 1,10-$MeC_2B_8H_8$ results in the formation of 1,10-$(CCl_3)_2C_2B_8Cl_8$.[100] The dianions derived from 1,6- and 1,10-$C_2B_8H_{10}$ form a wide range of complexes with transition metals[98,103].

σ_i = +0.10 and +0.05 and σ_R° = −0.02 and −0.01 have been determined for the 1,6-$C_2B_8H_9$ and 1,10-$C_2B_8H_9$ carbonyl groups. The results indicate a weak electron-accepting effect of these groups. The latter is enhanced on passing from a pentacoordinate to a hexacoordinate carbon atom (σ_R^- = +0.19 for the 1-1,7-$C_2B_{10}H_{11}$ group). When the carbon atoms are remote from one another, as in $C_2B_{10}H_{12}$, σ_R° diminishes[104].

Undecahydromonocarba-*closo*-undecaborate(1-) ($CB_{10}H_{11}^-$)

Five isomers are possible, of which only one, 2-carba-*closo*-undecaborate(1-), is known at present[42,93] (Fig. 18) The ^{11}B NMR spectrum of this isomer at 80.5 MHz consists of three doublets with the relative intensities 1 : 5 : 4. The authors suggest that the carbon atom is in the 2-position, the structure undergoing a rapid rearrangement via the *dsd* mechanism to an equivalent structure (Fig. 18). For this reason, the boron atoms in the 1-, 4-, 5-, and 8-positions and also in the 3-, 6-, 7-, 10-, and 11-positions are indistinguishable in the ^{11}B NMR spectra, while the atom in the 9-position gives rise to a signal with a relative intensity of unity[94]. It is noteworthy that another mechanism has been proposed for the isomerisation of 2-$CB_{10}H_{11}^-$ to account for the observed spectrum and has been used by Tolpin and Lipscomb[105] for $B_{11}H_{11}^{2-}$ (Fig. 19). If the "opening–closure" of the structure of 2-$CB_{10}H_{11}^-$ involves the atoms in the 1-, 4-, 5-, and 8-positions adjoining the carbon atom in the 2-position, the ^{11}B NMR spectrum should also show three doublets with the intensity ratios 1 : 5 : 4, referring to the boron atoms in the 9-position, the 3-, 7-, 6-, 10-, and 11-positions, and the 1-, 4-, 5-, and 8-positions respectively.

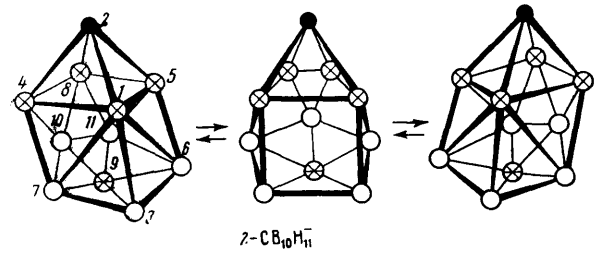

Figure 18.

Dicarba-*closo*-undecaborane(11) ($C_2B_9H_{11}$)

Of the 20 possible isomers of this carborane, only one (2,3-$C_2B_9H_{11}$) is known (Fig. 20); it is formed on pyrolysis of $C_2B_9H_{13}$ at 100°C in a yield of about 22%. Under the same conditions, the yield of the *CC*-dimethyl derivative from the corresponding dicarbaundecaborate reaches 75%.[32,106] A structure was proposed for $C_2B_9H_{11}$ on the basis of ^{11}B NMR and ^1H NMR data and the formation of the optically inactive $C_2B_9H_{10}Ph$ from the optically active

anion $C_2B_9H_{11}Ph^-$ (this shows that the plane of symmetry passes through the carbon atoms [107]). It was subsequently confirmed by X-ray diffraction [108].

Oxidation of 2,3-$C_2B_9H_{11}$ by iron(III) salts or $H_2Cr_2O_7$ in aqueous solutions results in partial decomposition of the initial carborane with formation of $C_2B_7H_{13}$. [32,109] Treatment of 2,3-$C_2B_9H_{11}$ in benzene at 0°C with chromic acid leads to the "oxidative hydroxylation" product 4,5-$(OH)_2$-2,3-$C_2B_9H_9$. [110]

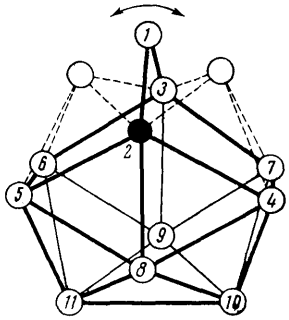

Figure 19.

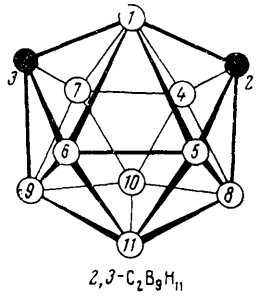

Figure 20.

Nucleophilic agents react with $C_2B_9H_{11}$ to form adducts of the type $C_2B_9H_{11}L$. [106,111,112] The interaction of 2,3-$C_2B_9H_{11}$ with a number of Lewis bases (L) leads to the opening of the *closo*-carborane structure and the formation of 10-L-7,9-$C_2B_9H_{11}^-$. Bu^-, Me^-, H^-, malonic acid derivatives, and the carboranyl anions $C_2B_8H_9^-$ and $C_2B_{10}H_{11}^-$ have been used as L. [111] However, the reaction with other Lewis bases, such as EtO^-, PPh_3, and NMe_3, results in the formation of a 3-substituted derivative 3-L-7,9-$C_2B_9H_{11}$. [112] The formation of 10-substituted dicarbaundecaborate anions in one case and of 3-substituted derivatives in the other may be associated, according to the authors [112], with the fact that, on being attacked by L, the boron atom in the 1-position in $C_2B_9H_{11}$ moves in one case to the side opposite to that from which the Lewis base attacks, with formation of the isomer 10-L-7,9-$C_2B_9H_{11}$, while in the other case the boron atom moves in the opposite direction and 3-L-7,9-$C_2B_9H_{11}$ is formed (Fig. 21). However, we believe that this explanation is inadequate (see Section VI).

2,3-$C_2B_9H_{11}$ interacts with two equivalents of sodium in THF, the second equivalent adding on only in the presence of naphthalene and treatment of the reaction mixture with $CoCl_2$ and NaC_5H_5 followed by oxidation with air results in the formation of a mixture of complexes [88]. $\sigma_i = +0.12$ and $\sigma_R^\circ = +0.01$ for the 2-$C_2B_9H_{10}$ carbonyl group [114,115].

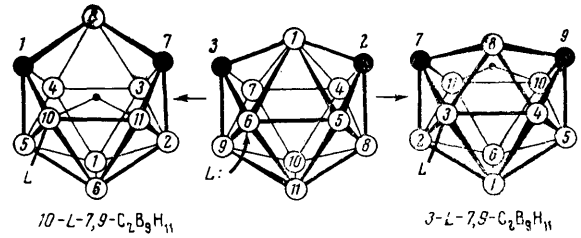

Figure 21.

Dodecahydromonocarba-*closo*-dodecaborate(1-) ($CB_{11}H_{12}^-$)

The only possible isomer $CB_{11}H_{12}^-$ (Fig. 22) is formed together with $CB_9H_{10}^-$ from cyanodecaborane [93,42]. A structure was proposed for the carborane on the basis of the ^{11}B NMR spectrum, which contains three doublets with the relative intensities 1 : 5 : 5. The carborane is not oxidised at the anode in acetonitrile up to a potential of 2.4 V. [94]

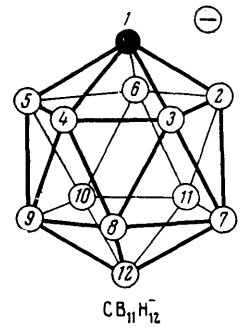

Figure 22.

Dicarba-*closo*-dodecaborane(12) ($C_2B_{10}H_{12}$)

All three possible isomers, 1,2-, 1,7-, and 1,12-$C_2B_{10}H_{12}$, are known (Fig. 23). Since there are very numerous data for the properties of the $C_2B_{10}H_{12}$ isomers, we shall consider only their most general properties. More detailed information can be found in a number of reviews [2,3,15,113].

The thermodynamic stability of the carborane(12) isomers varies in the series $o > m \sim p$.

$$1,2\text{-}C_2B_{10}H_{12} \xrightarrow{450^\circ} 1,7\text{-}C_2B_{10}H_{12}. \quad (1)$$

$$1,7\text{-}C_2B_{10}H_{12} \xrightleftharpoons{600^\circ} 1,12\text{-}C_2B_{10}H_{12} \quad . \quad (2)$$

At a high temperature an equilibrium mixture of the *m*- and *p*-isomers is formed [116] [Eqn.(2)]. Under the influence of strong bases, protons are readily abstracted at room temperature from the carbon atoms with formation of the corresponding carboranyl anions.

The p*K*a, determined by various methods for the *o*-, *m*-, and *p*-isomers, are respectively 19, 24, and 26 (Kashin et al.[117]) and 23.3, 22.9, and 30 (Petrov et al.[118]). Hawthorne and coworkers showed that treatment with alkalis under severe conditions results in the cleavage of the *o*- and *m*-carborane nuclei with formation of 1,2- and 1,7-$C_2B_9H_{12}^-$.[30,119] 1,12-$C_2B_{10}H_{12}$ undergoes a similar cleavage in low yield to 2,9-$C_2B_9H_{12}$ only in a 20% KOH solution in boiling propanediol. Protonation of this anion leads to the non-polar compound 2,9-$C_2B_9H_{13}$.[120]

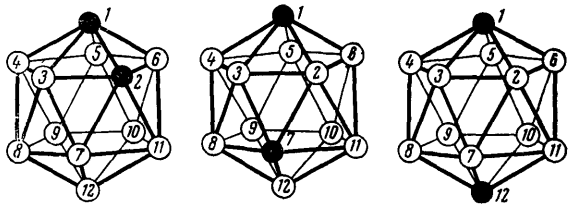

Figure 23.

The stability of the carborane(12) isomers varies in the sequence $o < m < p$. The interaction of derivatives containing one or two alkali metal and alkaline earth metal atoms with electrophilic agents leads to *C*-derivatives. Electrophilic substitution takes place at the boron atoms most remote from the carbon atoms. Substitution in 1,2-$C_2B_{10}H_{12}$ takes place primarily in the 9(12)-position; the 1,7-isomer is substituted in the 9(10)-position and the 1,12-isomer in the 2-position, the only one possible. The ease and rates of electrophilic reactions of the three carborane isomers also vary in the sequence $o > m > p$.

The oxidation of the $C_2B_{10}H_{12}$ isomers by $KMnO_4$ in an acid medium leads to the formation of all the possible *B*-hydroxy-derivatives[121]. Reduction with sodium in liquid ammonia or THF leads to dianions[122] and the oxidation of the dianion obtained from 1,12-carborane(12) gives rise to 1,7-carborane(12), while the oxidation of the dianions derived from 1,7- and 1,2-carboranes(12) leads to the formation of 1,2-carborane(12).[123,124] Treatment of the dianions with $CoCl_2$ or other transition metal salts and NaC_5H_5 results in the formation of complexes where the metal atom constitutes the thirteenth vertex of the polyhedron[125,126]. Protonation of the dianions leads to the dicarbadodecaborate(1-) monoanions. The structures of some of these have been determined by X-ray diffraction[127,128]. The molecular structures of *o*-, *m*-, and *p*-$C_2B_{10}H_{12}$ have been determined by electron diffraction[129]. $\sigma_I = +0.295$ and $+0.213$, and $\sigma_R^0 = +0.004$ and -0.036 have been found for the fluorophenyl derivatives of the corresponding 1,2- and 1,7-carborane isomers respectively[114].

IV. THE SYNTHESIS, STRUCTURE, AND PROPERTIES OF *NIDO*- AND *ARACHNO*-CARBORANES

1. *NIDO*-CARBORANES

Dicarbo-*nido*-pentaborane(7) ($C_2B_3H_7$)

Three isomers of $C_2B_3H_7$ are possible. The only one of these obtained, 1,2-$C_2B_3H_7$, was isolated after the reaction of the tetraborane(10) B_4H_{10} with acetylene in the gas phase at 50°C. Its structure (Fig. 24) is based on ^{11}B and ^1H NMR data[130]. The carborane is stable in the gas phase at 50°C, but decomposes at 100°C. In the liquid state polymerisation with formation of $(C_2B_3H_7)_X$ takes place at temperatures as low as 25°C. The polymerisation is greatly accelerated in the presence of HCl, polar solvents, and other polar substances. In dilute non-polar solutions this compound is comparatively stable. The schemes quoted below illustrate its chemical properties[131]:

$$C_2B_3H_7 + C_2H_2 \xrightarrow{50^\circ} C_4B_2H_6 + \text{solid residue}\ .$$

To determine the characteristics of the formation of $C_4B_2H_6$, the reaction of $C_2B_3H_7$ with acetylenic compounds labelled with deuterium and ^{13}C was investigated. It was shown that the alkyne is inserted preferentially in the C–B bond and to a lesser extent in the C–C bond[132].

$$C_2B_3H_7 + C_2H_4 \xrightarrow{90^\circ} BEt_3 + B_2H_2Et_4;$$
$$C_2B_3H_7 + BMe_3 \rightarrow B_5H_8 + H_2 + \text{solid residue};$$
$$C_2B_3H_7 + NEt_3 \rightarrow C_2B_3H_7 \cdot NEt_3;$$
$$C_2B_3H_7 + NaH \rightarrow \text{polymerisation};$$
$$C_2B_3H_7 + Br_2 \rightarrow Br_2C_2B_3H_7 \xrightarrow{Br_2} BBr_3 + HBr + \text{solid residue}.$$

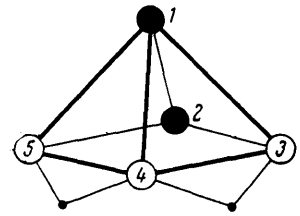

Figure 24.

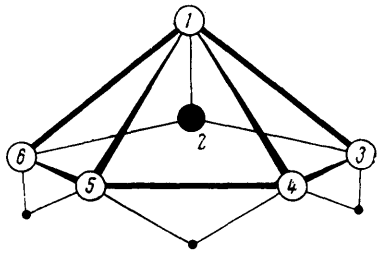
1,2-$C_2B_3H_7$ reacts with iron pentacarbonyl to form a π complex[131]. The reaction of $(\pi\text{-}C_2B_3H_7)Co(\pi\text{-}C_5H_5)$, an analogue of $(\pi\text{-}C_2B_3H_7)Fe(CO)_3$, with sodium hydride, followed by treatment with $CoCl_2$ and NaC_5H_5, results in the formation of a complex of the type $[(\pi\text{-}C_5H_5)Co]_2.(\pi\text{-}C_2B_3H_5)$, which is an example of a dinuclear complex with three parallel planar ligands[76].

Monocarba-*nido*-hexaborane(9) (CB_5H_9)

Of the two possible isomers of this carborane, only the 2-CB_5H_9 isomer with the carbon atom at the base of a pentagonal pyramid is known (Fig. 25). This compound is

one of the products of the pyrolysis of methylpentaborane[63]. 2-Et-2-CB_5H_8 is formed in 3.3% yield by the reaction of pentaborane with lithium methylacetylide[133]. Methyl derivatives of 2-CB_5H_8 are also formed as side products in the synthesis of 2,3-$C_2B_4H_8$.[134] The fully alkylated monocarba-*nido*-hexaborane(9) ($MeCB_5H_3Me_5$) is a side product in the reaction of acetylene with tetraethyldiborane[135,136]. The structure of CB_5H_9, proposed on the basis of ^{11}B NMR data[137,138], was confirmed by microwave spectroscopy[139]. Pyrolysis of CB_5H_9 at 250°C for 3.5 days leads to 1,7-$C_2B_{10}H_{12}$ and $C_2B_7H_{13}$.[140] This method of synthesis of the higher carboranes from the lower carboranes is of definite theoretical interest†.



2-CB_5H_9

Figure 25.

Dicarba-*nido*-hexaborane(8) ($C_2B_4H_8$)

Three isomers of this carborane are possible, two of which have been obtained (Fig. 26). A derivative of 2,4-$C_2B_4H_8$ has been synthesised, namely the ammonium inner salt $C_2B_4H_7^-N^+Me_3$ (see p.647).[73] The second isomer 2,3-$C_2B_4H_8$ can be synthesised and is well known. It is formed in a yield of about 40% in the pyrolysis of a mixture of pentaborane(9) and acetylene at 235°C for 40 h.[72] The structure of the carborane, proposed on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopic data[34,72,141], was confirmed by the X-ray diffraction of its *CC*-dimethyl-derivative[142,143]. The vibrational spectra of the unsubstituted and *C*-methyl-substituted carboranes have been published and discussed[144]. Pyrolysis of 2,3-$C_2B_4H_8$ leads to a mixture of the lowere *closo*-carboranes, the process being the most convenient method for the synthesis of the *closo*-carboranes $C_2B_3H_5$, $C_2B_4H_6$, and $C_2B_5H_7$.[57,58,77] The electrophilic halogenation of 2,3-$C_2B_4H_8$ and its *C*-methyl derivatives involves the boron atoms adjoining the carbon atoms at the base of the molecule[145,146]. This mode of reaction is inconsistent with the charges calculated by the SCF method, according to which electrophilic reactions should involve the boron atom in the 1-position. To account for the above course of reaction, Marynick and Lipscomb[49] carried out a comparative assessment of the bonding orbitals in the molecule and demonstrated the considerable role of the orbitals of the skeleton in the reaction (see Section VI).

† Rietz and Hawthorne[140] suggest that 1,2-$C_2B_{10}H_{12}$ can be obtained from 2,3-$C_2B_4H_8$ and B_6H_{10} and that the composition of the products formed from B_6H_{10}, $C_3B_3H_7$, and $C_4B_2H_6$ should be investigated.

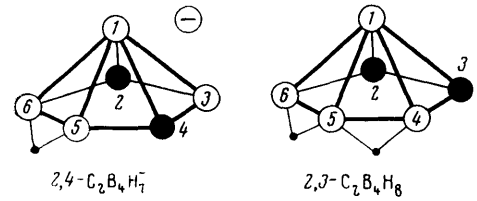


Figure 26.

Isotope exchange between 2,3-$C_2B_4H_8$ on the one hand, and D_2 and B_2D_6 on the other has been studied and various deuterio-derivatives of this carborane have been obtained[147]. When an ethereal solution of $C_2B_4H_8$ is treated with sodium hydride, the product is dicarba-*nido*-hexaborate(1-) anion ($C_2B_4H_7^-$),[148] which reacts with alkyl halide derivatives of silicon, germanium, boron, lead, tin, and also with chlorosilane and chlorogermane to give the corresponding bridged derivatives, in which the atom of the element is linked by a three-centre bond with two boron atoms of the carborane[149,151]. The interaction of SiH_2Cl_2 with two equivalents of $C_2B_4H_7^-$ in THF at 0°C leads to a 70% yield of a compound with two carborane ligands bound to the SiH_2 group by two three-centre bonds—$\mu\mu'$-$SiH_2(C_2B_4H_7)_2$ (Fig. 27).[151,152] The compounds obtained with an MR_3 or MR_2 bridge group containing non-transition elements are good examples illustrating the possibility of the formation of a non-classical chemical bond not only by boron atoms but also by a number of non-electron-deficient elements, including carbon (see Section VI).

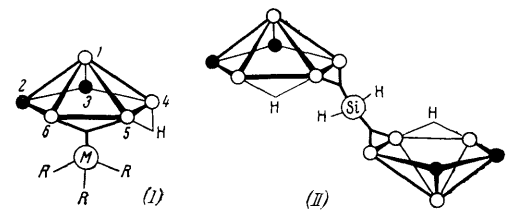

Figure 27.

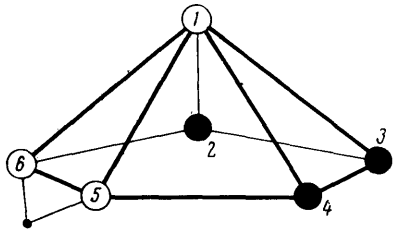
The reaction of $Na^+C_2B_4H_7^-$ with $(\pi\text{-}C_5H_5)Fe(CO)_2I$ initially leads to a complex in which iron is bounded by a three-centre bond to the carborane ligand, namely μ-[$(\pi\text{-}C_5H_5)$.$Fe(CO)_2$]$C_2H_4B_7$; this compound can be converted in 90% yield into the π complexes $(\pi\text{-}C_5H_5)Fe^{II}(\pi\text{-}C_2B_4H_7)$ and $(\pi\text{-}C_5H_5)Fe^{III}(\pi\text{-}C_2B_4H_6)$.[84,153] The interaction of Na^+.$C_2B_4H_7^-$ with NaC_5H_5 and $CoCl_2$ in THF with subsequent oxidation by air leads to 1,7,2,3-$(C_5H_5Co)_2C_2B_3H_5$.[76] The reaction of 2,3-$C_2B_4H_8$ with an excess of $Fe(CO)_5$ at 240°C also leads to π complexes of the transition metal with carborane ligands. 1,2,3-$(CO)_3FeC_2B_4H_6$ and 1,2,3-$(CO)_3FeC_2B_3H_7$ were obtained by this reaction[84,154]

Tricarba-*nido*-hexaborane(7) ($C_3B_3H_7$)

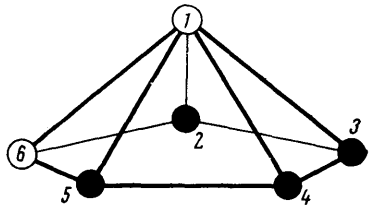
Of the four possible isomers, only one (2,3,4-$C_3B_3H_7$) has been obtained (Fig. 28). *C*-Methyl derivatives of this carborane are formed at 50°C in the gas-phase reaction

between tetraborane(10) (B_4H_{10}) with acetylene. The yields of the methyl derivatives 2-$MeC_3B_3H_6$ and 2,3- and 2,4-$Me_2C_3B_3H_5$ are respectively 3.3, 6.5, and 5.3%.[155,156] The interaction of B_4H_{10} with C_2H_2 is a first-order reaction with respect to B_4H_{10} and a zero-order reaction with respect to acetylene. The proposed reaction mechanism involves the formation of B_4H_8 in the first, slowest stage, and this compound then interacts rapidly with acetylene, giving a solid polymeric residue $(C_2BH_4)_x$ (80%) and a mixture of volatile products, in which 4-$MeCB_5H_8$, 2,3-$C_2B_4H_8$, and 2,3,4-$C_3B_3H_7$ are also present in an overall yield of 2%.[156] In many studies the mechanism of the formation of tricarbohexaborane (7) and its methyl derivatives was studied using C_2D_2.[156,157] When 2,4-$Me_2C_3B_3H_5$ and other $C_3B_3H_7$ derivatives are treated with strong bases, a proton is abstracted from the bridging position with formation of the corresponding anions. Treatment of these anions with DCl leads to μ-D-derivatives of $C_3B_3H_7$.[157,158] Treatment of the anion 2-$MeC_3B_3H_5^-$ with pentacarbonylmanganese bromide leads to an adduct, where Mn is linked to a σ bond to the boron atom of the carborane ligand according to the authors[153]. When the adduct is heated, two equivalents of CO are evolved and 2Me-1,2,3,4-$(CO)_3MnC_3B_3H_5$ is formed. Heating of 2-$MeC_3B_3H_6$ and 2,3-$Me_2C_3B_3H_6$ with $Mn_2(CO)_{10}$ in the gas phase leads to similar complexes[158].



2,3,4,-$C_3B_3H_7$

Figure 28.



2,3,4,5-$C_4B_2H_6$

Figure 29.

Tetracarba-*nido*-hexacarborane(6) ($C_4B_2H_6$)

This compound completes the family of the *nido*-carboranes $CnB_6-nH_{10}-n$ having the structure of a pentagonal pyramid. Of the three possible isomers, only one has been obtained, in which all the carbon atoms are located at the base of the pyramid (Fig. 29). The fully alkylated carborane was synthesised according to the scheme[159]

$$NaR_3BC \equiv CR + ClBR_2 \rightarrow R_2BRC = CRBR_2 \rightarrow C_4B_2R_6.$$

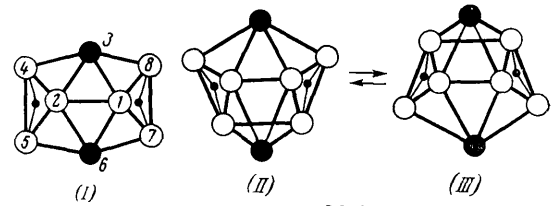
The unsubstituted carborane $C_4B_2H_6$ was obtained by the pyrolysis of 1,2-tetramethylenediborane[63]. The carborane is also formed in 5–10% yield in the reaction of $C_2B_3H_7$ with C_2H_2.[131,132] Its structure was established by ^{11}B NMR, ^1H NMR, infrared[63,159,160] and microwave[161] spectroscopy. According to the authors[161], $C_4B_2H_6$ can be regarded as an analogue of the π complexes of the cyclopentadienyl anion in which one of the carbon atoms at the base and the transition metal atom have been replaced by two boron atoms, but this similarity is extremely formal.

Dicarba-*nido*-octaborane(10) ($C_2B_6H_{10}$)

Of the seven possible isomers, only one (3,6-$C_2B_6H_{10}$) has been obtained (Fig. 30). Its yield in the reaction of $C_2B_3H_5$ with diborane is less than 5%:

$$C_2B_3H_5 + {}^3/_2B_2H_6 \xrightarrow{300^\circ} C_2B_6H_{10} + 4H_2.$$

It is suggested that, under the reaction conditions, B_3H_7 is formed from B_2H_6 and reacts with $C_2B_3H_5$ to give $C_2B_6H_{10}$.[61] The low yield of this carborane is probably due to its instability. Thus in the liquid state 3,6-$C_2B_6H_{10}$ decomposes with formation of mainly $C_2B_6H_8$ and $C_2B_5H_7$. 3,6-$C_2B_6H_{10}$ is the first carborane isoelectronic with B_8H_{12}. The structure (I) of the compound was established on the basis of ^{11}B and ^1H NMR data. The authors[61] also do not rule out the possibility of tautomeric transitions between the equivalent structures (II) and (III) (Fig. 30). They also quote the interatomic distances in the molecule[61].



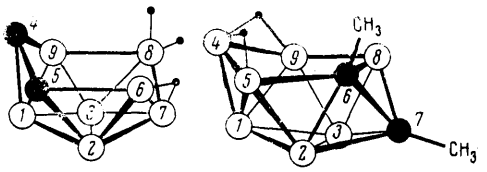
3,6-$C_2B_6H_{10}$

Figure 30.

Dicarba-*nido*-nonaborane(11) ($C_2B_7H_{11}$)

This carborane can have 25 isomers depending on the position of the carbon atoms in the molecule. The reaction of octaborane(12) (B_8H_{12}) with acetylenic compounds gives an approximately 65% yield of a mixture of two *nido*-carboranes with seven and eight boron atoms in the molecule[40,162]. The unsubstituted carborane $C_2B_7H_{11}$ is interesting because, according to ^{11}B NMR, ^1H NMR, and infrared spectroscopic data, one of the boron atoms, in the 8-position, is linked by σ bonds to two hydrogen atoms, i.e. this compound is the first example of a carborane containing the BH_2 group (Fig. 31).[161] It is striking that the *CC*-dimethyl derivative of this carborane, obtained by the

reaction of B_8H_{12} with dimethylacetylene, has a structure different from that of the unsubstituted $C_2B_7H_{11}$ (Fig. 31), which is shown clearly by the ^{11}B and ^1H NMR spectra[181]. X-Ray diffraction[163] confirmed the structure proposed for $Me_2C_2B_7H_9$ on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopy[40]. The structural differences and the greater stability of the *CC*-dimethyl derivative of $C_2B_7H_{11}$ have been explained by the steric or electronic influence of the methyl groups[162].

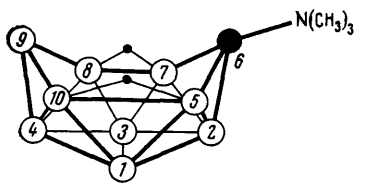


4,5-$C_2B_7H_{11}$ 6,7-$(CH_3)_2$-$C_2B_7H_9$

Figure 31.

Monocarba-*nido*-decaborane(13) ($C_1B_9H_{13}$)

Four isomers of $C_1B_9H_{13}$ are possible, of which only the 6-CB_9H_{13} isomer, obtained in the form of the derivative $B_9H_{11}CNMe_3$, is known (Fig. 32). The structure of this carborane was established on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopic data[42].



6-$N(CH_3)_3$-CB_9H_{11}

Figure 32.

Dicarba-*nido*-decaborane(12) ($C_2B_8H_{12}$)

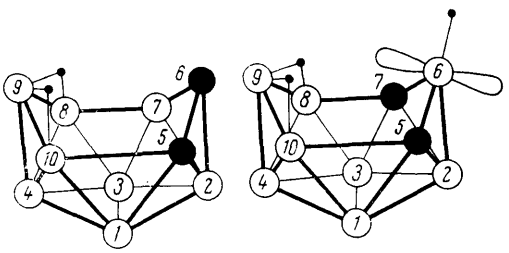
Of the sixteen possible isomers of $C_2B_8H_{12}$, two have been obtained: 5,6- and 5,7-$C_2B_8H_{12}$ (Fig. 33). As already mentioned, the 5,6-$C_2B_8H_{12}$ isomer is the main product of the reaction of octaborane(12) (B_8H_{12}) with acetylene. The *CC*-dimethylderivative is obtained by the analogous reaction with dimethylacetylene. A structure has been proposed for the carboranes on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopic data and also the fact that the decomposition of the *CC*-dimethyl derivative in propionic acid on a palladium catalyst results in the formation of n-butane[40,162]. 5,6-$C_2B_8H_{12}$ is also formed in 90% yield in the oxidation of 7,8-$C_2B_9H_{12}$ by Fe^{3+} in an acid medium at 20°C in the course of 4 h.[95] As already mentioned, heating of the 5,6-isomer in *N*-ethylpiperidineborane yields 1,2-$C_2B_8H_{10}$.[95] Certain other reactions of 5,6-$C_2B_8H_{12}$ have been described[99]:

$$5,6\text{-}C_{12}B_8H_{12} \xrightarrow[\text{vacuum}]{500^\circ} 1,6\text{-} + 1,10\text{-}C_2B_8H_{10};$$

$$5,6\text{-}C_2B_8H_{11}^- \xrightarrow{120\text{–}200^\circ} 1,2\text{-}C_2B_8H_{10} + C_2B_8H_{10}^{2-} + H_2;$$

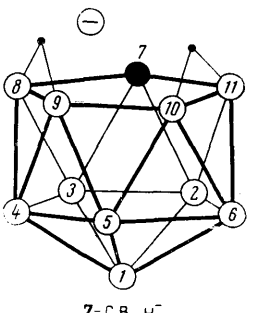
$$5,6\text{-}C_2B_8H_{12} + 2e \rightarrow C_2B_8H_{12}^{2-} \xrightarrow[H_3O^+]{200^\circ} 5,7\text{-}C_2B_8H_{10}^{2-} \rightarrow C_2B_7H_{13}.$$

The interaction of 5,6-$C_2B_8H_{12}$ with EtO^- gives a low yield of a new compound of the class of *arachno*-carboranes—6,9-$C_2B_8H_{14}$.[36] Another isomer, 5,7-$C_2B_8H_{12}$ (Fig. 33), was obtained by the reaction of $C_2B_7H_{12}^-$ with diborane[41]. According to the authors[41], the boron atom in the 6-position in this compound is *sp*-hybridised, one *p* orbital remaining free. In the interaction with trimethylamine this orbital and the orbital with the electron pair of the nitrogen atom form the B—N bond. When $C_2B_8H_{12}NMe_3$ is heated to 150°C, *closo*-1,6-$C_2B_8H_{10}$ is formed and treatment with anhydrous HCl in CH_2Cl_2 at 80°C gives rise to the initial carborane—5,7-$C_2B_8H_{12}$. Furthermore, treatment with an excess of HCl results in the substitution of the hydrogen atom in the 6-position by chlorine and the formation of 6-Cl-5,7-$C_2B_8H_{11}$, the carborane containing, like the unsubstituted compound, a free *p* orbital. Pyrolysis of the chlorocarborane *in vacuo* leads to *closo*-Cl-1,6-$C_2B_8H_9$ and treatment with D_2O yields $C_2B_7H_{11}D_2$, deuterium being linked to carbon atoms[41].



5,6-$C_2B_8H_{12}$ 5,7-$C_2B_8H_{12}$

Figure 33.



7-$CB_{10}H_{13}^-$

Figure 34.

Monocarba-*nido*-undecaborane(14) ($C_1B_{10}H_{14}$)

Among the three possible isomers, the derivatives of only one isomer, with the carbon atom in the open face, have been obtained (Fig. 34). The anion derived from this carborane ($CB_{10}H_{13}^-$) can be obtained either from cyanodecaborane[42,93] or by the reaction of decaborane with alkyl isocyanides[42,93,164-167]. Among the chemical properties of $C_{10}H_{13}^-$, electrophilic halogenation reactions have been mentioned. The reaction with Br_2 leads to mono- and di-bromo-derivatives. At 0°C chlorine decomposes this anion. The reaction with iodine does not occur even in the presence of catalysts. In electrophilic halogenation reactions $R_3NCB_{10}H_{12}$ is less reactive[167]; for example, bromination takes place only in the presence of $AlCl_3$. Numerous *C*- and *B*-derivatives of $CB_{10}H_{13}^-$ have been described[42]. π Complexes with transition metals have been obtained from $CB_{10}H_{11}^{3-}$ and $H_3NCB_{10}H_{10}^{2-}$.[42]

Dicarba-*nido*-undecaborane(13) ($C_2B_9H_{13}$)

Of the nine possible isomers, two compounds with the carbon atoms in the open face and the isomer with the carbon atoms in the 2,9-positions have been synthesised[120] (Fig. 35). 7,8-, 7,9-, and 2,9-$C_2B_9H_{13}$ are obtained on protonation of the corresponding dicarbaundecaborate anions, which are synthesised by the alkaline cleavage of 1,2- 1,7-, and 1,12-$C_2B_{10}H_{12}$. Structures have been proposed for the carboranes and their anions on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopic data[30,31,32,106,119,120]. The 7,9-isomer is much less stable than the 7,8-isomer[32].

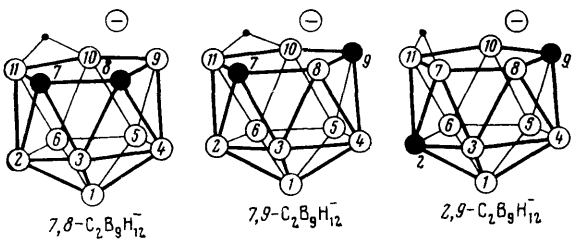


Figure 35.

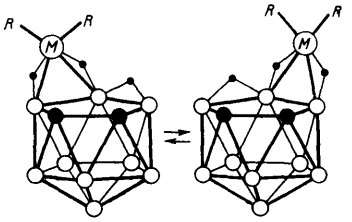

Figure 36.

The thermal decomposition of these carboranes, leading to *closo*-2,3-$C_2B_9H_{11}$, has already been mentioned[31,32]. The interaction of 7,8-$C_2B_9H_{13}$ with trialkylaluminium and trialkylgallium leads to $R_2Al.C_2B_9H_{12}$ and the corresponding gallium derivatives[168]. According to ^{11}B and ^1H NMR, the $AlMe_2$ group undergoes tautomeric transitions between two equivalent positions (Fig. 36).[169] X-Ray diffraction confirmed the conclusion that the $AlMe_2$ group is in the "bridging" position[170]. Heating of *nido*-$B_9C_2H_{12}MR_2$ (M = Al or Ga) in benzene leads to *closo*-1,2,3-$RMC_2B_9H_{11}$. On heating to 450°C, these compounds isomerise to a metallocarborane with the carbon atoms in the *m*-positions.

The reactions of both *nido*- and *closo*-metallocarboranes with $TiCl_4$ result in the formation of catalysts resembling Ziegler catalysts, in the presence of which ethylene polymerises at 25°C and 1 atm.[168] 7,8-$C_2B_9H_{13}$ can be titrated as a strong monobasic acid[30,32] and under the influence of strong bases the second bridge proton is also abstracted[119].

The structure of dicarba-*nido*-undecaborate(1-) anions was determined on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopic data. The hydrogen atom in the bridge position in 7,8-$C_2B_9H_{12}$ undergoes rapid tautomeric transitions between the 9,10- and 10,11-positions. In 7,9-$C_2B_9H_{12}$ the bridge hydrogen atom is linked to the atoms in the 10- and 11-positions. The isotope exchange involving 7,8- and 7,9-$C_2B_9H_{12}^-$ and their derivatives has also been studied[171]. Comparison of the spectra of various 7,8-$C_2B_9H_{12}$ derivatives led to the assignment of the peaks in the ^{11}B NMR spectrum of this anion[171,172]. 7,9-$C_2B_9H_{12}$ is thermodynamically more stable than the 7,8-isomer and on heating to 300°C the latter is converted into the former[119,173].

The electrophilic substitution reactions of 7,8-$C_2B_9H_{12}^-$ take place at the open face with formation of 9-substituted derivatives of 7,8-$C_2B_9H_{11}^-$. For example, iodination with I_2 in an aqueous ethanol solution yields 9-I-7,8-$C_2B_9H_{11}^-$. The oxidative substitution reaction leads to the 9- and 10-substituted derivatives of the 7,8-isomer[174,175]. Alkylation of 7,9-$C_2B_9H_{11}^{2-}$ yields 10-Alk-7,9-$C_2B_9H_{11}^-$ (Fig. 37).[176]

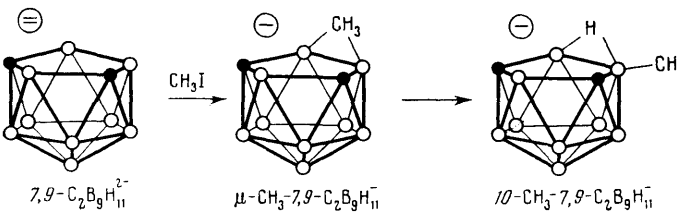

Figure 37.

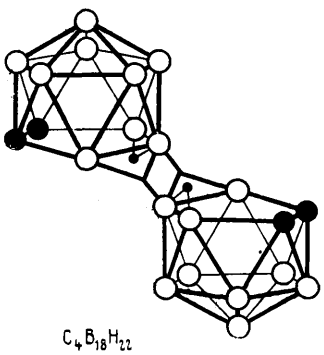
Oxidation of 7,9-$C_2B_9H_{12}^-$ with chromic acid results in the formation of $C_2B_7H_{13}$ in a high yield[177]. Cautious oxidation of 7,8-$C_2B_9H_{12}^-$ in an acid medium at −15°C with $K_2Cr_2O_7$ leads to the stable carborane $C_4B_{18}H_{22}$. ^{11}B NMR, ^1H NMR, and infrared and ultraviolet spectroscopic data indicate a structure in which two $C_2B_9H_{11}$ fragments are joined by two three-centre bonds (Fig. 38).[178] As already mentioned, the oxidation of 7,8-$C_2B_9H_{12}^-$ by iron(III) salts in an acid medium leads to 5,6-$C_2B_8H_{12}$.[95] Numerous transition metal complexes were obtained with the dicarbollide ions $C_2B_9H_{11}^{2-}$.[2,19-23,179] The interaction of 7,8-$C_2B_9H_{11}^{2-}$ with GeI_2, $SnCl_2$, and $Pb(OAc)_2$ leads to heteroanalogues of tricarba-*closo*-dodecaborane(11).[180] ^{119}Sn Mössbauer spectroscopic data for 3-Sn-1,2-$C_2B_9H_{11}$ have

shown that the outer electronic shell of the tin(II) atom is of the $5s^2$ type [181]. The analogous germanium compound was obtained from 7,9-$C_2B_9H_{11}^{2-}$. The reaction of 7,9-$C_2B_9H_{11}^{2-}$ with $SnCl_2$ results in the formation of 2,3-$C_2B_9H_{11}$. 3-Sn-1,7-$C_2B_9H_9$ is formed as an intermediate [112]:

$$7,9\text{-}C_2B_9H_{11}^{2-} + SnCl_2 \rightarrow (3\text{-Sn-}1,7\text{-}C_2B_9H_{11}) \rightarrow 2,3\text{-}C_2B_9H_{11}.$$



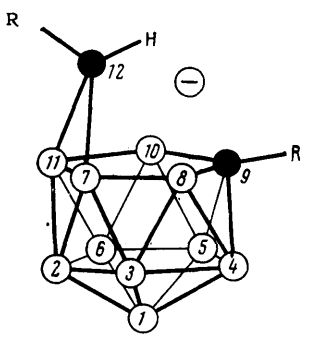
$C_4B_{18}H_{22}$

Figure 38.

The interaction of the dicarbollide ions with $RBCl_2$ leads to the restoration of the icosahedral structure, involving the formation of 3-R-$C_2B_{10}H_{11}$. [182-185] σ_i and σ_R^o have been determined for 7,8- and 7,9-$C_2B_9H_{12}^-$ and the corresponding dicarbollide ions [114,186]. Zakharkin et al. [186] believe that the second negative charge in $C_2B_9H_{11}^{2-}$ is located mainly at the boron atoms not in the open face.

Dicarbarba-*nido*-dodecaborane(14) ($C_2B_{10}H_{14}$)

The neutral compound have not been obtained. The anions of the corresponding *nido*-carboranes are formed when the dianions $(C_2B_{10}H_{12})^{2-}$ obtained from 1,2-, 1,7-, and 1,12-$C_2B_{10}H_{12}$ are protonated [187]. The structure of one of the $C_2B_{10}H_{13}^-$ isomers, based on X-ray diffraction data, is presented in Fig. 39. [127,128]



$R_2C_2B_{10}H_{11}^-$
(R=CH_3,C_6H_5)

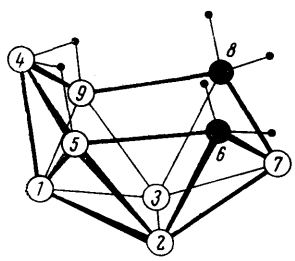
Figure 39.

2. *ARACHNO*-CARBORANES

arachno-Carboranes have the general formula $C_{0-6}B_nH_{n+6}$. This class of carboranes has been least thoroughly investigated. Only two *arachno*-carboranes have been obtained hitherto. They have an open structure, like *nido*-carboranes, and differ only by the number of hydrogen atoms in the open face. The most objective feature characterising *closo*, *nido*-, and *arachno*-carboranes is the electronic structure of compounds of these classes (see Section V).

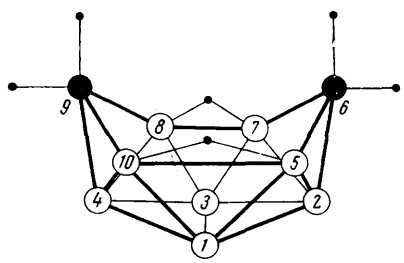
Dicarba-*arachno*-nonaborane(13) ($C_2B_7H_{13}$)

$C_2B_7H_{13}$ can have nineteen isomers. As already mentioned, the only one obtained (6,8-$C_2B_7H_{13}$) is formed as a result of the oxidation of $C_2B_9H_{11}$ in aqueous solution [32,35] or by the oxidation of 7,9-$C_2B_9H_{12}^-$ with chromic acid [177]. The structure of $C_2B_7H_{13}$ (Fig. 40) was established on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopic data and also the study of the chemical properties of this carborane [32,35]. X-Ray diffraction data have been published for *CC*-$Me_2C_2B_7H_{11}$. [188] As already stated, thermal decomposition leads to a mixture of the *closo*-carboranes $C_2B_6H_8$, $C_2B_7H_9$, and $C_2B_8H_{10}$. [32,85] Interaction with strong bases leads to the abstraction of two "axial" protons from the carbon atoms with formation of $C_2B_7H_{11}^{2-}$, whose treatment with D^+ yields $C_2B_7H_{11}D_2$. [32] The interaction of $C_2B_7H_{11}^{2-}$ with $CoCl_2$ leads to the formation of π complexes containing two $C_2B_7H_9^{2-}$ carborane ligands with carbon atoms in the 1,6- or 6,9-positions, depending on the reaction conditions. The 1,10-isomer has been obtained by thermal isomerisation [189]. The reactions of $C_2B_7H_{11}^{2-}$ with $Mn(CO)_5Br$, $Mn_2(CO)_{10}$, and $Mn(CO)_2Cl$ in THF lead to 1,4,6-$(CO)_3MnC_2B_6H_8^-$. [190]



6,8-$C_2B_7H_{13}$

Figure 40.



6,9-$C_2B_8H_{14}$

Figure 41.

6,9-Dicarba-*arachno*-decaborane(14) ($C_2B_8H_{14}$)

As already mentioned, this carborane is formed when 5,6-$C_2B_8H_{12}$ is acted upon by EtO^-. Its structure has been proposed on the basis of ^{11}B NMR, ^1H NMR, and infrared spectroscopic data (Fig. 41).[36]

V. THE CHARACTERISTIC FEATURES OF THE VARIATION OF THE PHYSICOCHEMICAL PROPERTIES OF CARBORANES

The experimental data on the properties of *closo*-, *nido*- and *arachno*-carboranes which have accumulated can be treated in general terms and make it possible to discover a relation between their structure and the variation of their physicochemical and chemical properties in the light of the characteristics of the three-centre bonds in these compounds. The Table lists certain physicochemical parameters of carboranes, such as the interatomic distances l, the C–H bond stretching vibration wavenumbers ν(C–H), the chemical shifts of the C–B bond protons τ, and the coordination numbers (C.N.) of the carbon and boron atoms. When the interatomic distances in carboranes and other similar structures are compared, a striking feature is the greater distances between the atoms of the molecular skeleton compared with the bond lengths in classical organic and organoboron compounds. For example, the C–C distance in 1,2-$C_2B_{10}H_{12}$ is 1.65 Å,[129] which greatly exceeds l_{C-C} for the σ bond in organic compounds of different types ($l_{C-C} \leq 1.55$ Å).[194] The B–C distance in the same carborane is of the order of 1.71 Å [129] and in the 1,7-isomer it is 1.73 Å, while in trimethylboron the C–B bond length is 1.578 Å.[195] The greater C–C and B–C interatomic distances in carboranes undoubtedly reflect the specific nature of the bonds in these compounds. Evidently the increase of the C–C and B–C interatomic distances is associated with the deficiency of electrons and the specific features of the three-centre bond. In contrast to the bonds in the skeleton, where in the general case two-centre bonds also do not coincide with the straight line joining the two atoms, the external C–H and B–H bonds as well as the bonds with the substituents are ordinary σ bonds. As a result of this, comparison of the characteristics of these bonds with the behaviour familiar in organic chemistry and the chemistry of organic derivatives of the elements can yield useful information about the state of the atoms constituting the molecular skeleton. In organic compounds the C–H and C–Me bond lengths are known to depend on the hybrid state of the carbon atoms, amounting to 1.09 and 1.54 Å (sp^3), 1.07 and 1.49–1.53 Å (sp^2), and 1.06 and 1.46 Å (sp) respectively. The C–H and C–Me bond lengths in *closo*-carboranes are of the order of 1.1 and 1.53 Å, the corresponding values in *nido*-carboranes being 1.07 and 1.51 Å respectively. Comparison of these results (see Table) indicates the predominant sp^3 hybridisation of the carbon atoms in the majority of *closo*-carboranes‡ and sp^2 hybridisation in *nido*-carboranes. The shorter C–Me and particularly C–Hal bond lengths are in many cases apparently associated with the appreciable electron-accepting properties of the carbonyl groups. For example, the C–I bond length in 1,12-I_2-1,12-$C_2B_{10}H_{11}$ is 2.082 Å,[196] while in MeI it amounts to 2.132 Å;[194] on the other hand, in CF_3I the bond length is 2.101 Å.[197]

‡ In many cases, for example in the 1,6-$C_2B_8H_{10}$ molecule, carbon atoms are apparently in the sp^2 hybrid state.

Bearing in mind the σ bonding with the substituent, the state of the boron atoms in the polyhedron can be inferred also from the properties of the substituents linked to the polyhedron (H, halogen, alkyl, etc.); however, the lack of adequate experimental data still precludes such a comparison. Molecular orbital calculations indicate sp^3 or sp^2 hybridisation[4,24], while in the theory of three-centre orbitals an sp^3 hybrid state of the boron atoms is postulated[4]. Despite the insufficiency of experimental data, certain conclusions about the characteristics of the state of the boron atoms can be reached from a formal comparison of the coordination number with the possible distribution of electron density among the atoms of the polyhedron. Thus it is easy to note a tendency towards an increase of the distance between the atoms of the polyhedron with increase of the coordination number. An interesting approach to this problem was proposed by Wade in relation to the borane anions $B_nH_n^{2-}$. On the basis of the fact that the bond in *closo*-structures is formed by the $(n+1)$th electron pair [198], the author determined the formal number of electrons corresponding to each edge of the polyhedron, i.e. the "bond order" between the atoms as a function of n and the number of adjacent atoms (x_1 and x_2)§:

$$\text{"bond order"} = \frac{(n+1)(x_1+x_2)}{nx_1x_2}.$$

He attributed the decrease of the interatomic distance with decrease of the coordination number to the increase of the "bond order". Since the observed decrease of the interatomic distance is greater than expected, Wade concluded that in the given molecule the electronic charge is distributed non-uniformly, being higher on atoms with a lower coordination number than on atoms with a higher coordination number [199].

Evidently the absence of a direct relation between the interatomic distances and the coordination number can be explained if one considers the distribution of the $(n+1)$th electron pair over the localised bonding orbitals rather than over the atoms of the polyhedron. Each atom supplies three atomic orbitals for the formation of the bonds in the nucleus, i.e. is involved in the formation of three bonding orbitals, and the number of electrons joining the central atom to its x neighbours is six. Thus the formal number of electrons corresponding to the given atom will decrease with increase of the coordination number. The higher thermodynamic stability of the isomer of the given carborane in which the carbon atoms have a smaller coordination number¶ can be attributed to the fact that in these isomers the excess positive charge on the carbon atoms (see Section II) is more compensated compared with the isomers in which the carbon atoms have higher coordination numbers.

With increase of the number of atoms n forming the polyhedron (in consequence of the decrease of the quantity $n + 1/n$—the average number of electron pairs at each atom of the polyhedral molecule), there is an increase of the excess positive charge on the atoms of the polyhedron, including the carbon atoms with identical coordination numbers, which is manifested in the properties of the C–H bonds (see Table).

§ x = C.N. – 1, i.e. the outer σ bond is disregarded.

¶ In all the known unsubstituted carboranes the carbon atoms occupy the positions with the minimum coordination numbers. If several isomers of the given carborane are known, then the isomers in which the carbon atoms have a higher coordination number are converted into isomers with a smaller number coordination number[3], for example 1,6-$C_2B_8H_{10}$ → 1,10-$C_2B_8H_{10}$.[32]

In his study of the relation between the individual classes of carboranes, boron hydrides, and related structures, Wade noted that n-atomic molecules with *closo*-, *nido*-, and *arachno*-structures have respectively $n + 1$, $n + 2$, and $n + 3$ electron pairs binding together the molecular skeleton. The addition of an electron pair to the *closo*-structure $B_nH_n^{2-}$ leads to the *nido*-structure $B_nH_n^{4-}$ with a rearrangement of the skeleton and the formation of a fragment of the next polyhedron with one vertex missing[198]. Having combined with two electrons, the molecules of *closo*-carboranes are converted to the electronic analogues of *nido*-carboranes, corresponding to the *nido*-structures of derivatives of carborane dianions, and having combined with four electrons they are converted into analogues of *arachno*-carboranes. The addition of one proton per unit negative charge gives rise to structural analogues of *nido*- and *arachno*-carboranes[200]. For example:

$$2,3\text{-}C_2B_9H_{11} \xrightarrow{2e} C_2B_9H_{11}^{2-} \xrightarrow{H^+} 7,9\text{-}C_2B_9H_{12}^-\ ,$$
$$1,2\text{-}C_2B_8H_{10} \xrightarrow{2e} C_2B_8H_{10}^{2-} \xrightarrow{2H^+} 5,6\text{-}C_2B_8H_{12}\ .$$

VI. THE POSSIBLE MECHANISMS OF THE CHEMICAL REACTIONS OF CARBORANES

The nature of the chemical bond in carboranes and boron hydrides is manifested not only in the characteristics of their structure but naturally also in the nature of their chemical reactions, such as reduction, oxidation, and interaction with nucleophilic and electrophilic agents. We shall attempt to consider the reactions involving localised three-centre as well as two-centre bonds.

1. Reduction of Carboranes

One of the most general and interesting reactions of carboranes, mainly *closo*-carboranes, is their ability to combine with electrons when acted upon by alkali metals. The addition of electrons to *closo*-structure with n-atoms in the polyhedron is accompanied by a rearrangement of the carborane molecule, the resulting anions being isolated in the form of transition metal complexes or protonation products with the metal atom inserted at the missing vertex of the polyhedron with $n + 1$ atoms.

In the light of ideas concerning three-centre bonds, the addition of two electrons can be formally represented as follows. The electrons can add on successively to the three-centre bond with formation of a two-centre bond and an atomic orbital with an electron pair. At the intermediate stages of their transfer electrons can be accommodated at a non-bonding orbital, if such is present, or at the nearest antibonding orbital (Fig. 42). Next, the system of bonding orbitals probably rearranges with formation of two two-centre orbitals, from the atomic orbital with the electron pair and a second three-centre orbital. Thus two three-centre orbitals are formally rearranged

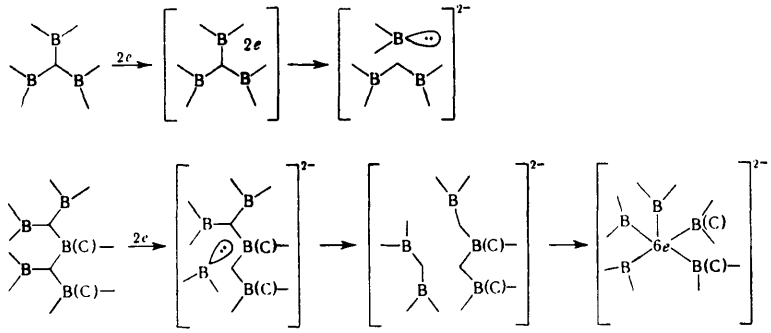

Figure 42.

into three two-centre orbitals, and the electron pair is located in the resulting additional bonding orbital. The bonding two-centre orbitals formed are probably to some extent delocalised, i.e. there is a possibility of the formation of (three) bonding five-centre orbitals, made up of the atomic orbitals of the atoms in the open face (Fig. 42). The last structure in Fig. 42 does not reflect the real directions of the atomic orbitals but merely the possibility of the formation of bonding orbitals common to the atoms in the open face (by analogy with Hawthorne's ideas concerning the nature of the bond in transition metal complexes with the carborane ligands $C_2B_9H_{11}^{2-}$ and in the dicarbollide ions themselves [179]).

The scheme in Fig. 42 illustrates the proposed mechanism of the addition of electrons to the *closo*-carborane molecule (a fragment of the possible valence structure is indicated). Two of the five atoms are carbon atoms. The scheme shows that the addition of electrons is accompanied by the opening of the structure, with formation of a pentagonal face. The possibility of the opening of the carborane nucleus with formation of a hexagonal face is illustrated by the scheme in Fig. 43. [201] Similarly to the scheme in Fig. 42, two of the six atoms are carbon atoms. It is noteworthy that the addition of electrons to the carborane molecule must involve primarily the immediate environment of the carbon atoms (the site with the lowest electron density) and in the resulting anions the carbon atoms must be located in the open face—the site with the maximum electron density. Accordingly, electrophilic reactions, for example protonation and interaction with transition metal salts (formation of metallocarboranes), proceed at the open face containing at least one carbon atom.

Substituents in the carborane nucleus may play an important role in determining the sites of addition of electrons. Depending on the nature of the substituent and its location in the polyhedron, the attack by electrons can take place at three-centre bonds other than in the unsubstituted carboranes. Furthermore, polarisation of the three-centre bond itself under the influence of the substituent can lead to the opening of the three-centre bond and hence of the polyhedral molecule in different directions, i.e. to the formation of an atomic orbital with an electron pair at different atoms of the polyhedron. All these factors lead to different sets of dynamic structures [201].

The addition of electrons must be accompanied by a considerable increase in the energy of the bonding orbitals of the carborane nucleus and the corresponding decrease of the energy of the antibonding orbitals. This must facilitate the corresponding rearrangements of the molecular skeleton. The rearrangements can lead either to a superposition of the physicochemical characteristics of the individual isomers or, when they are sufficiently rapid, to an averaging of the spectroscopic physicochemical parameters of the dianions in solutions [201].

The high reactivity of the dianions is shown also by the ease of occurrence of various chemical reactions, such as disproportionation, interaction with various electrophilic agents, with the solvent, etc. Thus, when electrons add to $2,4\text{-}C_2B_5H_7$, with subsequent treatment by $CoCl_2$ and NaC_5H_5 and then oxidation by air, a mixture of compounds is formed, eight of which have been isolated [83]. When the dianions are treated with transition metal salts, the resulting complexes have different structures [88], probably owing to the different electronic structures of the transition

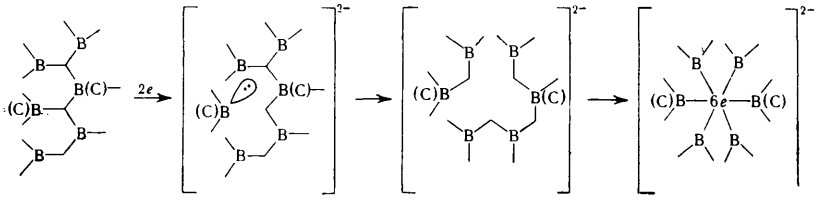

Figure 43.

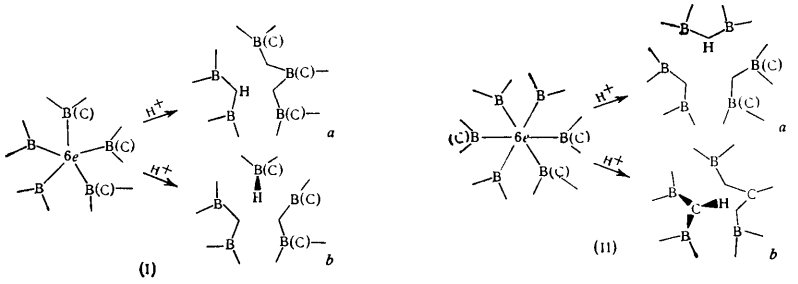

Figure 44.

metal atoms, for example cobalt(III) and iron(III), and the consequent stabilisation of various dynamic structures of the dianions. On formation of complexes with transition metals, the given electronic system of the dianion is fixed to a greater or smaller extent and it is possible to isolate complexes having a definite structure.

The structure of the dianions is also fixed on protonation. However, it is not always identical with the structure of the corresponding carborane ligands in transition metal complexes. On interaction of the bonding orbitals in the open face with a proton, the electron pairs are localised. Two versions of such localisation are possible. In the first a system of two two-centre orbitals and a three-centre B—H—B bond is formed as a result of the protonation of the dianion. (The formation of a B—H—C bond and even more so a C—H—C bond in the final structure is unlikely in view of the excess positive charge on the carbon atoms relative to the boron atoms in the open face.) The initial pentagonal or hexagonal face of the dianion is then fixed. In the second version the system of bonding orbitals in the open face is disturbed owing to the localisation of electrons at one of the atoms with formation of a C—H or B—H σ bond. For understandable reasons, the formation of a C—H σ bond is preferable (localisation of an electron pair at the given atom). The carbon atom thus forms two σ bonds with two substituents. The remaining four electrons are accommodated at two two-centre orbitals. In the case of a hexagonal face one may then expect its narrowing, since the four electrons in the two two-centre orbitals cannot bind a system of six atoms (Fig. 44). The protonation of $R_2C_2B_{10}H_{10}^{2-}$, leading to the monoanion $R_2C_2B_{10}H_{11}^{-}$, one of the isomers of which has a structure (Fig. 39) where one of the carbon atoms is linked by σ bonds to R and H and is located above the plane of the open pentagonal face [127,128], may serve as an example.

Scheme Ia in Fig. 44 occurs in the protonation of, for example, the dicarbollide ions $C_2B_9H_{11}^{2-}$ (the fragments of the possible valence structures are indicated in the Figure). The protonation of the dianion with formation of a monoanion having the structure IB is not so far known. Scheme II can describe the protonation of $C_2B_8H_{10}^{2-}$ derived from 1,2-$C_2B_8H_{10}$ (II*a*) and of $C_2B_{10}H_{12}^{2-}$ derived from 1,2-$C_2B_{10}H_{10}R_2$ (II*b*). The II*b* fragment was taken from Tolpin and Lipscomb [127].

Similarly to the formation of dianions (Figs. 42 and 43), one may expect the addition of not only two but also of four and more electrons to carborane molecules with the corresponding structural rearrangements. If one begins with a carborane containing n atoms in the polyhedron, the tetra-anions should give rise to a molecule isoelectronic with *arachno*-carboranes having a structure representing a fragment of a polyhedron with two vertices more than in the initial *closo*-carborane, i.e. $n + 2$, while in the case of hexa-anions the resulting structure should have three vertices more, i.e. $n + 3$, and so on. Indeed, complexes have been obtained with cobalt(III) in which the carborane ligands can be regarded as tetra-anions and hexa-anions: $C_2B_6H_8^{4-}$, $C_2B_8H_{10}^{4-}$, $C_2B_7H_9^{6-}$, etc. [83,88,202]

2. Oxidation of Carboranes

Molecules with the closed structure of the isoelectronic series $B_nH_n^{2-}$, $CB_{n-1}H_n^{-}$, and $C_2B_{n-2}H$ can not only combine with two electrons, but theoretically can also give up two electrons. Indeed the system of bonding orbitals in the skeleton of these molecules includes three two-centre and $n - 2$ three-centre bonds, which follows from the solution of the equations †

$$2x + 2y = 2n + 2 \text{ (electron balance)},$$
$$3n = 2x + 3y \text{ (orbital balance)},$$
$$x = 3,\ y = n - 2,$$

where n is the number of atoms in the polyhedron, x the number of two-centre orbitals, and y the number of three-centre orbitals. After the removal of two electrons, three two-centre bonds can rearrange to two three-centre bonds with retention of the structure as a whole or, if possible, with increase of molecular symmetry. Thus, in principle, it is possible to obtain, for example, the species $C_2B_nH_{n+2}^{2+}$ or the corresponding derivatives $C_2B_nH_{n+1}^{+}$ and $C_2B_nH_n^{0}$—their deprotonation products. Isoelectronic analogues of such systems are known in the series of boron hydrides, for example B_4Cl_4 (tetrahedron), [203-205] B_8Cl_8 (dodecahedron), [206-209] and B_9Cl_9H. [210] The last two compounds are isoelectronic with $C_2B_6H_8^{2+}$ and $C_2B_7H_9^{2+}$ respectively.

The oxidation of the dianions to neutral *closo*-carboranes can be treated formally as a process which is the reverse of the addition of electrons (Figs. 42 and 43) and which leads to the closure of the open structure of the dianion. The oxidant interacts with the bonding two-electron five- or six-centre orbitals, but, in contrast to the usual electrophilic agents, does not fix the possible structures of the dianion, forming a bond with the carborane ligand and resulting in the closure of the *nido*-structure and to a *closo*-structure as a result of electron transfer from the dianion [211]. The formation of particular isomers of *closo*-carboranes may be determined both by the existence of dynamic structures and, mainly, by the mode of closure of the pentagonal and hexagonal faces of the dianions, i.e. by the energy of the transition state whose structure is probably close to that of the dianion—oxidant transition complex.

3. Reactions of Carboranes with Nucleophilic Agents

The mechanism of the interaction of carboranes with nucleophilic agents resembles in the first stage the interaction with an electron pair. The nucleophilic agent interacts with a three-centre orbital, with formation of a two-centre orbital and a boron—nucleophilic agent σ bond (Fig. 45). As a result, the *closo*-structure opens at the site of attack by the nucleophilic agent, as in electron addition, and an open face is formed. Depending on the nature of the carborane and the attacking nucleophilic species, the  linkage may be retained in the residual part of the carborane molecule, or the boron atom may be eliminated after the addition of a second molecule of the nucleophilic agent. For example, the reaction of 1,6-$C_2B_4H_6$ with Me_3N leads to the opening of the *closo*-carborane molecule [73]. The sequence of the electronic and structural rearrangements of the molecule in this reaction

† This set of equations is a special case of the set of Lipscomb's equations put forward to describe boron hydrides and other compounds in terms of the topological theory [4].

can be represented by the scheme in Fig. 46. The electron pair of the nitrogen atom interacts with the three-centre $C_{(1)}-B_{(2)}-B_{(3)}$ orbital to form the $Me_3N-B_{(2)}$ σ bond. The $B_{(2)}-H$, $B_{(2)}-B_{(5)}$, and $B_{(4)}-B_{(5)}-B_{(6)}$ bond orbitals then rearrange in such a way that the molecule is opened still more, and a pentagonal pyramid is formed, the hydrogen atom linked by a σ bond to the $B_{(2)}$ atom migrating to the bridge position.

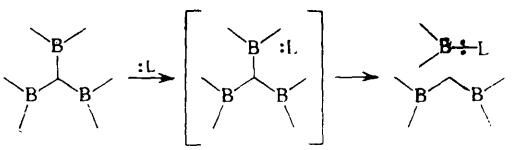

Figure 45.

Another example is provided by the reaction of $C_2B_9H_{11}$ with Lewis bases. The nucleophilic agent L interacts with a three-centre orbital, for example between the $B_{(1)}$, $C_{(3)}$, and $B_{(6)}$ atoms, as a result of which a $B_{(6)}-L$ σ bond is formed and the structure opens. The hydrogen atom linked to $B_{(6)}$ in the initial carborane moves to the bridge position in the product (Fig. 47). According to this scheme, the formation of the 3-isomer for certain L as a result of the opening of the $C_2B_9H_{11}$ structure on the side of the attacking L species [112] is unlikely. The 10-L-7,9-$C_2B_9H_{11}$ isomer is probably formed initially and is converted into 3-L-7,9-$C_2B_9H_{11}$ as a result of the migration of the $B_{(8)}$ atom.

The cleavage of 1,2-(1,7)-$C_2B_{10}H_{12}$ with alkali [119] is illustrated by the scheme in Fig. 48. The mechanisms of the cleavage of $R_2C_2B_{10}H_{10}$ by other nucleophilic agents, such as BuLi, RMgX, piperidine, etc., are similar [212-214]. The intermediate $C_2B_{10}H_{12}R^-$ is an electronic analogue of the dicarbadodecaborate monoanion $C_2B_{10}H_{13}^-$ formed on protonation of the dianion $C_2B_{10}H_{12}^{2-}$. The mechanism of the formation of $C_2B_7H_{13}$ in the cleavage of 1,6-$C_2B_8H_{10}$ with alkali can be represented similarly [100]. Apart from the addition of OH and the elimination of a boron atom, there is in this case a reduction stage, i.e. the transfer of two electrons to the molecule with formation of an *arachno*-carborane.

The general characteristics of the interaction of nucleophilic agents with a three-centre bond are probably manifested not only for *closo*-carboranes but also for *nido*-carboranes having an open B–H–B three-centre bond. Naturally reactions involving the closed B–B–B bonds of the nucleus are also possible. The reactions involving B–H–B bonds must begin, like the reactions involving the three-centre B–B–B bond, with the supply of electrons to the energetically lowest unfilled B–H–B orbital and a subsequent rearrangement of the resulting system via schemes I and II (Fig. 49). Reactions such as the addition of electrons to diborane with formation of $B_2H_6^{2-}$ [215] and the elimination of the bridge hydrogen atom from *nido*-carboranes and boron hydrides by bases or alkali metals proceed similarly. The reactions of carboranes with open three-centre B–C–B bonds (for example, 1,2-$C_2B_4H_6$) [50] can be described by similar schemes. As in reactions involving a closed three-centre bond, in this case the interaction with nucleophilic agents (or electron addition) must evidently be accompanied by the opening of the carborane molecule and the ligand must apparently form a bond with a boron atom. Subsequently, in the interaction with a second ligand molecule, the boron atom may be eliminated.

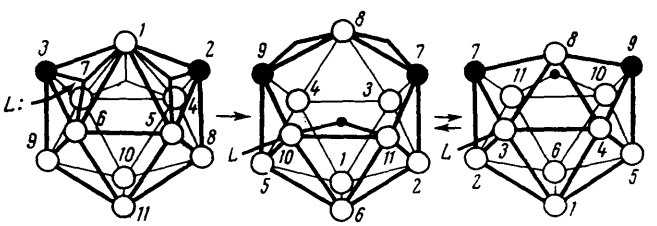

Figure 47.

4. Reactions of Carboranes with Electrophilic Agents

In considering the reactions of carboranes with electrophilic agents, it is logical to treat them as reactions involving two-centre bonds. Indeed there are atoms in carboranes with free electrons, i.e. not involved in the formation of a bond, and the vacant orbital of the electrophilic agent E (which is present or formed in the course of the reaction) interacts with a bonding two-centre orbital (possibly with an antibonding orbital in the transition state, as suggested, for example, by Nefedov et al. [216]); this

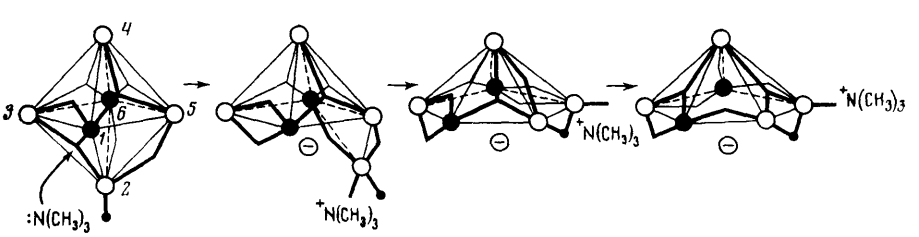

Figure 46.

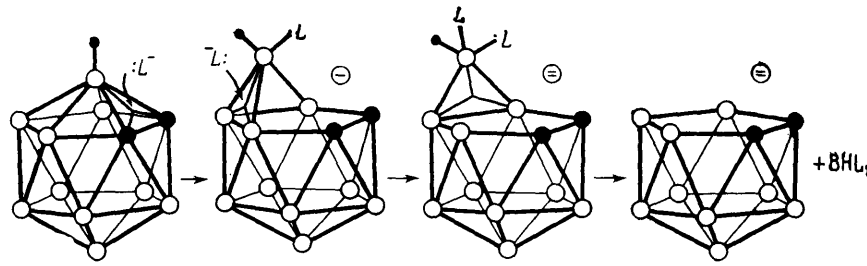

Figure 48.

involves the formation of a three-centre orbital. The possible versions of the three-centre bond formed are presented in Fig. 50 (I)‡.

The nature of the intermediate complex of the carborane with the electrophilic agent and the type of the three-centre bond formed depend on the distribution of electron density among the bonds, the bond polarisabilities, and the characteristics of E, i.e. ultimately on the energy of the orbitals of the reactants and the transition state. On formation of a three-centre bond, the reaction can proceed in several ways.

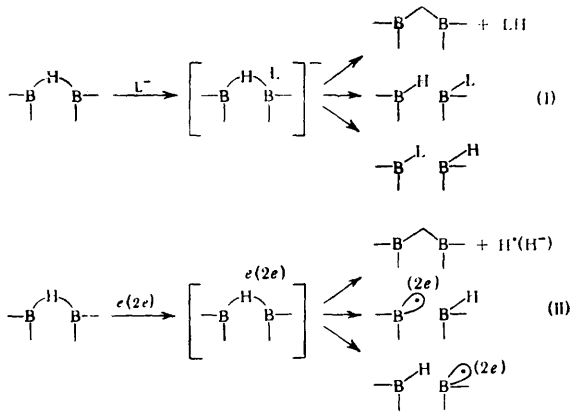

Figure 49.

1. The removal of a proton (H^+) and the formation of substitution products, as, for example, in Fig. 50 (II). The possibility of the formation of isomeric substitution products follows from this scheme. Indeed, depending on the reaction conditions and the nature of the catalyst, the ratio of the isomers formed in the halogenation of carborane(12) varies [217]. In many cases electrophilic substitution leads to a unique product, for example alkylation and halogenation of $4,5\text{-}C_2B_7H_9$ lead to $6\text{-}E\text{-}4,5\text{-}C_2B_7H_9$ (E = Me, Et, or Br). [92] In the series of boron hydrides protonation of $B_{10}H_{10}^{2-}$ leads to the formation of $B_{10}H_{12}$ containing three-centre B–H–B bonds involving the boron atoms at the vertices, which in an acid medium take part in the isotope exchange of hydrogen atoms for deuterium atoms [38]. Deuterium exchange involving $1,2\text{-}C_2B_{10}H_{12}$ in an acid medium leads to the substitution of the hydrogen atoms at all the boron atoms [218].

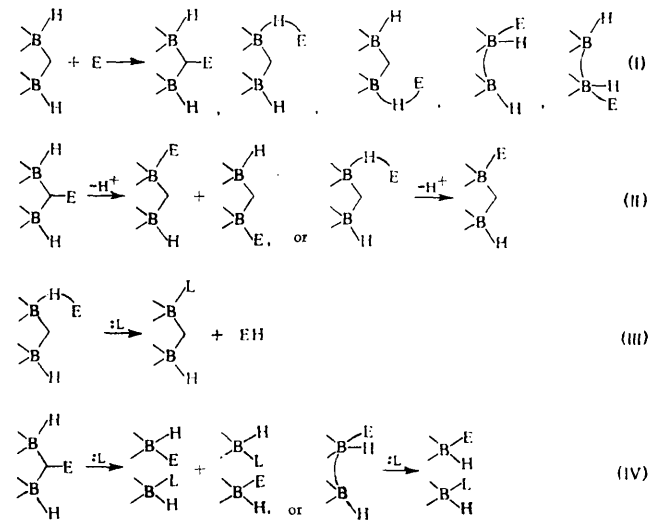

Figure 50.

2. The rupture of a three-centre B–H–E bond, possibly under the influence of the nucleophilic agent (see the interaction of three-centre bonds with nucleophilic agents), with formation of an E–H bond and a vacant orbital at the B atom, which interacts rapidly with an electron donor (when a nucleophilic agent is involved in the process, simultaneously with formation of an E–H bond), as shown, for example, in Fig. 50 (III). The oxidative hydroxylation of carboranes formally proceeds via a similar mechanism [110,121].

3. The rupture of a three-centre B–B–E bond. This stage can also be initiated by the nucleophilic agent [Fig. 50 (IV)]. The *closo*-structure is then of course opened

‡ The generally accepted notation for three-centre bonds is used. For bonds of the open type, such representation can be inconsistent in certain cases with the geometrical structure, i.e. in the transition state the B–H–E bond may prove to be linear.

with formation of B–E and B–L bonds. The opening of the $B_{10}H_{12}^{2-}$ structure in the series of boron hydrides takes place in this way in the interaction with Et_2S in an acid medium, resulting in the formation of $B_{10}H_{12}(SEt_2)_2$.[219] The reaction of 1,6-$C_2B_8H_{10}$ with hydrochloric acid does not stop at any intermediate stage and the opening is accompanied by the breakdown of the structure; boric acid is formed[100]. The breakdown of carboranes in an acid medium in the presence of a palladium catalyst and the oxidative degradation of carboranes, for example of 2,3-$C_2B_9H_{11}$ to $C_2B_7H_{13}$ [32] or of 7,8-$C_2B_9H_{12}^-$ to 5,6-$C_2B_8H_{12}$,[95] can probably be included among reactions of this type.

---o0o---

In conclusion we must note that there may be an alternative to the proposed reaction mechanisms, i.e. in principle, nucleophilic reactions, including the addition of electrons to two-centre bonds and electrophilic reactions involving three-centre bonds, can proceed via the following mechanisms.

1. As already mentioned, the interaction with nucleophilic agents begins with the accommodation of electrons in the nearest orbital (the energetically lowest unoccupied orbital), which is a non-bonding or weakly antibonding orbital in a three-centre bond and an antibonding orbital in a two-centre bond (Fig. 51). It is easily seen that in the general case the reaction involving a three-centre bond is energetically preferable ($E^0_{ABC} < E^*_{AB}$). However, in many cases the two-centre bond is weak, i.e. the energy of the bonding orbital is enhanced and that of the antibonding orbital is reduced. For example, electrons add to *C*-halogenocarboranes(12) at the C–halogen bond with formation of a halide ion and $\geq C^-$: after hydrolysis, the unsubstituted carborane is formed[201]. The reaction of *B*-halogenocarboranes involves both the boron–halogen bond and the three-centre bonds in the nucleus. The former process leads to unsubstituted carboranes and the latter to the dianion of the halogenocarborane, the oxidation of which leads to a mixture of the possible isomers of the halogenocarborane[201].

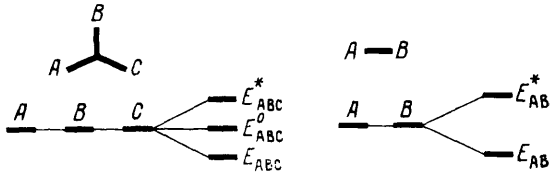

Figure 51.

2. The reactions of electrophilic agents via three-centre bonds can be, in principle, represented by the scheme in Fig. 52:[220,221] the carborane structure is opened with formation of a vacant orbital at one of the atoms, this being followed by rapid interaction of the latter with the nucleophilic agent and the formation of a B–E bond. We believe this mechanism to be unlikely, although it can account for certain reactions, for example the degradation of the carborane nucleus.

Comparison of the foregoing considerations with data from other chemical fields suggests that the interactions of electrophilic agents with two-centre bonds, particularly σ bonds, with formation of three-centre bonds are of a general type. For example, electrophilic reactions of compounds containing an "electron-deficient" atom (B, Be, Al, Ga, etc.), carbenes, and other similar compounds or 'onium compounds, including carbonium ions, proceed in this way. For example, Olah and coworkers have been successfully developing the concept of the intermediate formation of three-centre C–E–C and C–E–H bonds in organic chemistry (here E = R^+, NO_2^+, H^+, etc.).[222–228]

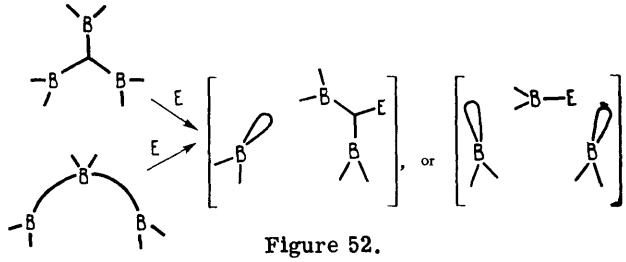

Figure 52.

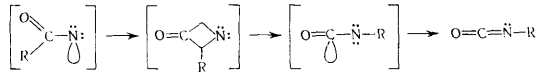

Figure 53.

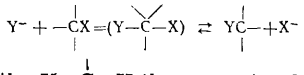
The concept of the intermediate formation of three-centre bonds can be used successfully in describing certain intermediate stages in electrophilic substitution reactions of aromatic compounds. Such bonds are undoubtedly formed in many rearrangements involving a carbonium ion or an atom with a vacant atomic orbital (sextet rearrangements) (Fig. 53). Thus, three-centre bonds, which are so characteristic of "electron-deficient" compounds (Group III elements) are characteristic also of compounds formed by Group IV–VII elements. This applies in the first place to the intermediates and transition states in such reactions when the element can form a vacant orbital. We may note that three-centre bonds have been successfully invoked to described many inert gas compounds. For example, in the linear XeF_2 molecule the atoms are joined by a three-centre bond of the open type: Xe (the central atom) supplies the 5*p* orbital containing an electron pair and the two fluorine atoms each provide a 2*p* orbital containing one electron. The four electrons are accommodated in the bonding and non-bonding orbitals. All synchronous reactions involving three (and more) centres probably also proceed via an intermediate state in which three-centre (and many-centre) orbitals are formed. For example, in the S_N2 reactions



the formation of the Y–C–X three-centre bond may be expected in the transition state, two electrons being accommodated in the bonding orbital and two in the non-bonding three-centre orbital.

We believe that consideration of the reactions of carboranes, boron hydrides, and related compounds with nucleophilic and electrophilic agents in the light of ideas concerning three-centre and two-centre bonds permits a prediction of the possible modes of the reactions and leads to a better understanding of their mechanisms.

The Stereochemistry of Optically Active Thio-derivatives of Phosphorus-based Acids

M.Mikołajczyk and M.Leitloff

The review deals with the literature on the separation of chiral thio- and seleno-derivatives of phosphorus-based acids into optical isomers and their most important stereospecific transformations are discussed. Particular attention is concentrated on the analysis of the configurational relations between chemical and physicochemical methods for the determination of the absolute configurations of optically active thio-derivatives of phosphorus-based acids.
The bibliography includes 121 references.

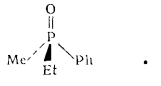
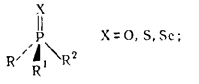
I. INTRODUCTION

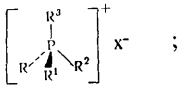
The stereochemistry of organic compounds containing a heteroatom in the molecule as the centre of asymmetry began to develop at the beginning of the present century. At the same time the first attempts were made to resolve chiral organophosphorus compounds into optical isomers. In 1911 Meisenheimer and Lichtenstadt[1] obtained the optically active ethylmethylphenylphosphine oxide and demonstrated for the first time the steric configuration of tetracoordinate phosphorus derivatives:



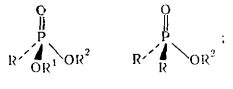
Although subsequently many investigators attempted to resolve chiral organophosphorus compounds, in the course of several decades these were successful in only a few cases. The failure of the majority of the experiments was due to the difficulties associated with the selection of the appropriate resolving agent, forming crystalline diastereoisomers with the test compounds. It was not until the 1950s that much progress was achieved in this field. Many phosphorus compounds which have been resolved into optical isomers are now known. They can be combined into at least six main classes, namely:
(a) phosphine oxides, sulphides, and selenides[2-4]:



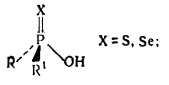
(b) quaternary phosphonium salts[5,6]:



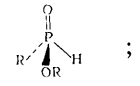
(c) esters of phosphonic and phosphinic acids[7]:



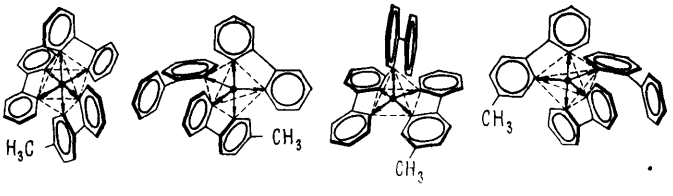
(d) thio- and seleno-derivatives of phosphorus-based acids:



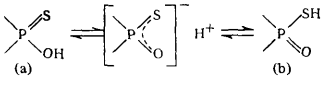
(e) phosphinates[8-20]:



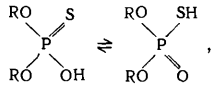
(f) compounds of pentacovalent and hexacovalent phosphorus[21]:



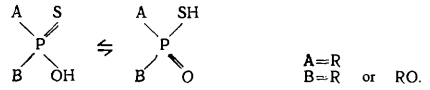
The recent considerable progress in research on the stereochemistry of phosphorus has been reflected in many reviews[6,22-29]. Together with optically active phosphine oxides and quaternary phosphonium salts, monothio-derivatives of phosphorus-based acids are of greatest importance for the development of the stereochemistry of organophosphorus compounds. The special role of these compounds in phosphorus chemistry is a consequence of their high reactivity and interesting chemical structure. In contrast to the oxygen-containing phosphorus-based acids >P(O)OH and the dithio-derivatives of phosphorus-based acids >P(S)SH, the monothio-derivatives can exist in two tautomeric forms: thionic (a) and thiolic (b):



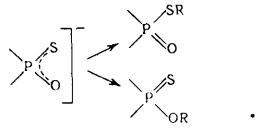
The tautomeric equilibrium between these compounds has been investigated in detail by Kabachnik et al.[30], who showed that both tautomeric forms of dialkylphosphorothioic acids are involved in the equilibrium in comparable amounts:



while in the case of phosphonothioic and phosphinothioic acids the equilibrium is almost completely displaced towards the thionic form:



The monothioacids have ambident anions[31, 32] which can react in two ways with electrophilic agents with the consequent formation of two types of derivatives: thiolo- and thiono-:



The reactivity of the anion can be satisfactorily accounted for with the aid of Pearson's concept[33,34] of "hard" and "soft" acids and bases. The "hard" basic centre of the anion is the more electronegative oxygen atom, which reacts more readily with "hard" acid centres, such as the phosphoryl or thiophosphoryl phosphorus atom, the silicon atom in silyl halides, the carbon atom in the carbonyl group, etc. On the other hand, the sulphur atom in the anion of the thioacid, which is a "soft" base, reacts more readily with "soft" electrophilic agents such as the sp^3-hybridised carbon atom in alkyl halides or halogen cations.

After the publication of the first successful experiments on the resolution of chiral thio-derivatives of phosphorus-based acids into optical isomers, the rapid development of the search for new easy methods of synthesising other representatives of compounds of this class began. At the same time research was started on the stereochemistry of the reactions of optically active thio-derivatives of phosphorus-based acids, the main aim of which was to investigate the stereochemistry of nucleophilic substitution at the asymmetric phosphoryl and thiophosphoryl centres. The studies by Aaron in the USA, Hudson in England, and Michalski and Ratajczak and Mikolajczyk in Poland have been of great importance in the development of the dynamic stereochemistry of thio-derivatives of phosphorus-based acids.

In studies on the stereochemistry of phosphorus much attention has been devoted recently to the problem of the absolute configuration of the optically active thioacids in connection with their exceptionally important position in the numerous family of chiral phosphorus compounds and the great biological activity of some of their derivatives (particularly thiolate esters and acid fluorides). Vigorous research during the last five–six years led to the determination of the absolute configurations of almost all the known optically active thioacids and to the development of many convenient chemical and physicochemical methods for the determination of the chirality of the phosphorus atom in the thioacids.

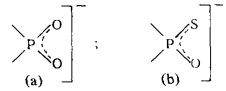
The above considerations led the present authors to write this review of research on the stereochemistry of thio-derivatives of phosphorus-based acids, which constitutes the first survey of the results of studies on the absolute configurations of the chiral acids together with a description of data concerning methods for their resolution into optical isomers and the analysis of their stereospecific transformations.

II. METHODS FOR THE SEPARATION OF CHIRAL PHOSPHORUS-BASED THIOACIDS INTO OPTICAL ISOMERS

The first attempts at the separation of phosphorus-based acids into optical isomers were undertaken as early as 70 years ago. However, initially attention was concentrated mainly on unsuccessful attempts to resolve oxygen-containing phosphorus-based acids:

The names of Caven[35], Kipping[36], Pope[37], Gibson[37], Ephraim[38], Arbuzov[39], and many other investigators are associated with research in this field.

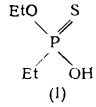
The study by Ephraim (1911), who demonstrated that oxygen-containing phosphorus-based acids cannot be separated into optical isomers since their anions (a) are symmetrical, merits special attention:



Ephraim was the first to draw attention to the fact that the substitution of one of the oxygen atoms by a sulphur atom leads to the formation of an asymmetric anion (b) and his further research was concerned with the resolution of chiral monothio-derivatives of phosphorus-based acids. However, his first attempt at the resolution of phosphoramidothioic acid,

was unsuccessful, since this acid did not form crystalline diastereoisomeric salts with the alkaloids which he had chosen. The later attempts by Arbuzov and Kamai[39] to resolve chiral thio-derivatives of phosphorus-based acids were likewise unsuccessful for the same reason.

It was not until 1956 that Aaron and Miller[40,41] succeeded for the first time in separating a chiral thioacid of phosphorus into enantiomers. This was *O*-ethyl ethylphosphonothioic acid (I), which was separated into optical isomers with the aid of the alkaloids quinine and brucine:



A somewhat simplified process for the preparation of this acid was described later by Michalski and Ratajczak[42].

In recent years Aaron and coworkers[43] resolved a series of *O*-alkyl alkylphosphonothioic acids (II–VI) by the fractional crystallisation of their diastereoisomeric salts with quinine:

(II) R=Me, R^1=Me; (V) R=Et, R^1=Me;
(III) R=Me, R^1=Et; (VI) R=i-Pr, R^1=Et.
(IV) R=Me, R^1=i-Pr;

The characteristics of the optical isomers which they obtained are given in Table 1.

Table 1. Characteristics of the optical isomers of *O*-alkyl alkylphosphonothioic acids $(R^1O)R^2P(S)OH$.

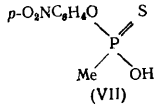
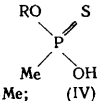
[a] Free acid.

In 1963 Boter and Ooms[44] separated *O*-p-nitrophenylmethylphosphonothioic acid (VII) into optical isomers:



(VII)

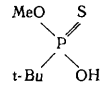
In his search for a simple method of synthesising optically active Sarin, one of the most important inhibitors of cholinesterase, Boter[45] developed in 1967 a new method for the separation of chiral *O*-alkyl methylphosphonothioic acids (II–IV, VIII):



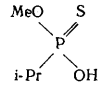
(II) R=Me; (IV) R=i-Pr;
(III) R=Et; (VIII) R=n-Bu.

He used optically active α-phenylethylamine (both optical isomers) as the resolving agent. The first stage in the resolution consisted in the introduction of half a mole of the dextrorotatory amine into an etheral solution of one mole of the racemic acid and the separation of the rapidly crystallised salt of the (+)-amine with the (+)-thioacid. In the second stage the acid remaining in solution was treated with an equimolar amount of the laevorotatory amine and the diastereoisomeric salt of the latter with the laevorotatory acid was isolated.

α-Phenylethylamine is nowadays finding extensive application in the separation of chiral thio-derivatives of phosphorus acids in view of its ability to form readily crystallisable salts and because of the ready availability of both its enantiomers. The resolution by this amine of *O*-methyl t-butylphosphonothioic acid (IX) by Krawiecka and Michalski[46] and of *O*-methyl isopropylphosphonothioic acid (X) by Mikołajczyk and Omelańczuk[47] can serve as examples:



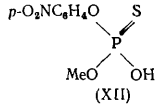
(IX)



(X)

Leitloff[48] attempted to separate *O*-propyl methylphosphonothioic acid (XI) into optical isomers with the aid of α-phenylethylamine by Boter's method. However, the inadequate optical purity of the enantiomers obtained by this method shows that the latter must be modified for this acid.

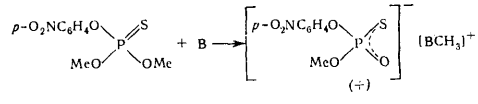
One year after the publication of Aaron's first communication concerning the separation of the optical isomers of *O*-ethyl ethylphosphonothioic acid (I) Hilgetag and Lehman[49] described a method for the separation of *O*-methyl *O*-*p*-nitrophenyl phosphorothioic acid (XII):



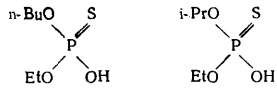
(XII)

OO-Dimethyl *O*-*p*-nitrophenyl phosphorothionate was converted by this method into the silver salt of the acid (XII) as a result of dealkylation with silver nitrate; the salt was then treated with methylstrychnine iodide. The diastereoisomeric methylstrychnine salts with the rotations $[\alpha]_D = -12.4°$ and $[\alpha]_D = +9.7°$ were separated by fractional crystallisation. In an acid medium both salts give rise to unstable optically active isomers of the acid (XII), which were converted into lead salts with the rotations $[\alpha]_D = -17.4°$ and $[\alpha]_D = +18.9°$ respectively. The optical isomers of the acid (XII) were the first examples of optically active phosphorus-based thioacids.

The same workers[50] also developed a new interesting method for the separation of the isomers of the acid (XII), which is in the nature of partial asymmetric synthesis. It consists in the asymmetric demethylation of *OO*-dimethyl *O*-*p*-nitrophenyl phosphorothionate by strychnine. The dextrorotatory salt of the thioacid with $[\alpha]_D = +13.8°$ (60–80%) predominated in the mixture of the diastereoisomeric methylstrychnine salts of the acid (XII):



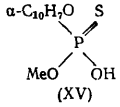
The next examples of optically active phosphorothioic acids are *O*-butyl *O*-ethyl phosphorothioic acid (XIII) and *O*-ethyl *O*-isopropyl phosphorothioic acid (XIV), which were separated into their isomers by Michalski et al.[51]



(XIII) (XIV)

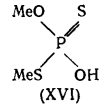
These thioacids were resolved with the aid of cinchonidine and quinine. Although the optical rotations of the resulting enantiomers of both thioacids were too low to be measured (on apparatus with a sodium source), nevertheless their derivatives were optically active, which demonstrated their partial separation.

In 1968 yet another chiral phosphoromonothioic acid was resolved, namely *O*-methyl *O*-α-naphthyl phosphorothioic acid (XV). Donninger and Hutson[52] achieved this by the fractional crystallisation of the diastereoisomeric salts of (XV) with the aid of (+)- and (−)-ephedrine:



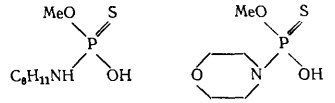
(XV)

In the following year Teichmann[53] resolved the dimethyl ester of phosphorothiolothionic acid (XVI), which contains two sulphur atoms in the molecule. The resolution was achieved by the asymmetric demethylation of *OOS*-trimethyl phosphorothiolothionate with strychnine:



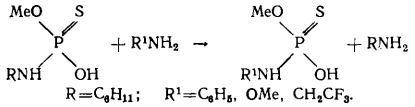
(XVI)

The optically active phosphoromidothioic acids obtained by Hamer[54] constitute a separate group. In 1965 Hamer resolved *N*-cyclohexyl *O*-methyl phosphoramidothioic acid (XVII) by the fractional crystallisation of its diastereoisomeric quinine salts:



(XVII) (XVIII)

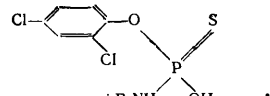
Then, by substituting the amino-residue, he obtained a whole series of optically active phosphoramidothioic acids:



R=C_6H_{11}; R^1=C_6H_5, OMe, CH_2CF_3.

Several years later Gerrard and Hamer[55] resolved by the same method *O*-methyl phosphoromorpholidothioic acid (XVIII) and isolated its dextrorotatory isomer in the form of the ammonium salt.

The methylammonium salts of both optically active forms of *O*-2,4-dichlorophenyl *N*-isopropyl phosphoramidothioic acid (XIX) were obtained in 1969 by Seiber and Tolkmith[56]. The methylammonium salt of the racemic acid (XIX), synthesised by the demethylation of the corresponding *O*-methyl phosphoramidothioate, was converted into a mixture of diastereoisomeric salts with quinine using quinine sulphate. The diastereoisomers were separated by fractional crystallisation and then, as a result of the substitution of quinine by methylamine, the enantiomeric (+)- and (−)-salts were obtained from them with the rotations $[\alpha]_D = +15.9°$ and $-23.4°$ respectively:



(XIX)

Certain physicochemical properties of optically active phosphorothioic, phosphonothioic, and phosphoramidothioic acids are listed in Table 2.

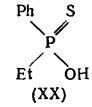
The first example of the series of phosphinothioic acids resolved into optical isomers was ethylphenylphosphinothioic acid (XX). Its partial resolution was achieved by Green and Hudson[57] in 1963 with the aid of quinine as the optically active resolving agent:



(XX)

Several years later other chiral phosphinothioic acids were resolved: methylphenylphosphinothioic acid (XXI), resolved in 1968 by Benschop's group[58], and t-butylphenylphosphinothioic (XXII), resolved in 1971 by Trippet and coworkers[59]. In both cases quinine was used as the resolving agent:

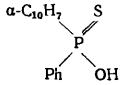
(XXI) (XXII)

The results of studies on ethylmethylphosphinothioic acid (XXIII), partially resolved by Ratajczak, were published in the proceedings of the International Colloquium on Organic Chemistry held in Paris in 1969:[60]

(XXIII)

However, no information about the method used to resolve this acid was published.

Recently Chauzov and Lutsenko[61] resolved α-naphthylphenylphosphinothioic acid (XXIV) by the fractional crystallisation of its diastereoisomeric salts with quinine:



(XXIV)

The characteristics of the optical isomers of this acid and other phosphinothioic acids are given in Table 3.

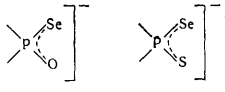
An interesting class of chiral organophosphorus compounds consists of selenium-containing phosphorus-based acids and thioacids. The negative charge in the anions of these compounds is distributed between selenium and oxygen and selenium and sulphur atoms respectively:



The first example of optically active selenium-containing phosphorus-based acids was *O*-ethyl ethylphosphonothioselenoic acid (XXV), resolved into optical isomers by Krawiecki et al.[62]:

(XXV)

Recently Krawiecka et al.[63] resolved t-butylphenylphosphinoselenoic acid (XXVI) with the aid of α-phenylethylamine:

(XXVI)

Somewhat later Nuretdinov et al.[64] succeeded in resolving *O*-ethyl ethylphosphonoselenoic acid (XXVII) into optical isomers:

(XXVII)

The alkaloids quinine and brucine were used as the resolving bases. The optical rotations of the selenium-containing acids are listed in Table 4.

Table 4. Optical isomers of phosphoroselenoic acids.

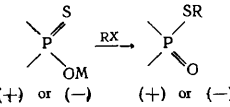
III. STEREOSPECIFIC REACTIONS OF OPTICALLY ACTIVE PHOSPHORUS-BASED MONOTHIOACIDS

Since optically active monothio-derivatives of phosphorus-based acids have ambident anions, they are very convenient starting materials for the synthesis of thiolo- and thiono-derivatives. Further stereospecific transformations of the compounds obtained directly from the thioacids lead to the synthesis of almost all types of optically active organophosphorus compounds. A detailed description of the many-stage reactions of the thioacids would require the examination of the overall dynamic stereochemistry of phosphorus and would be outside the scope of the present review. We shall therefore consider only those reactions in which the phosphorus-based thioacids are directly involved. The study of the stereochemistry of these reactions greatly assisted in the investigation of the mechanism of nucleophilic substitution at both phosphoryl [P(O)] and thiophosphoryl [P(S)] centres[65].

Optically Active Thiolate Esters

An example of reactions in which the chiral centre is unaffected is provided by the alkylation of the salts of optically active phosphorus-based thioacids, which leads to the formation of optically active thiolate esters:



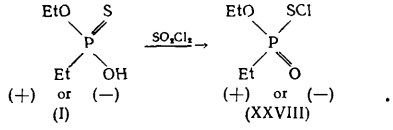
(+) or (−) (+) or (−) (1)

Alkyl halides, and among these alkyl iodides, are usually employed as alkylating agents[66-68]. Dimethyl sulphate is frequently used in the synthesis of methyl thiolate esters[57]. Since none of the bonds involving phosphorus is ruptured in the course of alkylation, the optically active thiolate esters retain the configuration of the initial thioacid.

According to Brewster's asymmetry rule, the sign of the optical rotation of the thiolate esters must be the same as that of the initial thioacids. This has been confirmed in each case described hitherto.

Optically Active Oxophosphoranesulphenyl Chlorides and Diphosphoryl Disulphides

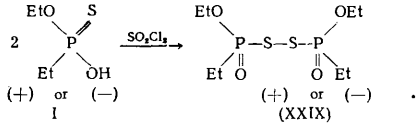
The reactions of phosphorus-based thioacids with chlorine or sulphuryl chloride leads to the formation of optically active oxophosphoranesulphenyl chlorides[42,68]. This was first discovered by Michalski and Ratajczak, who obtained optically active ethoxyethyloxophosphoranesulphenyl chloride (XXVIII) as a result of the chlorination of optically active *C*-ethyl ethylphosphonothioic acid (I):



(2)

As in alkylation, in reaction (2) the bonds involving the chiral phosphorus atom are not ruptured and the configuration of the initial thioacid is retained in the product. Optically active oxophosphoranesulphenyl chlorides are effective starting materials for further syntheses[69].

Optically active diphosphoryl disulphides can also be obtained by the reactions of optically active phosphorus-based monothioacids with sulphuryl chloride[70]. They are formed in the interaction of one molecule of sulphuryl chloride with two molecules of the thioacid:

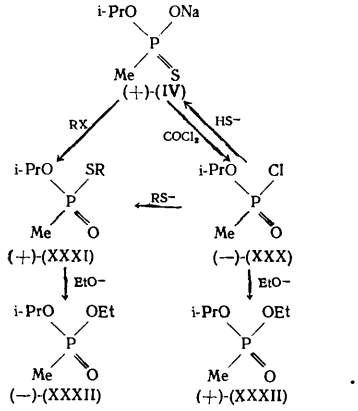


(3)

The disulphide (XXIX) is formed in two stages. Oxophosphoranesulphenyl chloride (XXVIII) is formed in the first stage and in the next stage it reacts with a second molecule of the thioacid. The chiral phosphorus atom is not attacked in either stage and the configuration of the initial acid is retained at both centres of chirality in the disulphide.

Optically Active Phosphoryl and Thiophosphoryl Halides

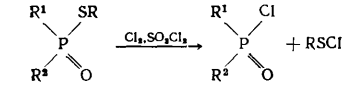
Optically active phosphorus-based monothioacids are the main starting materials for the synthesis of optically active phosphoryl [>P(O)X] and thiophosphoryl [>P(S)X] halides. One of the methods for the preparation of optically active phosphoryl chlorides involves the chlorination of salts of phosphorus-based thioacids with phosgene[66]. Aaron and Miller investigated the stereochemistry of this reaction in connection with the transformation of [−)-*O*-isopropyl methylphosphonochloridate (XXX), obtained by treating (+)-*O*-isopropyl methylphosphonothioic acid (IV) with phosgene:



(4)

The authors concluded that the reaction of the thioacid (IV) with phosgene and the formation of the compound (XXXI) take place with inversion of the configuration at the phosphorus atom.

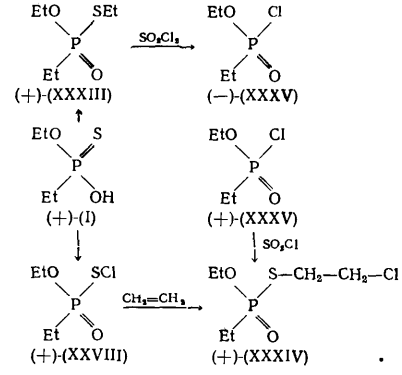
Green and Hudson[71] and independently Michalski and Ratajczak[72] obtained optically active phosphoryl chlorides by chlorinating *S*-alkyl esters of optically active phosphorus-based monothioacids:



(5)

The studies by Green and Hudson showed that chlorination of *S*-alkyl phosphinothioates leads to the formation of the corresponding chlorides with inversion of the configuration at the phosphorus atom.

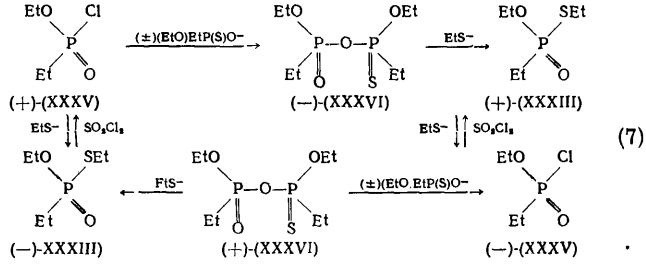
The studies of Michalski and Ratajczak led them to the conclusion that the stereochemistry of the chlorination of phosphonothioates depends on the structure of the substituent R. The mechanism of this reaction has not been elucidated so far. The studies which have been carried out hitherto suggest that the chlorination of the *S*-β-chloroethyl ester proceeds largely with retention of the configuration at the phosphorus atom, while the *S*-ethyl ester is chlorinated with inversion of configuration:



(6)

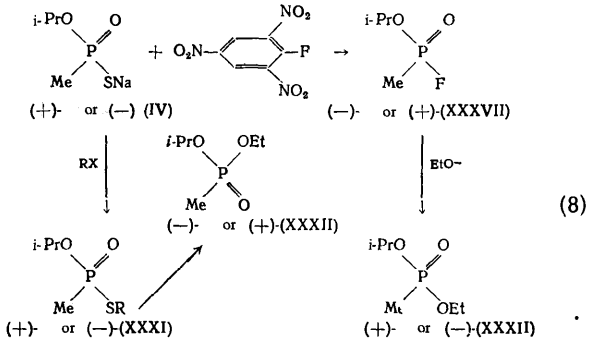
In connection with the stereochemistry of optically active phosphoryl chlorides and thiolate esters, mention should be made of the cyclic process, developed by Ratajczak[73], consisting of six reactions each of which

probably proceeds with inversion of the configuration at the phosphorus atom:



(7)

The reaction of optically active phosphorus-based thioacids with picryl fluoride leads to the formation of optically active phosphoryl fluorides. This reaction was carried out by Boter et al.[74] in the synthesis of optically active Sarin (XXXVII), the well known chlolinesterase inhibitor:



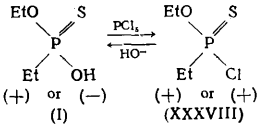
(8)

The sign of the optical rotation of the acid fluoride (XXXVII) obtained in this way is the opposite of that of the initial thioacid. Ethanolysis of the product, which is known to proceed with inversion of the configuration, leads to the formation of the ester (XXXII), which, according to Aaron, has the configuration of the initial acid. On this basis, the authors concluded that the reaction of the thioacid with picryl fluoride takes place with inversion of the configuration at the phosphorus atom.

Although phosphoryl compounds are very interesting, they are not, however, convenient objects for stereochemical studies because of their low optical stabilities†. For this reason, the results obtained can indicate only that the mechanism involving the inversion or retention of the configuration at the phosphorus atom predominates. It was found that the less reactive thiophosphoryl compounds are much more suitable for stereochemical studies.

The difference between the reactivities of phosphoryl and thiophosphoryl compounds is a consequence of the difference between the electron densities at the phosphorus atom in these compounds and the different polarisabilities of the phosphoryl and thiophosphoryl groups[75].

The synthesis by Michalski and Mikołajczak[76-78] of optically active *O*-ethyl ethylphosphonochloridothioate (XXXVIII) was an important achievement in the stereochemistry of thiophosphoryl compounds. This acid chloride is formed in a high yield and with a high optical purity in the reaction of optically active *O*-ethyl ethylphosphonothioic acid (I) with phosphorus pentachloride:

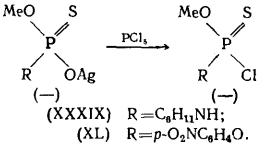


(9)

To determine the mechanism of the chlorination with phosphorus pentachloride, the resulting acid chloride (XXXVIII) was hydrolysed[78], the hydrolysis having been shown previously to involve usually the inversion of the configuration. As a result of the hydrolysis, the authors obtained the initial acid (I). This led them to the conclusion that the chlorination also proceeds with a change of configuration at the phosphorus atom. The high purity and optical activity of the resulting acid chloride (XXXVIII) make the compound a suitable starting material for the synthesis of other optically active organophosphorus compounds and for the investigation of reaction mechanisms[80].

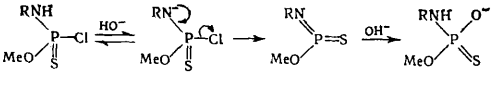
Phosphonochloridothioate derivatives of all optically active *O*-alkyl alkylphosphonothioic acids known at present were obtained similarly[81].

Using the reaction with phosphorus pentachloride, Gerrard and Hamer[82,83] also obtained optically active *O*-methyl *N*-cyclohexyl phosphoramidochloridothionate (XXXIX) and *O*-methyl *p*-nitrophenyl phosphorochloridothionate (XL):



(10)

It is interesting that alkaline hydrolysis of the phosphoramidochloridothionate (XXXIX) leads, in conflict with the above, to the formation of a racemic product, while its solvolysis results in the formation of an optically active product with inversion of the configuration. Under alkaline conditions, the hydrolysis probably proceeds via the following mechanism:



(11)

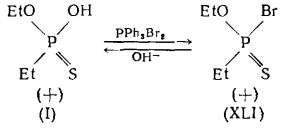
and the racemisation is associated with the formation of an intermediate optically inactive analogue of metaphosphate.

In contrast to the silver salts of optically active phosphorus-based thioacids, their ammonium salts are not convenient starting materials for the synthesis of optically active pure phosphorochloridothionates. Seiber and Tolkmith[56] showed that the reaction of the optically active methylammonium salt of *O*-2,4-dichlorophenyl *N*-isopropyl phosphoramidothioic acid (XIX) with phosphorus pentachloride results in the formation of a partly racemised product (probably via a chlorine–chlorine exchange reaction at the phosphorus atom).

Michalski et al.[84] found that optically active thiophosphonyl bromides can be obtained as a result of the reaction of triphenylphosphine dibromide with optically active

† Optically active phosphoryl halides with high optical stability were obtained recently from phosphorus-based thioacids in which the phosphorus atom is linked to a t-butyl group[63].

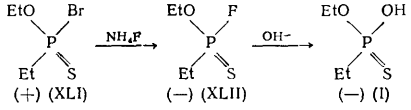
phosphorus-based monothioacids. Optically active *O*-ethyl ethylphosphonobromidothionate (XLI) was obtained by this method:



(12)

Hydrolysis of compound (XLI) leads to the reformation of the initial acid. This proves that the bromination of the thioacid with triphenylphosphine dibromide takes place with inversion of configuration at the phosphorus atom.

It is noteworthy that the optically active phosphonofluoridothionate (XLII) can be obtained from the optically active phosphonobromidothionate (XLI) as a result of the substitution of the bromine atom by a fluorine atom using ammonium fluoride[85]:

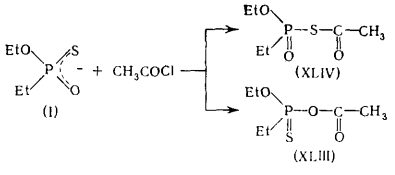


(13)

The result of the hydrolysis of compound (XLII) shows that the halogen exchange reaction is accompanied by the inversion of configuration.

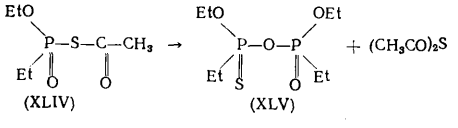
Optically Active *O*-Acyl Phosphonothionates

Omelańczuk and coworkers[86,88] studied compounds of this type and found that *O*-acetyl and *S*-acetyl anhydrides are formed in the reaction of a salt of the optically active *O*-ethyl ethylphosphonothioic acid (I) with acetyl chloride:



(14)

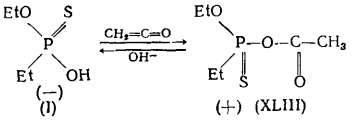
In contrast to the *O*-acetyl anhydride (XLIII), which can be readily isolated, its thiolo-isomer (XLIV) is unstable and "disproportionates" under the reaction conditions with formation of optically active *OO*-diethyl diethylpyrophosphonothioate (XLV) and diacetyl sulphide:



(15)

The ability of the thioacid anion to react in two different ways with acetyl chloride and to form similar decomposition products of the thiol type was observed by Kabachnik and coworkers[87] in the acetylation of diethylphosphinothioate salts.

Mikołajczyk et al.[88] modified the acetylation procedure using the free thioacid instead of its salt and developed a new method for the synthesis of active acetylthiophosphoryl anhydrides in the reaction of optically active phosphorus-based thioacids with keten. They showed that in the acetylation of the free acid with both acetyl chloride and acetic anhydride the amount of disproportionation products of the thiol anhydride (XLIV) diminishes appreciably and the yield of the *O*-acetylanhydride (XLIII) increases. On the other hand, the reaction with keten leads to the exclusive formation of the *O*-acetylation product:

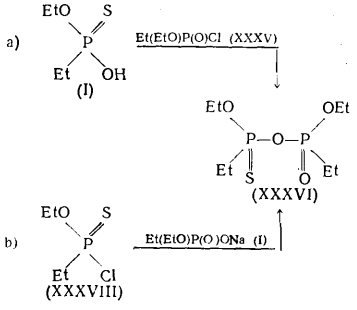


(16)

The configuration of the resulting anhydride (XLIII) corresponds to that of the initial acid, since the centre of chirality is not involved in the reaction. This was confirmed by the hydrolysis of the (+)-isomer of (XLIII) which yielded the initial (−)-acid (I). As expected, in this case the attack by the hydroxy-group is directed to the most electrophilic centre in the molecule, i.e. to the carbonyl group. The configuration of the thioacid residue, which is the group eliminated, does not change.

Optically Active Pyrophosphonothioates and Pyrophosphonodithioates

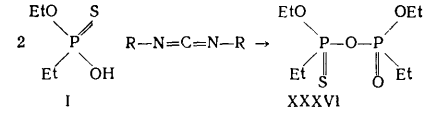
Pyrophosphonomonothioates and pyrophosphonodithioates have been the subject of research by Michalski for several years[89]. The optically active *OO*-diethyl diethylpyrophosphonothionate (XLV) [90] is particularly convenient to investigate because of its ready availability. The starting material for the synthesis is *OO*-ethyl ethylphosphonothioic acid (I) or *O*-ethyl ethylphosphonochloridothioate (XXXVIII) [91] obtained from it:



(17)

Pyrophosphonothioates with one or two optically active centres can be obtained via pathway (a) indicated above. However, in view of the low stability of *O*-ethyl ethylphosphonochloridate (XXXV), the pyrophosphonothioate with two optically active phosphorus atoms obtained in this way has a low optical purity of the phosphoryl centre.

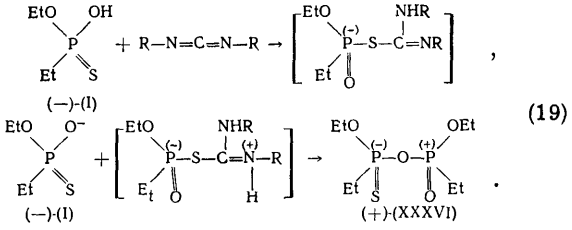
Mikołajczyk[92] developed an interesting method for the synthesis of pyrophosphonothioates with two optically active centres by the reaction of an optically active thioacid with dicyclohexylcarbodiimide:



(18)

OO-Diethyl diethylpyrophosphonothioate (XXXVI) obtained by this method has a high optical purity of the phosphoryl centre. This reaction proceeds in two stages and leads

to the formation of the optically active pyrophosphonothioate (XXXVI) with the opposite configurations at the phosphorus atoms:



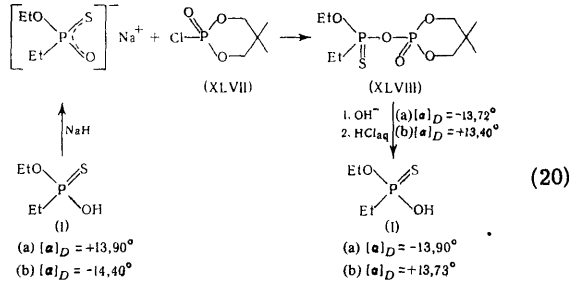
(19)

The relative configurations and the optical purities of both chiral centres in pyrophosphonothioates of this type can be readily determined by cleaving them with nucleophilic agents. The cleavage of compound (XXXVI) is associated exclusively with attack on the phosphoryl centre P(O) and takes place with inversion of the configuration at the attacked phosphorus atom. The thioacid residue is the group eliminated and its configuration is unaltered in the cleavage reaction.

Stereochemical studies on the cleavage of other pyrophosphonothioates showed that nucleophilic attack can be directed also to the thiophosphoryl centre, depending on the type of substituent at the two phosphorus atoms and on the reaction medium.

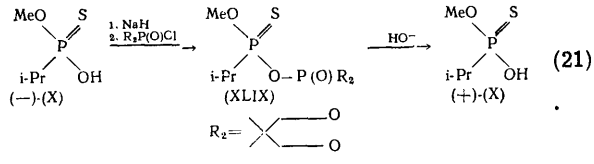
The Walden cycle, developed by Michalski et al.[93], in which the authors employed pyrophosphonothioates (XLVIII) with marked steric hindrance at the phosphoryl centre, merits particular attention in connection with this research.

As a result of two consecutive reactions, condensation of the thioacid (I) with 2-chloro-5,5-dimethyl-2-oxo-1,3-dioxa-2-phosphorinane (XLVII) followed by hydrolysis, one of the enantiomers of *O*-ethyl ethylphosphonothioic acid was converted into its antipode. Since the condensation reaction does not affect the symmetry of the chiral centre, this result proves unambiguously that alkaline hydrolysis proceeds with inversion of configuration at the thiophosphoryl phosphorus atom:



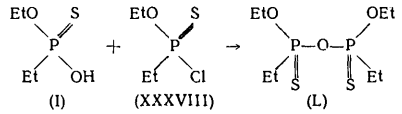
(20)

The Walden cycle was developed for *O*-methyl isopropylphosphonothioic acid (X) in order to demonstrate that nucleophilic substitution in isopropylphosphonothioates proceeds in the same way as in ethylphosphonothioates, i.e. with inversion of the configuration at the phosphorus atom[81]:



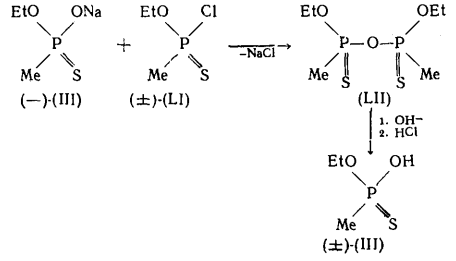
(21)

Pyrophosphonodithioates are formed as a result of the reaction between an optically active thioacid and a phosphonochloridothioate[91,94]:



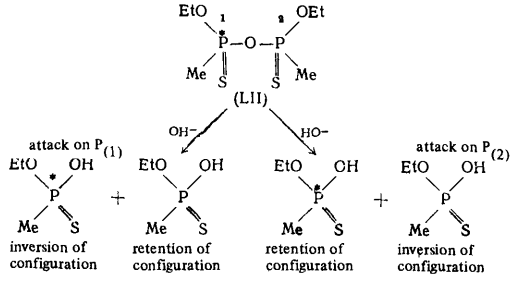
(22)

Using pyrophosphonodithioates, Green and Hudson[94] investigated for the first time nucleophilic substitution at the thiophosphoryl centre and found that it proceeds with inversion of the configuration at the phosphorus atom. They studied the hydrolysis of the optically active *OO*-diethyl dimethylpyrophosphonodithioate (LII), obtained by the reaction of a salt of the optically active acid (III) with (+)-*O*-ethyl methylphosphonochloridothionate (LI):



(23)

They found that the hydrolysis leads to the formation of racemic *O*-ethyl methylphosphonothioic acid (III). There are two equivalent phosphorus atoms in pyrophosphonodithioates. Consequently attack by the nucleophilic agent can be directed with equal probabilities to both thiophosphoryl centres. The formation of the racemic acid (III) as a result of the hydrolysis of the pyrophosphonodithioate (LII) with one optically active centre demonstrates the inversion of the configuration at the phosphorus atom. The interpretation of the results obtained by Green and Hudson may be illustrated by the following scheme:



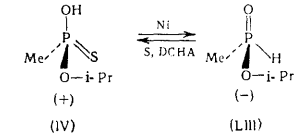
(24)

Further studies on the alcoholysis, mercaptanolysis, and aminolysis of *OO*-diethyl diethylpyrophosphonodithioates[86,88] confirmed that nucleophilic substitution at the thiophosphoryl centre proceeds with inversion of the configuration.

Optically Active Phosphonites

Much attention has been devoted recently to optically active phosphonites:

Reiff and Aaron[12] found that desulphuration of optically active phosphonothioic acids in the presence of nickel as the catalyst is a convenient method for the synthesis of compounds of this type. On heating (*R*)-(+)-*O*-isopropyl methylphosphonothioic acid (IV) in ethanol in the presence of Raney nickel, they obtained the optically active (*S*)-(−)-*O*-isopropyl methylphosphonite (LIII):



(25)

(+) (IV) (−) (LIII)

DCHA = dicyclohexylamine.

The addition of sulphur to the resulting phosphonite in the presence of dicyclohexylamine, which undoubtedly takes place with the retention of the configuration, leads to the reformation of the initial acid. This shows that desulphuration of the acid proceeds without a change in the configuration at the phosphorus atom.

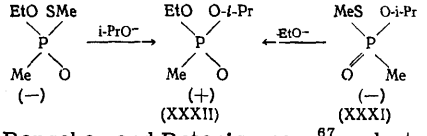
Another method for the synthesis of optically active phosphonites involves their stereospecific inclusion in cyclodextrins[14,18].

IV. DETERMINATION OF THE CONFIGURATIONS OF OPTICALLY ACTIVE PHOSPHORUS-BASED MONOTHIOACIDS BY CHEMICAL CORRELATION‡ AND X-RAY DIFFRACTION

The relative configurations of optically active monothioacids were mentioned for the first time by Aaron et al.[43], who described the resolution of chiral *O*-alkyl alkylphosphonothioic acids (I–VI) into optical isomers. Studies on the biological activities of the corresponding derivatives synthesised from the optically active thioacids showed that the optical isomers obtained from the (−)-thioacids are much more powerful inhibitors of cholinesterases than the enantiomers obtained from the (+)-thioacids. On this basis the authors concluded that the *O*-alkyl alkylphosphonothioic acids (I–VI) with the same sign of optical rotation have the same configuration:

(I) R = Et, R¹ = Et; (IV) R = Me, R¹ = i-Pr;
(II) R = Me, R¹ = Me; (V) R = Et, R¹ = Me;
(III) R = Me, R¹ = Et; (VI) R = i-Pr; R¹ = Et

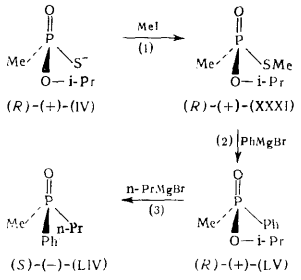
This conclusion was confirmed also by the chemical correlation of the (−)-isomers of *O*-isopropyl methylphosphonothioic (IV) and *O*-ethyl methylphosphonothioic (III) acids:



(26)

(−) (+) (−)
(XXXII) (XXXI)

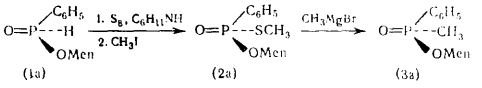
In 1968 Benschop and Boter's group[67] undertook studies whose aim was to determine the absolute configurations of the anticholinesterases obtained from optically active *O*-isopropyl methylphosphonothioic acid (IV); it was therefore necessary to elucidate the absolute configuration of the initial thioacid (IV). Benschop and Boter chose the method of chemical correlation between (+)-*O*-isopropylmethylphosphonothioic acid and (*S*)-(−)-methylphenyl-n-propylphosphine oxide (LIV). Their chemical comparison of the configurations is illustrated below:



(27)

(*R*)-(+)-(IV) (*R*)-(+)-(XXXI) (*S*)-(−)-(LIV) (*R*)-(+)-(LV)

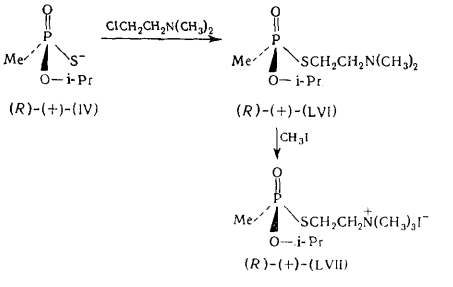
The thioacid (IV) was converted into the phosphine oxide (LIV) by three stereospecific reactions. The first of these (*S*-methylation) proceeds with retention of the configuration at the phosphorus atom[66]. As shown previously[95,96], the third reaction is accompanied by the inversion of the configuration. Consequently the correct determination of the configuration of the (+)-thioacid (IV) requires the knowledge of the stereochemistry of reaction (2):



(1a) (2a) (3a)

Benschop and Boter initially postulated that this reaction proceeds with inversion of the configuration at the phosphorus atom (as in the analogous nucleophilic substitution reactions at the phosphorus atom in similar systems). However, the latest reports[97], which have been confirmed by X-ray diffraction data, indicate that the stereospecific conversion of phosphonothiolates into the corresponding phosphinates proceeds with retention of the configuration at the phosphorus atom§.

Knowing the absolute configuration of the phosphine oxide and the stereochemistry of the successive chemical transformations, the configuration of *O*-isopropyl methylphosphonothioic acid (IV) was determined as (*R*)-(+). The final proof of the correctness of the determination of the absolute configuration of *O*-isopropyl methylphosphonothioic acid was obtained by X-ray diffraction[98] of the *S*-alkyl ester (LVII) synthesised from the (+)-acid (IV) as a result of reactions which do not affect the symmetry of the chiral centre:



(28)

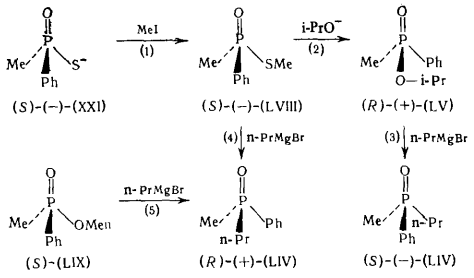
(*R*)-(+)-(IV) (*R*)-(+)-(LVI) (*R*)-(+)-(LVII)

‡ The chemical correlation method involves the determination of the configurations of optically active compounds by chemical reactions which relate compounds of known configuration to those whose configuration is to be determined.

§ The retention of the configuration when phosphonothiolates are acted upon by Grignard reagents has been demonstrated by X-ray diffraction of the phosphonothiolate (2a), which is an intermediate in the conversion of (*R*p)-*O*-menthyl phenylphosphonite (1a) into (*R*p)-*O*-menthyl methylphenylphosphinate (3a).

The absolute configuration of the ester (LVII) was determined by X-ray diffraction as (*R*)-(+), since the initial *O*-isopropylmethylphosphonothioic acid (IV) should also have the (*R*)-(+)-configuration.

Using the same procedure, involving extrapolation to phosphine oxide, Benschop and Boter determined the absolute configuration of methylphenylphosphinothioic acid (XXI):

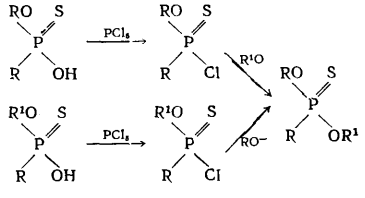


(29)

The acid (XXI) and the phosphinothiolate (LVIII) obtained from it have the same absolute configurations, since *S*-methylation does not affect any of the bonds involving the phosphorus atom. The reaction involving the synthesis of methylphenyl-n-propylphosphine oxide (*R*)-(+)-(LIV) from (*S*p)-menthyl methylphenylphosphinate (LIX) in the presence of n-propylmagnesium bromide [reaction 5, scheme (29)] proceeds with inversion of the configuration. Therefore Benschop and Boter suggested that the similar reaction of isopropyl methylphenylphosphinate (LV) with n-propylmagnesium bromide (reaction 3) also takes place with inversion of the configuration at the phosphorus atom. It is known that the substitution of the methylthio-group by an alkoxy-group (reaction 2) leads to a change in the configuration of the phosphoryl centre. Thus the conversion of (*S*)-(−)-phosphinothiolate (LVIII) into (*S*)-(−)-phosphine oxide (LIV), occurring as a result of two consecutive reactions proceeding with inversion of the configuration, enabled the authors to attribute the absolute (*S*)-configuration to (−)-methylphenylphosphinothioic acid (XXI).

On the other hand, the formation of (*R*)-(+)-phosphine oxide (LIV) on treating (−)-methylphenylphosphinothiolate (LVIII) with n-propylmagnesium bromide proved that, in contrast to *S*-methyl phosphonothiolates, methyl phosphinothiolates react with Grignard reagents, at the same time undergoing an inversion of the configuration at the phosphorus atom.

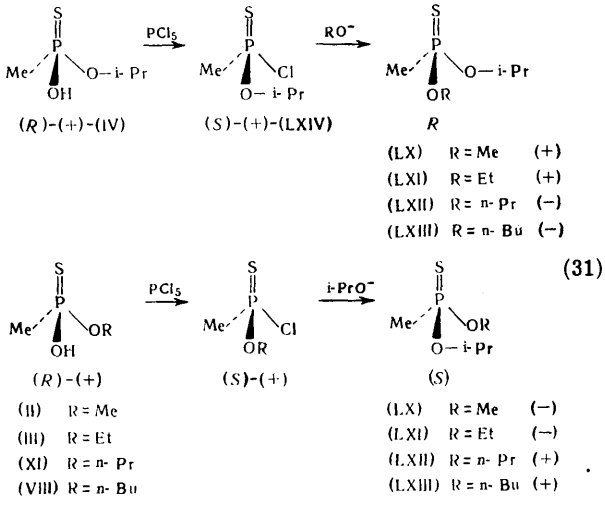
Recently, Mikołajczyk et al.[81] determined the absolute configurations of a series of optically active *O*-alkyl alkylphosphonothioic acids using (*R*)-(+)-*O*-isopropyl methylphosphonothioic acid as the configuration standard. The chemical correlation was based on the stereospecific two-stage conversion of the thioacids into optically active phosphonothionates:



(30)

According to the results of previous studies, both the reaction of the thioacids with phosphorus pentachloride and the substitution of the chlorine atom in phosphonochloridothionates by an alkoxy-group proceed with inversion of the configuration at the phosphorus atom.

The chemical correlation between the configurations of dextrorotatory *O*-alkyl methylphosphonothioic acids is illustrated below:



(31)

(*R*)-(+)-*O*-isopropyl methylphosphonothioic acid (IV) was converted into the (*S*)-(+)-phosphonochloridothionate (LXIV), from which the corresponding optically active *O*-alkyl *O*-isopropyl methylphosphonothioates (LX–LXIII) with the (*R*)-configuration were obtained as a result of reactions with alkoxides RO^- (R = Me, Et, n-Pr, or n-Bu).

On the other hand, the same reactions of (+)-*O*-alkyl methylphosphonothioic acids (II, III, VIII, and XI) (under the influence of PCl_5 and $i\text{-}PrO^-$) yielded the same esters but with rotations of the opposite sign, i.e. with the opposite configurations. Comparison of both types of thionate esters obtained shows that all the *O*-alkyl methylphosphonothioic acids have the (*R*)-(+)-configuration. The chemical correlation between acids of the *O*-alkyl ethylphosphonothioic (I and V) and *O*-alkyl isopropylphosphonothioic (VI and X) series was carried out in the same way.

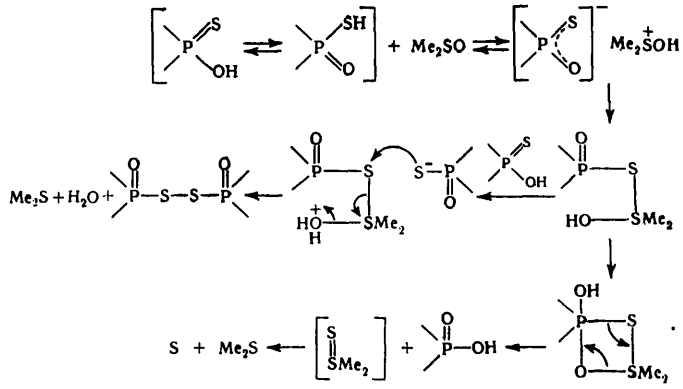
All the results based on chemical correlations show that (+)-*O*-alkyl alkylphosphonothioic acids have the same (*R*)-configuration regardless of the dimensions of the alkyl groups linked directly or by an oxygen bridge to the phosphorus atom.

V. ASYMMETRIC REDUCTION OF SULPHOXIDES BY OPTICALLY ACTIVE PHOSPHORUS-BASED THIOACIDS

Asymmetric syntheses and reactions in which the racemate is resolved kinetically as well as stereospecific transformations are frequently sources of information about the absolute configurations of the optically active reactants. It may therefore be of interest to examine the results obtained by the authors of the review in a study of the asymmetric reduction of chiral sulphoxides with the aid of optically active phosphorus-based thioacids.

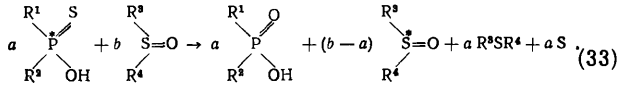
Phosphorus-based thioacids react with sulphoxides in two ways, forming respectively oxygen-containing acids,

sulphides, and elemental sulphur or diphosphoryl disulphides, sulphides, and water[99-102]. The proposed mechanism explained satisfactorily the dual nature of the reaction and the formation of all its products:



(32)

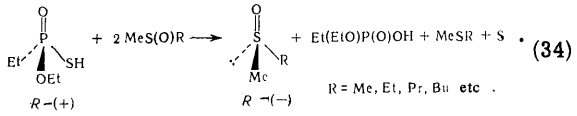
The mode of desulphuration of the acids, usually observed in the presence of an excess of the sulphoxide, constitutes an ideal model reaction for the investigation of the asymmetric reduction of chiral sulphoxides. Mikołajczyk and coworkers[48,102] found that, after the reaction of optically active phosphonothioic acids with an excess of racemic sulphoxides, the sulphoxides which failed to react exhibited optical activity, i.e. had been enriched in the more slowly reacting enantiomers:



(33)

Asymmetric reduction is observed also for equimolar amounts of the reactants and when the reaction has not gone to completion.

It must be emphasised that, regardless of whether the sulphoxide has been used in an excess of in an equimolar amount, the mode of the asymmetric reaction is the same. Thus alkyl methyl sulphoxides with the (S)-configuration always react faster with the dextrorotatory (*R*)-(+)-*O*-ethylphosphonothioate [so that the enantiomer with the (*R*)-configuration predominates after isolation in the sulphoxide which failed to react] and conversely:

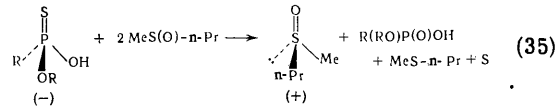


(34)

This has also been confirmed for allyl methyl sulphoxide, whose (–)- and (+)-isomers have, in contrast to simple saturated alkyl methyl sulphoxides, the (*S*)- and (*R*)-configurations respectively.

The above results show that there is a definite relation between the chirality of the optically active thioacid and the chirality of the sulphoxides which react with it. This relation is shown to an even more marked extent in the asymmetric reduction of methyl n-propyl sulphoxide, which has been investigated with the aid of a series of optically active *O*-alkyl alkylphosphonothioic acids. The results of these studies are presented in Table 5.

They show that in all cases the sulphoxide, recovered after the reaction with the (*S*)-(–)-thioacid was dextrorotatory, i.e. contained an excess of the (*S*)-enantiomer, while the sulphoxide regenerated after the reaction with the (*R*)-(+)-thioacid had the *R*-(–)-configuration:



(35)

Table 5. Asymmetric reduction of methyl n-propyl sulphoxide by *O*-alkyl alkylphosphonothioic acids $(RO)R^1P(S)OH$.

No.	R	R^1	Thioacid		Sulphoxide	
			$[\alpha]_D$, °	absolute configuration	$[\alpha]_D$, °	absolute configuration

			+10.72	*R*	−3.51	*R*
XI	n-Pr	Me	−1.03	*S*	+0.32	*S*
			+1.30	*R*	−0.35	*R*
IV	i-Pr	Me	−13.9	*S*	+1.29	*S*
			+12.6	*R*	−3.66	*R*
VIII	n-Bu	Me	−12.6	*S*	+3.30	*S*
			+13.02	*R*	−3.34	*R*
V	Me	Et	−8.34	*S*	+2.80	*S*
			+4.70	*R*	−1.78	*R*
I	Et	Et	−13.50	*S*	+5.27	*S*
			+12.90	*R*	−4.92	*R*
X	Me	i-Pr	−13.00	*S*	+0.58	*S*
			−14.67	*R*	−2.17	*R*
VI	Et	i-Pr	+21.54	*S*	+6.45	*S*
			+7.34	*R*	−2.97	*R*

The existence of a definite relation between the chirality of the thioacids and sulphoxides in the reaction being analysed not only demonstrates the possibility of the employment of this reaction to determine the relative or absolute configurations of phosphorus-based thioacids but also consitutes a basis for a model of the transition state in the asymmetric reduction process.

VI. THE APPLICATION OF NMR IN THE DETERMINATION OF THE OPTICAL PURITIES AND CONFIGURATIONS OF OPTICALLY ACTIVE PHOSPHORUS-BASED THIOACIDS

According to general considerations concerning the symmetry of species[103], the groups of nuclei or single nuclei having the same chemical environment either externally or internally, which cannot be interchanged by any symmetry operation, are in a diastereotopic environment in both achiral and chiral solvents. Such nuclei are anisochronic and as a rule should exhibit different chemical shifts and different spin–spin coupling constants. In contrast to these, enantiopic nuclei are screened to the same extent in achiral solvents and are isochronic. However, in chiral solvents or in achiral solvents containing chiral paramagnetic shift reagents, these nuclei become diastereotopic.

These relations make it possible to apply NMR to determine the optical purities of chiral compounds. It permits the determination of the composition of the diastereoisomers obtained from a mixture of enantiomers

and an optically pure reagent (stable diastereoisomers) or to determine the enantiomeric composition in chiral solvents or in achiral solvents containing chiral paramagnetic shift reagents (dynamic diastereoisomeric systems).

The magnetic non-equivalence of diastereoisomers in which the chiral centres are linked covalently in a single molecule was noted for the first time by Mateos and Cram[104]. This phenomenon was used to determine the optical purities of many chiral organic compounds[105,106]. A similar effect was observed by Pirkle and Beare[107] for a mixture of enantiomers in optically active solvents. Here unstable solvation diastereoisomers are formed in consequence of the interaction between the solute and the solvent (for example, as a result of the formation of hydrogen bonds). Because of this, the enantiomers have different chemical environments, which is the reason for the appearance of the magnetic non-equivalence in the NMR spectra.

Pirkle also found that, within the limits of a single class of compounds, the signals corresponding to enantiomers with the same configuration shift in the same direction relative to the signals corresponding to enantiomers with opposite configurations. He called this phenomenon *the sense of magnetic non-equivalence* (*s.m.n.*). Thus, when the signals of the given enantiomer are located in a weaker field, the enantiomer exhibits a "low" *s.m.n.*, while the enantiomer with the opposite configuration is characterised by a "high" *s.m.n.* Knowing the configuration and the *s.m.n.* of a single representative of a given class of compounds, it is possible to determine the configuration of any other compound in this class on the basis of NMR spectra alone.

Diastereoisomeric salts are systems in which there are stronger interactions between the components (acid–base) than in the solvation diastereoisomers investigated by Pirkle. Therefore the NMR spectra of diastereoisomeric salts should presumably also be different and the magnetic non-equivalences $\Delta\delta$ should be more marked.

The magnetic non-equivalence in systems of this type was noted for the first time by Horeau and coworkers[108], who studied the NMR spectra of diastereoisomeric chiral salts of carboxylic acids with optically active α-phenylethylamine.

Mikołajczyk and coworkers[47,109,110], continuing the studies on the absolute configurations of chiral phosphorus-based thioacids, found that they form with optically active amines diastereoisomeric dynamic systems, which give

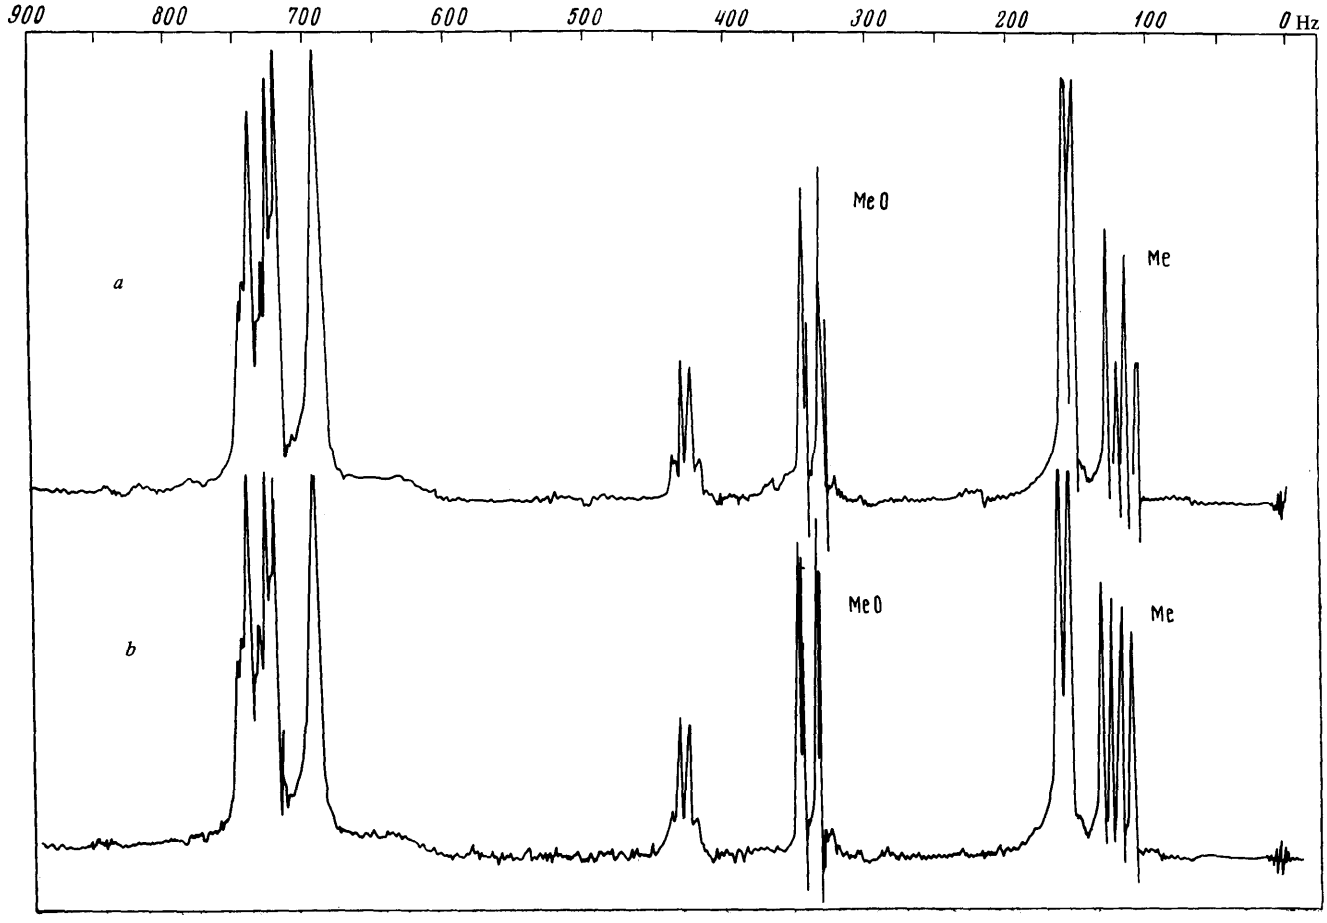

Figure 1. ^{1}H NMR spectra of the diastereoisomeric salts of *O*-methyl methylphosphonothioic acid (II) with (–)-α-phenylethylamine: *a*) 70% of (*S*)-(–)-(II); *b*) racemic (II).

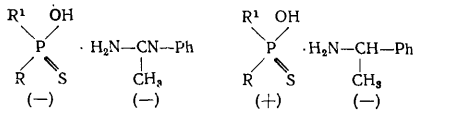
rise to ^{1}H and ^{31}P NMR spectra. Optically active α-phenylethylamine was used in these studies because of the ready availability of both its enantiomers, the ready solubility of its salts in non-polar solvents, and also because they are usually employed for the optical resolution of phosphorus-based thioacids:



The magnetic non-equivalence of *O*-alkyl methylphosphonothioic acids is most effectively observed on the basis of signals due to the *P*-methyl group and that of the class of *O*-methyl alkylphosphonothioic acids on the basis of signals due to the methoxy-group. The ^{1}H NMR spectra of diastereoisomeric salts of *O*-methyl methylphosphonothioic acid presented in Fig. 1 illustrate these two cases.

Fig. 2 presents the ^{31}P NMR spectra of diastereoisomeric salts of *O*-isopropyl methylphosphonothioic acid.

The application of a double resonance technique by Mikołajczyk and Omelańczuk[47,110], as a result of which the ^{31}P NMR spectra of the diastereoisomeric salts are simplified to two single signals corresponding to the enantiomeric acids, merits special attention. Fairly large chemical shifts $\Delta\delta$ are then observed (Table 6), which makes it possible to determine readily the enantiomeric compositions and hence the optical purities of the chiral phosphorus-based thioacids[59,63].

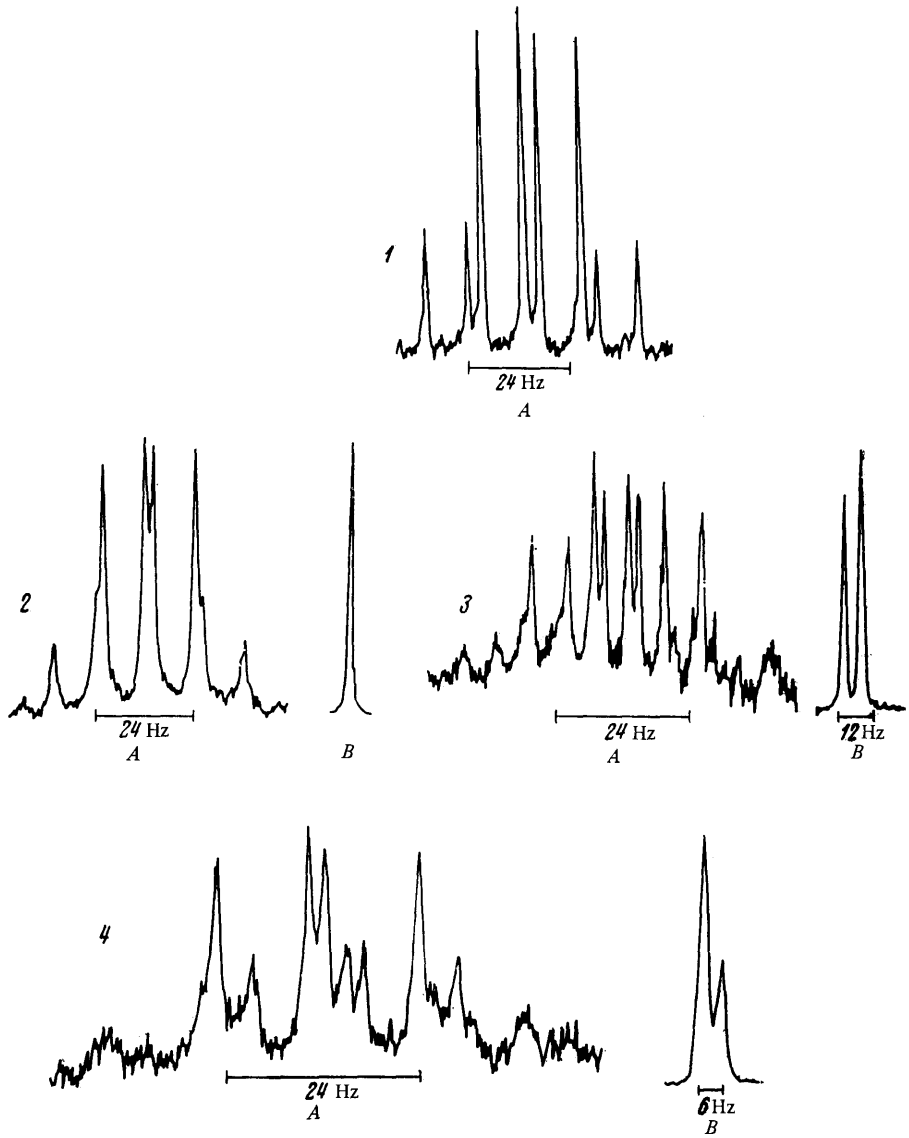


Figure 2. ^{31}P NMR spectra of the diastereoisomeric salts of *O*-isopropyl methylphosphonothioic acid (IV) with α-phenylethylamine (PhEA): *A*) fundamental spectra; *B*) double resonance spectra; 1) (±)-(IV); 2) (±)-(IV).(±)-PhEA; 3) (±)-(IV).(−)-PhEA; 4) (−)-(IV).(−)-PhEA [the thioacid (IV) in which the (−)-enantiomer predominated was used].

Furthermore, it has been noted that a low *s.m.n.* is characteristic of all *O*-alkyl alkylphosphonothioic acids with the (*S*)-configuration and, as for solvation diastereoisomers, remains unchanged within the limits of a single class of compounds. Thus the magnetic non-equivalence of diastereoisomeric salts can also be used to determine the relative or absolute configurations of phosphorus-based thioacids.

Table 6. The magnetic non-equivalences Δδ and *s.m.n.* for the diastereoisomeric salts of phosphorus-based thioacids with (−)-α-phenylethylamine.

Thioacid	Δδ*, Hz ^{1}H NMR**	Δδ, Hz ^{31}P NMR***	*s. m. n.*
Me (MeO) P (S) OH (*II*)	9.2	2.0	low for (*S*)-(−)-
Me (EtO) P (S)OH (III)	18.9	2.1	low for (*S*)-(−)-
Me (i-PrO) P (S) OH (IV)	7.0	6.4	low for (*S*)-(−)-
Me (n-PrO) P (S) OH (XI)	6.9	3.9	low for (*S*)-(−)-
Me (BuO) P (S) OH (VIII)	18.6	3.5	low for (*S*)-(−)-
Et (MeO) P (S) OH (V)	2.9	2.1	low for (*S*)-(−)-
i-Pr (MeO) P (S) OH (X)	0.6	1.2	low for (*S*)-(−)-
t-Bu (MeO) P (S) OH (IX)	4.2	—	—
Et (EtO) P (S) OH (I)	—	2.1	low for (*S*)-(−)-
i-Pr (EtO) P (S) OH (VI)	—	1.1	low for (*S*)-(−)-

* The values of Δδ refer to racemic salts of the thioacids.

** The spectra were obtained on a Varian-HR-60 apparatus in a 60 MHz field in the presence of tetramethylsilane as the internal standard. Groups containing the protons for which the Δδ are quoted have been underlined.

*** The spectra were obtained by a double resonance technique on an INM-60-HL apparatus in a 24.3 MHz field in the presence of phosphoric acid as the internal standard.

The results of studies on the dependence of the magnetic non-equivalence on temperature, the solvent, and concentration[111] suggest that in non-polar solvents there is an acid–base equilibrium:

$$A_RH + A_SH + 2B_R \begin{cases} \xrightarrow{k_1} A_RHB_R \overset{k_3}{\rightleftarrows} A_R^- + B_RH^+ \\ \xrightarrow{k_2} A_SHB_R \overset{k_4}{\rightleftarrows} A_{(S)}^- + B_{(R)}H^+ \end{cases} \quad (36)$$

The undissociated salts, i.e. A_RHB_R and A_SHB_R, the existence of which in the form of ion pairs is favoured by the non-polar medium and the low temperature, are responsible for the observed magnetic non-equivalence. A more detailed mathematical approach to the problem of diastereoisomeric dynamic systems has been described elsewhere[112,113].

The measurement of the magnetic non-equivalence of diastereoisomeric salts has been finding increasing application in the determination of the optical purities and configurations of other chiral compounds[114–118], particularly since the majority of them are in fact resolved by the classical method involving the crystallisation of diastereoisomeric salts.

VII. CIRCULAR DICHROIC STUDIES ON OPTICALLY ACTIVE PHOSPHORUS-BASED THIOACIDS

Following the development of accurate spectrophotometric apparatus, methods for the determination of configurations based on the use of the phenomenon of optical rotatory dispersion (ORD) and circular dichroism (CD) have assumed increasing importance recently[119]. Since CD spectra are more readily susceptible to analysis, particularly for complex organic molecules containing various functional groups, CD is more widely used to determine the configurations of chiral molecules. CD spectra for optically active phosphorus-based thioacids yielded valuable information and confirmed the validity of the configurations[120] assigned by other methods.

Table 7. The specific rotations $[\alpha]_D$, circular dichroic data, and ultraviolet spectroscopic parameters for *O*-alkyl alkylphosphonothioic acids R(R^{1}O)P(S)OH.

Thioacid R	Thioacid R^1	$[\alpha]_D$ °	Absolute configuration	Solvent	CD: λ_{max}, (nm (Δε)	u.v.: λ_{max}, nm (ε)

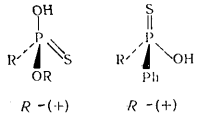
				water	210 (−4.4)	196 (5800)
						207 (4950)
						185 (7700)

The CD spectra for all the *O*-alkyl alkylphosphonothioic acids investigated exhibit only one intense transition near 200 nm, which is shown most distinctly in non-polar solvents. The values of Δε and χ_{max} are listed in Table 7. Evidently the negative Cotton effect is characteristic of acids with the (*R*)-(+)-configuration and the positive effect is characteristic of acids with the (*S*)-(−)-configuration. The position of the absorption band is almost independent of the type of solvent and a distinct bathochromic shift is observed only in water. This is probably a result of the dissociation of the acids P(S)OH and a change in the nature of the chromophoric group.

The CD spectra for alkylphenylphosphinothioic acids (XXI and XX) are much more complex owing to the presence of an aromatic ring in the molecule and contain at least four absorption bands in the region near 270,

230, 215–220, and below 200 nm. The second band can be attributed to the chromophore P(S)OH. It has been observed that both phosphinic acids investigated, with the same signs of optical rotation, are homochiral, i.e. have the same configuration:



R -(+) *R* -(+)

It is noteworthy that the application of conformational asymmetry rules[121] leads to the same conclusion, namely that (+)-*O*-alkyl alkylphosphonothioic and (+)-alkylphenylphosphinothioic acids have the (*R*)-configuration and exist in solution in the thiono-form.

Chemical Effects of Heat on Cellulose

O.P.Golova

The mechanism of rupture of the glucosidic bond in the thermal decomposition of cellulose is examined, and data are given on the primary steps of formation of levoglycosan. The effect of inorganic components on carbon-carbon bond rupture and on the direction of decomposition is considered. Possible practical uses of the results are discussed.

I. INTRODUCTION

The thermal decomposition of cellulose in a vacuum, with the formation of 1,6-anhydro-β-glucopyranose, was first accomplished in 1918 by Picter and Sarasin[1]. Interest in this process has continued to the present time; this can be ascribed to its importance from both scientific and practical points of view.

The thermal decomposition of cellulose to the monomeric levoglycosan involves formation of a new 1,6-anhydro-bond replacing the ruptured 1,4-carbon–oxygen–carbon bond (with preservation of the composition of the monomer unit of cellulose); during this process at 300° to 400°C cellulose retains its hydroxy-groups. Furthermore, thermal breakdown involves formation of a new conformation of the glucopyranose unit, with transition from $C-1$ to $1-C$ and of all the hydroxyls from equatorial to axial positions. Investigations of the thermal decomposition of cellulose are of interest for establishing its mechanism, in assessing the possibility of controlling thermal changes in cellulose (which may occur both in its extraction and in the exploitation of cellulosic materials), and also for producing new and more thermostable materials.

Surveys have been published[2,3] of research undertaken between 1918 and 1970 on the thermal decomposition of cellulose in a vacuum. However, Shafizadeh's review[2] has several important defects. In particular, it ignores results obtained on the mechanism[4-8], including data on the rates of the process and its possible retardation[5,8]. Furthermore, on the fundamental question of obtaining a high yield (up to 73%) of levoglycosan by the thermal decomposition of cellulose Shafizadeh refers to the work of Sandermann and Augustin published[9] in 1964, whereas analogous results had appeared[5] as early as 1960. Černý and Staněk's review[3] paid very little attention to the problem of obtaining levoglycosan by the thermal degradation of cellulose. The mechanism is not analysed, the reviewers merely mentioning that it should be analogous to that of the acid cleavage of glycosides. Rogovin's monograph[10] also makes a one-sided approach to the mechanism of the thermal breakdown of cellulose to levoglycosan. The author considers merely a radical mechanism on the basis of Arthur's results[11].

Thus until recently the mechanism of the thermal decomposition of cellulose to levoglycosan had not been sufficiently fully and objectively discussed. The aim of the present Review is to give the modern view of the mechanism of thermal breakdown with the formation of 1,6-anhydro-β-D-glucopyranose (levoglycosan) and other anhydro-sugars. Special attention will be paid to a critical assessment of work during the last five or six years, taking into account earlier investigations on these lines. Research on the further degradation of the monomer units of cellulose is not considered in this Review.

II. MECHANISM OF RUPTURE OF A GLUCOSIDIC BOND IN THE THERMAL DECOMPOSITION OF CELLULOSE

(*a*) Transglucosidation

Recent publications[12,13] reveal no generally accepted view on the mechanism of rupture of a glucosidic bond with subsequent formation of 1,6-anhydro-β-glucopyranose (levoglycosan) and other products of the action of heat on cellulose. Two mechanisms of cleavage of the cellulose molecule—homolytic with the formation of free radicals or heterolytic to give intermediate carbonium ions with subsequent formation of 1,2-, 1,4-, and 1,6-anhydrosugars—have been suggested. Shafizadeh and his coworkers[12,14,15] regard these mechanisms as somewhat hypothetical, and insufficient experimental evidence is available to support either. Furthermore, a single route for formation of each decomposition product is thought to be improbable under pyrolytic conditions. Under normal conditions chemical reactions follow the path of minimum energy consumption, and the solvent plays a considerable part in the transfer of ionic charges, while contributing to intramolecular interactions. During pyrolysis, however, many molecular rearrangements and reactions may be taking place simultaneously. It follows from general considerations that the pyrolytic degradation of the cellulose molecule should involve fission of a glucosidic bond or dehydration and breakdown of anhydroglucose units. Shafizadeh et al. used a combination of physical and chemical methods, including thermogravimetric analysis, to obtain a deeper insight into the complicated thermal reactions of hydrocarbons. Spectroscopic methods were also used, as well as modern methods of chemical and radiochemical analysis of the decomposition products. Radiochemical analysis was applied to the products obtained from levoglycosan labelled with carbon-14 and from its

polymer. The above combined approach was used initially to study the thermal decomposition of model compounds [16-18]. Several phenyl and substituted phenyl 2-amino-2-deoxy-β-D-glucopyranosides and various acetylated phenyl glucosides were examined with the aim of determining the effect of substituents in the sugar molecule and the accessibility of free hydroxy- and amino-groups [17].

Table 1. Analysis of volatile products of the pyrolysis of various phenyl glycosides [17].

Phenyl glycoside	Free phenols, %	Initial compound, %
β-D-Glucopyranoside	100	0
2-Amino-2-deoxy-β-D-glucopyranoside	82	2
2-Acetamido-2-deoxy-β-D-glucopyranoside	99	0
2-Deoxy-β-D-*arabino*-hexopyranoside	82	4
2-Acetamidotri-*O*-acetyl-2-deoxy-β-D-glucopyranoside	29	42
Tetra-*O*-acetyl-β-D-glucopyranoside	0	62
Tri-*O*-acetyl-2-deoxy-D-*arabino*-hexopyranoside	0	63

We must consider in greater detail the experimental results on the thermal decomposition of phenyl glucosides, since they form the basis of the suggested mechanism of rupture of the glucosidic bond with subsequent formation of anhydro-sugars. Table 1 gives analyses of volatile products from the pyrolysis of various glucosides. The model compounds used show that the pyrolytic reactions involve rupture of glucosidic bonds. The aglycone group abstracts a proton with the liberation of phenol, which is removed, while the glycosyl group forms the anhydro-sugar or condenses to randomly combined oligosaccharides. Thermal analysis, together with analytical data on the pyrolysis products, indicates that acetylated phenyl glucosides are considerably more stable than the original compounds. Table 1 shows also that free hydroxyls play an important role in the thermolysis of glucosides: almost 100% of phenol is formed by rupture of the glucosidic bond in phenyl β-D-glucopyranoside; yet this bond is stable when the hydroxy-groups have been substituted (phenyl tetra-*O*-acetyl-β-D-glucopyranoside), and phenol is not formed, up to 62% of the starting material remaining unchanged.

From the thermal analysis together with an analysis of the distillation products it was concluded that thermolysis involved intramolecular transglucosidation. Since thermal reactions are less specific, various hydroxyls may take part. Substitution of hydroxyls in the aglucone or the glucosyl moiety may affect the accessibility, i.e. the reactivity, of the sites of glucosidation. Products of the pyrolysis of polymers obtained from levoglycosans labelled with carbon-14 at $C_{(1)}$, $C_{(2)}$, and $C_{(6)}$ were separated by thin-layer chromatography and then subjected to radiolysis [18]. The results suggested that thermal decomposition involved rupture of a glucosidic bond, opening of the cyclic structure, and subsequent fragmentation of the monomer unit of cellulose. The formation of two molecules of formaldehyde from the anhydroglucose unit was shown to result from the $C_{(1)}-C_{(5)}$ fragment of levoglycosan. It was found also that the production of a 3,6-anhydro-ring leads to the formation of furyl methyl ketone, whose decomposition yields furaldehyde from the $C_{(2)}-C_{(6)}$ fragment of the monomer unit. These investigations showed the identity of products obtained in the pyrolysis of cellulose and polymeric levoglycosan with analogous isotopic labelling.

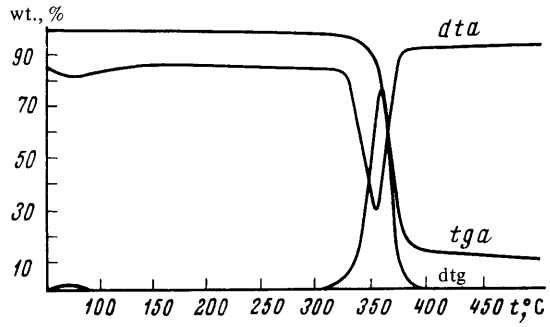

Figure 1. Thermogram of untreated cellulose.

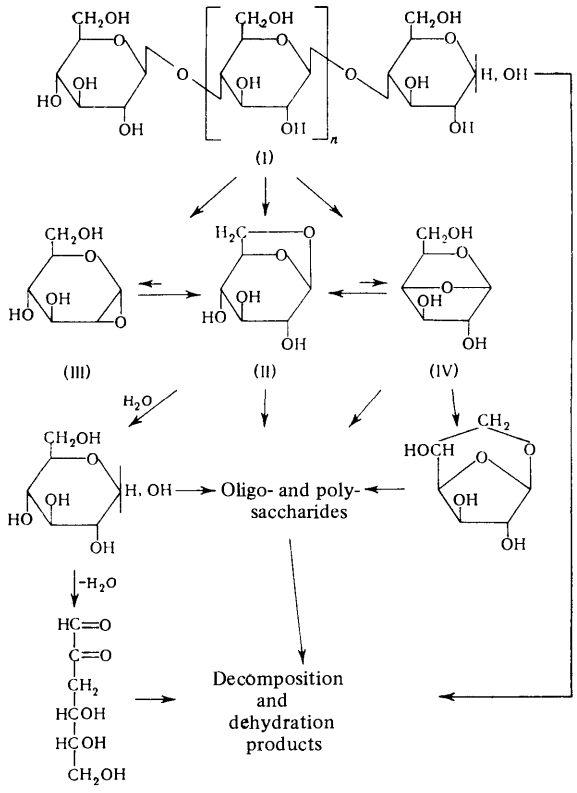

Figure 2. Pyrolysis of cellulose and transformation of products.

Developing their investigations on the thermal decomposition of carbohydrates [14-18], these workers used in a later study [12] a combined approach (previously applied to model compounds) to examine the mechanism of the thermal decomposition of cellulose. Fig. 1 illustrates the principal results, and Table 2 gives the composition of the pyrolysis products. The curves show that these reactions occur very slowly up to 300°C, after which they accelerate (when the temperature becomes high enough for rapid rupture of the glucosidic bond and distillation of the products). Thermogravimetric analysis (Fig. 1) and identification of the pyrolysis products from data obtained with model compounds [14-18] lead to the conclusion [12] that such rupture occurs by a transglucosidation mechanism involving one of the three free hydroxyls. Theoretically the 2-, 3-, or 6-hydroxyl might be involved in intramolecular transglucosidation, with fission of the $C_{(1)}-C_{(4)}$ polymer bond. This produces a new terminal group with an unsubstituted 4-hydroxyl, which in turn may be involved in further transglucosidation during pyrolysis. The suggested mechanism is set out in Fig. 2.

Table 2. Composition of pyrolysis products (% on initial quantity of cellulose) obtained in a stream of nitrogen at 300°C.

Product	Pressure	
	1 atm	5 mmHg
Product of distillation (tar)	19.1	55.8
Levoglycosan	3.57	28.1
1,6-Anhydro-β-D-glucofuranose	0.38	5.6
D-Glucose	traces	traces
Hydrolysable material	6.08	20.8

(*b*) Homolytic Rupture

A combination of different methods must be used to study the mechanism of thermal decomposition of a polymer, as is known from the chemistry of macromolecular compounds [19-21]: the mechanism can be assessed only from the totality of the results. Investigations on the thermal breakdown of cellulose took place in three stages.

The process was studied initially in a high vacuum (10^{-5} mmHg) by examining the effects of several factors—temperature, residual pressure, design of apparatus, degree of polymerisation of the original cellulose, and additions of glucose—on the yield of levoglycosan in the apparatus illustrated in Fig. 3 under conditions which ensured that this was the main product [4]. During an experiment the vacuum was maintained at 10^{-5} mmHg and the temperature at 305 ± 1°C (after the initial 5–10 min). The products were analysed after 10, 20, 40, 90, and 300 min, when the proportions of cellulose that had decomposed were 2–4%, 10%, 30%, 50%, and 80% respectively. The design of apparatus and the experimental conditions were published somewhat later [4]. The experiments established that conditions for obtaining a constant and quite high yield of levoglycosan (50–60% on the weight of cotton cellulose) [22,23]. The yield was independent of the degree of polymerisation of the initial cotton cellulose over the range 1000–150, [24] and was lowered considerably by the addition of glucose to the cellulose [25].

Subsequent investigations were aimed at establishing the mechanism of the thermal breakdown of cellulose to levoglycosan. It had originally been shown [27] that the yield of this compound from β-D-glucose and from cellobiose is far lower than from cellulose with degrees of polymerisation 1000–150 (respectively 14%, 5%, and 50%). [24] The addition of glucose to cellulose lowered the yield of levoglycosan [25]. Thus the hypothesis that levoglycosan is formed under pyrolytic conditions by the hydrolysis of cellulose to glucose followed by dehydration of the latter was not confirmed [27].

More recent examination [28] of the composition of the distillate from the thermal decomposition of cellulose has established that the formation of 3–4% of 1,6-anhydro-β-glucofuranose accompanies the levoglycosan. The former compound was present (8%) also among the thermal decomposition products from glucose, and was accompanied by 2–3% of phenols. Special experiments undertaken to establish the presence of 1,4-anhydroglucopyranose and of its 2,3,6-trimethyl derivative among the thermolysis products from cellulose and from trimethylcellulose respectively were unsuccessful. According to a personal communication, Shaw regards the formation of 1,4-anhydroglucopyranose and its trimethyl derivatives as impossible for steric reasons.

It was thus established that under certain conditions levoglycosan is the main product of the thermal decomposition of cellulose. However, neither the results nor the identification of volatile products were sufficient to assess the mechanism of breakdown of the polymeric molecule. Subsequent studies were therefore concerned with the changes in the cellulose molecule itself produced by heat and with the distillation products. Attention was concentrated on the following characteristics—(i) the quantity of chemically unchanged monomer units in the cellulose, (ii) the degree of polymerisation, (iii) the content of formyl and carboxyl functional groups, (iv) the physical structure of heat-treated specimens, (v) the yield of levoglycosan, and (vi) the rate of the process (and its possible inhibition).

A marked difference in yields of levoglycosan—50% and 3–4% respectively—was found when cotton cellulose and cellulose hydrate were heated [4]. This was originally attributed to a difference in the physical structure of the celluloses, but it was subsequently demonstrated [5] that the quantity and the composition of ash elements present in

the cellulose affect the path of decomposition and hence the yield of products. After the ash content of both specimens had been reduced to < 0.002%, the yield of monomer on thermal decomposition amounted to 73% of the cellulose decomposed for both modifications[5]. The results indicated that a hydroxylated polymer (cellulose) is capable of thermal depolymerisation at the glucosidic bonds[5] and permitted an approach to a study of the mechanism (apart from the effect of salt cations, whose role has been discussed separately[5,30,31]).

Table 3. Thermal decomposition of cotton cellulose (ash content 0.05%)*.

N, %	*W*, %	*n*	*M*, %	Content	
				C, %	H, %
0	—	2000—700	99.4	44.4	6.17
2	5	400	99.4	44.4	6.17
3	10	200	87.0	44.4	6.17
10	40	200	80.4	44.9	6.17
36	50	200	80.4	45.0	6.2
64	45	200	52.7	51.5	5.5
86	40	200	7.7	67.5	4.7

*N = degree of decomposition (% on initial cellulose);
W = yield of levoglycosan (% on cellulose decomposed);
n = degree of polymerisation;
M = content of chemically unchanged monomer units.

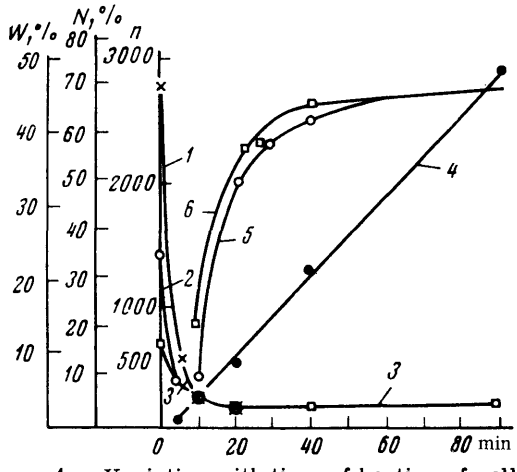

Figure 4. Variation with time of heating of cellulose [see footnote to Table 3)]: 1) n (initially 2800); 2) n (1500); 3) n (700); 4) N; 5) W (n = 2800); 6) W (700 obtained by partial hydrolysis).

Table 3 presents data on the quantity of cellulosic units remaining unchanged in specimens that have been heated for various times. A striking fact is that levoglycosan is formed in low yield (5—10% of the cellulose decomposed) from a cellulose containing 99.4% of monomer units chemically unchanged in the initial stages of decomposition. Quite a high proportion of monomer units remain chemically unchanged almost throughout the decomposition of cellulose: only at ~90% decomposition does the quantity of unchanged units fall to ~8%.[4,5]

Results for the time variation of the degree of polymerisation of cellulose[4,6] are given in Table 3 and illustrated by Figs. 4 and 5. The latter show that decomposition begins with a sharp decrease in n with losses in weight of 5% and 20—30% for cotton cellulose and cellulose hydrate respectively. After this, the degree of polymerisation remains constant up to 80% decomposition, at 200—300 and 30—50 for the two modifications[5]. These limiting values of n agree with those obtained in the heterogeneous hydrolysis of cellulose. The first stage of the process is characterised by a low yield of levoglycosan and a sharp drop in the degree of polymerisation; the second stage gives a high yield, which n remains constant.

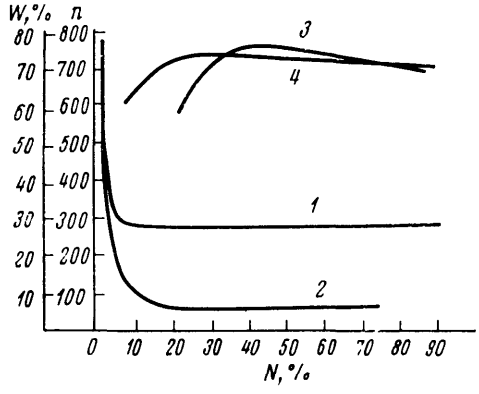

Figure 5. Influence of degree of decomposition N on: 1) n for cotton cellulose; 2) n for cellulose hydrate; 3) W for cotton cellulose; 4) W for cellulose hydrate (ash content < 0.002%).

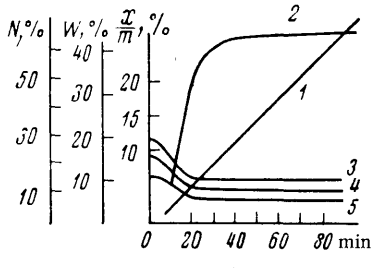

Figure 6. Time variation of: 1) N; 2) W; and sorption capacity x/m (where x is the quantity of moisture and m the weight of the specimen) at different relative humidities (p_1/p_0, %): 3) 90; 4) 80; 5) 60.

The results can be interpreted on the basis that the cellulose molecule is a periodic aggregation of segments of differing structure. The first stage of thermal decomposition involves rupture of the chain links with the accumulation of fragments having degrees of polymerisation of 200—300 and 30—50 for cotton cellulose and cellulose hydrate respectively. Dehydration predominates at this stage, followed by far-reaching breakdown of the

monomer unit with the formation of volatile products (yield of levoglycosan only 5–10%) (Figs. 4 and 5). The yield of levoglycosan reaches its maximum value in the second stage, after the degree of polymerisation has become constant, when thermal decomposition involves the consecutive chemical conversion of monomer units of the cellulose fragment accompanied by detachment of a monomer unit, which is converted by internal isomerisation into levoglycosan. The degree of polymerisation is maintained at 200 with degrees of decomposition of the cellulose from 4% to 70–80% (Table 3), and remains unchanged in a vacuum at 300°C for 80 min.

In this connection it is interesting to consider the light thrown on the physical structure of cotton cellulose by the water-vapour sorption isotherms obtained during heat-treatment [32]. Fig. 6 shows that the sharp drop in the degree of polymerisation to limiting values (which represents a sharp increase in the yield of levoglycosan) is accompanied by a fall in the sorption capacity of cellulose during the first few minutes of heat-treatment. Both the sorption capacity and the yield of levoglycosan then remain constant. These facts indicate that in the first stage the cellulose chain breaks down mainly in amorphous regions.

Table 4. Variation in content of carboxyl and carbonyl groups during the thermal decomposition of cotton cellulose [4].

N, %	Content, %		n	N, %	Content, %		n
	COOH	CO			COOH	CO	
0	0.02	0.26	800	3	0.05	0.80	200
1	0.02	0.35	400	7	0.10	0.78	200
2	0.03	0.75	200	30	0.32	0.87	200

In order to characterise the two-stage breakdown of cellulose to limiting degrees of polymerisation it was important to trace the variation in the content of functional groups with the time of heat-treatment under conditions of maximum inhibition of oxidising processes (10^{-5} mmHg vacuum). [4] Table 4 shows that the rapid change in degree of polymerisation in the first stage of decomposition is not accompanied by a change in the content of functional groups. In the second stage the numbers of carboxyl and carbonyl groups increase, while the degree of polymerisation remains constant. Thus these groups do not become weak points in the cellulose molecule right until limiting degrees of polymerisation.

The rate of the process was then studied [5] by means of a McBain spring balance specially equipped for decomposition studies at 300–400°C. Figs. 7 and 8 show the rate curves for cotton cellulose and for cellulose hydrate with an ash content < 0.002%, when the curves are similar in shape with maxima within the same limits of decomposition. Decomposition occurs quite fast, with maximum rates per minute of 2% and 3% respectively for the cotton cellulose and cellulose hydrate decomposed. Fig. 9 illustrates the possibility of slowing down the thermal decomposition of cellulose, such retardation being accompanied by an intensification of secondary processes of extensive decomposition [8].

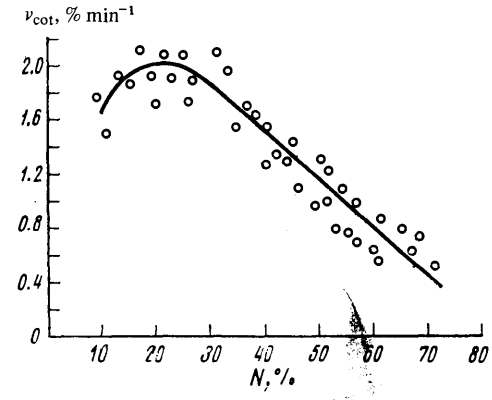

Figure 7. Rate v_{cot} of thermal decomposition of cotton cellulose (ash content < 0.002%).

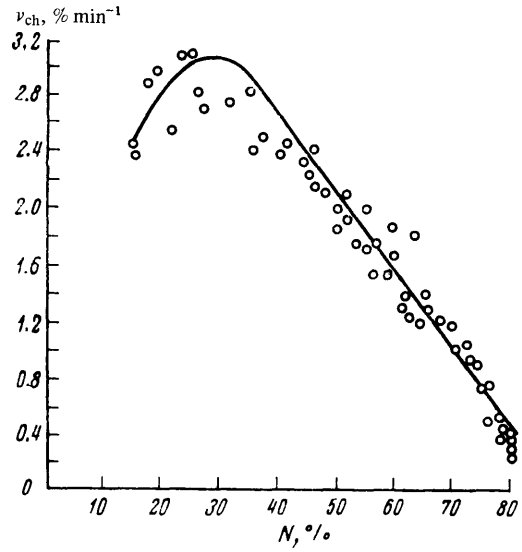

Figure 8. Rate v_{ch} of thermal decomposition of cellulose hydrate (ash content < 0.002%).

It is noteworthy that, while cellulose hydrate has degrees of polymerisation of 30–50, compared with the 200–300 of cotton cellulose, its rate of decomposition exceeds that of the latter by 50%. This indicates the importance of the absolute number of terminal monomer units in thermal decomposition. All segments of the polymer molecule are equally accessible to the action of heat in both modifications, so that the differences observed in the quantities of cellulose decomposed at the first stage, in the limiting degrees of polymerisation, and hence in the rates of the process are determined by the structural inhomogeneity of the cellulose macromolecules themselves and by their different proportions of amorphous and crystalline regions. Formation of levoglycosan—the principal route of thermal decomposition—takes place in the second stage (with the degree of polymerisation constant) after removal of the amorphous regions of the cellulose.

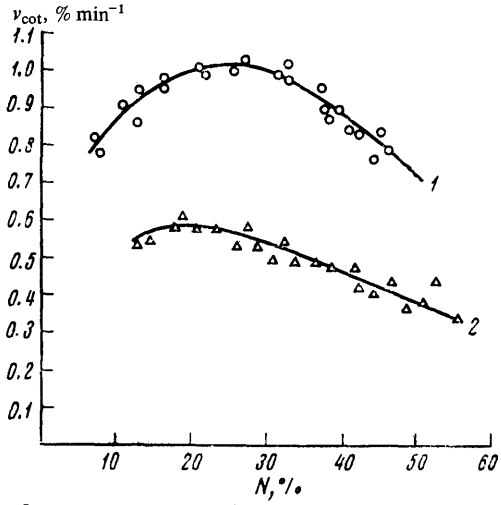

Figure 9. Rates v_{cot} of thermal decomposition of cotton cellulose: 1) in absence of an inhibitor; 2) in presence of an inhibitor.

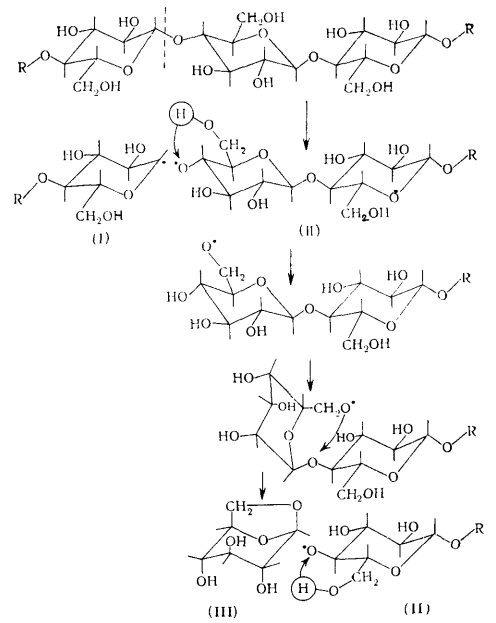

Figure 10. Scheme of depolymerisation of cellulose by a radical–chain mechanism, in which (I) and (II) are radicals.

The high rates with a high yield of levoglycosan, the constancy of the degree of polymerisation of cellulose throughout the decomposition following an initial sharp fall to a limiting value, and also the possibility of slowing down the process by means of radical inhibitors suggest that the thermal depolymerisation of cellulose can be regarded as a radical–chain process which, having begun in some activated region of the macromolecule, leads to the complete breakdown of cellulose with the detachment of one glucose anhydride molecule after the other from the initiated end of the chain. It was suggested[5,7] that the appearance of an active centre in a monomer unit tends to weaken the glucosidic bond nearest to the glucose unit, and its rupture leads to the appearance of a new active centre (Fig. 10). Change in conformation of the monomer unit makes isomerisation possible, leading to the formation of glucose anhydride (levoglycosan) molecules.

Table 5. Effect of an inhibitor (di-2′-naphthylphenylenediamine) on yield of levoglycosan from the pyrolysis of cellulose[35].

Inhibitor, mole %	Yield, %
0.00	34±3.0
0.90	26.0±2.0
2.25	17.4±3.0
4.50	4.4±2.0

Kislitsyn and his coworkers[33–36] paid special attention to the choice of a suitable inhibitor for the thermal decomposition of cellulose, and selected di-2′-naphthylphenylene-diamine, a well known inhibitor of free-radical reactions. With an inhibitor concentration of 4.5 mole % the yield of levoglycosan is 4.9% on the cellulose, instead of the 36.4% obtained in a control experiment (Table 5). The justification of the transition of a monomer unit from the $C-1$ to the $1-C$ conformation[34] is especially interesting. Kislitsyn remarks that the very fact of the formation of levoglycosan in the $1-C$ conformation is convincing evidence of the changes occurring during thermolysis. The energy barriers opposing the transitions are low, and are easily overcome even by thermal motion. The difference in energy observed between the chair and boat conformations of cyclohexane is only 5.3 ± 0.3 kcal.[35,36] The main problem is whether the terminal monomer unit is situated in the limited space of the crystallite between the cellulose chains after transition to the $1-C$ conformation. In a crystalline zone the planes containing the chains are 3.95 Å apart[34]. Calculations and measurements on a model show that after such a transition the terminal unit is located about 2.5 Å above the plane of the chain. A vacant space >1 Å high separates the adjacent planes. Conformational changes can therefore occur without steric hindrance.

(*c*) Mechanism of Rupture of a Glucosidic Bond in the Thermal Decomposition of Cellulose

Recent results have led to a denial[12] of a homolytic mechanism for rupture of the glucosidic bond, which was attributed to intramolecular rearrangements, i.e. transglucosidation of a free hydroxy-group with subsequent formation of levoglycosan. This mechanism was based mainly on experiments with model compounds[15–18] and also on thermographic results and identification of the thermal decomposition products from cellulose. It is extremely significant that the role of free hydroxyls in the thermal rupture of a glucosidic bond was shown convincingly on model compounds having different degrees of substitution

of their hydroxy-groups. The results provide a good illustration that protecting the hydroxy-groups almost changes the direction of the process.

These results will also explain the different directions of thermal decomposition in amorphous and in crystalline regions of cellulose [6,32], where the change in direction depends on the blocking of hydroxy-groups by hydrogen bonds. Thus intramolecular rearrangement may predominate in monosaccharides and probably disaccharides, in which hydrogen bonds are absent, and the glucosidic bond may be ruptured by the mechanism shown in Fig. 2.

These conclusions are consistent with the hypothesis [6] that the thermal decomposition of cellulose takes place in two stages. In the first stage (in the amorphous regions) dehydration occurs, and a small quantity of levoglycosan (5–10% based on the cellulose decomposed) may be formed by transglucosidation at the carbon-(6) atom [5,6,32]. This stage involves a decrease in the molecular weight to that corresponding to the limiting degree of polymerisation. The postulate that all hydroxyls are equivalent in decomposition by a transglucosidation mechanism would have suggested a continuous decrease in the molecular weight of cellulose, which is not observed in practice. A second characteristic feature [5] is the increasing rate of the process, which passes through a maximum. With equal accessibility of the hydroxy-groups (Fig. 2) there is no reason to expect intramolecular rearrangements to show a maximum rate. Extremely significant evidence of a homolytic process is provided by the possibility of slowing down decomposition [8,34,35], which could not be achieved with a heterolytic process.

The mechanism shown in Fig. 2 is based on extremely interesting results [17] on the thermal decomposition of phenyl glucosides and their derivatives. The monomer units of cellulose were considered [12] in isolation from the actual polymer and existing intermolecular interactions, and the mechanism of the formation of levoglycosan was regarded as analogous to reactions occurring in monosaccharides. However, there is little justification for transferring the mechanism of rupture of a glucosidic bond in a monomeric compound to the cellulose polymer, with its supermolecular structure, inhomogeneity of physical structure, and hydrogen bonds blocking hydroxyls in crystalline regions. The absence of radicals in the thermal decomposition of corresponding model compounds of anhydro-sugars [12] is no proof of their absence in the rupture of a glucosidic bond in cellulose. Decomposition of the latter, because of its polymeric nature, may take place by a mechanism differing from that of the degradation of a disaccharide. As noted above, the yields of levoglycosan from cellulose and from cellobiose under the same conditions were respectively 50% and 4%. [26] Such a difference in behaviour between a dimer and a polymer was explained by the influence of the supermolecular structure of the latter (hydrogen bonds and other intermolecular interactions). The effect of hydrogen bonds on the reactivity of hydroxyls in oxidation, etherification, etc. is well known.

Identification of the products of thermal decomposition has also suggested a mechanism. Using modern methods (chromatography, mass spectrometry, etc.) Shafizadeh et al. detected in the distillate 1,6-anhydro-β-D-glucopyranose and also 1,6-anhydro-β-D-glucofuranose, which had been found previously [28,37]. The presence of 3-deoxy-D-*erythro*-hexulose in the distillate has been established for the first time; it is assumed to be formed from glucose (Fig. 2). Thirty-seven different volatile products—among them acids (lactic, acetic, formic), aldehydes, ketones, water, carbon monoxide, and carbon dioxide—had been detected somewhat earlier [38], also by gas–liquid chromatography, among the products of the pyrolysis of cellulose at 375°C.

However, conclusions on the mechanism of the depolymerisation of cellulose and on the primary steps in the formation of levoglycosan cannot be based on the composition of the distillation products. Yet Shafizadeh and Fu [12] have made the completely valid remark that electron spin resonance data showing the presence in the reaction medium of free radicals, which in the opinion of other workers [10,11] support a homolytic mechanism of rupture of glucosidic bonds in the thermal decomposition of cellulose, cannot provide direct evidence of the mechanism of bond rupture, since thermal depolymerisation may be accompanied by far-reaching decomposition by a radical mechanism.

The results of the comprehensive investigations on the complicated pyrolytic process involved in the thermal decomposition of cellulose support a radical–chain mechanism of the thermal depolymerisation of cellulose.

III. PRIMARY STEPS IN THE FORMATION OF LEVOGLYCOSAN IN THERMAL DECOMPOSITION

Hypotheses on the primary steps in the thermal depolymerisation of cellulose with the formation of levoglycosan cannot yet be confirmed experimentally. The usual methods of labelled atoms and deuterium exchange are inapplicable to cellulose, since no methods are yet available for introducing labelled hydrogen or oxygen into its molecule. Several possible schemes of primary reactions have been suggested, and are examined below.

Shafizadeh et al., on the assumption that rupture of a 1,4-polymeric (glucosidic) bond in cellulose is a consequence of intermolecular transglucosidation, consider that this reaction produces new terminal groups with unblocked 4-hydroxyls, which in turn may be involved in further transglucosidation on the continuation of the pyrolysis. Thus levoglycosan may be formed either directly from cellulose or via the intermediate formation of 1,2- or 1,4-anhydroglucopyranose (Fig. 2). The formation of 1,6-anhydroglucofuranose (in 3–4% yield) in addition to the main product—1,6-anhydroglucopyranose (yield 36%)—is regarded by these workers as direct proof of the intermediate formation of 1,4-anhydroglucopyranose, which may be converted into the 1,6-isomer. These workers assume that pyrolytic reactions can occur by various routes: 1,4-reaction does not exclude the direct involvement of 6-hydroxyls; formation of 1,2-anhydroglucopyranose is entirely possible, although thermal decomposition with formation of levoglycosan takes place when the 2-hydroxyl has been methylated just as in a control experiment without protection of this hydroxy-group [39]. The Reviewer regards the intermediate formation of 1,4-anhydroglucopyranose as improbable; this is supported by the failure of attempts to detect this compound among the distillation products from the thermal decomposition of cellulose. Special studies also showed that 1,4-anhydro-2,3,6-trimethylglucose was not the main product of the thermolysis of 2,3,6-trimethylcellulose. An earlier report [40] of the presence of 2,3,6-trimethylglucosan among hydrolysis products from the thermal decomposition of trimethylcellulose quite obviously does not prove the presence of 1,4-anhydroglucopyranose. This report [40] produced the objection by Shaw that, according to theoretical calculations, 1,4-anhydroglucopyranose cannot be

formed either as intermediate or as final product. Thus a mechanism of transglucosidation suggests that levoglycosan can be formed only directly via the 6-hydroxyl, by hydrogen transfer to the glucosidic oxygen, and only from amorphous segments of cellulose, in which the hydroxy-groups are not blocked by hydrogen bonds.

Gardiner [37] and Madorsky [41], who favoured the hypothesis that cleavage of a glucosidic bond occurred by a heterolytic mechanism, assumed that terminal units having a levoglycosan structure were formed via a 1,2-oxiran ring appearing with detachment of part of the cellulose molecule. However, this mechanism is inconsistent with the above features of depolymerisation, which show it to be a radical–chain process. Kilzer and Broido [42] assume that the thermal decomposition of cellulose is a chain process, with initial formation of an active oxygen anion in a terminal glucoside unit. The glucosidic 1-oxygen atom is replaced by the 4-oxygen of the same unit by an S_N2 type of reaction. The 1,4-anhydroglucopyranose formed as intermediate is then converted into either levoglucosan or 1,6-anhydroglucofuranose, while the active centre of the anion migrates to the next unit in the chain. However, this transition is impossible from steric considerations, since carbon atom (1) would be attacked on the side opposite to the primary hydroxy-group [35]. Furthermore, the formation of levoglycosan via 1,4-anhydroglucopyranose cannot be regarded as proved (see above).

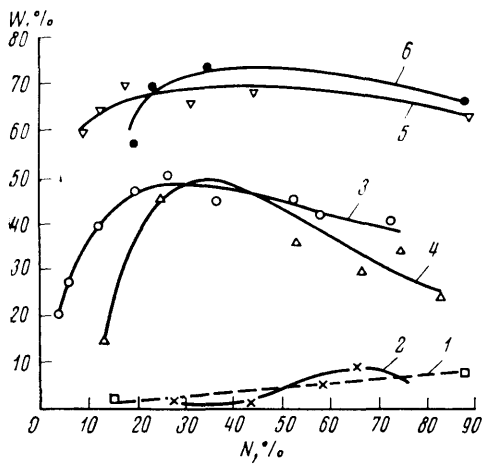

Figure 11. Effect of ash content on yield of levoglycosan W from the thermal decomposition of: 1) cotton cellulose (ash content 0.20%); 2) cellulose hydrate (0.20%); 3) cotton cellulose (0.05–0.09%); 4) cellulose hydrate (0.05–0.09); 6) cellulose hydrate (< 0.002%).

Investigators who favour a homolytic mechanism of rupture of the glucosidic bond suggest several possible ways in which levoglycosan may be formed, but these can be reduced to two main processes. Cleavage of the polymeric 1,4-bond may be followed by formation of an unsaturated bond at carbon atom (1) (radical I) at the 4-oxygen atom (radical II) (Fig. 10). The radical (I) formed at carbon (1) affects the stability of the 1,4-glucosidic bond of the next unit and causes it to break, after which the hydrogen atom migrates from the 6-hydroxy-group to carbon atom (4) with formation of a 1,6-anhydro-ring [7]. Formation of the alkoxy-radical (II) at carbon (4) of the monomer unit leads to intramolecular detachment of the hydrogen atom from the 6-hydroxyl and the appearance of a new alkoxy-radical [36,38]. The glucosidic link to the next unit is then attacked and broken by the alkoxy-radical, the free-radical centre is transferred to the next unit, and levoglycosan is formed at the same time.

The above sequence of primary steps in the formation of levoglycosan is shown in Fig. 10. One of these steps involves transition from the $C-1$ conformation to $1-C$. The formation of an uncompensated bond (a radical) in an acetal is a necessary precondition for a conformational change in the molecule. We can expect a similar effect if we regard cellulose as a polyacetal.

Kislitsyn [34–36] made a detailed examination of the mechanism of rupture of the glucosidic bond, and our analysis of his published experimental results supports the proposed scheme. However, doubt must be cast on his hypothesis that only one of the two macroradicals—the alkoxy-radical (II)—undergoes thermal depolymerisation with the formation of levoglycosan, while radical (I) undergoes far-reaching decomposition or is stabilised, since the yield of levoglycosan would not then exceed 50%, whereas yields up to 73% have been observed experimentally. Several workers [37,41–44] have given analogous schemes of rupture of a glucosidic bond differing only slightly from those considered above.

IV. EFFECT OF INORGANIC COMPONENTS ON CARBON–CARBON BOND RUPTURE AND DIRECTION OF THERMAL DECOMPOSITION

The influence of inorganic impurities on the yield of levoglycosan from the thermal decomposition of cellulose has been mentioned in a review [2]. Several papers [41,45,46] have referred to a diminished yield when inorganic salts are introduced into cellulose, but these investigations were not systematic. It therefore seems useful to consider here the effect of inorganic components on the rupture of a carbon–carbon bond and on the direction of the thermal decomposition of cellulose.

For a long time after Picter and Sarasin's paper [1] (1918) a high yield of levoglycosan could not be obtained, probably owing to insufficient information on the influence of inorganic components on the mechanism of the thermal decomposition of cellulose, and hence on the yield of levoglycosan. The marked difference in yields observed from cotton cellulose and from cellulose hydrate with ash contents respectively of 0.07% and 0.25% suggested [4,5] that not only the quantity of the mineral elements present but also their composition affected the direction of thermal decomposition. This hypothesis was supported by spectroscopic analysis of ash specimens from the two modifications, which showed that sodium salts changed abruptly the direction of thermal breakdown of cellulose hydrate: in the presence of 0.1–0.02% of sodium salts (reckoned as the mass ratio of sodium cation to cellulose) the process extends to products of far-reaching decomposition at carbon–carbon bonds: with < 0.007% of sodium, breakdown to levoglycosan becomes possible. The same workers then made systematic investigations on cotton cellulose and cellulose hydrate with ash contents of 0.2%, 0.05%, and < 0.002%. Fig. 11 shows that predominant formation of levoglycosan becomes possible with both modifications at an ash content of 0.09%, and is most complete with < 0.002% of ash.

Table 6 summarises the main results obtained [30,31] on the role of salt cations and anions. The average yield of levoglycosan from cellulose with initial spectroscopic contents of 0.03% of ash and 0.0003% of sodium is 48%, while the remaining 52% of products results from far-reaching breakdown. Introduction of chlorides of univalent metals (caesium, sodium, and potassium chlorides) as well as sodium thiocyanate produces a sharp decrease in yield of levoglycosan (to 0–1%) and an increase in the quantity of the latter products to almost 100% (experiments 2–5).

Table 6. Dependence of yields of levoglycosan W_l and of products W_s of the far-reaching decomposition of cotton cellulose on the salt content S (where R is the ionic radius, C the content of cations, and n the number of gram-atoms of cation per mole of cellulose unit).

Expt. No.	Salt	S, %	C, g-atom	n	R, Å	W_l, %*	W_f, %*

23	$(CH_3COO)_3Cr$	2.60	$1.0\cdot10^{-3}$	3.4	0.52	19.0	81

*Mean values from several parallel experiments.

These workers [30] then compared the influence of inorganic salts on the thermal decomposition of cellulose with the physical properties of the cation and the anion of the salt. They tried to establish whether the process was directly dependent on the stoichiometric proportions of salt cation and cellulose hydroxyls or whether it was catalytic. Calculation for the extreme salt contents of 0.05% and 3% showed that one cation corresponded to 2780 and 46.4 hydroxy-groups. Hence only a small proportion of the hydroxyls can be in direct contact with a salt cation; monomer units free from a cation should have decomposed with the formation of levoglycosan, which in fact does not occur. It was therefore assumed that the action of the salt was catalytic. Furthermore, calculation [30] of the ratio of the specific surfaces of salt and cellulose showed that the cellulose surface occupied by the salt was only around 2% of the total cellulose surface [30], which supports the hypothesis of a catalytic effect.

Thus the researches lead to the conclusions that inorganic salts contained in or introduced into cellulose promote thermal cleavage at carbon–carbon bonds with the formation of products of far-reaching decomposition. The nature of both cation and anion influences the direction of the thermal breakdown of cellulose.

V. USE OF RESULTS FOR PRACTICAL PURPOSES

Investigation of the directed thermal degradation of cellulose indicates [4–8,26] a low yield of levoglycosan at the first stage with both modifications, i.e. easily hydrolysable polysaccharides and monosaccharides.

The results made possible the development of a new combined method for processing plant material (instead of the hydrolytic process adopted at present) with the aim of obtaining monosaccharides as substrates for growing yeast and for other purposes. Industrially, a single, fairly narrow régime of hydrolysis (high temperature and pressure) is used to convert both readily and difficultly hydrolysable polysaccharides into monoses. Under the conditions adopted the monosaccharides break down, which leads to a loss of 30–40% of the carbohydrate components of the plant material.

At present there are no industrial methods for the combined processing of plant materials that, by organically coupling hydrolytic and pyrolytic processes, would permit the successive conversion of readily and difficultly hydrolysable polysaccharides and lignin of vegetable tissues into valuable chemical products. Study of the thermal degradation of cellulose in a high vacuum with external heating [7,23] yielded laws governing the direction of the process and a suggested mechanism for its thermal depolymerisation with the formation of levoglycosan. A high vacuum was necessary because of the low vapour pressure of levoglycosan, and a satisfactory yield could then be obtained by conducting the decomposition at a sufficiently low pressure; the same conditions also ensure maximum suppression of oxidising processes.

Comparison of results obtained by several workers showed [47] that increasing the residual pressure to 2–5 mmHg in reaction vessels with external heating produced a sharp drop in the yield of levoglycosan. This fact, together with the difficulty of ensuring uniform heating of large quantities of cellulose in the evacuated apparatus, made this method impracticable. For the first time, therefore, the directed thermal decomposition of cellulose was attempted [47] in a stream of superheated steam or an inert gas at a low pressure and preheated to a temperature below that required for the decomposition. This enabled (i) air to be displaced from the reaction vessel independently of the residual pressure, thereby preventing oxidising processes; (ii) direct contact to be established between the heat-transfer agent and any quantity of material, so that heating was more uniform; and (iii) the heat-transfer agent to be used to accelerate exhaustion of the decomposition products from the high-temperature zone. This method has since been applied successfully on laboratory and pilot-plant scales.

Researches undertaken by a group of workers [48–50] laid the foundations of a new technology for the combined processing of vegetable materials in which hydrolytic processes are used only to convert readily hydrolysable polysaccharides into monosaccharides or furaldehyde, while difficultly hydrolysable polysaccharides and lignin are converted into several valuable products by the thermal decomposition of cellulose and lignin in a single technical cycle. The total yield of products is 78% in the combined method, instead of 30–40% in the modern hydrolytic industry. Results of this work were shown at the VDNKh "Science 1967" Exhibition and at the "Chemistry 70" International Exhibition.

Thus the coupling of hydrolytic and thermal processes enables vegetable material to be processed with more efficient utilisation of its components and also yields

products that can be exploited in various branches of the national economy. This method achieves degradation of cellulose to a monomer (levoglycosan) and the thermolysis of lignin in a single industrial cycle. A carbonaceous residue remains (10–15%).

The furaldehyde and the monosaccharide formed in the combined method are used on existing lines. The tar from the vacuum thermolysis (the water-insoluble part) can be employed for the preparation of tanning agents, foundry binding agents, etc. The carbonaceous residue (Karbost) has been tested as a substitute for difficultly available materials—Megrozin, sawdust, lampblack.

Since levoglycosan might become a commercial product for the first time, and experience of its application is lacking, both abroad and in the Soviet Union, research was undertaken on possible uses for it and its derivatives, and on developing methods for preparing some of them. Research on the application of levoglycosan is the subject of a separate paper. Only certain possibilities will be mentioned below. It may find application as a monomer for synthesising the polymer dextran[51,52]. Copolymers of the methacrylic ester of levoglycosan have been claimed[53] in the production of artificial membranes with carbohydrate residues in medicine. Levoglycosan can yield pigments used in the manufacture of daylight-fluorescent paints and enamels[54]. Chemically pure levoglycosan can be employed as a substitute for pharmacopoeial glucose in the tableting of medicinal preparations.

Rheological Properties of Thermosetting Compositions

M.S.Akutin, G.V.Vinogradov, B.V.Yarlykov, N.V.Afanas'ev, and I.K.Sanin

The current state of research on the plastic properties of compositions based on reactive oligomers is assessed. Methods used to study their properties during deformation are examined. The influence of external factors, composition, and specific structural features of the compositions on their residence time in the plastic state and on their deformation characteristics is discussed. Possible lines of investigation on the rheological properties of thermosetting compositions are considered. A list of 135 references is included.

I. INTRODUCTION

Thermosetting compositions are based on reactive oligomers and fillers, plus any required additives. The distinguishing feature of these materials is their inherent ability, when heated or at a low temperature, to pass into an infusible and insoluble state by the formation of steric bonds (a three-dimensional network) as a result of chemical reactions[1-4]. Thermosetting resins, in contrast to many thermo plastics, are highly resistant to arcing and possess good dielectric properties; they are stable in many corrosive media and exhibit considerable rigidity. Because of this combination of valuable properties thermosetting plastics find diverse applications in the national economy[5].

The character of the reactions which cause the setting of reactive oligomers largely determines the conditions of formation of high polymers, and hence should be taken into account in the choice of technical scheme for the processing of oligomeric substances into a polymeric material. Reactive oligomers can be divided[6] into several groups: (1) those having multiple bonds and cyclic oligomers, able to undergo chain and stepwise polymerisation — "polymerisation oligomers" —including oligoester-acrylates, oligosiloxanes, polymers and copolymers of butadiene and isoprene, etc.; (2) oligomers containing functional groups are able to undergo polycondensation, migration copolymerisation, or polycoordination — "oligomers with functional groups" (phenol-formaldehyde, urea, glyptal, etc.); and (3) oligomers having a chain of π-conjugation which may contain functional groups, including oligovinylenes, oligophenylenes, etc.

In the present Review we shall consider mainly materials of the second type. Actual cross-linked polymers are characterised by various structural inhomogeneities, which explains in particular their diminished strength (in comparison with the calculated value), as well as the ability to flow at high temperatures and pressures possessed by certain irregular polymers with a low density of cross-linking.

Structural inhomogeneity affects not only the mechanical and physical properties of the material but also the kinetics of further cross-linking, which may involve both groups attached to the existing three-dimensional structure and those located at more accessible sites. It may therefore be expected that the same primary reaction, especially at relatively high degrees of conversion, will exhibit different rate constants, representing different kinetic mobilities of the units of the three-dimensional structure.

The properties of polymers may vary within wide limits depending on the structure, chemical nature, and frequency of cross-links[6] Polymers possessing neither solubility nor the capacity of viscous flow are formed only on the attainment of quite high degrees of conversion of the initial multifunctional compounds. The formation of three-dimensional cross-linked polymers is accompanied by a gradual loss of fluidity and concomitant increase in viscosity. It is therefore important to assess the rheological properties of the system in order to elucidate the nature of the processes occurring in reactive oligomers and filled compositions based on them.

Three types of processes — direct extrusion, transfer moulding, and injection moulding with preliminary mastication of the material —are now widely employed for converting thermosetting compositions into finished articles[7].

Many publications on the processing of thermosetting resins usually point out the need to establish high injection pressures[8-10]. Materials based on phenol-formaldehyde oligomers can be processed properly with almost all types of equipment, including moulding machines with worm mastication. The considerable heat resistance of materials based on reactive oligomers enables them to be processed in ordinary extruders[11-14].

The difficulty of processing lies in the near impossibility of drawing a boundary between the end of mastication and the beginning of setting, since irreversible cross-linking begins to develop at the same time as softening of the material[15]. No significant part is played by the particle size of the thermosetting compositions when the material is fed into the channel of the worm. However, the friability of the mass to be processed is significant[9].

Pressure is another important variable in processing. The permissible pressure is lower for materials that tend to undergo mechanical degradation and disintegration at high rates of processing. Thus aminoplasts are processed at only half the rates of deformation used with phenoplasts[16]. The maximum rate of injection can be realised in the processing of phenol-formaldehyde compositions and materials based on melamine-formaldehyde oligomers.

High pressures and rates of injection of thermosetting melts cause intense wear of moulds and gates, but in some

cases this is attributed to inadequate mastication of the material[16]. This is probably responsible also for the vigorous evolution of heat when an attempt is made to increase the capacity of the machine by rotating the worm more rapidly. Few if any data are available on the homogeneity of the melt in the channel of the worm. Estimation of this property from the extruded material emerging from the die is unreliable, since intense mixing may occur during extrusion, as in the processing of elastomers and thermoplasts. It has been suggested[17] that the quality of mastication can be assessed in several cases e.g. from the temperature of the material leaving the masticator.

This optimisation of the processing of thermosetting compositions requires an investigation of the change in their properties on passing from initial to plastic and then to hardened state, i.e. the rate of passing from one state to another, the duration of the plastic state. It is also necessary to study the effects of numerous technical factors—temperature, speed, pressure, degree of filling, and particle size of filler—at all stages of processing.

II. ASSESSMENT OF PLASTIC PROPERTIES OF THERMOSETTING COMPOSITIONS BY RHEOLOGICAL METHODS

The maximum amount of information on the state of the material and the role of various factors in its processing can be obtained by making rheological measurements under conditions approximating to actual moulding.

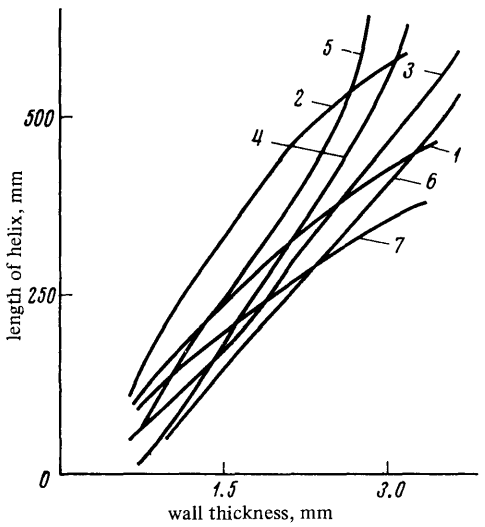

Figure 1. Comparison of fluidities of phenoplasts and various thermoplastics with longitudinal filling of a helical cavity (injection pressure 700 kg cm^{-2}): *1*) Genal 4000 phenoplast; *2*) Genal 4050 phenoplast; *3*) polypropylene; *4*) glass-filled nylon; *5*) polystyrene: *6*) ABS; *7*) Genal 4300 phenoplast.

The standards required for the composition to be processed are increasing because of the great sensitivity of injection moulding to variations in the properties of the material; in particular, the scatter of material characteristics from batch to batch must be as small as possible. It is also desirable to lengthen the time the material remains in a plastic state, and to diminish the viscosity of thermosetting compositions. A single system for assessing the viscosity properties of the latter is lacking, because of the poor reproducibility of measurements made with different designs of apparatus[18].

The principal characteristics which must be used to compare thermosetting compositions are the initial viscosity, the time the material remains in a plastic state, the duration of setting, and the change in fluidity during setting. The initial viscosity and the duration of the transition from plastic to hardened state are often determined at a standard temperature[18]. It is noteworthy that thermosetting compositions in a plastic state approach melts of ordinary thermoplastics in their viscosity characteristics (Fig. 1).[19]

The most diverse methods are used for determining those technical characteristics of thermosetting compositions that may be useful under practical conditions, but systematic accounts of them can be found[20,21]. The first group involves estimating fluidity during extrusion, when the results depend on the conditions of deformation. In the second group of methods the viscosity is determined under conditions approximating to those of injection moulding and extrusion.

Among the numerous methods of the first group the most widely used are the examination of fluidity by compression between two plane-parallel plates[22], the "beaker method"[23,24], extrusion through different channels[25–29] and its *Rossi-Peaks* modification, determination of fluidity during flow into a conical channel[31] or into a mould in the form of an Archimedean screw[24,32,33], etc.[34–36]. All these methods involve obtaining arbitrary characteristics, which does not permit adequate assessment of the fluidity of thermosetting compositions.

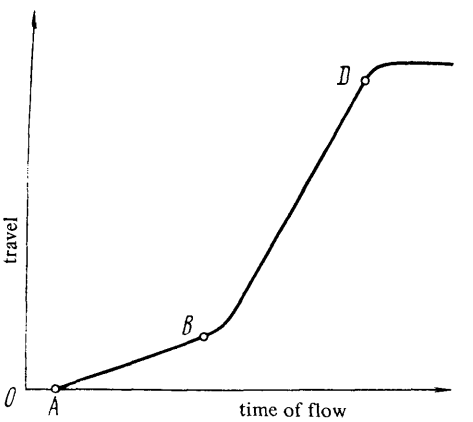

Figure 2. Assessment of viscosity properties of thermosetting compositions by Meysenbug's method (Darmstadt test): *OA*) heating range; *AB*) softening range; *BD*) flow range; *D*) start of setting of composition.

The second group of methods are based mainly on rotary viscosimetry, which enables the experimental conditions (temperature, duration, régime of deformation) to be varied within very wide limits[37–46]. Those most widely used for thermosetting compositions are Meysenbug's method[47,48],

the flow test[49,50], the Kanavets apparatus[51–55], and the Brabender plastograph[49,56–59]. The test results are used to determine the duration of the plastic state, the viscosity properties of the material, the rate of setting, etc.[60]. Figs. 2[20] and 3[61] illustrate typical relations. The methods differ in the mode of deformation, either specifying a constant torque and recording the variation in rate of flow with time, or using a specified constant rate of travel and measuring the resulting torque.

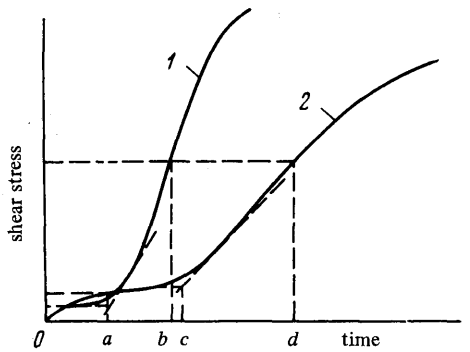

Figure 3. Kinetics of the hardening recorded on a Kanavets plastometer[35] of thermosetting materials of: *1*) Novolak type; *2*) resol type; *Oa*, *Oc*) periods of time in plastic state; *Ob*, *Od*) setting times.

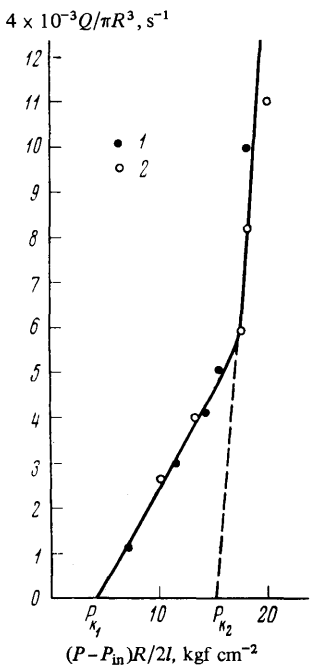

Figure 4. Flow curve of K-18-2 composition: P_{k_1}) lower fluidity limit; P_{k_2}) upper fluidity limit; R) radius of gate; *1*) 1 mm; *2*) 1.5 mm; Q) bulk flow rate; l) length of gate; $P-P_{in}$) pressure drop in channel.

Knowledge of the rheological properties of the compositions under processing conditions is necessary in order to compare the mouldability of different thermosetting materials and describe the flow of the melt in the pouring channels and the mould cavity[62–65]. Capillary and capillary–rotary instruments are also used[66]. Rheological properties were determined[62] by extruding the material through gates of different diameters, the main result being the discovery of two fluidity limits for a composition (Fig. 4). The flow curves were described analytically by means of Bingham's law. Capillary viscosimetry yielded[67,68] flow curves for a composition analogous to the Soviet material K-18-2 at shear stresses not exceeding 5 kg cm^{-2}, below the lower fluidity limit P_{k_1} (Fig. 4). The flow curve was satisfactorily described[67] by a power relation of the type

$$\tau = k \cdot \left(\frac{4Q}{\pi R^3}\right)^{\frac{1}{n_1}},$$

where τ is the shear stress, Q the space velocity, and R the radius of the capillary, while the constants were k = = 1.0 (kg cm^{-2})^{n_1} s and n_1 = 2.07. However, both here and in other work[37,68,69] capillary flow curves were obtained only at one temperature. Hence the results do not permit calculation of the activation energy of deformation, which would have permitted a fuller comparison of the technical properties of the compositions.

Use of a PPR-1 rotary instrument to examine the rheological properties of K-18-2 composition with deformation at a constant rate of shear revealed a limiting shear strength, which rose with increase in the intensity of deformation[70]. However, no limiting stresses like the Bingham fluidity limit were detected[70], in contrast to earlier statements[62,66]. A limiting shearing strength is typical[71–73] of the breakdown of the three-dimensional structural framework formed by the disperse phase (sawdust). Plastic disperse systems, among which thermosetting melts may be included, exhibit a fall in shear stress with increase in rate of deformation on passing through the limiting shearing strength.

Investigation of the rheological properties of K-18-2 moulding powder on a Brabender plastograph revealed[43] considerable boundary-layer slippage during movement of the mass in the gap between the working members. However, another worker[68] observed no slippage of material in the boundary region.

Thus results of the above work on the viscosity properties of thermosetting materials by capillary and rotary viscosimetry have occasionally been contradictory.

Dynamic methods are currently in widespread use for investigating the most diverse materials. Information obtained in this way enables us not only to determine the temperature of transition from one state to another but also to record the development of particular processes with time. The use of dynamic methods also avoids breakdown of the structure, like that occurring during deformation in rotary and capillary viscosimeters.

Despite the promise of the dynamic method, very few results have been obtained on thermosetting compositions, although the first attempts have been made to determine the duration of the plastic state of the binder at various temperatures. Thus the setting of phenolic oligomers and unsaturated oligoesters has been investigated[74] by means of a torsional pendulum, and a similar determination has been made[75] of the viscoelastic properties of the binder. Somewhat apart from these investigations are experiments on the viscoelastic properties of oil-filled phenolic oligomers near their glass point[76]. By varying the oil content

from 0 to 50% the temperature dependence of the mechanical loss angle tan δ was obtained for four frequencies. The results indicated the relation

$$T_g = A \cdot \lg \varphi + B$$

between the degree of cross-linking φ and the glass point of the oligomer T_g, where A and B are constants. The molecular mobility of the phenolic oligomer is assumed to be independent of the degree of cross-linking.

III. EFFECTS ACCOMPANYING THE DEFORMATION OF COMPOSITIONS BASED ON REACTIVE OLIGOMERS

Results obtained by the above methods are sometimes used to plot relations between shear stress and rate, (flow curves), as in the investigation of the viscosity properties of thermoplastics and elastomers. However, most workers do not regard this as possible, probably because it is not generally accepted that viscous flow can take place in thermosetting compositions. Indeed, until recently no studies had been made of their viscosity properties at low rates of shear by means of various rotary instruments, nor had the constancy of the flow curves been verified when compositions were extruded through capillaries of different radii.

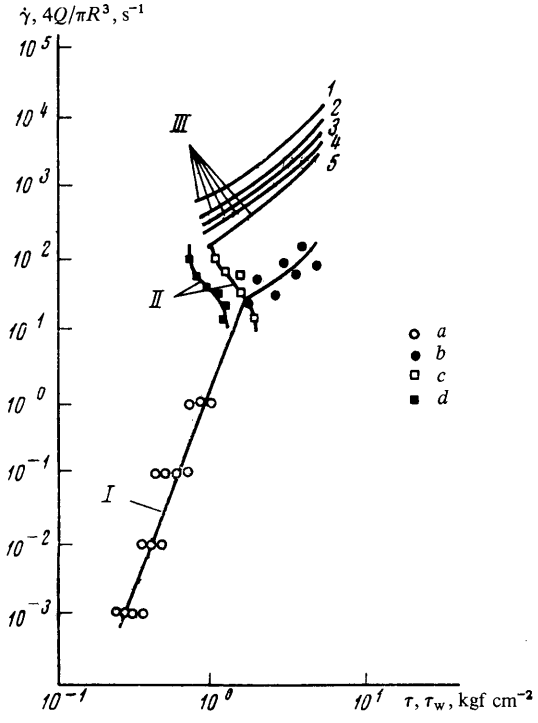

Figure 5. Flow curves of K-18-2 compositions without a hardener at 120°C: I) region of flow (viscosimeter: *a*) REV-1; *b*) capillary); II) pressure dependence of bulk flow rate measured with cylinder–cylinder type of viscosimeter (surfaces of working members: *c*) grooved; *d*) smooth); III) dependence of $4Q/\pi R^3$ on τ_w obtained with capillary viscosimeter [diameters of capillaries (1–5 mm) indicated on curves].

Boundary-layer slippage plays a decisive role[77,78] over wide ranges of shear stress and rate of shear (at rates of deformation of phenoplasts closely similar to those of actual processing conditions). External friction between the material and the wall of the channel may lead to a sharp increase in rate of rotation of the worm. Similar results are obtained in the deformation of thermoplastics[79], for which it has been shown in particular that the rate of slippage is independent of temperature. Region (II) in Fig. 5,[77] in which the shear stress falls with increase in rate, is especially interesting. In the case of raw rubbers this phenomenon was at one time attributed to breakdown of the structure[80,81]. In this case slippage of the material relative to the measuring surfaces is possible[79,82], and the same conclusion was reached by the above workers[77,78].

However, a decrease in stress with increase in rate cannot always be detected in the tests. Thus with elastomers the transition from internal to external friction during extrusion through a capillary takes place at constant stress while the rate increases several dozen times[83]. An analogous phenomenon has been recorded in the investigation of thermosetting compositions, although it was explained by the development of degradation[84].

A characteristic sign of the development of rubberlike elasticity in a polymeric material during extrusion through a capillary is the swelling of the jet of extrudate. Since thermosetting compositions are based on reactive oligomers with different degrees of filling, strongly developed rubberlike elasticity is hardly to be expected. This is supported by results obtained with phenolic compositions[85] which showed that the mould was filled by a molten jet equal in diameter to the gate, this work also indicated that binder and filler may separate, which would impair the homogeneity and the strength characteristics of the final article[85]. This effect was due not only to poor adhesion between binder and filler but also to inadequate homogenisation during mastication. An experiment was therefore undertaken in which the extrudate emerging from the nozzle was divided into four parts, the fluidity of each of which was determined by a standard method. The pouring properties deteriorated along the extrudate, which confirmed the hypothesis that the initial composition had been insufficiently homogeneous.

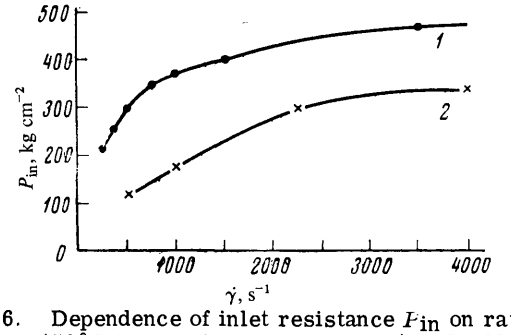

Figure 6. Dependence of inlet resistance P_{in} on rate of shear $\dot{\gamma}$ at 150°C for moulding material: *1*) K-21-22; *2*) K-214-2.

A specific problem in the processing of thermosetting compositions is the need to establish considerable pressures in the dispensing zone, owing to the great pressure losses on entry to the gate. This hypothesis is supported

by the experimental results[63,77,86] plotted in Figs. 6 and 7. Such considerable pressure losses might apparently be due to the development of cross-linking, but the same results are observed in the absence of a hardening agent[77] as in its presence[63,86]. The need to establish high pressures is probably due to the high viscosity and considerable limiting shear strength of thermosetting compositions with finite degrees of filling. The pressure in the dispensing zone can be somewaht lowered if the geometry of the inlet is modified. Thus by changing the inlet angle by 60° we can not only eliminate stagnant zones but also reduce the input losses on the average by 25%.[87]

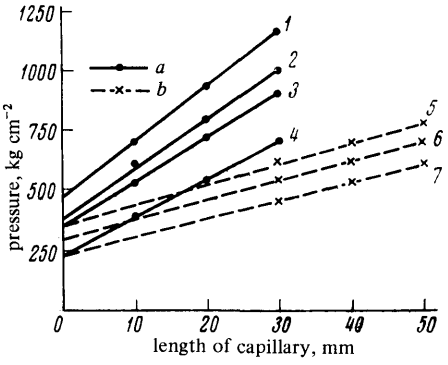

Figure 7. Dependence of pressure on length of capillary for the flow of K-21-22 moulding material at 150°C through an orifice of diameter: *a*) 2 mm; *b*) 4 mm with different rates of shear (s^{-1}): *1*) 3500–3800; *2*) 1400 to 1500; *3*) 950–1000; *4*) 330–360; *5*) 720; *6*) 480; *7*) 200 to 300.

Examination of the fluidity of moulding materials by Meysenbug's method showed[88] that adding up to 1% of a plasticiser considerably improves the reproducibility of estimates of the properties of the compositions. However, the fluidity remains almost unchanged with variation in the plasticiser content from 1% to 3%. The reproducibility of the properties of thermosetting compositions in quite convincing evidence of the favourable effect of the plasticiser[89]. It is interesting that plasticisers that do not react chemically with the oligomer enhance the plasticity of the composition at all stages while hardly affecting the duration of the plastic state[90]. However, if chemical reaction occurs between plasticiser and oligomer, not only a decrease in viscosity but also a longer period in the plastic state is observed.

An attempt was made[62,63] to use the measured coefficients of friction of the test materials to calculate the loss of pressure at the inlet to the nozzle. Thus for K-21-22 material with a rate of shear of 500 s^{-1} the pressure difference at the inlet to the channel found by Bagley's method[91] was 300 kg cm^{-2}, while the pressure loss due to friction of the thermosetting composition was 90 kg cm^{-2}. The difference between these values was then taken in the viscosity calculations to be the pressure loss at the inlet to the die. These workers considered that slippage of material relative to the walls of the capillary was almost completely absent in the deformation of thermosetting compositions at such considerable rates of shear. Their results enabled the input correction P_{in} to be related to the rate of shear $\dot{\gamma}$ by the power formula

$$P_{in} = C \cdot \dot{\gamma}^a,$$

in which C and a are constants depending on the properties of the moulding materials and the temperature[63]. A formally similar relation was obtained[77] with the rate of slippage as variable, when the input correction was unaffected by temperature.

Study of the rheological properties of thermosetting compositions shows that careful reproduction of the test conditions is necessary for the results to be comparable. Plastometers with parallel plates and rotary viscosimeters are therefore becoming ever more widely used. A comparison was made[58] between results obtained with a Brabender plastograph using an extruder as mixer and those obtained with a Kanavets type of rotary viscosimeter. Experiments with a phenol–cresol–formaldehyde oligometer filled with sawdust are noteworthy[58]. With 5 g of material at 100°C and the rotor rotating at 30 rev/min almost complete irreproducibility was found, since the test mass stuck to the mixer paddles and the drag fell sharply. Analogous disintegration of the specimen can occur also in tests with rotary instruments of the cone–plane type, in which hydrostatic pressure is absent. As a consequence, the dependence of rate on torque may acquire the form described by other workers[77,78,80–82].

It is of the greatest interest in investigating the rheological properties of thermosetting compositions to establish flow in a capillary, since conditions then approach those of actual injection moulding. The need for high pressures, the almost complete absence of rubberlike elasticity after emergence from the capillary, and also the rheological results indicate the "rodlike" motion of the compositions[77]. The experimental results show that the rate of discharge is almost entirely determined not by flow but by the rate of boundary-layer slippage v_0. The dependence of stress τ on this rate is then[77]

$$\tau = A_s \cdot v_0^m,$$

where A_S and m are constants. Measurements for technical purposes can be speeded up by using a capillary viscosimeter[93] with automatic recording of the relation between stress and rate of deformation. Deformation conditions accompanying slippage and calculations of the chief parameters (stress and rate of shear, rates of slippage) have been discussed in detail[94–100].

Investigation of the flow at low rates of deformation of compositions based on reactive oligomers has shown[101–106] that the rheological properties of the oligomers—Newtonian liquids—change abruptly when fillers are added to them. At a certain filler content a régime of boundary-layer slippage is established when the compositions undergo deformation in capillary and in rotary viscosimeters.

IV. EFFECT OF TECHNICAL MOULDING CONDITIONS ON PROPERTIES OF THERMOSETTING COMPOSITIONS IN THE PLASTIC STATE

In order to investigate the viscosity properties of thermosetting compositions under conditions as close as possible to actual processing schedules, a Kanavets type of plastometer was fixed to the outlet from the masticator nozzle, enabling the viscosity of the material to be determined at a rate of shear of 0.014 s^{-1}, low enough for the effect of the heat produced by friction to be neglected[107].

Application of relations used[40,61,108] to describe the behaviour of thermosetting materials showed that the temperature in the masticator should not exceed 120°C when standard compositions were processed: otherwise premature setting takes place[109]. Fig. 8 illustrates the temperature dependence of the time during which the material remains in a plastic state[107].

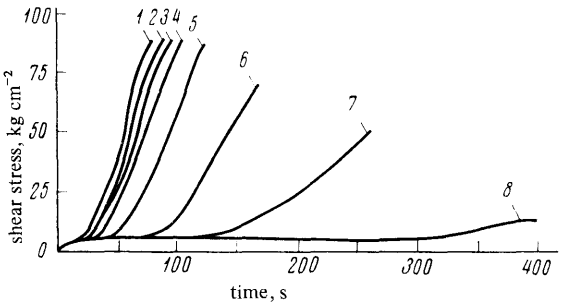

Figure 8. Kinetics of the setting of a phenol–formaldehyde composition at different temperatures (°C): *1*) 190; *2*) 180; *3*) 170; *4*) 160; *5*) 150; *6*) 140; *7*) 130; *8*) 120.

The physicochemical properties of articles made from thermosetting compositions exhibit anisotropy owing to orientation of the filler particles[85,107,110]. Orientation of the oligomer itself during injection moulding probably makes no contribution[85]. At some distance from the gate filler particles are usually oriented perpendicular to the direction of flow; in narrow channels the orientation is parallel. The orientation effect is diminished by under extrusion: i.e. injection takes place into an open mould; parts which initially break off under the influence of pressure, then join with great force[32].

The use of high pressures in the processing of thermosetting compositions naturally raises the question of the effect of pressure on their fluidity and on the duration of the plastic state. Results obtained[31] by the methods of Schwittmann and of Meysenbug were quite reproducible, but were not compared with those obtained by other methods. Work on melamine and phenolic oligomers showing that the duration of the plastic state becomes shorter with increase in pressure[88] is of greater interest. A study of flow during extrusion[64] revealed direct proportionality between rate of flow and pressure up to around 600 kg cm^{-2}, which suggested that Newtonian flow was maintained up to high pressures. However, no more data have appeared on the Newtonian flow of a filled composition, despite the numerous investigations in this field made with various types of viscosimeters[37,43,62,63,66–70,77,78,111–114].

In the "beaker" method it was suggested[64] that pressure, viscosity η, and dimensions of a standard "beaker" were interrelated by the formula

$$\frac{\bar{p}}{\eta\bar{\omega}H} \approx 0{,}5\left(\frac{R}{d}\right)^2,$$

where d is the thickness of the wall of the vessel, H the depth of the specimen, and $\bar{\omega}$ the mean speed of the plunger, while $\bar{p} = \pi R^2 \Delta\bar{p}$, in which $\Delta\bar{p}$ is the mean extrusion pressure.

The fluidity of a composition not only varies on passing from one type of oligomer to another but also is largely dependent on the moisture content of the initial material[115,116]. Usually the latter does not exceed a few percent, since further increase, in spite of the consequent decrease in viscosity, produces a sharp deterioration in physicomechanical properties of the hardened composition.

The particle size of the filler has a noteable effect on the viscosity properties of the thermosetting composition: it was shown for the typical compositions K-18-2, K-21-22, and others that increase in the particle size from 0.1 to 0.5–0.6 mm not only increases the viscosity of the system but also considerably shortens the period in a plastic state[117]. Unfortunately, very few data have been published on the effect of the filler content on the rheological properties of thermosetting materials[101–106].

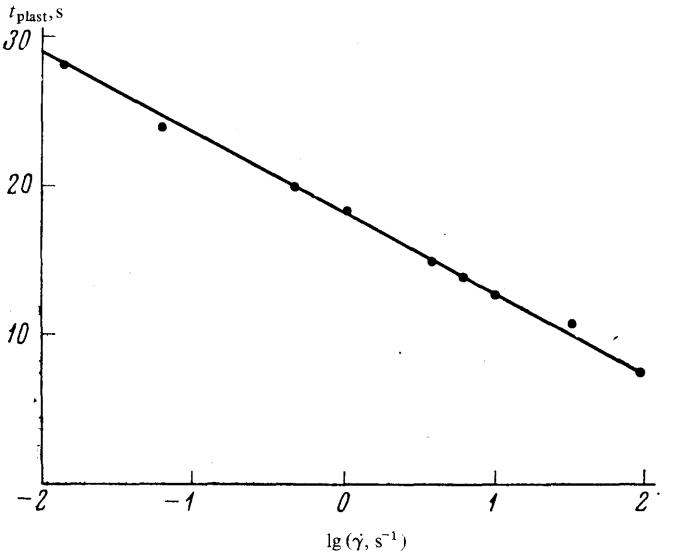

Figure 9. Dependence of length of stay of K-18-2 in plastic state t_{plast} on rate of deformation $\dot{\gamma}$ at 170°C.

This latter omission is aggravated by the impossibility of transferring to thermosetting materials methods of calculating deformation régimes developed for thermoplastics[71,72], because of their specific character. In moulding machines with worm mastication the former materials are processed at very high rates of deformation. Analogous conditions in the processing of thermoplastics may cause the polymer to crystallise[118,119] or to break down[120–122]. Intense deformation also intensifies chemical reactions[78], which is of especial interest for the processing of thermosetting materials. Fig. 9 shows that the time in the plastic state becomes shorter with increase in rate of deformation[41,123]. The role of deformation in the setting of a composition is largely determined by the temperature: e.g. deformation at 120°C may shorten the period in the plastic state by factors of about 4–5, whereas at 170°C by factors of only 2–3 for the same range of shear rates. These conclusions are supported by the results of capillary viscosimetry[37]. The preliminary rolling of thermosetting

compositions also shortens the period the material remains in a plastic state.

The kinetics of setting— the second most important process occurring during the moulding of articles from thermosetting compositions— is mostly assessed by a rheological method[40,61] which has found widespread use both in the Soviet Union and abroad. However, several other methods are known for studying the hardening process, based on the measurement of physicomechanical, electrical, and thermal characteristics of the material, as well as chemical methods. Thus rates of setting have been determined by a thermochemical method[124], from the volume shrinkage[125,126], the variation in molecular weight[127], the variation in dielectric properties[128], chromatographically[129,130], by infrared spectroscopy[131], from the proportion of acetone-insoluble oligomer[132], etc.[111]. The quantity of ammonia evolved has been used[133,134] to study the kinetics of the hardening by hexamethylenediamine of the phenol-formaldehyde oligomer No. 18 and the composition K-18-2 based on it.

Many different theories have been suggested to account for the rheological behaviour of elastomers and thermoplastics during deformation. No mathematical model which would describe the behaviour of thermosetting compositions during deformation is yet available, despite our knowledge of the variation in their properties with various factors and the accumulation of much experimental information. We shall therefore consider only an attempt[135] to describe the flow of a thermosetting material in a cylindrical mould. This started from the pressure dependence of the bulk flow rate Q

$$a_n \frac{d^n Q}{d p^n} + a_{n-1} \frac{d^{n-1} Q}{d p^{n-1}} + \ldots + a_0 Q = Q_0, \qquad (1)$$

and was confined to the simplest cases with $n = 1$ and $n = 2$. The constants $a_1, a_2, \ldots, a_n$ depend on the properties of the material undergoing processing and on the conditions of filling of the mould, while Q_0 is the volume of the casting. With the boundary conditions $p = 0$ when $Q = 0$ and $p \to \infty$ when $dQ/dp = 0$, the relation

$$Q = Q_0 (1 - e^{-\frac{p}{r}}) \qquad (2)$$

was obtained for $n = 1$. The constant r depends on the length l and cross-section S of the die, the duration of flow t_v, and the effective viscosity of the composition η^*:

$$r = r(l, S, t_v, \eta^*).$$

This dependence was written

$$r = (l \sqrt{S})^{\alpha} \frac{\eta^*}{t_v},$$

in which α is constant for the apparatus used. Solving the differential equation (1) for $n = 2$ yields

$$Q = Q_0 + C_1 e^{-\frac{p}{r_1}} + C_2 e^{-\frac{p}{r_2}}, \qquad (3)$$

where r_1 and r_2 depend on the properties of the composition and the conditions of filling of the channel, while C_1 and C_2 are integration constants. The value of r was found from the slope of the plot of $\ln (Q_0 - Q)$ against p. The results[135] indicate that the deformation of polymerisation oligomers is well described by formula (2), and that of polycondensation oligomers by formula (3).

In view of the above results of investigations on the deformation of thermosetting compositions, in which the rate of slippage predominates (under conditions approximating closely to actual processing), it is necessary to set up a mathematical model of the injection moulding of these materials allowing for the "rodlike" character of their motion in channels, and also to develop a rheological model to describe the flow of materials based on reactive oligomers.

Applications of Heteroligand Complexes in the Analytical Chemistry of Niobium and Tantalum

S.V.Elinson

Modern precision spectrophotometric and extraction-spectrophotometric methods for the determination of niobium and tantalum are based on the use of heteroligand (ternary, quaternary, and mixed) complexes of these elements with organic reagents. These methods make it possible to determine niobium and tantalum in complex materials without separating the components, which has greatly extended the scope of analytical methods in the chemistry of niobium and tantalum. The bibliography includes 131 references.

I. INTRODUCTION

Inorganic chemical analysis has been developing recently in two main directions. On the one hand, much attention has been devoted to problems of specific synthesis of organic reagents used in spectrophotometric, extraction-photometric, chromatographic, and other analytical methods to ensure their greater specificity and sensitivity in relation to inorganic ions. The second trend is associated with more extensive use in inorganic analysis of ternary, quaternary, and multicomponent (mixed) chemical complexes, which are also referred to as heteroligand complexes. In mixed complexes containing different types of groups, the individual characteristics of the elements are manifested more clearly, namely their capacity for coordination (which is not quite so clearly shown in homoligand complexes), the stabilisation of unstable valence states, and the creation of more favourable conditions for transitions from one valence state to another. The use of reactions involving the formation of heteroligand complexes in spectrophotometric analysis has greatly extended the scope of the methods for the determination of many elements, including niobium and tantalum.

The chemistry of heteroligand complexes has been developed in relation to analytical chemistry in studies by Babko[1,2], Alimarin[3], Pilipenko[4], and others. The applications of heteroligand complexes have been reviewed in detail[1-5].

The use of organic reagents has greatly extended the scope of the spectrophotometric analysis of inorganic ions. During the first period, mainly two-component systems

were investigated, while problems of sensitivity and selectivity associated with the employment of metal ion–organic reagent systems were still not adequately solved.

The sensitivity of photometric reactions, expressed by the molar extinction coefficient ϵ, is greatly influenced by the stability of the chelates formed. The maximum value of ϵ can be estimated theoretically [6] as $\epsilon_{max} = 1 \times 10^5$. However, this sensitivity is provided by only a few reagents. To increase the sensitivity, new chromophoric groups are introduced into the organic reagents, using complexing agents which are as selective as possible; it is necessary that the spectrum of the resulting two-component complex should differ markedly from that of the initial reagent. The choice of selective reagents is also difficult because certain metal ions (niobium and tantalum, zirconium and hafnium, molybdenum and tungsten, etc.) have very similar electronic structures, ionic radii, and ionic potentials. An enhanced selectivity can be achieved by changing the ligand, by introducing substituents, and by altering the distances of the electron-donating groups within the molecule. Selectivity in an analytical reaction can be appreciably improved by masking, but this too has its limits, since the analytical reagent can react also with the masked ion.

A great increase of sensitivity and selectivity can be achieved with the aid of heteroligand complexes, using their optical properties. Mention should first be made of ternary complexes, although recently a number of reports have been published on the applications of quaternary complexes in spectrophotometric analysis [7,8].

In many cases (particularly for heavy metals with high valences) the mechanism of complex formation in the interaction of a two-component system MX with a new ligand Y is not based on competitive relations, i.e. on the displacement of one of the previous components by a third component, and the interaction in the system is more complex than the process

$$MX + Y \rightleftarrows MY + X. \qquad (1)$$

The new ligand enters into the composition of the coordination sphere, forming a heteroligand complex:

$$M^{z+} + mH_aX + nH_bY \rightleftarrows [MX_mY_n]^{z-am-bn} + [am + bn]H^+... \qquad (2)$$

The formation of the heteroligand complex is a fairly complicated process. The new ligand can form an associated ionic species with the initial homoligand complex; it can displace water molecules from the coordination sphere, although in principle complexes such as $M(H_2O)_nX_m$ and MH_nX_m belong to the group of heteroligand complexes themselves. In many cases heteroligand complexes are also formed in extraction processes.

Complexes with different metals, obtained in accordance with the equation

$$pM^{z+} + qM'^{u+} + H_aX \rightleftarrows (M_pM'_qX)^{pz+qu-a} + aH^+, \qquad (3)$$

are less important in analytical chemistry, because in practice one employs an excess of the ligands and the formation of such complexes is suppressed. One can quote only a few examples of their employment in analytical practice: (a) indirect polarographic determination of zirconium as zirconium lead tartrate [9] and photometric determination of cadmium as cadmium iron tartrate [10]; (b) the tin–iron–dimethylglyoxime system has been investigated by Babko and Mikhel'son in relation to analytical chemistry [11,12]; the complex has been used by Elinson and Tsvetkova [13] to develop a method for the determination of tin in alloys with zirconium and niobium; (c) the formation of complexes of the type $M_pM'_qX$ can explain the extraction of metal ions by two other metal ions, which has been observed by Alimarin and Gibalo [14].

Coordination compounds formed in accordance with Eqn.(2) by one metal with two or several ligands are particularly important. It has been shown in a number of studies that the electrostatic interaction in the complex and the ligand effect promote the formation of a heteroligand complex. Electrostatic calculations have demonstrated that the formation of heteroligand complexes is always energetically more favourable than the formation of homoligand complexes [15–20]. Heteroligand complexes can be formed in two ways. They can be produced when complex formation with one ligand gives rise to coordination-unsaturated compounds. The second ligand can then be incorporated by occupying some or all the remaining coordination sites at the metal ion. The second possibility occurs when a single-ligand complex is in fact saturated but not all the valences of the inorganic ion have been compensated. Under these conditions, the heteroligand complex is formed by association of the second ligand and the first charged complex. The formation of the association complex of chlorogallate with diantipyrinylmethane or its detivatives ($GaCl_4$–DAPM), which can be extracted with chloroform, as well as numerous association complexes described by Blyum [21] and other workers [22–26] may serve as typical examples.

The chemistry of transition metal complexes in solution is to a large extent concerned with the chemistry of heteroligand complexes. The wide variety of heteroligand complexes (MX_mY_n) can be accounted for by their higher stability in solution compared with complexes containing identical ligand species. The formation of complexes with different ligand species also leads to appreciable changes in the physicochemical properties of the compounds: changes in their optical properties, an increase or decrease of solubility, and the appearance of capacity to be extracted by organic solvents; it is therefore useful to employ the extraction of coloured heteroligand complexes containing an organic complex-forming agent (for example polyphenols) as one of the ligands. However, one of the main advantages of heteroligand complexes is the possibility of a great increase in the sensitivity and selectivity of analytical reactions owing to their high coordination capacity. The absorption spectra of such complexes differ from those of homoligand systems.

Here, one should emphasise that, since analytical chemistry is concerned with solution chemistry, the majority of analytical reactions are based on the use of heteroligand complexes and, according to Pilipenko and Tananaiko [27], the formation of heteroligand complexes in solution is the rule rather than the exception. The contrary view was held previously. Bearing in mind that, apart from the main components, a homoligand complex can include water or organic solvent molecules as well as hydroxide ions, which are formed on hydrolysis, the vast majority of analytical systems will prove to be of the heteroligand type.

The role of heteroligand complexes in analytical chemistry can be hardly overestimated. Hundreds of spectrophotometric and extraction-photometric methods for the determination of inorganic ions are based on the use of heteroligand complexes. During the last 8 years (1966 to 1973), more than 600 papers dealing with such complexes were published. The text below deals with the applications of heteroligand complexes in one of the most difficult branches of analytical chemistry, namely the analysis of niobium and tantalum [28].

II. SPECTROPHOTOMETRIC DETERMINATION OF NIOBIUM AND TANTALUM IN HETEROLIGAND COMPLEXES

1. METAL COMPLEXES WITH TWO DIFFERENT ELECTRONEGATIVE LIGANDS

Until recently, it was believed that reagents such as metallochromic indicators do not undergo colour reactions with niobium and tantalum. The explanation was that hydrolysis results in the formation of various relatively inactive hydrolysed and polynuclear species, incapable of reacting with the metallochromic indicators used in weakly acid solutions. However, experiments showed that, in the presence of powerful complex-forming agents (tartrate, oxalate, and fluoride ions, etc.), certain organic reagents undergo highly differentiating colour reactions with niobium and tantalum owing to the formation of heteroligand complexes. One of the ligands decomposes polymeric niobium or tantalum ions and maintains them in solution, while the other (the metallochromic indicator) serves as the chromophore in the stable ternary complex formed[29]. In the chemistry of niobium and tantalum heteroligand complexes play a special role, which serves as a basis for the most highly differentiating, sensitive, and selective modern spectrophotometric methods for the determination of these elements[28].

(a) Complexes with Polyphenols

Tantalum–pyrogallol complexes can serve as an example of heteroligand complexes with two electronegative ligands. In the absence of other complex formation agents, tantalum forms with pyrogallol a colourless complex in an acid medium (with an absorption band at 340 nm); when oxalate ions are introduced into the solution of the tantalum–pyrogallol complex, the band at 340 nm is weakened and a new band appears at 420 nm. The formation of this heteroligand complex constitutes the basis of familiar photometric methods[30-34].

Babko and Lukachina[35] examined the pyrogallol method for the determination of tantalum and niobium in their joint presence, based on the fact that in an acid medium a coloured ternary tantalum oxalate–pyrogallol complex is formed, while the niobium gives rise to a colourless oxalate complex. Thus the differentiating ligand for niobium and tantalum in an acid medium is not pyrogallol but the third component, in the present instance oxalic acid. With increase of pH, the concentration of $C_2O_4^{2-}$ and pyrogallol (Pg^{2-}) ions increases. However, oxalic acid is a stronger acid and therefore at $pH > pK_2$, i.e. at $pH > 4$, and a constant overall oxalic acid concentration, the concentration of $C_2O_4^{2-}$ does not increase, while that of the Pg^{2-} ions derived from the weaker acid (pyrogallol) continues to rise. As a result, with increase of pH, the $C_2O_4^{2-}$ ions are displaced from the coordination spheres of tantalum and niobium and only the pyrogallol complexes remain: the coloured niobium complex and the colourless tantalum complex. On the other hand, in a more acid medium ($pH < 4$), the equilibrium shifts towards the formation of colourless niobium oxalate complexes with displacement of Pg^{2-} from the coordination sphere. The study optimised conditions for the determination of niobium and tantalum. Niobium is determined in a weakly alkaline medium at pH 7–8 with $[Pg^{2-}_{tot}] = 0.2$ and $[C_2O_4^{2-}]$ 0.1 M. Tantalum is determined in the heteroligand complex $[TaOC_2O_4Pg_2]^{3-}$ at 400 nm and pH 2–3 with $[Pg^{2-}] = 1.3$ to 1.4 M and $[C_2O_4^{2-}] \geq 0.2$ M.

The formation of heteroligand niobium complexes with pyrogallol and ethylenediaminetetraacetic acid (EDTA) has been noted. Pyrogallol complexes have been used to develop extraction-photometric methods for the determination of tantalum in the presence of niobium, which are discussed below. Among other polyphenols, heteroligand complexes are formed by tantalum with catechol in the presence of $C_2O_4^{2-}$. A photometric method for the determination of tantalum has been developed on this basis[36,37]. It has been modified[38] by the introduction of EDTA. The author[38] drew attention to the fact that EDTA, which usually decolorises the majority of metal complexes, actually enhances the colour of the catechol complex of niobium and enters into the composition of the heteroligand complexes. Thus one can claim that coloured heteroligand compounds of the type of MX_mY_n are formed in those cases where the chromophore is not one of the ligands but the central atom. The complex was investigated in detail in later studies[39,40]. Nevertheless, the method remains relatively unselective and insensitive. In the measurements of the optical density of the complex in the region of 385–395 nm the influence of niobium is to a large extent eliminated, but titanium interferes.

A number of methods involving tetraphenylarsonium have been described[41,42]. Methods in which tetraphenylarsonium and thiocyanate ions are both used are of considerable interest. Niobium and tantalum peroxide complexes with various organic dyes[43] as well as niobium thiocyanate complexes with benzoylphenylhydroxylamine (BPHA)[44] and with dihydroxy-3,4-phenyl-4-azobenzene[45] can also be included among heteroligand complexes.

Niobium and tantalum tartrate, oxalate, citrate, and peroxide complexes with many metallochromic indicators form part of the group of complexes with different electronegative ligands. Reagents containing hydroxypyridylazo- and *oo*-dihydroxyazo-groups are the most sensitive and give rise to contrasting and deep colours with niobium. These include 4-(2-pyridylazo)resorcinol (PAR) and its derivatives, analogues of lumogallion–bisazo-derivatives of chromotropic acid, and monoazo-compounds based on the R-salt. Azo-compounds with complexone groups are also promising reagents for niobium. Arylmethanes and other basic dyes are the most sensitive and selective reagents for tantalum.

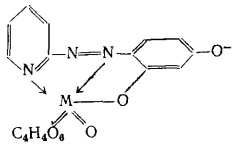
(b) Heteroligand Niobium and Tantalum Complexes of Pyridylazo-compounds

Pyridylazo-compounds are known as reagents forming stable ternary metal–reagent–ligand complexes with niobium and tantalum[46]. Complexing agents used to solubilise these elements, namely peroxide, oxalate, tartrate, and citrate ions, are normally used as the third components.

Among reagents of the pyridine series, 4-(2-pyridylazo)resorcinol has been most thoroughly investigated. It has been proposed as a highly sensitive reagent (molar extinction coefficient of about $3.5\ 10^4$) for the photometric determination of niobium and tantalum in weakly acid solutions (pH 5–6) in tartrate[47-49], peroxide[50], or oxalate[51] solutions. Pyridylazo-compounds are highly reactive but relatively unselective. The explanation is that salt-forming compounds of the type of PAR give rise to complexes with ions having small radii and high positive

charges, i.e. heavy metal and transition metal ions, which thereby complete their *d* and *f* shells[52]. Apart from niobium and tantalum, PAR forms coloured complexes with 40 elements (U, Co, Ga, In, the lanthanides V, Pb, Cu, etc.)[53,54].

In order to choose conditions under which the greatest sensitivity and selectivity of the reactions of niobium and tantalum with PAR are attained, a detailed study was made of the complexes formed by PAR and its analogues with the above elements[55,56]. It has been established that coloured niobium and tantalum complexes are formed by reagents of the pyridyl series (12 such compounds have been investigated) which contain the OH group in the *ortho*-position relative to the diazo-group. In these compounds OH groups or other electron-donating groups, which are in the *para*-position relative to the azo-group, play the role of groups active in analysis, which sharply increase the sensitivity of the reagents. It has been demonstrated[55,56] that niobium and tantalum form heteroligand complexes with pyridylazo-compounds and complex-forming ligands (tartrate, oxalate, fluoride, etc.) with a valence bond via the hydroxy-group in the *ortho*-position relative to the diazo-group and a coordinate bond via the nitrogen of the azo-group:



The high reactivity of PAR in reactions with niobium and tantalum can be explained to some extent by the formation of such compounds. The tartrate ions (or other similar ligands), which enter into the composition of the complex as the third component, disrupt the polymeric niobium and tantalum ions and maintain them in solution in a monomeric form, while the organic reagent—the metallochromic indicator (PAR) and its analogues—plays the role of the chromophore in the ternary complex. The existence of such heteroligand complexes has been demonstrated experimentally. 5-(3,5-Dibromo-2-pyridylazo)-monoethylamino-*p*-cresol (3,5-di-Br-PAAC), which forms a coloured sparingly water-soluble complex with niobium in the presence of tartrate ions, has been synthesised. Analysis of the heteroligand complex isolated in a crystalline form showed that its composition can be described by the formula

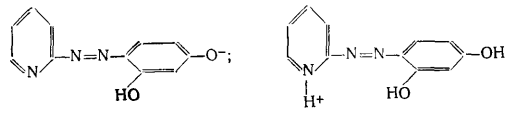
$$\text{Nb - 3,5-di-Br-PAAC - } C_4H_4O_6^2 \cdot 5H_2O,$$

and its molecular weight is 778, i.e. direct confirmation of the formation of a ternary complex with the component ratios Nb : R : tartrate = 1 : 1 : 1 was obtained.

The calculated instability constants of the complexes showed that the most stable complexes are formed by brominated pyridylazo-compounds, which react with niobium or tantalum in more acid media. Consequently, electronegative substituents in the pyridine ring increase the selectivity of the reagents. Two new selective and sensitive reagents were suggested on this basis: 5-(5-bromo-2-pyridylazo)-2-monoethylamino-*p*-cresol (5-Br-PAAC) and 4-(5-bromo-2-pyridylazo)resorcinol (5-Br-PAR), which give rise to a marked bathochromic effect ($\Delta\lambda$ = 130–160 nm) and high molar extinction coefficients (4.17×10^4 and 3.8×10^4 respectively). The determination of niobium and tantalum with the aid of the proposed reagents in highly acid solutions (up to an HCl concentration of 2 M) is not interfered with by molybdenum, tungsten, uranium, zirconium, titanium, iron, rhenium, and other elements.

4-(2-Thiazolylazo)resorcinol (TAR) has a structure similar to that of PAR and like the latter forms with niobium coloured complexes in weakly acid solutions (pH 5–5.5). However, thiazolylazo-compounds, containing the less basic thiazole ring instead of the pyridine ring, should give rise to niobium complexes in more acid media and hence should be more selective than pyridylazo-compounds. 5-(2-Thiazolylazo)-2-monoethylamino-*p*-cresol (TAAC) is of considerable interest in this respect; a method for the determination of niobium in alloys containing uranium, zirconium, and molybdenum involving the use of TAAC has been developed[57].

Studies have shown that, in contrast to other media, in tartrate solutions the heteroligand PAR complex of niobium is formed not only at pH 5–6 but also at higher acidities (HCl concentrations in the range 0.5–1 M),[49] different compounds being formed, since the ionic state of PAR depends greatly on the acidity. At pH 5–6 a proton dissociates initially from the OH group in the *para*-position with formation of a singly charged ion in solution[53,58]. In the solution where [HCl] = 1 *N* PAR exists in the form of a singly charged cation as a result of the protonation of the heterocyclic nitrogen of the pyridine ring:



(pH 5–6) (1 M HCl)

The absorption spectra of these compounds differ from one another[59]. The ternary complex has an absorption maximum in 1 M HCl solution only in the region of 405 nm, while at pH 5–6 the maximum is at 520–540 nm (depending on the nature of the third complex-forming component). Furthermore, in weakly acid media a second indistinct maximum is also observed in the region of about 400 nm, which is extremely characteristic of heteroligand complexes. Since the absorption maximum of the complex in an acid solution is close to that of the reagent (395 nm), a differential curve with a maximum at 540 nm was used in practice. In an acid solution we have the ratio Nb : PAR = 1 : 2 (instead of 1 : 1 at pH 5–6). With increase of acidity, there is a sharp increase of the selectivity of PAR. Iron, aluminium, titanium, zirconium, molybdenum, tungsten, the lanthanides, and other elements do not interfere with the determination of niobium.

Methods have been developed for the determination of niobium under such conditions in steels[60], minerals[59], and complex copper-based alloys[61]. A differential method has been devised for the determination of large amounts of niobium in alloys and ferroalloys[62], particularly in ferroniobium.

Masking of tantalum with a large excess of tartrate ions made it possible to develop a procedure for the determination of niobium and tantalum without their separation[63]. In tartrate solution tantalum is bound in a stable polynuclear complex, with a polymerisation factor of about 670, which does not form compounds with PAR, and therefore in 3–4% ammonium tartrate solutions at pH 4.5–4.8 tantalum does not interfere with the development of the colour of the PAR complex of niobium. The method proved to be extremely effective and permits the determination of 0.1%

of niobium and more in tantalum concentrates and in metallic tantalum. The heteroligand PAR complex of tantalum has been used to determine tantalum in steels and alloys with a high tantalum content [64]. It has been shown that, in the presence of ligands used to solubilise niobium and tantalum (oxalate, citrate, etc.), PAR forms coloured complexes with both tantalum and niobium. The most sensitive and stable complex is formed in 0.01 M citrate solution at pH 5.4. Under these conditions, niobium does not form a coloured compound. However, a concentration corresponding to more than 1 mg of niobium in 50 ml increases the optical density of the tantalum solution. Stable and reproducible results can be obtained only for the same reactive tantalum species, which is achieved by selecting identical conditions for the preparation of solutions of the sample and standard solutions (boiling of the initial solutions at the same pH 2.3–2.8 after dissolving the alloys, introduction of nickel into standard tantalum solutions). When the steel specimen contains less than 5% of tantalum, the latter is determined relative to a standard steel specimen and not with the aid of a calibration graph [64].

Thus, using heteroligand PAR complexes, it is possible to increase greatly the selectivity in the determination of niobium and tantalum. Ways of increasing the selectivity still further, involving the use of reagents with electronegative substituents and the ligands of the heteroligand complex as masking agents (tartrate and citrate) as well as an increase of acidity in the preparation of PAR complexes of niobium, have been discussed [65].

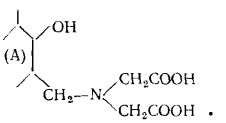
Other complexes of resorcinol derivatives have also been investigated. A method has been determined for the determination of niobium as a heteroligand complex with H_2O_2 and sulphonaphtholazoresorcinol [66]. In another study H_2O_2 was used in combination with morin [67]. The fluorescence method developed with the aid of these reagents makes it possible to determine niobium with a sensitivity of 0.004 $\mu g\ ml^{-1}$.

(c) Heteroligand Niobium Complexes with *oo'*-dihydroxyazo-compounds

Organic compounds containing the *oo'*-dihydroxyazo-group undergo extremely characteristic colour reactions with niobium. Compounds of this type can be divided into two groups on the basis of their structural features. The first includes Lumogallion and many bisazo-derivatives of chromotropic acid—structural analogues of Arsenazo III (Sulphochlorophenol S, Sulphomethanylphenol Nitrosulphophenol S, and others) and the second group includes Anthracene Chrome Violet and other monosubstituted R-salt derivatives (Picramine R, Magneson, Picramine-epsilon, etc.); they all form heteroligand complexes with the niobium tartrate complex or with niobium complexes of other hydroxy-acids. In the first group of reagents Sulphochlorophenol S or 3,6-bis[(5-chloro-2-hydroxy-3-sulphophenyl)azo]-4,5-dihydroxynaphthalene-2,7-disulphonic acid (SCPS) is of greatest interest. This dye is widely used to determine niobium [68–72]. The most interesting compound in the second group is Picramine R or 3-hydroxy-4-[(2-hydroxy-3,5-dinitrophenyl)azo]naphthalene-2,7-disulphonic acid. Both reagents, SCPS and Picramine R, form coloured complexes with niobium at a high acidity of the solution, are satisfactorily selective, and permit the determination of niobium in metals and alloys without the separation of components. SCPS and its analogues are three times more sensitive ($\epsilon = 3.6 \times 10^4$) than Picramine R ($\epsilon = 1.1 \times 10^4$). SCPS is used to determine microamounts of niobium in metals [73], while Picramine R is used for the determination by photometric or differential methods of large amounts of niobium in alloys and intermetallic compounds containing up to 70–80% of niobium [74].

(d) Heteroligand Niobium Complexes with Metallochromic Indicators Containing Complexone Groups

The importance of heteroligand complexes for the determination of niobium and tantalum can be readily demonstrated for reagents containing complexone groups: Xylenol Orange (XO) and Methylthymol Blue (MTB). It appeared likely that these reagents, which do not contain an OH group in the *ortho*-position relative to the azo-group (a characteristic of niobium and tantalum reagents), are capable of forming complexes with these metals. Indeed, in the first relevant reports the reaction of niobium with Xylenol Orange was classified as insensitive, because the experiments were performed without additional ligands (oxalate or tartrate ions) at room temperature. Later it was found that, in the presence of either of these ligands, an intensely coloured complex is formed on heating. A fairly stable niobium complex is known to be formed at pH 3–3.5 with EDTA, while tantalum forms a fairly weak complex with this substance. Similarly, XO and MTB, which contain complexone groups, form in oxalate or tartrate solution at pH 2–4 fairly stable brightly coloured complexes with niobium and interact only weakly with tantalum. XO has been proposed as a reagent for niobium by Babko and Shtokalo [75] and has been used to determine niobium in certain alloys [76]. MTB has been investigated as a reagent for niobium by Elinson and Mirzoyan [74]. The fact that niobium reacts with MTB in 1 : 1 molar proportions, while in the absence of sufficient oxalate or other similar ligands the niobium–MTB complex is not formed at all suggests that, as for pyridylazo-compounds, oxalate ions enter into the composition of the coloured compound, forming a heteroligand complex with the component ratios $Nb : C_2O_4^{2-} : MTB = 1 : 1 : 1$. Oxalate and tartrate ions decompose polymeric niobium ions. At pH 2–3 niobium readily hydrolyses and in the absence of these ligands could not compete with the MTB or XO protons in the formation of a complex. Experiments have shown that the formation of MTB and XO complexes of niobium is due to the group (A), i.e. to the most reactive hydroxy-, amino-, and carboxy-groups:



2. DETERMINATION OF NIOBIUM AND TANTALUM IN THE FORM OF COMPLEX HETEROPOLYACIDS

Niobium and tantalum form heteroligands phosphorus–niobium–molybdenum complexes which are more stable and more soluble than the usual heteropolyacids. The absorption bands of these complexes are displaced further towards the visible region, while the reduced binary tantalum–molybdenum complex absorbs in the infrared ($\lambda = 820$ nm). [78] The phosphorus–niobium–molybdenum complex can be reduced to a blue complex, the intensity of

the colour of which is proportional to the concentration of niobium (sensitivity 0.1 μg ml^{-1}). The conditions governing this reaction have been refined [79] and methods have been developed for the determination of niobium in ores together with a differential spectrophotometric method for the determination of large amounts of niobium [80]. Titanium interferes with the determination of niobium; the influence of tungsten can be eliminated by an excess of phosphate. Methods for determination of niobium and titanium in alloys [81] and of niobium in steels [82] have been developed on the basis of the formation of heteroligand heteropolycomplexes. A technique has been devised for the determination of low niobium concentrations based on the formation of niobium–molybdenum blue [83].

3. COMPLEXES WITH TWO DIFFERENT ELECTROPOSITIVE ATOMS AND ONE ELECTRONEGATIVE LIGAND

Complexes with two electropositive metals have not found such extensive application as heteroligand complexes with two electronegative ligands. However, it is possible to quote certain instances of the formation of mixed niobium and tantalum complexes with an electronegative ion, whereupon tantalum becomes an obstacle, which is difficult to overcome, to the determination of niobium when the two metals are present jointly in large amounts. For example, compounds are formed by mixtures of niobium and tantalum with H_2O_2. Niobium combines with one H_2O_2 molecule so strongly that in a weakly acid medium it is not titrated by potassium permanganate. When an excess of a standardised H_2O_2 solution is added, the concentration of niobium can be determined in the absence of tantalum by titrating the free H_2O_2 with permanganate [84], but in the presence of tantalum niobium does not retain the H_2O_2 molecule in consequence of the formation of a mixed niobium–tantalum peroxide complex. In the presence of phosphoric acid the niobium peroxide complex decomposes, whereupon only tantalum forms a stable peroxide [85].

Another example involves the formation of mixed niobium–tantalum complexes with tartrate ions. In the method developed for the determination of niobium in the presence of large amounts of tantalum with the aid of PAR [63] at pH 4.5–4.8 it is possible to bind tantalum with a large excess of tartrate ions into a stable relatively unreactive polynuclear complex and thus avoid the formation of a mixed niobium–tantalum complex with PAR. Niobium can then be determined with a high accuracy even in metallic tantalum [63]. In the determination of large amounts of niobium (10–80%) by a differential spectrophotometric method with PAR more than 50 μg of tantalum in 1 M HCl solution [62] is already sufficient to interfere with the determination, since in such a solution the tantalum tartrate complex is not sufficiently stable to prevent the formation of a mixed complex with niobium and PAR.

Such interference by tantalum in the determination of niobium has been called by some investigators (Babko, Belcher) "the loss of individual properties", which does not accurately reflect the true behaviour of these elements in solution. We believe it to be a typical instance of the formation of a mixed complex of different metals not with loss but with manifestation of the individuality of elements with similar physicochemical properties (the copolymerisation and complex formation phenomena when the ionic radii are similar, etc.).

Mixed tantalum–zirconium tartrate complexes can serve as an example of mixed complexes of two different metals [86]. Studies by the equilibrium shift and isomal series [continuous variations] methods established that, in 0.5 M tartaric acid solution at pH 2 and in the presence of a tenfold excess of zirconium, a complex with the component ratios Ta : Zr : Tart = 1 : 1 : 2 is formed. The tantalum in the mixed tartrate complex does not react with PAR, [28] which must be taken into account in the analysis of such systems.

III. THE USE OF HETEROLIGAND NIOBIUM AND TANTALUM COMPLEXES IN EXTRACTION PROCESSES

1. EXTRACTION-PHOTOMETRIC METHODS FOR THE DETERMINATION OF NIOBIUM

A number of compounds which constitute the basis of extremely sensitive and selective extraction-photometric methods for the determination of niobium and tantalum belong to the group of heteroligand complexes formed when niobium or tantalum interact with two electronegative ligands.

Extraction is a widely used procedure for improving the sensitivity and selectivity of analytical reactions; in this way it is possible to increase sharply the sensitivity of photometric methods.

Extraction with formation of heteroligand complexes can be described by the equation

$$M^{z+}(w) + mH_aX(w) + hH_bY(o) \rightleftarrows MX_mY_n(o) + (am + bn)H^+(w), \quad (4)$$

where w is the aqueous fraction and o the organic fraction. Numerous extraction-photometric methods are based on the measurement of the optical density of the compound $MX_mY_n(o)$ formed in the organic phase. If the partition coefficient of MX_m is very small, the affinity of HbY for MX_m plays a significant role. The equilibrium in the system shifts continuously during the extraction process towards the formation of MX_mY_n and a higher partition coefficient may be obtained for MX_mY_n than for MX_m.
